i.e., $W \cup D$. For example, web pages could be simplified as streams of words and URLs, and papers are actually sequences of words and cited DOIs.

If a document id d_t with some surrounding words C appear in the hyper-doc of d_s, *i.e.,* H_{d_s}, we stipulate that a *hyper-link* $\langle d_s, C, d_t \rangle$ is formed. Herein $d_s, d_t \in D$ are ids of the *source* and *target* documents, respectively; $C \subseteq W$ are *context words*. Figure 1(a) exemplifies a hyperlink.

3.2 Problem Statement

Given a corpus of hyper-docs $\{H_d\}_{d \in D}$ with D and W, we want to learn document and word embedding matrices $\mathbf{D} \in \mathbb{R}^{k \times |D|}$ and $\mathbf{W} \in \mathbb{R}^{k \times |W|}$ simultaneously. The i-th column $\mathbf{d}_i$ of $\mathbf{D}$ is a k-dimensional embedding vector for the i-th hyper-doc with id d_i. Similarly, $\mathbf{w}_j$, the j-th column of $\mathbf{W}$, is the vector for word w_j. Once embeddings for hyper-docs and words are learned, they can facilitate applications like hyper-doc classification and citation recommendation.

3.3 Criteria for Embedding Models

A reasonable model should learn how contents and hyperlinks in hyper-docs impact both $\mathbf{D}$ and $\mathbf{W}$. We propose the following criteria for models:

- **Content aware.** Content words of a hyper-doc play the main role in describing it, so the document representation should depend on its own content. For example, the words in Zhao and Gildea (2010) should affect and contribute to its embedding.

- **Context aware.** Hyperlink contexts usually provide a summary for the target document. Therefore, the target document's vector should be impacted by words that others use to summarize it, *e.g.,* paper Papineni et al. (2002) and the word "*BLEU*" in Figure 1(a).

- **Newcomer friendly.** In a hyper-document network, it is inevitable that some documents are not referred to by any hyperlink in other hyper-docs. If such "newcomers" do not get embedded properly, downstream tasks involving them are infeasible or deteriorated.

- **Context intent aware.** Words around a hyperlink, *e.g.,* "evaluate ... by" in Figure 1(a), normally indicate why the source hyper-doc makes the reference, *e.g.,* for general reference or to follow/oppose the target hyper-doc's opinion or practice. Vectors of those context words should be influenced by both documents to characterize such semantics or intents between the two documents.

We note that the first three criteria are for hyper-docs, while the last one is desired for word vectors.

4 Representing Hypertext Documents

In this section, we first give the background of two prevailing techniques, `word2vec` and `doc2vec`. Then we present two conversion approaches for hyper-documents so that `w2v` and `d2v` can be applied. Finally, we address their weaknesses w.r.t. the aforementioned four criteria, and propose our `hyperdoc2vec` model. In the remainder of this paper, when the context is clear, we mix the use of terms hyper-doc/hyperlink with paper/citation.

4.1 `word2vec` and `doc2vec`

`w2v` (Mikolov et al., 2013) has proven effective for many NLP tasks. It integrates two models, *i.e.,* `cbow` and `skip-gram`, both of which learn two types of word vectors, *i.e.,* IN and OUT vectors. `cbow` sums up IN vectors of context words and make it predictive of the current word's OUT vector. `skip-gram` uses the IN vector of the current word to predict its context words' OUT vectors.

As a straightforward extension to `w2v`, `d2v` also has two variants: `pv-dm` and `pv-dbow`. `pv-dm` works in a similar manner as `cbow`, except that the IN vector of the current document

Desired Property	Impacts Task?		Addressed by Approach?			
	Classification	Citation Recommendation	w2v	d2v-nc	d2v-cac	h-d2v
Context aware	✓	✓	✓	×	✓	✓
Content aware	✓	✓	×	✓	✓	✓
Newcomer friendly	✓	✓	×	✓	✓	✓
Context intent aware	×	✓	×	×	×	✓

Table 1: Analysis of tasks and approaches w.r.t. desired properties.

Model	Output			
	$\mathbf{D}^I$	$\mathbf{D}^O$	$\mathbf{W}^I$	$\mathbf{W}^O$
w2v	✓	✓	✓	✓
d2v (pv-dm)	✓	×	✓	✓
d2v (pv-dbow)	✓	×	×	✓
h-d2v	✓	✓	✓	✓

Table 2: Output of models.

is regarded as a special context vector to average. Analogously, `pv-dbow` uses IN document vector to predict its words' OUT vectors, following the same structure of `skip-gram`. Therefore in `pv-dbow`, words' IN vectors are omitted.

4.2 Adaptation of Existing Approaches

To represent hyper-docs, a straightforward strategy is to convert them into plain documents in a certain way and apply `w2v` and `d2v`. Two conversions following this strategy are illustrated below.

Citation as word. This approach is adopted by Berger et al. (2017).[2] As Figure 1(b) shows, document ids D are treated as a collection of special words. Each citation is regarded as an occurrence of the target document's special word. After applying standard word embedding methods, *e.g.,* `w2v`, we obtain embeddings for both ordinary words and special "words", *i.e.,* documents. In doing so, this approach allows target documents interacting with context words, thus produces context-aware embeddings for them.

Context as content. It is often observed in academic papers when citing others' work, an author briefly summarizes the cited paper in its citation context. Inspired by this, we propose a context-as-content approach as in Figure 1(c). To start, we remove all citations. Then all citation contexts of a target document d_t are copied into d_t as additional contents to make up for the lost information. Finally, `d2v` is applied to the augmented documents to generate document embeddings. With this approach, the generated document embeddings are both context- and content-aware.

4.3 `hyperdoc2vec`

Besides citation-as-word with `w2v` and context-as-content with `d2v` (denoted by `d2v-cac` for short), there is also an alternative using `d2v` on documents with citations removed (`d2v-nc` for short). We made a comparison of these approaches in Table 1 in terms of the four criteria stated in Section 3.3. It is observed that none of them satisfy all criteria, where the reasons are as follows.

First, `w2v` is not content aware. Following our examples in the academic paper domain, consider the paper (hyper-doc) Zhao and Gildea (2010) in Figure 1(a), from `w2v`'s perspective in Figure 1(b), "…computing the machine translation BLEU …" and other text no longer have association with Zhao and Gildea (2010), thus not contributing to its embedding. In addition, for papers being just published and having not obtained citations yet, they will not appear as special "words" in any text. This makes `w2v` newcomer-unfriendly, *i.e.,* unable to produce embeddings for them. Second, being trained on a corpus without citations, `d2v-nc` is obviously not context aware. Finally, in both `w2v` and `d2v-cac`, context words interact with the target documents without treating the source documents as backgrounds, which forces IN vectors of words with context intents, *e.g.,* "*evaluate*" and "*by*" in Figure 1(a), to simply remember the target documents, rather than capture the semantics of the citations.

The above limitations are caused by the conversions of hyper-docs where certain information in citations is lost. For a citation $\langle d_s, C, d_t\rangle$, citation-as-word only keeps the co-occurrence information between C and d_t. Context-as-content, on the other hand, mixes C with the original content of d_t. Both approaches implicitly downgrade citations $\langle d_s, C, d_t\rangle$ to $\langle C, d_t\rangle$ for adaptation purposes.

To learn hyper-doc embeddings without such limitations, we propose `hyperdoc2vec`. In this model, two vectors of a hyper-doc d, *i.e.,* IN and OUT vectors, are adopted to represent the document of its two roles. The IN vector $\mathbf{d}^I$ characterizes d being a source document. The OUT vector $\mathbf{d}^O$ encodes its role as a target document. We note that learning those two types of vectors is advantageous. It enables us to model citations and con-

[2]It is designed for document visualization purposes.

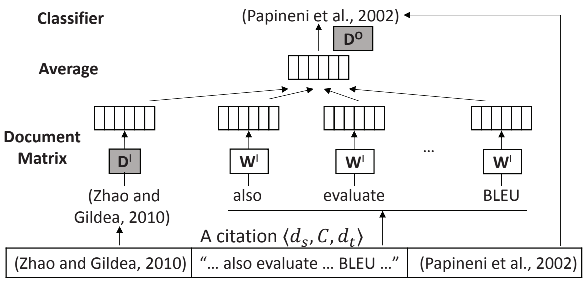

Figure 2: The `hyperdoc2vec` model.

tents simultaneously without sacrificing information on either side. Next, we describe the details of `h-d2v` in modeling citations and contents.

To model citations, we adopt the architecture in Figure 2. It is similar to `pv-dm`, except that documents rather than words are predicted at the output layer. For a citation $\langle d_s, C, d_t \rangle$, to allow context words C interacting with both vectors, we average $\mathbf{d}_s^I$ of d_s with word vectors of C, and make the resulted vector predictive of $\mathbf{d}_t^O$ of d_t. Formally, for all citations $\mathcal{C} = \{\langle d_s, C, d_t \rangle\}$, we aim to optimize the following average log probability objective:

$$\max_{\mathbf{D}^I,\mathbf{D}^O,\mathbf{W}^I} \frac{1}{|\mathcal{C}|} \sum_{\langle d_s,C,d_t\rangle \in \mathcal{C}} \log P(d_t|d_s, C) \quad (1)$$

To model the probability $P(d_t|d_s, C)$ where d_t is cited in d_s with C, we average their IN vectors

$$\mathbf{x} = \frac{1}{1+|C|}\left(\mathbf{d}_s^I + \sum_{w\in C} \mathbf{w}^I\right) \quad (2)$$

and use $\mathbf{x}$ to compose a multi-class softmax classifier on all OUT document vectors

$$P(d_t|d_s, C) = \frac{\exp(\mathbf{x}^\top \mathbf{d}_t^O)}{\sum_{d\in D}\exp(\mathbf{x}^\top \mathbf{d}^O)} \quad (3)$$

To model contents' impact on document vectors, we simply consider an additional objective function that is identical to `pv-dm`, *i.e.,* enumerate words and contexts, and use the same input architecture as Figure 2 to predict the OUT vector of the current word. Such convenience owes to the fact that using two vectors makes the model parameters compatible with those of `pv-dm`. Note that combining the citation and content objectives leads to a joint learning framework. To facilitate easier and faster training, we adopt an alternative pre-training/fine-tuning or *retrofitting* framework (Faruqui et al., 2015). We initialize with a predefined number of `pv-dm` iterations, and then optimize Eq. 1 based on the initialization.

Dataset		Docs	Citations	Years
NIPS	Train	1,590	512	Up to 1998
	Test	150	89	1999
	Total	1,740	601	Up to 1999
ACL	Train	18,845	91,792	Up to 2012
	Test	1,563	16,937	2013
	Total	20,408	108,729	Up to 2013
DBLP	Train	593,378	2,565,625	Up to 2009
	Test	55,736	308,678	From 2010
	Total	649,114	2,874,303	All years

Table 3: The statistics of three datasets.

Finally, similar to `w2v` (Mikolov et al., 2013) and `d2v` (Le and Mikolov, 2014), to make training efficient, we adopt negative sampling:

$$\log\sigma(\mathbf{x}^\top \mathbf{d}_t^O) + \sum_{i=1}^{n} \mathbb{E}_{d_i\sim P_N(d)} \log\sigma(-\mathbf{x}^\top \mathbf{d}_i^O) \quad (4)$$

and use it to replace every $\log P(d_t|d_s, C)$. Following Huang et al. (2015b), we adopt a uniform distribution on D as the distribution $P_N(d)$.

Unlike the other models in Table 1, `h-d2v` satisfies all four criteria. We refer to the example in Figure 2 to make the points clear. First, when optimizing Eq. 1 with the instance in Figure 2, the update to $\mathbf{d}^O$ of Papineni et al. (2002) depends on $\mathbf{w}^I$ of context words such as "*BLEU*". Second, we pre-train $\mathbf{d}^I$ with contents, which makes the document embeddings content aware. Third, newcomers can depend on their contents for $\mathbf{d}^I$, and update their OUT vectors when they are sampled[3] in Eq. 4. Finally, the optimization of Eq. 1 enables mutual enhancement between vectors of hyper-docs and context intent words, *e.g.,* "*evaluate by*". Under the background of a machine translation paper Zhao and Gildea (2010), the above two words help point the citation to the BLEU paper (Papineni et al., 2002), thus updating its OUT vector. The intent "*adopting tools/algorithms*" of "evaluate by" is also better captured by iterating over many document pairs with them in between.

5 Experiments

In this section, we first introduce datasets and basic settings used to learn embeddings. We then discuss additional settings and present experimental results of the two tasks, *i.e.,* document classification and citation recommendation, respectively.

5.1 Datasets and Experimental Settings

We use three datasets from the academic paper domain, *i.e.,* NIPS[4], ACL anthology[5] and DBLP[6], as shown in Table 3. They all contain full text of papers, and are of small, medium, and large size, respectively. We apply ParsCit[7] (Councill et al., 2008) to parse the citations and bibliography sections. Each identified citation string referring to a paper in the same dataset, *e.g.,* [1] or (Author et al., 2018), is replaced by a global paper id. Consecutive citations like [1, 2] are regarded as multiple ground truths occupying one position. Following He et al. (2010), we take 50 words before and after a citation as the citation context.

Gensim (Řehůřek and Sojka, 2010) is used to implement all `w2v` and `d2v` baselines as well as `h-d2v`. We use `cbow` for `w2v` and `pv-dbow` for `d2v`, unless otherwise noted. For all three baselines, we set the (half) context window length to 50. For `w2v`, `d2v`, and the `pv-dm`-based initialization of `h-d2v`, we run 5 epochs following Gensim's default setting. For `h-d2v`, its iteration is set to 100 epochs with 1000 negative samples. The dimension size k of all approaches is 100. All other parameters in Gensim are kept as default.

5.2 Document Classification

In this task, we classify the research fields of papers given their vectors learned on DBLP. To obtain labels, we use Cora[8], a small dataset of Computer Science papers and their field categories. We keep the first levels of the original categories, *e.g.,* "Artificial Intelligence" of "Artificial Intelligence - Natural Language Processing", leading to 10 unique classes. We then intersect the dataset with DBLP, and obtain 5,975 labeled papers.

For `w2v` and `h-d2v` outputing both IN and OUT document vectors, we use IN vectors or concatenations of both vectors as features. For newcomer papers without `w2v` vectors, we use zero vectors instead. To enrich the features with network structure information, we also try concatenating them with the output of DeepWalk (Perozzi et al., 2014), a representative network embedding model. The model is trained on the citation network of DBLP with an existing implementation[9] and default parameters. An SVM classifier with RBF kernel is used. We perform 5-fold cross validation, and report Macro- and Micro-F_1 scores.

5.2.1 Classification Performance

In Table 4, we demonstrate the classification results. We have the following observations.

First, adding DeepWalk information almost always leads to better classification performance, except for Macro-F_1 of the `d2v-cac` approach.

Second, owning to different context awareness, `d2v-cac` consistently outperforms `d2v-nc` in terms of all metrics and settings.

Third, `w2v` has the worst performance. The reason may be that `w2v` is neither content aware nor newcomer friendly. We will elaborate more on the impacts of the two properties in Section 5.2.2.

Finally, no matter whether DeepWalk vectors are used, `h-d2v` achieves the best F_1 scores. However, when OUT vectors are involved, `h-d2v` with DeepWalk has slightly worse performance. A possible explanation is that, when `h-d2v` IN and DeepWalk vectors have enough information to train the SVM classifiers, adding another 100 features (OUT vectors) only increase the parameter

Table 6: Top-10 citation recommendation results (dimension size $k = 100$).

space of the classifiers and the training variance. For `w2v` with or without DeepWalk, it is also the case. This may be because information in `w2v`'s IN and OUT vectors is fairly redundant.

5.2.2 Impacts of Content Awareness and Newcomer Friendliness

Because content awareness and newcomer friendliness are highly correlated in Table 1, to isolate and study their impacts, we decouple them as follows. In the 5,975 labeled papers, we keep 2,052 with at least one citation, and redo experiments in Table 4. By carrying out such controlled experiments, we expect to remove the impact of newcomers, and compare all approaches only with respect to different content awareness. In Table 5, we provide the new scores obtained.

By comparing Tables 4 and 5, we observe that `w2v` benefits from removing newcomers with zero vectors, while all newcomer friendly approaches get lower scores because of fewer training examples. Even though the change, `w2v` still cannot outperform the other approaches, which reflects the positive impact of content awareness on the classification task. It is also interesting that DeepWalk becomes very competitive. This implies that structure-based methods favor networks with better connectivity. Finally, we note that Table 5 is based on controlled experiments with intentionally skewed data. The results are not intended for comparison among approaches in practical scenarios.

5.3 Citation Recommendation

When writing papers, it is desirable to recommend proper citations for a given context. This could be achieved by comparing the vectors of the context and previous papers. We use all three datasets for this task. Embeddings are trained on papers before 1998, 2012, and 2009, respectively. The remaining papers in each dataset are used for testing.

We compare `h-d2v` with all approaches in Section 4.2, as well as NPM[10] (Huang et al., 2015b) mentioned in Section 2, the first embedding-based approach for the citation recommendation task. Note that the inference stage involves interactions between word and document vectors and is nontrivial. We describe our choices as below.

First, for `w2v` vectors, Nalisnick et al. (2016) suggest that the IN-IN similarity favors word pairs with similar functions (*e.g.,* “red” and “blue”), while the IN-OUT similarity characterizes word co-occurrence or compatibility (*e.g.,* “red” and “bull”). For citation recommendation that relies on the compatibility between context words and cited papers, we hypothesize that the IN-for-OUT (or I4O for short) approach will achieve better results. Therefore, for `w2v`-based approaches, we average IN vectors of context words, then score and and rank OUT document vectors by dot product.

Second, for `d2v`-based approaches, we use the learned model to infer a document vector $\mathbf{d}$ for the context words, and use $\mathbf{d}$ to rank IN document vectors by cosine similarity. Among multiple attempts, we find this choice to be optimal.

Third, for `h-d2v`, we adopt the same scoring and ranking configurations as for `w2v`.

Finally, for NPM, we adopt the same ranking strategy as in Huang et al. (2015b). Following them, we focus on top-10 results and report the Recall, MAP, MRR, and nDCG scores.

5.3.1 Recommendation Performance

In Table 6, we report the citation recommendation results. Our observations are as follows.

First, among all datasets, all methods perform relatively well on the medium-sized ACL dataset. This is because the smallest NIPS dataset provides

[10]Note that the authors used $n = 1000$ for negative sampling, and did not report the number of training epoches. After many trials, we find that setting the number of both the negative samples and epoches at 100 to be relatively effective and affordable w.r.t. training time.

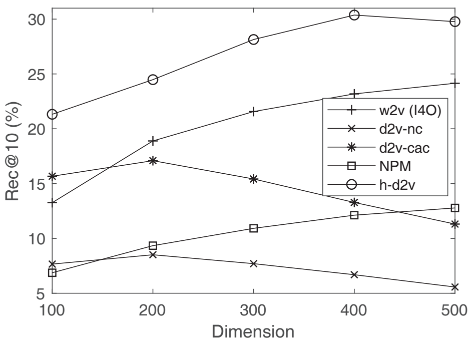

Figure 3: Varying k on DBLP. The scores of w2v keeps increasing to 26.63 at $k = 1000$, and then begins to drop. Although at the cost of a larger model and longer training/inference time, it still cannot outperform h-d2v of 30.37 at $k = 400$.

too few citation contexts to train a good model. Moreover, DBLP requires a larger dimension size k to store more information in the embedding vectors. We increase k and report the Rec@10 scores in Figure 3. We see that all approaches have better performance when k increases to 200, though d2v-based ones start to drop beyond this point.

Second, the I4I variant of w2v has the worst performance among all approaches. This observation validates our hypothesis in Section 5.3.

Third, the d2v-cac approach outperforms its variant d2v-nc in terms of all datasets and metrics. This indicates that context awareness matters in the citation recommendation task.

Fourth, the performance of NPM is sandwiched between those of w2v's two variants. We have tried our best to reproduce it. Our explanation is that NPM is citation-as-word-based, and only depends on citation contexts for training. Therefore, it is only context aware but neither content aware nor newcomer friendly, and behaves like w2v.

Finally, when retrofitting pv-dm, h-d2v generally has the best performance. When we substitute pv-dm with random initialization, the performance is deteriorated by varying degrees on different datasets. This implies that content awareness is also important, if not so important than context awareness, on the citation recommendation task.

5.3.2 Impact of Newcomer Friendliness

Table 7 analyzes the impact of newcomer friendliness. Opposite from what is done in Section 5.2.2, we only evaluate on testing examples where at least a ground-truth paper is a newcomer. Please note that newcomer unfriendly approaches do not necessarily get zero scores. The table shows that newcomer friendly approaches are superior to unfriendly ones. Note that, like Table 5, this table is also based on controlled experiments and not intended for comparing approaches.

Model	Newcomer Friendly	Rec	MAP	MRR	nDCG
w2v (I4O)	×	3.64	3.23	3.41	2.73
NPM	×	1.37	1.13	1.15	0.92
d2v-nc	✓	6.48	3.52	3.54	3.96
d2v-cac	✓	**8.16**	**5.13**	**5.24**	**5.21**
h-d2v	✓	6.41	4.95	5.21	4.49

Table 7: DBLP results evaluated on 63,342 citation contexts with newcomer ground-truth.

Category	Description
Weak	Weakness of cited approach
CoCoGM	Contrast/Comparison in Goals/Methods (neutral)
CoCo-	Work stated to be superior to cited work
CoCoR0	Contrast/Comparison in Results (neutral)
CoCoXY	Contrast between 2 cited methods
PBas	Author uses cited work as basis or starting point
PUse	Author uses tools/algorithms/data/definitions
PModi	Author adapts or modifies tools/algorithms/data
PMot	This citation is positive about approach used or problem addressed (used to motivate work in current paper)
PSim	Author's work and cited work are similar
PSup	Author's work and cited work are compatible/provide support for each other
Neut	Neutral description of cited work, or not enough textual evidence for above categories, or unlisted citation function

Table 8: Annotation scheme of citation functions in Teufel et al. (2006).

5.3.3 Impact of Context Intent Awareness

In this section, we analyze the impact of context intent awareness. We use Teufel et al. (2006)'s 2,824 citation contexts[11] with annotated citation functions, *e.g.,* emphasizing weakness (Weak) or using tools/algorithms (PBas) of the cited papers. Table 8 from Teufel et al. (2006) describes the full annotating scheme. Teufel et al. (2006) also use manual features to evaluate citation function classification. To test all models on capturing context intents, we average all context words' IN vectors (trained on DBLP) as features. Noticing that pv-dbow does not output IN word vectors, and OUT vectors do not provide reasonable results, we use pv-dm here instead. We use SVM with RBF

[11]The number is 2,829 in the original paper. The inconsistency may be due to different regular expressions we used.

Table 9: Papers recommended by different approaches for a citation context in Zhao and Gildea (2010).

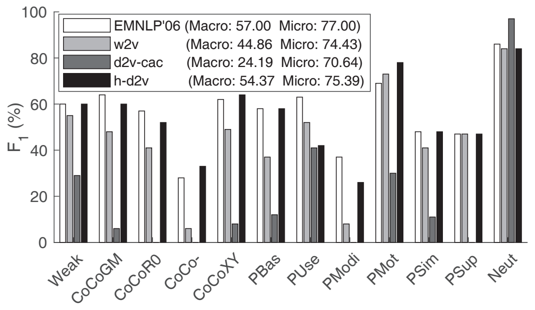

Figure 4: F_1 of citation function classification.

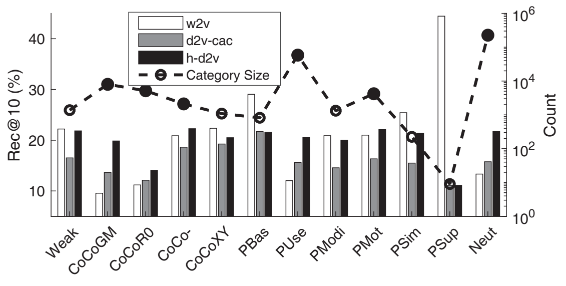

Figure 5: Rec@10 w.r.t. citation functions.

kernels and default parameters. Following Teufel et al. (2006), we use 10-fold cross validation.

Figure 4 depicts the F_1 scores. Scores of Teufel et al. (2006)'s approach are from the original paper. We omit `d2v-nc` because it is very inferior to `d2v-cac`. We have the following observations.

First, Teufel et al. (2006)'s feature-engineering-based approach has the best performance. Note that we cannot obtain their original cross validation split, so the comparison may not be fair and is only for consideration in terms of numbers.

Second, among all embedding-based methods, `h-d2v` has the best citation function classification results, which is close to Teufel et al. (2006)'s.

Finally, the `d2v-cac` vectors are only good at Neutral, the largest class. On the other classes and global F_1, they are outperformed by `w2v` vectors.

To study how citation function affects citation recommendation, we combine the 2,824 labeled citation contexts and another 1,075 labeled contexts the authors published later to train an SVM, and apply it to the DBLP testing set to get citation functions. We evaluate citation recommendation performance of `w2v` (I4O), `d2v-cac`, and `h-d2v` on a per-citation-function basis. In Figure 5, we break down Rec@10 scores on citation functions. On the six largest classes (marked by solid dots), `h-d2v` outperforms all competitors.

To better investigate the impact of context intent awareness, Table 9 shows recommended papers of the running example of this paper. Here, Zhao and Gildea (2010) cited the BLEU metric (Papineni et al., 2002) and Moses tools (Koehn et al., 2007) of machine translation. However, the additional words "machine translation" lead both `w2v` and `d2v-cac` to recommend many machine translation papers. Only our `h-d2v` manages to recognize the citation function "using tools/algorithms (PBas)", and concentrates on the citation intent to return the right papers in top-5 results.

6 Conclusion

We focus on the hyper-doc embedding problem. We propose that hyper-doc embedding algorithms should be content aware, context aware, newcomer friendly, and context intent aware. To meet all four criteria, we propose a general approach, `hyperdoc2vec`, which assigns two vectors to each hyper-doc and models citations in a straightforward manner. In doing so, the learned embeddings satisfy all criteria, which no existing model is able to. For evaluation, paper classification and citation recommendation are conducted on three academic paper datasets. Results confirm the effectiveness of our approach. Further analyses also demonstrate that possessing the four properties helps `h-d2v` outperform other models.

Abstract

This paper presents the Entity-Duet Neural Ranking Model (`EDRM`), which introduces knowledge graphs to neural search systems. `EDRM` represents queries and documents by their words and entity annotations. The semantics from knowledge graphs are integrated in the distributed representations of their entities, while the ranking is conducted by interaction-based neural ranking networks. The two components are learned end-to-end, making `EDRM` a natural combination of entity-oriented search and neural information retrieval. Our experiments on a commercial search log demonstrate the effectiveness of `EDRM`. Our analyses reveal that knowledge graph semantics significantly improve the generalization ability of neural ranking models.

1 Introduction

The emergence of large scale knowledge graphs has motivated the development of *entity-oriented search*, which utilizes knowledge graphs to improve search engines. The recent progresses in entity-oriented search include better text representations with entity annotations (Xiong et al., 2016; Raviv et al., 2016), richer ranking features (Dalton et al., 2014), entity-based connections between query and documents (Liu and Fang, 2015; Xiong and Callan, 2015), and soft-match query and documents through knowledge graph relations or embeddings (Xiong et al., 2017c; Ensan and Bagheri, 2017). These approaches bring in entities and semantics from knowledge graphs and have greatly improved the effectiveness of feature-based search systems.

[*]Corresponding author: M. Sun (sms@tsinghua.edu.cn)

Another frontier of information retrieval is the development of neural ranking models (*neural-IR*). Deep learning techniques have been used to learn distributed representations of queries and documents that capture their relevance relations (*representation-based*) (Shen et al., 2014), or to model the query-document relevancy directly from their word-level interactions (*interaction-based*) (Guo et al., 2016a; Xiong et al., 2017b; Dai et al., 2018). Neural-IR approaches, especially the *interaction-based* ones, have greatly improved the ranking accuracy when large scale training data are available (Dai et al., 2018).

Entity-oriented search and neural-IR push the boundary of search engines from two different aspects. Entity-oriented search incorporates human knowledge from entities and knowledge graph semantics. It has shown promising results on feature-based ranking systems. On the other hand, neural-IR leverages distributed representations and neural networks to learn more sophisticated ranking models form large-scale training data. However, it remains unclear how these two approaches interact with each other and whether the entity-oriented search has the same advantage in neural-IR methods as in feature-based systems.

This paper explores the role of entities and semantics in neural-IR. We present an Entity-Duet Neural Ranking Model (`EDRM`) that incorporates entities in interaction-based neural ranking models. `EDRM` first learns the distributed representations of entities using their semantics from knowledge graphs: descriptions and types. Then it follows a recent state-of-the-art entity-oriented search framework, the word-entity duet (Xiong et al., 2017a), and matches documents to queries with both bag-of-words and bag-of-entities. Instead of manual features, `EDRM` uses interaction-based neural models (Dai et al., 2018) to match query and documents with word-entity duet representations. As a result, EDRM combines entity-oriented search and the interaction based neural-IR; it brings the knowledge graph semantics to neural-IR and enhances entity-oriented search with neural networks.

One advantage of being neural is that EDRM can be learned end-to-end. Given a large amount of user feedback from a commercial search log, the integration of knowledge graph semantics to neural ranker, is learned jointly with the modeling of query-document relevance in EDRM. It provides a convenient data-driven way to leverage external semantics in neural-IR.

Our experiments on a Sogou query log and CN-DBpedia demonstrate the effectiveness of entities and semantics in neural models. EDRM significantly outperforms the word-interaction-based neural ranking model, K-NRM (Xiong et al., 2017a), confirming the advantage of entities in enriching word-based ranking. The comparison with Conv-KNRM (Dai et al., 2018), the recent state-of-the-art neural ranker that models phrase level interactions, provides a more interesting observation: Conv-KNRM predicts user clicks reasonably well, but integrating knowledge graphs using EDRM significantly improves the neural model's generalization ability on more difficult scenarios.

Our analyses further revealed the source of EDRM's generalization ability: the knowledge graph semantics. If only treating entities as ids and ignoring their semantics from the knowledge graph, the entity annotations are only a cleaner version of phrases. In neural-IR systems, the embeddings and convolutional neural networks have already done a decent job in modeling phrase-level matches. However, the knowledge graph semantics brought by EDRM can not yet be captured solely by neural networks; incorporating those human knowledge greatly improves the generalization ability of neural ranking systems.

2 Related Work

Current neural ranking models can be categorized into two groups: representation based and interaction based (Guo et al., 2016b). The earlier works mainly focus on representation based models. They learn good representations and match them in the learned representation space of query and documents. DSSM (Huang et al., 2013) and its convolutional version CDSSM (Shen et al., 2014) get representations by hashing letter-tri-grams to a low dimension vector. A more recent work uses pseudo-labeling as a weak supervised signal to train the representation based ranking model (Dehghani et al., 2017).

The interaction based models learn word-level interaction patterns from query-document pairs. ARC-II (Hu et al., 2014) and MatchPyramind (Pang et al., 2016) utilize Convolutional Neural Network (CNN) to capture complicated patterns from word-level interactions. The Deep Relevance Matching Model (DRMM) (Guo et al., 2016b) uses pyramid pooling (histogram) to summarize the word-level similarities into ranking models. K-NRM and Conv-KNRM use kernels to summarize word-level interactions with word embeddings and provide soft match signals for learning to rank. There are also some works establishing position-dependent interactions for ranking models (Pang et al., 2017; Hui et al., 2017). Interaction based models and representation based models can also be combined for further improvements (Mitra et al., 2017).

Recently, large scale knowledge graphs such as DBpedia (Auer et al., 2007), Yago (Suchanek et al., 2007) and Freebase (Bollacker et al., 2008) have emerged. Knowledge graphs contain human knowledge about real-word entities and become an opportunity for search system to better understand queries and documents. There are many works focusing on exploring their potential for ad-hoc retrieval. They utilize knowledge as a kind of pseudo relevance feedback corpus (Cao et al., 2008) or weight words to better represent query according to well-formed entity descriptions. Entity query feature expansion (Dietz and Verga, 2014) uses related entity attributes as ranking features.

Another way to utilize knowledge graphs in information retrieval is to build the additional connections from query to documents through related entities. Latent Entity Space (LES) builds an unsupervised model using latent entities' descriptions (Liu and Fang, 2015). EsdRank uses related entities as a latent space, and performs learning to rank with various information retrieval features (Xiong and Callan, 2015). AttR-Duet develops a four-way interaction to involve cross matches between entity and word representations to catch more semantic relevance patterns (Xiong et al., 2017a).

There are many other attempts to integrate knowledge graphs in neural models in related tasks (Miller et al., 2016; Gupta et al., 2017; Ghazvininejad et al., 2018). Our work shares a similar spirit and focuses on exploring the effectiveness of knowledge graph semantics in neural-IR.

3 Entity-Duet Neural Ranking Model

This section first describes the standard architecture in current interaction based neural ranking models. Then it presents our Entity-Duet Neural Ranking Model, including the semantic entity representation which integrates the knowledge graph semantics, and then the entity-duet ranking framework. The overall architecture of EDRM is shown in Figure 1.

3.1 Interaction based Ranking Models

Given a query q and a document d, interaction based models first build the word-level translation matrix between q and d (Berger and Lafferty, 1999). The translation matrix describes word pairs similarities using word correlations, which are captured by word embedding similarities in interaction based models.

Typically, interaction based ranking models first map each word t in q and d to an L-dimensional embedding $\vec{v}_t$ with an embedding layer Emb_w:

$$\vec{v}_t = \text{Emb}_w(t). \tag{1}$$

It then constructs the interaction matrix M based on query and document embeddings. Each element M^{ij} in the matrix, compares the ith word in q and the jth word in d, e.g. using the cosine similarity of word embeddings:

$$M^{ij} = \cos(\vec{v}_{t_i^q}, \vec{v}_{t_j^d}). \tag{2}$$

With the translation matrix describing the term level matches between query and documents, the next step is to calculate the final ranking score from the matrix. Many approaches have been developed in interaction base neural ranking models, but in general, that would include a feature extractor $\phi()$ on M and then one or several ranking layers to combine the features to the ranking score.

3.2 Semantic Entity Representation

EDRM incorporates the semantic information about an entity from the knowledge graphs into its representation. The representation includes three embeddings: entity embedding, description embedding, and type embedding, all in L dimension and are combined to generate the semantic representation of the entity.

Entity Embedding uses an L-dimensional embedding layer Emb_e to get an entity embedding $\vec{v}_e^{\text{emb}}$ for e:

$$\vec{v}_e^{\text{emb}} = \text{Emb}_e(e). \tag{3}$$

Description Embedding encodes an entity description which contains m words and explains the entity. EDRM first employs the word embedding layer Emb_w to embed the description word w to $\vec{v}_w$. Then it combines all embeddings in text to an embedding matrix $\vec{V}_w$. Next, it leverages convolutional filters to slide over the text and compose the h length n-gram as $\vec{g}_e^j$:

$$\vec{g}_e^j = \text{ReLu}(W_{\text{CNN}} \cdot \vec{V}_w^{j:j+h} + \vec{b}_{\text{CNN}}), \tag{4}$$

where W_{CNN} and $\vec{b}_{\text{CNN}}$ are two parameters of the covolutional filter.

Then we use max pooling after the convolution layer to generate the description embedding $\vec{v}_e^{\text{des}}$:

$$\vec{v}_e^{\text{des}} = \max(\vec{g}_e^1, ..., \vec{g}_e^j, ..., \vec{g}_e^m). \tag{5}$$

Type Embedding encodes the categories of entities. Each entity e has n kinds of types $F_e = \{f_1, ..., f_j, ..., f_n\}$. EDRM first gets the f_j embedding $\vec{v}_{f_j}$ through the type embedding layer Emb_{tp}:

$$\vec{v}_{f_j}^{\text{emb}} = \text{Emb}_{\text{tp}}(e). \tag{6}$$

Then EDRM utilizes an attention mechanism to combine entity types to the type embedding $\vec{v}_e^{\text{type}}$:

$$\vec{v}_e^{\text{type}} = \sum_j^n a_j \vec{v}_{f_j}, \tag{7}$$

where a_j is the attention score, calculated as:

$$a_j = \frac{\exp(P_j)}{\sum_l^n \exp(P_l)}, \tag{8}$$

$$P_j = (\sum_i W_{\text{bow}} \vec{v}_{t_i}) \cdot \vec{v}_{f_j}. \tag{9}$$

P_j is the dot product of the query or document representation and type embedding f_j. We leverage bag-of-words for query or document encoding. W_{bow} is a parameter matrix.

Combination. The three embeddings are combined by an linear layer to generate the semantic representation of the entity:

$$\vec{v}_e^{\text{sem}} = \vec{v}_e^{\text{emb}} + W_e(\vec{v}_e^{\text{des}} \oplus \vec{v}_e^{\text{type}})^T + \vec{b}_e. \tag{10}$$

W_e is an $L \times 2L$ matrix and $\vec{b}_e$ is an L-dimensional vector.

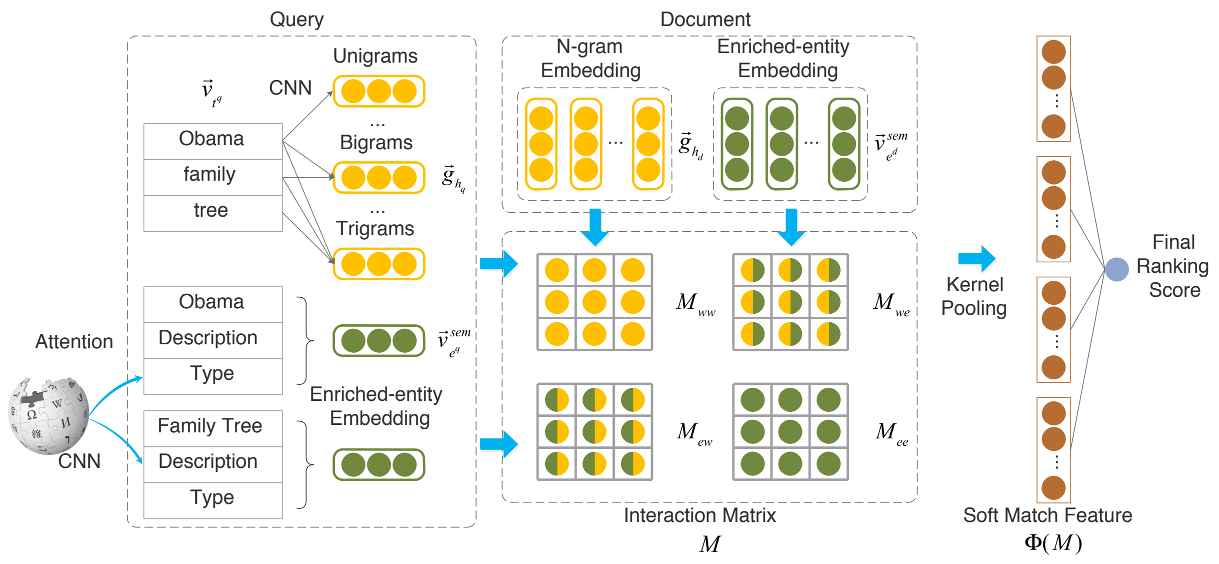

Figure 1: The architecture of EDRM.

3.3 Neural Entity-Duet Framework

Word-entity duet (Xiong et al., 2017a) is a recently developed framework in entity-oriented search. It utilizes the duet representation of bag-of-words and bag-of-entities to match q-d with hand crafted features. This work introduces it to neural-IR.

We first construct bag-of-entities q^e and d^e with entity annotation as well as bag-of-words q^w and d^w for q and d. The duet utilizes a four-way interaction: query words to document words (q^w-d^w), query words to documents entities (q^w-d^e), query entities to document words (q^e-d^w) and query entities to document entities (q^e-d^e).

Instead of features, EDRM uses a translation layer that calculates similarity between a pair of query-document terms: ($\vec{v}^i_{w^q}$ or $\vec{v}^i_{e^q}$) and ($\vec{v}^j_{w^d}$ or $\vec{v}^j_{e^d}$). It constructs the interaction matrix $M = \{M_{ww}, M_{we}, M_{ew}, M_{ee}\}$. And $M_{ww}, M_{we}, M_{ew}, M_{ee}$ denote interactions of q^w-d^w, q^w-d^e, q^e-d^w, q^e-d^e respectively. And elements in them are the cosine similarities of corresponding terms:

$$M^{ij}_{ww} = \cos(\vec{v}^i_{w^q}, \vec{v}^j_{w^d}); M^{ij}_{ee} = \cos(\vec{v}^i_{e^q}, \vec{v}^j_{e^d})$$
$$M^{ij}_{ew} = \cos(\vec{v}^i_{e^q}, \vec{v}^j_{w^d}); M^{ij}_{we} = \cos(\vec{v}^i_{w^q}, \vec{v}^j_{e^d}). \quad (11)$$

The final ranking feature $\Phi(\mathcal{M})$ is a concatenation ($\oplus$) of four cross matches ($\phi(M)$):

$$\Phi(\mathcal{M}) = \phi(M_{ww}) \oplus \phi(M_{we}) \oplus \phi(M_{ew}) \oplus \phi(M_{ee}), \quad (12)$$

where the ϕ can be any function used in interaction based neural ranking models.

The entity-duet presents an effective way to cross match query and document in entity and word spaces. In EDRM, it introduces the knowledge graph semantics representations into neural-IR models.

4 Integration with Kernel based Neural Ranking Models

The duet translation matrices provided by EDRM can be plugged into any standard interaction based neural ranking models. This section expounds special cases where it is integrated with K-NRM (Xiong et al., 2017b) and Conv-KNRM (Dai et al., 2018), two recent state-of-the-arts.

K-NRM uses K Gaussian kernels to extract the matching feature $\phi(M)$ from the translation matrix M. Each kernel K_k summarizes the translation scores as soft-TF counts, generating a K-dimensional feature vector $\phi(M) = \{K_1(M), ..., K_K(M)\}$:

$$K_k(M) = \sum_j \exp(-\frac{M^{ij} - \mu_k}{2\delta_k^2}). \quad (13)$$

μ_k and δ_k are the mean and width for the kth kernel. Conv-KNRM extend K-NRM incorporating h-gram compositions $\vec{g}^i_h$ from text embedding $\vec{V}_T$ using CNN:

$$\vec{g}^i_h = \text{relu}(W_h \cdot \vec{V}^{i:i+h}_T + \vec{v}_h). \quad (14)$$

Then a translation matrix M_{h_q,h_d} is constructed. Its elements are the similarity scores of h-gram pairs between query and document:

$$M_{h_q,h_d} = \cos(\vec{g}^{i}_{h_q}, \vec{g}^{j}_{h_d}). \quad (15)$$

We also extend word n-gram cross matches to word entity duet matches:

$$\Phi(\mathcal{M}) = \phi(M_{1,1}) \oplus ... \oplus \phi(M_{h_q,h_d}) \oplus ... \oplus \phi(M_{ee}). \quad (16)$$

Each ranking feature $\phi(M_{h_q,h_d})$ contains three parts: query h_q-gram and document h_d-gram match feature ($\phi(M_{ww^{h_q,h_d}})$), query entity and document h_d-gram match feature ($\phi(M_{ew^{1,h_d}})$), and query h_q-gram and document entity match feature ($\phi(M_{ww^{h_q,1}})$):

$$\phi(M_{h_q,h_d}) = \phi(M_{ww^{h_q,h_d}}) \oplus \phi(M_{ew^{1,h_d}}) \oplus \phi(M_{we^{h_q,1}}). \quad (17)$$

We then use learning to rank to combine ranking feature $\Phi(\mathcal{M})$ to produce the final ranking score:

$$f(q,d) = \tanh(\omega_r^T \Phi(\mathcal{M}) + b_r). \quad (18)$$

ω_r and b_r are the ranking parameters. tanh is the activation function.

We use standard pairwise loss to train the model:

$$l = \sum_q \sum_{d^+,d^- \in D_q^{+,-}} \max(0, 1 - f(q,d^+) + f(q,d^-)), \quad (19)$$

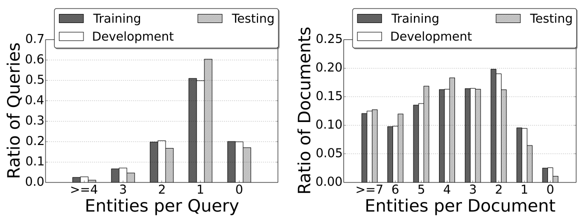
where the d^+ is a document ranks higher than d^-.

With sufficient training data, the whole model is optimized end-to-end with back-propagation. During the process, the integration of the knowledge graph semantics, entity embedding, description embeddings, type embeddings, and matching with entities-are learned jointly with the ranking neural network.

5 Experimental Methodology

This section describes the dataset, evaluation metrics, knowledge graph, baselines, and implementation details of our experiments.

Dataset. Our experiments use a query log from Sogou.com, a major Chinese searching engine (Luo et al., 2017). The exact same dataset and training-testing splits in the previous research (Xiong et al., 2017b; Dai et al., 2018) are used. They defined the ad-hoc ranking task in this dataset as re-ranking the candidate documents provided by the search engine. All Chinese texts are segmented by ICTCLAS (Zhang et al., 2003), after that they are treated the same as English.



(a) Statistic of queries (b) Statistic of documents

Figure 2: Query and document distributions. Queries and documents are grouped by the number of entities.

Prior research leverages clicks to model user behaviors and infer reliable relevance signals using click models (Chuklin et al., 2015). DCTR and TACM are two click models: DCTR calculates the relevance scores of a query-document pair based on their click through rates (CTR); TACM (Wang et al., 2013) is a more sophisticated model that uses both clicks and dwell times. Following previous research (Xiong et al., 2017b), both DCTR and TACM are used to infer labels. DCTR inferred relevance labels are used in training. Three testing scenarios are used: Testing-SAME, Testing-DIFF and Testing-RAW.

Testing-SAME uses DCTR labels, the same as in training. Testing-DIFF evaluates models performance based on TACM inferred relevance labels. Testing-RAW evaluates ranking models through user clicks, which tests ranking performance for the most satisfying document. Testing-DIFF and Testing-RAW are harder scenarios that challenge the generalization ability of all models, because their training labels and testing labels are generated differently (Xiong et al., 2017b).

Evaluation Metrics. NDCG@1 and NDCG@10 are used in Testing-SAME and Testing-DIFF. MRR is used for Testing-Raw. Statistic significances are tested by permutation test with P$<$ 0.05. All are the same as in previous research (Xiong et al., 2017b).

Knowledge Graph. We use CN-DBpedia (Xu et al., 2017), a large scale Chinese knowledge graph based on Baidu Baike, Hudong Baike, and Chinese Wikipedia. CN-DBpedia contains 10,341,196 entities and 88,454,264 relations. The query and document entities are annotated by CMNS, the commonness (popularity) based entity linker (Hasibi et al., 2017). CN-DBpedia and CMNS provide good coverage on our queries and

documents. As shown in Figure 2, the majority of queries have at least one entity annotation; the average number of entity annotated per document title is about four.

Baselines. The baselines include feature-based ranking models and neural ranking models. Most of the baselines are borrowed from previous research (Xiong et al., 2017b; Dai et al., 2018).

Feature-based baselines include two learning to rank systems, RankSVM (Joachims, 2002) and coordinate ascent (Coor-Accent) (Metzler and Croft, 2006). The standard word-based unsupervised retrieval model, BM25, is also compared.

Neural baselines include CDSSM (Shen et al., 2014), MatchPyramid (MP) (Pang et al., 2016), DRMM (Grauman and Darrell, 2005), K-NRM (Xiong et al., 2017b) and Conv-KNRM (Dai et al., 2018). CDSSM is representation based. It uses CNN to build query and document representations on word letter-tri-grams (or Chinese characters). MP and DRMM are both interaction based models. They use CNNs or histogram pooling to extract features from embedding based translation matrix.

Our main baselines are K-NRM and Conv-KNRM, the recent state-of-the-art neural models on the Sogou-Log dataset. The goal of our experiments is to explore the effectiveness of knowledge graphs in these state-of-the-art interaction based neural models.

Implementation Details. The dimension of word embedding, entity embedding and type embedding are 300. Vocabulary size of entities and words are 44,930 and 165,877. Conv-KNRM uses one layer CNN with 128 filter size for the n-gram composition. Entity description encoder is a one layer CNN with 128 and 300 filter size for Conv-KNRM and K-NRM respectively.

All models are implemented with PyTorch. Adam is utilized to optimize all parameters with learning rate $= 0.001$, $\epsilon = 1e - 5$ and early stopping with the practice of 5 epochs.

There are two versions of EDRM: EDRM-KNRM and EDRM-CKNRM, integrating with K-NRM and Conv-KNRM respectively. The first one (K-NRM) enriches the word based neural ranking model with entities and knowledge graph semantics; the second one (Conv-KNRM) enriches the n-gram based neural ranking model.

6 Evaluation Results

Four experiments are conducted to study the effectiveness of EDRM: the overall performance, the contributions of matching kernels, the ablation study, and the influence of entities in different scenarios. We also do case studies to show effect of EDRM on document ranking.

6.1 Ranking Accuracy

The ranking accuracies of the ranking methods are shown in Table 1. K-NRM and Conv-KNRM outperform other baselines in all testing scenarios by large margins as shown in previous research.

EDRM-KNRM out performs K-NRM by over 10% improvement in Testing-SAME and Testing-DIFF. EDRM-CKNRM has almost same performance on Testing-SAME with Conv-KNRM. A possible reason is that, entity annotations provide effective phrase matches, but Conv-KNRM is also able to learn phrases matches automatically from data. However, EDRM-CKNRM has significant improvement on Testing-DIFF and Testing-RAW. Those demonstrate that EDRM has strong ability to overcome domain differences from different labels.

Table 2: Ranking accuracy of adding diverse semantics based on K-NRM and Conv-KNRM. Relative performances compared are in percentages. †, ‡, §, ¶, $*$, $**$ indicate statistically significant improvements over K-NRM† (or Conv-KNRM†), +Embed‡, +Type§, +Description¶, +Embed+Type* and +Embed+Description** respectively.

(a) Kernel weight distribution for EDRM-KNRM. (b) Kernel weight distribution for EDRM-CKNRM.

Figure 3: Ranking contribution for EDRM. Three scenarios are presented: Exact VS. Soft compares the weights of exact match kernel and others; Solo Word VS. Others shows the proportion of only text based matches; In-space VS. Cross-space compares in-space matches and cross-space matches.

These results show the effectiveness and the generalization ability of `EDRM`. In the following experiments, we study the source of this generalization ability.

6.2 Contributions of Matching Kernels

This experiment studies the contribution of knowledge graph semantics by investigating the weights learned on the different types of matching kernels.

As shown in Figure 3(a), most of the weight in `EDRM-KNRM` goes to soft match (Exact VS. Soft); entity related matches play an as important role as word based matches (Solo Word VS. Others); cross-space matches are more important than in-space matches (In-space VS. Cross-space). As shown in Figure 3(b), the percentages of word based matches and cross-space matches are more important in `EDRM-CKNRM` compared to in `EDRM-KNRM`.

The contribution of each individual match type in `EDRM-CKNRM` is shown in Figure 4. The weight of unigram, bigram, trigram, and entity is almost uniformly distributed, indicating the effectiveness of entities and all components are important in `EDRM-CKNRM`.

6.3 Ablation Study

This experiment studies which part of the knowledge graph semantics leads to the effectiveness and generalization ability of `EDRM`.

There are three types of embeddings incorporating different aspects of knowledge graph information: entity embedding (Embed), description embedding (Description) and type embedding (Type). This experiment starts with the word-only `K-NRM` and `Conv-KNRM`, and adds these three types of embedding individually or two-by-two (Embed+Type and Embed+Description).

The performances of `EDRM` with different groups of embeddings are shown in Table 2. The description embeddings show the greatest improvement among the three embeddings. Entity

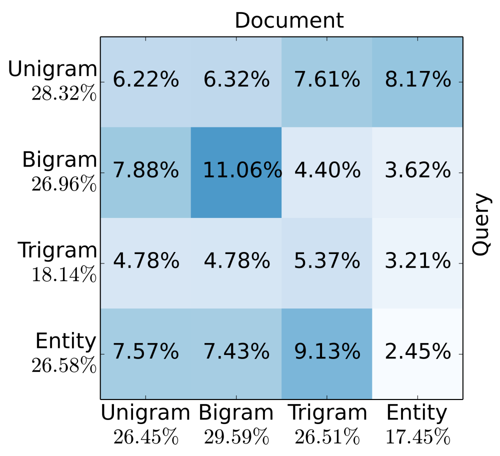

Figure 4: Individual kernel weight for EDRM-CKNRM. X-axis and y-axis denote document and query respectively.

type plays an important role only combined with other embeddings. Entity embedding improves `K-NRM` while has little effect on `Conv-KNRM`. This result further confirms that the signal from entity names are captured by the n-gram CNNs in `Conv-KNRM`. Incorporating all of three embeddings usually gets the best ranking performance.

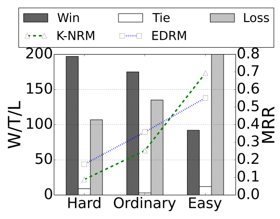
This experiments shows that knowledge graph semantics are crucial to `EDRM`'s effectiveness. `Conv-KNRM` learns good phrase matches that overlap with the entity embedding signals. However, the knowledge graph semantics (descriptions and types) is hard to be learned just from user clicks.

6.4 Performance on Different Scenarios

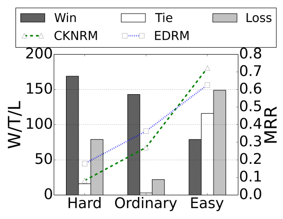
This experiment analyzes the influence of knowledge graphs in two different scenarios: multiple difficulty degrees and multiple length degrees.

Query Difficulty Experiment studies `EDRM`'s performance on testing queries at different difficulty, partitioned by `Conv-KNRM`'s MRR value: Hard (MRR $<$ 0.167), Ordinary (MRR $\in [0.167, 0.382]$, and Easy (MRR $>$ 0.382). As shown in Figure 5, `EDRM` performs the best on hard queries.

Query Length Experiment evaluates `EDRM`'s effectiveness on Short (1 words), Medium (2-3 words) and Long (4 or more words) queries. As shown in Figure 6, `EDRM` has more win cases and achieves the greatest improvement on short queries. Knowledge embeddings are more crucial when limited information is available from the original query text.

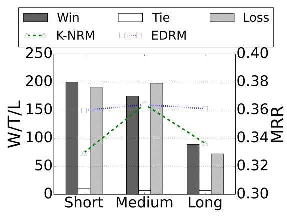


(a) K-NRM VS. EDRM

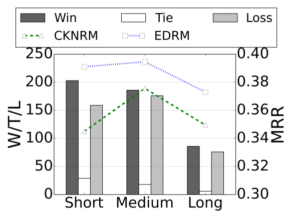


(b) Conv-KNRM VS. EDRM

Figure 5: Performance VS. Query Difficulty. The x-axises mark three query difficulty levels. The y-axises are the Win/Tie/Loss (left) and MRR (right) in the corresponding group.



(a) K-NRM VS. EDRM



(b) Conv-KNRM VS. EDRM

Figure 6: Performance VS. Query Length. The x-axises mark three query length levels, and y-axises are the Win/Tie/Loss (left) and MRR (right) in the corresponding group.

These two experiments reveal that the effectiveness of `EDRM` is more observed on harder or shorter queries, whereas the word-based neural models either find it difficult or do not have sufficient information to leverage.

6.5 Case Study

Table 3 provide examples reflecting two possible ways, in which the knowledge graph semantics could help the document ranking.

First, the entity descriptions explain the meaning of entities and connect them through the word space. *Meituxiuxiu web version* and *Meilishuo* are two websites providing image processing and shopping services respectively. Their descriptions provide extra ranking signals to promote the related documents.

Second, entity types establish underlying relevance patterns between query and documents. The underlying patterns can be captured by cross-space matches. For example, the types of the query entity *Crayon Shin-chan* and *GINTAMA* overlaps with the bag-of-words in the relevant documents. They can also be captured by the entity-based matches through their type overlaps,

Table 3: Examples of entity semantics connecting query and title. All the examples are correctly ranked by EDRM-CKNRM. Table 3a shows query-document pairs. Table 3b lists the related entity semantics that include useful information to match the query-document pair. The examples and related semantics are picked by manually examining the ranking changes between different variances of `EDRM-CKNRM`.

(a) Query and document examples. *Entities* are emphasized.

Query	Document
Meituxiuxiu web version	*Meituxiuxiu web version*: An online picture processing tools
Home page of *Meilishuo*	Home page of *Meilishuo* - Only the correct popular fashion
Master Lu	Master Lu official website: *System optimization*, hardware test, phone evaluation
Crayon Shin-chan: The movie	*Crayon Shin-chan*: The movie online - Anime
GINTAMA	*GINTAMA*: The movie online - Anime - Full HD online watch

(b) Semantics of related entities. The first two rows and last two rows show entity descriptions and entity types respectively.

Entity	Content
Meituxiuxiu web version	Description: Meituxiuxiu is the most popular Chinese image processing software, launched by the Meitu company
Meilishuo	Description: Meilishuo, the largest women's fashion e-commerce platform, dedicates to provide the most popular fashion shopping experience
Crayon Shin-chan, *GINTAMA*	Type: Anime; Cartoon characters; Comic
Master Lu, *System Optimization*	Type: Hardware test; Software; System tool

for example, between the query entity *Master Lu* and the document entity *System Optimization*.

7 Conclusions

This paper presents `EDRM`, the Entity-Duet Neural Ranking Model that incorporating knowledge graph semantics into neural ranking systems. `EDRM` inherits entity-oriented search to match query and documents with bag-of-words and bag-of-entities in neural ranking models. The knowledge graph semantics are integrated as distributed representations of entities. The neural model leverages these semantics to help document ranking. Using user clicks from search logs, the whole model—the integration of knowledge graph semantics and the neural ranking networks–is trained end-to-end. It leads to a data-driven combination of entity-oriented search and neural information retrieval.

Our experiments on the Sogou search log and CN-DBpedia demonstrate `EDRM`'s effectiveness and generalization ability over two state-of-the-art neural ranking models. Our further analyses reveal that the generalization ability comes from the integration of knowledge graph semantics. The neural ranking models can effectively model n-gram matches between query and document, which overlaps with part of the ranking signals from entity-based matches: Solely adding the entity names may not improve the ranking accuracy much. However, the knowledge graph semantics, introduced by the description and type embeddings, provide novel ranking signals that greatly improve the generalization ability of neural rankers in difficult scenarios.

This paper preliminarily explores the role of structured semantics in deep learning models. Though mainly fouced on search, we hope our findings shed some lights on a potential path towards more intelligent neural systems and will motivate more explorations in this direction.

Abstract

Modeling natural language inference is a very challenging task. With the availability of large annotated data, it has recently become feasible to train complex models such as neural-network-based inference models, which have shown to achieve the state-of-the-art performance. Although there exist relatively large annotated data, can machines learn all knowledge needed to perform natural language inference (NLI) from these data? If not, how can neural-network-based NLI models benefit from external knowledge and how to build NLI models to leverage it? In this paper, we enrich the state-of-the-art neural natural language inference models with external knowledge. We demonstrate that the proposed models improve neural NLI models to achieve the state-of-the-art performance on the SNLI and MultiNLI datasets.

1 Introduction

Reasoning and inference are central to both human and artificial intelligence. Natural language inference (NLI), also known as recognizing textual entailment (RTE), is an important NLP problem concerned with determining inferential relationship (e.g., entailment, contradiction, or neutral) between a premise p and a hypothesis h. In general, modeling informal inference in language is a very challenging and basic problem towards achieving true natural language understanding.

In the last several years, larger annotated datasets were made available, e.g., the SNLI (Bowman et al., 2015) and MultiNLI datasets (Williams et al., 2017), which made it feasible to train rather complicated neural-network-based models that fit a large set of parameters to better model NLI. Such models have shown to achieve the state-of-the-art performance (Bowman et al., 2015, 2016; Yu and Munkhdalai, 2017b; Parikh et al., 2016; Sha et al., 2016; Chen et al., 2017a,b; Tay et al., 2018).

While neural networks have been shown to be very effective in modeling NLI with large training data, they have often focused on end-to-end training by assuming that all inference knowledge is learnable from the provided training data. In this paper, we relax this assumption and explore whether external knowledge can further help NLI. Consider an example:

- p: A lady standing in a *wheat* field.
- h: A person standing in a *corn* field.

In this simplified example, when computers are asked to predict the relation between these two sentences and if training data do not provide the knowledge of relationship between "wheat" and "corn" (e.g., if one of the two words does not appear in the training data or they are not paired in any premise-hypothesis pairs), it will be hard for computers to correctly recognize that the premise contradicts the hypothesis.

In general, although in many tasks learning *tabula rasa* achieved state-of-the-art performance, we believe complicated NLP problems such as NLI could benefit from leveraging knowledge accumulated by humans, particularly in a foreseeable future when machines are unable to learn it by themselves.

In this paper we enrich neural-network-based NLI models with external knowledge in co-attention, local inference collection, and inference composition components. We show the proposed model improves the state-of-the-art NLI models to achieve better performances on the SNLI and MultiNLI datasets. The advantage of using external knowledge is more significant when the size of training data is restricted, suggesting that if more knowledge can be obtained, it may bring more benefit. In addition to attaining the state-of-the-art performance, we are also interested in understanding how external knowledge contributes to the major components of typical neural-network-based NLI models.

2 Related Work

Early research on natural language inference and recognizing textual entailment has been performed on relatively small datasets (refer to MacCartney (2009) for a good literature survey), which includes a large bulk of contributions made under the name of RTE, such as (Dagan et al., 2005; Iftene and Balahur-Dobrescu, 2007), among many others.

More recently the availability of much larger annotated data, e.g., SNLI (Bowman et al., 2015) and MultiNLI (Williams et al., 2017), has made it possible to train more complex models. These models mainly fall into two types of approaches: sentence-encoding-based models and models using also inter-sentence attention. Sentence-encoding-based models use Siamese architecture (Bromley et al., 1993). The parameter-tied neural networks are applied to encode both the premise and the hypothesis. Then a neural network classifier is applied to decide relationship between the two sentences. Different neural networks have been utilized for sentence encoding, such as LSTM (Bowman et al., 2015), GRU (Vendrov et al., 2015), CNN (Mou et al., 2016), BiLSTM and its variants (Liu et al., 2016c; Lin et al., 2017; Chen et al., 2017b; Nie and Bansal, 2017), self-attention network (Shen et al., 2017, 2018), and more complicated neural networks (Bowman et al., 2016; Yu and Munkhdalai, 2017a,b; Choi et al., 2017). Sentence-encoding-based models transform sentences into fixed-length vector representations, which may help a wide range of tasks (Conneau et al., 2017).

The second set of models use inter-sentence attention (Rocktäschel et al., 2015; Wang and Jiang, 2016; Cheng et al., 2016; Parikh et al., 2016; Chen et al., 2017a). Among them, Rocktäschel et al. (2015) were among the first to propose neural attention-based models for NLI. Chen et al. (2017a) proposed an enhanced sequential inference model (ESIM), which is one of the best models so far and is used as one of our baselines in this paper.

In this paper we enrich neural-network-based NLI models with external knowledge. Unlike early work on NLI (Jijkoun and de Rijke, 2005; MacCartney et al., 2008; MacCartney, 2009) that explores external knowledge in conventional NLI models on relatively small NLI datasets, we aim to merge the advantage of powerful modeling ability of neural networks with extra external inference knowledge. We show that the proposed model improves the state-of-the-art neural NLI models to achieve better performances on the SNLI and MultiNLI datasets. The advantage of using external knowledge is more significant when the size of training data is restricted, suggesting that if more knowledge can be obtained, it may have more benefit. In addition to attaining the state-of-the-art performance, we are also interested in understanding how external knowledge affect major components of neural-network-based NLI models.

In general, external knowledge has shown to be effective in neural networks for other NLP tasks, including word embedding (Chen et al., 2015; Faruqui et al., 2015; Liu et al., 2015; Wieting et al., 2015; Mrksic et al., 2017), machine translation (Shi et al., 2016; Zhang et al., 2017b), language modeling (Ahn et al., 2016), and dialogue systems (Chen et al., 2016b).

3 Neural-Network-Based NLI Models with External Knowledge

In this section we propose neural-network-based NLI models to incorporate external inference knowledge, which, as we will show later in Section 5, achieve the state-of-the-art performance. In addition to attaining the leading performance we are also interested in investigating the effects of external knowledge on major components of neural-network-based NLI modeling.

Figure 1 shows a high-level general view of the proposed framework. While specific NLI systems vary in their implementation, typical state-of-the-art NLI models contain the main components (or equivalents) of representing premise and hypothesis sentences, collecting local (e.g., lexical) inference information, and aggregating and composing local information to make the global decision at the sentence level. We incorporate and investigate external knowledge accordingly in these major NLI components: computing co-attention, collecting local inference information, and composing inference to make final decision.

3.1 External Knowledge

As discussed above, although there exist relatively large annotated data for NLI, can machines learn all inference knowledge needed to perform NLI from the data? If not, how can neural network-based NLI models benefit from external knowledge and how to build NLI models to leverage it?

We study the incorporation of external, inference-related knowledge in major components of neural networks for natural language inference. For example, intuitively knowledge about *synonymy*, *antonymy*, *hypernymy* and *hyponymy* between given words may help model soft-alignment between premises and hypotheses; knowledge about *hypernymy* and *hyponymy* may help capture entailment; knowledge about *antonymy* and *co-hyponyms* (words sharing the same hypernym) may benefit the modeling of contradiction.

In this section, we discuss the incorporation of basic, lexical-level semantic knowledge into neural NLI components. Specifically, we consider external lexical-level inference knowledge between word w_i and w_j, which is represented as a vector $\boldsymbol{r}_{ij}$ and is incorporated into three specific components shown in Figure 1. We will discuss the details of how $\boldsymbol{r}_{ij}$ is constructed later in the experiment setup section (Section 4) but instead focus on the proposed model in this section. Note that while we study lexical-level inference knowledge in the paper, if inference knowledge about larger pieces of text pairs (e.g., inference relations between phrases) are available, the proposed model can be easily extended to handle that. In this paper, we instead let the NLI models to compose lexical-level knowledge to obtain inference relations between larger pieces of texts.

3.2 Encoding Premise and Hypothesis

Same as much previous work (Chen et al., 2017a,b), we encode the premise and the hypothesis with bidirectional LSTMs (BiLSTMs). The premise is represented as $\boldsymbol{a} = (a_1, \ldots, a_m)$ and the hypothesis is $\boldsymbol{b} = (b_1, \ldots, b_n)$, where m and n are the lengths of the sentences. Then $\boldsymbol{a}$ and $\boldsymbol{b}$ are embedded into d_e-dimensional vectors $[\mathbf{E}(a_1), \ldots, \mathbf{E}(a_m)]$ and $[\mathbf{E}(b_1), \ldots, \mathbf{E}(b_n)]$ using the embedding matrix $\mathbf{E} \in \mathbb{R}^{d_e \times |V|}$, where $|V|$ is the vocabulary size and $\mathbf{E}$ can be initialized with the pre-trained word embedding. To represent words in its context, the premise and the hypothesis are fed into BiLSTM encoders (Hochreiter and Schmidhuber, 1997) to obtain context-dependent hidden states $\boldsymbol{a}^s$ and $\boldsymbol{b}^s$:

$$\boldsymbol{a}_i^s = \text{Encoder}(\mathbf{E}(\boldsymbol{a}), i)\,, \tag{1}$$

$$\boldsymbol{b}_j^s = \text{Encoder}(\mathbf{E}(\boldsymbol{b}), j)\,. \tag{2}$$

where i and j indicate the i-th word in the premise and the j-th word in the hypothesis, respectively.

3.3 Knowledge-Enriched Co-Attention

As discussed above, soft-alignment of word pairs between the premise and the hypothesis may benefit from knowledge-enriched co-attention mechanism. Given the relation features $\boldsymbol{r}_{ij} \in \mathbb{R}^{d_r}$ between the premise's i-th word and the hypothesis's j-th word derived from the external knowledge, the co-attention is calculated as:

$$e_{ij} = (\boldsymbol{a}_i^s)^{\mathrm{T}} \boldsymbol{b}_j^s + F(\boldsymbol{r}_{ij})\,. \tag{3}$$

The function F can be any non-linear or linear functions. In this paper, we use $F(\boldsymbol{r}_{ij}) = \lambda \mathbb{1}(\boldsymbol{r}_{ij})$, where λ is a hyper-parameter tuned on the development set and $\mathbb{1}$ is the indication function as follows:

$$\mathbb{1}(\boldsymbol{r}_{ij}) = \begin{cases} 1 & \text{if } \boldsymbol{r}_{ij} \text{ is not a zero vector}\,; \\ 0 & \text{if } \boldsymbol{r}_{ij} \text{ is a zero vector}\,. \end{cases} \tag{4}$$

Intuitively, word pairs with semantic relationship, e.g., synonymy, antonymy, hypernymy, hyponymy and co-hyponyms, are probably aligned together. We will discuss how we construct external knowledge later in Section 4. We have also tried a two-layer MLP as a universal function approximator in function F to learn the underlying combination function but did not observe further improvement over the best performance we obtained on the development datasets.

Figure 1: A high-level view of neural-network-based NLI models enriched with external knowledge in co-attention, local inference collection, and inference composition.

Soft-alignment is determined by the co-attention matrix $\mathbf{e} \in \mathbb{R}^{m\times n}$ computed in Equation (3), which is used to obtain the local relevance between the premise and the hypothesis. For the hidden state of the i-th word in the premise, i.e., $\boldsymbol{a}_i^s$ (already encoding the word itself and its context), the relevant semantics in the hypothesis is identified into a context vector $\boldsymbol{a}_i^c$ using e_{ij}, more specifically with Equation (5).

$$\alpha_{ij} = \frac{\exp(e_{ij})}{\sum_{k=1}^{n}\exp(e_{ik})}\,,\ \boldsymbol{a}_i^c = \sum_{j=1}^{n}\alpha_{ij}\boldsymbol{b}_j^s\,, \quad (5)$$

$$\beta_{ij} = \frac{\exp(e_{ij})}{\sum_{k=1}^{m}\exp(e_{kj})}\,,\ \boldsymbol{b}_j^c = \sum_{i=1}^{m}\beta_{ij}\boldsymbol{a}_i^s\,, \quad (6)$$

where $\boldsymbol{\alpha} \in \mathbb{R}^{m\times n}$ and $\boldsymbol{\beta} \in \mathbb{R}^{m\times n}$ are the normalized attention weight matrices with respect to the 2-axis and 1-axis. The same calculation is performed for each word in the hypothesis, i.e., $\boldsymbol{b}_j^s$, with Equation (6) to obtain the context vector $\boldsymbol{b}_j^c$.

3.4 Local Inference Collection with External Knowledge

By way of comparing the inference-related semantic relation between $\boldsymbol{a}_i^s$ (individual word representation in premise) and $\boldsymbol{a}_i^c$ (context representation from hypothesis which is align to word $\boldsymbol{a}_i^s$), we can model local inference (i.e., word-level inference) between aligned word pairs. Intuitively, for example, knowledge about hypernymy or hyponymy may help model entailment and knowledge about antonymy and co-hyponyms may help model contradiction. Through comparing $\boldsymbol{a}_i^s$ and $\boldsymbol{a}_i^c$, in addition to their relation from external knowledge, we can obtain word-level inference information for each word. The same calculation is performed for $\boldsymbol{b}_j^s$ and $\boldsymbol{b}_j^c$. Thus, we collect knowledge-enriched local inference information:

$$\boldsymbol{a}_i^m = G([\boldsymbol{a}_i^s; \boldsymbol{a}_i^c; \boldsymbol{a}_i^s - \boldsymbol{a}_i^c; \boldsymbol{a}_i^s \circ \boldsymbol{a}_i^c; \sum_{j=1}^{n}\alpha_{ij}\boldsymbol{r}_{ij}])\,, \quad (7)$$

$$\boldsymbol{b}_j^m = G([\boldsymbol{b}_j^s, \boldsymbol{b}_j^c; \boldsymbol{b}_j^s - \boldsymbol{b}_j^c; \boldsymbol{b}_j^s \circ \boldsymbol{b}_j^c; \sum_{i=1}^{m}\beta_{ij}\boldsymbol{r}_{ji}])\,, \quad (8)$$

where a heuristic matching trick with difference and element-wise product is used (Mou et al., 2016; Chen et al., 2017a). The last terms in Equation (7)(8) are used to obtain word-level inference information from external knowledge. Take Equation (7) as example, $\boldsymbol{r}_{ij}$ is the relation feature between the i-th word in the premise and the j-th word in the hypothesis, but we care more about semantic relation between aligned word pairs between the premise and the hypothesis. Thus, we use a soft-aligned version through the soft-alignment weight α_{ij}. For the i-th word in the premise, the last term in Equation (7) is a word-level inference information based on external knowledge between the i-th word and the aligned word. The same calculation for hypothesis is performed in Equation (8). G is a non-linear mapping function to reduce dimensionality. Specifically, we use a 1-layer feed-forward neural network with the ReLU activation function with a shortcut connection, i.e., concatenate the hidden states after ReLU with the input $\sum_{j=1}^{n}\alpha_{ij}\boldsymbol{r}_{ij}$ (or $\sum_{i=1}^{m}\beta_{ij}\boldsymbol{r}_{ji}$) as the output $\boldsymbol{a}_i^m$ (or $\boldsymbol{b}_j^m$).

3.5 Knowledge-Enhanced Inference Composition

In this component, we introduce knowledge-enriched inference composition. To determine the overall inference relationship between the premise and the hypothesis, we need to explore a composition layer to compose the local inference vectors ($\boldsymbol{a}^m$ and $\boldsymbol{b}^m$) collected above:

$$\boldsymbol{a}_i^v = \text{Composition}(\boldsymbol{a}^m, i)\,, \tag{9}$$

$$\boldsymbol{b}_j^v = \text{Composition}(\boldsymbol{b}^m, j)\,. \tag{10}$$

Here, we also use BiLSTMs as building blocks for the composition layer, but the responsibility of BiLSTMs in the inference composition layer is completely different from that in the input encoding layer. The BiLSTMs here read local inference vectors ($\boldsymbol{a}^m$ and $\boldsymbol{b}^m$) and learn to judge the types of local inference relationship and distinguish crucial local inference vectors for overall sentence-level inference relationship. Intuitively, the final prediction is likely to depend on word pairs appearing in external knowledge that have some semantic relation. Our inference model converts the output hidden vectors of BiLSTMs to the fixed-length vector with pooling operations and puts it into the final classifier to determine the overall inference class. Particularly, in addition to using mean pooling and max pooling similarly to ESIM (Chen et al., 2017a), we propose to use weighted pooling based on external knowledge to obtain a fixed-length vector as in Equation (11)(12).

$$\boldsymbol{a}^{\mathrm{w}} = \sum_{i=1}^{m} \frac{\exp(H(\sum_{j=1}^{n} \alpha_{ij}\boldsymbol{r}_{ij}))}{\sum_{i=1}^{m}\exp(H(\sum_{j=1}^{n} \alpha_{ij}\boldsymbol{r}_{ij}))}\boldsymbol{a}_i^v\,, \tag{11}$$

$$\boldsymbol{b}^{\mathrm{w}} = \sum_{j=1}^{n} \frac{\exp(H(\sum_{i=1}^{m} \beta_{ij}\boldsymbol{r}_{ji}))}{\sum_{j=1}^{n}\exp(H(\sum_{i=1}^{m} \beta_{ij}\boldsymbol{r}_{ji}))}\boldsymbol{b}_j^v\,. \tag{12}$$

In our experiments, we regard the function H as a 1-layer feed-forward neural network with ReLU activation function. We concatenate all pooling vectors, i.e., mean, max, and weighted pooling, into the fixed-length vector and then put the vector into the final multilayer perceptron (MLP) classifier. The MLP has one hidden layer with *tanh* activation and *softmax* output layer in our experiments. The entire model is trained end-to-end, through minimizing the cross-entropy loss.

4 Experiment Set-Up

4.1 Representation of External Knowledge

Lexical Semantic Relations As described in Section 3.1, to incorporate external knowledge (as a knowledge vector $\boldsymbol{r}_{ij}$) to the state-of-the-art neural network-based NLI models, we first explore semantic relations in WordNet (Miller, 1995), motivated by MacCartney (2009). Specifically, the relations of lexical pairs are derived as described in (1)-(4) below. Instead of using Jiang-Conrath WordNet distance metric (Jiang and Conrath, 1997), which does not improve the performance of our models on the development sets, we add a new feature, i.e., *co-hyponyms*, which consistently benefit our models.

(1) *Synonymy*: It takes the value 1 if the words in the pair are synonyms in WordNet (i.e., belong to the same synset), and 0 otherwise. For example, [felicitous, good] = 1, [dog, wolf] = 0.

(2) *Antonymy*: It takes the value 1 if the words in the pair are antonyms in WordNet, and 0 otherwise. For example, [wet, dry] = 1.

(3) *Hypernymy*: It takes the value $1 - n/8$ if one word is a (direct or indirect) hypernym of the other word in WordNet, where n is the number of edges between the two words in hierarchies, and 0 otherwise. Note that we ignore pairs in the hierarchy which have more than 8 edges in between. For example, [dog, canid] = 0.875, [wolf, canid] = 0.875, [dog, carnivore] = 0.75, [canid, dog] = 0

(4) *Hyponymy*: It is simply the inverse of the hypernymy feature. For example, [canid, dog] = 0.875, [dog, canid] = 0.

(5) *Co-hyponyms*: It takes the value 1 if the two words have the same hypernym but they do not belong to the same synset, and 0 otherwise. For example, [dog, wolf] = 1.

As discussed above, we expect features like *synonymy*, *antonymy*, *hypernymy*, *hyponymy* and *co-hyponyms* would help model co-attention alignment between the premise and the hypothesis. Knowledge of *hypernymy* and *hyponymy* may help capture entailment; knowledge of *antonymy* and *co-hyponyms* may help model contradiction. Their final contributions will be learned in end-to-end model training. We regard the vector $\boldsymbol{r} \in \mathbb{R}^{d_r}$ as the relation feature derived from external knowledge, where d_r is 5 here. In addition, Table 1 reports some key statistics of these features.

Feature	#Words	#Pairs
Synonymy	84,487	237,937
Antonymy	6,161	6,617
Hypernymy	57,475	753,086
Hyponymy	57,475	753,086
Co-hyponyms	53,281	3,674,700

Table 1: Statistics of lexical relation features.

In addition to the above relations, we also use more relation features in WordNet, including *instance*, *instance of*, *same instance*, *entailment*, *member meronym*, *member holonym*, *substance meronym*, *substance holonym*, *part meronym*, *part holonym*, summing up to 15 features, but these additional features do not bring further improvement on the development dataset, as also discussed in Section 5.

Relation Embeddings In the most recent years graph embedding has been widely employed to learn representation for vertexes and their relations in a graph. In our work here, we also capture the relation between any two words in WordNet through relation embedding. Specifically, we employed TransE (Bordes et al., 2013), a widely used graph embedding methods, to capture relation embedding between any two words. We used two typical approaches to obtaining the relation embedding. The first directly uses 18 relation embeddings pretrained on the WN18 dataset (Bordes et al., 2013). Specifically, if a word pair has a certain type relation, we take the corresponding relation embedding. Sometimes, if a word pair has multiple relations among the 18 types; we take an average of the relation embedding. The second approach uses TransE's word embedding (trained on WordNet) to obtain relation embedding, through the objective function used in TransE, i.e., $\boldsymbol{l} \approx \boldsymbol{t} - \boldsymbol{h}$, where $\boldsymbol{l}$ indicates relation embedding, $\boldsymbol{t}$ indicates tail entity embedding, and $\boldsymbol{h}$ indicates head entity embedding.

Note that in addition to relation embedding trained on WordNet, other relational embedding resources exist; e.g., that trained on Freebase (WikiData) (Bollacker et al., 2007), but such knowledge resources are mainly about facts (e.g., relationship between Bill Gates and Microsoft) and are less for commonsense knowledge used in general natural language inference (e.g., the color yellow potentially contradicts red).

4.2 NLI Datasets

In our experiments, we use Stanford Natural Language Inference (SNLI) dataset (Bowman et al., 2015) and Multi-Genre Natural Language Inference (MultiNLI) (Williams et al., 2017) dataset, which focus on three basic relations between a premise and a potential hypothesis: the premise entails the hypothesis (*entailment*), they contradict each other (*contradiction*), or they are not related (*neutral*). We use the same data split as in previous work (Bowman et al., 2015; Williams et al., 2017) and classification accuracy as the evaluation metric. In addition, we test our models (trained on the SNLI training set) on a new test set (Glockner et al., 2018), which assesses the lexical inference abilities of NLI systems and consists of 8,193 samples. WordNet 3.0 (Miller, 1995) is used to extract semantic relation features between words. The words are lemmatized using Stanford CoreNLP 3.7.0 (Manning et al., 2014). The premise and the hypothesis sentences fed into the input encoding layer are tokenized.

4.3 Training Details

For duplicability, we release our code[1]. All our models were strictly selected on the development set of the SNLI data and the in-domain development set of MultiNLI and were then tested on the corresponding test set. The main training details are as follows: the dimension of the hidden states of LSTMs and word embeddings are 300. The word embeddings are initialized by *300D GloVe 840B* (Pennington et al., 2014), and out-of-vocabulary words among them are initialized randomly. All word embeddings are updated during training. Adam (Kingma and Ba, 2014) is used for optimization with an initial learning rate of 0.0004. The mini-batch size is set to 32. Note that the above hyperparameter settings are same as those used in the baseline ESIM (Chen et al., 2017a) model. ESIM is a strong NLI baseline framework with the source code made available at *https://github.com/lukecq1231/nli* (the ESIM core code has also been adapted to summarization (Chen et al., 2016a) and question-answering tasks (Zhang et al., 2017a)).

The trade-off λ for calculating co-

[1]https://github.com/lukecq1231/kim

attention in Equation (3) is selected in $[0.1, 0.2, 0.5, 1, 2, 5, 10, 20, 50]$ based on the development set. When training TransE for WordNet, relations are represented with vectors of 20 dimension.

5 Experimental Results

5.1 Overall Performance

Table 2 shows the results of state-of-the-art models on the SNLI dataset. Among them, ESIM (Chen et al., 2017a) is one of the previous state-of-the-art systems with an 88.0% test-set accuracy. The proposed model, namely Knowledge-based Inference Model (**KIM**), which enriches ESIM with external knowledge, obtains an accuracy of 88.6%, the best single-model performance reported on the SNLI dataset. The difference between ESIM and KIM is statistically significant under the one-tailed paired t-test at the 99% significance level. Note that the KIM model reported here uses five semantic relations described in Section 4. In addition to that, we also use 15 semantic relation features, which does not bring additional gains in performance. These results highlight the effectiveness of the five semantic relations described in Section 4. To further investigate external knowledge, we add TransE relation embedding, and again no further improvement is observed on both the development and test sets when TransE relation embedding is used (concatenated) with the semantic relation vectors. We consider this is due to the fact that TransE embedding is not specifically sensitive to inference information; e.g., it does not model co-hyponyms features, and its potential benefit has already been covered by the semantic relation features used.

Table 3 shows the performance of models on the MultiNLI dataset. The baseline ESIM achieves 76.8% and 75.8% on in-domain and cross-domain test set, respectively. If we extend the ESIM with external knowledge, we achieve significant gains to 77.2% and 76.4% respectively. Again, the gains are consistent on SNLI and MultiNLI, and we expect they would be orthogonal to other factors when external knowledge is added into other state-of-the-art models.

5.2 Ablation Results

Figure 2 displays the ablation analysis of different components when using the external knowledge. To compare the effects of external knowledge under different training data scales, we randomly sample different ratios of the entire training set, i.e., 0.8%, 4%, 20% and 100%. "A" indicates adding external knowledge in calculating the co-attention matrix as in Equation (3), "I" indicates adding external knowledge in collecting local inference information as in Equation (7)(8), and "C" indicates adding external knowledge in composing inference as in Equation (11)(12). When we only have restricted training data, i.e., 0.8% training set (about 4,000 samples), the baseline ESIM has a poor accuracy of 62.4%. When we only add external knowledge in calculating co-attention ("A"), the accuracy increases to 66.6% (+ absolute 4.2%). When we only utilize external knowledge in collecting local inference information ("I"), the accuracy has a significant gain, to 70.3% (+ absolute 7.9%). When we only add external knowledge in inference composition ("C"), the accuracy gets a smaller gain to 63.4% (+ absolute 1.0%). The comparison indicates that "I" plays the most important role among the three components in using external knowledge. Moreover, when we com-

Model	**Test**
LSTM Att. (Rocktäschel et al., 2015)	83.5

Match-LSTM (Wang and Jiang, 2016)	86.1
LSTMN (Cheng et al., 2016)	86.3
Decomposable Att. (Parikh et al., 2016)	86.8
NTI (Yu and Munkhdalai, 2017b)	87.3
Re-read LSTM (Sha et al., 2016)	87.5
BiMPM (Wang et al., 2017)	87.5
DIIN (Gong et al., 2017)	88.0
BCN + CoVe (McCann et al., 2017)	88.1
CAFE (Tay et al., 2018)	88.5
ESIM (Chen et al., 2017a)	88.0
KIM (This paper)	**88.6**

Table 2: Accuracies of models on SNLI.

Model	**In**	**Cross**
CBOW (Williams et al., 2017)	64.8	64.5
BiLSTM (Williams et al., 2017)	66.9	66.9
DiSAN (Shen et al., 2017)	71.0	71.4
Gated BiLSTM (Chen et al., 2017b)	73.5	73.6
SS BiLSTM (Nie and Bansal, 2017)	74.6	73.6
DIIN * (Gong et al., 2017)	77.8	**78.8**
CAFE (Tay et al., 2018)	**78.7**	77.9
ESIM (Chen et al., 2017a)	76.8	75.8
KIM (This paper)	**77.2**	**76.4**

Table 3: Accuracies of models on MultiNLI. * indicates models using extra SNLI training set.

pose the three components ("A,I,C"), we obtain the best result of 72.6% (+ absolute 10.2%). When we use more training data, i.e., 4%, 20%, 100% of the training set, only "I" achieves a significant gain, but "A" or "C" does not bring any significant improvement. The results indicate that external semantic knowledge only helps co-attention and composition when limited training data is limited, but always helps in collecting local inference information. Meanwhile, for less training data, λ is usually set to a larger value. For example, the optimal λ on the development set is 20 for 0.8% training set, 2 for the 4% training set, 1 for the 20% training set and 0.2 for the 100% training set.

Figure 3 displays the results of using different ratios of external knowledge (randomly keep different percentages of whole lexical semantic relations) under different sizes of training data. Note that here we only use external knowledge in collecting local inference information as it always works well for different scale of the training set. Better accuracies are achieved when using more external knowledge. Especially under the condition of restricted training data (0.8%), the model obtains a large gain when using more than half of external knowledge.

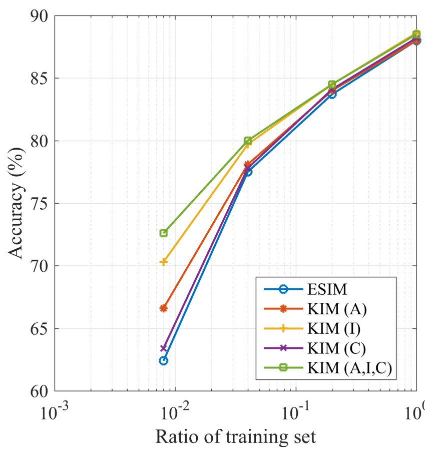

Figure 2: Accuracies of models of incorporating external knowledge into different NLI components, under different sizes of training data (0.8%, 4%, 20%, and the entire training data).

5.3 Analysis on the (Glockner et al., 2018) Test Set

In addition, Table 4 shows the results on a newly published test set (Glockner et al., 2018). Compared with the performance on the SNLI test

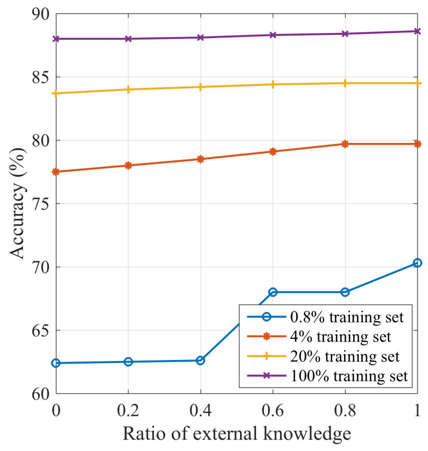

Figure 3: Accuracies of models under different sizes of external knowledge. More external knowledge corresponds to higher accuracies.

Model	SNLI	Glockner's(Δ)
(Parikh et al., 2016)*	84.7	51.9 (-32.8)
(Nie and Bansal, 2017)*	86.0	62.2 (-23.8)
ESIM *	87.9	65.6 (-22.3)
KIM (This paper)	**88.6**	**83.5** (-5.1)

Table 4: Accuracies of models on the SNLI and (Glockner et al., 2018) test set. * indicates the results taken from (Glockner et al., 2018).

set, the performance of the three baseline models dropped substantially on the (Glockner et al., 2018) test set, with the differences ranging from 22.3% to 32.8% in accuracy. Instead, the proposed KIM achieves 83.5% on this test set (with only a 5.1% drop in performance), which demonstrates its better ability of utilizing lexical level inference and hence better generalizability.

Figure 5 displays the accuracy of ESIM and KIM in each replacement-word category of the (Glockner et al., 2018) test set. KIM outperforms ESIM in 13 out of 14 categories, and only performs worse on synonyms.

5.4 Analysis by Inference Categories

We perform more analysis (Table 6) using the supplementary annotations provided by the MultiNLI dataset (Williams et al., 2017), which have 495 samples (about 1/20 of the entire development set) for both in-domain and out-domain set. We compare against the model outputs of the ESIM model across 13 categories of inference. Table 6 reports the results. We can see that KIM outperforms ESIM on overall accuracies on both in-domain and

Category	Instance	ESIM	KIM
Antonyms	1,147	70.4	**86.5**
Cardinals	759	75.5	**93.4**
Nationalities	755	35.9	**73.5**

Overall	77.1	**77.9**	76.7	**77.4**

Table 6: Detailed Analysis on MultiNLI.

cross-domain subset of development set. KIM outperforms or equals ESIM in 10 out of 13 categories on the cross-domain setting, while only 7 out of 13 categories on in-domain setting. It indicates that external knowledge helps more in cross-domain setting. Especially, for antonym category in cross-domain set, KIM outperform ESIM significantly (+ absolute 5.0%) as expected, because antonym feature captured by external knowledge would help unseen cross-domain samples.

5.5 Case Study

Table 7 includes some examples from the SNLI test set, where KIM successfully predicts the inference relation and ESIM fails. In the first example, the premise is "An African person standing in a **wheat** field" and the hypothesis "A person standing in a **corn** field". As the KIM model knows that "wheat" and "corn" are both a kind of cereal, i.e, the *co-hyponyms* relationship in our relation features, KIM therefore predicts the premise contradicts the hypothesis. However, the baseline ESIM cannot learn the relationship between "wheat" and "corn" effectively due to lack of enough samples in the training sets. With the help of external knowledge, i.e., "wheat" and "corn" having the same hypernym "cereal", KIM predicts contradiction correctly.

P/G	Sentences
e/c	*p*: An African person standing in a **wheat** field. *h*: A person standing in a **corn** field.
e/c	*p*: Little girl is flipping an **omelet** in the kitchen. *h*: A young girl cooks **pancakes**.
c/e	*p*: A middle eastern **marketplace**. *h*: A middle easten **store**.
c/e	*p*: Two boys are swimming with boogie **boards**. *h*: Two boys are swimming with their **floats**.

Table 7: Examples. Word in bold are key words in making final prediction. **P** indicates a predicted label and **G** indicates gold-standard label. *e* and *c* denote *entailment* and *contradiction*, respectively.

6 Conclusions

Our neural-network-based model for natural language inference with external knowledge, namely KIM, achieves the state-of-the-art accuracies. The model is equipped with external knowledge in its main components, specifically, in calculating co-attention, collecting local inference, and composing inference. We provide detailed analyses on our model and results. The proposed model of infusing neural networks with external knowledge may also help shed some light on tasks other than NLI.

Abstract

We consider the problem of learning textual entailment models with limited supervision (5K-10K training examples), and present two complementary approaches for it. First, we propose knowledge-guided adversarial example generators for incorporating large lexical resources in entailment models via only a handful of rule templates. Second, to make the entailment model—a discriminator—more robust, we propose the first GAN-style approach for training it using a natural language example generator that iteratively adjusts based on the discriminator's performance. We demonstrate effectiveness using two entailment datasets, where the proposed methods increase accuracy by 4.7% on SciTail and by 2.8% on a 1% training sub-sample of SNLI. Notably, even a single hand-written rule, NEGATE, improves the accuracy on the negation examples in SNLI by 6.1%.

1 Introduction

The impressive success of machine learning models on large natural language datasets often does not carry over to moderate training data regimes, where models often struggle with infrequently observed patterns and simple adversarial variations. A prominent example of this phenomenon is *textual entailment*, the fundamental task of deciding whether a *premise* text entails ($\models$) a *hypothesis* text. On certain datasets, recent deep learning entailment systems (Parikh et al., 2016; Wang et al., 2017; Gong et al., 2018) have achieved close to human level performance. Nevertheless, the problem is far from solved, as evidenced by how easy it is to generate minor adversarial examples that break even the best systems. As Table 1 illustrates, a state-of-the-art neural system for this task, namely the Decomposable Attention Model (Parikh et al., 2016), fails when faced with simple linguistic phenomena such as negation, or a re-ordering of words. This is not unique to a particular model or task. Minor adversarial examples have also been found to easily break neural systems on other linguistic tasks such as reading comprehension (Jia and Liang, 2017).

Table 1: Failure examples from the SNLI dataset: negation (Top) and re-ordering (Bottom). **P** is premise, **H** is hypothesis, and **S** is prediction made by an entailment system (Parikh et al., 2016).

P: The dog did not eat all of the chickens.
H: The dog ate all of the chickens.
S: entails (score 56.5%)
P: The red box is in the blue box.
H: The blue box is in the red box.
S: entails (score 92.1%)

A key contributor to this brittleness is the use of specific datasets such as SNLI (Bowman et al., 2015) and SQuAD (Rajpurkar et al., 2016) to drive model development. While large and challenging, *these datasets also tend to be homogeneous*. E.g., SNLI was created by asking crowd-source workers to generate entailing sentences, which then tend to have limited linguistic variations and annotation artifacts (Gururangan et al., 2018). Consequently, models overfit to sufficiently repetitive patterns—and sometimes idiosyncrasies—in the datasets they are trained on. They fail to cover long-tail and rare patterns in the training distribution, or linguistic phenomena such as negation that would be obvious to a layperson.

To address this challenge, we propose to *train textual entailment models more robustly using ad-*

versarial examples generated in two ways: (a) by incorporating knowledge from large linguistic resources, and (b) using a sequence-to-sequence neural model in a GAN-style framework.

The motivation stems from the following observation. While deep-learning based textual entailment models lead the pack, they generally do not incorporate intuitive rules such as negation, and ignore large-scale linguistic resources such as PPDB (Ganitkevitch et al., 2013) and WordNet (Miller, 1995). These resources could help them generalize beyond specific words observed during training. For instance, while the SNLI dataset contains the pattern *two men* $\vDash$ *people*, it does not contain the analogous pattern *two dogs* $\vDash$ *animals* found easily in WordNet.

Effectively integrating simple rules or linguistic resources in a deep learning model, however, is challenging. Doing so directly by substantially adapting the model architecture (Sha et al., 2016; Chen et al., 2018) can be cumbersome and limiting. Incorporating such knowledge indirectly via modified word embeddings (Faruqui et al., 2015; Mrkšić et al., 2016), as we show, can have little positive impact and can even be detrimental.

Our proposed method, which is task-specific but model-independent, is inspired by data-augmentation techniques. We generate new training examples by applying knowledge-guided rules, via only a handful of rule templates, to the original training examples. Simultaneously, we also use a sequence-to-sequence or seq2seq model for each entailment class to generate new hypotheses from a given premise, adaptively creating new adversarial examples. These can be used with any entailment model without constraining model architecture.

We also introduce the first approach to train a robust entailment model using a Generative Adversarial Network or GAN (Goodfellow et al., 2014) style framework. We iteratively improve both the entailment system (the *discriminator*) and the differentiable part of the data-augmenter (specifically the neural *generator*), by training the generator based on the discriminator's performance on the generated examples. Importantly, unlike the typical use of GANs to create a strong generator, we use it as a mechanism to create a strong and robust discriminator.

Our new entailment system, called AdvEntuRe, demonstrates that in the moderate data regime, adversarial iterative data-augmentation via only a handful of linguistic rule templates can be surprisingly powerful. Specifically, we observe 4.7% accuracy improvement on the challenging SciTail dataset (Khot et al., 2018) and a 2.8% improvement on 10K-50K training subsets of SNLI. An evaluation of our algorithm on the negation examples in the test set of SNLI reveals a 6.1% improvement from just a single rule.

2 Related Work

Adversarial example generation has recently received much attention in NLP. For example, Jia and Liang (2017) generate adversarial examples using manually defined templates for the SQuAD reading comprehension task. Glockner et al. (2018) create an adversarial dataset from SNLI by using WordNet knowledge. Automatic methods (Iyyer et al., 2018) have also been proposed to generate adversarial examples through paraphrasing. These works reveal how neural network systems trained on a large corpus can easily break when faced with carefully designed unseen adversarial patterns at test time. Our motivation is different. We use adversarial examples at training time, in a data augmentation setting, to train a more robust entailment discriminator. The generator uses explicit knowledge or hand written rules, and is trained in a end-to-end fashion along with the discriminator.

Incorporating external rules or linguistic resources in a deep learning model generally requires substantially adapting the model architecture (Sha et al., 2016; Liang et al., 2017; Kang et al., 2017). This is a model-dependent approach, which can be cumbersome and constraining. Similarly non-neural textual entailment models have been developed that incorporate knowledge bases. However, these also require model-specific engineering (Raina et al., 2005; Haghighi et al., 2005; Silva et al., 2018).

An alternative is the model- and task-independent route of incorporating linguistic resources via word embeddings that are *retro-fitted* (Faruqui et al., 2015) or *counter-fitted* (Mrkšić et al., 2016) to such resources. We demonstrate, however, that this has little positive impact in our setting and can even be detrimental. Further, it is unclear how to incorporate knowledge sources into advanced representations such as contextual embeddings (McCann et al., 2017; Peters et al., 2018). We thus focus on a task-specific but model-independent approach.

Logical rules have also been defined to label existing examples based on external resources (Hu et al., 2016). Our focus here is on generating *new* training examples.

Our use of the GAN framework to create a better discriminator is related to CatGANs (Wang and Zhang, 2017) and TripleGANs (Chongxuan et al., 2017) where the discriminator is trained to classify the original training image classes as well as a new 'fake' image class. We, on the other hand, generate examples belonging to the same classes as the training examples. Further, unlike the earlier focus on the vision domain, this is the first approach to train a discriminator using GANs for a natural language task with discrete outputs.

3 Adversarial Example Generation

We present three different techniques to create adversarial examples for textual entailment. Specifically, we show how external knowledge resources, hand-authored rules, and neural language generation models can be used to generate such examples. Before describing these generators in detail, we introduce the notation used henceforth.

We use lower-case letters for single instances (e.g., x, p, h), upper-case letters for sets of instances (e.g., X, P, H), blackboard bold for models (e.g., $\mathbb{D}$), and calligraphic symbols for discrete spaces of possible values (e.g., class labels $\mathcal{C}$). For the textual entailment task, we assume each example is represented as a triple (p, h, c), where p is a premise (a natural language sentence), h is a hypothesis, and c is an entailment label: (a) *entails* ($\sqsubseteq$) if h is true whenever p is true; (b) *contradicts* ($\curlywedge$) if h is false whenever p is true; or (c) *neutral* (#) if the truth value of h cannot be concluded from p being true.[1]

We will introduce various example generators in the rest of this section. Each such generator, $\mathbb{G}_\rho$, is defined by a partial function f_ρ and a label g_ρ. If a sentence s has a certain property required by f_ρ (e.g., contains a particular string), f_ρ transforms it into another sentence s' and g_ρ provides an entailment label from s to s'. Applied to a sentence s, $\mathbb{G}_\rho$ thus either "fails" (if the pre-requisite isn't met) or generates a new entailment example triple, $\big(s, f_\rho(s), g_\rho\big)$. For instance, consider the generator for ρ:=hypernym(car, vehicle) with the (partial) transformation function f_ρ:="Replace *car* with *vehicle*" and the label g_ρ:=*entails*. f_ρ would fail when applied to a sentence not containing the word "car". Applying f_ρ to the sentence s="*A man is driving the car*" would generate s'="*A man is driving the vehicle*", creating the example $(s, s', \textit{entails})$.

[1]The symbols are based on Natural Logic (Lakoff, 1970) and use the notation of MacCartney and Manning (2012).

Table 2: Various generators $\mathbb{G}_\rho$ characterized by their source, (partial) transformation function f_ρ as applied to a sentence s, and entailment label g_ρ

The seven generators we use for experimentation are summarized in Table 2 and discussed in more detail subsequently. While these particular generators are simplistic and one can easily imagine more advanced ones, we show that training using adversarial examples created using even these simple generators leads to substantial accuracy improvement on two datasets.

3.1 Knowledge-Guided Generators

Large knowledge-bases such as WordNet and PPDB contain lexical equivalences and other relationships highly relevant for entailment models. However, even large datasets such as SNLI generally do not contain most of these relationships in the training data. E.g., that *two dogs* entails *animals* isn't captured in the SNLI data. We define simple generators based on lexical resources to create adversarial examples that capture the underlying knowledge. This allows models trained on these examples to learn these relationships.

As discussed earlier, there are different ways of incorporating such symbolic knowledge into neural models. Unlike task-agnostic ways of approaching this goal from a word embedding perspective (Faruqui et al., 2015; Mrkšić et al., 2016) or the model-specific approach (Sha et al., 2016; Chen et al., 2018), we use this knowledge to generate task-specific examples. This allows any entailment model to learn how to use these relationships *in the context of the entailment task*, helping them outperform the above task-agnostic alternative.

Our knowledge-guided example generators, $\mathbb{G}_{\rho}^{\text{KB}}$, use lexical relations available in a knowledge-base: $\rho := r(x, y)$ where the relation r (such as synonym, hypernym, etc.) may differ across knowledge bases. We use a simple (partial) transformation function, $f_\rho(s)$:="Replace x in s with y", as described in an earlier example. In some cases, when part-of-speech (POS) tags are available, the partial function requires the tags for x in s and in $r(x, y)$ to match. The entailment label g_ρ for the resulting examples is also defined based on the relation r, as summarized in Table 2.

This idea is similar to Natural Logic Inference or NLI (Lakoff, 1970; Sommers, 1982; Angeli and Manning, 2014) where words in a sentence can be replaced by their hypernym/hyponym to produce entailing/neutral sentences, depending on their context. We propose a context-agnostic use of lexical resources that, despite its simplicity, already results in significant gains. We use three sources for generators:

WordNet (Miller, 1995) is a large, hand-curated, semantic lexicon with synonymous words grouped into *synsets*. Synsets are connected by many semantic relations, from which we use *hyponym* and *synonym* relations to generate entailing sentences, and *antonym* relations to generate contradicting sentences[2]. Given a relation $r(x, y)$, the (partial) transformation function f_ρ is the POS-tag matched replacement of x in s with y, and requires the POS tag to be noun or verb. NLI provides a more robust way of using these relations based on context, which we leave for future work.

PPDB (Ganitkevitch et al., 2013) is a large resource of lexical, phrasal, and syntactic paraphrases. We use 24,273 lexical paraphrases in their smallest set, PPDB-S (Pavlick et al., 2015), as equivalence relations, $x \equiv y$. The (partial) transformation function f_ρ for this generator is POS-tagged matched replacement of x in s with y, and the label g_ρ is *entails*.

[2]A similar approach was used in a parallel work to generate an adversarial dataset from SNLI (Glockner et al., 2018).

SICK (Marelli et al., 2014) is dataset with entailment examples of the form (p, h, c), created to evaluate an entailment model's ability to capture compositional knowledge via hand-authored rules. We use the 12,508 patterns of the form $c(x, y)$ extracted by Beltagy et al. (2016) by comparing sentences in this dataset, with the property that for each SICK example (p, h, c), replacing (when applicable) x with y in p produces h. For simplicity, we ignore positional information in these patterns. The (partial) transformation function f_ρ is replacement of x in s with y, and the label g_ρ is c.

3.2 Hand-Defined Generators

Even very large entailment datasets have no or very few examples of certain otherwise common linguistic constructs such as negation,[3] causing models trained on them to struggle with these constructs. A simple model-agnostic way to alleviate this issue is via a negation example generator whose transformation function $f_\rho(s)$ is NEGATE(s), described below, and the label g_ρ is *contradicts*.

NEGATE(s): If s contains a 'be' verb (e.g., is, was), add a "not" after the verb. If not, also add a "did" or "do" in front based on its tense. E.g., change "A person is crossing" to "A person is not crossing" and "A person crossed" to "A person did not cross." While many other rules could be added, we found that this single rule covered a majority of the cases. Verb tenses are also considered[4] and changed accordingly. Other functions such as dropping adverbial clauses or changing tenses could be defined in a similar manner.

Both the knowledge-guided and hand-defined generators make local changes to the sentences based on simple rules. It should be possible to extend the hand-defined rules to cover the long tail (as long as they are procedurally definable). However, a more scalable approach would be to extend our generators to trainable models that can cover a wider range of phenomena than hand-defined rules. Moreover, the applicability of these rules generally depends on the context which can also be incorporated in such trainable generators.

3.3 Neural Generators

For each entailment class c, we use a trainable sequence-to-sequence neural model (Sutskever

[3]Only 211 examples (2.11%) in the SNLI training set contain negation triggers such as not, 'nt, etc.

[4]https://www.nodebox.net/code/index.php/Linguistics

et al., 2014; Luong et al., 2015) to generate an entailment example (s, s', c) from an input sentence s. The seq2seq model, trained on examples labeled c, itself acts as the transformation function f_ρ of the corresponding generator $\mathbb{G}_c^{\text{s2s}}$. The label g_ρ is set to c. The joint probability of seq2seq model is:

$$\mathbb{G}_c^{\text{s2s}}(X_c; \phi_c) = \mathbb{G}_c^{\text{s2s}}(H_c, P_c; \phi_c) \quad (1)$$
$$= \Pi_i P(h_{i,c}|p_{i,c}; \phi_c)P(h_i) \quad (2)$$

The loss function for training the seq2seq is:

$$\hat{\phi}_c = \underset{\phi_c}{\text{argmin}}\, L(H_c, \mathbb{G}_c^{\text{s2s}}(X_c; \phi_c)) \quad (3)$$

where L is the cross-entropy loss between the original hypothesis H_c and the predicted hypothesis. Cross-entropy is computed for each predicted word w_i against the same in H_c given the sequence of previous words in H_c . $\hat{\phi}_c$ are the optimal parameters in $\mathbb{G}_c^{\text{s2s}}$ that minimize the loss for class c. We use the single most likely output to generate sentences in order to reduce decoding time.

3.4 Example Generation

The generators described above are used to create new entailment examples from the training data. For each example (p, h, c) in the data, we can create two new examples: $\big(p, f_\rho(p), g_\rho\big)$ and $\big(h, f_\rho(h), g_\rho\big)$.

The examples generated this way using $\mathbb{G}^{\text{KB}}$ and $\mathbb{G}^{\text{H}}$ can, however, be relatively easy, as the premise and hypothesis would differ by only a word or so. We therefore compose such simple ("first-order") generated examples with the original input example to create more challenging "second-order" examples. We can create second-order examples by composing the original example (p, h, c) with a generated sentence from hypothesis, $f_\rho(h)$ and premise, $f_\rho(p)$. Figure 1 depicts how these two kinds of examples are generated from an input example (p, h, c).

First, we consider the second-order example between the original premise and the transformed hypothesis: $(p, f_\rho(h), \bigoplus(c, g_\rho))$, where $\bigoplus$, defined in the left half of Table 3, composes the input example label c (connecting p and h) and the generated example label g_ρ to produce a new label. For instance, if p entails h and h entails $f_\rho(h)$, p would entail f_ρ. In other words, $\bigoplus(\sqsubseteq, \sqsubseteq)$ is $\sqsubseteq$. For example, composing ("A man is playing

soccer", "A man is playing a game", ⊑) with a generated hypothesis $f_\rho(h)$: "A person is playing a game." will give a new second-order entailment example: ("A man is playing soccer", "A person is playing a game", ⊑).

Second, we create an example from the generated premise to the original hypothesis: $(f_\rho(p), h, \bigotimes(g_\rho, c))$. The composition function here, denoted $\bigotimes$ and defined in the right half of Table 3, is often undetermined. For example, if p entails $f_\rho(p)$ and p entails h, the relation between $f_\rho(p)$ and h is undetermined i.e. $\bigotimes(\sqsubseteq, \sqsubseteq) = ?$. While this particular composition $\bigotimes$ often leads to undetermined or neutral relations, we use it here for completeness. For example, composing the previous example with a generated *neutral* premise, $f_\rho(p)$: "A person is wearing a cap" would generate an example ("A person is wearing a cap", "A man is playing a game", #)

The composition function $\bigoplus$ is the same as the "join" operation in natural logic reasoning (Icard III and Moss, 2014), except for two differences: (a) relations that do not belong to our three entailment classes are mapped to '?', and (b) the exclusivity/alternation relation is mapped to *contradicts*. The composition function $\bigotimes$, on the other hand, does not map to the join operation.

3.5 Implementation Details

Given the original training examples X, we generate the examples from each premise and hypothesis in a batch using $\mathbb{G}^{\text{KB}}$ and $\mathbb{G}^{\text{H}}$. We also generate new hypothesis per class for each premise using $\mathbb{G}_c^{\text{s2s}}$. Using all the generated examples to train the model would, however, overwhelm the original training set. For examples, our knowledge-guided generators $\mathbb{G}^{\text{KB}}$ can be applied in 17,258,314 different ways.

To avoid this, we sub-sample our synthetic examples to ensure that they are proportional to the input examples X, specifically they are bounded to $\alpha|X|$ where α is tuned for each dataset. Also, as seen in Table 3, our knowledge-guided generators are more likely to generate *neutral* examples than any other class. To make sure that the labels are not skewed, we also sub-sample the examples to ensure that our generated examples have the same class distribution as the input batch. The SciTail dataset only contains two classes: *entails* mapped to $\sqsubseteq$ and *neutral* mapped to $\curlywedge$. As a result, generated examples that do not belong to these two classes are ignored.

The sub-sampling, however, has a negative side-effect where our generated examples end up using a small number of lexical relations from the large knowledge bases. On moderate datasets, this would cause the entailment model to potentially just memorize these few lexical relations. Hence, we generate new entailment examples for each mini-batch and update the model parameters based on the training+generated examples in this batch.

The overall example generation procedure goes as follows: For each mini-batch X (1) randomly choose 3 applicable rules per source and sentence (e.g., replacing men with people based on PPDB in premise is one rule), (2) produce examples Z_{all} using $\mathbb{G}^{\text{KB}}$, $\mathbb{G}^{\text{H}}$ and $\mathbb{G}^{\text{s2s}}$, (3) randomly sub-select examples Z from Z_{all} to ensure the balance between classes and $|Z|= \alpha|X|$.

4 AdvEntuRe

Figure 2 shows the complete architecture of our model, AdvEntuRe (ADVersarial training for textual ENTailment Using Rule-based Examples.). The entailment model $\mathbb{D}$ is shown with the white box and two proposed generators are shown using black boxes. We combine the two symbolic untrained generators, $\mathbb{G}^{\text{KB}}$ and $\mathbb{G}^{\text{H}}$ into a single $\mathbb{G}^{\text{rule}}$ model. We combine the generated adversarial examples Z with the original training examples X to train the discriminator. Next, we describe how the individual models are trained and finally present our new approach to train the generator based on the discriminator's performance.

4.1 Discriminator Training

We use one of the state-of-the-art entailment models (at the time of its publication) on SNLI, decomposable attention model (Parikh et al., 2016) with intra-sentence attention as our discriminator $\mathbb{D}$. The model attends each word in hypothesis with each word in the premise, compares each pair of the attentions, and then aggregates them as a final representation. This discriminator model can be easily replaced with any other entailment model without any other change to the AdvEntuRe architecture. We pre-train our discriminator $\mathbb{D}$ on the original dataset, X=(P, H, C) using:

$$\mathbb{D}(X;\theta) = \underset{\hat{C}}{\operatorname{argmax}}\, \mathbb{D}(\hat{C}|P,H;\theta) \tag{4}$$

$$\hat{\theta} = \underset{\theta}{\operatorname{argmin}}\, L(C, \mathbb{D}(X;\theta)) \tag{5}$$

where L is cross-entropy loss function between the true labels, Y and the predicted classes, and $\hat{\theta}$ are the learned parameters.

4.2 Generator Training

Our knowledge-guided and hand-defined generators are symbolic parameter-less methods which are not currently trained. For simplicity, we will refer to the set of symbolic rule-based generators as $\mathbb{G}^{\text{rule}} := \mathbb{G}^{\text{KB}} \cup \mathbb{G}^{\text{H}}$. The neural generator $\mathbb{G}^{\text{s2s}}$, on the other hand, can be trained as described earlier. We leave the training of the symbolic models for future work.

4.3 Adversarial Training

We now present our approach to iteratively train the discriminator and generator in a GAN-style framework. Unlike traditional GAN (Goodfellow et al., 2014) on image/text generation that aims to obtain better generators, our goal is to build a robust discriminator regularized by the generators ($\mathbb{G}^{\text{s2s}}$ and $\mathbb{G}^{\text{rule}}$). The discriminator and generator are iteratively trained against each other to

12:     Update $\theta \leftarrow \hat{\theta}; \phi \leftarrow \hat{\phi}$
```

achieve better discrimination on the augmented data from the generator and better example generation against the learned discriminator. Algorithm 1 shows our training procedure.

First, we pre-train the discriminator $\mathbb{D}$ and the seq2seq generators $\mathbb{G}^{s2s}$ on the original data X. We alternate the training of the discriminator and generators over K iterations (set to 30 in our experiments).

For each iteration, we take a mini-batch B from our original data X. For each mini-batch, we generate new entailment examples, Z_G using our adversarial examples generator. Once we collect all the generated examples, we balance the examples based on their source and label (as described in Section 3.5). In each training iteration, we optimize the discriminator against the augmented training data, $X + Z_G$ and use the discriminator loss to guide the generator to pick challenging examples. For every mini-batch of examples $X + Z_G$, we compute the discriminator loss $L(C; \mathbb{D}(X + Z_G; \theta))$ and apply the negative of this loss to each word of the generated sentence in $\mathbb{G}^{s2s}$. In other words, the discriminator loss value replaces the cross-entropy loss used to train the seq2seq model (similar to a REINFORCE (Williams, 1992) reward). This basic approach uses the loss over the entire batch to update the generator, ignoring whether specific examples were hard or easy for the discriminator. Instead, one could update the generator per example based on the discriminator's loss on that example. We leave this for future work.

5 Experiments

Our empirical assessment focuses on two key questions: (a) Can a handful of rule templates improve a state-of-the-art entailment system, especially with moderate amounts of training data? (b) Can iterative GAN-style training lead to an improved discriminator?

To this end, we assess various models on the two entailment **datasets** mentioned earlier: SNLI (570K examples) and SciTail (27K examples).[5] To test our hypothesis that adversarial example based training prevents overfitting in small to moderate training data regimes, we compare model accuracies on the test sets when using 1%, 10%, 50%, and 100% subsamples of the train and dev sets.

We consider two baseline **models**: $\mathbb{D}$, the Decomposable Attention model (Parikh et al., 2016) with intra-sentence attention using pre-trained word embeddings (Pennington et al., 2014); and $\mathbb{D}_{\text{retro}}$ which extends $\mathbb{D}$ with word embeddings initialized by retrofitted vectors (Faruqui et al., 2015). The vectors are retrofitted on PPDB, Word-

[5]SNLI has a 96.4%/1.7%/1.7% split and SciTail has a 87.3%/4.8%/7.8% split on train, valid, and test sets, resp.

∟ $\mathbb{D}$ + $\mathbb{G}^{\text{rule}}$	61.74	66.53	73.99	**79.03**
∟ $\mathbb{D}$ + $\mathbb{G}^{\text{rule}}$ + $\mathbb{G}^{\text{s2s}}$	63.28	66.78	**74.77**	78.60

Net, FrameNet, and all of these, with the best results for each dataset reported here.

Our proposed model, AdvEntuRe, is evaluated in three flavors: $\mathbb{D}$ augmented with examples generated by $\mathbb{G}^{\text{rule}}$, $\mathbb{G}^{\text{s2s}}$, or both, where $\mathbb{G}^{\text{rule}} = \mathbb{G}^{\text{KB}} \cup \mathbb{G}^{\text{H}}$. In the first two cases, we create new examples for each batch in every epoch using a fixed generator (cf. Section 3.5). In the third case ($\mathbb{D}$ + $\mathbb{G}^{\text{rule}}$ + $\mathbb{G}^{\text{s2s}}$), we use the GAN-style training.

We uses grid search to find the best hyper-parameters for $\mathbb{D}$ based on the validation set: hidden size 200 for LSTM layer, embedding size 300, dropout ratio 0.2, and fine-tuned embeddings.

The ratio between the number of generated vs. original examples, α is empirically chosen to be 1.0 for SNLI and 0.5 for SciTail, based on validation set performance. Generally, very few generated examples (small α) has little impact, while too many of them overwhelm the original dataset resulting in worse scores (cf. Appendix for more details).

5.1 Main Results

Table 4 summarizes the test set accuracies of the different models using various subsampling ratios for SNLI and SciTail training data.

We make a few observations. First, $\mathbb{D}_{\text{retro}}$ is ineffective or even detrimental in most cases, except on SciTail when 1% (235 examples) or 10% (2.3K examples) of the training data is used. The gain in these two cases is likely because retrofitted lexical rules are helpful with extremely less data training while not as data size increases.

On the other hand, our method always achieves the best result compared to the baselines ($\mathbb{D}$ and $\mathbb{D}_{\text{retro}}$). Especially, significant improvements are made in less data setting: +2.77% in SNLI (1%) and 9.18% in SciTail (1%). Moreover, $\mathbb{D}$ + $\mathbb{G}^{\text{rule}}$'s accuracy on SciTail (100%) also outperforms the previous state-of-the-art model (DGEM (Khot et al., 2018), which achieves 77.3%) for that dataset by 1.7%.

Among the three different generators combined with $\mathbb{D}$, both $\mathbb{G}^{\text{rule}}$ and $\mathbb{G}^{\text{s2s}}$ are useful in SciTail, while $\mathbb{G}^{\text{rule}}$ is much more useful than $\mathbb{G}^{\text{s2s}}$ on SNLI. We hypothesize that seq2seq model trained on large training sets such as SNLI will be able to reproduce the input sentences. Adversarial examples from such a model are not useful since the entailment model uses the same training examples. However, on smaller sets, the seq2seq model would introduce noise that can improve the robustness of the model.

Table 5: Test accuracies across various rules $\mathcal{R}$ and classes $\mathcal{C}$. Since SciTail has two classes, we only report results on two classes of $\mathbb{G}^{\text{s2s}}$

	$\mathcal{R}/\mathcal{C}$	SNLI (5%)	SciTail (10%)
$\mathbb{D}$ + $\mathbb{G}^{\text{rule}}$	$\mathbb{D}$	69.18	60.84
	+ PPDB	**72.81 (+3.6%)**	65.52 (+4.6%)
	+ SICK	71.32 (+2.1%)	67.49 (+6.5%)
	+ WordNet	71.54 (+2.3%)	64.67 (+3.8%)
	+ HAND	71.15 (+1.9%)	**69.05 (+8.2%)**
	+ all	71.31 (+2.1%)	64.16 (+3.3%)
$\mathbb{D}$ + $\mathbb{G}^{\text{s2s}}$	$\mathbb{D}$	69.18	60.84
	+ positive	71.21 (+2.0%)	67.49 (+6.6%)
	+ negative	71.76 (+2.6%)	68.95 (+8.1%)
	+ neutral	71.72 (+2.5%)	-
	+ all	**72.28 (+3.1%)**	**70.77 (+9.9%)**

5.2 Ablation Study

To evaluate the impact of each generator, we perform ablation tests against each symbolic generator in $\mathbb{D}$ + $\mathbb{G}^{\text{rule}}$ and the generator $\mathbb{G}_c^{\text{s2s}}$ for each entailment class c. We use a 5% sample of SNLI and a 10% sample of SciTail. The results are summarized in Table 5.

Interestingly, while PPDB (phrasal paraphrases) helps the most (**+3.6%**) on SNLI, simple negation rules help significantly (**+8.2%**) on SciTail dataset. Since most entailment examples in SNLI are minor rewrites by Turkers, PPDB often contains these simple paraphrases. For SciTail, the sentences are authored independently with limited gains from simple paraphrasing. However, a model trained on only 10% of the dataset (2.3K

Table 6: Given a premise **P** (underlined), examples of hypothesis sentences **H'** generated by seq2seq generators $\mathbb{G}^{\mathrm{s2s}}$, and premise sentences **P'** generated by rule based generators $\mathbb{G}^{\mathrm{rule}}$, on the full SNLI data. Replaced words or phrases are shown in **bold**. This illustrates that even simple, easy-to-define rules can generate useful adversarial examples.

P	a person on a horse jumps over a broken down airplane
H': $\mathbb{G}^{\mathrm{s2s}}_{c=\sqsubseteq}$	a person is on a horse jumps over a rail, a person jumping over a plane
H': $\mathbb{G}^{\mathrm{s2s}}_{c=\curlywedge}$	a person is riding a horse in a field with a dog in a red coat
H': $\mathbb{G}^{\mathrm{s2s}}_{c=\#}$	a person is in a blue dog is in a park
P (or **H**)	a dirt bike rider catches some air going off a large hill
P': $\mathbb{G}^{\mathrm{KB(PPDB)}}_{\rho=\equiv,g_\rho=\sqsubseteq}$	a dirt **motorcycle** rider catches some air going off a large hill
P': $\mathbb{G}^{\mathrm{KB(SICK)}}_{\rho=c,g_\rho=\#}$	a dirt bike **man on yellow bike** catches some air going off a large hill
P': $\mathbb{G}^{\mathrm{KB(WordNet)}}_{\rho=syno,g_\rho=\sqsubseteq}$	a dirt bike rider catches some **atmosphere** going off a large hill
P': $\mathbb{G}^{\mathrm{Hand}}_{\rho=\mathrm{NEG},g_\rho=\curlywedge}$	a dirt bike rider **do not catch** some air going off a large hill

examples) would end up learning a model relying on purely word overlap. We believe that the simple negation examples introduce *neutral* examples with high lexical overlap, forcing the model to find a more informative signal.

On the other hand, using all classes for $\mathbb{G}^{\mathrm{s2s}}$ results in the best performance, supporting the effectiveness of the GAN framework for penalizing or rewarding generated sentences based on $\mathbb{D}$'s loss. Preferential selection of rules within the GAN framework remains a promising direction.

5.3 Qualitative Results

Table 6 shows examples generated by various methods in AdvEntuRe. As shown, both seq2seq and rule based generators produce reasonable sentences according to classes and rules. As expected, seq2seq models trained on very few examples generate noisy sentences. The quality of our knowledge-guided generators, on the other hand, does not depend on the training set size and they still produce reliable sentences.

5.4 Case Study: Negation

For further analysis of the negation-based generator in Table 1, we collect only the negation examples in test set of SNLI, henceforth referred to as nega-SNLI. Specifically, we extract examples where either the premise or the hypothesis contains "not", "no", "never", or a word that ends with "n't'. These do not cover more subtle ways of expressing negation such as "seldom" and the use of antonyms. nega-SNLI contains 201 examples with the following label distribution: 51 (25.4%) neutral, 42 (20.9%) entails, 108 (53.7%) contradicts. Table 7 shows examples in each category.

Table 7: Negation examples in nega-SNLI

$\sqsubseteq$	P: several women are playing volleyball. H: this doesn't look like soccer.
#	P: a man with no shirt on is performing with a baton. H: a man is trying his best at the national championship of baton.
$\curlywedge$	P: island native fishermen reeling in their nets after a long day's work. H: the men did not go to work today but instead played bridge.

While $\mathbb{D}$ achieves an accuracy of only 76.64%[6] on nega-SNLI, $\mathbb{D}$ + $\mathbb{G}^{\mathrm{H}}$ with NEGATE is substantially more successful (+6.1%) at handling negation, achieving an accuracy of 82.74%.

6 Conclusion

We introduced an adversarial training architecture for textual entailment. Our seq2seq and knowledge-guided example generators, trained in an end-to-end fashion, can be used to make any base entailment model more robust. The effectiveness of this approach is demonstrated by the significant improvement it achieves on both SNLI and SciTail, especially in the low to medium data regimes. Our rule-based generators can be expanded to cover more patterns and phenomena, and the seq2seq generator extended to incorporate per-example loss for adversarial training.

[6]This is much less than the full test accuracy of 84.52%.

Abstract

Research on distributed word representations is focused on widely-used languages such as English. Although the same methods can be used for other languages, language-specific knowledge can enhance the accuracy and richness of word vector representations. In this paper, we look at improving distributed word representations for Korean using knowledge about the unique linguistic structure of Korean. Specifically, we decompose Korean words into the *jamo* level, beyond the character-level, allowing a systematic use of subword information. To evaluate the vectors, we develop Korean test sets for word similarity and analogy and make them publicly available. The results show that our simple method outperforms word2vec and character-level Skip-Grams on semantic and syntactic similarity and analogy tasks and contributes positively toward downstream NLP tasks such as sentiment analysis.

1 Introduction

Word vector representations built from a large corpus embed useful semantic and syntactic knowledge. They can be used to measure the similarity between words and can be applied to various downstream tasks such as document classification (Yang et al., 2016), conversation modeling (Serban et al., 2016), and machine translation (Neishi et al., 2017). Most previous research for learning the vectors focuses on English (Collobert and Weston, 2008; Mikolov et al., 2013b,a; Pennington et al., 2014; Liu et al., 2015; Cao and Lu, 2017) and thus leads to difficulties and limitations in directly applying those techniques to a language with a different internal structure from that of English.

The mismatch is especially significant for morphologically rich languages such as Korean where the morphological richness could be captured by subword level embedding such as character embedding. It has been already shown that decomposing a word into subword units and using them as inputs improves performance for downstream NLP such as text classification (Zhang et al., 2015), language modeling (Kim et al., 2016), and machine translation (Ling et al., 2015; Lee et al., 2017). Despite their effectiveness in capturing syntactic features of diverse languages, decomposing a word into a set of n-grams and learning n-gram vectors does not consider the unique linguistic structures of various languages. Thus, researchers have integrated language-specific structures to learn word vectors, for example subcharacter components of Chinese characters (Yu et al., 2017) and syntactic information (such as prefixes or post-fixes) derived from external sources for English (Cao and Lu, 2017).

For Korean, integrating Korean linguistic structure at the level of *jamo*, the consonants and vowels that are much more rigidly defined than English, is shown to be effective for sentence parsing (Stratos, 2017). Previous work has looked at improving the vector representations of Korean using the character-level decomposition (Choi et al., 2017), but there is room for further investigation because Korean characters can be decomposed to *jamos* which are smaller units than the characters.

In this paper, we propose a method to integrate Korean-specific subword information to learn Korean word vectors and show improvements over previous baselines methods for word similarity, analogy, and sentiment analysis. Our first contribution is the method to decompose the words into both character-level units and jamo-level units and train the subword vectors through the Skip-Gram model. Our second major contribution is the Korean evaluation datasets for word similarity and analogy tasks, a translation of the WS-353 with annotations by 14 Korean native speakers, and 10,000 items for semantic and syntactic analogies, developed with Korean linguistic expertise. Using those datasets, we show that our model improves performance over other baseline methods without relying on external resources for word decomposition.

2 Related Work

2.1 Language-specific features for NLP

Recent studies in NLP field flourish with development of various word vector models. Although such studies aim for universal usage, distinct characteristics of individual languages still remain as a barrier for a unified model. The aforementioned issue is even more prominent when it comes to languages that have rich morphology but lack resources for research (Berardi et al., 2015). Accordingly, various studies dealing with language specific NLP technique proposed considering linguistics traits in models.

A large portion of these papers was dedicated to Chinese. Since Chinese is a logosyllabic language, (Yu et al., 2017) relevant studies focused on incorporation of different subword level features on word embedding, such as word internal structure (Wang et al., 2017), subcharacter component,(Yu et al., 2017), syllable (Assylbekov et al., 2017), radicals (Yin et al., 2016), and sememe (Niu et al., 2017).

The Korean language is a member of the agglutinative languages (Song, 2006), so previous studies have tried fusing the complex internal structure into the model. For example, a grammatical composition called 'Josa' in combination with word embedding is utilized in semantic role labeling (Nam and Kim, 2016) and exploiting *jamo* to handle morphological variation (Stratos, 2017). Also considered in prior work to obtain the word vector presentations for Korean is the syllable (Choi et al., 2017).

2.2 Subword features for NLP

Applying subword features to various NLP tasks has become popular in the NLP field. Typically, character-level information is useful when combined with the neural network based models. (Vania and Lopez, 2017; Assylbekov et al., 2017; Cao and Lu, 2017) Previous papers showed performance enhancement in various tasks including language modeling (Bojanowski et al., 2017, 2015), machine translation (Ling et al., 2015), text classification (Zhang et al., 2015; Ling et al., 2015) and parsing (Yu and Vu, 2017). In addition, the character n-gram fused model was suggested as a solution for a small dataset due to its robustness against data sparsity (Cao and Lu, 2017).

3 Model

We introduce our model training Korean word vector representations based on a subword-level information Skip-Gram. First, we briefly explain the hierarchical composition structure of Korean words to show how we decompose a Korean word into a sequence of subword components (*jamo*). Then, we extract character and *jamo* n-grams from the decomposed sequence to compute word vectors as a mean of the extracted n-grams. We train the vectors by widely-used Skip-Gram model.

3.1 Decomposition of Korean Words

Korean words are formed by an explicit hierarchical structure which can be exploited for better modeling. Every word can be decomposed into a sequence of characters, which in turn can be decomposed into *jamo*s, the smallest lexicographic units representing the consonants and vowels of the language. Unlike English which has a more flexible sequences of consonants and vowels making up syllables (e.g., "straight"), a Korean "character" which is similar to a syllable in English has a rigid structure of three *jamo*s. They have names that reflect the position in a character: 1) chosung (syllable onset), 2) joongsung (syllable nucleus), and 3) jongsung (syllable coda). The prefix *cho* in *chosung* means "first", *joong* in *joongsung* means "middle", and *jong* in *jongsung* means "end" of a character. Each component indicates how the character should be pronounced. With the exception of empty consonants, chosung and jongsung are consonants while joongsung are vowels. The *jamo*s are written with the chosung on top, with joongsung on the right of or below chosung, and jongsung on the bottom (see Fig. 1).

As shown in the top of Fig. 1, some characters such as '해Sun' lack jongsung. In this case, we add

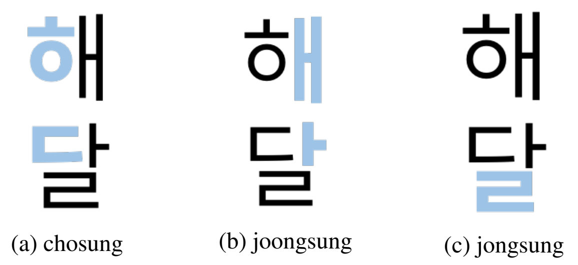

Figure 1: Example of the composition of a Korean character. Each character is comprised of 3 parts as shown in example of '달Moon'. On the other hand, as in the top case '해Sun', some characters lack the last component, 'jongsung'.

an empty jongsung symbol e such that a character always has three (*jamo*s). Thus, the character '달Moon' is decomposed into {ㄷ, ㅏ, ㄹ}, and '해Sun' into {ㅎ, ㅐ, e}.

When decomposing a word, we keep the order of the characters and the order of *jamo*s (chosung, joongsung, and jongsung) within the character. By following this rule, we ensure that a Korean word with N characters will have $3N$ *jamo*s in order. Lastly, the symbols for start of a word < and end of a word > are added to the sequence. For example, the word '강아지puppy' will be decomposed to a sequence of *jamo*s: {<, ㄱ, ㅏ, ㅇ, ㅇ, ㅏ, e, ㅈ, ㅣ, e, >}.

3.2 Extracting N-grams from *jamo* Sequence

We extract the following *jamo*-level and character-level n-grams from the decomposed Korean words: 1) character-level n-grams, and 2) inter-character *jamo*-level n-grams. These two levels of subword features can be successfully integrated into *jamo*-level n-grams by ensuring a character has three *jamo*s, adding empty jongsung symbol to the sequence. For better understanding, we start with the word '먹었다ate'.

Character-level n-grams. Since we add the empty jongsung symbol e when decomposing characters, we can find *jamo*-level trigrams representing a single character in the decomposed *jamo* sequence of a word. For example, there are three character-level unigrams in the word '먹었다ate':

{ㅁ, ㅓ, ㄱ},{ㅇ, ㅓ, ㅆ},{ㄷ, ㅏ, e}

Next, we find character-level n-grams by using the extracted unigrams. Adjacent unigrams are attached to construct n-grams. There are two character-level bigrams, and one trigram in the example:

{ㅁ, ㅓ, ㄱ, ㅇ, ㅓ, ㅆ},{ㅇ, ㅓ, ㅆ, ㄷ, ㅏ, e}
{ㅁ, ㅓ, ㄱ, ㅇ, ㅓ, ㅆ, ㅇ, ㅓ, ㅆ, ㄷ, ㅏ, e}

Lastly, we add the total *jamo* sequence of a word including < and > to the set of extracted character-level n-grams.

Inter-character *jamo*-level n-grams. Since Korean is a member of the agglutinative language, a syntactic character is attached to the semantic part in the word, and this generates many variations. These variations are often determined by *jamo*-level information. For example, usage of the subjective case '이' or '가' is determined by the existence of jongsung in the previous character. In order to learn these regularities, we consider *jamo*-level n-grams across adjacent characters as well. For instance, there are 6 inter-character *jamo*-level trigrams in the example:

{<, ㅁ, ㅓ},{ㅓ, ㄱ, ㅇ},{ㄱ, ㅇ, ㅓ},
{ㅆ, ㄷ, ㅏ},{ㅓ, ㅆ, ㄷ},{ㅏ, e, >}

3.3 Subword Information Skip-Gram

Suppose the training corpus contains a sequence of words $\{..., w_{t-2}, w_{t-1}, w_t, w_{t+1}, w_{t+2}, ...\}$, the Skip-Gram model maximizes the log probability of context word w_{t+j} under a target word w_t:

$$\frac{1}{T}\sum_{t=1}^{T}\sum_{-c\leq j\leq c, j\neq 0}^{2c} \log p(w_{t+j}|w_t) \tag{1}$$

where c is the size of context window, t is total number of words in the corpus. The original Skip-Gram model use softmax function outputs for $\log p(w_{t+j}|w_t)$ in Eq. 1, however, it requires large computational cost. To avoid computing softmax precisely, we approximately maximize the log probability by Noise Contrastive Estimation, and it can be simplified to the negative sampling using the binary logistic loss:

$$\log(1+e^{-s(w_{t+j},w_t)}) + \sum_{n=1}^{n_c}\log(1+e^{s(w_{t+j},w_n)}) \tag{2}$$

where n_c is the number of negative samples, and $s(w_{t+j}, w_t)$ is a scoring function. The function computes the dot product between the input of the target word vector w_t and the output of the context word vector w_{t+j}. In Skip-Gram (Mikolov et al., 2013a), an input of a word w_t is uniquely assigned over the training corpus; however, the vector in the Subword Information Skip-Gram model (Bojanowski et al., 2017) is the mean vector of the set of n-grams extracted from the word. Formally, the scoring function $s(w_t, w_{t+j})$ is:

$$\frac{1}{|G_t|}\sum_{g_t \in G_t}^{|G_t|} \mathbf{z}_{g_t}^{\mathrm{T}} \mathbf{v}_{t+j} \tag{3}$$

where the decomposed set of n-grams of w_t is G_t and its elements are g_t, $|G_t|$ is total number of elements of G_t. In general, the n-grams for $3 \leq n \leq 6$ is extracted from a word, regardless of the subword-level or compositionality of a word.

Similarly, we construct a vector representation of a Korean word by using the extracted two types of n-grams. We compute the sum of *jamo*-level n-grams, sum of character-level n-grams, and compute mean of the vectors. Let us denote character-level n-grams of w_t to G_{ct}, and inter-character *jamo*-level n-grams G_{jt}, then we obtain the scoring function $s(w_t, w_{t+j})$ as follows:

$$\frac{1}{N}\Big(\sum_{g_{ct} \in G_{ct}}^{|G_{ct}|} \mathbf{z}_{g_{ct}}^{\mathrm{T}} \mathbf{v}_{t+j} + \sum_{g_{jt} \in G_{jt}}^{|G_{jt}|} \mathbf{z}_{g_{jt}}^{\mathrm{T}} \mathbf{v}_{t+j}\Big) \tag{4}$$

where $\mathbf{z}_{g_{jt}}$ is the vector representation of the *jamo*-level n-gram g_{jt}, and $\mathbf{z}_{g_{ct}}$ is that of the character-level n-gram g_{ct}. N is sum of the number of character-level n-grams and the number of inter-character *jamo*-level n-grams $|G_{ct}| + |G_{jt}|$.

4 Experiments

4.1 Corpus

We collect a corpus of Korean documents from various sources to cover a wide context of word usages. The corpus used to train the models include: 1) Korean Wikipedia, 2) online news articles, and 3) Sejong Corpus. The corpus contains 0.12 billion tokens with 638,708 unique words. We discard words that occur fewer than ten times in the entire corpus. Details of the corpus are shown in Table 1.

Korean Wikipedia. First, we choose Korean Wikipedia articles[1] for training word vector representations. The corpus contains 0.4M articles, 3.3M sentences and 43.4M words.

Online News Articles. We collect online news articles of 5 major press from following sections: 1) society, 2) politics, 3) economics, 4) foreign, 5) culture, 6) digital. The articles were published from September to November, 2017. The corpus contains 3.2M sentences and 47.1M words.

[1]https://dumps.wikimedia.org/kowiki/20171103/

	# of words	# of sentences	# of unique words
Wikipedia	43.4M	3.3M	299,528
Online News	47.1M	3.2M	282,955
Sejong Corpus	31.4M	2.2M	231,332
Total	121.9M	8.8M	638,708

Table 1: Number of tokens, sentences and unique words of corpus used to train the word vector representations. We aggregate three sources to make the corpus containing 0.12 billions word tokens with 0.6M unique words.

Sejong Corpus. This data is a publicly available corpus[2] which is collected under a national research project named the “21st century Sejong Project”. The corpus was developed from 1998 to 2007, and contains formal text (newpapers, dictionaries, novels, etc) and informal text (transcriptions of TV shows and radio programs, etc). Thus, the corpus covers topics and context of language usage which could not be dealt with Wikipedia or news articles. We exclude some documents containing unnatural sentences such as POS-tagged sentences.

4.2 Evaluation Tasks and Datasets

We evaluate the performance of word vectors through word similarity task and word analogy task. However, to best of our knowledge, there is no Korean evaluation dataset for either task. Thus we first develop the evaluation datasets. We also test the word vectors for sentiment analysis.

4.2.1 Word Similarity Evaluation Dataset

Translating the test set. We develop a Korean version of the word similarity evaluation set. Two graduate students who speak Korean as native language translated the English word pairs in WS-353 (Finkelstein et al., 2001). Then, 14 Korean native speakers annotated the similarity between pairs by giving scores from 0 to 10 for the translated pairs, following written instructions. The original English instructions were translated into Korean as well. Among the 14 scores for each pair, we exclude the minimum and maximum scores and compute the mean of the rest of the scores. The correlation between the original scores and the annotated scores of the translated pairs is .82, which

[2]https://ithub.korean.go.kr/user/main.do

indicates that the translations are sufficiently reliable. We attribute the difference to the linguistic and cultural differences. We make the Korean version of WS-353 publicly available.[3]

4.2.2 Word Analogy Evaluation Dataset

We develop the word analogy test items to evaluate the performance of word vectors. The evaluation dataset consists of 10,000 items and includes 5,000 items for evaluating the semantic features and 5,000 for the syntactic features. We also release our word analogy evaluation dataset for future research.

Semantic Feature Evaluation To evaluate the semantic features of word vectors, we refer to the English version of the word analogy test sets. (Mikolov et al., 2013a; Gladkova et al., 2016). We cover the features in both sets and translated items into Korean. The items are clustered to five categories including miscellaneous items. Each category consists of 1,000 items.

- *Capital-Country (Capt.)* includes two word pairs representing the relation between the country name and its capital:
  아테네Athens : 그리스Greece = 바그다드Baghdad : 이라크Iraq
- *Male-Female (Gend.)* evaluates the relation between male and female:
  왕자prince:공주princess = 신사gentlemen:숙녀ladies
- *Name-Nationality (Name)* evaluates the relation between the name of celebrities or stars and their nationality:
  간디Gandhi : 인도India = 링컨Lincoln : 미국USA
- *Country-Language (Lang.)* evaluates the relation between the country name and its official language:
  아르헨티나Argentina : 스페인어Spanish = 미국USA : 영어English
- *Miscellaneous (Mics.)* includes various semantic features, such as pairs of a young animals, sound of animals, and Korean-specific color-words or regions, etc..
  개구리Frog : 올챙이tadpole = 말horse : 망아지pony
  닭chicken:꼬꼬댁cackling=호랑이tiger:으르렁growl
  파란blue:새파란bluish=노란yellow:샛노란yellowish
  부산Busan : 경상남도South Gyeongsang Province
  = 대구Daegu : 경상북도North Gyeongsang Province

Syntactic Feature Evaluation We define five representative syntactic categories and develop Korean-specific test items, rather than trying to cover the existing categories in the original sets (Mikolov et al., 2013a; Gladkova et al., 2016). This is because most of the syntactic features in these sets are not available in Korean.

We develop the test set with linguistic expert knowledge of Korean. The following case is a good example. In Korean, the subject marker is attached to the back of a word, and other case markers are also explicit at the word level. Here, word level refers to 'a phrase delimited by two whitespaces around it'. Unlike Korean, in English, subjects are determined by the position in a sentence (i.e., subject comes before the verb), so the case is not explicitly marked in the word. Similarly, there are other important and unique syntactic features of the Korean language, of which we choose the following five categories to evaluate the word vectors:

- *Case* contains various case markers attached to common nouns. This evaluates a case in Korean which is represented within a word-level:
  교수Professor : 교수가Professor+case가
  = 축구soccer : 축구가soccer+case가
- *Tense* includes a verb variation of two tenses, one of which is a present tense and a past tense for the other:
  싸우다fight : 싸웠다fought = 오다come : 왔다came
- *Voice* has a pair of verb voice, one for an active voice and a passive voice for the other. It evaluates the voice which is represented by a verbal suffix:
  팔았다sold : 팔렸다be sold
  = 평가했다evaluated : 평가됐다was evaluated
- *Verb ending form* includes various verb ending forms. The various forms are part of verbal inflection in Korean:
  가다go : 가고go+form고
  = 쓰다write : 쓰고write+form고
- *Honorific (Honr.)* evaluates a morphological variation for verbs in Korean. An honorific expression is one of the most distinctive feature in Korean compared to other languages. This test set introduces the honorific morpheme '-시-' which is used in verbs:
  도왔다helped : 도우셨다helped+honorific시
  = 됐다done : 되셨다done+honorific시

4.2.3 Sentiment Analysis

We perform a binary sentiment classification task for evaluation of word vectors. Given a sequence

[3]https://github.com/SungjoonPark/KoreanWordVectors

of words, the trained classifier should predict the sentiment from the inputs while maintaining the input word vectors fixed.

Dataset We choose Naver Sentiment Movie Corpus[4]. Scraped from Korean portal site Naver, the dataset contains 200K movie reviews. Each review is no longer than 140 characters and contain binary label according to its sentiment (1 for positive and 0 for negative). The number of samples in both sentiments is equal with 100K of positives and 100K of negatives in sum. We sample from the dataset for training (100K), validation (25K), and test set (25K). Again, each set's ratio of sentiment class is balanced. Although we apply simple preprocessing of stripping out punctuation and emoticon, the dataset is still noisy with typos, segmentation errors and abnormal word usage since its original source is raw comments from portal site.

Classifier In order to build sentiment classifier, we adopt single layer LSTM with 300 hidden units and 0.5 dropout rates. Given the final state of LSTM unit, sigmoid activation function is applied for output prediction. We use cross-entropy loss and optimize parameters through Adam optimizer (Kingma and Ba, 2014) with learning rate of 0.001.

4.3 Comparison Models

We compare performance of our model to comparison models including word-level, character-level, and *jamo*-level Skip-Gram models trained by negative sampling. Hyperparameters of each models are tuned over word similarity task. We fix the number of training epochs 5.

Skip-Gram (SG) We first compare the performance with word-level Skip-Gram model (Mikolov et al., 2013a) where a unique vector is assigned for every unique words in the corpus. We set the number of dimensions as 300, number of negative samples to 5, and window size to 5.

Character-level Skip-Gram (SISG(ch)) splits words to character-level n-grams based on subword information skip-gram. (Bojanowski et al., 2017). We set the number of dimensions as 300, number of negative samples to 5, and window size to 5. The n was set to 2-4.

***Jamo*-level Skip-Gram with Empty Jongsung Symbol (SISG(jm))** splits words to *jamo*-level n-grams based on subword information skip-gram. (Bojanowski et al., 2017). In addition, if a character lacks jongsung, the symbol ⓔ is added. We set the number of dimensions as 300, number of negative samples to 5, and window size to 5. The n was set to 3-6. Note that setting n=3-6 and adding the jongsung symbol makes this model as a specific case of our model, containing *jamo*-level n-grams (n=3-6) and character-level n-grams (n=1-2) as well.

[4]https://github.com/e9t/nsmc

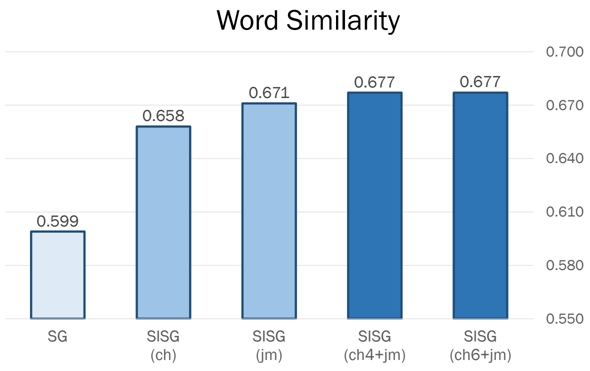

Figure 2: Spearman's correlation coefficient of word similarity task for each models. The results show higher consistency to human word similarity judgment on our method.

4.4 Optimization

In order to train our model, we apply stochastic gradient descent with linearly scheduled learning rate decay. Initial learning rate is set to .025. To speed up the training, we train the vectors in parallel with shared parameters, and they are updated asynchronously.

For our model, we set n of character n-grams to 1-4 or 1-6, and n of inter-character *jamo*-level n-grams to 3-5. We name both model as SISG(ch4+jm) and SISG(ch6+jm), respectively. The number of dimension is set to 300, window size to 5, and negative samples to 5. We train our model 5 epochs over training corpus.

5 Results

Word Similarity. We report Spearman's correlation coefficient between the human judgment and model's cosine similarity for the similarity of word pairs. Fig. 2 presents the results. For word-level skip-gram, Spearman's correlation is .599. If we decompose words into characters n-grams in order to construct word vectors (SISG(Ch)), performance is highly improved to .658. It indicates that decomposing words itself is helpful to learn good

Model	Analogy									
	Semantic					Syntactic				
	Capt	Gend	Name	Lang	Misc	Case	Tense	Voice	Form	Honr
SG	0.460	0.551	**0.537**	0.435	0.574	0.521	0.597	0.594	0.685	0.634
SISG(ch)	0.469	0.584	0.608	0.439	0.614	0.422	0.559	0.550	0.656	0.489
SISG(jm)	0.442	0.515	0.574	0.362	0.565	0.228	0.421	0.434	0.537	0.367
SISG(ch4+jm)	0.431	0.504	0.570	0.361	0.556	0.212	0.415	0.434	**0.501**	**0.364**
SISG(ch6+jm)	**0.425**	**0.498**	0.561	**0.354**	**0.554**	**0.210**	**0.414**	**0.426**	0.507	0.367

Table 2: Performance of our method and comparison models. Average cosine distance for each category in word analogy task are reported. Overall, our model outperforms comparison models, showing close distance between predicted vector $a + b - c$ and the target vector d (a:b=c:d). Specifically, performance is improved more in syntactic analogies.

Korean word vectors, which is morphologically rich language. Moreover, if the words are decomposed to deeper level (SISG(jm)), performance is further improved to .671.

Next, addition of an empty jongsung symbol ⓔ to *jamo* sequence, which reflects Korean-specific linguistic regularities, improves the quality of word vectors. SISG(jm), specific case of our model, shows higher correlation coefficient than the other baselines. Lastly, when we extend number of characters to learn in a word to 4 or 6, our models outperform others.

Word Analogy. In general, given an item a:b=c:d and corresponding word vectors u_a, u_b, u_c, u_d, the vector $u_a + u_b - u_c$ is used to compute cosine distances between the vector and the others. Then the vectors are ranked in terms of the distance by ascending order and if the vector u_d is found at the top, the item is counted as correct. Top 1 accuracy or error rate for each category is frequently used metric for this task, however, in this case these rank-based measures may not be an appropriate measure since the total number of unique n-grams (e.g., SISG) or unique words (e.g., SG) over the same corpus largely differ from each other. For fair comparison, we directly report cosine distances between the vector $u_a + u_b - u_c$ and u_d of each category, rather than evaluating ranks of the vectors. Formally, given an item a:b=c:d, we compute 3COSADD based metric:

$$1 - \cos(\mathbf{u}_a + \mathbf{u}_b - \mathbf{u}_c, \mathbf{u}_d) \qquad (5)$$

We report the average cosine distance between predicted vector $u_a + u_b - u_c$ and target vector u_d of each category.

In semantic analogies, decomposing word into character helps little for learning semantic features. However, *jamo*-level n-grams help representing overall semantic features and our model show higher performance compared to baseline models. One exception is Name-Nationality category since it mainly consists of items including proper nouns, and decomposing these nouns does not help learning the semantic feature of the word. For example, it is obvious that the semantic features of both words '간디Ghandi' and '인도India' could not be derived from that of characters or *jamo* n-grams comprising those words.

On the other hand, decomposing words does help to learn syntactic features for all categories, and decomposing a word to even deeper levels makes learning those features more effectively. Our model outperforms all other baselines, and the amount of decreased cosine distances compared to that of word-level Skip-Gram is larger than semantic categories. Korean language is agglutinative language that character-level syntactic affixes are attached to the root of the word, and the combination of them determines final form the word. Also, the form can be reduced with *jamo*-level transformation. This is the main reason that we can learn syntactic feature of Korean words if we decompose a word into character-level and *jamo*-level simultanously. We observe similar tendency when using 3COSMUL distance metric. (Levy and Goldberg, 2014)

Sentiment Analysis. We report accuracy, loss, precision, recall and f1 score for binary sentiment classification task over test set. Although overall performance is homogeneous, our method which decompose a word to 1-6 character n-grams and 3-5 *jamo* n-grams show slightly higher performance over comparison models. In addition, our approach show better results compared to character-

Model	Acc. (%)	Prc.	Rec.	F1
SG	76.15	.746	.792	.768
SISG(ch)	76.26	.774	.741	.757
SISG(jm)	76.53	**.790**	.722	.754
SISG(ch4+jm)	76.28	.755	.776	.765
SISG(ch6+jm)	**76.54**	.750	**.795**	**.772**

Table 3: Performance of sentiment classification task. 3-5 *jamo* n-grams and 1-6 chracter n-grams show slightly higher performance in terms of accuracy and f1-score over comparison models.

Word Sim.		# of chars			
		4	5	6	all
# of *jamo*s	2-4	0.660	0.655	0.659	0.651
	3-4	0.660	0.650	0.652	0.660
	3-5	**0.677**	0.672	**0.677**	0.675
	3-6	0.665	0.663	0.664	0.669

Table 4: Spearman's correlation coefficient of Word similarity task by n-gram of *jamo*s and characters. Performance are improved when the 3-5 gram of *jamo*s and 1-4 or 1-6 gram of characters.

level SISG or *jamo*-level SISG. On the other hand, word-level Skip-Gram show comparable F1-score to our model, and is even higher than other comparison models. This is because the dataset contains significant amount of proper nouns, such as movie or actor names, and these word's semantic representations are captured better by word-level representations, as shown in word analogy task.

Effect of Size n in both n-grams. Table. 4 shows performance of word similarity task for each number of inter-character *jamo*-level n-grams and character-level n-grams. For the n of *jamo*-level n-grams, including n=5,6 of n-grams and excluding bigrams show higher performance. Meanwhile, n of character-level n-grams, including all of the character n-grams while decomposing a word does not guarantee performance improvement. Since most of the Korean word consists of no more than 6 characters (97.2% of total corpus), it seems maximum number of n=6 in character n-gram is large enough to learn word vectors. In addition, words with no more than 4 characters takes 82.6% of total corpus, so that n=4 sufficient to learn character n-grams as well.

6 Conclusion and Discussions

In this paper, we present how to decompose a Korean character into a sequence of *jamo*s with empty jongsung symbols, then extract character-level n-grams and intercharacter *jamo*-level n-grams from that sequence. Both n-grams construct a word vector representation by computing the average of n-grams, and these vectors are trained by subword-level information Skip-Gram. Prior to evaluating the performance of the vectors, we developed test set for word similarity and word analogy tasks for Korean.

We demonstrated the effectiveness of the learned word vectors in capturing the semantic and syntactic information by evaluating these vectors with word similarity and word analogy tasks. Specifically, the vectors using both *jamo* and character-level information can represent syntactic features more precisely even in an agglutinative language. Furthermore, sentiment classification results of our work indicate that the representative power of the vectors positively contributes to downstream NLP task.

Decomposing Korean word into *jamo*-level or character unigram helps capturing syntactic information. For example, Korean words add a character to the root of the word (e.g., '-은' subjective case, '-었' for past tense '-시-' for honorific, '-히-' for voice, and '-고-' for verb ending form.) Then composed word can be reduced to have fewer characters by transforming *jamo*s, such as '되었다' to '됐다'. Hence, the inter-character *jamo*-level n-grams also help capture these features. On the other hand, larger n-grams such as character-level trigram will learn unique meaning of that word since those larger component of the word will mostly occur with that word. By leveraging both features, our method produces word vectors reflecting linguistic features effectively, and thus, outperforms previous word-level approaches.

Since Korean words are divisible once more into grapheme level, resulting in longer sequence of *jamo*s for a given word, we plan to explore potential applicability of deeper level of subword information in Korean. Meanwhile, we will further train our model over noisy data and investigate how it is dealing with noisy words. Generally, informal Korean text contains intentional typos ('맛잇다'delicious' with typo'), stand-alone *jamo* as a character, ('ㅋㅋlol') and segmentation errors. ('같이가다'go together' without space'). Since these errors occur frequently, it is important to apply the vectors in training NLP models over real-word data. We plan to apply these vectors for various neural network based NLP models, such as conversation modeling. Lastly, since our method can capture Korean syntactic features through *jamo* and character n-grams, we can apply the same idea to other tasks such as POS tagging and parsing.

Abstract

Sememes are minimum semantic units of concepts in human languages, such that each word sense is composed of one or multiple sememes. Words are usually manually annotated with their sememes by linguists, and form linguistic common-sense knowledge bases widely used in various NLP tasks. Recently, the lexical sememe prediction task has been introduced. It consists of automatically recommending sememes for words, which is expected to improve annotation efficiency and consistency. However, existing methods of lexical sememe prediction typically rely on the external context of words to represent the meaning, which usually fails to deal with low-frequency and out-of-vocabulary words. To address this issue for Chinese, we propose a novel framework to take advantage of both internal character information and external context information of words. We experiment on HowNet, a Chinese sememe knowledge base, and demonstrate that our framework outperforms state-of-the-art baselines by a large margin, and maintains a robust performance even for low-frequency words. [i]

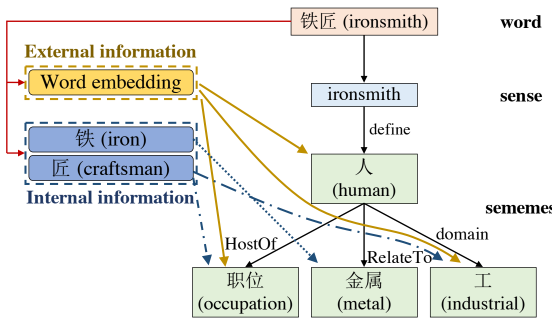

Figure 1: Sememes of the word “铁匠” (ironsmith) in HowNet, where *occupation*, *human* and *industrial* can be inferred by both external (contexts) and internal (characters) information, while *metal* is well-captured only by the internal information within the character “ 铁” (iron).

1 Introduction

A sememe is an indivisible semantic unit for human languages defined by linguists (Bloomfield, 1926). The semantic meanings of concepts (e.g., words) can be composed by a finite number of sememes. However, the sememe set of a word is not explicit, which is why linguists build knowledge bases (KBs) to annotate words with sememes manually.

HowNet is a classical widely-used sememe KB (Dong and Dong, 2006). In HowNet, linguists manually define approximately 2,000 sememes, and annotate more than 100,000 common words in Chinese and English with their relevant sememes in hierarchical structures. HowNet is well developed and has a wide range of applications in many NLP tasks, such as word sense disambiguation (Duan et al., 2007), sentiment analysis (Fu et al., 2013; Huang et al., 2014) and cross-lingual word similarity (Xia et al., 2011).

Since new words and phrases are emerging every day and the semantic meanings of existing concepts keep changing, it is time-consuming and work-intensive for human experts to annotate new

i Code is available at `https://github.com/thunlp/Character-enhanced-Sememe-Prediction`

concepts and maintain consistency for large-scale sememe KBs. To address this issue, Xie et al. (2017) propose an automatic sememe prediction framework to assist linguist annotation. They assumed that words which have similar semantic meanings are likely to share similar sememes. Thus, they propose to represent word meanings as embeddings (Pennington et al., 2014; Mikolov et al., 2013) learned from a large-scale text corpus, and they adopt collaborative filtering (Sarwar et al., 2001) and matrix factorization (Koren et al., 2009) for sememe prediction, which are concluded as Sememe Prediction with Word Embeddings (SPWE) and Sememe Prediction with Sememe Embeddings (SPSE) respectively. However, those methods ignore the internal information within words (e.g., the characters in Chinese words), which is also significant for word understanding, especially for words which are of low-frequency or do not appear in the corpus at all. In this paper, we take Chinese as an example and explore methods of taking full advantage of both external and internal information of words for sememe prediction.

In Chinese, words are composed of one or multiple characters, and most characters have corresponding semantic meanings. As shown by Yin (1984), more than 90% of Chinese characters in modern Chinese corpora are morphemes. Chinese words can be divided into single-morpheme words and compound words, where compound words account for a dominant proportion. The meanings of compound words are closely related to their internal characters as shown in Fig. 1. Taking a compound word "铁匠" (ironsmith) for instance, it consists of two Chinese characters: "铁" (iron) and "匠" (craftsman), and the semantic meaning of "铁匠" can be inferred from the combination of its two characters (*iron* + *craftsman* $\rightarrow$ *ironsmith*). Even for some single-morpheme words, their semantic meanings may also be deduced from their characters. For example, both characters of the single-morpheme word "徘徊" (hover) represent the meaning of "hover" or "linger". Therefore, it is intuitive to take the internal character information into consideration for sememe prediction.

In this paper, we propose a novel framework for Character-enhanced Sememe Prediction (CSP), which leverages both internal character information and external context for sememe prediction. CSP predicts the sememe candidates for a target word from its word embedding and the corresponding character embeddings. Specifically, we follow SPWE and SPSE as introduced by Xie et al. (2017) to model external information and propose Sememe Prediction with Word-to-Character Filtering (SPWCF) and Sememe Prediction with Character and Sememe Embeddings (SPCSE) to model internal character information. In our experiments, we evaluate our models on the task of sememe prediction using HowNet. The results show that CSP achieves state-of-the-art performance and stays robust for low-frequency words.

To summarize, the key contributions of this work are as follows: (1) To the best of our knowledge, this work is the first to consider the internal information of characters for sememe prediction. (2) We propose a sememe prediction framework considering both external and internal information, and show the effectiveness and robustness of our models on a real-world dataset.

2 Related Work

Knowledge Bases. Knowledge Bases (KBs), aiming to organize human knowledge in structural forms, are playing an increasingly important role as infrastructural facilities of artificial intelligence and natural language processing. KBs rely on manual efforts (Bollacker et al., 2008), automatic extraction (Auer et al., 2007), manual evaluation (Suchanek et al., 2007), automatic completion and alignment (Bordes et al., 2013; Toutanova et al., 2015; Zhu et al., 2017) to build, verify and enrich their contents. WordNet (Miller, 1995) and BabelNet (Navigli and Ponzetto, 2012) are the representative of linguist KBs, where words of similar meanings are grouped to form thesaurus (Nastase and Szpakowicz, 2001). Apart from other linguistic KBs, sememe KBs such as HowNet (Dong and Dong, 2006) can play a significant role in understanding the semantic meanings of concepts in human languages and are favorable for various NLP tasks: information structure annotation (Gan and Wong, 2000), word sense disambiguation (Gan et al., 2002), word representation learning (Niu et al., 2017; Faruqui et al., 2015), and sentiment analysis (Fu et al., 2013) inter alia. Hence, lexical sememe prediction is an important task to construct sememe KBs.

Automatic Sememe Prediction. Automatic sememe prediction is proposed by Xie et al. (2017).

For this task, they propose SPWE and SPSE, which are inspired by collaborative filtering (Sarwar et al., 2001) and matrix factorization (Koren et al., 2009) respectively. SPWE recommends the sememes of those words that are close to the unlabelled word in the embedding space. SPSE learns sememe embeddings by matrix factorization (Koren et al., 2009) within the same embedding space of words, and it then recommends the most relevant sememes to the unlabelled word in the embedding space. In these methods, word embeddings are learned based on external context information (Pennington et al., 2014; Mikolov et al., 2013) on large-scale text corpus. These methods do not exploit internal information of words, and fail to handle low-frequency words and out-of-vocabulary words. In this paper, we propose to incorporate internal information for lexical sememe prediction.

Subword and Character Level NLP. Subword and character level NLP models the internal information of words, which is especially useful to address the out-of-vocabulary (OOV) problem. Morphology is a typical research area of subword level NLP. Subword level NLP has also been widely considered in many NLP applications, such as keyword spotting (Narasimhan et al., 2014), parsing (Seeker and Çetinoğlu, 2015), machine translation (Dyer et al., 2010), speech recognition (Creutz et al., 2007), and paradigm completion (Sutskever et al., 2014; Bahdanau et al., 2015; Cotterell et al., 2016a; Kann et al., 2017; Jin and Kann, 2017). Incorporating subword information for word embeddings (Bojanowski et al., 2017; Cotterell et al., 2016b; Chen et al., 2015; Wieting et al., 2016; Yin et al., 2016) facilitates modeling rare words and can improve the performance of several NLP tasks to which the embeddings are applied. Besides, people also consider character embeddings which have been utilized in Chinese word segmentation (Sun et al., 2014).

The success of previous work verifies the feasibility of utilizing internal character information of words. We design our framework for lexical sememe prediction inspired by these methods.

3 Background and Notation

In this section, we first introduce the organization of *sememes*, *senses* and *words* in HowNet. Then we offer a formal definition of lexical sememe prediction and develop our notation.

3.1 Sememes, Senses and Words in HowNet

HowNet provides sememe annotations for Chinese words, where each word is represented as a hierarchical tree-like sememe structure. Specifically, a word in HowNet may have various *senses*, which respectively represent the semantic meanings of the word in the real world. Each *sense* is defined as a hierarchical structure of *sememes*. For instance, as shown in the right part of Fig. 1, the word “铁匠” (ironsmith) has one sense, namely *ironsmith*. The sense *ironsmith* is defined by the sememe “人” (human) which is modified by sememe “职位” (occupation), “金属” (metal) and “工” (industrial). In HowNet, linguists use about $2,000$ sememes to describe more than $100,000$ words and phrases in Chinese with various combinations and hierarchical structures.

3.2 Formalization of the Task

In this paper, we focus on the relationships between the *words* and the *sememes*. Following the settings of Xie et al. (2017), we simply ignore the senses and the hierarchical structure of sememes, and we regard the sememes of all senses of a word together as the sememe set of the word.

We now introduce the notation used in this paper. Let $G = (W, S, T)$ denotes the sememe KB, where $W = \{w_1, w_2, \ldots, w_{|W|}\}$ is the set of words, S is the set of sememes, and $T \subseteq W \times S$ is the set of relation pairs between words and sememes. We denote the Chinese character set as C, with each word $w_i \in C^+$. Each word w has its sememe set $S_w = \{s|(w, s) \in T\}$. Take the word “铁匠” (ironsmith) for example, the sememe set $S_{\text{铁匠}\,(\textit{ironsmith})}$ consists of “人” (human), “职位” (occupation), “金属” (metal) and “工” (industrial).

Given a word $w \in C^+$, the task of lexical sememe prediction aims to predict the corresponding $P(s|w)$ of sememes in S to recommend them to w.

4 Methodology

In this section, we present our framework for lexical sememe prediction (SP). For each unlabelled word, our framework aims to recommend the most appropriate sememes based on the internal and external information. Because of introducing character information, our framework can work for both high-frequency and low-frequency words.

Our framework is the ensemble of two parts: sememe prediction with internal information (i.e., *internal* models), and sememe prediction with external information (i.e., *external* models). Explicitly, we adopt SPWE, SPSE, and their ensemble (Xie et al., 2017) as *external* models, and we take SPWCF, SPCSE, and their ensemble as *internal* models.

In the following sections, we first introduce SPWE and SPSE. Then, we show the details of SPWCF and SPCSE. Finally, we present the method of model ensembling.

4.1 SP with External Information

SPWE and SPSE are introduced by Xie et al. (2017) as the state of the art for sememe prediction. These methods represent word meanings with embeddings learned from external information, and apply the ideas of collaborative filtering and matrix factorization in recommendation systems for sememe predication.

SP with Word Embeddings (SPWE) is based on the assumption that similar words should have similar sememes. In SPWE, the similarity of words are measured by cosine similarity. The score function $P(s_j|w)$ of sememe s_j given a word w is defined as:

$$P(s_j|w) \sim \sum_{w_i \in W} \cos(\mathbf{w}, \mathbf{w_i}) \cdot \mathbf{M}_{ij} \cdot c^{r_i}, \quad (1)$$

where $\mathbf{w}$ and $\mathbf{w_i}$ are pre-trained word embeddings of words w and w_i. $\mathbf{M}_{ij} \in \{0, 1\}$ indicates the annotation of sememe s_j on word w_i, where $\mathbf{M}_{ij} = 1$ indicates the word $s_j \in S_{w_i}$ and otherwise is not. r_i is the descend cosine word similarity rank between w and w_i, and $c \in (0, 1)$ is a hyper-parameter.

SP with Sememe Embeddings (SPSE) aims to map sememes into the same low-dimensional space of the word embeddings to predict the semantic correlations of the sememes and the words. This method learns two embeddings $\mathbf{s}$ and $\bar{\mathbf{s}}$ for each sememe by solving matrix factorization with the loss function defined as:

$$\mathcal{L} = \sum_{w_i \in W, s_j \in S} \left(\mathbf{w}_i \cdot (\mathbf{s}_j + \bar{\mathbf{s}}_j) + \mathbf{b}_i + \mathbf{b}'_j - \mathbf{M}_{ij}\right)^2 + \lambda \sum_{s_j, s_k \in S} (\mathbf{s}_j \cdot \bar{\mathbf{s}}_k - \mathbf{C}_{jk})^2, \quad (2)$$

where $\mathbf{M}$ is the same matrix used in SPWE. $\mathbf{C}$ indicates the correlations between sememes, in which $\mathbf{C}_{jk}$ is defined as the point-wise mutual information $\text{PMI}(s_j, s_k)$. The sememe embeddings are learned by factorizing the word-sememe matrix $\mathbf{M}$ and the sememe-sememe matrix $\mathbf{C}$ synchronously with fixed word embeddings. $\mathbf{b}_i$ and $\mathbf{b}'_j$ denote the bias of w_i and s_j, and λ is a hyper-parameter. Finally, the score of sememe s_j given a word w is defined as:

$$P(s_j|w) \sim \mathbf{w} \cdot (\mathbf{s}_j + \bar{\mathbf{s}}_j). \quad (3)$$

4.2 SP with Internal Information

We design two methods for sememe prediction with only internal character information without considering contexts as well as pre-trained word embeddings.

4.2.1 SP with Word-to-Character Filtering (SPWCF)

Inspired by collaborative filtering (Sarwar et al., 2001), we propose to recommend sememes for an unlabelled word according to its similar words based on internal information. Instead of using pre-trained word embeddings, we consider words as *similar* if they contain the same characters at the same positions.

In Chinese, the meaning of a character may vary according to its position within a word (Chen et al., 2015). We consider three positions within a word: `Begin`, `Middle`, and `End`. For example, as shown in Fig. 2, the character at the `Begin` position of the word "火车站" (railway station) is "火" (fire), while "车" (vehicle) and "站" (station) are at the `Middle` and `End` position respectively. The character "站" usually means *station* when it is at the `End` position, while it usually means *stand* at the `Begin` position like in "站立" (stand), "站岗哨兵" (standing guard) and "站起来" (stand up).

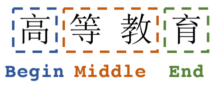

Figure 2: An example of the position of characters in a word.

Formally, for a word $w = c_1 c_2 ... c_{|w|}$, we define $\pi_B(w) = \{c_1\}$, $\pi_M(w) = \{c_2, ..., c_{|w-1|}\}$, $\pi_E(w) = \{c_{|w|}\}$, and

$$P_p(s_j|c) \sim \frac{\sum_{w_i \in W \wedge c \in \pi_p(w_i)} \mathbf{M}_{ij}}{\sum_{w_i \in W \wedge c \in \pi_p(w_i)} |S_{w_i}|}, \quad (4)$$

that represents the score of a sememe s_j given a character c and a position p, where π_p may be π_B, π_M, or π_E. $\mathbf{M}$ is the same matrix used in Eq. (1). Finally, we define the score function $P(s_j|w)$ of sememe s_j given a word w as:

$$P(s_j|w) \sim \sum_{p \in \{B,M,E\}} \sum_{c \in \pi_p(w)} P_p(s_j|c). \tag{5}$$

SPWCF is a simple and efficient method. It performs well because compositional semantics are pervasive in Chinese compound words, which makes it straightforward and effective to find similar words according to common characters.

4.2.2 SP with Character and Sememe Embeddings (SPCSE)

The method Sememe Prediction with Word-to-Character Filtering (SPWCF) can effectively recommend the sememes that have strong correlations with characters. However, just like SPWE, it ignores the relations between sememes. Hence, inspired by SPSE, we propose Sememe Prediction with Character and Sememe Embeddings (SPCSE) to take the relations between sememes into account. In SPCSE, we instead learn the sememe embeddings based on internal character information, then compute the semantic distance between sememes and words for prediction.

Inspired by GloVe (Pennington et al., 2014) and SPSE, we adopt matrix factorization in SPCSE, by decomposing the word-sememe matrix and the sememe-sememe matrix simultaneously. Instead of using pre-trained word embeddings in SPSE, we use pre-trained character embeddings in SPCSE. Since the ambiguity of characters is stronger than that of words, multiple embeddings are learned for each character (Chen et al., 2015). We select the most representative character and its embedding to represent the word meaning. Because low-frequency characters are much rare than those low-frequency words, and even low-frequency words are usually composed of common characters, it is feasible to use pre-trained character embeddings to represent rare words. During factorizing the word-sememe matrix, the character embeddings are fixed.

We set N_e as the number of embeddings for each character, and each character c has N_e embeddings $\mathbf{c}^1, ..., \mathbf{c}^{N_e}$. Given a word w and a sememe s, we select the embedding of a character of w closest to the sememe embedding by cosine distance as the representation of the word w,

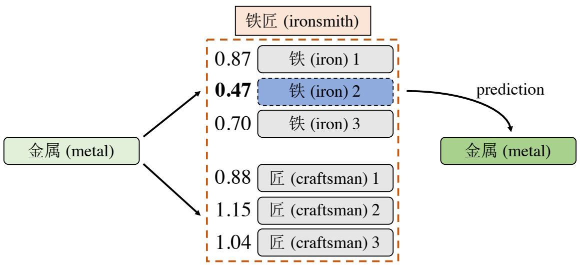

Figure 3: An example of adopting multiple-prototype character embeddings. The numbers are the cosine distances. The sememe "金属" (metal) is the closest to one embedding of "铁" (iron).

as shown in Fig. 3. Specifically, given a word $w = c_1...c_{|w|}$ and a sememe s_j, we define

$$\hat{k}, \hat{r} = \arg\min_{k,r} \left[1 - \cos(\mathbf{c}_k^r, (\mathbf{s}'_j + \bar{\mathbf{s}}'_j))\right], \tag{6}$$

where $\hat{k}$ and $\hat{r}$ indicate the indices of the character and its embedding closest to the sememe s_j in the semantic space. With the same word-sememe matrix $\mathbf{M}$ and sememe-sememe correlation matrix $\mathbf{C}$ in Eq. (2), we learn the sememe embeddings with the loss function:

$$\mathcal{L} = \sum_{w_i \in W, s_j \in S} \left(\mathbf{c}_{\hat{k}}^{\hat{r}} \cdot (\mathbf{s}'_j + \bar{\mathbf{s}}'_j) + \mathbf{b}_{\hat{k}}^c + \mathbf{b}''_j - \mathbf{M}_{ij}\right)^2 + \lambda' \sum_{s_j, s_q \in S} \left(\mathbf{s}'_j \cdot \bar{\mathbf{s}}'_q - \mathbf{C}_{jq}\right)^2, \tag{7}$$

where $\mathbf{s}'_j$ and $\bar{\mathbf{s}}'_j$ are the sememe embeddings for sememe s_j, and $\mathbf{c}_{\hat{k}}^{\hat{r}}$ is the embedding of the character that is the closest to sememe s_j within w_i. Note that, as the characters and the words are not embedded into the same semantic space, we learn new sememe embeddings instead of using those learned in SPSE, hence we use different notations for the sake of distinction. $\mathbf{b}_k^c$ and $\mathbf{b}''_j$ denote the biases of c_k and s_j, and λ' is the hyper-parameter adjusting the two parts. Finally, the score function of word $w = c_1...c_{|w|}$ is defined as:

$$P(s_j|w) \sim \mathbf{c}_{\hat{k}}^{\hat{r}} \cdot \left(\mathbf{s}'_j + \bar{\mathbf{s}}'_j\right). \tag{8}$$

4.3 Model Ensembling

SPWCF / SPCSE and SPWE / SPSE take different sources of information as input, which means that they have different characteristics: SPWCF / SPCSE only have access to internal information, while SPWE / SPSE can only make use of external information. On the other hand, just like the difference between SPWE and SPSE, SPWCF originates from collaborative filtering, whereas SPCSE uses matrix factorization. All of those methods have in common that they tend to recommend the sememes of *similar* words, but they diverge in their interpretation of *similar*.

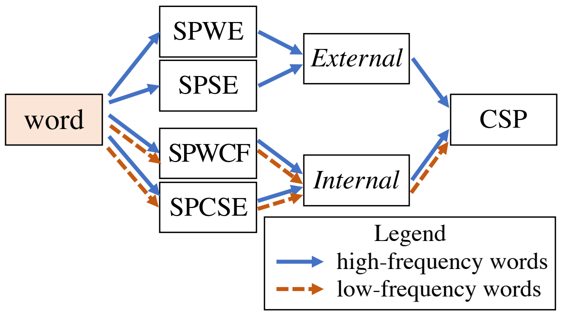

Figure 4: The illustration of model ensembling.

Hence, to obtain better prediction performance, it is necessary to combine these models. We denote the ensemble of SPWCF and SPCSE as the *internal* model, and we denote the ensemble of SPWE and SPSE as the *external* model. The ensemble of the *internal* and the *external* models is our novel framework CSP. In practice, for words with reliable word embeddings, i.e., high-frequency words, we can use the integration of the *internal* and the *external* models; for words with extremely low frequencies (e.g., having no reliable word embeddings), we can just use the *internal* model and ignore the *external* model, because the external information is noise in this case. Fig. 4 shows model ensembling in different scenarios. For the sake of comparison, we use the integration of SPWCF, SPCSE, SPWE, and SPSE as CSP in our all experiments. In this paper, two models are integrated by simple weighted addition.

5 Experiments

In this section, we evaluate our models on the task of sememe prediction. Additionally, we analyze the performance of different methods for various word frequencies. We also execute an elaborate case study to demonstrate the mechanism of our methods and the advantages of using internal information.

5.1 Dataset

We use the human-annotated sememe KB HowNet for sememe prediction. In HowNet, $103,843$ words are annotated with $212,539$ senses, and each sense is defined as a hierarchical structure of sememes. There are about $2,000$ sememes in HowNet. However, the frequencies of some sememes in HowNet are very low, such that we consider them unimportant and remove them. Our final dataset contains $1,400$ sememes. For learning the word and character embeddings, we use the Sogou-T corpus[ii] (Liu et al., 2012), which contains 2.7 billion words.

5.2 Experimental Settings

In our experiments, we evaluate SPWCF, SPCSE, and SPWCF + SPCSE which only use internal information, and the ensemble framework CSP which uses both internal and external information for sememe prediction. We use the state-of-the-art models from Xie et al. (2017) as our baselines. Additionally, we use the SPWE model with word embeddings learned by fastText (Bojanowski et al., 2017) that considers both internal and external information as a baseline.

For the convenience of comparison, we select $60,000$ high-frequency words in Sogou-T corpus from HowNet. We divide the $60,000$ words into train, dev, and test sets of size $48,000$, $6,000$, and $6,000$, respectively, and we keep them fixed throughout all experiments except for Section 5.4. In Section 5.4, we utilize the same train and dev sets, but use other words from HowNet as the test set to analyze the performance of our methods for different word frequency scenarios. We select the hyper-parameters on the dev set for all models including the baselines and report the evaluation results on the test set.

We set the dimensions of the word, sememe, and character embeddings to be 200. The word embeddings are learned by GloVe (Pennington et al., 2014). For the baselines, in SPWE, the hyper-parameter c is set to 0.8, and the model considers no more than $K = 100$ nearest words. We set the probability of decomposing zero elements in the word-sememe matrix in SPSE to be 0.5%. λ in Eq. (2) is 0.5. The model is trained for 20 epochs, and the initial learning rate is 0.01, which decreases through iterations. For fastText, we use skip-gram with hierarchical softmax to learn word embeddings, and we set the minimum length of character n-grams to be 1 and the maximum length

ii Sogou-T corpus is provided by Sogou Inc., a Chinese commercial search engine company. https://www.sogou.com/labs/resource/t.php of character n-grams to be 2. For model ensembling, we use $\frac{\lambda_{SPWE}}{\lambda_{SPSE}} = 2.1$ as the addition weight.

For SPCSE, we use Cluster-based Character Embeddings (Chen et al., 2015) to learn pre-trained character embeddings, and we set N_e to be 3. We set λ' in Eq. (7) to be 0.1, and the model is trained for 20 epochs. The initial learning rate is 0.01 and decreases during training as well. Since generally each character can relate to about 15 - 20 sememes, we set the probability of decomposing zero elements in the word-sememe matrix in SPCSE to be 2.5%. The ensemble weight of SPWCF and SPCSE $\frac{\lambda_{SPWCF}}{\lambda_{SPCSE}} = 4.0$. For better performance of the final ensemble model CSP, we set $\lambda = 0.1$ and $\frac{\lambda_{SPWE}}{\lambda_{SPSE}} = 0.3125$, though 0.5 and 2.1 are the best for SPSE and SPWE + SPSE. Finally, we choose $\frac{\lambda_{internal}}{\lambda_{external}} = 1.0$ to integrate the *internal* and *external* models.

5.3 Sememe Prediction

5.3.1 Evaluation Protocol

The task of sememe prediction aims to recommend appropriate sememes for unlabelled words. We cast this as a multi-label classification task, and adopt mean average precision (MAP) as the evaluation metric. For each unlabelled word in the test set, we rank all sememe candidates with the scores given by our models as well as baselines, and we report the MAP results. The results are reported on the test set, and the hyper-parameters are tuned on the dev set.

5.3.2 Experiment Results

The evaluation results are shown in Table 1. We can observe that:

Method	MAP
SPSE	0.411
SPWE	0.565
SPWE+SPSE	0.577
SPWCF	0.467
SPCSE	0.331
SPWCF + SPCSE	**0.483**
SPWE + fastText	0.531
CSP	**0.654**

Table 1: Evaluation results on sememe prediction. The result of SPWCF + SPCSE is bold for comparing with other methods (SPWCF and SPCSE) which use only internal information.

(1) Considerable improvements are obtained via model ensembling, and the CSP model achieves state-of-the-art performance. CSP combines the internal character information with the external context information, which significantly and consistently improves performance on sememe prediction. Our results confirm the effectiveness of a combination of internal and external information for sememe prediction; since different models focus on different features of the inputs, the ensemble model can absorb the advantages of both methods.

(2) The performance of SPWCF + SPCSE is better than that of SPSE, which means using only internal information could already give good results for sememe prediction as well. Moreover, in *internal* models, SPWCF performs much better than SPCSE, which also implies the strong power of collaborative filtering.

(3) The performance of SPWCF + SPCSE is worse than SPWE + SPSE. This indicates that it is still difficult to figure out the semantic meanings of a word without contextual information, due to the ambiguity and meaning vagueness of internal characters. Moreover, some words are not compound words (e.g., single-morpheme words or transliterated words), whose meanings can hardly be inferred directly by their characters. In Chinese, internal character information is just partial knowledge. We present the results of SPWCF and SPCSE merely to show the capability to use the internal information in isolation. In our case study, we will demonstrate that *internal* models are powerful for low-frequency words, and can be used to predict senses that do not appear in the corpus.

5.4 Analysis on Different Word Frequencies

To verify the effectiveness of our models on different word frequencies, we incorporate the remaining words in HowNet[iii] into the test set. Since the remaining words are low-frequency, we mainly focus on words with long-tail distribution. We count the number of occurrences in the corpus for each word in the test set and group them into eight categories by their frequency. The evaluation results are shown in Table 2, from which we can observe that:

iii In detail, we do not use the numeral words, punctuations, single-character words, the words do not appear in Sogou-T corpus (because they need to appear at least for one time to get the word embeddings), and foreign abbreviations.

word frequency occurrences	⩽ 50 8537	51– 100 4868	101 – 1,000 3236	1,001 – 5,000 2036	5,001 – 10,000 663	10,001 – 30,000 753	>30,000 686
SPWE	0.312	0.437	0.481	0.558	0.549	0.556	0.509
SPSE	0.187	0.273	0.339	0.409	0.407	0.424	0.386
SPWE + SPSE	0.284	0.414	0.478	0.556	0.548	0.554	0.511
SPWCF	0.456	0.414	0.400	0.443	0.462	0.463	0.479
SPCSE	0.309	0.291	0.286	0.312	0.339	0.353	0.342
SPWCF + SPCSE	0.467	0.437	0.418	0.456	0.477	0.477	0.494
SPWE + fastText	0.495	0.472	0.462	0.520	0.508	0.499	0.490
CSP	**0.527**	**0.555**	**0.555**	**0.626**	**0.632**	**0.641**	**0.624**

Table 2: MAP scores on sememe prediction with different word frequencies.

words	models	Top 5 sememes
钟表匠 (clockmaker)	internal	人**(human)**, 职位**(occupation)**, 部件(part), 时间**(time)**, 告诉**(tell)**
	external	人**(human)**, 专(ProperName), 地方(place), 欧洲(Europe), 政(politics)
	ensemble	人**(human)**, 职位**(occupation)**, 告诉**(tell)**, 时间**(time)**, 用具**(tool)**
奥斯卡 (Oscar)	internal	专**(ProperName)**, 地方(place), 市(city), 人(human), 国都(capital)
	external	奖励**(reward)**, 艺**(entertainment)**, 专**(ProperName)**, 用具(tool), 事情**(fact)**
	ensemble	专**(ProperName)**, 奖励**(reward)**, 艺**(entertainment)**, 著名(famous), 地方(place)

Table 3: Examples of sememe prediction. For each word, we present the top 5 sememes predicted by the *internal* model, *external* model and the final ensemble model (CSP). Bold sememes are correct.

(1) The performances of SPSE, SPWE, and SPWE + SPSE decrease dramatically with low-frequency words compared to those with high-frequency words. On the contrary, the performances of SPWCF, SPCSE, and SPWCF + SPCSE, though weaker than that on high-frequency words, is not strongly influenced in the long-tail scenario. The performance of CSP also drops since CSP also uses external information, which is not sufficient with low-frequency words. These results show that the word frequencies and the quality of word embeddings can influence the performance of sememe prediction methods, especially for *external* models which mainly concentrate on the word itself. However, the *internal* models are more robust when encountering long-tail distributions. Although words do not need to appear too many times for learning good word embeddings, it is still hard for *external models* to recommend sememes for low-frequency words. While since *internal* models do not use external word embeddings, they can still work in such scenario. As for the performance on high-frequency words, since these words are used widely, the ambiguity of high-frequency words is thus much stronger, while the *internal* models are still stable for high-frequency words.

(2) The results also indicate that even low-frequency words in Chinese are mostly composed of common characters, and thus it is possible to utilize internal character information for sememe prediction on words with long-tail distribution (even on those new words that never appear in the corpus). Moreover, the stability of the MAP scores given by our methods on various word frequencies also reflects the reliability and universality of our models in real-world sememe annotations in HowNet. We will give detailed analysis in our case study.

5.5 Case Study

The results of our main experiments already show the effectiveness of our models. In this case study, we further investigate the outputs of our models to confirm that character-level knowledge is truly incorporated into sememe prediction.

In Table 3, we demonstrate the top 5 sememes for "钟表匠" (clockmaker) and "奥斯卡" (Oscar, i.e., the Academy Awards). "钟表匠" (clockmaker) is a typical compound word, while "奥斯卡" (Oscar) is a transliterated word. For each word, the top 5 results generated by the internal model (SPWCF + SPCSE), the *external* model (SPWE + SPSE) and the ensemble model (CSP) are listed.

The word "钟表匠" (clockmaker) is composed of three characters: "钟" (bell, clock), "表" (clock, watch) and "匠" (craftsman). Humans can intuitively conclude that *clock* + *craftsman* $\rightarrow$ *clockmaker*. However, the *external* model does not perform well for this example. If we investigate the word embedding of “钟表匠” (clockmaker), we can know why this method recommends these unreasonable sememes. The closest 5 words in the train set to “钟表匠” (clockmaker) by cosine similarity of their embeddings are: “瑞士” (Switzerland), “卢梭” (Jean-Jacques Rousseau), “鞋匠” (cobbler), “发明家” (inventor) and “奥地利人” (Austrian). Note that none of these words are directly relevant to *bells*, *clocks* or *watches*. Hence, the sememes “时间” (time), “告诉” (tell), and “用具” (tool) cannot be inferred by those words, even though the correlations between sememes are introduced by SPSE. In fact, those words are related to *clocks* in an indirect way: Switzerland is famous for watch industry; Rousseau was born into a family that had a tradition of watchmaking; cobbler and inventor are two kinds of occupations as well. With the above reasons, those words usually co-occur with “钟表匠” (clockmaker), or usually appear in similar contexts as “钟表匠” (clockmaker). It indicates that related word embeddings as used in an *external* model do not always recommend related sememes.

The word “奥斯卡” (Oscar) is created by the pronunciation of *Oscar*. Therefore, the meaning of each character in “奥斯卡” (Oscar) is unrelated to the meaning of the word. Moreover, the characters “奥”, “斯”, and “卡” are common among transliterated words, thus the *internal* method recommends “专” (ProperName) and “地方” (place), etc., since many transliterated words are proper nouns or place names.

6 Conclusion and Future Work

In this paper, we introduced character-level internal information for lexical sememe prediction in Chinese, in order to alleviate the problems caused by the exclusive use of external information. We proposed a Character-enhanced Sememe Prediction (CSP) framework which integrates both internal and external information for lexical sememe prediction and proposed two methods for utilizing internal information. We evaluated our CSP framework on the classical manually annotated sememe KB HowNet. In our experiments, our methods achieved promising results and outperformed the state of the art on sememe prediction, especially for low-frequency words.

We will explore the following research directions in the future: (1) Concepts in HowNet are annotated with hierarchical structures of senses and sememes, but those are not considered in this paper. In the future, we will take structured annotations into account. (2) It would be meaningful to take more information into account for blending external and internal information and design more sophisticated methods. (3) Besides Chinese, many other languages have rich subword-level information. In the future, we will explore methods of exploiting internal information in other languages. (4) We believe that sememes are universal for all human languages. We will explore a general framework to recommend and utilize sememes for other NLP tasks.

Abstract

Because word semantics can substantially change across communities and contexts, capturing domain-specific word semantics is an important challenge. Here, we propose SemAxis, a simple yet powerful framework to characterize word semantics using many semantic axes in word-vector spaces beyond sentiment. We demonstrate that SemAxis can capture nuanced semantic representations in multiple online communities. We also show that, when the sentiment axis is examined, SemAxis outperforms the state-of-the-art approaches in building domain-specific sentiment lexicons.

1 Introduction

In lexicon-based text analysis, a common, tacit assumption is that the meaning of each word does not change significantly across contexts. This approximation, however, falls short because context can strongly alter the meaning of words (Fischer, 1958; Eckert and McConnell-Ginet, 2013; Hovy, 2015; Hamilton et al., 2016b). For instance, the word *kill* may be used much more positively in the context of video games than it would be in a news story; the word *soft* may be used much more negatively in the context of sports than it is in the context of toy animals (Hamilton et al., 2016a). Thus, lexicon-based analysis exhibits a clear limitation when two groups with strongly dissimilar lexical contexts are compared.

Recent breakthroughs in vector-space representation, such as `word2vec` (Mikolov et al., 2013b), provide new opportunities to tackle this challenge of context-dependence, because in these approaches, the representation of each word is learned from its context. For instance, a recent study shows that a propagation method on the vector space embedding can infer context-dependent sentiment values of words (Hamilton et al., 2016a). Yet, it remains to be seen whether it is possible to generalize this idea to general word semantics other than sentiment.

In this work, we propose SemAxis, a lightweight framework to characterize domain-specific word semantics beyond sentiment. SemAxis characterizes word semantics with respect to many semantic perspectives in a domain-specific word-vector space. To systematically discover the manifold of word semantics, we induce 732 semantic axes based on the antonym pairs from ConceptNet (Speer et al., 2017). We would like to emphasize that, although some of the induced axes can be considered as an extended version of sentiment analysis, such as an axis of 'respectful' (positive) and 'disrespectful' (negative), some cannot be mapped to a positive and negative relationship, such as 'exogeneous' and 'endogeneous,' and 'loose' and 'monogamous.' Based on this rich set of semantic axes, SemAxis captures nuanced semantic representations across corpora. The key contributions of this paper are:

- We propose a general framework to characterize the manifold of domain-specific word semantics.
- We systematically identify semantic axes based on the antonym pairs in ConceptNet.
- We demonstrate that SemAxis can capture semantic differences between two corpora.
- We provide a systematic evaluation in comparison to the state-of-the-art, domain-specific sentiment lexicon construction methodologies.

Although the idea of defining a semantic axis and assessing the meaning of a word with a vector projection is not new, it has not been demonstrated that this simple method can effectively induce context-aware semantic lexicons. All of the inferred lexicons along with code for SEMAXIS and all methods evaluated are made available in the SEMAXIS package released with this paper[1].

2 Related Work

For decades, researchers have been developing computational techniques for text analysis, including: sentiment analysis (Pang and Lee, 2004), stance detection (Biber and Finegan, 1988), point of view (Wiebe, 1994), and opinion mining (Pang and Lee, 2004). The practice of creating and sharing large-scale annotated lexicons also accelerated the research (Stone et al., 1966; Bradley and Lang, 1999; Pennebaker et al., 2001; Dodds et al., 2011; Mohammad et al., 2016, 2017).

These approaches can be roughly grouped into two major categories: lexicon-based approach (Turney, 2002; Taboada et al., 2011) and classification-based approach (Pang et al., 2002; Kim, 2014; Socher et al., 2013). Although the recent advancement of neural networks increases the potential of the latter approach, the former has been widely used for its simplicity and transparency. ANEW (Bradley and Lang, 1999), LIWC (Pennebaker et al., 2001), SO-CAL (Taboada et al., 2011), SentiWordNet (Esuli and Sebastiani, 2006), and LabMT (Dodds et al., 2011) are well-known lexicons.

A clear limitation of the lexicon-based approach is that it overlooks the context-dependent semantic changes. Scholars reported that the meaning of a word can be altered by context, such as communities (Yang and Eisenstein, 2015; Hamilton et al., 2016a), diachronic changes (Hamilton et al., 2016b) or demographic (Rosenthal and McKeown, 2011; Eckert and McConnell-Ginet, 2013; Green, 2002; Hovy, 2015), geography (Trudgill, 1974), political and cultural attitudes (Fischer, 1958) and personal variations (Yang and Eisenstein, 2017). Recently, a few studies have shown the importance of taking such context into accounts. For example, Hovy *et al.* (2015) showed that, by including author demographics such as age and gender, the accuracy of sentiment analysis and topic classification can be improved. It was also shown that, without domain-specific lexicons, the performance of sentiment analysis can be significantly degraded (Hamilton et al., 2016a).

Building domain-specific sentiment lexicons through human input (crowdsourcing or experts) requires not only significant resources but also careful control of biases (Dodds et al., 2011; Mohammad and Turney, 2010). The challenge is exacerbated because 'context' is difficult to concretely operationalize and there can be numerous contexts of interest. For resource-scarce languages, such problems become even more critical (Hong et al., 2013). Automatically building lexicons from web-scale resources (Velikovich et al., 2010; Tang et al., 2014) may solve this problem but poses a severe risk of unintended biases (Loughran and McDonald, 2011).

Inducing domain-specific lexicons from the unlabeled corpora reduces the cost of dictionary building (Hatzivassiloglou and McKeown, 1997; Rothe et al., 2016). Although earlier research utilize syntactic (grammatical) structures (Hatzivassiloglou and McKeown, 1997; Widdows and Dorow, 2002), the approach of learning word-vector representations has gained a lot of momentum (Rothe et al., 2016; Hamilton et al., 2016a; Velikovich et al., 2010; Fast et al., 2016).

The most relevant work is SENTPROP (Hamilton et al., 2016a), which constructs domain-specific sentiment lexicons using graph propagation techniques (Velikovich et al., 2010; Rao and Ravichandran, 2009). In contrast to SENTPROP's sentiment-focused approach, we provide a framework to understand the semantics of words with respect to 732 semantic axes based on ConceptNet (Speer et al., 2017).

3 SEMAXIS Framework

Our framework, SEMAXIS, involves three steps: constructing a word embedding, defining a semantic axis, and mapping words onto the semantic axis. Although they seem straightforward, the complexities and challenges in each step can add up. In particular, we tackle the issues of treating small corpora and selecting pole words.

3.1 The Basics of SEMAXIS

3.1.1 Building word embeddings

The first step in our approach is to obtain word vectors from a given corpus. In principle, any standard method, such as Positive Pointwise Mutual Information (PPMI), Singular-Value Decomposition (SVD), or `word2vec`, can be used. Here, we use the `word2vec` model because `word2vec` is easier to train and is known to be more robust than

[1]`https://github.com/ghdi6758/SemAxis`

competing methods (Levy et al., 2015).

3.1.2 Defining a semantic axis and computing the semantic axis vector

A semantic axis is defined by the vector between two sets of 'pole' words that are antonymous to each other. For instance, a sentiment axis can be defined by a set of the most positive words on one end and the most negative words on the other end. Similarly, any antonymous word pair can be used to define a semantic axis (e.g., 'clean' vs. 'dirty' or 'respectful' vs. 'disrespectful').

Once two sets of pole words for the corresponding axis are chosen, we compute the average vector for each pole. Then, by subtracting one vector from the other, we obtain the semantic axis vector that encodes the antonymous relationship between two sets of words. More formally, let $S^{+}=\{v_1^{+}, v_2^{+}, ..., v_n^{+}\}$ and $S^{-}=\{v_1^{-}, v_2^{-}, ..., v_m^{-}\}$ be two sets of pole word vectors that have an antonym relationship. Then, the average vectors for each set are computed as $\mathbf{V}^{+}=\frac{1}{n}\sum_1^n v_i^{+}$ and $\mathbf{V}^{-}=\frac{1}{m}\sum_1^m v_j^{-}$. From the two average vectors, the semantic axis vector, $\mathbf{V}_{\text{axis}}$ (from S^{-} to S^{+}), can be defined as:

$$\mathbf{V}_{\text{axis}} = \mathbf{V}^{+} - \mathbf{V}^{-} \tag{1}$$

3.1.3 Projecting words onto a semantic axis

Once the semantic axis vector is obtained, we can compute the cosine similarity between the axis vector and a word vector. The resulting cosine similarity captures how closely the word is aligned to the semantic axis. Given a word vector v_w for a word w, the score of the word w along with the given semantic axis, $\mathbf{V}_{\text{axis}}$, is computed as:

$$\begin{aligned} score(w)_{\mathbf{V}_{\text{axis}}} &= \cos(v_w, \mathbf{V}_{\text{axis}}) \\ &= \frac{v_w \cdot \mathbf{V}_{\text{axis}}}{\parallel v_w \parallel \parallel \mathbf{V}_{\text{axis}} \parallel} \end{aligned} \tag{2}$$

A higher score means that the word w is more closely aligned to S^{+} than S^{-}. When $\mathbf{V}_{\text{axis}}$ is a sentiment axis, a higher score is corresponds to more positive sentiment.

3.2 SEMAXIS for Comparative Text Analysis

Although aforementioned steps are conceptually simple, there are two practical challenges: 1) dealing with small corpus and 2) finding good pole words for building a semantic axis.

3.2.1 Semantic relations encoded in word embeddings

Since semantic relations are particularly important in our method, we need to ensure that our word embedding maintains general semantic relations. This can be evaluated by analogy tasks. In particular, we use the Google analogy test dataset (Mikolov et al., 2013a), which contains 19,544 questions — 8,869 semantic and 10,675 syntactic questions — in 14 relation types, such as capital-world pairs and opposite relationships.

3.2.2 Dealing with small corpus

As in other machine learning tasks, the amount of data critically influences the performance of word embedding methods. However, the corpora of our interest are often too small to facilitate the learning of rich semantic relationships therein. To mitigate this issue, we propose to pre-train a word embedding using a background corpus and update with the target corpora. In doing so, we capture the semantic changes while maintaining general semantic relations offered by the large reference model.

The vector-space embedding drifts from the reference model as we train with the target corpus. If trained too much with the smaller target corpus, it will lose the 'good' initial embedding from the huge reference corpus. If trained too little, it will not be able to capture context-dependent semantic changes. Our goal is thus to minimize the loss in general semantic relations while maximizing the characteristic semantic relations in the new texts.

Consider a corpus of our interest C and a reference corpus R. The model M is pre-trained on R, and then we start training it on C. We use the superscript e to represent the e-th epoch of training. That is, M_C^e is the model after the e-th epoch trained on C. Then, we evaluate the model regarding two aspects: general semantic relations and context-dependent semantic relations. The former is measured by the overall accuracy of the analogy test (Mikolov et al., 2013a). The latter is measured by tracking the semantic changes of the top k words in the given corpus C. The semantic changes of the words are measured by the changes in their scores, Δ, on a certain axis; for instance, a sentiment axis, between consecutive epochs. We stop learning when two conditions are satisfied: (1) When the accuracy of the analogy test drops by α; and (2) When Δ is lower than β. In principle, the model can be updated with the target corpus as long as the accuracy does not drop. We then use β

to control the epochs. When Δ is low, the gain by updating the model becomes negligible compared to the cost and thus we can stop updating.

3.3 Identifying rich semantic axes for SEMAXIS

The primary advantage of SEMAXIS is that it can be easily extended to examine diverse perspectives of texts as it is lightweight. Although the axis can be defined by any pair of words in principle, we propose a systematic way to define the axes.

3.3.1 732 Pre-defined Semantic Axes

We begin with a pair of antonyms, called *initial pole words*. For instance, a sentiment axis, which is a basis of sentiment analyses, can be defined by a pair of sentiment antonyms, such as 'good' and 'bad.'

To build a comprehensive set of initial pole words, we compile a list of antonyms from ConceptNet 5.5, which is the latest release of a knowledge graph among concepts (Speer et al., 2017). We extract all the antonym concepts marked as '/r/Antonym' edges. Then, we filter out non-English concepts and multi-word concepts. In addition, we eliminate duplicated antonyms that involve synonyms. For instance, only one of the (empower, prohibit) and (empower, forbid) needs to be kept because 'prohibit' and 'forbid' are synonyms, marked as '/r/Synonym' in ConceptNet.

To further refine the antonym pairs, we create a crowdsourcing task on *Figure Eight*, formerly known as *CrowdFlower*. Specifically, we ask crowdworkers: *Do these two words have opposite meanings?* We include those word pairs that a majority of crowdworkers agree to have an opposite meaning. The word pairs that the majority of crowdsource workers disagree were mostly erroneous antonym pairs, such as '5' and '3', and 'have' and 'has.' We then filter out the antonyms that are highly similar to each other. For example, ('advisedly' and 'accidentally') and ('purposely' and 'accidentally') show the cosine similarity of 0.5148, while 'advisedly' and 'purposely' are not marked as synonyms in ConceptNet. Although we use the threshold of 0.4 in this work, a different threshold can be chosen depending on the purpose. Finally, we eliminate concepts that do not appear in the pre-trained Google News 100B word embeddings. As a result, we obtain 732 pairs of antonyms. Each pair of antonyms becomes initial pole words to define one of the diverse axes for SEMAXIS.

We assess the semantic diversity of the axes by computing cosine similarity between every possible pair of the axes. The absolute mean value of the cosine similarity is 0.062, and the standard deviation is 0.050. These low cosine similarity and standard deviation values indicate that the chosen axes have a variety of directions, covering diverse and distinct semantics.

3.3.2 Augmenting pole words

We then expand the two initial pole words to larger sets of pole words, called *expanded pole words*, to obtain more robust results. If we use only two initial pole words to define the corresponding axis, the result will be sensitive to the choice of those words. Since the initial pole words are not necessarily the best combinations possible, we would like to augment it so that it is more robust to the choice of the initial pole words.

To address this issue, we find the l closest words of each initial pole word in the word embedding. We then compute the geometric center (average vector) of l+1 words (including the initial pole word) and regard it as the vector representation of that pole of the axis. For instance, refining an axis representing a 'good' and 'bad' relation, we first find the l closest words for each of 'good' and 'bad' and then compute the geometric center of them. The newly computed geometric centers then become both ends of the axis representing a 'good' and 'bad' relation. We demonstrate how this approach improves the explanatory power of an axis describing a corresponding antonym relation in Section 4.3.

4 SEMAXIS Validation

In this section, we quantitatively evaluate our approach using the ground-truth data and by comparing our method against the standard baselines and state-of-the-art approaches. We reproduce the evaluation task introduced by Hamilton *et al.* (2016a), recreating Standard English and Twitter sentiment lexicons for evaluation. We then compare the accuracy of sentiment classification with three other methods that generate domain-specific sentiment lexicons.

It is worth noting that we validate SEMAXIS based on a sentiment axis mainly due to the availability of the well-established ground-truth data and evaluation process. Nevertheless, as the sentiment axis in the SEMAXIS framework is not specifically or manually designed but established based on the corresponding pole words, the validation based on the sentiment axis can be generalized to other axes that are similarly established based on other corresponding pole words.

Standard English: We use well-known General Inquirer lexicon (Stone et al., 1966) and continuous valence scores collected by Warriner *et al.* (2013) to evaluate the performance of SemAxis compared to other state-of-the-art methods. We test all of the methods by using the off-the-shelf Google news embedding constructed from 10^{11} tokens (Google, 2013).

Twitter: We evaluate our approach with the test dataset from the 2015 SemEval task 10E competition (Rosenthal et al., 2015) using the embedding constructed by Rothe *et al.* (2016).

Domain	Positive pole words	Negative pole words
Standard	good, lovely, excellent, fortunate, pleasant, delightful, perfect, loved, love, happy	bad, horrible, poor, unfortunate, unpleasant, disgusting, evil, hated, hate, unhappy
Twitter	love, loved, loves, awesome, nice, amazing, best, fantastic, correct, happy	hate, hated, hates, terrible, nasty, awful, worst, horrible, wrong, sad

Table 1: Manually selected pole words used for the evaluation task in (Hamilton et al., 2016a). These pole words are called seed words in (Hamilton et al., 2016a)

4.1 Evaluation Setup

We compare our method against state-of-the-art approaches that generate domain-specific sentiment lexicons.

State-of-the-art approaches: Our baseline for the standard English is a WordNet-based method, which performs label propagation over a WordNet-derived graph (San Vicente et al., 2014). For Twitter, we use Sentiment140, a distantly supervised approach that uses signals from emoticons (Mohammad and Turney, 2010). Moreover, on both datasets, we compare against two state-of-the-art sentiment induction methods: Densifier, a method that learns orthogonal transformations of word vectors (Rothe et al., 2016), and SentProp, a method with a label propagation approach on word embeddings (Hamilton et al., 2016a). Seed words, which are called pole words in our work, are listed in Table 1.

Evaluation metrics: We evaluate the aforementioned approaches according to (i) their binary classification accuracy (positive and negative), (ii) ternary classification performance (positive, neutral, and negative), and (iii) Kendall τ rank-correlation with continuous human-annotated polarity scores. Since all methods result in sentiment scores of words rather than assigning a class of sentiment, we label words as positive, neutral, or negative using the class-mass normalization method (Zhu et al., 2003). This normalization uses knowledge of the label distribution of a test dataset and simply assigns labels to best match this distribution. For the implementation of other methods, we directly use the source code without any modification or tuning (SocialSent, 2016) used in (Hamilton et al., 2016a).

4.2 Evaluation Results

Table 2 summarizes the performance. Surprisingly, SemAxis — the simplest approach — outperforms others on both Standard English and Twitter datasets across all measures.

Standard English			
Method	AUC	Ternary F1	Tau

Sentiment140	86.2	57.7	0.51

Table 2: Evaluation results. Our method performs best on both Standard English and Twitter.

4.3 Sensitivity to Pole Words

As discussed in Section 3.3.2, because the axes are derived from pole words, the choice of the pole words can significantly affect the performance. We compare the robustness of three methods for selecting pole words: 1) using sentiment lexicons; 2) using two pole words only (initial pole words); and 3) using l closest words on the `word2vec` model as well as the two initial pole words (expanded pole words). For the first, we choose two sets of pole words that have the highest scores and the lowest scores in two widely used sentiment lexicons, ANEW (Bradley and Lang, 1999) and LabMT (Dodds et al., 2011). Then, for the two pole words, we match 1-of-10 positive pole words and 1-of-10 negative pole words in Table 1, resulting in 100 pairs of pole words. For these 100 pairs, in addition to the two initial pole words, we then use the l closest words ($l = 10$) of each of them to evaluate the third method.

We compare these three methods by quantifying how well SEMAXIS performs for the evaluation task. The average AUC for the two pole words method is 78.2. We find that one of the 100 pairs — 'good' and 'bad' — shows the highest AUC (92.4). However, another random pair ('happy' and 'evil') results in the worst performance with the AUC of 67.2. In other words, an axis defined by only two pole words is highly sensitive to the choice of the word pair. By contrast, when an axis is defined by aggregating l closest words, the average AUC increases to 80.6 (the minimum performance is above 71.2). Finally, using pre-established sentiment lexicons results in the worst performance (the AUC of 77.8 for ANEW and 67.5 for LabMT). These results show that identifying an axis is a crucial step in SEMAXIS, and using l closest words in addition to initial pole words is a more robust method to define the axis.

5 SEMAXIS in the Wild

We now demonstrate how SEMAXIS can be used in comparative text analysis to capture nuanced linguistic representations beyond the sentiment. As an example, we use Reddit (Reddit, 2005), one of the most popular online communities. Reddit is known to serve diverse sub-communities with different linguistic styles (Zhang et al., 2017). We focus on a few pairs of subreddits that are known to express different views. We also choose them to capture a wide range of topics from politics to religion, entertainment, and daily life to demonstrate the broad applicability of SEMAXIS.

5.1 Dataset, Pre-processing, Reference model, and Hyper-parameters

We use Reddit 2016 comment datasets that are publicly available (/u/Dewarim, 2017). We build a corpus from each subreddit by extracting all the comments posted on that subreddit. When the size of two corpora used for comparison is considerably different, we undersample the bigger corpus for a fair comparison. Every corpus then undergoes the same pre-processing, where we first remove punctuation and stop words, then replace URLs with its domain name.

Reference model for Reddit data As we discussed earlier, many datasets of our interest are likely too small to obtain good vector representations. For example, two popular subreddits, `/r/The_Donald` and `/r/SandersForPresident`[2], show only 59.8% and 42.1% in analogy test, respectively.[3] Therefore, as we proposed, we first create a pre-trained word embedding with a larger background corpus and perform additional training with target subreddits. We sample 1 million comments from each of the top 200 subreddits, resulting in 20 million comments. Using this sample, we build a word embedding, denoted as Reddit20M, using the CBOW model with a window size of five, a minimum word count of 10, the negative sampling, and down-sampling of frequent terms as suggested in (Levy et al., 2015). For the subsequent training with the target corpora, we train the model with a small starting learning rate, 0.005; Using different rates, such as 0.01 and 0.001, did not make much difference. We further tune the model with the dimension size of 300 and the number of the epoch of 100 using the analogy test results.

Category	Reddit20M	Google300D
World	28.34	70.2
family	94.58	90.06
Gram1-9	70.21	73.40
Total	67.88	77.08

Table 3: Results of analogy tests, comparing 20M sample texts from Reddit vs. Google 100B News.

Table 3 shows the results of the analogy test using our Reddit20M in comparison with Google300D, which is the Google News embedding used in previous sections. As one can expect, Reddit20M shows worse performance than Google300D. However, the four categories (capital-common-countries, capital-world, currency, and city-in-state denoted by **World**), which require some general knowledge on the world, drive the 10% decrease in overall accu-

[2] `/r/` is a common notation for indicating subreddits.

[3] For both corpora, continuous bag-of-words (CBOW) model with the dimension size of 300 achieves the highest accuracy in the analogy test.

racy. Other categories show comparable or even better accuracy. For example, Reddit20M outperforms Google300D by 4.52% in the family category. Since Reddit is a US-based online community, the Reddit model may not be able to properly capture semantic relationships in **World** category. By contrast, for the categories for testing grammar (denoted by **Gram1-9**), Reddit20M shows comparable performances with Google300D (70.21 vs. 73.4). In this study, we use Reddit20M as a reference model and update it with new target corpora.

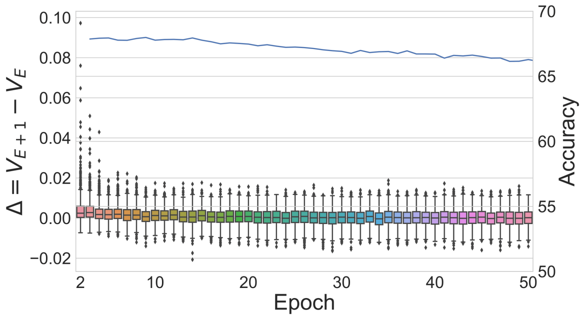

Figure 1: Changes of word semantics (box plot) and accuracy (line graph) over epoch for the model for `/r/SandersForPresident`

Updating the reference model As we explained in Section 3.2.2, we stop updating the reference model depending on the accuracy of the analogy test and semantic changes of the top 1000 words of the given corpus. In our experiments, we set $\alpha = 0.3$ and $\beta = 0.001$. Figure 1 shows the accuracy of the analogy test over epoch as a line plot and the semantic changes of words as a box plot for the model for `/r/SandersForPresident`. The model gradually loses general semantic relation over epochs, and the characteristic semantic changes stabilize after about 10 epochs. Given the α and β, we use the embedding after 10 epochs of training with the target subreddit data. We note that the results are consistent when epoch is greater than 10. We choose the number of epoch for other corpora based on the same tactic.

5.2 Confirming well-known language representations

Once we have word embeddings for given subreddits by updating the pre-trained model, we can compare the languages of two subreddits. As a case study, we compare supporters of Donald Trump (`/r/The_Donald`) and Bernie Sanders (`/r/SandersForPresident`)[4], and examine the semantic differences in diverse issues, such as gun and minority, based on different axes. This can be easily compared with our educated guess learned from the 2016 U.S. Election.

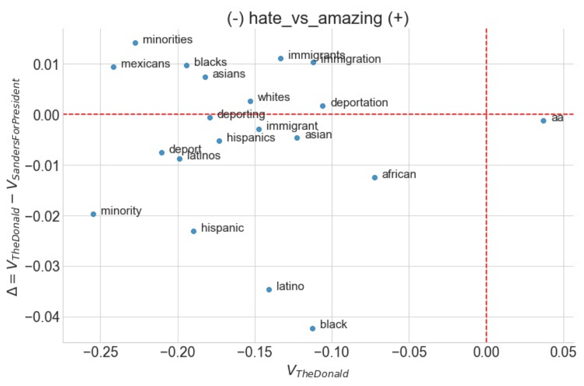
Starting from a topic word (e.g., 'gun') and its closest word (e.g., 'guns'), we compute the average vector of the two words. We then find the closest word from the computed average vector and repeat this process to collect 30 topical terms in each word embedding. Then, we remove words that have appeared less than n times in both corpora. The higher n leads to less coverage of topical terms but eliminate noise. We set $n = 100$ in the following experiments. We consider the remaining words as topic words.

Figure 2 compares how the minority-related terms are depicted in the two subreddits. Figure 2(a) and 2(b) show how minority issues are perceived in two communities with respect to 'Sentiment' and 'Respect' . The x-axis is the value for each word on the Sentiment axis for Trump supporters, and the y-axis is the difference between the value for Trump and Sanders supporters. If the y-value is greater than 0, then it means the word is more 'positive' among Trump supporters compared to that among Sanders supporters.

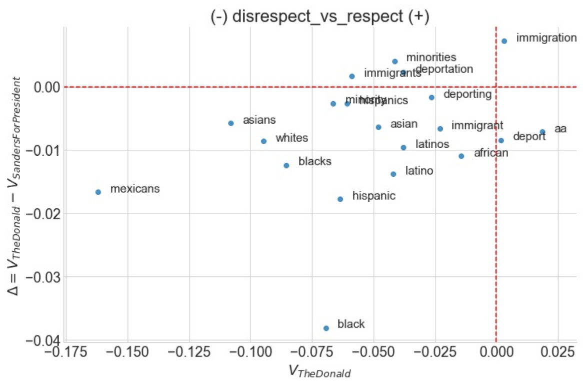
Some terms perceived more positively (e.g., 'immigration' and 'minorities') while other terms were perceived more negatively ('black', 'latino', 'hispanic') among Trump supporters (Figure 2(a)). As this positive perception on immigration and minorities is unexpected, we examine the actual comments. Through the manual inspection of relevant comments, we find that Trump supporters often mention that they 'agree' with or 'support' the idea of banning immigration, resulting in having a term 'immigration' as more positive than Sanders supporters. However, when examining those words on the 'Disrespect' vs. 'Respect' axis (Figure 2(b)), most of the minority groups are considered disrespectful by Trump supporters compared to Sanders supporters, demonstrating a benefit of examining multiple semantic axes that can reflect rich semantics beyond basic sentiments.

Then, one would expect that 'Gun' would be more positively perceived for Trump supporters compared to for Sanders supporters. Beyond the sentiment, we examine how 'gun' is perceived in

[4]Both subreddits have a policy of banning users who post content critical of the candidate. Thus, we assume most of the users in these subreddits are supporters of the candidate.



(a) Minority (Hate vs Amazing)



(b) Minority (Disrespect vs Respect)

Figure 2: Trump supporters vs Sanders supporters on Minority issue

two communities for 'Arousal' and 'Safety' axes. We find that Trump supporters are generally positive about gun-related issues, and Sanders supporters associate 'gun' with more arousal and danger.

We also examine two other subreddits: /r/atheism and /r/Christianity. As their names indicate, the former is the subreddit for atheists and the latter is the subreddit for Christians. We expect that the two groups would have different perspectives regarding 'god' and 'evolution.' When examining the four words 'god,' 'pray,' 'evolution,' and 'science' on the 'Unholy' vs. 'Holy' axis, 'god' and 'pray' appear to be more 'holy' in /r/Christianity while 'evolution' and 'science' appear more 'unholy' than in /r/Atheism, which fits in our intuition.

As another example, we examine the /r/PS4 and /r/NintendoSwitch subreddits. PS4 is a video game console released by Sony and Nintendo Switch is released by Nintendo. Although both video game consoles originated from Japan, Nintendo Switch targets more family (children) and casual gamers with more playful and easier games while the games for PS4 target adult and thus tend to be more violent and more difficult to play. We examine three terms ('Nintendo,' 'Mario,' and 'Zelda') from Nintendo Switch and three terms ('Sony,' 'Uncharted,' and 'Killzone') from Sony on the 'Casual' vs. 'Hardcore' axis.[5] We find that 'Mario' and 'Zelda' are perceived more casual in /r/PS4, and 'Uncharted' and 'Killzone' are more hardcore in /r/PS4 than /r/NintendoSwitch. Although both 'Nintendo' and 'Sony' have negative values, 'Nintendo' was considered more casual than 'Sony' in /r/PS4. Overall, our method effectively captures context-dependent semantic changes beyond the basic sentiments.

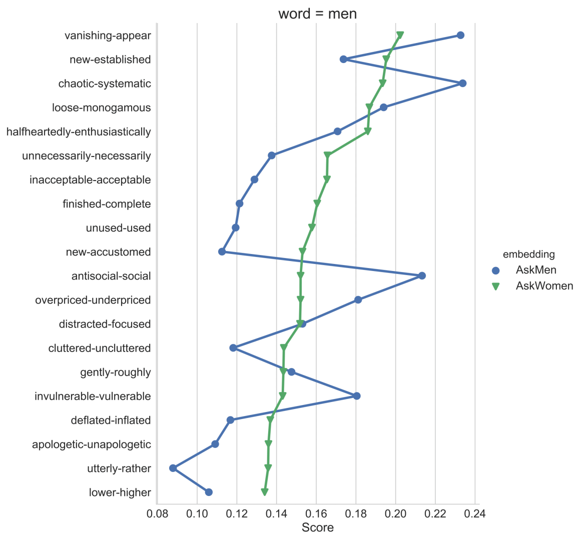
[5]Mario and Zelda are popular Nintendo Switch games, and Uncharted and Killzone are popular PS4 games.

5.3 Comparative Text Analysis with Diverse Axes

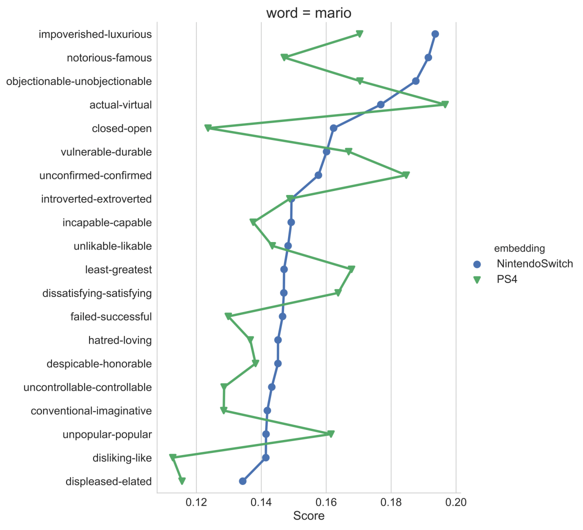
Let us show how SEMAXIS can find, for a given word, a set of the best axes that describe its semantic. We map the word on our predefined 732 axes, which are explained in Section 3.3.1, and rank the axes based on the projection values on the axes. In other words, the top axes describe the word with the highest strength.

Figure 3(a) shows the top 20 axes with the largest projection values for 'Men' in /r/AskWomen and /r/AskMen, which are the subreddits where people expect replies from each gender. In /r/AskWomen, compared with /r/AskMen, 'Men' seems to be perceived as more vanishing, more established, less systematic, less monogamous, more enthusiastic, less social, more uncluttered, less vulnerable, and more unapologetic. This observed perception of men from women's perspective seems to concur with the common gender stereotype, demonstrating strong potential of SEMAXIS.

Likewise, in Figure 3(b), we examine how a word 'Mario' is perceived in two subreddits /r/NintendoSwitch and /r/PS4. In /r/NintendoSwitch, 'Mario' is perceived, compared with /r/PS4, as more luxurious, famous, unobjectionable, open, capable, likable, successful, loving, honorable, and controllable. On the other hand, users in /r/PS4 consider 'Mario' to be more virtual, creative, durable,



(a) Men in /r/AskWomen and /r/AskMen



(b) Mario in /r/NintendoSwitch and /r/PS4

Figure 3: An example of comparative text analysis using SEMAXIS: (a) 'Men' in `/r/AskWomen` and `/r/AskMen` and (b) 'Mario' in `/r/NintendoSwitch` and `/r/PS4`

satisfying, popular, undetectable, and unstoppable. 'Mario' is perceived more positively in `/r/NintendoSwitch` than in `/r/PS4`, as expected. Furthermore, SEMAXIS reveals detailed and nuanced perceptions of different communities.

6 Discussion and Conclusion

We have proposed SEMAXIS to examine a nuanced representation of words based on diverse semantic axes. We have shown that SEMAXIS can construct good domain-specific sentiment lexicons by projecting words on the sentiment axis. We have also demonstrated that our approach can reveal nuanced context-dependence of words through the lens of numerous semantic axes.

There are two major limitations. First, we performed the quantitative evaluation only with the sentiment axis, even though we supplemented it with more qualitative examples. We used the sentiment axis because it is better studied and more methods exist, but ideally it would be better to perform evaluation across many semantic axes. We hope that SEMAXIS can facilitate research on other semantic axes so that we will have labeled datasets for other axes as well. Secondly, Gaffney and Matias (2018) recently reported the Reddit data used in this study is incomplete. The authors suggest using the data with caution, particularly when analyzing user interactions. Although our work examine communities in Reddit, we focus on the difference of the word semantics. Thus, we believe the effect of deleted comment would be marginal in our analyses.

Despite these limitations, we identify the following key implications. First, SEMAXIS offers a framework to examine texts on diverse *semantic axes* beyond the sentiment axis, through the 732 systematically induced semantic axes that capture common antonyms. Our study may facilitate further investigations on context-dependent text analysis techniques and applications. Second, the unsupervised nature of SEMAXIS provides a powerful way to build lexicons of any semantic axis, including the sentiment axis, for non-English languages, particularly the resource-scarce languages.

Abstract

We present a novel end-to-end reinforcement learning approach to automatic taxonomy induction from a set of terms. While prior methods treat the problem as a two-phase task (*i.e.*, detecting hypernymy pairs followed by organizing these pairs into a tree-structured hierarchy), we argue that such two-phase methods may suffer from error propagation, and cannot effectively optimize metrics that capture the holistic structure of a taxonomy. In our approach, the representations of term pairs are learned using multiple sources of information and used to determine *which* term to select and *where* to place it on the taxonomy via a policy network. All components are trained in an end-to-end manner with cumulative rewards, measured by a holistic tree metric over the training taxonomies. Experiments on two public datasets of different domains show that our approach outperforms prior state-of-the-art taxonomy induction methods up to 19.6% on ancestor F1. [1]

1 Introduction

Many tasks in natural language understanding (*e.g.*, information extraction (Demeester et al., 2016), question answering (Yang et al., 2017), and textual entailment (Sammons, 2012)) rely on lexical resources in the form of term taxonomies (cf. rightmost column in Fig. 1). However, most existing taxonomies, such as WordNet (Miller, 1995) and Cyc (Lenat, 1995), are manually curated and thus may have limited coverage or become unavailable in some domains and languages. Therefore, recent efforts have been focusing on *automatic taxonomy induction*, which aims to organize a set of terms into a taxonomy based on relevant resources such as text corpora.

[1]Code and data can be found at `https://github.com/morningmoni/TaxoRL`

Prior studies on automatic taxonomy induction (Gupta et al., 2017; Camacho-Collados, 2017) often divide the problem into two sequential subtasks: (1) *hypernymy detection* (*i.e.*, extracting term pairs of "is-a" relation); and (2) *hypernymy organization* (*i.e.*, organizing is-a term pairs into a tree-structured hierarchy). Methods developed for hypernymy detection either harvest new terms (Yamada et al., 2009; Kozareva and Hovy, 2010) or presume a vocabulary is given and study term semantics (Snow et al., 2005; Fu et al., 2014; Tuan et al., 2016; Shwartz et al., 2016). The hypernymy pairs extracted in the first subtask form a noisy hypernym graph, which is then transformed into a tree-structured taxonomy in the hypernymy organization subtask, using different graph pruning methods including maximum spanning tree (MST) (Bansal et al., 2014; Zhang et al., 2016), minimum-cost flow (MCF) (Gupta et al., 2017) and other pruning heuristics (Kozareva and Hovy, 2010; Velardi et al., 2013; Faralli et al., 2015; Panchenko et al., 2016).

However, these two-phase methods encounter two major limitations. First, most of them ignore the taxonomy structure when estimating the probability that a term pair holds the hypernymy relation. They estimate the probability of different term pairs independently and the learned term pair representations are fixed during hypernymy organization. In consequence, there is no feedback from the second phase to the first phase and possibly wrong representations cannot be rectified based on the results of hypernymy organization, which causes the error propagation problem. Secondly, some methods (Bansal et al., 2014; Zhang et al., 2016) do explore the taxonomy space by regarding the induction of taxonomy structure as inferring the conditional distribution of edges. In other words, they use the product of edge proba-

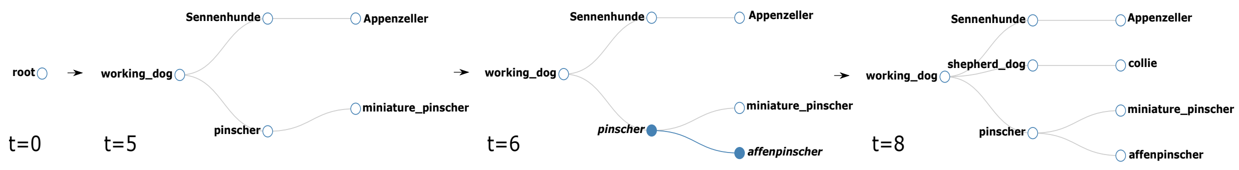

Figure 1: An illustrative example showing the process of taxonomy induction. The input vocabulary V_0 is {"*working dog*", "*pinscher*", "*shepherd dog*", ...}, and the initial taxonomy T_0 is empty. We use a virtual "*root*" node to represent T_0 at $t = 0$. At time $t = 5$, there are 5 terms on the taxonomy T_5 and 3 terms left to be attached: V_t = {"*shepherd dog*", "*collie*", "*affenpinscher*"}. Suppose the term "*affenpinscher*" is selected and put under "*pinscher*", then the remaining vocabulary V_{t+1} at next time step becomes {"*shepherd dog*", "*collie*"}. Finally, after $|V_0|$ time steps, all the terms are attached to the taxonomy and $V_{|V_0|} = V_8 = \{\}$. A full taxonomy is then constructed from scratch.

bilities to represent the taxonomy quality. However, the edges are treated equally, while in reality, they contribute to the taxonomy differently. For example, a high-level edge is likely to be more important than a bottom-out edge because it has much more influence on its descendants. In addition, these methods cannot *explicitly* capture the holistic taxonomy structure by optimizing global metrics.

To address the above issues, we propose to jointly conduct hypernymy detection and organization by learning term pair representations and constructing the taxonomy simultaneously. Since it is infeasible to estimate the quality of all possible taxonomies, we design an end-to-end reinforcement learning (RL) model to combine the two phases. Specifically, we train an RL agent that employs the term pair representations using multiple sources of information and determines *which* term to select and *where* to place it on the taxonomy via a policy network. The feedback from hypernymy organization is propagated back to the hypernymy detection phase, based on which the term pair representations are adjusted. All components are trained in an end-to-end manner with cumulative rewards, measured by a holistic tree metric over the training taxonomies. The probability of a full taxonomy is no longer a simple aggregated probability of its edges. Instead, we assess an edge based on how much it can contribute to the whole quality of the taxonomy.

We perform two sets of experiments to evaluate the effectiveness of our proposed approach. First, we test the end-to-end taxonomy induction performance by comparing our approach with the state-of-the-art two-phase methods, and show that our approach outperforms them significantly on the quality of constructed taxonomies. Second, we use the same (noisy) hypernym graph as the input of all compared methods, and demonstrate that our RL approach does better hypernymy organization through optimizing metrics that can capture holistic taxonomy structure.

Contributions. In summary, we have made the following contributions: (1) We propose a deep reinforcement learning approach to unify hypernymy detection and organization so as to induct taxonomies in an end-to-end manner. (2) We design a policy network to incorporate semantic information of term pairs and use cumulative rewards to measure the quality of constructed taxonomies holistically. (3) Experiments on two public datasets from different domains demonstrate the superior performance of our approach compared with state-of-the-art methods. We also show that our method can effectively reduce error propagation and capture global taxonomy structure.

2 Automatic Taxonomy Induction

2.1 Problem Definition

We define a taxonomy $T = (V, R)$ as a tree-structured hierarchy with term set V (*i.e.*, *vocabulary*), and edge set R (which indicates is-a relationship between terms). A term $v \in V$ can be either a unigram or a multi-word phrase. The task of *end-to-end taxonomy induction* takes a set of training taxonomies and related resources (*e.g.*, background text corpora) as input, and aims to learn a *model* to construct a full taxonomy T by adding terms from a given vocabulary V_0 onto an empty hierarchy T_0 *one at a time*. An illustration of the taxonomy induction process is shown in Fig. 1.

2.2 Modeling Hypernymy Relation

Determining which term to select from V_0 and where to place it on the current hierarchy requires understanding of the semantic relationships between the selected term and all the other terms. We consider multiple sources of information (*i.e.*, resources) for learning hypernymy relation representations of term pairs, including dependency path-based contextual embedding and distributional term embeddings (Shwartz et al., 2016).

Path-based Information. We extract the shortest dependency paths between each co-occurring term pair from sentences in the given background corpora. Each path is represented as a sequence of edges that goes from term x to term y in the dependency tree, and each edge consists of the word lemma, the part-of-speech tag, the dependency label and the edge direction between two contiguous words. The edge is represented by the concatenation of embeddings of its four components:

$$\mathbf{V}_e = [\mathbf{V}_l, , \mathbf{V}_{\text{pos}}, \mathbf{V}_{\text{dep}}, \mathbf{V}_{\text{dir}}].$$

Instead of treating the entire dependency path as a single feature, we encode the sequence of dependency edges $\mathbf{V}_{e_1}, \mathbf{V}_{e_2}, ..., \mathbf{V}_{e_k}$ using an LSTM so that the model can focus on learning from parts of the path that are more informative while ignoring others. We denote the final output of the LSTM for path p as $\mathbf{O}_p$, and use $\mathcal{P}(x, y)$ to represent the set of all dependency paths between term pair (x, y). A single vector representation of the term pair (x, y) is then computed as $\mathbf{P}_{\mathcal{P}(x,y)}$, the weighted average of all its path representations by applying an average pooling:

$$\mathbf{P}_{\mathcal{P}(x,y)} = \frac{\sum_{p \in \mathcal{P}(x,y)} c_{(x,y)}(p) \cdot \mathbf{O}_p}{\sum_{p \in \mathcal{P}(x,y)} c_{(x,y)}(p)},$$

where $c_{(x,y)}(p)$ denotes the frequency of path p in $\mathcal{P}(x, y)$. For those term pairs without dependency paths, we use a randomly initialized *empty path* to represent them as in Shwartz et al. (2016).

Distributional Term Embedding. The previous path-based features are only applicable when two terms co-occur in a sentence. In our experiments, however, we found that only about 17% of term pairs have sentence-level co-occurrences.[2] To alleviate the sparse co-occurrence issue, we concatenate the path representation $\mathbf{P}_{\mathcal{P}(x,y)}$ with the word embeddings of x and y, which capture the distributional semantics of two terms.

[2]In comparison, more than 70% of term pairs have sentence-level co-occurrences in BLESS (Baroni and Lenci, 2011), a standard hypernymy detection dataset.

Surface String Features. In practice, even the embeddings of many terms are missing because the terms in the input vocabulary may be multi-word phrases, proper nouns or named entities, which are likely not covered by the external pre-trained word embeddings. To address this issue, we utilize several surface features described in previous studies (Yang and Callan, 2009; Bansal et al., 2014; Zhang et al., 2016). Specifically, we employ *Capitalization*, *Ends with*, *Contains*, *Suffix match*, *Longest common substring* and *Length difference*. These features are effective for detecting hypernyms solely based on the term pairs.

Frequency and Generality Features. Another feature source that we employ is the hypernym candidates from TAXI[3] (Panchenko et al., 2016). These hypernym candidates are extracted by lexico-syntactic patterns and may be noisy. As only term pairs and the co-occurrence frequencies of them (under specific patterns) are available, we cannot recover the dependency paths between these terms. Thus, we design two features that are similar to those used in (Panchenko et al., 2016; Gupta et al., 2017). [4]

- *Normalized Frequency Diff.* For a hyponym-hypernym pair (x_i, x_j) where x_i is the hyponym and x_j is the hypernym, its normalized frequency is defined as $\text{freq}_n(x_i, x_j) = \frac{\text{freq}(x_i,x_j)}{\max_k \text{freq}(x_i,x_k)}$, where $\text{freq}(x_i, x_j)$ denotes the raw frequency of (x_i, x_j). The final feature score is defined as $\text{freq}_n(x_i, x_j) - \text{freq}_n(x_j, x_i)$, which down-ranks synonyms and co-hyponyms. Intuitively, a higher score indicates a higher probability that the term pair holds the hypernymy relation.

- *Generality Diff.* The generality $g(x)$ of a term x is defined as the logarithm of the number of its distinct hyponyms, *i.e.*, $g(x) = log(1+|\mathbf{hypo}|)$, where for any $hypo \in \mathbf{hypo}$, $(hypo, x)$ is a hypernym candidate. A high $g(x)$ of the term x implies that x is general since it has many distinct hyponyms. The generality of a term pair is defined as the difference in generality between x_j and x_i: $g(x_j) - g(x_i)$. This feature would

[3]http://tudarmstadt-lt.github.io/taxi/

[4]Since the features use additional resource, we wouldn't include them unless otherwise specified.

promote term pairs with the right level of generality and penalize term pairs that are either too general or too specific.

The surface, frequency, and generality features are binned and their embeddings are concatenated as a part of the term pair representation. In summary, the final term pair representation $\mathbf{R}_{xy}$ has the following form:

$$\mathbf{R}_{xy} = [\mathbf{P}_{\mathcal{P}(x,y)}, \mathbf{V}_{w_x}, \mathbf{V}_{w_y}, \mathbf{V}_{F(x,y)}],$$

where $\mathbf{P}_{\mathcal{P}(x,y)}$, $\mathbf{V}_{w_x}$, $\mathbf{V}_{w_y}$, $\mathbf{V}_{F(x,y)}$ denote the path representation, the word embedding of x and y, and the feature embeddings, respectively.

Our approach is general and can be flexibly extended to incorporate different feature representation components introduced by other relation extraction models (Zhang et al., 2017; Lin et al., 2016; Shwartz et al., 2016). We leave in-depth discussion of the design choice of hypernymy relation representation components as future work.

3 Reinforcement Learning for End-to-End Taxonomy Induction

We present the reinforcement learning (RL) approach to taxonomy induction in this section. The RL agent employs the term pair representations described in Section 2.2 as input, and explores how to generate a whole taxonomy by selecting one term at each time step and attaching it to the current taxonomy. We first describe the environment, including the actions, states, and rewards. Then, we introduce how to choose actions via a policy network.

3.1 Actions

We regard the process of building a taxonomy as making a sequence of actions. Specifically, we define that an action a_t at time step t is to (1) select a term x_1 from the remaining vocabulary V_t; (2) remove x_1 from V_t, and (3) attach x_1 as a hyponym of one term x_2 that is already on the current taxonomy T_t. Therefore, the size of action space at time step t is $|V_t| \times |T_t|$, where $|V_t|$ is the size of the remaining vocabulary V_t, and $|T_t|$ is the number of terms on the current taxonomy. At the beginning of each episode, the remaining vocabulary V_0 is equal to the input vocabulary and the taxonomy T_0 is empty. During the taxonomy induction process, the following relations always hold: $|V_t| = |V_{t-1}| - 1$, $|T_t| = |T_{t-1}| + 1$, and $|V_t| + |T_t| = |V_0|$. The episode terminates when all the terms are attached to the taxonomy, which makes the length of one episode equal to $|V_0|$.

A remaining issue is how to select the first term when no terms are on the taxonomy. One approach that we tried is to add a virtual node as root and consider it as if a real node. The *root embedding* is randomly initialized and updated with other parameters. This approach presumes that all taxonomies share a common root representation and expects to find the real root of a taxonomy via the term pair representations between the virtual root and other terms. Another approach that we explored is to postpone the decision of root by initializing T with a random term as current root at the beginning of one episode, and allowing the selection of *new root* by attaching one term as the hypernym of current root. In this way, it overcomes the lack of prior knowledge when the first term is chosen. The size of action space then becomes $|A_t| = |V_t| \times |T_t| + |V_t|$, and the length of one episode becomes $|V_0| - 1$. We compare the performance of the two approaches in Section 4.

3.2 States

The *state* **s** at time t comprises the current taxonomy T_t and the remaining vocabulary V_t. At each time step, the environment provides the information of current state, based on which the RL agent takes an action. Once a term pair (x_1, x_2) is selected, the position of the new term x_1 is automatically determined since the other term x_2 is already on the taxonomy and we can simply attach x_1 by adding an edge between x_1 and x_2.

3.3 Rewards

The agent takes a scalar *reward* as feedback of its actions to learn its policy. One obvious reward is to wait until the end of taxonomy induction, and then compare the predicted taxonomy with gold taxonomy. However, this reward is delayed and difficult to measure individual actions in our scenario. Instead, we use reward shaping, *i.e.*, giving intermediate rewards at each time step, to accelerate the learning process. Empirically, we set the reward r at time step t to be the difference of Edge-F1 (defined in Section 4.2 and evaluated by comparing the current taxonomy with the gold taxonomy) between current and last time step: $r_t = F1_{e_t} - F1_{e_{t-1}}$. If current Edge-F1 is better than that at last time step, the reward would be positive, and vice versa. The cumula-

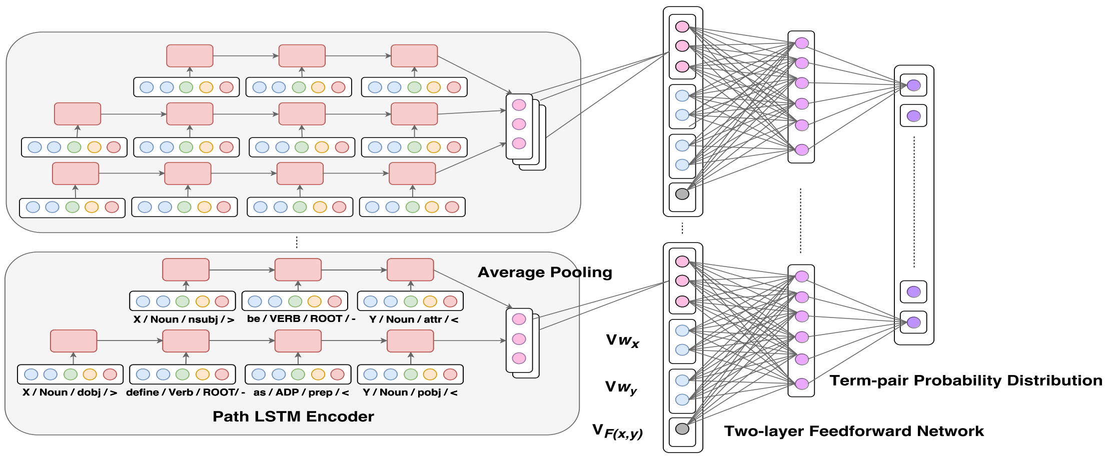

Figure 2: The architecture of the policy network. The dependency paths are encoded and concatenated with word embeddings and feature embeddings, and then fed into a two-layer feed-forward network.

tive reward from current time step to the end of an episode would cancel the intermediate rewards and thus reflect whether current action improves the overall performance or not. As a result, the agent would not focus on the selection of current term pair but have a long-term view that takes following actions into account. For example, suppose there are two actions at the same time step. One action attaches a leaf node to a high-level node, and the other action attaches a non-leaf node to the same high-level node. Both attachments form a wrong edge but the latter one is likely to receive a higher cumulative reward because its following attachments are more likely to be correct.

3.4 Policy Network

After we introduce the term pair representations and define the states, actions, and rewards, the problem becomes how to choose an action from the action space, *i.e.*, which term pair (x_1, x_2) should be selected given the current state? To solve the problem, we parameterize each action a by a policy network $\pi(\mathbf{a} \mid \mathbf{s}; \mathbf{W}_{RL})$. The architecture of our policy network is shown in Fig. 2. For each term pair, its representation is obtained by the path LSTM encoder, the word embeddings of both terms, and the embeddings of features. By stacking the term pair representations, we can obtain an action matrix $\mathbf{A}_t$ with size $(|V_t| \times |T_t|) \times dim(\mathbf{R})$, where $(|V_t| \times |T_t|)$ denotes the number of possible actions (term pairs) at time t and $dim(\mathbf{R})$ denotes the dimension of term pair representation $\mathbf{R}$. $\mathbf{A}_t$ is then fed into a two-layer feed-forward network followed by a softmax layer which outputs the probability distribution of actions.[5] Finally, an action a_t is sampled based on the probability distribution of the action space:

$$\begin{aligned}
\mathbf{H}_t &= \mathrm{ReLU}(\mathbf{W}^1_{RL}\mathbf{A}^T_t + \mathbf{b}^1_{RL}),\\
\pi(\mathbf{a} \mid \mathbf{s}; \mathbf{W}_{RL}) &= \mathrm{softmax}(\mathbf{W}^2_{RL}\mathbf{H}_t + \mathbf{b}^2_{RL}),\\
a_t &\sim \pi(\mathbf{a} \mid \mathbf{s}; \mathbf{W}_{RL}).
\end{aligned}$$

At the time of inference, instead of sampling an action from the probability distribution, we greedily select the term pair with the highest probability.

We use *REINFORCE* (Williams, 1992), one instance of the policy gradient methods as the optimization algorithm. Specifically, for each episode, the weights of the policy network are updated as follows:

$$\mathbf{W}_{RL} = \mathbf{W}_{RL} + \alpha \sum_{t=1}^{T} \nabla log\pi(\mathbf{a}_t \mid \mathbf{s}; \mathbf{W}_{RL}) \cdot v_t,$$

where $v_i = \sum_{t=i}^{T} \gamma^{t-i} r_t$ is the culmulative future reward at time i and $\gamma \in [0, 1]$ is a discounting factor of future rewards.

To reduce variance, 10 rollouts for each training sample are run and the rewards are averaged. Another common strategy for variance reduction is to use a baseline and give the agent the difference between the real reward and the baseline reward instead of feeding the real reward directly. We use a moving average of the reward as the baseline for simplicity.

[5]We tried to encode induction history by feeding representations of previously selected term pairs into an LSTM, and leveraging the output of the LSTM as history representation (concatenating it with current term pair representations or passing it to a feed-forward network). However, we didn't observe clear performance change.

3.5 Implementation Details

We use pre-trained GloVe word vectors (Pennington et al., 2014) with dimensionality 50 as word embeddings. We limit the maximum number of dependency paths between each term pair to be 200 because some term pairs containing general terms may have too many dependency paths. We run with different random seeds and hyperparameters and use the validation set to pick the best model. We use an Adam optimizer with initial learning rate 10^{-3}. We set the discounting factor γ to 0.4 as it is shown that using a smaller discount factor than defined can be viewed as regularization (Jiang et al., 2015). Since the parameter updates are performed at the end of each episode, we cache the term pair representations and reuse them when the same term pairs are encountered again in the same episode. As a result, the proposed approach is very time efficient – each training epoch takes less than 20 minutes on a single-core CPU using DyNet (Neubig et al., 2017).

4 Experiments

We design two experiments to demonstrate the effectiveness of our proposed RL approach for taxonomy induction. First, we compare our end-to-end approach with two-phase methods and show that our approach yields taxonomies with higher quality through reducing error propagation and optimizing towards holistic metrics. Second, we conduct a controlled experiment on hypernymy organization, where the same hypernym graph is used as the input of both our approach and the compared methods. We show that our RL method is more effective at hypernymy organization.

4.1 Experiment Setup

Here we introduce the details of our two experiments on validating that (1) the proposed approach can effectively reduce error propagation; and (2) our approach yields better taxonomies via optimizing metrics on holistic taxonomy structure.

Performance Study on End-to-End Taxonomy Induction. In the first experiment, we show that our joint learning approach is superior to two-phase methods. Towards this goal, we compare with TAXI (Panchenko et al., 2016), a typical two-phase approach, two-phase HypeNET, implemented by pairwise hypernymy detection and hypernymy organization using MST, and Bansal et al. (2014). The dataset we use in this experiment is from Bansal et al. (2014), which is a set of medium-sized full-domain taxonomies consisting of bottom-out full subtrees sampled from WordNet. Terms in different taxonomies are from various domains such as animals, general concepts, daily necessities. Each taxonomy is of height four (*i.e.*, 4 nodes from root to leaf) and contains (10, 50] nodes. The dataset contains 761 non-overlapped taxonomies in total and is partitioned by 70/15/15% (533/114/114) as training, validation, and test set, respectively.

Testing on Hypernymy Organization. In the second experiment, we show that our approach is better at hypernymy organization by leveraging the global taxonomy structure. For a fair comparison, we reuse the hypernym graph as in TAXI (Panchenko et al., 2016) and SubSeq (Gupta et al., 2017) so that the inputs of each model are the same. Specifically, we restrict the action space to be the same as the baselines by considering only term pairs in the hypernym graph, rather than all $|V| \times |T|$ possible term pairs. As a result, it is possible that at some point no more hypernym candidates can be found but the remaining vocabulary is still not empty. If the induction terminates at this point, we call it a *partial induction*. We can also continue the induction by restoring the original action space at this moment so that all the terms in V are eventually attached to the taxonomy. We call this setting a *full induction*. In this experiment, we use the English environment and science taxonomies in the SemEval-2016 task 13 (TExEval-2) (Bordea et al., 2016). Each taxonomy is composed of hundreds of terms, which is much larger than the WordNet taxonomies. The taxonomies are aggregated from existing resources such as WordNet, Eurovoc[6], and the Wikipedia Bitaxonomy (Flati et al., 2014). Since this dataset provides no training data, we train our model using the WordNet dataset in the first experiment. To avoid possible overlap between these two sources, we exclude those taxonomies constructed from WordNet.

In both experiments, we combine three public corpora – the latest Wikipedia dump, the UMBC web-based corpus (Han et al., 2013) and the One Billion Word Language Modeling Benchmark (Chelba et al., 2013). Only sentences where term pairs co-occur are reserved, which results in

[6]http://eurovoc.europa.eu/drupal/

Model	P_a	R_a	$F1_a$	P_e	R_e	$F1_e$
TAXI	66.1	13.9	23.0	54.8	18.0	27.1
HypeNET	32.8	26.7	29.4	26.1	17.2	20.7
HypeNET+MST	33.7	41.1	37.0	29.2	29.2	29.2
TaxoRL (RE)	35.8	47.4	40.8	35.4	35.4	35.4
TaxoRL (NR)	41.3	49.2	**44.9**	35.6	35.6	**35.6**
Bansal et al. (2014)	48.0	55.2	51.4	-	-	-
TaxoRL (NR) + FG	52.9	58.6	**55.6**	43.8	43.8	**43.8**

Table 1: Results of the end-to-end taxonomy induction experiment. Our approach significantly outperforms two-phase methods (Panchenko et al., 2016; Shwartz et al., 2016; Bansal et al., 2014). Bansal et al. (2014) and TaxoRL (NR) + FG are listed separately because they use extra resources.

a corpus with size 2.6 GB for the WordNet dataset and 810 MB for the TExEval-2 dataset. Dependency paths between term pairs are extracted from the corpus via spaCy[7].

4.2 Evaluation Metrics

Ancestor-F1. It compares the ancestors ("is-a" pairs) on the predicted taxonomy with those on the gold taxonomy. We use P_a, R_a, $F1_a$ to denote the precision, recall, and F1-score, respectively:

$$P_a = \frac{|\text{is-a}_{\text{sys}} \wedge \text{is-a}_{\text{gold}}|}{|\text{is-a}_{\text{sys}}|}, R_a = \frac{|\text{is-a}_{\text{sys}} \wedge \text{is-a}_{\text{gold}}|}{|\text{is-a}_{\text{gold}}|}.$$

Edge-F1. It is more strict than *Ancestor-F1* since it only compares predicted edges with gold edges. Similarly, we denote edge-based metrics as P_e, R_e, and $F1_e$, respectively. Note that $P_e = R_e = F1_e$ if the number of predicted edges is the same as gold edges.

4.3 Results

Comparison on End-to-End Taxonomy Induction. Table 1 shows the results of the first experiment. HypeNET (Shwartz et al., 2016) uses additional surface features described in Section 2.2. HypeNET+MST extends HypeNET by first constructing a hypernym graph using HypeNET's output as weights of edges and then finding the MST (Chu, 1965) of this graph. TaxoRL (RE) denotes our RL approach which assumes a common *Root Embedding*, and TaxoRL (NR) denotes its variant that allows a *New Root* to be added.

We can see that TAXI has the lowest $F1_a$ while HypeNET performs the worst in $F1_e$. Both TAXI and HypeNET's $F1_a$ and $F1_e$ are lower than 30. HypeNET+MST outperforms HypeNET in both $F1_a$ and $F1_e$, because it considers the global taxonomy structure, although the two phases are performed independently. TaxoRL (RE) uses exactly the same input as HypeNET+MST and yet achieves significantly better performance, which demonstrates the superiority of combining the phases of hypernymy detection and hypernymy organization. Also, we found that presuming a shared root embedding for all taxonomies can be inappropriate if they are from different domains, which explains why TaxoRL (NR) performs better than TaxoRL (RE). Finally, after we add the frequency and generality features (TaxoRL (NR) + FG), our approach outperforms Bansal et al. (2014), even if a much smaller corpus is used.[8]

	Model	P_a	R_a	$F1_a$	P_e	R_e	$F1_e$
Env	TAXI (DAG)	50.1	32.7	39.6	33.8	26.8	29.9
	TAXI (tree)	**67.5**	30.8	42.3	**41.1**	23.1	29.6
	SubSeq	-	-	-	-	-	22.4
	TaxoRL (Partial)	51.6	36.4	42.7	37.5	24.2	29.4
	TaxoRL (Full)	47.2	**54.6**	**50.6**	32.3	**32.3**	**32.3**
Sci	TAXI (DAG)	61.6	41.7	49.7	38.8	34.8	36.7
	TAXI (tree)	76.8	38.3	51.1	44.8	28.8	35.1
	SubSeq	-	-	-	-	-	39.9
	TaxoRL (Partial)	**84.6**	34.4	48.9	**56.9**	33.0	**41.8**
	TaxoRL (Full)	68.3	**52.9**	**59.6**	37.9	**37.9**	37.9

Table 2: Results of the hypernymy organization experiment. Our approach outperforms Panchenko et al. (2016); Gupta et al. (2017) when the same hypernym graph is used as input. The precision of partial induction in both metrics is high. The precision of full induction is relatively lower but its recall is much higher.

Analysis on Hypernymy Organization. Table 2 lists the results of the second experiment. TAXI (DAG) (Panchenko et al., 2016) denotes TAXI's original performance on the TExEval-2 dataset.[9] Since we don't allow DAG in our setting, we convert its results to trees (denoted by TAXI (tree)) by only keeping the first parent of each node. SubSeq (Gupta et al., 2017) also reuses TAXI's hypernym candidates. TaxoRL (Partial) and TaxoRL (Full) denotes partial induction and full induction, respectively. Our joint RL approach outperforms baselines in both domains substantially. TaxoRL (Partial) achieves higher precision in both ancestor-based and edge-based metrics but has rel-

[7]https://spacy.io/

[8]Bansal et al. (2014) use an unavailable resource (Brants and Franz, 2006) which contains one trillion tokens while our public corpus contains several billion tokens. The frequency and generality features are sparse because the vocabulary that TAXI (in the TExEval-2 competition) used for focused crawling and hypernymy detection was different.

[9]alt.qcri.org/semeval2016/task13/index.php?id=evaluation

atively lower recall since it discards some terms. In addition, it achieves the best $F1_e$ in science domain. TaxoRL (Full) has the highest recall in both domains and metrics, with the compromise of lower precision. Overall, TaxoRL (Full) performs the best in both domains in terms of $F1_a$ and achieves best $F1_e$ in environment domain.

5 Ablation Analysis and Case Study

In this section, we conduct ablation analysis and present a concrete case for better interpreting our model and experimental results.

Table 3 shows the ablation study of TaxoRL (NR) on the WordNet dataset. As one may find, different types of features are complementary to each other. Combining distributional and path-based features performs better than using either of them alone (Shwartz et al., 2016). Adding surface features helps model string-level statistics that are hard to capture by distributional or path-based features. Significant improvement is observed when more data is used, meaning that standard corpora (such as Wikipedia) might not be enough for complicated taxonomies like WordNet.

Fig. 3 shows the results of taxonomy about *filter*. We denote the selected term pair at time step t as (hypo, hyper, t). Initially, the term *water filter* is randomly chosen as the taxonomy root. Then, a wrong term pair (water filter, air filter, 1) is selected possibly due to the noise and sparsity of features, which makes the term *air filter* become the new root. (air filter, filter, 2) is selected next and the current root becomes *filter* that is identical to the real root. After that, term pairs such as (fuel filter, filter, 3), (coffee filter, filter, 4) are selected correctly, mainly because of the substring inclusion intuition. Other term pairs such as (colander, strainer, 13), (glass wool, filter, 16) are discovered later, largely by the information encoded in the dependency paths and embeddings. For those undiscovered relations, (filter tip, air filter) has no dependency path in the corpus. *sifter* is attached to the taxonomy before its hypernym *sieve*. There is no co-occurrence between *bacteria bed* (or *drain basket*) and other terms. In addition, it is hard to utilize the surface features since they "look different" from other terms. That is also why (bacteria bed, air filter, 17) and (drain basket, air filter, 18) are attached in the end: our approach prefers to select term pairs with high confidence first.

Model	P_a	R_a	$F1_a$	$F1_e$
Distributional Info	27.1	24.3	25.6	13.8
Path-based Info	27.8	48.5	33.7	27.4
D + P	36.6	39.4	37.9	28.3
D + P + Surface Features	41.3	49.2	44.9	35.6
D + P + S + FG	**52.9**	**58.6**	**55.6**	**43.8**

Table 3: Ablation study on the WordNet dataset (Bansal et al., 2014). P_e and R_e are omitted because they are the same as $F1_e$ for each model. We can see that our approach benefits from multiple sources of information which are complementary to each other.

6 Related Work

6.1 Hypernymy Detection

Finding high-quality hypernyms is of great importance since it serves as the first step of taxonomy induction. In previous works, there are mainly two categories of approaches for hypernymy detection, namely pattern-based and distributional methods. Pattern-based methods consider lexico-syntactic patterns between the joint occurrences of term pairs for hypernymy detection. They generally achieve high precision but suffer from low recall. Typical methods that leverage patterns for hypernym extraction include (Hearst, 1992; Snow et al., 2005; Kozareva and Hovy, 2010; Panchenko et al., 2016; Nakashole et al., 2012). Distributional methods leverage the contexts of each term separately. The co-occurrence of term pairs is hence unnecessary. Some distributional methods are developed in an unsupervised manner. Measures such as symmetric similarity (Lin et al., 1998) and those based on distributional inclusion hypothesis (Weeds et al., 2004; Chang et al., 2017) were proposed. Supervised methods, on the other hand, usually have better performance than unsupervised methods for hypernymy detection. Recent works towards this direction include (Fu et al., 2014; Rimell, 2014; Yu et al., 2015; Tuan et al., 2016; Shwartz et al., 2016).

6.2 Taxonomy Induction

There are many lines of work for taxonomy induction in the prior literature. One line of works (Snow et al., 2005; Yang and Callan, 2009; Shen et al., 2012; Jurgens and Pilehvar, 2015) aims to complete existing taxonomies by attaching new terms in an incremental way. Snow et al. (2005) enrich WordNet by maximizing the probability of an extended taxonomy given evidence of relations from text corpora. Shen et al. (2012) determine whether an entity is on the taxonomy and either attach it to the right category or link it to an existing one based on the results. Another line of works (Suchanek et al., 2007; Ponzetto and Strube, 2008; Flati et al., 2014) focuses on the taxonomy induction of existing encyclopedias (*e.g.*, Wikipedia), mainly by employing the nature that they are already organized into semi-structured data. To deal with the issue of incomplete coverage, some works (Liu et al., 2012; Dong et al., 2014; Panchenko et al., 2016; Kozareva and Hovy, 2010) utilize data from domain-specific resources or the Web. Panchenko et al. (2016) extract hypernyms by patterns from general purpose corpora and domain-specific corpora bootstrapped from the input vocabulary. Kozareva and Hovy (2010) harvest new terms from the Web by employing Hearst-like lexico-syntactic patterns and validate the learned is-a relations by a web-based concept positioning procedure.

Many works (Kozareva and Hovy, 2010; Anh et al., 2014; Velardi et al., 2013; Bansal et al., 2014; Zhang et al., 2016; Panchenko et al., 2016; Gupta et al., 2017) cast the task of hypernymy organization as a graph optimization problem. Kozareva and Hovy (2010) begin with a set of root terms and leaf terms and aim to generate intermediate terms by deriving the longest path from the root to leaf in a noisy hypernym graph. Velardi et al. (2013) induct a taxonomy from the hypernym graph via optimal branching and a weighting policy. Bansal et al. (2014) regard the induction of a taxonomy as a structured learning problem by building a factor graph to model the relations between edges and siblings, and output the MST found by the Chu-Liu/Edmond's algorithm (Chu, 1965). Zhang et al. (2016) propose a probabilistic Bayesian model which incorporates visual features (images) in addition to text features (words) to improve the performance. The optimal taxonomy is also found by the MST. Gupta et al. (2017) extract hypernym subsequences based on hypernym pairs, and regard the task of taxonomy induction as an instance of the minimum-cost flow problem.

7 Conclusion and Future Work

This paper presents a novel end-to-end reinforcement learning approach for automatic taxonomy induction. Unlike previous two-phase methods

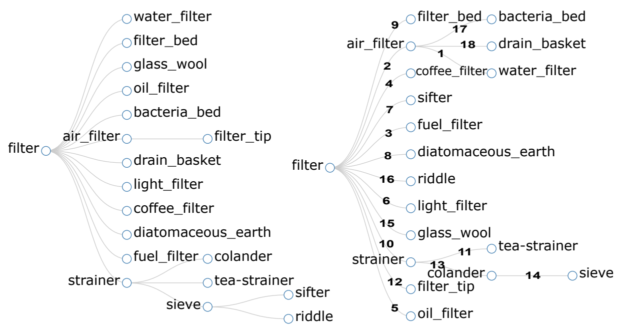

Figure 3: The gold taxonomy in WordNet is on the left. The predicted taxonomy is on the right. The numbers indicate the order of term pair selections. Term pairs with high confidence are selected first.

that treat term pairs independently or equally, our approach learns the representations of term pairs by optimizing a holistic tree metric over the training taxonomies. The error propagation between two phases is thus effectively reduced and the global taxonomy structure is better captured. Experiments on two public datasets from different domains show that our approach outperforms state-of-the-art methods significantly. In the future, we will explore more strategies towards term pair selection (*e.g.*, allow the RL agent to remove terms from the taxonomy) and reward function design. In addition, study on how to effectively encode induction history will be interesting.

Abstract

Word Sense Disambiguation (WSD) aims to identify the correct meaning of polysemous words in the particular context. Lexical resources like WordNet which are proved to be of great help for WSD in the knowledge-based methods. However, previous neural networks for WSD always rely on massive labeled data (context), ignoring lexical resources like glosses (sense definitions). In this paper, we integrate the context and glosses of the target word into a unified framework in order to make full use of both labeled data and lexical knowledge. Therefore, we propose **GAS**: a **g**loss-**a**ugmented W**S**D neural network which jointly encodes the context and glosses of the target word. GAS models the semantic relationship between the context and the gloss in an improved memory network framework, which breaks the barriers of the previous supervised methods and knowledge-based methods. We further extend the original gloss of word sense via its semantic relations in WordNet to enrich the gloss information. The experimental results show that our model outperforms the state-of-the-art systems on several English all-words WSD datasets.

1 Introduction

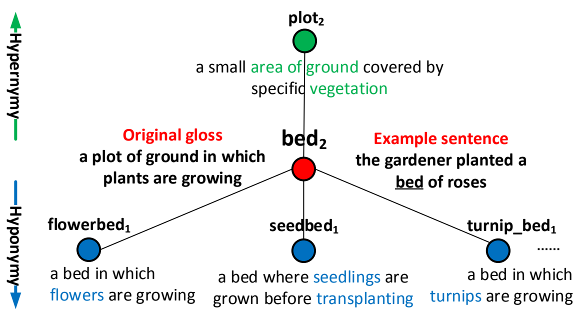
Word Sense Disambiguation (WSD) is a fundamental task and long-standing challenge in Natural Language Processing (NLP). There are several lines of research on WSD. Knowledge-based methods focus on exploiting lexical resources to infer the senses of word in the context. Supervised methods usually train multiple classifiers with manual designed features. Although supervised methods can achieve the state-of-the-art performance (Raganato et al., 2017b,a), there are still two major challenges.

Firstly, supervised methods (Zhi and Ng, 2010; Iacobacci et al., 2016) usually train a dedicated classifier for each word individually (often called *word expert*). So it can not easily scale up to all-words WSD task which requires to disambiguate all the polysemous word in texts [1]. Recent neural-based methods (Kågebäck and Salomonsson, 2016; Raganato et al., 2017a) solve this problem by building a unified model for all the polysemous words, but they still can't beat the best *word expert* system.

Secondly, all the neural-based methods always only consider the local context of the target word, ignoring the lexical resources like WordNet (Miller, 1995) which are widely used in the knowledge-based methods. The gloss, which extensionally defines a word sense meaning, plays a key role in the well-known Lesk algorithm (Lesk, 1986). Recent studies (Banerjee and Pedersen, 2002; Basile et al., 2014) have shown that enriching gloss information through its semantic relations can greatly improve the accuracy of Lesk algorithm.

To this end, our goal is to incorporate the gloss information into a unified neural network for all of the polysemous words. We further consider extending the original gloss through its semantic relations in our framework. As shown in Figure 1, the glosses of hypernyms and hyponyms can enrich the original gloss information as well as help to build better a sense representation. Therefore, we integrate not only the original gloss but also the related glosses of hypernyms and hyponyms into the neural network.

[1] If there are N polysemous words in texts, they need to train N classifiers individually.



Hypernymy
Hyponymy
plot₂
a small area of ground covered by specific vegetation
Original gloss
a plot of ground in which plants are growing
bed₂
Example sentence
the gardener planted a bed of roses
flowerbed₁
a bed in which flowers are growing
seedbed₁
a bed where seedlings are grown before transplanting
turnip_bed₁
......
a bed in which turnips are growing

Figure 1: The hypernym (green node) and hyponyms (blue nodes) for the 2nd sense bed_2 of bed, which means *a plot of ground in which plants are growing*, rather than the bed for sleeping in. The figure shows that bed_2 is a kind of $plot_2$, and bed_2 includes $flowerbed_1$, $seedbed_1$, etc.

In this paper, we propose a novel model **GAS**: a gloss-augmented WSD neural network which is a variant of the memory network (Sukhbaatar et al., 2015b; Kumar et al., 2016; Xiong et al., 2016). GAS jointly encodes the context and glosses of the target word and models the semantic relationship between the context and glosses in the memory module. In order to measure the inner relationship between glosses and context more accurately, we employ multiple passes operation within the memory as the re-reading process and adopt two memory updating mechanisms.

The main contributions of this paper are listed as follows:

- To the best of our knowledge, our model is the first to incorporate the glosses into an end-to-end neural WSD model. In this way, our model can benefit from not only massive labeled data but also rich lexical knowledge.
- In order to model semantic relationship of context and glosses, we propose a gloss-augmented neural network (GAS) in an improved memory network paradigm.
- We further expand the gloss through its semantic relations to enrich the gloss information and better infer the context. We extend the gloss module in GAS to a hierarchical framework in order to mirror the hierarchies of word senses in WordNet.
- The experimental results on several English all-words WSD benchmark datasets show that our model outperforms the state-of-the-art systems.

2 Related Work

Knowledge-based, supervised and neural-based methods have already been applied to WSD task (Navigli, 2009).

Knowledge-based WSD methods mainly exploit two kinds of knowledge to disambiguate polysemous words: **1)** The gloss, which defines a word sense meaning, is mainly used in Lesk algorithm (Lesk, 1986) and its variants. **2)** The structure of the semantic network, whose nodes are synsets [2] and edges are semantic relations, is mainly used in graph-based algorithms (Agirre et al., 2014; Moro et al., 2014).

Supervised methods (Zhi and Ng, 2010; Iacobacci et al., 2016) usually involve each target word as a separate classification problem (often called *word expert*) and train classifiers based on manual designed features.

Although *word expert* supervised WSD methods perform best in terms of accuray, they are less flexible than knowledge-based methods in the all-words WSD task (Raganato et al., 2017a). To deal with this problem, recent neural-based methods aim to build a unified classifier which shares parameters among all the polysemous words. Kågebäck and Salomonsson (2016) leverages the bidirectional long short-term memory network which shares model parameters among all the polysemous words. Raganato et al. (2017a) transfers the WSD problem into a neural sequence labeling task. However, none of the neural-based methods can totally beat the best *word expert* supervised methods on English all-words WSD datasets.

What's more, all of the previous supervised methods and neural-based methods rarely take the lexical resources like WordNet (Fellbaum, 1998) into consideration. Recent studies on sense embeddings have proved that lexical resources are helpful. Chen et al. (2015) trains word sense embeddings through learning sentence level embeddings from glosses using a convolutional neural networks. Rothe and Schütze (2015) extends word embeddings to sense embeddings by using the constraints and semantic relations in WordNet. They achieve an improvement of more than 1% in WSD performance when using sense embeddings as WSD features for SVM classifier. This work shows that integrating structural information of lexical resources can help to *word expert* supervised methods. However, sense embeddings

[2] A synset is a set of words that denote the same sense.

can only indirectly help to WSD (as SVM classifier features). Raganato et al. (2017a) shows that the coarse-grained semantic labels in WordNet can help to WSD in a multi-task learning framework. As far as we know, there is no study directly integrates glosses or semantic relations of the WordNet into an end-to-end model.

In this paper, we focus on how to integrate glosses into a unified neural WSD system. Memory network (Sukhbaatar et al., 2015b; Kumar et al., 2016; Xiong et al., 2016) is initially proposed to solve question answering problems. Recent researches show that memory network obtains the state-of-the-art results in many NLP tasks such as sentiment classification (Li et al., 2017) and analysis (Gui et al., 2017), poetry generation (Zhang et al., 2017), spoken language understanding (Chen et al., 2016), etc. Inspired by the success of memory network used in many NLP tasks, we introduce it into WSD. We make some adaptations to the initial memory network in order to incorporate glosses and capture the inner relationship between the context and glosses.

3 Incorporating Glosses into Neural Word Sense Disambiguation

In this section, we first give an overview of the proposed model **GAS**: a gloss-augmented WSD neural network which integrates the context and the glosses of the target word into a unified framework. After that, each individual module is described in detail.

3.1 Architecture of GAS

The overall architecture of the proposed model is shown in Figure 2. It consists of four modules:

- **Context Module**: The context module encodes the local context (a sequence of surrounding words) of the target word into a distributed vector representation.

- **Gloss Module**: Like the context module, the gloss module encodes all the glosses of the target word into a separate vector representations of the same size. In other words, we can get $|s_t|$ word sense representations according to $|s_t|$ [3] senses of the target word, where $|s_t|$ is the sense number of the target word w_t .

[3] s_t is the sense set $\{s_t^1, s_t^2, \ldots, s_t^p\}$ corresponding to the target word x_t

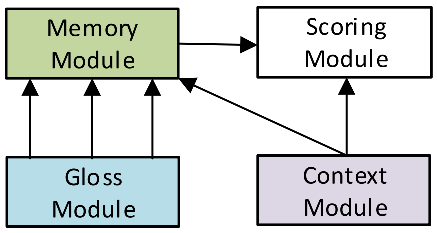


Figure 2: Overview of Gloss-augmented Memory Network for Word Sense Disambiguation.

- **Memory Module**: The memory module is employed to model the semantic relationship between the context embedding and gloss embedding produced by context module and gloss module respectively.

- **Scoring Module**: In order to benefit from both labeled contexts and gloss knowledge, the scoring module takes the context embedding from context module and the last step result from the memory module as input. Finally it generates a probability distribution over all the possible senses of the target word.

Detailed architecture of the proposed model is shown in Figure 3. The next four sections will show detailed configurations in each module.

3.2 Context Module

Context module encodes the context of the target word into a vector representation, which is also called context embedding in this paper.

We leverage the bidirectional long short-term memory network (Bi-LSTM) for taking both the preceding and following words of the target word into consideration. The input of this module $[x_1, \ldots, x_{t-1}, x_{t+1}, \ldots, x_{T_x}]$ is a sequence of words surrounding the target word x_t, where T_x is the length of the context. After applying a lookup operation over the pre-trained word embedding matrix $\mathrm{M} \in \mathbb{R}^{D \times V}$, we transfer a one hot vector x_i into a D-dimensional vector. Then, the forward LSTM reads the segment $(x_1, \ldots, x_{t-1})$ on the left of the target word x_t and calculates a sequence of *forward hidden states* $(\overrightarrow{h}_1, \ldots, \overrightarrow{h}_{t-1})$. The backward LSTM reads the segment $(x_{T_x}, \ldots, x_{t+1})$ on the right of the target word x_t and calculates a sequence of *backward hidden states* $(\overleftarrow{h}_{T_x}, \ldots, \overleftarrow{h}_{t+1})$. The context vector c is finally concatenated as

$$c = [\overrightarrow{h}_{t-1} : \overleftarrow{h}_{t+1}] \qquad (1)$$

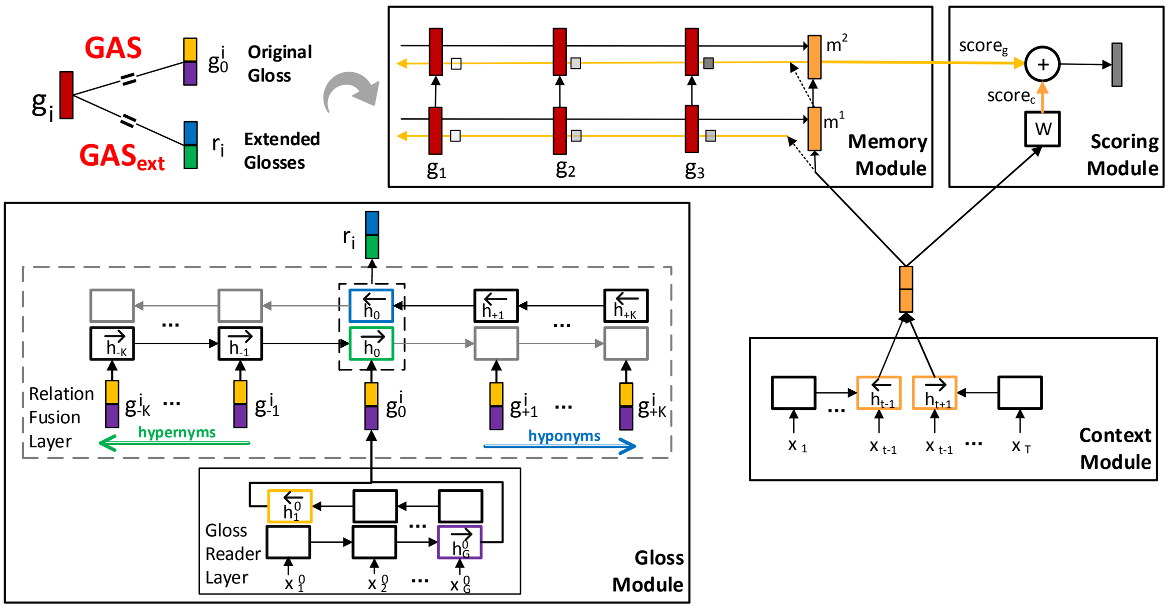

Figure 3: Detailed architecture of our proposed model, which consists of a context module, a gloss module, a memory module and a scoring module. The context module encodes the adjacent words surrounding the target word into a vector c. The gloss module encodes the original gloss or extended glosses into a vector g_i. In the memory module, we calculate the inner relationship (as attention) between context c and each gloss g_i and then update the memory as m_i at pass i. In the scoring module, we make final predictions based on the last pass attention of memory module and the context vector c. Note that GAS only uses the original gloss, while GAS$_{ext}$ uses the entended glosses through hypernymy and hyponymy relations. In other words, the relation fusion layer (grey dotted box) only belongs to GAS$_{ext}$.

where : is the concatenation operator.

3.3 Gloss Module

The gloss module encodes each gloss of the target word into a fixed size vector like the context vector c, which is also called gloss embedding. We further enrich the gloss information by taking semantic relations and their associated glosses into consideration.

This module contains a gloss reader layer and a relation fusion layer. Gloss reader layer generates a vector representations for a gloss. Relation fusion layer aims at modeling the semantic relations of each gloss in the expanded glosses list which consists of related glosses of the original gloss. Our model GAS with extended glosses is denoted as GAS$_{ext}$. GAS only encodes the original gloss, while GAS$_{ext}$ encodes the expanded glosses from hypernymy and hyponymy relations (details in Figure 3).

3.3.1 Gloss Reader Layer

Gloss reader layer contains two parts: gloss expansion and gloss encoder. Gloss expansion is to enrich the original gloss information through its hypernymy and hyponymy relations in WordNet. Gloss encoder is to encode each gloss into a vector representation.

Gloss Expansion: We only expand the glosses of nouns and verbs via their corresponding hypernyms and hyponyms. There are two reasons: One is that most of polysemous words (about 80%) are nouns and verbs; the other is that the most frequent relations among word senses for nouns and verbs are the hypernymy and hyponymy relations [4].

The original gloss is denoted as g_0. Breadth-first search method with a limited depth K is employed to extract the related glosses. The glosses of hypernyms within K depth are denoted as $[g_{-1}, g_{-2}, \ldots, g_{-L_1}]$. The glosses of hyponyms within K depth are denoted as $[g_{+1}, g_{+2}, \ldots, g_{+L_2}]$ [5]. Note that g_{+1} and g_{-1} are the glosses of the nearest word sense.

Gloss Encoder: We denote the j-th [6] gloss in

[4]In WordNet, more than 95% of relations for nouns and 80% for verbs are hypernymy and hyponymy relations.

[5]Since one synset has one or more direct hypernyms and hyponyms, $L_1 >= K$ and $L_2 >= K$.

[6]Since GAS don't have gloss expansion, j is always 0 and $g_i = g_0^i$. See more in Figure 3.

the expanded glosses list for i_{th} sense of the target word as a sequence of G words. Like the context encoder, the gloss encoder also leverages Bi-LSTM units to process the words sequence of the gloss. The gloss representation g_j^i is computed as the concatenation of the last hidden states of the *forward* and *backward* LSTM.

$$g_j^i = [\overrightarrow{h}_G^{i,j} : \overleftarrow{h}_1^{i,j}] \tag{2}$$

where $j \in [-L_1, \dots, -1, 0, +1, \dots, +L_2]$ and : is the concatenation operator .

3.3.2 Relation Fusion Layer

Relation fusion layer models the hypernymy and hyponymy relations of the target word sense. A forward LSTM is employed to encode the hypernyms' glosses of i_{th} sense $(g_{-L_1}^i, \cdots, g_{-1}^i, g_0^i)$ as a sequence of *forward hidden states* $(\overrightarrow{h}_{-L_1}^i, \dots, \overrightarrow{h}_{-1}^i, \overrightarrow{h}_0^i)$. A backward LSTM is employed to encode the hyponyms' glosses of i_{th} sense $(g_{+L_2}^i, \dots, g_{+1}^i, g_0^i)$ as a sequence of *backward hidden states* $(\overleftarrow{h}_{+L_2}^i, \dots, \overleftarrow{h}_{+1}^i, \overleftarrow{h}_0^i)$. In order to highlight the original gloss g_0^i, the enhanced i_{th} sense representation is concatenated as the final state of the forward and backward LSTM.

$$g_i = [\overrightarrow{h}_0^i : \overleftarrow{h}_0^i] \tag{3}$$

3.4 Memory Module

The memory module has two inputs: the context vector c from the context module and the gloss vectors $\{g_1, g_2, \dots, g_{|s_t|}\}$ from the gloss module, where $|s_t|$ is the number of word senses. We model the inner relationship between the context and glosses by attention calculation. Since one-pass attention calculation may not fully reflect the relationship between the context and glosses (details in Section 4.4.2), the memory module adopts a repeated deliberation process. The process repeats reading gloss vectors in the following passes, in order to highlight the correct word sense for the following scoring module by a more accurate attention calculation. After each pass, we update the memory to refine the states of the current pass. Therefore, memory module contains two phases: attention calculation and memory update.

Attention Calculation: For each pass k, the attention e_i^k of gloss g_i is generally computed as

$$e_i^k = f(g_i, m^{k-1}, c) \tag{4}$$

where m^{k-1} is the memory vector in the $(k-1)$-th pass while c is the context vector. The scoring function f calculates the semantic relationship of the gloss and context, taking the vector set (g_i, m^{k-1}, c) as input. In the first pass, the attention reflects the similarity of context and each gloss. In the next pass, the attention reflects the similarity of adapted memory and each gloss. A dot product is applied to calculate the similarity of each gloss vector and context (or memory) vector. We treat c as m^0. So, the attention α_i^k of gloss g_i at pass k is computed as a dot product of g_i and m^{k-1}:

$$e_i^k = g_i \cdot m^{k-1} \tag{5}$$

$$\alpha_i^k = \frac{\exp(e_i^k)}{\sum_{j=1}^{|s_t|} \exp(e_i^j)} \tag{6}$$

Memory Update: After calculating the attention, we store the memory state in u^k which is a weighted sum of gloss vectors and is computed as

$$u^k = \sum_{i=1}^{n} \alpha_i^k g_i \tag{7}$$

where n is the hidden size of LSTM in the context module and gloss module. And then, we update the memory vector m^k from last pass memory m^{k-1}, context vector c, and memory state u^k. We propose two memory update methods:

- *Linear*: we update the memory vector m^k by a linear transformation from m^{k-1}

$$m^k = Hm^{k-1} + u^k \tag{8}$$

  where $H \in \mathbb{R}^{2n \times 2n}$.

- *Concatenation*: we get a new memory for k-th pass by taking both the gloss embedding and context embedding into consideration

$$m^k = ReLU(W[m^{k-1} : u^k : c] + b) \tag{9}$$

  where : is the concatenation operator, $W \in \mathbb{R}^{n \times 6n}$ and $b \in \mathbb{R}^{2n}$.

3.5 Scoring Module

The scoring module calculates the scores for all the related senses $\{s_t^1, s_t^2, \dots, s_t^p\}$ corresponding to the target word x_t and finally outputs a sense probability distribution over all senses.

The overall score for each word sense is determined by gloss attention $\alpha_i^{T_M}$ from the last pass in the memory module, where T_M is the number of passes in the memory module. The e^{T_M} (α^{T_M} without Softmax) is regarded as the gloss score.

$$score_g = e^{T_M} \tag{10}$$

Meanwhile, a fully-connected layer is employed to calculate the context score.

$$score_c = W_{x_t} c + b_{x_t} \tag{11}$$

where $W_{x_t} \in \mathbb{R}^{|s_t| \times 2n}$, $b_{x_t} \in \mathbb{R}^{|s_t|}$, $|s_t|$ is the number of senses for the target word x_t and n is the number of hidden units in the LSTM.

It's noteworthy that in Equation 11, each ambiguous word x_t has its corresponding weight matrix W_{x_t} and bias b_{x_t} in the scoring module.

In order to balance the importance of background knowledge and labeled data, we introduce a parameter $\lambda \in \mathbb{R}^N$ [7] in the scoring module which is jointly learned during the training process. The probability distribution $\hat{y}$ over all the word senses of the target word is calculated as:

$$\hat{y} = Softmax(\lambda_{x_t} score_c + (1 - \lambda_{x_t}) score_g)$$

where λ_{x_t} is the parameter for word x_t, and $\lambda_{x_t} \in [0, 1]$.

During training, all model parameters are jointly learned by minimizing a standard cross-entropy loss between $\hat{y}$ and the true label y.

4 Experiments and Evaluation

4.1 Dataset

Evaluation Dataset: we evaluate our model on several English all-words WSD datasets. For fair comparison, we use the benchmark datasets proposed by Raganato et al. (2017b) which includes five standard all-words fine-grained WSD datasets from the Senseval and SemEval competitions. They are Senseval-2 (**SE2**), Senseval-3 task 1 (**SE3**), SemEval-07 task 17 (**SE7**), SemEval-13 task 12 (**SE13**), and SemEval-15 task 13 (**SE15**). Following by Raganato et al. (2017a), we choose SE7, the smallest test set as the development (validation) set, which consists of 455 labeled instances. The last four test sets consist of 6798 labeled instances with four types of target words, namely nouns, verbs, adverbs and adjectives. We extract word sense glosses from WordNet3.0 because Raganato et al. (2017b) maps all the sense annotations [8] from its original version to 3.0.

Training Dataset: We choose SemCor 3.0 as the training set, which was also used by Raganato et al. (2017a), Raganato et al. (2017b), Iacobacci et al. (2016), Zhi and Ng (2010), etc. It consists of 226,036 sense annotations from 352 documents, which is the largest manually annotated corpus for WSD. Note that all the systems listed in Table 1 are trained on SemCor 3.0.

4.2 Implementation Details

We use the validation set (SE7) to find the optimal settings of our framework: the hidden state size n, the number of passes $|T_M|$, the optimizer, etc. We use pre-trained word embeddings with 300 dimensions[9], and keep them fixed during the training process. We employ 256 hidden units in both the gloss module and the context module, which means n=256. Orthogonal initialization is used for weights in LSTM and random uniform initialization with range [-0.1, 0.1] is used for others. We assign gloss expansion depth K the value of 4. We also experiment with the number of passes $|T_M|$ from 1 to 5 in our framework, finding $|T_M| = 3$ performs best. We use Adam optimizer (Kingma and Ba, 2014) in the training process with 0.001 initial learning rate. In order to avoid overfitting, we use dropout regularization and set drop rate to 0.5. Training runs for up to 100 epochs with early stopping if the validation loss doesn't improve within the last 10 epochs.

4.3 Systems to be Compared

In this section, we describe several knowledge-based methods, supervised methods and neural-based methods which perform well on the English all-words WSD datasets for comparison.

4.3.1 Knowledge-based Systems

- **Lesk**$_{ext+emb}$: Basile et al. (2014) is a variant of Lesk algorithm (Lesk, 1986) by using a word similarity function defined on a distributional semantic space to calculate the gloss-context overlap. This work shows that glosses are important to WSD and enriching

[7] N is the number of polysemous words in the training corpora.

[8] The original WordNet version of SE2, SE3, SE7, SE13, SE15 are 1.7, 1.7.1, 2.1, 3.0 and 3.0, respectively.

[9] We download the pre-trained word embeddings from `https://github.com/stanfordnlp/GloVe`, and we select the smaller Wikipedia 2014 + Gigaword 5.

	Test Datasets				Concatenation of Test Datasets				
System	SE2	SE3	SE13	SE15	Noun	Verb	Adj	Adv	**All**
MFS baseline	65.6	66.0	63.8	67.1	67.7	49.8	73.1	80.5	65.5

Table 1: F1-score (%) for fine-grained English all-words WSD on the test sets. **Bold** font indicates best systems. The * represents the neural network models using external knowledge. The fives blocks list the MFS baseline, two knowledge-based systems, two supervised systems (feature-based), three neural-based systems and our models, respectively.

gloss information via its semantic relations can help to WSD.

- **Babelfy**: Moro et al. (2014) exploits the semantic network structure from BabelNet and builds a unified graph-based architecture for WSD and Entity Linking.

4.3.2 Supervised Systems

The supervised systems mentioned in this paper refers to traditional feature-based systems which train a dedicated classifier for every word individually (*word expert*).

- **IMS**: Zhi and Ng (2010) selects a linear Support Vector Machine (SVM) as its classifier and makes use of a set of features surrounding the target word within a limited window, such as POS tags, local words and local collocations.

- **IMS$_{+emb}$**: Iacobacci et al. (2016) selects IMS as the underlying framework and makes use of word embeddings as features which makes it hard to beat in most of WSD datasets.

4.3.3 Neural-based Systems

Neural-based systems aim to build an end-to-end unified neural network for all the polysemous words in texts.

- **Bi-LSTM**: Kågebäck and Salomonsson (2016) leverages a bidirectional LSTM network which shares model parameters among all words. Note that this model is equivalent to our model if we remove the gloss module and memory module of GAS.

- **Bi-LSTM$_{+att.+LEX}$** and its variant **Bi-LSTM$_{+att.+LEX+POS}$**: Raganato et al. (2017a) transfers WSD into a sequence learning task and propose a multi-task learning framework for WSD, POS tagging and coarse-grained semantic labels (LEX). These two models have used the external knowledge, for the LEX is based on lexicographer files in WordNet.

Moreover, we introduce **MFS** baseline, which simply selects the most frequent sense in the training data set.

4.4 Results and Discussion

4.4.1 English all-words results

In this section, we show the performance of our proposed model in the English all-words task. Table 1 shows the F1-score results on the four test sets mentioned in Section 4.1. The systems in the first four blocks are implemented by Raganato et al. (2017a,b) except for the single Bi-LSTM model. The last block lists the performance of our proposed model GAS and its variant GAS$_{ext}$ which extends the gloss module in GAS.

GAS and GAS$_{ext}$ achieves the state-of-the-art performance on the concatenation of all test datasets. Although there is no one system always performs best on all the test sets [10], we can find that GAS$_{ext}$ with *concatenation* memory updating strategy achieves the best results **70.6** on the concatenation of the four test datasets. Compared with other three neural-based methods in the

[10] Because the source of the four datasets are extremely different which belongs to different domains.

Context: He **plays** a pianist in the film					
Glosses	Pass 1	Pass 2	Pass 3	Pass 4	Pass 5
g_1: participate in games or sport	🟦				
g_2: perform music on a instrument	🟦	🟦	🟦	🟦	🟦
g_3: act a role or part	🟦	🟦	🟦	🟦	🟦

Table 2: An example of attention weights in the memory module within 5 passes. Darker colors mean that the attention weight is higher. Case studies show that the proposed multi-pass operation can recognize the correct sense by enlarging the attention gap between correct senses and incorrect ones.

Pass	**SE2**	**SE3**	**SE13**	**SE15**	**ALL**
1	71.6	70.3	67.0	72.5	70.3
2	71.9	70.2	67.1	**72.8**	70.4
3	**72.2**	**70.5**	**67.2**	72.6	**70.6**
4	72.1	70.4	**67.2**	72.4	70.5
5	72.0	70.4	67.1	71.5	70.3

Table 3: F1-score (%) of different passes from 1 to 5 on the test data sets. It shows that appropriate number of passes can boost the performance as well as avoid over-fitting of the model.

fourth block, we can find that our best model outperforms the previous best neural network models (Raganato et al., 2017a) on every individual test set. The IMS$_{+emb}$, which trains a dedicated classifier for each word individually (*word expert*) with massive manual designed features including word embeddings, is hard to beat for neural networks models. However, our best model can also beat IMS$_{+emb}$ on the SE3, SE13 and SE15 test sets.

Incorporating glosses into neural WSD can greatly improve the performance and extending the original gloss can further boost the results. Compared with the Bi-LSTM baseline which only uses labeled data, our proposed model greatly improves the WSD task by **2.2%** F1-score with the help of gloss knowledge. Furthermore, compared with the GAS which only uses original gloss as the background knowledge, GAS$_{ext}$ can further improve the performance with the help of the extended glosses through the semantic relations. This proves that incorporating extended glosses through its hypernyms and hyponyms into the neural network models can boost the performance for WSD.

4.4.2 Multiple Passes Analysis

To better illustrate the influence of multiple passes, we give an example in Table 2. Consider the situation that we meet an unknown word **x** [11], we look up from the dictionary and find three word senses and their glosses corresponding to **x**.

We try to figure out the correct meaning of **x** according to its context and glosses of different word senses by the proposed memory module. In the first pass, the first sense is excluded, for there are no relevance between the context and g_1. But the g_2 and g_3 may need repeated deliberation, for word *pianist* is similar to the word *music* and *role* in the two glosses. By re-reading the context and gloss information of the target word in the following passes, the correct word sense g_3 attracts much more attention than the other two senses. Such re-reading process can be realized by multi-pass operation in the memory module.

Furthermore, Table 3 shows the effectiveness of multi-pass operation in the memory module. It shows that multiple passes operation performs better than one pass, though the improvement is not significant. The reason of this phenomenon is that for most target words, one main word sense accounts for the majority of their appearances. Therefore, in most circumstances, one-pass inference can lead to the correct word senses. Case studies in Table 2 show that the proposed multi-pass inference can help to recognize the infrequent senses like the third sense for word *play*. In Table 3, with the increasing number of passes, the F1-score increases. However, when the number of passes is larger than 3, the F1-score stops increasing or even decreases due to over-fitting. It shows that appropriate number of passes can boost the performance as well as avoid over-fitting of the model.

5 Conclusions and Future Work

In this paper, we seek to address the problem of integrating the glosses knowledge of the ambiguous word into a neural network for WSD. We further extend the gloss information through its semantic relations in WordNet to better infer the context. In

[11]**x** refers to word *play* in reality.

this way, we not only make use of labeled context data but also exploit the background knowledge to disambiguate the word sense. Results on four English all-words WSD data sets show that our best model outperforms the existing methods.

There is still one challenge left for the future. We just extract the gloss, missing the structural properties or graph information of lexical resources. In the next step, we will consider integrating the rich structural information into the neural network for Word Sense Disambiguation.

Bilingual Sentiment Embeddings: Joint Projection of Sentiment Across Languages

Jeremy Barnes, Roman Klinger, and **Sabine Schulte im Walde**

Abstract

Sentiment analysis in low-resource languages suffers from a lack of annotated corpora to estimate high-performing models. Machine translation and bilingual word embeddings provide some relief through cross-lingual sentiment approaches. However, they either require large amounts of parallel data or do not sufficiently capture sentiment information. We introduce Bilingual Sentiment Embeddings (BLSE), which jointly represent sentiment information in a source and target language. This model only requires a small bilingual lexicon, a source-language corpus annotated for sentiment, and monolingual word embeddings for each language. We perform experiments on three language combinations (Spanish, Catalan, Basque) for sentence-level cross-lingual sentiment classification and find that our model significantly outperforms state-of-the-art methods on four out of six experimental setups, as well as capturing complementary information to machine translation. Our analysis of the resulting embedding space provides evidence that it represents sentiment information in the resource-poor target language without any annotated data in that language.

1 Introduction

Cross-lingual approaches to sentiment analysis are motivated by the lack of training data in the vast majority of languages. Even languages spoken by several million people, such as Catalan, often have few resources available to perform sentiment analysis in specific domains. We therefore aim to harness the knowledge previously collected in resource-rich languages.

Previous approaches for cross-lingual sentiment analysis typically exploit machine translation based methods or multilingual models. Machine translation (MT) can provide a way to transfer sentiment information from a resource-rich to resource-poor languages (Mihalcea et al., 2007; Balahur and Turchi, 2014). However, MT-based methods require large parallel corpora to train the translation system, which are often not available for under-resourced languages.

Examples of multilingual methods that have been applied to cross-lingual sentiment analysis include domain adaptation methods (Prettenhofer and Stein, 2011), delexicalization (Almeida et al., 2015), and bilingual word embeddings (Mikolov et al., 2013; Hermann and Blunsom, 2014; Artetxe et al., 2016). These approaches however do not incorporate enough sentiment information to perform well cross-lingually, as we will show later.

We propose a novel approach to incorporate sentiment information in a model, which does not have these disadvantages. *Bilingual Sentiment Embeddings* (BLSE) are embeddings that are jointly optimized to represent both (a) semantic information in the source and target languages, which are bound to each other through a small bilingual dictionary, and (b) sentiment information, which is annotated on the source language only. We only need three resources: (i) a comparably small bilingual lexicon, (ii) an annotated sentiment corpus in the resource-rich language, and (iii) monolingual word embeddings for the two involved languages.

We show that our model outperforms previous state-of-the-art models in nearly all experimental settings across six benchmarks. In addition, we offer an in-depth analysis and demonstrate that our model is aware of sentiment. Finally, we provide a qualitative analysis of the joint bilingual sentiment space. Our implementation is publicly available at https://github.com/jbarnesspain/blse.

2 Related Work

Machine Translation: Early work in cross-lingual sentiment analysis found that machine translation (MT) had reached a point of maturity that enabled the transfer of sentiment across languages. Researchers translated sentiment lexicons (Mihalcea et al., 2007; Meng et al., 2012) or annotated corpora and used word alignments to project sentiment annotation and create target-language annotated corpora (Banea et al., 2008; Duh et al., 2011; Demirtas and Pechenizkiy, 2013; Balahur and Turchi, 2014).

Several approaches included a multi-view representation of the data (Banea et al., 2010; Xiao and Guo, 2012) or co-training (Wan, 2009; Demirtas and Pechenizkiy, 2013) to improve over a naive implementation of machine translation, where only the translated data is used. There are also approaches which only require parallel data (Meng et al., 2012; Zhou et al., 2016; Rasooli et al., 2017), instead of machine translation.

All of these approaches, however, require large amounts of parallel data or an existing high quality translation tool, which are not always available. A notable exception is the approach proposed by Chen et al. (2016), an adversarial deep averaging network, which trains a joint feature extractor for two languages. They minimize the difference between these features across languages by learning to fool a language discriminator, which requires no parallel data. It does, however, require large amounts of unlabeled data.

Bilingual Embedding Methods: Recently proposed bilingual embedding methods (Hermann and Blunsom, 2014; Chandar et al., 2014; Gouws et al., 2015) offer a natural way to bridge the language gap. These particular approaches to bilingual embeddings, however, require large parallel corpora in order to build the bilingual space, which are not available for all language combinations.

An approach to create bilingual embeddings that has a less prohibitive data requirement is to create monolingual vector spaces and then learn a projection from one to the other. Mikolov et al. (2013) find that vector spaces in different languages have similar arrangements. Therefore, they propose a linear projection which consists of learning a rotation and scaling matrix. Artetxe et al. (2016, 2017) improve upon this approach by requiring the projection to be orthogonal, thereby preserving the monolingual quality of the original word vectors.

Given source embeddings S, target embeddings T, and a bilingual lexicon L, Artetxe et al. (2016) learn a projection matrix W by minimizing the square of Euclidean distances

$$\arg\min_{W} \sum_{i} ||S'W - T'||_F^2 \,, \tag{1}$$

where $S' \in S$ and $T' \in T$ are the word embedding matrices for the tokens in the bilingual lexicon L. This is solved using the Moore-Penrose pseudoinverse $S'^{+} = (S'^{T} S')^{-1} S'^{T}$ as $W = S'^{+} T'$, which can be computed using SVD. We refer to this approach as ARTETXE.

Gouws and Søgaard (2015) propose a method to create a pseudo-bilingual corpus with a small task-specific bilingual lexicon, which can then be used to train bilingual embeddings (BARISTA). This approach requires a monolingual corpus in both the source and target languages and a set of translation pairs. The source and target corpora are concatenated and then every word is randomly kept or replaced by its translation with a probability of 0.5. Any kind of word embedding algorithm can be trained with this pseudo-bilingual corpus to create bilingual word embeddings.

These last techniques have the advantage of requiring relatively little parallel training data while taking advantage of larger amounts of monolingual data. However, they are not optimized for sentiment.

Sentiment Embeddings: Maas et al. (2011) first explored the idea of incorporating sentiment information into semantic word vectors. They proposed a topic modeling approach similar to latent Dirichlet allocation in order to collect the semantic information in their word vectors. To incorporate the sentiment information, they included a second objective whereby they maximize the probability of the sentiment label for each word in a labeled document.

Tang et al. (2014) exploit distantly annotated tweets to create Twitter sentiment embeddings. To incorporate distributional information about tokens, they use a hinge loss and maximize the likelihood of a true n-gram over a corrupted n-gram. They include a second objective where they classify the polarity of the tweet given the true n-gram. While these techniques have proven useful, they are not easily transferred to a cross-lingual setting.

Zhou et al. (2015) create bilingual sentiment embeddings by translating all source data to the target language and vice versa. This requires the existence of a machine translation system, which is a prohibitive assumption for many under-resourced languages, especially if it must be open and freely accessible. This motivates approaches which can use smaller amounts of parallel data to achieve similar results.

3 Model

In order to project not only semantic similarity and relatedness but also sentiment information to our target language, we propose a new model, namely *Bilingual Sentiment Embeddings* (BLSE), which jointly learns to predict sentiment and to minimize the distance between translation pairs in vector space. We detail the projection objective in Section 3.1, the sentiment objective in Section 3.2, and the full objective in Section 3.3. A sketch of the model is depicted in Figure 1.

3.1 Cross-lingual Projection

We assume that we have two precomputed vector spaces $S = \mathbb{R}^{v \times d}$ and $T = \mathbb{R}^{v' \times d'}$ for our source and target languages, where v (v') is the length of the source vocabulary (target vocabulary) and d (d') is the dimensionality of the embeddings. We also assume that we have a bilingual lexicon L of length n which consists of word-to-word translation pairs $L = \{(s_1, t_1), (s_2, t_2), \dots, (s_n, t_n)\}$ which map from source to target.

In order to create a mapping from both original vector spaces S and T to shared sentiment-informed bilingual spaces $\mathbf{z}$ and $\hat{\mathbf{z}}$, we employ two linear projection matrices, M and M'. During training, for each translation pair in L, we first look up their associated vectors, project them through their associated projection matrix and finally minimize the mean squared error of the two projected vectors. This is very similar to the approach taken by Mikolov et al. (2013), but includes an additional target projection matrix.

The intuition for including this second matrix is that a single projection matrix does not support the transfer of sentiment information from the source language to the target language. Without M', any signal coming from the sentiment classifier (see Section 3.2) would have no affect on the target embedding space T, and optimizing M to predict sentiment and projection would only be detrimental to classification of the target language. We analyze this further in Section 6.3. Note that in this configuration, we do not need to update the original vector spaces, which would be problematic with such small training data.

The projection quality is ensured by minimizing the mean squared error[1][2]

$$\text{MSE} = \frac{1}{n} \sum_{i=1}^{n} (\mathbf{z_i} - \hat{\mathbf{z}}_\mathbf{i})^2 , \qquad (2)$$

where $\mathbf{z_i} = S_{s_i} \cdot M$ is the dot product of the embedding for source word s_i and the source projection matrix and $\hat{\mathbf{z}}_\mathbf{i} = T_{t_i} \cdot M'$ is the same for the target word t_i.

3.2 Sentiment Classification

We add a second training objective to optimize the projected source vectors to predict the sentiment of source phrases. This inevitably changes the projection characteristics of the matrix M, and consequently M' and encourages M' to learn to predict sentiment without any training examples in the target language.

To train M to predict sentiment, we require a source-language corpus $C_{\text{source}} = \{(x_1, y_1), (x_2, y_2), \dots, (x_i, y_i)\}$ where each sentence x_i is associated with a label y_i.

For classification, we use a two-layer feed-forward averaging network, loosely following Iyyer et al. (2015)[3]. For a sentence x_i we take the word embeddings from the source embedding S and average them to $\mathbf{a}_i \in \mathbb{R}^d$. We then project this vector to the joint bilingual space $\mathbf{z}_i = \mathbf{a}_i \cdot M$. Finally, we pass $\mathbf{z}_i$ through a softmax layer P to get our prediction $\hat{y}_i = \text{softmax}(\mathbf{z}_i \cdot P)$.

To train our model to predict sentiment, we minimize the cross-entropy error of our predictions

$$H = -\sum_{i=1}^{n} y_i \log \hat{y}_i - (1 - y_i) \log(1 - \hat{y}_i) \, . \quad (3)$$

3.3 Joint Learning

In order to jointly train both the projection component and the sentiment component, we combine the two loss functions to optimize the parameter

[1] We omit parameters in equations for better readability.

[2] We also experimented with cosine distance, but found that it performed worse than Euclidean distance.

[3] Our model employs a linear transformation after the averaging layer instead of including a non-linearity function. We choose this architecture because the weights M and M' are also used to learn a linear cross-lingual projection.

matrices M, M', and P by

$$J = \sum_{(x,y)\in C_{\text{source}}} \sum_{(s,t)\in L} \alpha H(x,y) + (1-\alpha)\cdot \text{MSE}(s,t)\,, \tag{4}$$

where α is a hyperparameter that weights sentiment loss vs. projection loss.

3.4 Target-language Classification

For inference, we classify sentences from a target-language corpus C_{target}. As in the training procedure, for each sentence, we take the word embeddings from the target embeddings T and average them to $\mathbf{a}_i \in \mathbb{R}^d$. We then project this vector to the joint bilingual space $\hat{\mathbf{z}}_i = \mathbf{a}_i \cdot M'$. Finally, we pass $\hat{\mathbf{z}}_i$ through a softmax layer P to get our prediction $\hat{y}_i = \text{softmax}(\hat{\mathbf{z}}_i \cdot P)$.

4 Datasets and Resources

4.1 OpeNER and MultiBooked

To evaluate our proposed model, we conduct experiments using four benchmark datasets and three bilingual combinations. We use the OpeNER English and Spanish datasets (Agerri et al., 2013) and the MultiBooked Catalan and Basque datasets (Barnes et al., 2018). All datasets contain hotel reviews which are annotated for aspect-level sentiment analysis. The labels include *Strong Negative* ($--$), *Negative* ($-$), *Positive* ($+$), and *Strong Positive* ($++$). We map the aspect-level annotations to sentence level by taking the most common label and remove instances of mixed polarity. We also create a binary setup by combining the strong and weak classes. This gives us a total of six experiments. The details of the sentence-level datasets are summarized in Table 1. For each of the experi-

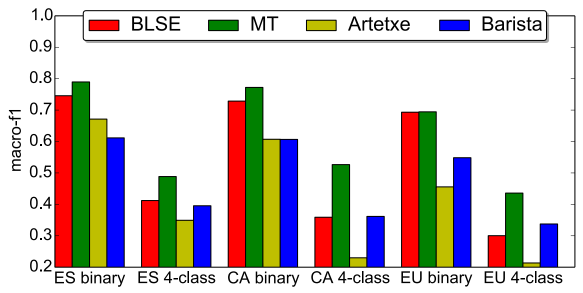

Figure 2: Binary and four class macro F_1 on Spanish (ES), Catalan (CA), and Basque (EU).

ments, we take 70 percent of the data for training, 20 percent for testing and the remaining 10 percent are used as development data for tuning.

4.2 Monolingual Word Embeddings

For BLSE, ARTETXE, and MT, we require monolingual vector spaces for each of our languages. For English, we use the publicly available GoogleNews vectors[4]. For Spanish, Catalan, and Basque, we train skip-gram embeddings using the Word2Vec toolkit[4] with 300 dimensions, subsampling of 10^{-4}, window of 5, negative sampling of 15 based on a 2016 Wikipedia corpus[5] (sentence-split, tokenized with IXA pipes (Agerri et al., 2014) and lowercased). The statistics of the Wikipedia corpora are given in Table 2.

4.3 Bilingual Lexicon

For BLSE, ARTETXE, and BARISTA, we also require a bilingual lexicon. We use the sentiment lexicon from Hu and Liu (2004) (to which we refer in the following as Bing Liu) and its translation into each target language. We translate the lexicon using Google Translate and exclude multi-word expressions.[6] This leaves a dictionary of 5700 translations in Spanish, 5271 in Catalan, and 4577 in Basque. We set aside ten percent of the translation pairs as a development set in order to check that the distances between translation pairs not seen during training are also minimized during training.

[4]https://code.google.com/archive/p/word2vec/
[5]http://attardi.github.io/wikiextractor/
[6]Note that we only do that for convenience. Using a machine translation service to generate this list could easily be replaced by a manual translation, as the lexicon is comparably small.

5 Experiments

5.1 Setting

We compare BLSE (Sections 3.1–3.3) to ARTETXE (Section 2) and BARISTA (Section 2) as baselines, which have similar data requirements and to machine translation (MT) and monolingual (MONO) upper bounds which request more resources. For all models (MONO, MT, ARTETXE, BARISTA), we take the average of the word embeddings in the source-language training examples and train a linear SVM[7]. We report this instead of using the same feed-forward network as in BLSE as it is the stronger upper bound. We choose the parameter c on the target language development set and evaluate on the target language test set.

Upper Bound MONO. We set an empirical upper bound by training and testing a linear SVM on the target language data. As mentioned in Section 5.1, we train the model on the averaged embeddings from target language training data, tuning the c parameter on the development data. We test on the target language test data.

Upper Bound MT. To test the effectiveness of machine translation, we translate all of the sentiment corpora from the target language to English using the Google Translate API[8]. Note that this approach is not considered a baseline, as we assume not to have access to high-quality machine translation for low-resource languages of interest.

Baseline ARTETXE. We compare with the approach proposed by Artetxe et al. (2016) which has shown promise on other tasks, such as word similarity. In order to learn the projection matrix W, we need translation pairs. We use the same word-to-word bilingual lexicon mentioned in Section 3.1. We then map the source vector space S to the bilingual space $\hat{S} = SW$ and use these embeddings.

Baseline BARISTA. We also compare with the approach proposed by Gouws and Søgaard (2015). The bilingual lexicon used to create the pseudo-bilingual corpus is the same word-to-word bilingual lexicon mentioned in Section 3.1. We follow the authors' setup to create the pseudo-bilingual corpus. We create bilingual embeddings by training skip-gram embeddings using the Word2Vec toolkit on the pseudo-bilingual corpus using the same parameters from Section 4.2.

[7]LinearSVC implementation from scikit-learn.
[8]https://translate.google.com

Our method: BLSE. We implement our model BLSE in Pytorch (Paszke et al., 2016) and initialize the word embeddings with the pretrained word embeddings S and T mentioned in Section 4.2. We use the word-to-word bilingual lexicon from Section 4.3, tune the hyperparameters α, training epochs, and batch size on the target development set and use the best hyperparameters achieved on the development set for testing. ADAM (Kingma and Ba, 2014) is used in order to minimize the average loss of the training batches.

Table 3: Precision (P), Recall (R), and macro F_1 of four models trained on English and tested on Spanish (ES), Catalan (CA), and Basque (EU). The **bold** numbers show the best results for each metric per column and the *highlighted* numbers show where BLSE is better than the other projection methods, ARTETXE and BARISTA (** $p < 0.01$, * $p < 0.05$).

Ensembles We create an ensemble of MT and each projection method (BLSE, ARTETXE, BARISTA) by training a random forest classifier on the predictions from MT and each of these approaches. This allows us to evaluate to what extent each projection model adds complementary information to the machine translation approach.

5.2 Results

In Figure 2, we report the results of all four methods. Our method outperforms the other projection methods (the baselines ARTETXE and BARISTA) on four of the six experiments substantially. It performs only slightly worse than the more resource-costly upper bounds (MT and MONO). This is especially noticeable for the binary classification task, where BLSE performs nearly as well as machine translation and significantly better than the other methods. We perform approximate randomization tests (Yeh, 2000) with 10,000 runs and highlight the results that are statistically significant (**$p <$ 0.01, *$p < 0.05$) in Table 3.

In more detail, we see that MT generally performs better than the projection methods (79–69 F_1 on binary, 52–44 on 4-class). BLSE (75–69 on binary, 41–30 on 4-class) has the best performance of the projection methods and is comparable with MT on the binary setup, with no significant difference on binary Basque. ARTETXE (67–46 on binary, 35–21 on 4-class) and BARISTA (61–55 on binary, 40–34 on 4-class) are significantly worse than BLSE on all experiments except Catalan and Basque 4-class. On the binary experiment, ARTETXE outperforms BARISTA on Spanish (67.1 vs. 61.2) and Catalan (60.7 vs. 60.1) but suffers more than the other methods on the four-class experiments, with a maximum F_1 of 34.9. Figure 3: Macro F_1 for translation pairs in the Spanish 4-class setup.

is relatively stable across languages.

ENSEMBLE performs the best, which shows that BLSE adds complementary information to MT. Finally, we note that all systems perform successively worse on Catalan and Basque. This is presumably due to the quality of the word embeddings, as well as the increased morphological complexity of Basque.

6 Model and Error Analysis

We analyze three aspects of our model in further detail: (i) where most mistakes originate, (ii) the effect of the bilingual lexicon, and (iii) the effect and necessity of the target-language projection matrix M'.

6.1 Phenomena

In order to analyze where each model struggles, we categorize the mistakes and annotate all of the test phrases with one of the following error classes: vocabulary (voc), adverbial modifiers (mod), negation (neg), external knowledge (know) or other. Table 4 shows the results.

Vocabulary: The most common way to express sentiment in hotel reviews is through the use of polar adjectives (as in "the room was great) or the mention of certain nouns that are desirable ("it had a pool"). Although this phenomenon has the largest total number of mistakes (an average of 71 per model on binary and 167 on 4-class), it is mainly due to its prevalence. MT performed the best on the test examples which according to the annotation require a correct understanding of the vocabulary (81 F_1 on binary /54 F_1 on 4-class), with BLSE (79/48) slightly worse. ARTETXE (70/35) and BARISTA (67/41) perform significantly worse. This suggests that BLSE is better ARTETXE and BARISTA at transferring sentiment of the most important sentiment bearing words.

Negation: Negation is a well-studied phenomenon in sentiment analysis (Pang et al., 2002; Wiegand et al., 2010; Zhu et al., 2014; Reitan et al., 2015). Therefore, we are interested in how these four models perform on phrases that include the negation of a key element, for example "In general, this hotel isn't bad". We would like our models to recognize that the combination of two negative elements "isn't" and "bad" lead to a *Positive* label.

Given the simple classification strategy, all models perform relatively well on phrases with negation (all reach nearly 60 F_1 in the binary setting). However, while BLSE performs the best on negation in the binary setting (82.9 F_1), it has more problems with negation in the 4-class setting (36.9 F_1).

Adverbial Modifiers: Phrases that are modified by an adverb, *e. g.*, the food was *incredibly* good, are important for the four-class setup, as they often differentiate between the base and *Strong* labels. In the binary case, all models reach more than 55 F_1. In the 4-class setup, BLSE only achieves 27.2 F_1 compared to 46.6 or 31.3 of MT and BARISTA, respectively. Therefore, presumably, our model does currently not capture the semantics of the target adverbs well. This is likely due to the fact that it assigns too much sentiment to functional words (see Figure 6).

External Knowledge Required: These errors are difficult for any of the models to get correct. Many of these include numbers which imply positive or negative sentiment (350 meters from the beach is *Positive* while 3 kilometers from the beach is *Negative*). BLSE performs the best (63.5 F_1) while MT performs comparably well (62.5). BARISTA performs the worst (43.6).

Binary vs. 4-class: All of the models suffer when moving from the binary to 4-class setting; an average of 26.8 in macro F_1 for MT, 31.4 for ARTETXE, 22.2 for BARISTA, and for 36.6 BLSE. The two vector projection methods (ARTETXE and BLSE) suffer the most, suggesting that they are currently more apt for the binary setting.

6.2 Effect of Bilingual Lexicon

We analyze how the number of translation pairs affects our model. We train on the 4-class Spanish setup using the best hyper-parameters from the previous experiment.

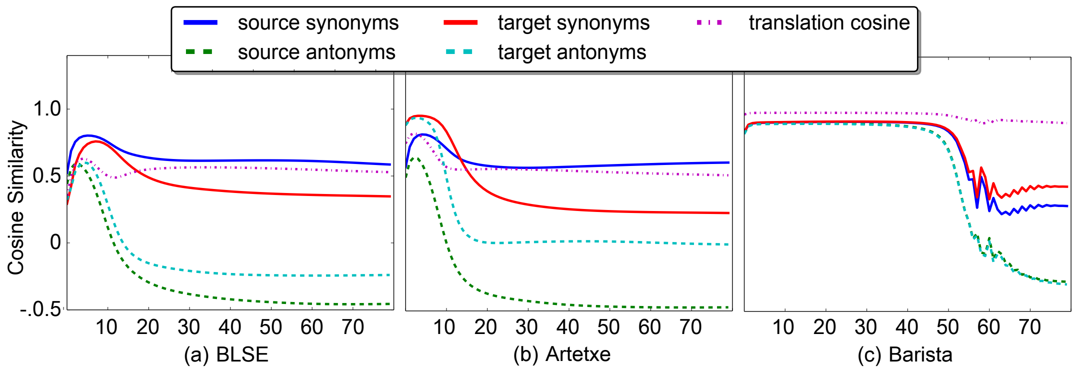

Figure 4: Average cosine similarity between a subsample of translation pairs of same polarity ("sentiment synonyms") and of opposing polarity ("sentiment antonyms") in both target and source languages in each model. The x-axis shows training epochs. We see that BLSE is able to learn that sentiment synonyms should be close to one another in vector space and sentiment antonyms should not.

Research into projection techniques for bilingual word embeddings (Mikolov et al., 2013; Lazaridou et al., 2015; Artetxe et al., 2016) often uses a lexicon of the most frequent 8–10 thousand words in English and their translations as training data. We test this approach by taking the 10,000 word-to-word translations from the Apertium English-to-Spanish dictionary[9]. We also use the Google Translate API to translate the NRC hashtag sentiment lexicon (Mohammad et al., 2013) and keep the 22,984 word-to-word translations. We perform the same experiment as above and vary the amount of training data from 0, 100, 300, 600, 1000, 3000, 6000, 10,000 up to 20,000 training pairs. Finally, we compile a small hand translated dictionary of 200 pairs, which we then expand using target language morphological information, finally giving us 657 translation pairs[10]. The macro F_1 score for the Bing Liu dictionary climbs constantly with the increasing translation pairs. Both the Apertium and NRC dictionaries perform worse than the translated lexicon by Bing Liu, while the expanded hand translated dictionary is competitive, as shown in Figure 3.

While for some tasks, *e. g.*, bilingual lexicon induction, using the most frequent words as translation pairs is an effective approach, for sentiment analysis, this does not seem to help. Using a translated sentiment lexicon, even if it is small, gives better results.

[9]http://www.meta-share.org

[10]The translation took approximately one hour. We can extrapolate that hand translating a sentiment lexicon the size of the Bing Liu lexicon would take no more than 5 hours.

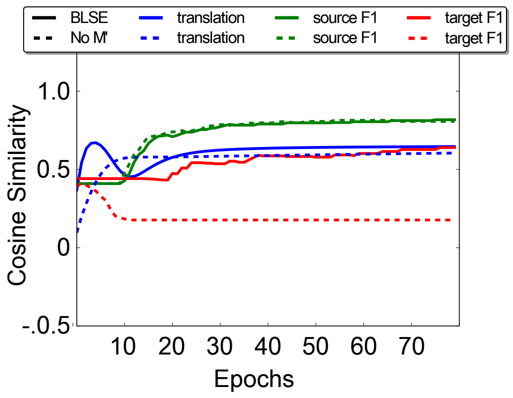

Figure 5: BLSE model (solid lines) compared to a variant without target language projection matrix M' (dashed lines). "Translation" lines show the average cosine similarity between translation pairs. The remaining lines show F_1 scores for the source and target language with both varints of BLSE. The modified model cannot learn to predict sentiment in the target language (red lines). This illustrates the need for the second projection matrix M'.

6.3 Analysis of M'

The main motivation for using two projection matrices M and M' is to allow the original embeddings to remain stable, while the projection matrices have the flexibility to align translations and separate these into distinct sentiment subspaces. To justify this design decision empirically, we perform an experiment to evaluate the actual need for the target language projection matrix M': We create a simplified version of our model without M', using M to project from the source to target and then P to classify sentiment.

The results of this model are shown in Figure 5. The modified model does learn to predict in the source language, but not in the target language. This confirms that M' is necessary to transfer sentiment in our model.

7 Qualitative Analyses of Joint Bilingual Sentiment Space

In order to understand how well our model transfers sentiment information to the target language, we perform two qualitative analyses. First, we collect two sets of 100 positive sentiment words and one set of 100 negative sentiment words. An effective cross-lingual sentiment classifier using embeddings should learn that two positive words should be closer in the shared bilingual space than a positive word and a negative word. We test if BLSE is able to do this by training our model and after every epoch observing the mean cosine similarity between the sentiment synonyms and sentiment antonyms after projecting to the joint space.

We compare BLSE with ARTETXE and BARISTA by replacing the Linear SVM classifiers with the same multi-layer classifier used in BLSE and observing the distances in the hidden layer. Figure 4 shows this similarity in both source and target language, along with the mean cosine similarity between a held-out set of translation pairs and the macro F_1 scores on the development set for both source and target languages for BLSE, BARISTA, and ARTETXE. From this plot, it is clear that BLSE is able to learn that sentiment synonyms should be close to one another in vector space and antonyms should have a negative cosine similarity. While the other models also learn this to some degree, jointly optimizing both sentiment and projection gives better results.

Secondly, we would like to know how well the projected vectors compare to the original space. Our hypothesis is that some relatedness and similarity information is lost during projection. Therefore, we visualize six categories of words in t-SNE (Van der Maaten and Hinton, 2008): positive sentiment words, negative sentiment words, functional words, verbs, animals, and transport.

The t-SNE plots in Figure 6 show that the positive and negative sentiment words are rather clearly separated after projection in BLSE. This indicates that we are able to incorporate sentiment information into our target language without any labeled data in the target language. However, the downside of this is that functional words and transportation words are highly correlated with positive sentiment.

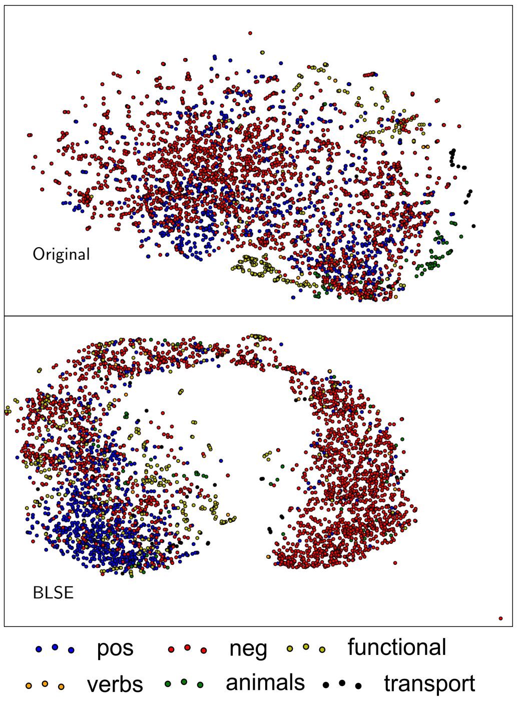

Figure 6: t-SNE-based visualization of the Spanish vector space before and after projection with BLSE. There is a clear separation of positive and negative words after projection, despite the fact that we have used no labeled data in Spanish.

8 Conclusion

We have presented a new model, BLSE, which is able to leverage sentiment information from a resource-rich language to perform sentiment analysis on a resource-poor target language. This model requires less parallel data than MT and performs better than other state-of-the-art methods with similar data requirements, an average of 14 percentage points in F_1 on binary and 4 pp on 4-class cross-lingual sentiment analysis. We have also performed a phenomena-driven error analysis which showed that BLSE is better than ARTETXE and BARISTA at transferring sentiment, but assigns too much sentiment to functional words. In the future, we will extend our model so that it can project multi-word phrases, as well as single words, which could help with negations and modifiers.

Abstract

Word embeddings have been widely used in sentiment classification because of their efficacy for semantic representations of words. Given reviews from different domains, some existing methods for word embeddings exploit sentiment information, but they cannot produce domain-sensitive embeddings. On the other hand, some other existing methods can generate domain-sensitive word embeddings, but they cannot distinguish words with similar contexts but opposite sentiment polarity. We propose a new method for learning domain-sensitive and sentiment-aware embeddings that simultaneously capture the information of sentiment semantics and domain sensitivity of individual words. Our method can automatically determine and produce domain-common embeddings and domain-specific embeddings. The differentiation of domain-common and domain-specific words enables the advantage of data augmentation of common semantics from multiple domains and capture the varied semantics of specific words from different domains at the same time. Experimental results show that our model provides an effective way to learn domain-sensitive and sentiment-aware word embeddings which benefit sentiment classification at both sentence level and lexicon term level.

1 Introduction

Sentiment classification aims to predict the sentiment polarity, such as "positive" or "negative", over a piece of review. It has been a long-standing research topic because of its importance for many applications such as social media analysis, e-commerce, and marketing (Liu, 2012; Pang et al., 2008). Deep learning has brought in progress in various NLP tasks, including sentiment classification. Some researchers focus on designing RNN or CNN based models for predicting sentence level (Kim, 2014) or aspect level sentiment (Li et al., 2018; Chen et al., 2017; Wang et al., 2016). These works directly take the word embeddings pre-trained for general purpose as initial word representations and may conduct fine tuning in the training process. Some other researchers look into the problem of learning task-specific word embeddings for sentiment classification aiming at solving some limitations of applying general pre-trained word embeddings. For example, Tang et al. (2014b) develop a neural network model to convey sentiment information in the word embeddings. As a result, the learned embeddings are **sentiment-aware** and able to distinguish words with similar syntactic context but opposite sentiment polarity, such as the words "good" and "bad". In fact, sentiment information can be easily obtained or derived in large scale from some data sources (e.g., the ratings provided by users), which allows reliable learning of such sentiment-aware embeddings.

Apart from these words (e.g. "good" and "bad") with consistent sentiment polarity in different contexts, the polarity of some sentiment words is **domain-sensitive**. For example, the word "lightweight" usually connotes a positive sentiment in the electronics domain since a lightweight device is easier to carry. In contrast, in the movie domain, the word "lightweight" usually connotes a negative opinion describing movies that do not invoke deep thoughts among the audience. This observation motivates the study of learning domain-sensitive word representations (Yang et al., 2017; Bollegala et al., 2015, 2014). They basically learn separate embeddings of the same word for different domains. To bridge the semantics of individual embedding spaces, they select a subset of words that are likely to be domain-insensitive and align the dimensions of their embeddings. However, the sentiment information is not exploited in these methods although they intend to tackle the task of sentiment classification.

In this paper, we aim at learning word embeddings that are both domain-sensitive and sentiment-aware. Our proposed method can jointly model the sentiment semantics and domain specificity of words, expecting the learned embeddings to achieve superior performance for the task of sentiment classification. Specifically, our method can automatically determine and produce domain-common embeddings and domain-specific embeddings. Domain-common embeddings represent the fact that the semantics of a word including its sentiment and meaning in different domains are very similar. For example, the words "good" and "interesting" are usually domain-common and convey consistent semantic meanings and positive sentiments in different domains. Thus, they should have similar embeddings across domains. On the other hand, domain-specific word embeddings represent the fact that the sentiments or meanings across domains are different. For example, the word "lightweight" represents different sentiment polarities in the electronics domain and the movie domain. Moreover, some polysemous words have different meanings in different domains. For example, the term "apple" refers to the famous technology company in the electronics domain or a kind of fruit in the food domain.

Our model exploits the information of sentiment labels and context words to distinguish domain-common and domain-specific words. If a word has similar sentiments and contexts across domains, it indicates that the word has common semantics in these domains, and thus it is treated as domain-common. Otherwise, the word is considered as domain-specific. The learning of domain-common embeddings can allow the advantage of data augmentation of common semantics of multiple domains, and meanwhile, domain-specific embeddings allow us to capture the varied semantics of specific words in different domains. Specifically, for each word in the vocabulary, we design a distribution to depict the probability of the word being domain-common. The inference of the probability distribution is conducted based on the observed sentiments and contexts. As mentioned above, we also exploit the information of sentiment labels for the learning of word embeddings that can distinguish words with similar syntactic context but opposite sentiment polarity.

To demonstrate the advantages of our domain-sensitive and sentiment-aware word embeddings, we conduct experiments on four domains, including books, DVSs, electronics, and kitchen appliances. The experimental results show that our model can outperform the state-of-the-art models on the task of sentence level sentiment classification. Moreover, we conduct lexicon term sentiment classification in two common sentiment lexicon sets to evaluate the effectiveness of our sentiment-aware embeddings learned from multiple domains, and it shows that our model outperforms the state-of-the-art models on most domains.

2 Related Works

Traditional vector space models encode individual words using the one-hot representation, namely, a high-dimensional vector with all zeroes except in one component corresponding to that word (Baeza-Yates et al., 1999). Such representations suffer from the curse of dimensionality, as there are many components in these vectors due to the vocabulary size. Another drawback is that semantic relatedness of words cannot be modeled using such representations. To address these shortcomings, Rumelhart et al. (1988) propose to use distributed word representation instead, called word embeddings. Several techniques for generating such representations have been investigated. For example, Bengio et al. propose a neural network architecture for this purpose (Bengio et al., 2003; Bengio, 2009). Later, Mikolov et al. (2013) propose two methods that are considerably more efficient, namely skip-gram and CBOW. This work has made it possible to learn word embeddings from large data sets, which has led to the current popularity of word embeddings. Word embedding models have been applied to many tasks, such as named entity recognition (Turian et al., 2010), word sense disambiguation (Collobert et al., 2011; Iacobacci et al., 2016; Zhang and Hasan, 2017; Dave et al., 2018), parsing (Roth and Lapata, 2016), and document classification (Tang et al., 2014a,b; Shi et al., 2017).

Sentiment classification has been a long-standing research topic (Liu, 2012; Pang et al., 2008; Chen et al., 2017; Moraes et al., 2013). Given a review, the task aims at predicting the sentiment polarity on the sentence level (Kim, 2014) or the aspect level (Li et al., 2018; Chen et al., 2017). Supervised learning algorithms have been widely used in sentiment classification (Pang et al., 2002). People usually use different expressions of sentiment semantics in different domains. Due to the mismatch between domain-specific words, a sentiment classifier trained in one domain may not work well when it is directly applied to other domains. Thus cross-domain sentiment classification algorithms have been explored (Pan et al., 2010; Li et al., 2009; Glorot et al., 2011). These works usually find common feature spaces across domains and then share learned parameters from the source domain to the target domain. For example, Pan et al. (2010) propose a spectral feature alignment algorithm to align words from different domains into unified clusters. Then the clusters can be used to reduce the gap between words of the two domains, which can be used to train sentiment classifiers in the target domain. Compared with the above works, our model focuses on learning both domain-common and domain-specific embeddings given reviews from all the domains instead of only transferring the common semantics from the source domain to the target domain.

Some researchers have proposed some methods to learn task-specific word embeddings for sentiment classification (Tang et al., 2014a,b). Tang et al. (2014b) propose a model named SSWE to learn sentiment-aware embedding via incorporating sentiment polarity of texts in the loss functions of neural networks. Without the consideration of varied semantics of domain-specific words in different domains, their model cannot learn sentiment-aware embeddings across multiple domains. Some works have been proposed to learn word representations considering multiple domains (Yang et al., 2017; Bach et al., 2016; Bollegala et al., 2015). Most of them learn separate embeddings of the same word for different domains. Then they choose pivot words according to frequency-based statistical measures to bridge the semantics of individual embedding spaces. A regularization formulation enforcing that word representations of pivot words should be similar in different domains is added into the original word embedding framework. For example, Yang et al. (2017) use Sørensen-Dice coefficient (Sørensen, 1948) for detecting pivot words and learn word representations across domains. Even though they evaluate the model via the task of sentiment classification, sentiment information associated with the reviews are not considered in the learned embeddings. Moreover, the selection of pivot words is according to frequency-based statistical measures in the above works. In our model, the domain-common words are jointly determined by sentiment information and context words.

3 Model Description

We propose a new model, named DSE, for learning **D**omain-sensitive and **S**entiment-aware word **E**mbeddings. For presentation clarity, we describe DSE based on two domains. Note that it can be easily extended for more than two domains, and we remark on how to extend near the end of this section.

3.1 Design of Embeddings

We assume that the input consists of text reviews of two domains, namely $\mathcal{D}^p$ and $\mathcal{D}^q$. Each review r in $\mathcal{D}^p$ and $\mathcal{D}^q$ is associated with a sentiment label y which can take on the value of 1 and 0 denoting that the sentiment of the review is positive and negative respectively.

In our DSE model, each word w in the whole vocabulary Λ is associated with a domain-common vector U_w^c and two domain-specific vectors, namely U_w^p specific to the domain p and U_w^q specific to the domain q. The dimension of these vectors is d. The design of U_w^c, U_w^p and U_w^q reflects one characteristic of our model: allowing a word to have different semantics across different domains. The semantic of each word includes not only the semantic meaning but also the sentiment orientation of the word. If the semantic of w is consistent in the domains p and q, we use the vector U_w^c for both domains. Otherwise, w is represented by U_w^p and U_w^q for p and q respectively.

In traditional cross-domain word embedding methods (Yang et al., 2017; Bollegala et al., 2015, 2016), each word is represented by different vectors in different domains without differentiation of domain-common and domain-specific words. In contrast to these methods, for each word w, we use a latent variable z_w to depict its domain commonality. When $z_w = 1$, it means that w is common in both domains. Otherwise, w is specific to the domain p or the domain q.

In the standard skip-gram model (Mikolov et al., 2013), the probability of predicting the context words is only affected by the relatedness with the target words. In our DSE model, predicting the context words also depends on the domain-commonality of the target word, i.e z_w. For example, assume that there are two domains, e.g. the electronics domain and the movie domain. If $z_w = 1$, it indicates a high probability of generating some domain-common words such as "good", "bad" or "satisfied". Otherwise, the domain-specific words are more likely to be generated such as "reliable", "cheap" or "compacts" for the electronics domain. For a word w, we assume that the probability of predicting the context word w_t is formulated as follows:

$$p(w_t|w) = \sum_{k\in\{0,1\}} p(w_t|w, z_w = k)p(z_w = k) \tag{1}$$

If w is a domain-common word without differentiating p and q, the probability of predicting w_t can be defined as:

$$p(w_t|w, z_w = 1) = \frac{\exp(U_w^c \cdot V_{w_t})}{\sum_{w'\in\Lambda} \exp(U_w^c \cdot V_{w'})} \tag{2}$$

where Λ is the whole vocabulary and $V_{w'}$ is the output vector of the word w'.

If w is a domain-specific word, the probability of $p(w_t|w, z_w = 0)$ is specific to the occurrence of w in $\mathcal{D}^p$ or $\mathcal{D}^q$. For individual training instances, the occurrences of w in $\mathcal{D}^p$ or $\mathcal{D}^q$ have been established. Then the probability of $p(w_t|w, z_w = 0)$ can be defined as follows:

$$p(w_t|w, z_w = 0) = \begin{cases} \frac{\exp(U_w^p \cdot V_{w_t})}{\sum_{w'\in\Lambda} \exp(U_w^p \cdot V_{w'})}, \text{if } w \in \mathcal{D}^p \\ \frac{\exp(U_w^q \cdot V_{w_t})}{\sum_{w'\in\Lambda} \exp(U_w^q \cdot V_{w'})}, \text{if } w \in \mathcal{D}^q \end{cases} \tag{3}$$

3.2 Exploiting Sentiment Information

In our DSE model, the prediction of review sentiment depends on not only the text information but also the domain-commonality. For example, the domain-common word "good" has high probability to be positive in different reviews across multiple domains. However, for the word "lightweight", it would be positive in the electronics domain, but negative in the movie domain. We define the polarity y_w of each word w to be consistent with the sentiment label of the review: if we observe that a review is associated with a positive label, the words in the review are associated with a positive label too. Then, the probability of predicting the sentiment for the word w can be defined as:

$$p(y_w|w) = \sum_{k\in\{0,1\}} p(y_w|w, z_w = k)p(z_w = k) \tag{4}$$

If $z_w = 1$, the word w is a domain-common word. The probability $p(y_w = 1|w, z_w = 1)$ can be defined as:

$$p(y_w = 1|w, z_w = 1) = \sigma(U_w^c \cdot \mathbf{s}) \tag{5}$$

where $\sigma(\cdot)$ is the sigmoid function and the vector s with dimension d represents the boundary of the sentiment. Moreover, we have:

$$p(y_w = 0|w, z_w = 1) = 1 - p(y_w = 1|w, z_w = 1) \tag{6}$$

If w is a domain-specific word, similarly, the probability $p(y_w = 1|w, z_w = 0)$ is defined as:

$$p(y_w = 1|w, z_w = 0) = \begin{cases} \sigma(U_w^p \cdot \mathbf{s}) & \text{if } w \in \mathcal{D}^p \\ \sigma(U_w^q \cdot \mathbf{s}) & \text{if } w \in \mathcal{D}^q \end{cases} \tag{7}$$

3.3 Inference Algorithm

We need an inference method that can learn, given $\mathcal{D}^p$ and $\mathcal{D}^q$, the values of the model parameters, namely, the domain-common embedding U_w^c, and the domain-specific embeddings U_w^p and U_w^q, as well as the domain-commonality distribution $p(z_w)$ for each word w. Our inference method combines the Expectation-Maximization (EM) method with a negative sampling scheme. It is summarized in Algorithm 1. In the E-step, we use the Bayes rule to evaluate the posterior distribution of z_w for each word and derive the objective function. In the M-step, we maximize the objective function with the gradient descent method and

Algorithm 1 EM negative sampling for DSE

```
1:  Initialize $U_w^c$, $U_w^p$, $U_w^q$, $V$, s, $p(z_w)$
2:  for $iter = 1$ to $Max\_iter$ do
3:      for each review $r$ in $\mathcal{D}^p$ and $\mathcal{D}^q$ do
4:          for each word $w$ in $r$ do
5:              Sample negative instances from the distribution P.
6:              Update $p(z_w|w, c_w, y_w)$ by Eq. 11 and Eq. 15 respectively.
7:          end for
8:      end for
9:      Update $p(z_w)$ using Eq. 13
10:     Update $U_w^c$, $U_w^p$, $U_w^q$, $V$, s via Maximizing Eq. 14
11: end for
```

update the corresponding embeddings U_w^c, U_w^p and U_w^q.

With the input of $\mathcal{D}^p$ and $\mathcal{D}^q$, the likelihood function of the whole training set is:

$$\mathcal{L} = \mathcal{L}^p + \mathcal{L}^q \tag{8}$$

where $\mathcal{L}^p$ and $\mathcal{L}^q$ are the likelihood of $\mathcal{D}^p$ and $\mathcal{D}^q$ respectively.

For each review r from $\mathcal{D}^p$, to learn domain-specific and sentiment-aware embeddings, we wish to predict the sentiment label and context words together. Therefore, the likelihood function is defined as follows:

$$\mathcal{L}^p = \sum_{r\in\mathcal{D}^p}\sum_{w\in r}\log p(y_w, c_w|w) \tag{9}$$

where y_w is the sentiment label and c_w is the set of context words of w. For the simplification of the model, we assume that the sentiment label y_w and the context words c_w of the word w are conditionally dependent. Then the likelihood $\mathcal{L}^p$ can be rewritten as:

$$\begin{aligned}\mathcal{L}^p = &\sum_{r\in\mathcal{D}^p}\sum_{w\in r}\sum_{w_t\in c_w}\log p(w_t|w)+\\ &\sum_{r\in\mathcal{D}^p}\sum_{w\in r}\log p(y_w|w)\end{aligned} \tag{10}$$

where $p(w_t|w)$ and $p(y_w|w)$ are defined in Eq. 1 and Eq. 4 respectively. The likelihood of the reviews from $\mathcal{D}^q$, i.e $\mathcal{L}^q$, is defined similarly.

For each word w in the review r, in the E-step, the posterior probability of z_w given c_w and y_w is:

$$p(z_w = k|w, c_w, y_w) = \frac{p(z_w = k)p(y_w|w, z_w = k)\prod_{w_t\in c_w} p(w_t|w, z_w = k)}{\sum_{k'\in\{0,1\}} p(z_w = k')p(y_w|w, z_w = k')\prod_{w_t\in c_w} p(w_t|w, z_w = k')} \tag{11}$$

In the M-step, given the posterior distribution of z_w in Eq. 11, the goal is to maxmize the following Q function:

$$\begin{aligned}\mathbf{Q} = &\sum_{r\in\{\mathcal{D}^p,\mathcal{D}^q\}}\sum_{w\in r}\sum_{z_w} p(z_w|w, y_w, w_{t+j})\\ &\times\log(p(z_w)p(c_w, y|z, w_t))\\ = &\sum_{r\in\{\mathcal{D}^p,\mathcal{D}^q\}}\sum_{w\in r}\sum_{z_w} p(z_w|w, y_w, c_w)\\ &[\log p(z_w) + \log(y_w|z, w)+\\ &\sum_{w_t\in c_w}\log p(w_t|z_w, w)]\end{aligned} \tag{12}$$

Using the Lagrange multiplier, we can obtain the update rule of $p(z_w)$, satisfying the normalization constraints that $\sum_{z_w\in 0,1} p(z_w) = 1$ for each word w:

$$p(z_w) = \frac{\sum_{r\in\{\mathcal{D}^p,\mathcal{D}^q\}}\sum_{w\in r} p(z_w|w, y_w, c_w)}{\sum_{r\in\{\mathcal{D}^p,\mathcal{D}^q\}} n(w, r)} \tag{13}$$

where $n(w, r)$ is the number of occurrence of the word w in the review r.

To obtain U_w^c, U_w^p and U_w^q, we collect the related items in Eq. 12 as follows:

$$\begin{aligned}\mathbf{Q_U} = &\sum_{r\in\{\mathcal{D}^p,\mathcal{D}^q\}}\sum_{w\in r}\sum_{z_w} p(z_w|w, y_w, w_{t+j})\\ &[\log(y_w|z_w, w) + \sum_{w_t\in c_w}\log p(w_t|z_w, w)]\end{aligned} \tag{14}$$

Note that computing the value $p(w_t|w, z_w)$ based on Eq. 2 and Eq. 3 is not feasible in practice, given that the computation cost is proportional to the size of Λ. However, similar to the skip-gram model, we can rely on negative sampling to address this issue. Therefore we estimate the probability of predicting the context word $p(w_t|w, z_w = 1)$ as follows:

$$\begin{aligned}\log p(w_t|w, z_w = 1) \propto &\log\sigma(U_w^c\cdot V_{w_t})\\ &+\sum_{i=1}^{n}\mathbf{E}_{w_i\sim P}[\log\sigma(-U_w^c\cdot V_{w_i})]\end{aligned} \tag{15}$$

where w_i is a negative instance which is sampled from the word distribution $P(.)$. Mikolov et al. (2013) have investigated many choices for $P(w)$ and found that the best $P(w)$ is equal to the unigram distribution $Unigram(w)$ raised to the $3/4rd$ power. We adopt the same setting. The probability $p(w_t|w, z_w = 0)$ in Eq. 3 can be approximated in a similar manner.

After the substitution of $p(w_t|w, z_w)$, we use the Stochastic Gradient Descent method to maximize Eq. 14, and obtain the update of U^c_w, U^p_w and U^q_w.

3.4 More Discussions

In our model, for simplifying the inference algorithm and saving the computational cost, we assume that the target word w_t in the context and the sentiment label y_w of the word w are conditionally independent. Such technique has also been used in other popular models such as the bi-gram language model. Otherwise, we need to consider the term $p(w_t|w, y_w)$, which complicates the inference algorithm.

We define the formulation of the term $p(w_t|w, z)$ to be similar to the original skip-gram model instead of the CBOW model. The CBOW model averages the context words to predict the target word. The skip-gram model uses pairwise training examples which are much easier to integrate with sentiment information.

Note that our model can be easily extended to more than two domains. Similarly, we use a domain-specific vector for each word in each domain and each word is also associated with a domain-common vector. We just need to extend the probability distribution of z_w from Bernoulli distribution to Multinomial distribution according to the number of domains.

4 Experiment

4.1 Experimental Setup

We conducted experiments on the Amazon product reviews collected by Blitzer et al. (2007). We use four product categories: books (**B**), DVDs (**D**), electronic items (**E**), and kitchen appliances (**K**). A category corresponds to a domain. For each domain, there are 17,457 unlabeled reviews on average associated with rating scores from 1.0 to 5.0 for each domain. We use unlabeled reviews with rating score higher than 3.0 as positive reviews and unlabeled reviews with rating score lower than 3.0 as negative reviews for embedding learning. We first remove reviews whose length is less than 5 words. We also remove punctuations and the stop words. We also stem each word to its root form using Porter Stemmer (Porter, 1980). Note that this review data is used for embedding learning, and the learned embeddings are used as feature vectors of words to conduct the experiments in the later two subsections.

Given the reviews from two domains, namely, $\mathcal{D}^p$ and $\mathcal{D}^q$, we compare our results with the following baselines and state-of-the-art methods:

SSWE The SSWE model[1] proposed by Tang et al. (2014b) can learn sentiment-aware word embeddings from tweets. We employ this model on the combined reviews from $\mathcal{D}^p$ and $\mathcal{D}^q$ and then obtain the embeddings.

Yang's Work Yang et al. (2017) have proposed a method[2] to learn domain-sensitive word embeddings. They choose pivot words and add a regularization item into the original skip-gram objective function enforcing that word representations of pivot words for the source and target domains should be similar. The method trains the embeddings of the source domain first and then fixes the learned embedding to train the embedding of the target domain. Therefore, the learned embedding of the target domain benefits from the source domain. We denote the method as Yang in short.

EmbeddingAll We learn word embeddings from the combined unlabeled review data of $\mathcal{D}^p$ and $\mathcal{D}^q$ using the skip-gram method (Mikolov et al., 2013).

EmbeddingCat We learn word embeddings from the unlabeled reviews of $\mathcal{D}^p$ and $\mathcal{D}^q$ respectively. To represent a word for review sentiment classification, we concatenate its learned word embeddings from the two domains.

EmbeddingP and EmbeddingQ In EmbeddingP, we use the original skip-gram method (Mikolov et al., 2013) to learn word

Table 1: Results of review sentiment classification. The markers † and $^{\natural}$ refer to p-value < 0.05 when comparing with Yang and SSWE respectively.

embeddings only from the unlabeled reviews of $\mathcal{D}^p$. Similarly, we only adopt the unlabeled reviews from $\mathcal{D}^q$ to learn embeddings in EmbeddingQ.

BOW We use the traditional bag of words model to represent each review in the training data.

For our DSE model, we have two variants to represent each word. The first variant DSE$_c$ represents each word via concatenating the domain-common vector and the domain-specific vector. The second variant DSE$_w$ concatenates domain-common word embeddings and domain-specific word embeddings by considering the domain-commonality distribution $p(z_w)$. For individual review instances, the occurrences of w in $\mathcal{D}_p$ or $\mathcal{D}_q$ have been established. The representation of w is specific to the occurrence of w in $\mathcal{D}_p$ or $\mathcal{D}_q$. Specifically, each word w can be represented as follows:

$$U_w = \begin{cases} \text{if } w \in \mathcal{D}^p \\ \quad U_w^c \times p(z_w) \oplus U_w^p \times (1.0 - p(z_w)) \\ \text{if } w \in \mathcal{D}^q \\ \quad U_w^c \times p(z_w) \oplus U_w^q \times (1.0 - p(z_w)) \end{cases} \tag{16}$$

where $\oplus$ denotes the concatenation operator.

For all word embedding methods, we set the dimension to 200. For the skip-gram based methods, we sample 5 negative instances and the size of the windows for each target word is 3. For our DSE model, the number of iterations for the whole reviews is 100 and the learning rate is set to 1.0.

4.2 Review Sentiment Classification

For the task of review sentiment classification, we use 1000 positive and 1000 negative sentiment reviews labeled by Blitzer et al. (2007) for each domain to conduct experiments. We randomly select 800 positive and 800 negative labeled reviews from each domain as training data, and the remaining 200 positive and 200 negative labeled reviews as testing data. We use the SVM classifier (Fan et al., 2008) with linear kernel to train on the training reviews for each domain, with each review represented as the average vector of its word embeddings.

We use two metrics to evaluate the performance of sentiment classification. One is the standard accuracy metric. The other one is Macro-F1, which is the average of F1 scores for both positive and negative reviews.

We conduct multiple trials by selecting every possible two domains from books (**B**), DVDs (**D**), electronic items (**E**) and kitchen appliances (**K**). We use the average of the results of each two domains. The experimental results are shown in Table 1.

From Table 1, we can see that compared with other baseline methods, our DSE$_w$ model can achieve the best performance of sentiment classification across most combinations of the four domains. Our statistical t-tests for most of the combinations of domains show that the improvement of our DSE$_w$ model over Yang and SSWE is statistically significant respectively (p-value < 0.05) at 95% confidence level. It shows that our method can capture the domain-commonality and sentiment information at the same time.

Even though both of the SSWE model and our DSE model can learn sentiment-aware word embeddings, our DSE$_w$ model can outperform SSWE. It demonstrates that compared with general sentiment-aware embeddings, our learned domain-common and domain-specific word em-

DSE	0.802	0.788	**0.833**	**0.828**	**0.832**	0.799	0.804	**0.797**	**0.796**	**0.786**	**0.725**	**0.683**

Table 2: Results of lexicon term sentiment classification.

beddings can capture semantic variations of words across multiple domains.

Compared with the method of Yang which learns cross-domain embeddings, our DSE$_w$ model can achieve better performance. It is because we exploit sentiment information to distinguish domain-common and domain-specific words during the embedding learning process. The sentiment information can also help the model distinguish the words which have similar contexts but different sentiments.

Compared with EmbeddingP and EmbeddingQ, the methods of EmbeddingAll and EmbeddingCat can achieve better performance. The reason is that the data augmentation from other domains helps sentiment classification in the original domain. Our DSE model also benefits from such kind of data augmentation with the use of reviews from $\mathcal{D}^p$ and $\mathcal{D}^q$.

We observe that our DSE$_w$ variant performs better than the variant of DSE$_c$. Compared with DSE$_c$, our DSE$_w$ variant adds the item of $p(z_w)$ as the weight to combine domain-common embeddings and domain-specific embeddings. It shows that the domain-commonality distribution in our DSE model, i.e $p(w_z)$, can effectively model the domain-sensitive information of each word and help review sentiment classification.

4.3 Lexicon Term Sentiment Classification

To further evaluate the quality of the sentiment semantics of the learned word embeddings, we also conduct lexicon term sentiment classification on two popular sentiment lexicons, namely **HL** (Hu and Liu, 2004) and **MPQA** (Wilson et al., 2005). The words with neutral sentiment and phrases are removed. The statistics of **HL** and **MPQA** are shown in Table 3.

We conduct multiple trials by selecting every possible two domains from books (**B**), DVDs (**D**), electronics items (**E**) and kitchen appliances (**K**).

Lexicon	Positive	Negative	Total
HL	1,331	2,647	3,978
MPQA	1,932	2,817	3,075

Table 3: Statistics of the sentiment lexicons.

For each trial, we learn the word embeddings. For our DSE model, we only use the domain-common part to represent each word because the lexicons are usually not associated with a particular domain. For each lexicon, we select 80% to train the SVM classifier with linear kernel and the remaining 20% to test the performance. The learned embedding is treated as the feature vector for the lexicon term. We conduct 5-fold cross validation on all the lexicons. The evaluation metric is Macro-F1 of positive and negative lexicons.

Table 2 shows the experimental results of lexicon term sentiment classification. Our DSE method can achieve competitive performance among all the methods. Compared with SSWE, our DSE is still competitive because both of them consider the sentiment information in the embeddings. Our DSE model outperforms other methods which do not consider sentiments such as Yang, EmbeddingCat and EmbeddingAll. Note that the advantage of domain-sensitive embeddings would be insufficient for this task because the sentiment lexicons are not domain-specific.

5 Case Study

Table 4 shows the probabilities of "lightweight", "die", "mysterious", and "great" to be domain-common for different domain combinations. For "lightweight", its domain-common probability for the books domain and the DVDs domain ("B & D") is quite high, i.e. $p(z = 1) = 0.999$, and the review examples in the last column show that the word "lightweight" expresses the meaning of lacking depth of content in books or movies. Note that most reviews of DVDs are about movies.

Term	Domain	$p(z=1)$	Sample Reviews
“lightweight”	B & D	0.999	- I find Seth Godin’s books incredibly **lightweight**. There is really nothing of any substance here.(`B`) - I love the fact that it’s small and **lightweight** and fits into a tiny pocket on my camera case so I never lose track of it.(`E`) - These are not ”**lightweight**” actors. (`D`) - This vacuum does a pretty good job. It is **lightweight** and easy to use.(`K`)
	B & E	0.404	
	B & K	0.241	
	D & E	0.380	
	D & K	0.013	
	E & K	0.696	
“die”	B & E	0.435	- I’m glad Brando lived long enough to get old and fat, and that he didn’t **die** tragically young like Marilyn, JFK, or Jimi Hendrix.(`B`) - Like many others here, my CD-changer **died** after a couple of weeks and it wouldn’t read any CD.(`E`) - I had this toaster for under 3 years when I came home one day and it smoked and **died**. (`K`)
	B & K	0.492	
	E & K	0.712	
“mysterious”	B & E	0.297	- This novel really does cover the gamut: stunning twists, genuine love, beautiful settings, desire for riches, **mysterious** murders, detective investigations, false accusations, and self vindication.(`B`) - Caller ID functionality for Vonage **mysteriously** stopped working even though this phone’s REN is rated at 0.1b. (`E`)
“great”	B & D	0.760	- This is a **great** book for anyone learning how to handle dogs.(`B`) - This is a **great** product, and you can get it, along with any other products on Amazon up to $500 Free!(`E`) - I grew up with drag racing in the 50s, 60s & 70s and this film gives a **great** view of what it was like.(`D`) - This is a **great** mixer its a little loud but worth it for the power you get.(`K`)
	B & E	0.603	
	B & K	0.628	
	D & E	0.804	
	D & K	0.582	
	E & K	0.805	

Table 4: Learned domain-commonality for some words. $p(z = 1)$ denotes the probability that the word is domain-common. The letter in parentheses indicates the domain of the review.

In the electronics domain and the kitchen appliances domain (“E & K”), “lightweight” means light material or weighing less than average, thus the domain-common probability for these two domains is also high, 0.696. In contrast, for the other combinations, the probability of “lightweight” to be domain-common is much smaller, which indicates that the meaning of “lightweight” varies. Similarly, “die” in the domains of electronics and kitchen appliances (“E & K”) means that something does not work any more, thus, we have $p(z = 1) = 0.712$. While for the books domain, it conveys meaning that somebody passed away in some stories. The word “mysterious” conveys a positive sentiment in the books domain, indicating how wonderful a story is, but it conveys a negative sentiment in the electronics domain typically describing that a product breaks down unpredictably. Thus, its domain-common probability is small. The last example is the word “great”, and it usually has positive sentiment in all domains, thus has large values of $p(z = 1)$ for all domain combinations.

6 Conclusions

We propose a new method of learning domain-sensitive and sentiment-aware word embeddings. Compared with existing sentiment-aware embeddings, our model can distinguish domain-common and domain-specific words with the consideration of varied semantics across multiple domains. Compared with existing domain-sensitive methods, our model detects domain-common words according to not only similar context words but also sentiment information. Moreover, our learned embeddings considering sentiment information can distinguish words with similar syntactic context but opposite sentiment polarity. We have conducted experiments on two downstream sentiment classification tasks, namely review sentiment classification and lexicon term sentiment classification. The experimental results demonstrate the advantages of our approach.

Abstract

The task of adopting a model with good performance to a target domain that is different from the source domain used for training has received considerable attention in sentiment analysis. Most existing approaches mainly focus on learning representations that are domain-invariant in both the source and target domains. Few of them pay attention to domain specific information, which should also be informative. In this work, we propose a method to simultaneously extract domain specific and invariant representations and train a classifier on each of the representation, respectively. And we introduce a few target domain labeled data for learning domain-specific information. To effectively utilize the target domain labeled data, we train the domain-invariant representation based classifier with both the source and target domain labeled data and train the domain-specific representation based classifier with only the target domain labeled data. These two classifiers then boost each other in a co-training style. Extensive sentiment analysis experiments demonstrated that the proposed method could achieve better performance than state-of-the-art methods.

1 Introduction

Sentiment classification aims to automatically predict sentiment polarity of user generated sentiment data like movie reviews. The exponential increase in the availability of online reviews and recommendations makes it an interesting topic in research and industrial areas. However, reviews can span so many different domains that it is difficult to gather annotated training data for all of them. This has motivated much research on cross-domain sentiment classification which transfers the knowledge from label rich domain (source domain) to the label few domain (target domain).

[*]Corresponding author.

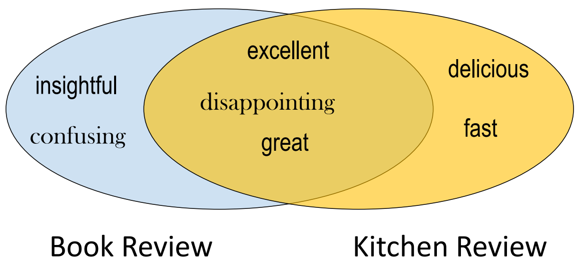

Figure 1: Top indicators extracted with logistic regression for Book and Kitchen domains. The overlap between the two ellipses denotes the shared features between these two domains.

In recent years, the most popular cross-domain sentiment classification approach is to extract domain invariant features, whose distribution in the source domain is close to that in the target domain. (Glorot et al., 2011; Fernando et al., 2013; Kingma and Welling, 2013; Aljundi et al., 2015; Baochen Sun, 2015; Long et al., 2015; Ganin et al., 2016; Zellinger et al., 2017). And based on this representation, it trains a classifier with the source rich labeled data. Specifically, for data of the source domain $\mathbf{X}_s$ and data of the target domain $\mathbf{X}_t$, it trains a feature generator $G(\cdot)$ with restriction $P(G(\mathbf{X}_s)) \approx P(G(\mathbf{X}_t))$. And the classifier is trained on $G(\mathbf{X}_s)$ with the source labels $\mathbf{Y}_s$. The main difference of these approaches is the mechanism to incorporate the restriction on $G(\cdot)$ into the system. The major limitation of this framework is that it losses the domain specific information. As depicted in Figure1, even if it can perfectly extract the domain invariant features (e.g., excellent), it will loss some strong indicators (e.g., delicious, fast) of the target Kitchen domain. We believe that it can achieve greater improvement if it can effectively make use of this information.

Thus, in this work, we try to explore a path to use the target domain specific information with as few as possible target labeled data. Specifically, we first introduce a novel method to extract the domain invariant and domain specific features of target domain data. Then, we treat these two representations as two different views of the target domain data and accordingly train a domain invariant classifier and a target domain specific classifier, respectively. Because the domain invariant representation is compatible with both source data and target data, we train the domain invariant classifier with both source and target labeled data. And for the target domain specific classifier, we train it with target labeled data only. Based on these two classifiers, we perform co-training on target unlabeled data, which can further improve the usage of target data in a bootstrap style.

In summary, the contributions of this paper include: (i) This is the first work to explore the usage of target domain specific information in cross-domain sentiment classification task. (ii) We propose a novel to extract the domain specific representation of target domain data, which encodes the individual characteristics of the target domain.

2 Related Work

Domain adaptation aims to generalize a classifier that is trained on a source domain, for which typically plenty of labeled data is available, to a target domain, for which labeled data is scarce. In supervised domain adaptation, cross-domain classifiers are learnt by using labeled source samples and a small number of labeled target samples (Hoffman et al., 2014). A common practice is training the cross-domain classifiers with the labeled source data and then fine-tuning the classifier with the target labeled data (Pan and Yang, 2010). Meanwhile, some unsupervised and semi-supervised cross domain methods (Ganin et al., 2016; Louizos et al., 2015; Zellinger et al., 2017) are proposed by combining the transfer of classifiers with the match of distributions. These methods focus on extracting the domain-invariant features with the help of unlabeled data. Specifically, Ganin et al., (2016) incorporated an adversarial framework to perform this task. It trained the feature generator to minimize the classification loss and simutaneously deceive the discriminator, which is trained to distinguish the domain of the input data coming from. Louizos et al., (2015) used the Maximum Mean Discrepancy (Borgwardt et al., 2006) regularizer to constrain the feature generator to extract the domain invariant features. And similarly, Zellinger et al., (2017) proposed the central moment discrepancy (CMD) metric for the role of domain regularizer. The above methods either treat it no difference between domain specific information and domain invariant information or just ignore the domain specific information during in the process of learning adaptive classifiers.

One of the most related work is the DSN model (Bousmalis et al., 2016). It proposed to extract the domain specific and the domain invariant representations, simultaneously. However, It does not explored the usage of the domain specific information. Its classifier was still only trained on the domain invariant representation. This work differs from it in the following two aspects. First, we make use of the source and target unlabeled data to extract domain specific information, instead of relying on the orthogonality constraint between the extra representation and the domain invariant counterpart. It is achieved by forcing the distribution of the source examples and that of the target examples in the domain specific space to be different. We argue that this can avoid the potential problem of the orthogonality constraint in that the domain specific representation can be well predicted by the domain invariant representation, while simultaneously meeting the orthogonality constraint. For example, let $\boldsymbol{X} = (\boldsymbol{0}, \boldsymbol{Z})$ be the domain invariant representation and $\boldsymbol{Y} = (\boldsymbol{Z}, \boldsymbol{0})$ be the domain specific representation, then $\boldsymbol{X}$ can be uniquely determined by $\boldsymbol{Y}$, while in the meanwhile $\boldsymbol{X} \perp \boldsymbol{Y}$. Second, we apply a co-training framework to make use of the domain specific representation, rather than simply treating it as a regularizer for extracting the domain invariant representation.

Another related work is the CODA model (Chen et al., 2011). It also applied a co-training framework for semi-supervised domain adaptation. However, instead of dividing the feature space into domain invariant and domain specific

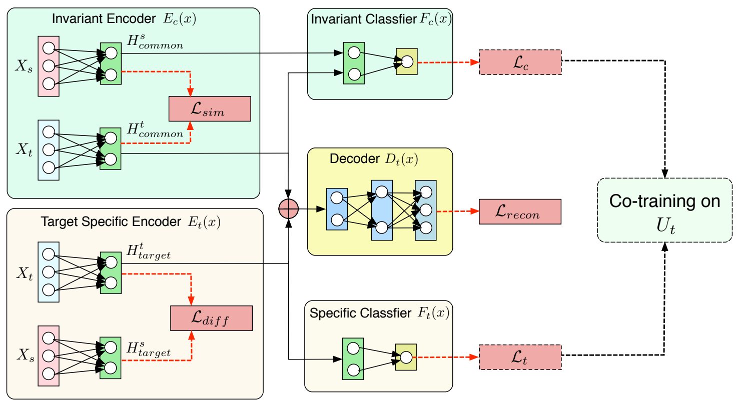

Figure 2: The general architecture of the proposed model. The source data $\boldsymbol{X}_s$ and target data $\boldsymbol{X}_t$ are mapped to a domain invariant representation and a target domain specific representation by feature maps E_c and E_t, respectively. In the space of the domain invariant representation, the distributions of source data $\boldsymbol{H}^s_{inv}$ and target data $\boldsymbol{H}^t_{common}$ are forced to be similar by minimizing a certain distance $\mathcal{L}_{sim}$. In contrast, in the space of the target domain specific representation, the distributions of source data $\boldsymbol{H}^s_{spec}$ and target data $\boldsymbol{H}^t_{spec}$ are forced to be different by minimizing the distance $\mathcal{L}_{diff}$. Based on the domain invariant representation, a classifier F_c is trained with the source rich labeled data and some of the target labeled data. In addition, based on the target domain specific representation, a classifier F_t is trained with the target labeled data only. These two classifiers teach each other in a co-training framework based on the target unlabeled data $\boldsymbol{U}_t$.

parts, it randomly separated the features space.

3 Approach

We consider the following domain adaptation setting. The source domain consists of a set of n_s fully labeled points $D_s = \{(\mathbf{x}^s_1, \mathbf{y}^s_1), \cdots, (\mathbf{x}^s_{n_s}, \mathbf{y}^s_{n_s})\} \subset R^d \times \mathcal{Y}$ drawn from the distribution $P_s(\mathbf{X}, \mathbf{Y})$. And the target data is divided into n_l ($n_l \ll n_s$) labeled points $D^l_t = \{(\mathbf{x}^t_1, \mathbf{y}^t_1), \cdots, (\mathbf{x}^t_{n_l}, \mathbf{y}^t_{n_l}\} \subset R^d \times \mathcal{Y}$ from the distribution $P_t(\mathbf{X}, \mathbf{Y})$ and n_u ($n_u \gg n_l$) unlabeled points $D^u_t = \{(\mathbf{x}^t_{n_l+1}, \mathbf{y}^t_{n_l+1}), \cdots, (\mathbf{x}^t_{n_l+n_u}, \mathbf{y}^t_{n_l+n_u}\} \subset R^d$ from the marginal distribution $P_t(\mathbf{X})$. The goal is to build a classifier for the target domain data using the source domain data and a few labeled target domain data.

In the following section, we first introduce the CMD metric, which is used to measure the probability distribution discrepancy between two random variables. Then, we describe our method to extract the domain specific and domain invariant representations of target domain examples, using the CMD-based regularizer. Finally, we show how to combine these two representations using a co-training framework.

3.1 Central Moment Discrepancy (CMD)

The CMD metric was proposed by Zellinger et al.(2017) to measure the discrepancy between the probability distributions of two (high-dimensional) random variables. It is one of the state-of-the-art metrics and is used as a domain regularizer for domain adaptation. Here, we introduce its definition as a domain regularizer.

Definition 1 *(CMD regularizer). Let X and Y be bounded random samples with respective probability distributions p and q on the interval $[a, b]^N$. The CMD regularizer CMD_K is defined by*

$$CMD_K(X,Y) = \frac{1}{|b-a|} \parallel E(X) - E(Y) \parallel_2 + \frac{1}{|b-a|^k} \sum_{k=2}^{K} \parallel C_k(X) - C_k(Y) \parallel_2, \tag{1}$$

where $E(X) = \frac{1}{|X|}\sum_{x \in X} x$ is the empirical expectation vector computed on the sample X and

$$C_k(X) = \left(E(\prod_{i=1}^{N}(X_i - E(X_i))^{r_i} \right)_{r_i \geq 0, \sum_i^N r_i = k},$$

is the vector of all k^{th} order sample central moments of the coordinates of X.

An intuitive understanding of this metric is that if two probability distributions are similar, their central moment of each order should be close.

3.2 Extract Domain Invariant and Domain Specific Representations

In this work, we aim to extract a domain invariant representation, as well as a domain specific counterpart, for each target example. This makes our work different from most of the existing works, which only focus on the domain invariant representation. The general architecture of the proposed model is illustrated in Figure 2. Data are mapped into a domain invariant hidden space and target domain specific hidden space using two different mappers E_t and E_c, respectively:

$$\begin{aligned} \boldsymbol{H}^s_{spec} &= E_t(\boldsymbol{X}_s; \boldsymbol{\theta}^t_e) \\ \boldsymbol{H}^t_{spec} &= E_t(\boldsymbol{X}_t; \boldsymbol{\theta}^t_e) \\ \boldsymbol{H}^s_{inv} &= E_c(\boldsymbol{X}_s; \boldsymbol{\theta}^c_e) \\ \boldsymbol{H}^t_{inv} &= E_c(\boldsymbol{X}_t; \boldsymbol{\theta}^c_e). \end{aligned} \tag{2}$$

Here, E_t refers to the domain invariant mapper and E_c is the target domain specific mapper. $\boldsymbol{\theta}^t_e$ and $\boldsymbol{\theta}^c_e$ denote their corresponding parameters. The subscript e denotes *encode*. Based on the hidden presentations $\boldsymbol{H}^t_{inv}$ and $\boldsymbol{H}^t_{spec}$, we build an auto-encoder for the target domain examples:

$$\hat{\boldsymbol{X}}_t = D_t(\boldsymbol{H}^t_{inv}, \boldsymbol{H}^t_{spec}; \boldsymbol{\theta}^t_d), \tag{3}$$

with respect to parameters $\boldsymbol{\theta}^t_d$, where the subscript d denotes *decode*. The corresponding reconstruction loss is defined by the mean square error:

$$\mathcal{L}_{recon} = \frac{1}{n_t} \sum_{i}^{n_t} \frac{1}{k} ||\boldsymbol{X}^i_t - \hat{\boldsymbol{X}}_t^{\,i}||^2_2, \tag{4}$$

where k is the dimension of the input feature vector, and $\boldsymbol{X}^i_t$ denotes the i^{th} example of the target domain data. Note that in this work, only target examples are passed to the auto-encoder because we only want to extract target domain specific information.

For E_c, we hope that it only encodes features shared by both the source and target domains. From the distribution view, we hope that the distributions of the mapped outputs, by E_c, of source and target data are similar. To this end, we apply the CMD regularizer onto the hidden representation of source data $\boldsymbol{H}^s_{inv}$ and that of target data $\boldsymbol{H}^t_{inv}$. The corresponding loss is defined by:

$$\mathcal{L}_{sim} = CMD_K(\boldsymbol{H}^s_{inv}, \boldsymbol{H}^t_{inv}). \tag{5}$$

Minimizing this loss will force the distribution of $\boldsymbol{H}^s_{inv}$ and $\boldsymbol{H}^t_{inv}$ to be similar, which in turn encourages E_c to encode domain invariant features.

And for the domain specific encoder E_t, we hope that it only encodes features dominated by the target domain. Ideally, these features should commonly appear in the target domain while hardly appear in the source domain. We argue that this can also be obtained by forcing the distribution of these features in the target domain to differ from that in the source domain, because the target specific auto-encoder D_t should filter out features that hardly appear in the target domain while commonly appear in the source domain. Based on this intuition, we apply a signal flipped CMD regularizer onto the mapped representation of source data $\boldsymbol{H}^s_{spec}$ and that of target data $\boldsymbol{H}^t_{spec}$. The corresponding loss is defined by:

$$\mathcal{L}_{diff} = -CMD_K(\boldsymbol{H}^s_{spec}, \boldsymbol{H}^t_{spec}). \tag{6}$$

Minimizing this loss encourages the distribution of $\boldsymbol{H}^s_{spec}$ to differ from that of $\boldsymbol{H}^t_{spec}$, which in turn encourage E_t to encode domain specific features.

3.3 Co-Training with Domain Invariant and Domain Specific Representations

The co-training algorithm assumes that the data set is presented in two separate views, and two classifiers are trained for each view. In each iteration, some unlabeled examples that are confidently predicted according to exactly one of the two classifiers are moved to the training set. In this way, one classifier provides the predicted labels to the unlabeled examples, on which the other classifier may be uncertain.

In this work, we treat the domain invariant representation and the domain specific representation as the two separate views of target domain examples. Based on the domain invariant representation, we train a domain invariant classifier, F_c, with respect to parameters $\boldsymbol{\theta}_c$. In addition, based on the domain specific representation, we train a domain specific classifier, F_t, with respect to parameters $\boldsymbol{\theta}_t$.

Because the distribution of the source examples is compatible with that of the target examples in

```
input:

        $H^t_{inv}$: Invariant representation of $L_t$
        $H^t_{spec}$: Specific representation of $L_t$
repeat
    Train classifier $F_c$ with $L_s$ and $L_t$ based on $H^s_{inv}$ and $H^t_{inv}$;
    Apply classifier $F_c$ to label $U_t$;
    Select $p$ positive and $n$ negative the most confidently predicted examples $U^c_t$ from $U_t$;
    Train classifier $F_t$ with $L_t$ based on $H^t_{spec}$;
    Apply classifier $F_t$ to label $U_t$;
    Select $p$ positive and $n$ negative the most confidently predicted examples $U^t_t$ from $U_t$;
    Remove examples $U^c_t \cup U^t_t$ from $U_t$;
    Add examples $U^c_t \cup U^t_t$ and their corresponding labels to $L_t$;
until best performance obtained on the developing data set;
```

Algorithm 1: Co-Training for Domain Adaptation

the domain invariant hidden space, we use both the source rich labels and a few target labels to train the classifier F_c. To train the classifier F_t, only the target labels are used. The entire procedure is described in Algorithm 1.

3.4 Model Learning

The training of this model is divided into two parts with one for the domain invariant classifier, F_c, and another one for the domain specific classifier, F_t. For F_c, the goal of training is to minimize the following loss with respect to parameters $\boldsymbol{\Theta} = \{\boldsymbol{\theta}^c_e, \boldsymbol{\theta}^c_e, \boldsymbol{\theta}^t_d, \boldsymbol{\theta}_c\}$:

$$\begin{aligned}\mathcal{L} = \mathcal{L}_{recon}(\boldsymbol{\theta}^c_e, \boldsymbol{\theta}^t_e, \boldsymbol{\theta}^t_d) + \alpha \mathcal{L}_c(\boldsymbol{\theta}^c_e, \boldsymbol{\theta}_c) \\ + \gamma \mathcal{L}_{sim}(\boldsymbol{\theta}^c_e) + \lambda \mathcal{L}_{diff}(\boldsymbol{\theta}^t_e),\end{aligned} \tag{7}$$

where α, γ, and λ are weights that control the interaction of the loss terms. $\mathcal{L}(\theta)$ means that loss, $\mathcal{L}$, is optimized on the parameters θ during training. And $\mathcal{L}_c$ denotes the classification loss on the domain invariant representation, which is defined by the negative log-likelihood of the ground truth class for examples of both source and target domains:

$$\begin{aligned}\mathcal{L}_c = \frac{1}{n_s + l_t} \sum_{i=1}^{n_s} -Y^i_s \log F_c(Y^i_s | E_c(L^i_s)) \\ + \frac{1}{n_s + l_t} \sum_{i=1}^{l_t} -Y^i_t \log F_c(Y^i_t | E_c(L^i_t)),\end{aligned} \tag{8}$$

where Y^i_s is the one-hot encoding of the class label for the i^{th} source example, Y^i_t is that for the i^{th} labeled target example, and l_t denotes the dynamic number of target labeled data in each iteration.

For F_t, the goal of training is to minimize the following loss with respect to parameters $\boldsymbol{\Theta} = \{\boldsymbol{\theta}^c_e, \boldsymbol{\theta}^t_e, \boldsymbol{\theta}^t_d, \boldsymbol{\theta}_t\}$:

$$\begin{aligned}\mathcal{L} = \mathcal{L}_{recon}(\boldsymbol{\theta}^c_e, \boldsymbol{\theta}^t_e, \boldsymbol{\theta}^t_d) + \beta \mathcal{L}_t(\boldsymbol{\theta}^t_e, \boldsymbol{\theta}_t) \\ + \gamma \mathcal{L}_{sim}(\boldsymbol{\theta}^c_e) + \lambda \mathcal{L}_{diff}(\boldsymbol{\theta}^t_e),\end{aligned} \tag{9}$$

where γ and λ are the same weights as those for the classifier F_c, and β is the weight that controls the portion of classification loss, $\mathcal{L}_t$, on the domain specific representation, which is defined by the negative log-likelihood of the ground truth class for examples of the target domain only:

$$\mathcal{L}_t = \frac{1}{l_t} \sum_{i=1}^{l_t} -Y^i_t \log F_t(Y^i_t | E_t(L^i_t)) \tag{10}$$

4 Experiment

4.1 Dataset

Domain adaptation for sentiment classification has been widely studied in the NLP community. The major experiments were performed on the benchmark made of reviews of Amazon products gathered by Blitzer et al. (2007). This data set[1] contains Amazon product reviews from four different domains: Books, DVD, Electronics, and Kitchen appliances from Amazon.com. Each review was originally associated with a rating of 1-5 stars. For simplicity, we are only concerned with whether or not a review is positive (higher than 3 stars) or negative (3 stars or lower). Reviews are encoded in 5,000 dimensional *tf-idf* feature vectors of bag-of-words unigrams and bigrams. From this data, we constructed 12 cross-domain binary classification tasks. Each domain adaptation task consists of 2,000 labeled source examples,

Table 1: Average prediction accuracy with 5 runs on target domain testing data set. The left group of models refer to previous state-of-the-art methods and the right group of models refer to the proposed model and some of its variants. We list the p-values of the T-test between CoCMD and CMD-ft for more intuitive understanding.

2,000 unlabeled target examples, and 50 labeled target examples for training. To fine-tune the hyper-parameters, we randomly select 500 target examples as developing data set, leaving 2,500-5,500 examples for testing. All of the compared methods and CoCMD share this setting.

4.2 Compared Methods

CoCMD is systematically compared with: 1) neural network classifier without any domain adaptation trained on labeled source data only (SO); 2) neural network classifier without any domain adaptation trained on the union of labeled source and target data (ST); 3) unsupervised central moment discrepancy trained with labeled source data only (CMD) (Zellinger et al., 2017); 4) unsupervised domain separation network (DSN) (Bousmalis et al., 2016); 5) semi-supervised CMD trained on labeled source data and then fine-tuned on labeled target data (CMD-ft); 6) semi-supervised DSN trained on labeled source data and then fine-tuned on labeled target data (DSN-ft); 7) semi-supervised Co-training for domain adaptation (CODA) (Chen et al., 2011).

4.3 Implementation Detail

CoCMD was imeplented with a similar architecture to that of Ganin et al., (2016) and Zellinger et al., (2017), with one dense hidden layer with 50 hidden nodes and sigmoid activation functions. The classifiers consist of a softmax layer with two dimensional outputs. And the decoder was implemented with a multilayer perceptron (MLP) with one dense hidden layer, tanh activation functions, and relu output functions.

Model optimization was performed using the RmsProp (Tieleman and Hinton, 2012) update rule with learning rate set to 0.005 for all of the tasks.Hyper-parameter K of the CMD regularizer was set to 3 for all of the tasks, according to the experiment result of Zellinger et al. (2017). For the hyper-parameters α, β, γ, and λ, we took the values that achieve the best performance on the developing data set via a grid search $\{0.01, 0.1, 1, 10, 100\}$. However, instead of building grids on α, β, γ, and λ all at the same time, we first fine-tuned the values of α and β with the values of γ and λ fixed at 1. After that, we fine-tuned the values of γ and λ with α and β fixed at the best values obtained at last step. Though, this practice may miss the best combination of these hyper-parameters, it can greatly reduce the time consuming for fine-tuning and still obtain acceptable results. And for each iteration of the co-training, we set $p = n = 5$.

4.4 Result

Table 1 shows the average classification accuracy of our proposed model and the baselines over all 12 domain adaptation tasks. We can first observe that the proposed model CoCMD outperforms the compared methods over almost all of the

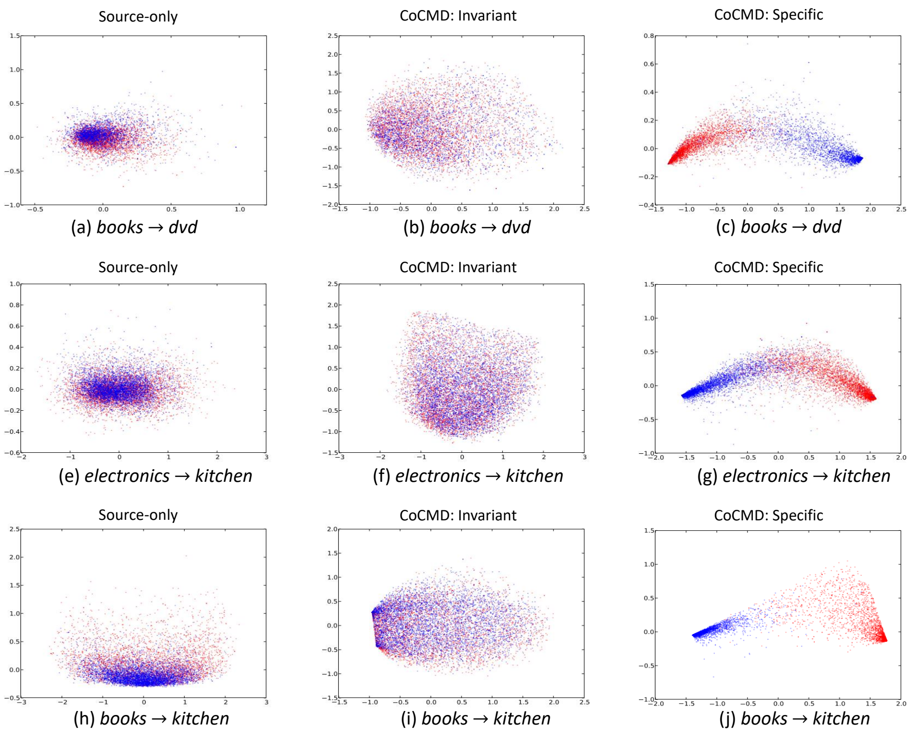

Figure 3: The distribution of source and target data in the hidden space of different representations. The red points denote the source examples and the blue ones denote the target examples. The pictures of each row correspond to the $B{\rightarrow}D$, $E{\rightarrow}K$, and $B{\rightarrow}K$ task. The pictures of each column correspond to the hidden space, H_c^e, of the source-only model, the domain invariant representation, and the target specific representation of the proposed model.

12 tasks except for the K→E task. And by comparing the results of CMD-based methods and DSN-based methods, we can find out that just extracting the domain specific information but not making further usage does not offer much improvement to the adaptation performance for sentiment classification task. This approves the necessary to explore the usage of domain specific information.

If organizing the domain B and D into a group and organizing the domain E and K into another group, we can observe that the domain adaptation methods achieve greater improvement on the standard classifiers over cross-group tasks (e.g., B $\rightarrow$ K) than over within-group tasks (e.g., B $\rightarrow$ D). Similar observation can also be observed by comparing ST with SO, CMD with CMD-ft, and DSN with DSN-ft. The possible explanation is that domains within the same group are more close. Thus adapting over within group tasks is easier than adapting over cross group tasks, if without any domain adaptation regularizer. In addition, we can also observe that CoCMD achieve relatively greater improvement on CMD baseline over the cross-group tasks that over the within-group tasks. We argue that this is because domains in the same group contain relatively less domain individual characteristic. While for domains cross the groups, the domain specific information usually takes a larger share of all of the information. Because the additional part of our proposed method compared to the CMD baseline, is built on the domain specific information, the improvement should be relatively less for within-group tasks. Further analysis of the proposed model in the next section empirically proves this explanation.

4.5 Model Analysis

In this section, we look into how similar two domains are to each other in the space of domain invariant representation and domain specific representation.

A-distance Study: Some of previous works proposed to make use of a proxy of the $\mathcal{A}$-distance (Ben-David et al., 2007) to measure

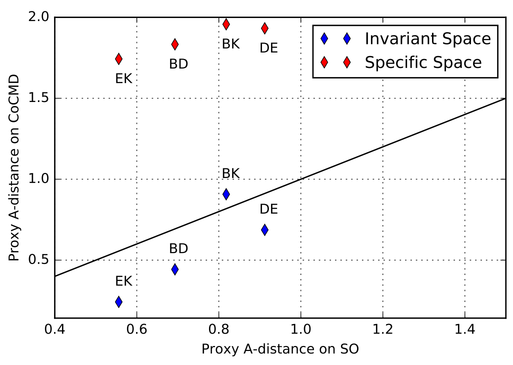

Figure 4: Proxy A-distance between domains of the Amazon benchmark for the 4 different tasks.

the distance of two domains. The proxy was defined by $2(1-2\epsilon)$, where ϵ is the generalization error of a linear SVM classifier trained on the binary classification problem to distinguish inputs between the source and target domains. Figure 4 shows the results of each pair of domains. We observe several trends: Firstly, the proxy A-distance of within-group domain pairs (i.e., BD and EK) is consistently smaller than that of the cross-group domain pairs (i.e., BK and DE) on all of the hidden spaces. Secondly, the proxy A-distance on the domain specific space is consistently larger than its corresponding value on the hidden space of SO model, as expected. While the proxy A-distance value on domain invariant space is generally smaller than its corresponding value on the hidden space of SO model, except for BK domain pair. A possible explanation is that the balance of classification loss and domain discrepancy loss makes there is still some target domain specific information in the domain invariant space, introduced by the target unlabeled data.

Visualization: For more intuitive understanding of the behaviour of the proposed model, we further perform a visualization of the domain invariant representation and the domain specific representation, respectively. For this purpose, we reduce the dimension of the hidden space to 2 using principle component analysis (PCA) (Wold et al., 1987). Due to space constraints we choose three tasks: two within-group tasks ($B \rightarrow D$ and $E \rightarrow K$) and a cross-group task ($B \rightarrow K$). For comparison, we also display the distribution of each domain in the hidden space of the SO model. The results are shown in Figure 3.

Pictures of the first column in Figure 3 show the original distribution of the source and target examples in the hidden space of SO model. As can be seen, there is a great overlap between the distributions of the domain B and the domain D domains and between the distributions of the domain E and the domain K. While there is quite a gap between the distribution of the domain B and the domain K. This strengthens our argument that within-group domains share relatively more common information than cross-group domains. Pictures of the second column show the distribution of the source and target examples in the domain invariant hidden space of the proposed model. From these pictures we can see that the distributions of the source and target data are quite similar in this presentation. This demonstrates the effectiveness of the CMD regularizer for extracting domain invariant representation. Pictures of the third column show the distribution of the source and target examples in the domain specific hidden space of the proposed model. As can be seen from these pictures, examples of the source and target domains are separated very well. This demonstrates the effectiveness of our proposed method for extracting domain specific information.

5 Conclusion

In this work, we investigated the importance of domain specific information for domain adaptation. In contrast with most of the previous methods, which pay more attention to domain invariant information, we showed that domain specific information could also be beneficially used in the domain adaptation task with a small amount of in-domain labeled data. Specifically, we proposed a novel method, based on the CMD metric, to simultaneously extract domain invariant feature and domain specific feature for target domain data. With these two different features, we performed co-training with labeled data from the source domain and a small amount of labeled data from the target domain. Sentiment analysis experiments demonstrated the effectiveness of this method.

Aspect Based Sentiment Analysis with Gated Convolutional Networks

Wei Xue and **Tao Li**
School of Computing and Information Sciences

{wxue004, taoli}@cs.fiu.edu

Abstract

Aspect based sentiment analysis (ABSA) can provide more detailed information than general sentiment analysis, because it aims to predict the sentiment polarities of the given aspects or entities in text. We summarize previous approaches into two subtasks: aspect-category sentiment analysis (ACSA) and aspect-term sentiment analysis (ATSA). Most previous approaches employ long short-term memory and attention mechanisms to predict the sentiment polarity of the concerned targets, which are often complicated and need more training time. We propose a model based on convolutional neural networks and gating mechanisms, which is more accurate and efficient. First, the novel Gated Tanh-ReLU Units can selectively output the sentiment features according to the given aspect or entity. The architecture is much simpler than attention layer used in the existing models. Second, the computations of our model could be easily parallelized during training, because convolutional layers do not have time dependency as in LSTM layers, and gating units also work independently. The experiments on SemEval datasets demonstrate the efficiency and effectiveness of our models. [1]

1 Introduction

Opinion mining and sentiment analysis (Pang and Lee, 2008) on user-generated reviews can provide valuable information for providers and consumers. Instead of predicting the overall sentiment polarity, fine-grained aspect based sentiment analysis (ABSA) (Liu and Zhang, 2012) is proposed to better understand reviews than traditional sentiment analysis. Specifically, we are interested in the sentiment polarity of aspect categories or target entities in the text. Sometimes, it is coupled with aspect term extractions (Xue et al., 2017). A number of models have been developed for ABSA, but there are two different subtasks, namely aspect-category sentiment analysis (ACSA) and aspect-term sentiment analysis (ATSA). The goal of ACSA is to predict the sentiment polarity with regard to the given aspect, which is one of a few predefined categories. On the other hand, the goal of ATSA is to identify the sentiment polarity concerning the target entities that appear in the text instead, which could be a multi-word phrase or a single word. The number of distinct words contributing to aspect terms could be more than a thousand. For example, in the sentence "*Average to good Thai food, but terrible delivery.*", ATSA would ask the sentiment polarity towards the entity *Thai food*; while ACSA would ask the sentiment polarity toward the aspect *service*, even though the word *service* does not appear in the sentence.

Many existing models use LSTM layers (Hochreiter and Schmidhuber, 1997) to distill sentiment information from embedding vectors, and apply attention mechanisms (Bahdanau et al., 2014) to enforce models to focus on the text spans related to the given aspect/entity. Such models include Attention-based LSTM with Aspect Embedding (ATAE-LSTM) (Wang et al., 2016b) for ACSA; Target-Dependent Sentiment Classification (TD-LSTM) (Tang et al., 2016a), Gated Neural Networks (Zhang et al., 2016) and Recurrent Attention Memory Network (RAM) (Chen et al., 2017) for ATSA. Attention mechanisms has been successfully used in many

[1]The code and data is available at `https://github.com/wxue004cs/GCAE`

NLP tasks. It first computes the alignment scores between context vectors and target vector; then carry out a weighted sum with the scores and the context vectors. However, the context vectors have to encode both the aspect and sentiment information, and the alignment scores are applied across all feature dimensions regardless of the differences between these two types of information. Both LSTM and attention layer are very time-consuming during training. LSTM processes one token in a step. Attention layer involves exponential operation and normalization of all alignment scores of all the words in the sentence (Wang et al., 2016b). Moreover, some models needs the positional information between words and targets to produce weighted LSTM (Chen et al., 2017), which can be unreliable in noisy review text. Certainly, it is possible to achieve higher accuracy by building more and more complicated LSTM cells and sophisticated attention mechanisms; but one has to hold more parameters in memory, get more hyper-parameters to tune and spend more time in training. In this paper, we propose a fast and effective neural network for ACSA and ATSA based on convolutions and gating mechanisms, which has much less training time than LSTM based networks, but with better accuracy.

For ACSA task, our model has two separate convolutional layers on the top of the embedding layer, whose outputs are combined by novel gating units. Convolutional layers with multiple filters can efficiently extract n-gram features at many granularities on each receptive field. The proposed gating units have two nonlinear gates, each of which is connected to one convolutional layer. With the given aspect information, they can selectively extract aspect-specific sentiment information for sentiment prediction. For example, in the sentence "*Average to good Thai food, but terrible delivery.*", when the aspect *food* is provided, the gating units automatically ignore the negative sentiment of aspect *delivery* from the second clause, and only output the positive sentiment from the first clause. Since each component of the proposed model could be easily parallelized, it has much less training time than the models based on LSTM and attention mechanisms. For ATSA task, where the aspect terms consist of multiple words, we extend our model to include another convolutional layer for the target expressions. We evaluate our models on the SemEval datasets, which contains restaurants and laptops reviews with labels on aspect level. To the best of our knowledge, no CNN-based model has been proposed for aspect based sentiment analysis so far.

2 Related Work

We present the relevant studies into following two categories.

2.1 Neural Networks

Recently, neural networks have gained much popularity on sentiment analysis or sentence classification task. Tree-based recursive neural networks such as Recursive Neural Tensor Network (Socher et al., 2013) and Tree-LSTM (Tai et al., 2015), make use of syntactic interpretation of the sentence structure, but these methods suffer from time inefficiency and parsing errors on review text. Recurrent Neural Networks (RNNs) such as LSTM (Hochreiter and Schmidhuber, 1997) and GRU (Chung et al., 2014) have been used for sentiment analysis on data instances having variable length (Tang et al., 2015; Xu et al., 2016; Lai et al., 2015). There are also many models that use convolutional neural networks (CNNs) (Collobert et al., 2011; Kalchbrenner et al., 2014; Kim, 2014; Conneau et al., 2016) in NLP, which also prove that convolution operations can capture compositional structure of texts with rich semantic information without laborious feature engineering.

2.2 Aspect based Sentiment Analysis

There is abundant research work on aspect based sentiment analysis. Actually, the name ABSA is used to describe two different subtasks in the literature. We classify the existing work into two main categories based on the descriptions of sentiment analysis tasks in SemEval 2014 Task 4 (Pontiki et al., 2014): Aspect-Term Sentiment Analysis and Aspect-Category Sentiment Analysis.

Aspect-Term Sentiment Analysis. In the first category, sentiment analysis is performed toward the aspect terms that are labeled in the given sentence. A large body of literature tries to utilize the relation or position between the target words and the surrounding context words either by using the tree structure of dependency or by simply counting the number of words between them as a relevance information (Chen et al., 2017).

Recursive neural networks (Lakkaraju et al., 2014; Dong et al., 2014; Wang et al., 2016a) rely on external syntactic parsers, which can be very inaccurate and slow on noisy texts like tweets and reviews, which may result in inferior performance.

Recurrent neural networks are commonly used in many NLP tasks as well as in ABSA problem. TD-LSTM (Tang et al., 2016a) and gated neural networks (Zhang et al., 2016) use two or three LSTM networks to model the left and right contexts of the given target individually. A fully-connected layer with gating units predicts the sentiment polarity with the outputs of LSTM layers.

Memory network (Weston et al., 2014) coupled with multiple-hop attention attempts to explicitly focus only on the most informative context area to infer the sentiment polarity towards the target word (Tang et al., 2016b; Chen et al., 2017). Nonetheless, memory network simply bases its knowledge bank on the embedding vectors of individual words (Tang et al., 2016b), which makes itself hard to learn the opinion word enclosed in more complicated contexts. The performance is improved by using LSTM, attention layer and feature engineering with word distance between surrounding words and target words to produce target-specific memory (Chen et al., 2017).

Aspect-Category Sentiment Analysis. In this category, the model is asked to predict the sentiment polarity toward a predefined aspect category. Attention-based LSTM with Aspect Embedding (Wang et al., 2016b) uses the embedding vectors of aspect words to selectively attend the regions of the representations generated by LSTMs.

3 Gated Convolutional Network with Aspect Embedding

In this section, we present a new model for ACSA and ATSA, namely Gated Convolutional network with Aspect Embedding (GCAE), which is more efficient and simpler than recurrent network based models (Wang et al., 2016b; Tang et al., 2016a; Ma et al., 2017; Chen et al., 2017). Recurrent neural networks sequentially compose hidden vectors $\mathbf{h}_i = f(\mathbf{h}_{i-1})$, which does not enable parallelization over inputs. In the attention layer, softmax normalization also has to wait for all the alignment scores computed by a similarity function. Hence, they cannot take advantage of highly-parallelized modern hardware and libraries. Our model is built on convolutional layers and gating units. Each convolutional filter computes n-gram features at different granularities from the embedding vectors at each position individually. The gating units on top of the convolutional layers at each position are also independent from each other. Therefore, our model is more suitable to parallel computing. Moreover, our model is equipped with two kinds of effective filtering mechanisms: the gating units on top of the convolutional layers and the max pooling layer, both of which can accurately generate and select aspect-related sentiment features.

We first briefly review the vanilla CNN for text classification (Kim, 2014). The model achieves state-of-the-art performance on many standard sentiment classification datasets (Le et al., 2017).

The CNN model consists of an embedding layer, a one-dimension convolutional layer and a max-pooling layer. The embedding layer takes the indices $w_i \in \{1, 2, \ldots, V\}$ of the input words and outputs the corresponding embedding vectors $\boldsymbol{v}_i \in \mathbb{R}^D$. D denotes the dimension size of the embedding vectors. V is the size of the word vocabulary. The embedding layer is usually initialized with pre-trained embeddings such as GloVe (Pennington et al., 2014), then they are fine-tuned during the training stage. The one-dimension convolutional layer convolves the inputs with multiple convolutional kernels of different widths. Each kernel corresponds a linguistic feature detector which extracts a specific pattern of n-gram at various granularities (Kalchbrenner et al., 2014). Specifically, the input sentence is represented by a matrix through the embedding layer, $\mathbf{X} = [\boldsymbol{v}_1, \boldsymbol{v}_2, \ldots, \boldsymbol{v}_L]$, where L is the length of the sentence with padding. A convolutional filter $\mathbf{W}_c \in \mathbb{R}^{D\times k}$ maps k words in the receptive field to a single feature c. As we slide the filter across the whole sentence, we obtain a sequence of new features $\mathbf{c} = [c_1, c_2, \ldots, c_L]$.

$$c_i = f(\mathbf{X}_{i:i+K} * \mathbf{W}_c + b_c) \quad , \qquad (1)$$

where $b_c \in \mathbb{R}$ is the bias, f is a non-linear activation function such as tanh function, $*$ denotes convolution operation. If there are n_k filters of the same width k, the output features form a matrix $\mathbf{C} \in \mathbb{R}^{n_k \times L_k}$. For each convolutional filter, the max-over-time pooling layer takes the maximal value among the generated convolutional features, resulting in a fixed-size vector whose size is equal to the number of filters n_k. Finally, a softmax layer uses the vector to predict the sentiment polarity of the input sentence.

Figure 1 illustrates our model architecture. The

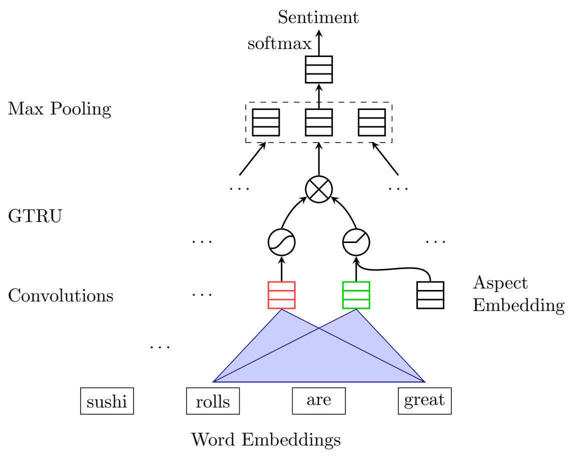

Figure 1: Illustration of our model GCAE for ACSA task. A pair of convolutional neuron computes features for a pair of gates: tanh gate and ReLU gate. The ReLU gate receives the given aspect information to control the propagation of sentiment features. The outputs of two gates are element-wisely multiplied for the max pooling layer.

Gated Tanh-ReLU Units (GTRU) with aspect embedding are connected to two convolutional neurons at each position t. Specifically, we compute the features c_i as

$$a_i = \text{relu}(\mathbf{X}_{i:i+k} * \mathbf{W}_a + \mathbf{V}_a \boldsymbol{v}_a + b_a) \quad (2)$$

$$s_i = \tanh(\mathbf{X}_{i:i+k} * \mathbf{W}_s + b_s) \quad (3)$$

$$c_i = s_i \times a_i \quad , \quad (4)$$

where $\boldsymbol{v}_a$ is the embedding vector of the given aspect category in ACSA or computed by another CNN over aspect terms in ATSA. The two convolutions in Equation 2 and 3 are the same as the convolution in the vanilla CNN, but the convolutional features a_i receives additional aspect information $\boldsymbol{v}_a$ with ReLU activation function. In other words, s_i and a_i are responsible for generating sentiment features and aspect features respectively. The above max-over-time pooling layer generates a fixed-size vector $\boldsymbol{e} \in \mathbb{R}^{d_k}$, which keeps the most salient sentiment features of the whole sentence. The final fully-connected layer with softmax function uses the vector $\boldsymbol{e}$ to predict the sentiment polarity $\hat{y}$. The model is trained by minimizing the cross-entropy loss between the ground-truth y and the predicted value $\hat{y}$ for all data samples.

$$\mathcal{L} = -\sum_i \sum_j y_i^j \log \hat{y}_i^j \quad , \quad (5)$$

where i is the index of a data sample, j is the index of a sentiment class.

4 Gating Mechanisms

The proposed Gated Tanh-ReLU Units control the path through which the sentiment information flows towards the pooling layer. The gating mechanisms have proven to be effective in LSTM. In aspect based sentiment analysis, it is very common that different aspects with different sentiments appear in one sentence. The ReLU gate in Equation 2 does not have upper bound on positive inputs but strictly zero on negative inputs. Therefore, it can output a similarity score according to the relevance between the given aspect information $\boldsymbol{v}_a$ and the aspect feature a_i at position t. If this score is zero, the sentiment features s_i would be blocked at the gate; otherwise, its magnitude would be amplified accordingly. The max-over-time pooling further removes the sentiment features which are not significant over the whole sentence.

In language modeling (Dauphin et al., 2017; Kalchbrenner et al., 2016; van den Oord et al., 2016; Gehring et al., 2017), Gated Tanh Units (GTU) and Gated Linear Units (GLU) have shown effectiveness of gating mechanisms. GTU is represented by $\tanh(\mathbf{X} * \mathbf{W} + b) \times \sigma(\mathbf{X} * \mathbf{V} + c)$, in which the sigmoid gates control features for predicting the next word in a stacked convolutional block. To overcome the gradient vanishing problem of GTU, GLU uses $(\mathbf{X} * \mathbf{W} + b) \times \sigma(\mathbf{X} * \mathbf{V} + c)$ instead, so that the gradients would not be downscaled to propagate through many stacked convolutional layers. However, a neural network that has only one convolutional layer would not suffer from gradient vanish problem during training. We show that on text classification problem, our GTRU is more effective than these two gating units.

5 GCAE on ATSA

ATSA task is defined to predict the sentiment polarity of the aspect terms in the given sentence. We simply extend GCAE by adding a small convolutional layer on aspect terms, as shown in Figure 2. In ACSA, the aspect information controlling the flow of sentiment features in GTRU is from one aspect word; while in ATSA, such information is provided by a small CNN on aspect terms $[w_i, w_{i+1}, \ldots, w_{i+k}]$. The additional CNN extracts the important features from multiple words

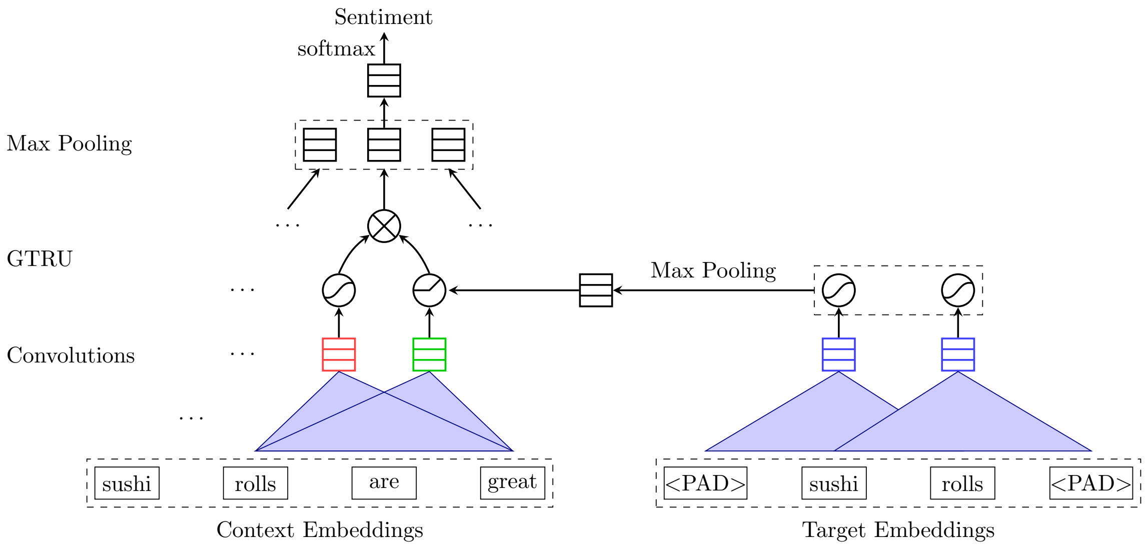

Figure 2: Illustration of model GCAE for ATSA task. It has an additional convolutional layer on aspect terms.

while retains the ability of parallel computing.

6 Experiments

6.1 Datasets and Experiment Preparation

We conduct experiments on public datasets from SemEval workshops (Pontiki et al., 2014), which consist of customer reviews about restaurants and laptops. Some existing work (Wang et al., 2016b; Ma et al., 2017; Chen et al., 2017) removed “conflict” labels from four sentiment labels, which makes their results incomparable to those from the workshop report (Kiritchenko et al., 2014). We reimplemented the compared methods, and used hyper-parameter settings described in these references.

The sentences which have different sentiment labels for different aspects or targets in the sentence are more common in review data than in standard sentiment classification benchmark. The sentence in Table 1 shows the reviewer's different attitude towards two aspects: food and delivery. Therefore, to access how the models perform on review sentences more accurately, we create small but difficult datasets, which are made up of the sentences having opposite or different sentiments on different aspects/targets. In Table 1, the two identical sentences but with different sentiment labels are both included in the dataset. If a sentence has 4 aspect targets, this sentence would have 4 copies in the data set, each of which is associated with different target and sentiment label.

For ACSA task, we conduct experiments on restaurant review data of SemEval 2014 Task 4. There are 5 aspects: food, price, service, ambience, and misc; 4 sentiment polarities: positive, negative, neutral, and conflict. By merging restaurant reviews of three years 2014 - 2016, we obtain a larger dataset called “Restaurant-Large”. Incompatibilities of data are fixed during merging. We replace conflict labels with neutral labels in the 2014 dataset. In the 2015 and 2016 datasets, there could be multiple pairs of “aspect terms” and “aspect category” in one sentence. For each sentence, let p denote the number of positive labels minus the number of negative labels. We assign a sentence a positive label if $p > 0$, a negative label if $p < 0$, or a neutral label if $p = 0$. After removing duplicates, the statistics are show in Table 2. The resulting dataset has 8 aspects: restaurant, food, drinks, ambience, service, price, misc and location.

For ATSA task, we use restaurant reviews and laptop reviews from SemEval 2014 Task 4. On each dataset, we duplicate each sentence n_a times, which is equal to the number of associated aspect categories (ACSA) or aspect terms (ATSA) (Ruder et al., 2016b,a). The statistics of the datasets are shown in Table 2.

The sizes of hard data sets are also shown in Table 2. The test set is designed to measure whether a model can detect multiple different sentiment polarities in one sentence toward different entities. Without such sentences, a classifier for overall sentiment classification might be good enough

Sentence	aspect category/term	sentiment label
Average to good Thai food, but terrible delivery.	food	positive
Average to good Thai food, but terrible delivery.	delivery	negative

Table 1: Two example sentences in one hard test set of restaurant review dataset of SemEval 2014.

for the sentences associated with only one sentiment label.

In our experiments, word embedding vectors are initialized with 300-dimension GloVe vectors which are pre-trained on unlabeled data of 840 billion tokens (Pennington et al., 2014). Words out of the vocabulary of GloVe are randomly initialized with a uniform distribution $U(-0.25, 0.25)$. We use Adagrad (Duchi et al., 2011) with a batch size of 32 instances, default learning rate of $1e-2$, and maximal epochs of 30. We only fine tune early stopping with 5-fold cross validation on training datasets. All neural models are implemented in PyTorch.

6.2 Compared Methods

To comprehensively evaluate the performance of GCAE, we compare our model against the following models.

NRC-Canada (Kiritchenko et al., 2014) is the top method in SemEval 2014 Task 4 for ACSA and ATSA task. SVM is trained with extensive feature engineering: various types of n-grams, POS tags, and lexicon features. The sentiment lexicons improve the performance significantly, but it requires large scale labeled data: 183 thousand Yelp reviews, 124 thousand Amazon laptop reviews, 56 million tweets, and 3 sentiment lexicons labeled manually.

CNN (Kim, 2014) is widely used on text classification task. It cannot directly capture aspect-specific sentiment information on ACSA task, but it provides a very strong baseline for sentiment classification. We set the widths of filters to 3, 4, 5 with 100 features each.

TD-LSTM (Tang et al., 2016a) uses two LSTM networks to model the preceding and following contexts of the target to generate target-dependent representation for sentiment prediction.

ATAE-LSTM (Wang et al., 2016b) is an attention-based LSTM for ACSA task. It appends the given aspect embedding with each word embedding as the input of LSTM, and has an attention layer above the LSTM layer.

IAN (Ma et al., 2017) stands for interactive attention network for ATSA task, which is also based on LSTM and attention mechanisms.

RAM (Chen et al., 2017) is a recurrent attention network for ATSA task, which uses LSTM and multiple attention mechanisms.

GCN stands for gated convolutional neural network, in which GTRU does not have the aspect embedding as an additional input.

6.3 Results and Analysis

6.3.1 ACSA

Following the SemEval workshop, we report the overall accuracy of all competing models over the test datasets of restaurant reviews as well as the hard test datasets. Every experiment is repeated five times. The mean and the standard deviation are reported in Table 4.

LSTM based model ATAE-LSTM has the worst performance of all neural networks. Aspect-based sentiment analysis is to extract the sentiment information closely related to the given aspect. It is important to separate aspect information and sentiment information from the extracted information of sentences. The context vectors generated by LSTM have to convey the two kinds of information at the same time. Moreover, the attention scores generated by the similarity scoring function are for the entire context vector.

GCAE improves the performance by 1.1% to 2.5% compared with ATAE-LSTM. First, our model incorporates GTRU to control the sentiment information flow according to the given aspect information at each dimension of the context vectors. The element-wise gating mechanism works at fine granularity instead of exerting an alignment score to all the dimensions of the context vectors in the attention layer of other models. Second, GCAE does not generate a single context vector, but two vectors for aspect and sentiment features respectively, so that aspect and sentiment information is unraveled. By comparing the performance on the hard test datasets against CNN, it is easy to see the convolutional layer of GCAE is able to differentiate the sentiments of multiple entities.

Convolutional neural networks CNN and GCN

	Positive		Negative		Neutral		Conflict	
	Train	Test	Train	Test	Train	Test	Train	Test
Restaurant-Large	2710	1505	1198	680	757	241	-	-
Restaurant-Large-Hard	182	92	178	81	107	61	-	-
Restaurant-2014	2179	657	839	222	500	94	195	52
Restaurant-2014-Hard	139	32	136	26	50	12	40	19

Table 2: Statistics of the datasets for ACSA task. The hard dataset is only made up of sentences having multiple aspect labels associated with multiple sentiments.

	Positive		Negative		Neutral		Conflict	
	Train	Test	Train	Test	Train	Test	Train	Test
Restaurant	2164	728	805	196	633	196	91	14
Restaurant-Hard	379	92	323	62	293	83	43	8
Laptop	987	341	866	128	460	169	45	16
Laptop-Hard	159	31	147	25	173	49	17	3

Table 3: Statistics of the datasets for ATSA task.

are not designed for aspect based sentiment analysis, but their performance exceeds that of ATAE-LSTM.

The performance of SVM (Kiritchenko et al., 2014) depends on the availability of the features it can use. Without the large amount of sentiment lexicons, SVM perform worse than neural methods. With multiple sentiment lexicons, the performance is increased by 7.6%. This inspires us to work on leveraging sentiment lexicons in neural networks in the future.

The hard test datasets consist of replicated sentences with different sentiments towards different aspects. The models which cannot utilize the given aspect information such as CNN and GCN perform poorly as expected, but GCAE has higher accuracy than other neural network models. GCAE achieves 4% higher accuracy than ATAE-LSTM on Restaurant-Large and 5% higher on SemEval-2014 on ACSA task. However, GCN, which does not have aspect modeling part, has higher score than GCAE on the original restaurant dataset. It suggests that GCN performs better than GCAE when there is only one sentiment label in the given sentence, but not on the hard test dataset.

6.3.2 ATSA

We apply the extended version of GCAE on ATSA task. On this task, the aspect terms are marked in the sentences and usually consist of multiple words. We compare IAN (Ma et al., 2017), RAM (Chen et al., 2017), TD-LSTM (Tang et al., 2016a), ATAE-LSTM (Wang et al., 2016b), and our GCAE model in Table 5. The models other than GCAE is based on LSTM and attention mechanisms. IAN has better performance than TD-LSTM and ATAE-LSTM, because two attention layers guides the representation learning of the context and the entity interactively. RAM also achieves good accuracy by combining multiple attentions with a recurrent neural network, but it needs more training time as shown in the following section. On the hard test dataset, GCAE has 1% higher accuracy than RAM on restaurant data and 1.7% higher on laptop data. GCAE uses the outputs of the small CNN over aspect terms to guide the composition of the sentiment features through the ReLU gate. Because of the gating mechanisms and the convolutional layer over aspect terms, GCAE outperforms other neural models and basic SVM. Again, large scale sentiment lexicons bring significant improvement to SVM.

6.4 Training Time

We record the training time of all models until convergence on a validation set on a desktop machine with a 1080 Ti GPU, as shown in Table 6. LSTM based models take more training time than convolutional models. On ATSA task, because of multiple attention layers in IAN and RAM, they need even more time to finish the training. GCAE is much faster than other neural models, because neither convolutional operation nor GTRU has time dependency compared with LSTM and attention layer. Therefore, it is easier for hardware and libraries to parallel the comput-

ing process. Since the performance of SVM is retrieved from the original paper, we are not able to compare the training time of SVM.

6.5 Gating Mechanisms

In this section, we compare GLU $(\mathbf{X} * \mathbf{W} + b) \times \sigma(\mathbf{X} * \mathbf{W}_a + \mathbf{V}\boldsymbol{v}_a + b_a)$ (Dauphin et al., 2017),

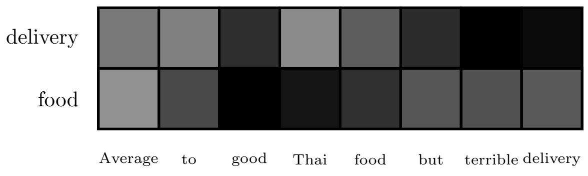

Figure 3: The outputs of the ReLU gates in GTRU.

GTU $\tanh(\mathbf{X} * \mathbf{W} + b) \times \sigma(\mathbf{X} * \mathbf{W}_a + \mathbf{V}\boldsymbol{v}_a + b_a)$ (van den Oord et al., 2016), and GTRU used in GCAE. Table 7 shows that all of three gating units achieve relatively high accuracy on restaurant datasets. GTRU outperforms the other gates. It has a convolutional layer generating aspect features via ReLU activation function, which controls the magnitude of the sentiment signals according to the given aspect information. On the other hand, the sigmoid function in GTU and GLU has the upper bound $+1$, which may not be able to distill sentiment features effectively.

7 Visualization

In this section, we take a concrete review sentence as an example to illustrate how the proposed gate GTRU works. It is more difficult to visualize the weights generated by the gates than the attention weights in other neural networks. The attention weight score is a global score over the words and the vector dimensions; whereas in our model, there are $N_{\text{word}} \times N_{\text{filter}} \times N_{\text{dimension}}$ gate outputs. Therefore, we train a small model with only one filter which is only three word wide. Then, for each word, we sum the $N_{\text{dimension}}$ outputs of the ReLU gates. After normalization, we plot the values on each word in Figure 3. Given different aspect targets, the ReLU gates would control the magnitude of the outputs of the tanh gates.

8 Conclusions and Future Work

In this paper, we proposed an efficient convolutional neural network with gating mechanisms for ACSA and ATSA tasks. GTRU can effectively control the sentiment flow according to the given aspect information, and two convolutional layers model the aspect and sentiment information separately. We prove the performance improvement compared with other neural models by extensive experiments on SemEval datasets. How to leverage large-scale sentiment lexicons in neural networks would be our future work.

Abstract

Deep convolutional neural networks excel at sentiment polarity classification, but tend to require substantial amounts of training data, which moreover differs quite significantly between domains. In this work, we present an approach to feed generic cues into the training process of such networks, leading to better generalization abilities given limited training data. We propose to induce sentiment embeddings via supervision on extrinsic data, which are then fed into the model via a dedicated memory-based component. We observe significant gains in effectiveness on a range of different datasets in seven different languages.

1 Introduction

Over the past decades, sentiment analysis has grown from an academic endeavour to an essential analytics tool. Across the globe, people are voicing their opinion in online social media, product review sites, booking platforms, blogs, etc. Hence, it is important to keep abreast of ongoing developments in all pertinent markets, accounting for different domains as well as different languages. In recent years, deep neural architectures based on convolutional or recurrent layers have become established as the preeminent models for supervised sentiment polarity classification. At the same time, it is also frequently observed that deep neural networks tend to be particularly data-hungry. This is a problem in many real-world settings, where large amounts of training examples may be too costly to obtain for every target domain. A model trained on movie reviews, for instance, will fare very poorly on the task of assessing restaurant or hotel reviews, let alone tweets about politicians.

In this paper, we investigate how extrinsic signals can be incorporated into deep neural networks for sentiment analysis. Numerous papers have found the use of regular pre-trained word vector representations to be beneficial for sentiment analysis (Socher et al., 2013; Kim, 2014; dos Santos and de C. Gatti, 2014). In our paper, we instead consider word embeddings specifically specialized for the task of sentiment analysis, studying how they can lead to stronger and more consistent gains, despite the fact that the embeddings were obtained using out-of-domain data.

An intuitive solution would be to concatenate regular embeddings, which provide semantic relatedness cues, with sentiment polarity cues that are captured in additional dimensions. We instead propose a bespoke convolutional neural network architecture with a separate memory module dedicated to the sentiment embeddings. Our empirical study shows that the sentiment embeddings can lead to consistent gains across different datasets in a diverse set of domains and languages if a suitable neural network architecture is used.

2 Approach

2.1 Sentiment Embedding Computation

Our goal is to incorporate external cues into a deep neural network such that the network is able to generalize better even when training data is scarce. While in computer vision, weights pre-trained on ImageNet are often used for transfer learning, the most popular way to incorporate external information into deep neural networks for text is to draw on word embeddings trained on vast amounts of word context information (Mikolov et al., 2013; Pennington et al., 2014; Peters et al., 2018). Indeed, the semantic relatedness signals provided by such representations often lead to slightly improved results in polarity classification tasks (Socher et al., 2013; Kim, 2014; dos Santos and de C. Gatti, 2014).

However, the co-occurrence-based objectives of word2vec and GloVe do not consider sentiment specifically. We thus seek to examine how complementary sentiment-specific information from an external source can give rise to further gains.

Transfer Learning. To this end, our goal is to induce sentiment embeddings that capture sentiment polarity signals in multiple domains and hence may be useful across a range of different sentiment analysis tasks. The multi-domain nature of these distinguish them from the kinds of generic polarity scores captured in sentiment polarity lexicons. We achieve this via transfer learning from trained models, benefiting from supervision on a series of sentiment polarity tasks from different domains. Given a training collection consisting of n binary classification tasks (e.g., with documents in n different domains), we learn n corresponding polarity prediction models. From these, we then extract token-level scores that are tied to specific prediction outcomes. Specifically, we train n linear models $f_i(\mathbf{x}) = \mathbf{w}_i^\intercal \mathbf{x} + b_i$ for tasks $i = 1, \ldots, n$. Then, each vocabulary word index j is assigned a new n-dimensional word vector $\mathbf{x_j} = (w_{1,j}, \cdots, w_{n,j})$ that incorporates the linear coefficients for that word across the different linear models.

A minor challenge is that naïvely using bag-of-word features can lead to counter-intuitive weights. If a word such as "*pleased*" in one domain mainly occurs after the word "*not*", while the reviews in another domain primarily used "*pleased*" in its unnegated form, then "*pleased*" would be assessed as possessing opposite polarities in different domains. To avoid this, we assume that features are preprocessed to better reflect whether words occur in a negated context. In our experiments, we simply treat occurrences of "*not* ⟨word⟩" as a single feature "*not_*⟨word⟩". Of course, one can replace this heuristic with much more sophisticated techniques that fully account for the scope of a wider range of negation constructions.

Graph-Based Extension. Most sentiment-related resources are available for the English language. To produce vectors for other languages in our experiments, we rely on cross-lingual projection via graph-based propagation (de Melo, 2015; de Melo, 2017; Dong and de Melo, 2018). At this point, we have a set of initial sentiment embedding vectors $\tilde{\mathbf{v}}_x \in \mathbb{R}^n$ for words $x \in V_0$. We assume that we have a lexical knowledge graph $G_\mathrm{L} = (V, A_\mathrm{L})$ with a node set consisting of an extended multilingual vocabulary $V \supseteq V_0$ and a set of weighted directed arcs $A_\mathrm{L} = \{(x_1, x'_1, w_1), \ldots, (x_m, x'_m, w_m)\}$. Each such arc reflects a weighted semantic connection between two vocabulary items $x, x' \in V$, where vocabulary items are words labeled with their respective language. Typically, many of the arcs in the G_L would reflect translational equivalence, but in our experiments, we also include monolingual links between semantically related words. Given this data, we aim to minimize

$$-\sum_{x \in V} \mathbf{v}_x^\intercal \left[\frac{1}{\sum\limits_{(x,x',w) \in A_\mathrm{L}} w} \sum_{(x,x',w) \in A_\mathrm{L}} w \mathbf{v}_{x'} \right] + C \sum_{x \in V_0} \|\mathbf{v}_x - \tilde{\mathbf{v}}_x\|_2 \qquad (1)$$

The first component of this objective seeks to ensure that sentiment embeddings of words accord with those of their connected words, in terms of the dot product. The second part ensures that the deviation from any available initial word vectors $\tilde{\mathbf{v}}_x$ is minimal (for some very high constant C). For optimization, we preinitialize $\mathbf{v}_x = \tilde{\mathbf{v}}_x$ for all $x \in V_0$, and then rely on stochastic gradient descent steps.

2.2 Dual-Module Memory based CNNs

To feed this sentiment information into our architecture, we propose a Dual-Module Memory based Convolutional Neural Network (DM-MCNN) approach, which incorporates a dedicated memory module to process the sentiment embeddings, as illustrated in Fig. 1. While the module with regular word embeddings enables the model to learn salient patterns and harness the nearest neighbour and linear substructure properties of word embeddings, we conjecture that a separate sentiment memory module allows for better exploiting the information brought to the table by the sentiment embeddings.

Convolutional Module Inputs and Filters. The Convolutional Module input of the DM-MCNN is a sentence matrix $\mathbf{S} \in \mathbb{R}^{s \times d}$, the rows of which represent the words of the input sentence after tokenization. In the case of $\mathbf{S}$, i.e., in the regular module, each word is represented by its conventional word vector representation. Here, s refers to the length of a sentence, and d represents the dimensionality of the regular word vectors.

We perform convolutional operations on these matrices via linear filters. Given rows representing discrete words, we rely on weight matrices $\mathbf{W} \in \mathbb{R}^{h \times d}$ with region size h. We use the notation $\mathbf{S_{i:j}}$ to denote the sub-matrix of $\mathbf{S}$ from row i to row

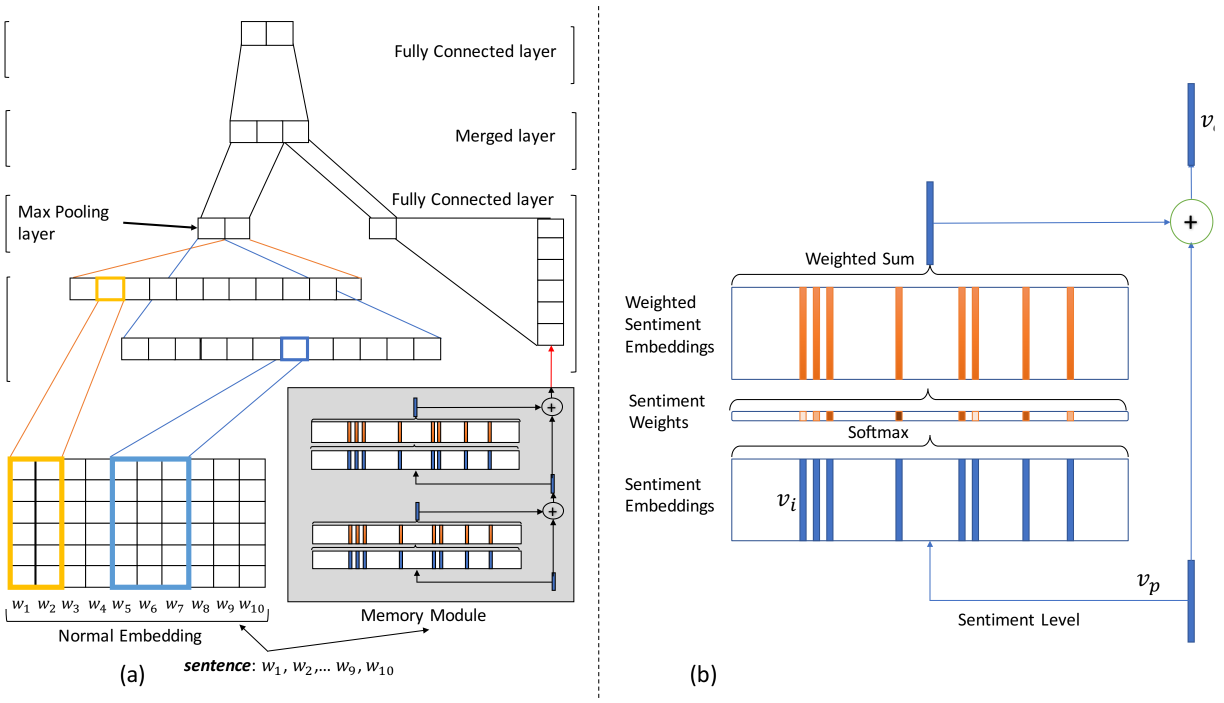

Figure 1: (a) Dual-Module Memory based Convolutional Neural Network architecture. (b) Single layer in Memory Module

j. Supposing that the weight matrix has a filter width of h, a wide convolution (Kalchbrenner et al., 2014) is induced such that out-of-range submatrix values $S_{i,j}$ with $i < 1$ or $i > s$ are taken to be zero. Thus, applying the filter on sub-matrices of $\mathbf{S}$ yields the output sequence $\mathbf{o} \in \mathbb{R}^{s+h-1}$ as

$$o_i = \mathbf{W} \odot \mathbf{S_{i:i+h-1}}, \tag{2}$$

where the $\odot$ operator provides the sum of an element-wise multiplication. Wide convolutions ensure that filters can cover words at the margins of the normal weight matrix.

Next, the c_i in feature maps $\mathbf{c} \in \mathbb{R}^{s+h-1}$ are computed as: $c_i = f(o_i + b)$, where $i = 1, \ldots, s + h - 1$, the parameter $b \in \mathbb{R}$ is a bias term, and f is an activation function.

Multiple Layers in Memory Module. The memory module obtains as input a sequence of sentiment embedding vectors for the input, and attempts to draw conclusions about the overall sentiment polarity of the entire input sequence. Given a set of sentence words $S = \{w_1, w_2, w_3, \ldots, w_n\}$, each word is mapped to its sentiment embedding vector of dimension d_s and we denote this set of vectors as V_s. The preliminary sentiment level $\mathbf{v}_\mathrm{p}$ is also a vector of dimensionality d_s. We take the mean of all sentiment vectors $\mathbf{v}_i$ for words $w_i \in S$ to initialize $\mathbf{v}_\mathrm{p}$. Next, we compute a vector $\mathbf{s}$ of similarities s_i between $\mathbf{v}_\mathrm{p}$ and each sentiment word vector $\mathbf{v}_i$, by taking the inner product, followed by ℓ_2-normalization and a softmax:

$$s_i = \frac{\exp \frac{\mathbf{v}_\mathrm{p}^\intercal \mathbf{v}_i}{\|\mathbf{v}_\mathrm{p}^\intercal \mathbf{v}_i\|_2}}{\sum_i \exp \frac{\mathbf{v}_\mathrm{p}^\intercal \mathbf{v}_i}{\|\mathbf{v}_\mathrm{p}^\intercal \mathbf{v}_i\|_2}} \tag{3}$$

As the sentiment embeddings used in our paper are generated from a linear model, the degree of correspondence between $\mathbf{v}_\mathrm{p}$ and $\mathbf{v}_i$ can adequately be assessed by the inner product. The resulting vector of scores $\mathbf{s}$ can be regarded as yielding sentiment weights for each word in the sentence. We apply ℓ_2-normalization to ensure a more balanced weight distribution. The output sentiment level vector $\mathbf{v}_\mathrm{o}$ is then a sum over the sentiment inputs $\mathbf{v}_i$ weighted by the ℓ_2-normalized vector of similarities:

$$\mathbf{v}_\mathrm{o} = \sum_i \frac{s_i}{\|\mathbf{s}\|_2} \mathbf{v}_i \tag{4}$$

This processing can be repeated in multiple passes, akin to how end-to-end memory networks for question answering often perform multiple hops (Sukhbaatar et al., 2015). While in the first iteration, $\mathbf{v}_\mathrm{p}$ was set to the mean sentiment vector, subsequent passes may allow us to iteratively refine this vector. Assuming that $\mathbf{v}_{\mathrm{o}}^{k}$ has been produced by the k-th pass, then the subsequent level $\mathbf{v}_{\mathrm{p}}^{k+1}$ in the next pass is:

$$\mathbf{v}_{\mathrm{p}}^{k+1} = \mathbf{v}_{\mathrm{o}}^{k} + \mathbf{v}_{\mathrm{p}}^{k} \tag{5}$$

The intuition here is that multiple passes can enable the model to adaptively retrieve iterative sentiment level statistics beyond the initial average sentiment information.

Merging Layer and Prediction. Subsequently, for the convolutional module, 1d-max pooling is applied to $\mathbf{c}$, which ought to capture the most prominent signals. In the memory module, the final sentiment vector is modulated by a weight matrix $\mathbf{W}_{\mathrm{s}} \in \mathbb{R}^{l \times d_{\mathrm{s}}}$ to form a feature vector of dimensionality l. In general, we can use multiple filters to obtain several features in the convolutional module, while the memory module allows for adjusting the number of passes over the memory.

Finally, the outputs of these two modules are concatenated to form a fixed-length vector, which is passed to a fully connected softmax layer to obtain the final output probabilities.

Loss Function and Training. Our loss function is the cross-entropy function

$$\mathcal{L} = -\frac{1}{n} \sum_{i=1}^{n} \sum_{c \in C} y_{i,c} \ln \hat{y}_{i,c}, \tag{6}$$

where n is the number of training examples, C is the set of (two) classes, $y_{i,c}$ are ground truth labels for a given training example and class c, and $\hat{y}_{i,c}$ are corresponding label probabilities predicted by the model, as emitted by the softmax layer. We train our model using Adam optimization (Kingma and Ba, 2014) for better robustness across different datasets. Further details about our training regime follow in the Experiments section.

3 Experiments

We now turn to our extensive empirical evaluation, which assesses the effectiveness of our novel architecture with sentiment word vectors.

3.1 Experimental Setup

Datasets. For evaluation, we use real world datasets for 7 different languages, taken from a range of different sources that cover several domains. These are summarized in Table 1, with ISO 639-3 language codes. In our experimental setup, these are all cast as binary polarity classification tasks, for which we use accuracy as our evaluation metric.

Table 1: Dataset Descriptions

Language	Source	Domain	train	test
en	SST	Movies	6,920	1,821
	AFF	Food	5,945	1,189
es	SE16-T5	Restaurants	2,070	881
ru	TA	Hotels	2,387	682
de	TA	Restaurants	1,687	481
cs	TA	Restaurants	1,722	491
it	TA	Hotels	3,437	982
ja	TA	Restaurants	1,435	411

- The Stanford Sentiment Treebank (**SST**) dataset (Socher et al., 2013) consists of movie reviews taken from the Rotten Tomatoes website, including binary labels. We only used sentence-level data in our experiment.
- The SemEval-2016 Task 5 (**SE16-T5**) dataset (Pontiki et al., 2016) provides Spanish reviews of restaurants. It targeted aspect-based sentiment analysis, so we converted the entity-level annotations to sentence-level polarity labels via voting. As the number of entities per sentence is often one or very low, this process is reasonably precise. In any case, it enables us to compare the ability of different model variants to learn to recognize pertinent words.
- From TripAdvisor (**TA**), we crawled German, Russian, Italian, Czech, and Japanese reviews of restaurants and hotels. We removed three-star reviews, as these can be regarded as neutral ones, so reviews with a rating < 3 are considered negative, while those with a rating > 3 were deemed positive.
- The Amazon Fine Food Reviews **AFF** (McAuley and Leskovec, 2013) dataset provides food reviews left on Amazon. We chose a random subset of it with preprocessing as for TripAdvisor.

As there was no test set provided for TripAdvisor or for the Amazon Fine Food Reviews data, we randomly partitioned this data into training, validation, and test splits with a 80%/10%/20% ratio. Additionally, 10% of the training sets from SE16-T5 were randomly extracted and reserved for validation, while SST provides its own validation set. The new datasets are available from `http://gerard.demelo.org/sentiment/`.

Embeddings. The standard pre-trained word vectors used for English are the GloVe (Pennington et al., 2014) ones trained on 840 billion tokens of

Table 2: DM-MCNN Model Parameter Settings.

α	0.003	0.003	0.003	

Common Crawl data[1], while for other languages, we rely on the Facebook fastText Wikipedia embeddings (Bojanowski et al., 2016) as input representations. All of these are 300-dimensional. The vectors are either fed to the CNN, or to the convolutional module of the DM-MCNN during initialization, while unknown words are initialized with zeros. All words, including the unknown ones, are fine-tuned during the training process.

For our transfer learning approach, our experiments rely on the multi-domain sentiment dataset by Blitzer et al. (2007), collected from Amazon customers reviews. This dataset includes 25 categories of products and is used to generate our sentiment embeddings using linear models. Specifically, we train linear SVMs using scikit-learn to extract word coefficients in each domain and also for the union of all domains together, yielding a 26-dimensional sentiment embedding.

For comparison and analysis, we also consider several alternative forms of infusing external cues. Firstly, lexicon-driven methods have often been used for domain-independent sentiment analysis. We consider a recent sentiment lexicon called VADER (Hutto and Gilbert, 2014). The polarity scores assigned to words by the lexicon are taken as the components of a set of 1-dimensional word vectors (dividing the original scores by the difference between max and min polarity scores for normalization). Secondly, as another particularly strong alternative, we consider the SocialSent Reddit community-specific lexicons mined by the Stanford NLP group (Hamilton et al., 2016). These contain separate domain-specific scores for 250 different Reddit communities, and hence result in 250-dimensional embeddings.

For cross-lingual projection, we extract links between words from a 2017 dump of the English edition of Wiktionary. We restrict the vocabulary link set to include the languages in Table 1, mining corresponding translation, synonymy, derivation, and etymological links from Wiktionary.

Neural Network Details. For CNNs, we make use of the well-known CNN-non-static architecture and hyperparameters proposed by Kim (2014), with a learning rate of 0.0006, obtained by tuning on the validation data. For our DM-MCNN models, the configuration of the convolutional module is the same as for CNNs, and the remaining hyperparameter values were as well tuned on the validation sets. An overview of the relevant network parameter values is given in Table 2.

For greater efficiency and better convergence properties, the training relies on mini-batches. Our implementation considers the maximal sentence length in each mini-batch and zero-pads all other sentences to this length under convolutional module, thus enabling uniform and fast processing of each mini-batch. All neural network architectures are implemented using the PyTorch framework[2].

3.2 Results and Analysis

Baseline Results. Our main results are summarized in Table 3. We compare both regular CNNs and our dual-module alternative DM-MCNNs under a variety of settings. A common approach is to use a CNN with randomly initialized word vectors. Comparing this to CNNs with GloVe/fastText embeddings, where GloVe is used for English, and fastText is used for all other languages, we observe substantial improvements across all datasets. This shows that word vectors do tend to convey pertinent word semantics signals that enable models to generalize better. Note also that the accuracy using GloVe on the English movies review dataset is consistent with numbers reported in previous work (Zhang and Wallace, 2015).

Dual-Module Architecture. Next, we consider our DM-MCNNs with their dual-module mechanism to take advantage of transfer learning. We observe fairly consistent and sometimes quite substan-

tial gains over CNNs with just the GloVe/fastText vectors. We see that the sentiment embeddings provide important complementary signals beyond what is provided in regular word embeddings, and that our dual-module approach succeeds at exploiting these signals across a range of different domains and languages. Our transfer learning approach leads to sentiment embeddings that capture signals from multiple domains. The model successfully picks the pertinent parts of this signal for datasets from domains as different as movie reviews and food reviews.

We report results for two different training conditions. In the first condition (with fine-tuning), the sentiment embedding matrix is preinitialized using the data from our transfer learning procedure, but the model is then able to modify these arbitrarily via backpropagation. In the second condition (no fine-tuning), we simply use our sentiment embedding matrix as is, and do not update it. Instead, the model is able to update its various other parameters, particularly its various weight matrices and bias vectors. While both training conditions outperform the CNN baseline, there is no obvious winner among the two. When the training data set is very small and hence there is a significant risk of overfitting, one may be best advised to forgo fine-tuning. In contrast, when it is somewhat larger (as for our English datasets, which each have over 5,000 training instances) or when the language is particularly idiosyncratic or not covered sufficiently well by our cross-lingual projection procedure (such as perhaps for Japanese), then fine-tuning is recommended. In this case, fine-tuning may allow the model to adjust the embeddings to cater to domain-specific meanings and corpus-specific correlations, while also overcoming possible sparsity of the cross-lingual vectors resulting from a lack of coverage of the translation dictionary.

It is important to note that many of the results in Table 3 stem from embeddings that were created automatically using cross-lingual projection. Our transfer learning embeddings were induced from entirely English data. Although the automatically projected cross-lingual embeddings are very noisy and limited in their coverage, particularly with respect to inflected forms, our model succeeds in exploiting them to obtain substantial gains in several different languages and domains.

Alternative Embedding Methods. For a more detailed analysis, we conducted additional experiments with alternative embedding conditions. In particular, as a simpler means of achieving gains over standard CNNs, we propose to use CNNs with word vectors augmented with sentiment cues. Given that regular word embeddings appear to be useful for capturing semantics, one may conjecture that extending these word vectors with additional dimensions to capture sentiment information can lead to improved results. For this, we simply concatenate the regular word embeddings with different forms of sentiment embeddings that we have obtained, including those from the sentiment lexicon VADER, from the Stanford SocialSent project, and from our transfer learning procedure via Amazon reviews. To conduct these experiments, we also produced cross-lingual projections of the VADER and SocialSent embedding data.

The results of using these embeddings as opposed to regular ones are somewhat mixed. Concatenating the VADER embeddings or our transfer learning ones leads to minor improvements on English, and our cross-lingual projection of them leads to occasional gains, but the results are far from consistent. Even on English, adding the 250-dimensional SocialSent embedding seems to degrade the effectiveness of the CNN, although all input information that was previously there continues to be provided to it. This suggests that a simple concatenation may harm the model's ability to harness the semantic information carried by regular word vectors. This risk seems more pronounced for larger-dimensional sentiment embeddings.

In contrast, with our DM-MCNNs approach, the sentiment information is provided to the model in a separate memory module that makes multiple passes over this data before combining it with the regular CNN module's signals. Thus, the model can exploit the two kinds of information independently, and learn a suitable way to aggregate them to produce an overall output classification.

This hence demonstrates not only that the sentiment embeddings tend to provide important complementary signals but also that a dual-module approach is best-suited to incorporate such signals into deep neural models.

We also analysed our DM-MCNNs with alternative embeddings. When we feed random sentiment embeddings into them, not unexpectedly, in many cases the results do not improve much. This is because our memory module has been designed to leverage informative prior information and to reweight its signals based on this assumption. Hence, it is important to feed genuine sentiment cues into the memory module. Yet, on some languages, we nevertheless note improvements over the CNN baseline. In these cases, even if similarities between pairs of sentiment vectors initially do not carry any significance, backpropagation may have succeeded in updating the sentiment embedding matrix such that eventually the memory module becomes able to discern salient patterns in the data.

We also considered our DM-MCNNs when feeding the VADER or SocialSent embeddings into the memory module. In this case, it also mostly succeeded in outperforming the CNN baseline. In fact, on the Italian TripAdvisor dataset, the SocialSent embeddings yielded the overall strongest results. In all other cases, however, our transfer learning embeddings proved more effective. We believe that this is because they are obtained in a data-driven manner based on an objective that directly seeks to optimize for classification accuracy.

Influence of Training Set Size. To look into the effect of our approach with restricted training data, we first consider the SST dataset as an instructive example. We set the training set size to 20%, 50%, 100% of its original size and compared our full dual module model with sentiment embeddings against state-of-the-art methods.

The results are given in Table 4. Our dual module CNN has a sizeable lead over other methods when only using 20% of SST training set. Given that we study how to incorporate extrinsic cues into a deep neural model, we consider CNN-Rule-q (Hu et al., 2016) and Gumbel Tree-LSTM (Choi et al., 2017) as the relevant baseline methods. The CNN-Rule-q method used an iterative distillation method that exploits structured information from logical rules, which for SST is based on the word *but* to determine the weights in the neural network. The Gumbel Tree-LSTM approach incorporates a Straight-Through Gumbel-Softmax into a tree-structured LSTM architecture that learns how to compose task-specific tree structures starting from plain raw text. They all require a large amount of data to pick up sufficient information during training, while our method is able to efficiently capture sentiment information from our transfer learning even though the data is scarce.

For further analysis, we also artificially reduce the training set sizes to 50% of the original sizes given in Table 1 for our multilingual datasets. The results are plotted in Fig. 2. We compare: 1) the CNN model baseline, 2) the CNN model but concatenating our sentiment embeddings from transfer learning, and 3) our full dual module model with these sentiment embeddings. We already saw in Table 3 that we obtain reasonable gains over generic embeddings when using the full training sets.

In Fig. 2, we additionally observe that the gains are overall much more remarkable on smaller training sets. This shows that the sentiment embeddings are most useful when they are of high quality and domain-specific training data is scarce, although a modest amount of training data is still needed for the model to be able to adapt to the target domain.

Inspection of the DM-MCNN-learned Deep Sentiment Information. To further investigate what the model is learning, we examine the changes of weights of words on the English SST dataset when using the VADER sentiment embeddings

Table 4: Accuracy on SST with increasing training sizes

Model	*20%*	*50%*	*100%*
CNN (Kim, 2014)	83.14	84.29	85.72
CNN-Rule-q (Hu et al., 2016)	83.75	85.45	86.49
Gumbel Tree-LSTM (Choi et al., 2017)	84.04	84.83	86.80
DC-MCNN (ours)	**85.06**	**86.16**	**86.99**

with DM-MCNNs. Although these are not as powerful as our transfer learning embeddings, the VADER embeddings are the most easily interpretable here, since they are one-dimensional, and thus can be regarded as word-specific weights. The result is visualized in Fig. 3. Here, the dark-shaded segments (in blue) refer to the original weights, while the light-shaded segments (in red) refer to the adjusted weights after training. The medium-shaded segments (in purple) reflect the overlap between the two. Hence, whenever we observe a dark (blue) segment above a medium (purple) segment in a bar, we can infer that the fine-tuned weight for a word (e.g., for "*plays*" in Fig. 3) was lower than the original weight of that word. Conversely, whenever we observe a light (red) segment at the top, the weight increased during training (e.g., for *hilarious*). Generally, dark (blue) segments reflect decreased weight magnitudes and light (red) ones reflect increased weight magnitudes, both on the positive and on the negative side.

We consider in Fig. 3 the top 50 weight changes only of words that were already covered by the original VADER sentiment embeddings. Here, it is worth noting that the weight magnitudes of positive words such as "*laugh*", "*appealing*" and negative words such as "*lack*", "*missing*" increase further, while words such as "*damn*", "*interest*", "*war*" see decreases in magnitude, presumably due to their ambiguity and context (e.g., "*damn good*", "*lost the interest*", descriptions of war movies). Hence, the figure confirms that our DM-MCNN approach is able to exploit and customize the provided sentiment weights for the target domain. However, unlike the VADER data, our transfer learning approach results in multi-dimensional sentiment embeddings that can more easily capture multiple domains right from the start, thus making it possible to use them even without further fine-tuning.

4 Related Work

Sentiment Mining and Embeddings. There is a long history of work on collecting word polarity scores manually (Hu and Liu, 2004) or via graph-based propagation from seeds (Kim and Hovy, 2004; Baccianella et al., 2010). Maas et al. (2011) present a probabilistic topic model that exploits sentiment supervision during training, leading to rep-

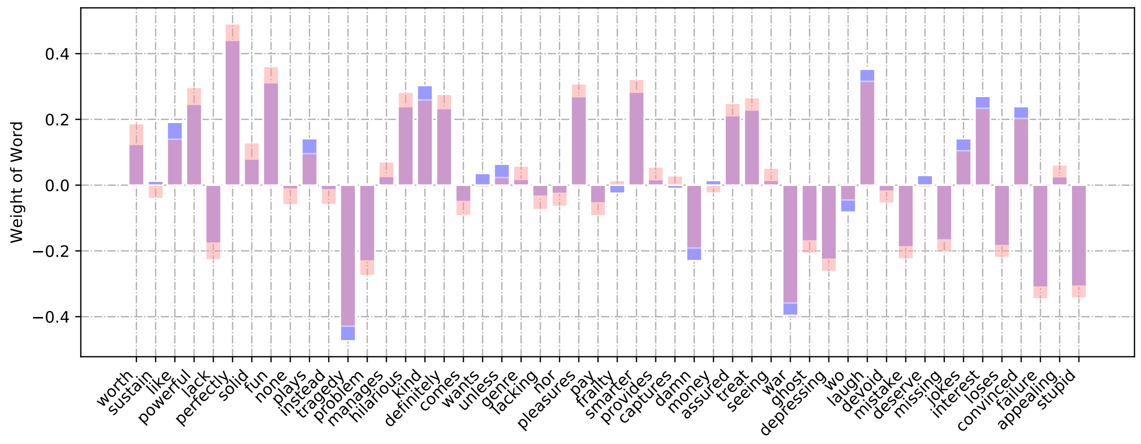

Figure 3: Top 50 weight changes of words fine-tuned by the sentiment memory module of the DM-MCNN, using the one-dimensional VADER embeddings, but considering only words with non-zero values in the original VADER data. Here, the dark shade (blue) refers to the original value of word vectors, while the light shade (red) refers to their fine-tuned values after training. The medium intensity (purple) corresponds to the overlap between the original and fine-tuned word vectors.

resentations that include sentiment signals. However, in their experiments, the semantic-only models mostly outperform the corresponding full models with extra sentiment signals. Tang et al. (2014) showed that one can acquire sentiment information by learning from millions of training examples via distant supervision. While prior work used such signals for rule-based sentiment analysis or for feature engineering in SVMs and other shallow models, our study examines how they are best be incorporated into deep neural models, as the baseline of naïvely feeding them into the model does not work sufficiently well.

Neural Architectures. In terms of architectures, deep recursive neural networks (Socher et al., 2013) were soon outperformed by deep convolutional and recurrent neural networks (İrsoy and Cardie, 2014; Kim, 2014). Recent work has investigated more involved models, with ingredients such as Tree-LSTMs (Tai et al., 2015; Looks et al., 2017), hierarchical attention (Yang et al., 2016), user and product attention (Chen et al., 2016), aspect-specific modeling (Wang et al., 2015), and part of speech-specific transition functions (Huang et al., 2017). Large ensemble models also tend to outperform individually trained sentiment analysis models (Looks et al., 2017). The goal of our study is not necessarily to devise the most sophisticated state-of-the-art neural architecture, but to demonstrate how external sentiment cues can be incorporated such architectures. Our initial explorations relied on a simple dual-channel convolutional neural network (Dong and de Melo, 2018). The present work proposes a more sophisticated approach, drawing on ideas from attention mechanisms in machine translation (Bahdanau et al., 2014) as well as from memory networks (Weston et al., 2014) and iterative attention (Kumar et al., 2015), which have proven useful for tasks such as question answering. We incorporate these ideas into a separate memory module that operates alongside the regular convolutional module.

5 Conclusions

Deep neural networks are widely used in sentiment polarity classification, but suffer from their dependence on very large annotated training corpora. In this paper, we study how to incorporate extrinsic cues into the network, beyond just generic word embeddings. We have found that this is best achieved using a dual-module approach that encourages the learning of models with favourable generalization abilities. Our experiments show that this can lead to gains across a number of different languages and domains. Our embeddings and multilingual datasets are freely available from `http://gerard.demelo.org/sentiment/`.

Cold-Start Aware User and Product Attention for Sentiment Classification

Reinald Kim Amplayo and **Jihyeok Kim** and **Sua Sung** and **Seung-won Hwang**
Yonsei University

{rktamplayo, zizi1532, dormouse, seungwonh}@yonsei.ac.kr

Abstract

The use of user/product information in sentiment analysis is important, especially for *cold-start* users/products, whose number of reviews are very limited. However, current models do not deal with the cold-start problem which is typical in review websites. In this paper, we present Hybrid Contextualized Sentiment Classifier (HCSC), which contains two modules: (1) a fast word encoder that returns word vectors embedded with short and long range dependency features; and (2) Cold-Start Aware Attention (CSAA), an attention mechanism that considers the existence of cold-start problem when attentively pooling the encoded word vectors. HCSC introduces **shared** vectors that are constructed from similar users/products, and are used when the original **distinct** vectors do not have sufficient information (i.e. cold-start). This is decided by a frequency-guided selective gate vector. Our experiments show that in terms of RMSE, HCSC performs significantly better when compared with on famous datasets, despite having less complexity, and thus can be trained much faster. More importantly, our model performs significantly better than previous models when the training data is sparse and has cold-start problems.

1 Introduction

Sentiment classification is the fundamental task of sentiment analysis (Pang et al., 2002), where we are to classify the sentiment of a given text. It is widely used on online review websites as they contain huge amounts of review data that can be classified a sentiment. In these websites, a sentiment is usually represented as an intensity (e.g. 4 out of 5). The reviews are written by users who have bought a product. Recently, sentiment analysis research has focused on personalization (Zhang, 2015) to recommend product to users, and vise versa.

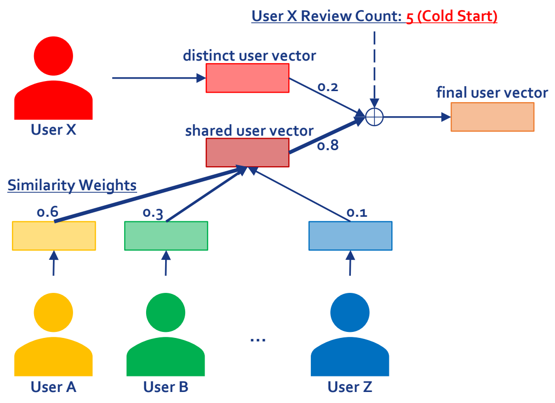

Figure 1: Conceptual schema of HCSC applied to users. The same idea can be applied to products.

To this end, many have used user and product information not only to develop personalization but also to improve the performance of the classification model (Tang et al., 2015). Indeed, these information are important in two ways. First, some expressions are user-specific for a certain sentiment intensity. For example, the phrase "*very salty*" may have different sentiments for a person who likes salty food and a person who likes otherwise. This is also apparent in terms of products. Second, these additional contexts help mitigate data sparsity and cold-start problems. Cold-start is a problem when the model cannot draw useful information from users/products where data is insufficient. User and product information can help by introducing a frequent user/product with similar attributes to the cold-start user/product.

Thanks to the promising results of deep neural networks to the sentiment classification task

(Glorot et al., 2011; Tang et al., 2014), more recent models incorporate user and product information to convolutional neural networks (Tang et al., 2015) and deep memory networks (Dou, 2017), and have shown significant improvements. The current state-of-the-art model, NSC (Chen et al., 2016a), introduced an attention mechanism called UPA which is based on user and product information and applied this to a hierarchical LSTM. The main problem with current models is that they use user and product information naively as an ordinary additional context, not considering the possible existence of cold-start problems. This makes NSC more problematic than helpful in reality since majority of the users in review websites have very few number of reviews.

To this end, we propose the idea shown in Figure 1. It can be described as follows: If the model does not have enough information to create a user/product vector, then we use a vector computed from other user/product vectors that are similar. We introduce a new model called Hybrid Contextualized Sentiment Classifier (HCSC), which consists of two modules. First, we build a fast yet effective word encoder that accepts word vectors and outputs new encoded vectors that are contextualized with short- and long-range contexts. Second, we combine these vectors into one pooled vector through a novel attention mechanism called Cold-Start Aware Attention (CSAA). The CSAA mechanism has three components: (a) a user/product-specific **distinct vector** derived from the original user/product information of the review, (b) a user/product-specific **shared vector** derived from other users/products, and (c) a frequency-guided **selective gate** which decides which vector to use. Multiple experiments are conducted with the following results: In the original non-sparse datasets, our model performs significantly better than the previous state-of-the-art, NSC, in terms of RMSE, despite being less complex. In the sparse datasets, HCSC performs significantly better than previous competing models.

2 Related work

Previous studies have shown that using additional contexts for sentiment classification helps improve the performance of the classifier. We survey several competing baseline models that use user and product information and other models using other kinds of additional context.

Baselines: Models with user and product information User and product information are helpful to improve the performance of a sentiment classifier. This argument was verified by Tang et al. (2015) through the observation at the consistency between user/product information and the sentiments and expressions found in the text. Listed below are the following models that employ user and product information:

- **JMARS** (Diao et al., 2014) jointly models the aspects, ratings, and sentiments of a review while considering the user and product information using collaborative filtering and topic modeling techniques.
- **UPNN** (Tang et al., 2015) uses a CNN-based classifier and extends it to incorporate user- and product-specific text preference matrix in the word level which modifies the word meaning.
- **TLFM+PRC** (Song et al., 2017) is a text-driven latent factor model that unifies user- and product-specific latent factor models represented using the consistency assumption by Tang et al. (2015).
- **UPDMN** (Dou, 2017) uses an LSTM classifier as the document encoder and modifies the encoded vector using a deep memory network with other documents of the user/product as the memory.
- **TUPCNN** (Chen et al., 2016b) extends the CNN-based classifier by adding temporal user and product embeddings, which are obtained from a sequential model and learned through the temporal order of reviews.
- **NSC** (Chen et al., 2016a) is the current state-of-the-art model that utilizes a hierarchical LSTM model (Yang et al., 2016) and incorporates user and product information in the attention mechanism.

Models with other additional contexts Other additional contexts used previously are spatial (Yang et al., 2017) and temporal (Fukuhara et al., 2007) features which help contextualize the sentiment based on the location where and the time when the text is written. Inferred contexts were also used as additional contexts for sentiment classifiers, such as latent topics (Lin and He, 2009) and aspects (Jo and Oh, 2011) from a topic model, argumentation features (Wachsmuth et al., 2015), and more recently, latent review clusters (Amplayo and Hwang, 2017). These additional con-

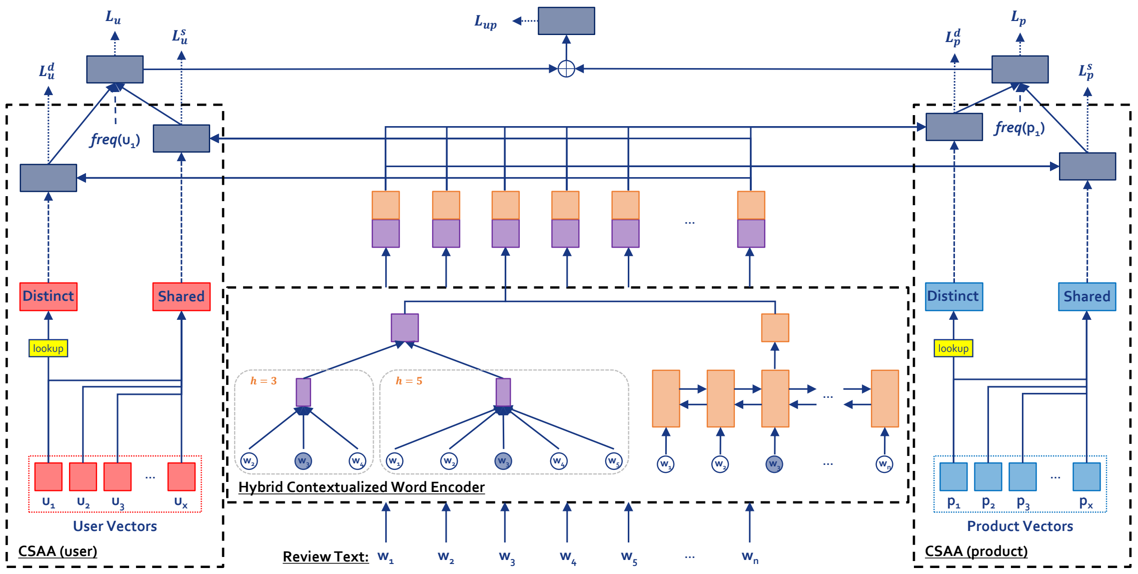

Figure 2: Full architecture of HCSC, which consists of the Hybrid Contextualized Word Encoder (middle), and user-specific (left) and product-specific (right) Cold-Start Aware Attention (CSAA).

texts were especially useful when data is sparse, i.e. number of instances is small or there exists cold-start entities.

Our model differs from the baseline models mainly because we consider the possible existence of the data sparsity problem. Through this, we are able to construct more effective models that are comparably powerful yet more efficient complexity-wise than the state-of-the-art, and are better when the training data is sparse. Ultimately, our goal is to demonstrate that, similar to other additional contexts, user and product information can be used to effectively mitigate the problem caused by cold-start users and products.

3 Our model

In this section, we present our model, **Hybrid Contextualized Sentiment Classifier (HCSC)**[1] which consists of a fast hybrid contextualized word encoder and an attention mechanism called Cold-Start Aware Attention (CSAA). The word encoder returns word vectors with both local and global contexts to cover both short and long range dependency relationship between words. The CSAA then incorporates user and product information to the contextualized words through an attention mechanism that considers the possible existence of cold-start problems. The full architecture of the model is presented in Figure 2. We describe the subparts of the model below.

3.1 Hybrid contextualized word encoder

The base model is a word encoder that transforms vectors of words $\{w_i\}$ in the text to new word vectors. In this paper, we present a fast yet very effective word encoder based on two different off-the-shelf classifiers.

The first part of HCWE is based on a CNN model which is widely used in text classification (Kim, 2014). This encoder contextualizes words based on local context words to capture short range relationships between words. Specifically, we do the convolution operation using filter matrices $W_f \in \mathbb{R}^{h \times d}$ with filter size h to a window of h words. We do this for different sizes of h. This produces new feature vectors $c_{i,h}$ as shown below, where $f(.)$ is a non-linear function:

$$c_{i,h} = f([w_{i-(h-1)/2}; ...; w_{i+(h-1)/2}]^\top W_f + b_f)$$

The convolution operation reduces the number of words differently depending on the filter size h. To prevent loss of information and to produce the same amount of feature vectors $c_{i,h}$, we pad the texts dynamically such that when the filter size is h, the number of paddings on each side is $(h-1)/2$. This requires the filter sizes to be odd numbers. Finally, we concatenate all feature vectors of different h's for each i as the new word vector:

$$w_{cnn_i} = [c_{i,h_1}; c_{i,h_2}; ...]$$

[1]The data and code used in this paper are available here: `https://github.com/rktamplayo/HCSC`.

The second part of HCWE is based on an RNN model which is used when texts are longer and include word dependencies that may not be captured by the CNN model. Specifically, we use a bidirectional LSTM and concatenate the forward and backward hidden state vectors as the new word vector, as shown below:

$$\begin{aligned}\overrightarrow{h}_i &= LSTM(w_i, \overrightarrow{h}_{i-1}) \\ \overleftarrow{h}_i &= LSTM(w_i, \overleftarrow{h}_{i+1}) \\ w_{rnn_i} &= [\overrightarrow{h}_i; \overleftarrow{h}_i]\end{aligned}$$

The answer to the question whether to use local or global context to encode words for sentiment classification is still unclear, and both CNN and RNN models have previous empirical evidence that they perform better than the other (Kim, 2014; McCann et al., 2017). We believe that both short and long range relationships, captured by CNN and RNN respectively, are useful for sentiment classification. There are already previous attempts to intricately combine both CNN and RNN (Zhou et al., 2016), resulting to a slower model. On the other hand, HCWE resorts to combine them by simply concatenating the word vectors encoded from both CNN and RNN encoders, i.e. $w_i = [w_{cnn_i}; w_{rnn_i}]$. This straightforward yet fast alternative outputs a word vector with semantics contextualized from both local and global contexts. Moreover, they perform as well as complex hierarchical structured models (Yang et al., 2016; Chen et al., 2016a) which train very slow.

3.2 Cold-start aware attention

Incorporating the user and product information of the text as context vectors u and p to attentively pool the word vectors, i.e. $e(w_i, u, p) = v^\top tanh(W_w w_i + W_u u + W_p p + b)$, has been proven to improve the performance of sentiment classifiers (Chen et al., 2016a). However, this method assumes that the user and product vectors are always present. This is not the case in real world settings where a user/product may be new and has just got its first review. In this case, the vectors u and p are rendered useless and may also contain noisy signals that decrease the overall performance of the models.

To this end, we present an attention mechanism called Cold-Start Aware Attention (CSAA). CSAA operates on the idea that a cold-start user/product can use the information of other similar users/products with sufficient number of reviews. CSAA separates the construction of pooled vectors for user and for product, unlike previous methods that use both user/product information to create a single pooled vector. Constructing a user/product-specific pooled vector consists of three parts: the distinct pooled vector created using the original user/product, the shared pooled vector created using similar users/products, and the selective gate to select between the distinct and shared vectors. Finally, the user- and product-specific pooled vectors are combined into one final pooled vector.

In the following paragraphs, we discuss the step-by-step process on how the user-specific pooled vector is constructed. A similar process is done to construct the product-specific pooled vector, but is not presented here for conciseness.

The user-specific **distinct pooled vector** v^d_u is created using a method similar to the additive attention mechanism (Bahdanau et al., 2014), i.e. $v^d_u = att(\{w_i\}, u)$, where the context vector is the distinct vector of user u, as shown in the equation below. An equivalent method is used to create the distinct product-specific pooled vector v^d_p.

$$\begin{aligned}e^d_u(w_i, u) &= v^{d\top} tanh(W^d_w w_i + W^d_u u + b^d) \\ a^d_{u_i} &= \frac{exp(e^d_u(w_i, u))}{\sum_j exp(e^d_u(w_j, u))} \\ v^d_u &= \sum_i a^d_{u_i} \times w_i\end{aligned}$$

The user-specific **shared pooled vector** v^s_u is created using the same method above, but using a shared context vector u'. The shared context vector u' is constructed using the vectors of other users and weighted based on a similarity weight. Similarity is defined as how similar the word usages of two users are. This means that if a user u_k uses words similarly to the word usage of the original user u, then u_k receives a high similarity weight. The similarity weight $a^s_{u_k}$ is calculated as the softmax of the product of $\mu(\{w_i\})$ and u_k with a project matrix in the middle, where $\mu(\{w_i\})$ is the average of the word vectors. The similarity weights are used to create u', as shown below. Similar method is used for the shared product-specific pooled vector v^s_p.

$$
\begin{aligned}
e^s_u(\mu(\{w_i\}), u_k) &= \mu(\{w_i\}) W^s_u u_k \\
a^s_{u_k} &= \frac{exp(e^s_u(w_i, u_k))}{\sum_j exp(e^s_u(w_i, u_j))} \\
u' &= \sum_k a^s_{u_k} \times u_k \\
v^s_u &= att(\{w_i\}, u')
\end{aligned}
$$

We select between the user-specific distinct and shared pooled vector, v^d_u and v^s_u, into one user-specific pooled vector v_u through a gate vector g_u. The vector g_u should put more weight to the distinct vector when user u is not cold-start and to the shared vector when u is otherwise. We use a **frequency-guided selective gate** that utilizes the frequency, i.e. the number of reviews user u has written. The challenge is that we do not know how many reviews should be considered cold-start or not. This is automatically learned through a two-parameter Weibull cumulative distribution where given the review frequency of the user $f(u)$, a learned shape vector k_u and a learned scale vector λ_u, a probability vector is sampled and is used as the gate vector g_u to create v_u, according to the equation below. We normalized $f(u)$ by dividing it to the average user review frequency. The relu function ensures that both k_u and λ_u are non-negative vectors. The final product-specific pooled vector v_p is created in a similar manner.

$$
\begin{aligned}
g_u &= 1 - exp\Bigg(- \Big(\frac{f(u)}{relu(\lambda_u)} \Big)^{relu(k_u)} \Bigg) \\
v_u &= g_u \times v^d_u + (1 - g_u) \times v^s_u
\end{aligned}
$$

Finally, we combine both the user- and product-specific pooled vector, v_u and v_p, into one pooled vector v_{up}. This is done by using a gate vector g_{up} created using a sigmoidal transformation of the concatenation of v_u and v_p, as illustrated in the equation below.

$$
\begin{aligned}
g_{up} &= \sigma(W_g[v_u; v_p] + b_g) \\
v_{up} &= g_{up} \times v_u + (1 - g_{up}) \times v_p
\end{aligned}
$$

We note that our attention mechanism can be applied to any word encoders, including the basic bag of words (BoW) to more recent models such as CNN and RNN. Later (in Section 4.2), we show that CSAA improves the performance of simpler models greatly.

3.3 Training objective

Normally, a sentiment classifier transforms the final vector v_{up}, usually in a linear fashion, into a vector with a dimension equivalent to the number of classes C. A softmax layer is then used to obtain a probability distribution y' over the sentiment classes. Finally, the full model uses a cross-entropy over all training documents D as objective function L during training, where y is the gold probability distribution:

$$
\begin{aligned}
y' &= softmax(W v_{up} + b) \\
L &= - \sum_{d \in D} \sum_{c \in C} y^{(d)}_c \cdot \log(y'^{(d)}_c)
\end{aligned}
$$

However, HCSC has a nice architecture which can be used to improve the training. It contains seven pooled vectors $\mathbb{V} = \{v^d_u, v^d_p, v^s_u, v^s_p, v_u, v_p, v_{up}\}$ that are essentially in the same vector space. This is because these vectors are created using weighted sums of either the encoded word vectors through attention or the parent pooled vectors through the selective gates. Therefore, we can train separate classifiers for each pooled vectors using the same parameters W and b. Specifically, for each $v \in \mathbb{V}$, we calculate the loss L_v using the above formulas. The final loss is then the sum of all the losses, i.e. $L = \sum_{v \in \mathbb{V}} L_v$.

4 Experiments

In this section, we present our experiments and the corresponding results. We use the models described in Section 2 as baseline models: **JMARS** (Diao et al., 2014), **UPNN** (Tang et al., 2015), **TLFM+PRC** (Song et al., 2017), **UPDMN** (Dou, 2017), **TUPCNN** (Chen et al., 2016b), and **NSC** (Chen et al., 2016a), where **NSC** is the model with state-of-the-art results.

4.1 Experimental settings

Implementation We set the size of the word, user, and product vectors to 300 dimensions. We use pre-trained GloVe embeddings[2] (Pennington et al., 2014) to initialize our word vectors. We simply set the parameters for both BiLSTMs and CNN to produce an output with 300 dimensions: For the BiLSTMs, we set the state sizes of the LSTMs to 75 dimensions, for a total of 150 dimensions. For CNN, we set $h = 3, 5, 7$, each with 50

Table 1: Dataset statistics

feature maps, for a total of 150 dimensions. These two are concatenated to create a 300-dimension encoded word vectors. We use dropout (Srivastava et al., 2014) on all non-linear connections with a dropout rate of 0.5. We set the batch size to 32. Training is done via stochastic gradient descent over shuffled mini-batches with the Adadelta update rule (Zeiler, 2012), with l_2 constraint (Hinton et al., 2012) of 3. We perform early stopping using a subset of the given development dataset. Training and experiments are all done using a NVIDIA GeForce GTX 1080 Ti graphics card.

Additionally, we also implement two versions of our model where the word encoder is a subpart of HCSC, i.e. (a) the CNN-based model (**CNN+CSAA**) and (b) the RNN-based model (**RNN+CSAA**). For the CNN-based model, we use 100 feature maps for each of the filter sizes $h = 3, 5, 7$, for a total of 300 dimensions. For the RNN-based model, we set the state sizes of the LSTMs to 150, for a total of 300 dimensions.

Datasets and evaluation We evaluate and compare our models with other competing models using two widely used sentiment classification datasets with available user and product information: IMDB and Yelp 2013. Both datasets are curated by Tang et al. (2015), where they are divided into train, dev, and test sets using a 8:1:1 ratio, and are tokenized and sentence-splitted using Stanford CoreNLP (Manning et al., 2014). In addition, we create three subsets of the train dataset to test the robustness of the models on sparse datasets. To create these datasets, we randomly remove all the reviews of $x\%$ of all users and products, where $x = 20, 50, 80$. These datasets are not only more sparse than the original datasets, but also have smaller number of users and products, introducing cold-start users and products. All datasets are summarized in Table 1. Evaluation is done using two metrics: the Accuracy which measures the overall sentiment classification performance and the RMSE which measures the divergence between predicted and ground truth classes. We notice very minimal differences among performances of different runs.

Models	IMDB		Yelp 2013	
	Acc.	RMSE	Acc.	RMSE
JMARS	-	1.773^*	-	0.985^*
UPNN	0.435^*	1.602^*	0.596^*	0.784^*
TLFM+PRC	-	1.352^*	-	0.716^*
UPDMN	0.465^*	1.351^*	0.639^*	0.662
TUPCNN	0.488^*	1.451^*	0.639^*	0.694^*
NSC	0.533	1.281^*	0.650	0.692^*
CNN+CSAA	0.522^*	1.256^*	0.654	0.665
RNN+CSAA	0.527^*	1.237^*	0.654	0.667
HCSC	**0.542**	**1.213**	**0.657**	**0.660**

Table 2: Accuracy and RMSE values of competing models on the original non-sparse datasets. An asterisk indicates that HCSC is significantly better than the model ($p < 0.01$).

4.2 Comparisons on original datasets

We report the results on the original datasets in Table 2. On both datasets, HCSC outperforms all previous models based on both accuracy and RMSE. Based on accuracy, HCSC performs significantly better than all previous models except NSC, where it performs slightly better with 0.9% and 0.7% increase on IMDB and Yelp 2013 datasets. Based on RMSE, HCSC performs significantly better than all previous models, except when compared with UPDMN on the Yelp 2013 datasets, where it performs slightly better. We note that RMSE is a better metric because it measures how close the wrongly predicted sentiment and the ground truth sentiment are. Although NSC performs as well as HCSC based on accuracy, it performs worse based on RMSE, which means that its predictions deviate far from the original sentiment.

It is also interesting to note that when CSAA is used as attentive pooling, both simple CNN and RNN models perform just as well as NSC, despite NSC being very complex and modeling the documents with compositionality (Chen et al., 2016a). This is especially true when com-

Models	Sparse20	Sparse50	Sparse80
NSC(LA)	0.469	0.428	0.309
NSC	0.497	0.408	0.292
CNN+CSAA	0.497	0.444	0.343

pared using RMSE, where both CNN+CSAA and RNN+CSAA perform significantly better ($p < 0.01$) than NSC. This proves that CSAA is an effective use of the user and product information for sentiment classification.

4.3 Comparisons on sparse datasets

Table 3 shows the accuracy of NSC (Chen et al., 2016a) and our models CNN+CSAA, RNN+CSAA, and HCSC on the sparse datasets. As shown in the table, on all datasets with different levels of sparsity, HCSC performs the best among the competing models. The difference between the accuracy of HCSC and NSC increases as the level of sparsity intensifies: While the HCSC only gains 0.8% and 1.0% over NSC on the less sparse Sparse20 IMDB and Yelp 2013 datasets, it improves over NSC significantly with 7.6% and 2.7% increase on the more sparse Sparse80 IMDB and Yelp 2013 datasets, respectively.

We also run our experiments using NSC without user and product information, i.e. NSC(LA) which reduces the model into a hierarchical LSTM model (Yang et al., 2016). Results show that although the use of user and product information in NSC improves the model on less sparse datasets (as also shown in the original paper (Chen et al., 2016a)), it decreases the performance of the model on more sparse datasets: It performs 2.0%, 1.7%, and 1.2% worse than NSC(LA) on Sparse50 IMDB, Sparse80 IMDB, and Sparse80 Yelp 2013 datasets. We argue that this is because NSC does not consider the existence of cold-start problems, which makes the additional user and product information more noisy than helpful.

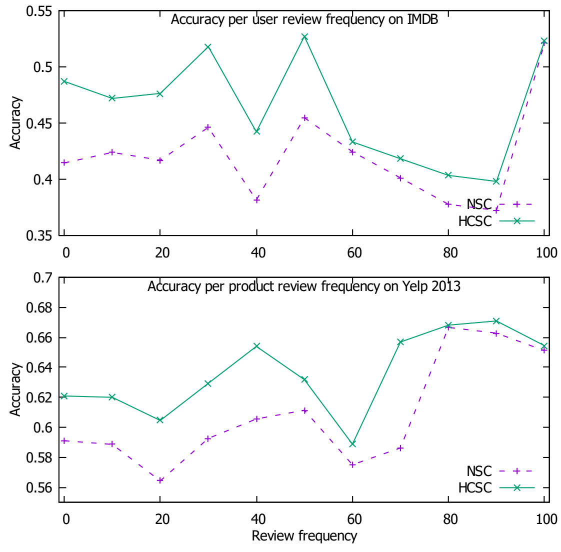

Figure 3: Accuracy per user/product review frequency on both datasets. The review frequency value f represents the frequencies in the range $[f, f + 10)$, except when $f = 100$, which represents the frequencies in the range $[f, \infty)$.

5 Analysis

In this section, we show further interesting analyses of the properties of HCSC. We use the Sparse50 datasets and the corresponding results of several models as the experimental data.

Performance per review frequency We investigate the performance of the model over users/products with different number of reviews. Figure 3 shows plots of accuracy of both NSC and HCSC over (a) different user review frequency on IMDB dataset and (b) different product review frequency on Yelp 2013 dataset. On both plots, we observe that when the review frequency is small, the performance gain of HCSC over NSC is very large. However, as the review frequency becomes larger, the performance gain of HCSC over NSC decreases to a very marginal increase. This means that HCSC finds its improvements over NSC from cold-start users and products, in which NSC does not consider explicitly.

How few is cold-start? One intriguing question is when do we say that a user/product is cold-start or not. Obviously, users/products with no previous reviews at all should be considered cold-start, however the cut-off point between cold-start and non-cold-start entities is vague. Although we

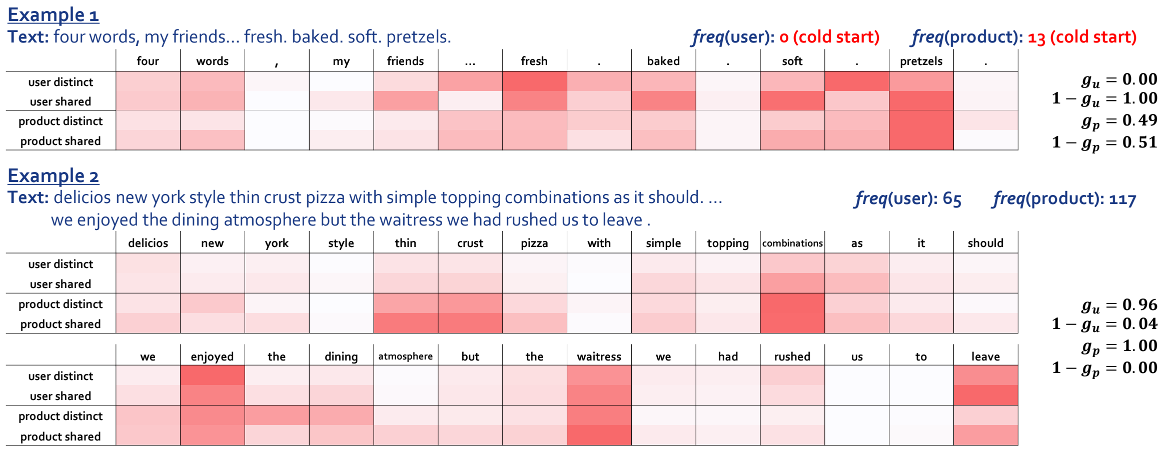

Figure 4: Visualization of attention and gate values of two examples from the Yelp 2013 dataset. Example 2 is truncated, leaving only the important parts. Gate values g's are the average of the values in the original gate vector.

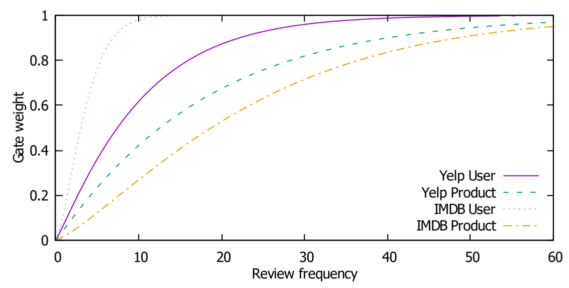

Figure 5: Graph of the user/product-specific Weibull cumulative distribution on both datasets.

Models	IMDB	Yelp 2013
NSC	7331	6569
CNN+CSAA	256 (28.6x)	146 (45.0x)
RNN+CSAA	968 (7.6x)	561 (11.7x)
HCSC	1110 (6.6x)	615 (10.7x)

Table 4: Time (in seconds) to process the first 100 batches of competing models for each dataset. The numbers in the parenthesis are the speedup of time when compared to NSC.

cannot provide an exact answer to this question, HCSC is able to provide a nice visualization by reducing the shape and scale vectors, k and λ, of the frequency-guided selective gate into their averages and draw a Weibull cumulative distribution graph, as shown in Figure 5. The figure provides us these observations: First, users have a more lenient cold-start cut-off point compared to products; in the IMDB dataset, a user only needs approximately at least five reviews to use at least 80% of its own information (i.e. distinct vector). On the other hand, products tend to need more reviews to be considered sufficient and not cold start; in the IMDB dataset, a product needs approximately 40 reviews to use at least 80% of its own information. This explains the marginal increase in performance of previous models when only product information is used as additional context, as reported by previous papers (Tang et al., 2015; Chen et al., 2016a).

On the different pooled vectors We visualize the attention and gate values of two example results from HCSC in Figure 4 to investigate on how user/product vectors, and distinct/shared vectors work. In the first example, both user and product are cold-start. The user distinct vector focuses its attention to wrong words, since it is not able to use any useful information from the user at all. In this case, HCSC uses the user shared vector by using a gate vector $g_u = 0$. The user shared vector correctly attends to important words such as *fresh*, *baked*, *soft*, and *pretzels*. In the second example, both user and product are not cold-start. In this case, the distinct vectors are used almost entirely by setting the gates close to 1. Still, the corresponding shared vectors are similar to the distinct vectors, proving that HCSC is able to create useful user/product-specific context from similar users/products. Finally, we look at the differing attention values of users and products. We observe that user vectors focus on words that describe the product or express their emotions (e.g. *fresh* and *enjoyed*). On the other hand, product vectors focus more on words pertaining to the products/services (e.g. *pretzels* and *waitress*).

On the time complexity of models Finally, we report the time in seconds to run 100 batches of data of the models NSC, CNN+CSAA, RNN+CSAA, and HCSC in Figure 4. NSC takes too long to train, needing at least 6500 seconds to process 100 batches of data. This is because it uses two non-parallelizable LSTMs on top of each other. Our models, on the other hand, only use one (or none in the case of CNN+CSAA) level of BiLSTM. This results to at least 6.6x speedup on the IMDB datasets, and at least 10.7x speedup on the Yelp 2013 datasets. This means that HCSC does not sacrifice a lot of time complexity to obtain better results.

6 Conclusion

We propose Hybrid Contextualized Sentiment Classifier (HCSC) with a fast word encoder which contextualizes words to contain both short and long range word dependency features, and an attention mechanism called Cold-start Aware Attention (CSAA) which considers the existence of the cold-start problem among users and products by using a shared vector and a frequency-guided selective gate, in addition to the original distinct vector. Our experimental results show that our model performs significantly better than previous models. These improvements increase when the level of sparsity in data increases, which confirm that HCSC is able to deal with the cold-start problem.

Abstract

This paper studies how the argumentation strategies of participants in deliberative discussions can be supported computationally. Our ultimate goal is to predict the best next deliberative move of each participant. In this paper, we present a model for deliberative discussions and we illustrate its operationalization. Previous models have been built manually based on a small set of discussions, resulting in a level of abstraction that is not suitable for move recommendation. In contrast, we derive our model statistically from several types of metadata that can be used for move description. Applied to six million discussions from Wikipedia talk pages, our approach results in a model with 13 categories along three dimensions: discourse acts, argumentative relations, and frames. On this basis, we automatically generate a corpus with about 200,000 turns, labeled for the 13 categories. We then operationalize the model with three supervised classifiers and provide evidence that the proposed categories can be predicted.

1 Introduction

Deliberation is the type of discussions where the aim is to find the best choice from a set of possible actions (Walton, 2010). This type is influential for making decisions in different processes including *collaborative writing*. Studies have shown the positive impact of deliberation on the quality of several document types, such as scientific papers, research proposals, political reports, and Wikipedia articles, among others (Kraut et al., 2012).

However, deliberative discussions may fail, either by agreeing on the wrong action, or by reaching no agreement. While the former is hard to measure, the latter is, for example, clearly reflected in the number of disputed discussions on Wikipedia (Wang and Cardie, 2014).

Although agreement can never be guaranteed, a deliberative argumentation strategy of a discussion's participants makes it more likely (Kittur et al., 2007). With *strategy*, we here mean the sequence of moves that participants take during the discussion. Such a sequence is effective if it leads to a successful discussion. To achieve effectiveness, every participant has to understand the current state of a discussion and to come up with a next deliberative move that *best* serves the discussion. For newcomers, this requires substantial effort and time, especially when a discussion grows due to conflicts and back-and-forth arguments. Here, automated tools can help by annotating ongoing discussions with a label for each move or by providing a textual summary of past moves (Zhang et al., 2017a,b). A way to go beyond that is to let the tool *recommend the best possible moves* according to an effective strategy. This is the ultimate goal of our research.

As a substantial step towards this goal, two fundamental research questions are addressed in the paper at hand: (1) How to model deliberative discussions in light of the aim of agreement, and (2) how to operationalize the model in order to identify different argumentation strategies and to learn about their effectiveness.

Different models of deliberative discussions have been proposed in previous studies. These models were developed based on expert analyses of a *small* set of sampled discussions (see Section 2). However, the small size, in fact, confines the ability to develop a *representative* model, which should ideally cover a wide range of moves while being abstract to fit the majority of discussions.

To overcome this limitation, we propose to derive a model statistically from a large set of discussions. We approach this based on different types of metadata that people use to describe their moves on Wikipedia talk pages, the richest source of deliberative discussions on the web. Particularly, we extract the entire set of about six million discussions from all English Wikipedia talk pages. We parse each discussion to identify its structural components, such as turns, users, and time stamps. Besides, we store four types of *metadata* from the turns: the user tag, a shortcut, an in-line template, and links. To learn from the metadata, we cluster the types' instances based on their semantic similarity. Then, we map each cluster to a specific concept (e.g., 'providing a source'), and the related concepts into a set of categories (e.g., 'providing evidence'). Table 2 shows the categories of our model.

Analyzing the distribution of these categories, we find that each turn ideally should have (1) one of six categories that we call *discourse acts*, (2) one of three categories that we call *argumentative relations*, and (3) one of four categories that we call *frames*. As such, our model is in line with three well-established theories: *speech act theory* (Searle, 1969), *argumentation theory* (Peldszus and Stede, 2013), and *framing theory* (P. Levin et al., 1998). A model instance is sketched in Figure 1.

Based on the model, we generate a new large-scale corpus using the metadata automatically: *Webis-WikiDebate-18* corpus. Basically, if a turn in a discussion has metadata that belongs to a specific category according to the above-mentioned analysis, it is labeled with that category. The corpus includes 2400 turns labeled with a discourse act, 7437 turns labeled with a relation, and 182,321 turns labeled with a frame.

To operationalize our model, we train three supervised classifiers for acts, relations, and frames on the corpus. The classifiers employ a rich set of linguistic features that has been shown to be effective in similar tasks (Ferschke et al., 2012). The results of our experiments suggest that we are able to predict the labels with a comparable performance to the one achieved in similar tasks.

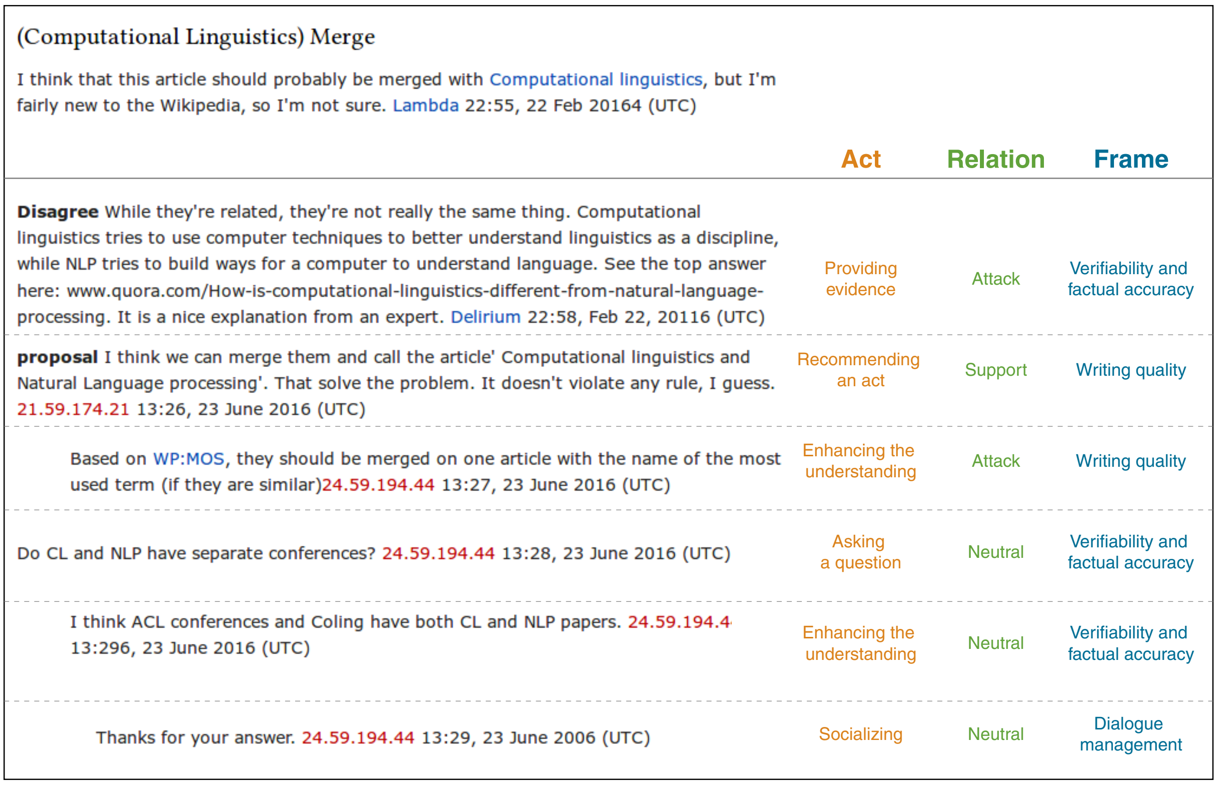
Overall, the contribution of this paper is threefold: (1) A data-driven approach for creating a new model of deliberative discussions that is aligned with well-established theories, (2) a corpus with about 200,000 turns labeled for 13 different categories, and (3) a classification approach that predicts the labels of turns. All developed resources are freely available at `https://www.webis.de/data/data.html`.

2 Related Work

Modeling deliberative discussions in Wikipedia has been already addressed in different studies. The central goal of these studies is to minimize the coordination effort among discussion participants. In particular, Ferschke et al. (2012) have proposed a model of 17 dialogue acts, each belonging to one of four categories: article criticism, explicit performative, information content, and interpersonal. The model was derived by performing a manual analysis of 30 talk pages in the Simple English Wikipedia. Based on the model, a new corpus of 1367 turns has been created and used to train and evaluate a multi-label classifier for predicting the model's acts. Another model is the one proposed by Viegas et al. (2007). The model consists of 11 different dialogue acts. These acts have been used to manually label 25 talk pages from the English Wikipedia. Furthermore, Bender et al. (2011) have developed a model for authority claims and alignment moves in Wikipedia discussions. The model then has been used to label 47 talk pages.

Rooted in the limitation of being derived from a small sample, these models obtain low coverage and/or are over-abstracted. This is indicated by labels such as 'other' (Viegas et al., 2007) or by a very abstract 'information providing' act (Ferschke et al., 2012), which covers 78% of the turns. We argue that recommending such moves for new participants will not be useful. On the other hand, the model of Ferschke et al. (2012) does not include anything similar to 'propose alternative action', for example, although such a concept was shown to be important in deliberative dialogues (Walton, 2010).

Moreover, no existing model distinguishes the three dimensions of turns: act, relation, and frame. They either consider only one dimension or mix an act with a relation, such as in the label: 'criticizing unsuitable or unnecessary content' (Ferschke et al., 2012). This is a problem for predicting the next best deliberative move. For example, consider a discussion about adding new content to an article, where the participants support the action with different acts (e.g., 'providing evidence'), but all of them consider the 'writing quality' frame. A new turn attacks the action by providing evidence that the action would violate the 'neutral point of view'. The best next move should actually consider this frame, since no content that violates 'neutral point of view' policy should be added, regardless of its adherence to the 'writing quality'.



(Computational Linguistics) Merge

I think that this article should probably be merged with Computational linguistics, but I'm fairly new to the Wikipedia, so I'm not sure. Lambda 22:55, 22 Feb 20164 (UTC)

	Act	Relation	Frame
Disagree While they're related, they're not really the same thing. Computational linguistics tries to use computer techniques to better understand linguistics as a discipline, while NLP tries to build ways for a computer to understand language. See the top answer here: www.quora.com/How-is-computational-linguistics-different-from-natural-language-processing. It is a nice explanation from an expert. Figure 1: Left: An excerpt of a discussion in a Wikipedia talk page. Right: The labels of each turn in the discussion according to our proposed model.

In contrast, our approach of deriving the model using thousands of different 'descriptions' of moves written by the numerous Wikipedia users is, in our view, more likely to give a representative picture of how people argue in deliberative discussions. This, in turn, leads not only to high coverage, but also to better abstraction. Our model is in line with three well-known theories, which we summarize in the next paragraph.

Speech act is a widely accepted theory in pragmatics (Searle, 1969). Based on this theory, many research papers have been proposed for modeling different domains, such as one-on-one live chat (Kim et al., 2010), persuasiveness in blogs (Anand et al., 2011), twitter conversations (Zarisheva and Scheffler, 2015), and online dialogues (Khanpour et al., 2016). In the context of *argumentation theory* (Peldszus and Stede, 2013), agreement detection is a related direction of work which has been studied in discussions (Rosenthal and McKeown, 2015). Notably, Andreas et al. (2012) annotated 822 turns from 50 talk pages with three labels: 'agreement', 'disagreement', and 'non'. Anyhow, over the last few years, argumentation mining became a hot topic in our community, where several studies have went beyond the agreement detection to investigate the identification of the 'support' and 'attack' relations in argumentation discourses (Peldszus and Stede, 2013). Finally, *framing* is one of the important theories in discourse analysis (Entman, 1993). This theory has been studied widely in different domains, such as news article (Naderi and Hirst, 2017) and political debates (Tsur et al., 2015). These three theories back up the essence of our proposed model. We found that a participant in a discussion writes her text considering a specific act, an argumentative relation, and a frame.

The metadata in Wikipedia have been used for different tasks. The 'infobox' has been exploited in the tasks of question answering (Morales et al., 2016) and summarization (Ye et al., 2009), among others. Moreover, Wang and Cardie (2014) have used specific discussion templates to identify discussions that are disputed. Besides Wikipedia, metadata such as 'point for', 'point against', and 'introduction' have been used successfully for modeling argumentativeness in debate platforms (Al-Khatib et al., 2016a). Also, The metadata for user interactions, such as the 'delta indicator' and users votes in Reddit ChangeMyView discussions have been used to model the persuasiveness of a text (Tan et al., 2016).

We started the investgation of strategies for writing argumentative texts in previous work. In (Al-Khatib et al., 2016b), we have presented a corpus for argumentation strategies in news editorials. We then used this corpus and other data in (Al-Khatib et al., 2017) to identify patterns of strategies across different general topics. In contrast to those two studies targeting monological texts, here we address argumentation strategies in dialogical texts.

3 Modeling Deliberative Discussions

The web is full of platforms where users can share and discuss opinions, beliefs, and ideas. In case of deliberative discussions, in particular, participants try to find the best action from several choices. Apparently, the participants there follow a strategy to achieve an effective discussion, i.e., each participant tries to come with the best deliberative move that leads to achieve the goal of discussion.

The numerous deliberative discussions on these platforms do not only include user-written text, but also different types of metadata that users add to benefit the coordination between them. For example, users vote for specific posts, summarize texts, include references to the sources they use, refer to the discussion policies of a platform, or report bad behavior of others. Overall, the available metadata represents a valuable resource that provides insights into three main aspects of a discussion: The functions of users' moves, the users' roles, and the discussion topics along with their flows. We propose to exploit the metadata for modeling argumentation strategies in deliberative discussions.

To this end, we proceed in four general steps: (1) *metadata inspection*, which includes investigating the used metadata and its functions, (2) *concept origination*, where clusters of similar metadata are created and mapped to corresponding concepts, (3) *concept categorization*, where similar concepts are abstracted into a defined set of categories, and (4) *category composition*, where possible overlaps between categories should be identified.

The idea of this approach is not only to model the strategies, but also to allow for an operationalization of the resulting model by providing a dataset for training classifiers. In particular, the metadata can also be used to label discussions based on distant supervision (Mintz et al., 2009). In the following, we describe how we implement our approach to derive a new model of Wikipedia discussions, using the metadata provided by the participants.

3.1 Discussion Parsing

As part of the management policies of Wikipedia, each article has an associated page called 'Talk'. The main purpose of the talk page is to allow users to discuss how to improve the article through specific actions that they agree on. Most of these discussions can be seen as deliberative, since all participants share the same goal: finding the best action to improve the article.

When a user has a proposal on how to improve an article, she can open a discussion on the article's talk page, specifying a title and the main topic of discussion. Usually, the topic denotes a suggestion to perform a specific action, such as adding, merging, or deleting certain content of the article, among others. Ideally, multiple users then participate in the discussion about whether the action would improve the article or not.

Each single comment written by a user at a specific time is called a 'turn'. A turn may reply directly to the main topic of the discussion or to any other turn. Overall, a discussion consists of the title, the main topic, and a number of turns written by users with attached time stamps (see Figure 1). Based on a manual inspection of the turns' texts of 50 discussions, we found four general types of metadata used by the participants: *user tags*, *shortcuts*, *inline-templates*, and *external links*.

To derive a model from Wikipedia, we need to extract and parse the whole set of discussions on all talk pages, including both ongoing and closed ones. This is all but trivial, particularly due to the fact that the creation of a discussion is solely done by the users; although Wikipedia describes the required format of the different parts of a discussion in detail, not all users follow the format, often forgetting required symbols or mistakenly confusing a symbol with another one. In the implementation of our approach, we built upon the English Wikipedia dump created on March 1st, 2017. Given a Wikipedia dump, we parse it in the following steps:

Extraction of Talk Pages First, we obtain the talk pages. We use the Java Wikipedia Library (JWPL) from Zesch et al. (2008), which converts a Wikipedia dump into a database that provides an easy-to-use access to the dump components.

Extraction of Discussions Next, we extract the discussions from the talk pages. To this end, we develop several regular expressions that capture the format for starting and ending a discussion.

Corpus Component	Instances
Page	5 807 046
Discussion	5 941 534
Discussion template	144 824
Turn	20 816 860
Registered users	739 244
Turns by registered users	10 926 670
Turns by anonymous user	9 890 190
Tag	99 889
Shortcut	425 583
Inline template	3 382 443
Links	4 824 085
Turns with tag and shortcut	2 347
Turns with tag and inline template	61 521
Turns with shortcut and inline template	170 065

Table 1: Instance counts of the different components of the Webis-WikiDiscussions-18 corpus.

Identification of Structure Given the discussion, we identify their structure. We created a specific template to mine the title. The topic of the discussion is simply given by the first turn. To identify and correctly segment all users' turns, we use several indicators, for instance, indentations.

Identification of Turn Metadata Finally, we identify the metadata of each turn. We analyzed how users include the tags in their turns, finding that they usually start a turn with a user tag in triple quotation marks. A shortcut starts with 'WP:', followed by a name for the shortcut, together encapsulated by brackets. Also templates are placed between double parentheses, but they do not start with 'WP:'. Links are simply identified by either of the affixes 'www.' and 'http:'.

3.2 The Webis-WikiDiscussions-18 Corpus

The result of the parsing process is a large-scale corpus of Wikipedia discussions. In particular, the *Webis-WikiDiscussions-18* corpus we created contains about six million discussions, consisting of about 20 million turns. The turns comprise around 74,000 different tags with a total of about 100,000 instances, around 7000 different shortcuts with about 400,000 instances, and around 51,000 different inline templates with about 3.3 million instances. Half of the turns are written by registered users. Table 1 lists the exact instance counts.

3.3 Model Derivation

We now explain how we derive a model of deliberative discussions from the metadata obtained in the previous subsection. The derivation process includes the four steps outlined in the beginning of this section.

Metadata Inspection As mentioned before, a turn on Wikipedia includes up to four types of metadata: user tag, shortcut, inline template, and external link. Each type has a specific definition, a suggested usage, and properties that we discuss in the following paragraphs.

A *user tag* is a short text that a discussion participant uses to describe or summarize her contribution. Most tags indicate the main function of the contribution, such as 'proposal' and 'question'. Users can define any free-text tag they want using a noun, verb, etc. Analyzing the tags in the crawled discussions, we found the most frequent tags to be rather general and meaningful, whereas less frequent tags often capture aspects of the topic of discussion, such as 'Israel-Venezuela relations' in the discussion about 'Foreign relations of Israel'. Sometimes, tags are used to get the attention of specific users, such as 'For who reverted my change'. Unfortunately, many users also misuse tags, for example, by including the whole turn's text there or by encoding meaningless information.

A *shortcut* is an abbreviation text link that redirects the user to some page on Wikipedia. Although shortcuts may link to any Wikipedia page, they are often used to link to rules or policies. The respective pages belong to one of five categories:
(1) Behavioral guidelines: Pages that describe how users should interact with each other (e.g., during a discussion). This includes that users should be "good-faith" (WP:AGF), among others.
(2) Content guidelines: Pages that describe how to identify and include information in the articles, such as those about how an article should have reliable and accepted sources (WP:RELIABLE).
(3) Style guidelines: Pages that contain advice on writing style, formatting, grammar, and similar. This includes how to write the introduction (WP:LEAD) and headings (WP:HEADINGS), and what style to use for the content (WP:MOS).
(4) Notability guidelines: Pages that illustrate the conditions of testing whether a given topic warrants its own article. The most common shortcut in this category is (WP:N).
(5) Editing guidelines: Pages that provide information on the metadata of articles, such as the articles' categories (WP:CAT).

Overall, we found that shortcuts are used particularly frequently for style, content, and behavioral guidelines in Wikipedia discussions. The participants mainly use them to discuss the impact of applying an action that has been proposed to be performed on a Wikipedia article. For example, adding a lot of content to the introduction of an article may violate the style guidelines. A user can indicate this by referring to the style rules using the shortcut (WP:LEAD).

An *inline template* is a Wikipedia page that has been created to be included in other pages. Inline templates usually comprise specific patterns that are used in many articles, such as standard warnings or boilerplate messages. For example, there are templates for including a quotation, citation, or code, among others. Templates are used frequently in Wikipedia discussions, with the objective of writing readable and well structured turns.

An *external link*, finally, points to a web page outside Wikipedia. External links occur both in Wikipedia articles and in Wikipedia discussions. While there are some restrictions for using them in articles, they can be used without restriction in discussions. We found that these links are used in Wikipedia discussions to point to evidence on the linked web pages. In particular, they often link to research, news, search engines, educational institutions, and blogs.

Concept Origination We analyzed the usage of the four types of metadata in Wikipedia discussions and identified a set of concepts. Each concept primarily describes the turn that a participant writes:

User tags: We explored all 376 tags that occurred at least 35 times. As discussed before, the tags could be seen as a keywords that describe the turns. Often, different tags refer to the same concept, for example, 'conclusion', 'summary', and 'overall' all capture the concept of 'summarization', i.e., the main function of the respective turns is to summarize the discussion. As a result, we identified 32 clusters. We examined some turns belonging to each cluster, and mapped each cluster to a specific concept that describes it.

Shortcuts: Analogously, we explored all 99 shortcuts that occurred at least 900 times. Since the shortcuts themselves do not describe the turn, but rather the policy pages they refer to, we analyzed these pages by reading their first paragraphs and by checking their relation to the pages of the five shortcut categories we discussed before (e.g., 'behavioral'). This resulted in the identification of 12 concepts. We found that each shortcut concept describes the main quality aspect that a turn addresses. For example, 'writing content' specifies how a proposed action influences the quality of the writing of the associated article.

Inline-templates: Our investigation of this type led only to concepts that we already found before for the tags and shortcuts, such as 'stating a fact'.

External links: Similar to the templates, we identified concepts in the links that we also observed in the tags, such as 'providing source'.

Concept Categorization The concepts that we identified in the user tags can be grouped into six categories that we see as 'discourse acts':

1. *Socializing:* All concepts related to social interaction, such as thanking, apologizing, or welcoming other users.
2. *Providing evidence:* All concepts concerning the provision of evidence. Evidence may be given in form of a quote, an example, a fact, references, a source, and similar.
3. *Enhancing the understanding:* All concepts related to helping users understand the topic of discussion or a discussion itself. This can be done by giving background information, by clarifying misunderstandings, or by summarizing the discussion, among others.
4. *Recommending an act:* All concepts proposing to add a new aspect to the discussion, to ask more users to participate in the discussion, or to come up with an alternative to the proposed action.
5. *Asking a question:* All concepts related to questions serving different purposes, such as obtaining information on the topic of discussion, requesting reasons of specific decisions, and similar.
6. *Finalizing the discussion:* All concepts related to the decision of a discussion, including reporting the decision, committing it, or closing the discussion to move it to the archive.

In addition, we identified three further categories based on the user tags, which we see as relevant to 'argumentation theory'. Each represents a relation between the turn and the topic of discussion or between the turn and another turn:

1. *Support relation:* The turn agrees with or supports another turn or the topic of discussion,

for instance, by providing an argument in favor of the one in the 'supported' turn.

2. *Attack relation:* The opposite of the 'support relation', i.e., the turn disagrees or attacks another turn or the topic of discussion.
3. *Neutral relation:* The turn has a neutral relation to another turn or the topic of discussion when it neither support nor attack it.

Finally, we identified four categories based on the shortcuts that we see as relevant to 'framing theory'. They target a quality dimension of the article or of the discussion itself:

1. *Writing quality:* Turns that mainly address issues related to the quality of writing of an article, such as whether adding new content complies with the style guidelines for lead sections, the layout, or similar.
2. *Verifiability and factual accuracy:* Turns that address issues related to the quality of references, the reliability of sources, copyright violations, plagiarism, and similar.
3. *Neutral point of view:* Turns that focus on a fair representation of viewpoints and on how to avoid bias.
4. *Dialogue management:* Turns that concentrate on issues related to managing the discussion, such as reporting abusive language, preserving respect between users, encouraging newcomer participants, and similar.

Category Composition Given these categories, we investigated the interaction between them in 20 discussions, for instance, to see whether the categories are orthogonal. We found that each turn may have one discourse act, one relation, and one frame at the same time. For example, a turn may support another turn by providing evidence (say, of the type 'source'), while focusing on the writing quality frame. Table 2 shows the categories of our model and their concepts.

4 Model Operationalization

In this section, we present the operationalization process of our proposed model for deliberative argumentation strategies. First, we explain the construction of *Webis-WikiDebate-18*: a large-scale corpus for our model that we generated automatically based on the metadata in discussions. Then, we discuss the development and evaluation of a classification approach which we use for predicting the model's categories.

4.1 The Webis-WikiDebate-18 Corpus

To create a corpus for our model, we decided to rely again on the metadata. In particular, for each category in our model, we retrieved the metadata instances that had been used to derive the category, and then labeled any turn that included any metadata with this category. For example, the user tag 'overall' was used to originate the concept 'summarization', which was abstracted into the category 'enhancing the understanding'. Accordingly, all the turns that included this tag were labeled with the category 'enhancing the understanding'. This process is in line with the distant supervision paradigm. In case a turn contained metadata belonging to two categories, we excluded it from the corpus. This happened with some shortcuts in particular. Basically, such cases indicate that some turns address more than one frame.

Overall, the corpus comprises 2400 turns labeled with one of the six discourse act categories, 7437 turns with one of the relation categories, and 182,321 turns with one of the frame categories. In order to verify the reliability of the corpus, we randomly sampled about 100 turns from each category, ensuring that all the category's concepts are taken into consideration. The turns in the samples were verified (i.e., whether they belong to the assigned category) by a worker hired from the freelancing platform `upwork.com`. The worker was a native speaker of English with deep expertise in writing. Table 3 shows statistics of the corpus, including the percentage of turns in each sample that belong to the assigned category according to the expert. In general, this verification result is comparable to the inter-annotator agreement achieved in some related studies (Ferschke et al., 2012).

4.2 Classification Approach

Based on the Webis-WikiDebate-18 corpus, we develop three supervised classifiers: one for the discourse acts, one for the relations, and one for the frames. Since this paper does not aim at proposing a novel approach for the classification tasks, but rather at showing the ability to operationalize the model, we follow existing work that has proposed methods for the tasks at hand. Particularly, we implement a rich set of features that have been used by others before. These features capture lexical, semantic, style, and pragmatic properties of turns.

Dimension	Category	Concepts
Discourse act	Socializing	(1) Thank a user, (2) Apologize from a user, (3) Welcome a user, (4) Express anger
	Providing evidence	(1) Provide a quote, (2) Reference, (3) Source, (4) Give an example, (5) State a fact, (6) Explain a rational
	Enhancing the understanding	(1) Provide background info, (2) Info on the history of similar discussions, (3) Introduce the topic of discussion, (4) Clarify a misunderstanding, (5) Correct previous own or other's turn, (6) Write a discussion summary, (7) Conduct a survey on participants, (8) Request info
	Recommending an act	(1) Propose alternative action on the article, (2) Suggest a new process of discussion, (3) Propose asking a third party
	Asking a question	(1) Ask a general question about the topic, (2) Question a proposal or arguments in a turn
	Finalizing the discussion	(1) Report the decision, (2) Commit the decision, (3) Close the discussion
Argumentative relation	Support	(1) Agree, (2) Support
	Neutral	(1) Be neutral.
	Attack	(1) Disagree, (2) Attack, (3) Counter-attack
Frame	Writing quality	(1) Naming articles, (2) Writing content, (3) Formatting, (4) images, (5) Layout and list
	Verifiability and factual accuracy	(1) Reliable sources, (2) Proper citation (3) Good argument
	Neutral point of view	(1) Neutral point of view
	Dialogue management	(1) Be bold. (2) Be civil, (3) Don't game the system

Table 2: The concepts covered by each category of each of the three principle dimensions of our model.

Dimension	Category	Turns	Prec.
Discourse act	Socializing	83	0.71
	Providing evidence	781	0.49
	Enhancing the understanding	671	0.56
	Recommending an act	137	0.82
	Asking a question	106	0.71
	Finalizing the discussion	622	0.71
Argumentative relation	Support	2895	1.00
	Neutral	1937	0.63
	Attack	2605	1.00
Frame	Writing quality	19893	0.51
	Verifiability and factual ac.	72049	0.89
	Neutral point of view	60007	0.89
	Dialogue management	30372	0.74

Table 3: Number of turns in each category of Webis-WikiDebate-18 corpus and the precision of sampled turns for each category according to an expert.

In short, we used the following features: The frequency of word 1–3-grams, character 1–3-grams, chunk 1–3-grams, function word 1–3-grams, and of the first 1–3 tokens in a turn. The number of characters, syllables, tokens, phrases, and sentences in a turn. the frequencies of part-of-speech tag 1–3-grams. The mean SentiWordNet score of the words in a turn (http://sentiwordnet.isti.cnr.it). The frequency of each word class of the General Inquirer (http://www.wjh.harvard.edu/~inquirer). The depth level of turns in the discussion. For the relation classifier, we had additional features that consider the target of the relation (the parent turn), namely, the cosine, euclidean, manhattan, and jaccard similarity between turn and parent turn.

4.3 Experiments and Results

As a preprocessing step, we cleaned the turns in the *Webis-WikiDebate-18* Corpus by removing all the metadata: user tags, shortcuts, user and time stamps, etc. Then, we grouped the turns that belong to the discourse act categories in a single dataset (say, the 'discourse act dataset'). The same was performed for the turns belonging to relations and frames. We then split each of the three datasets randomly into training (60%), development (20%), and test (20%) sets. We ensured that turns from the same discussion should appear only in either of the split sets, in order to avoid biasing the classifiers by topical information.

We trained different machine learning models on the training sets and evaluated them on the development sets. The models included those which had been used before in similar tasks, such as naive bayes, logistic regression, support vector machine, and random forest. We tried both under and over-sampling on the training sets. The best results in the three tasks were achieved by using support vector

Dimension	Category	Prec.	Rec.	F_1

	Dialogue management	0.64	0.56	0.60

Table 4: The precision, recall, and F_1-score of our classifiers for all categories of the three dimensions.

machine without sampling the training sets.

We used the support vector machine implementation from the LibLinear library (Fan et al., 2008) on the test sets and report the results in Table 4. Overall, the three classifiers achieved results that are comparable to the results of previous methods on the corresponding tasks (Ferschke et al., 2012; Zhang et al., 2017a). We obtained the best results in the frame task, followed by relations and then discourse acts. Apparently, the results correlate with the size of the datasets. In case of discourse acts, the classifier achieves low F_1-scores for 'socializing', 'recommending an act', and 'asking a question'. These categories have a significantly smaller number of turns compared to other categories, which makes identifying them harder. The effectiveness of classifying the relation and frame categories, on the other hand, appears promising given the difficulty of these tasks.

We point that we considered mainly the turns' texts in our experiments. In principle, this helps to get an idea about the effectiveness of our approach in Wikipedia as well as other registers for discussions. Nevertheless, including the metadata and structural information of the analyzed discussions is definitely worthwhile in general, and will naturally tend to lead to notably higher effectiveness.

5 Discussion and Conclusion

While our approach to modeling argumentation strategies in deliberative discussions may seem Wikipedia-specific, the derivation of concepts and categories from metadata can be transferred to other online discussion platforms. We expect the general derivation steps to be the same, whereas the techniques applied within each step may differ depending on the types, frequency, and quality of metadata. For example, the consistent usage of the most common user tags in Wikipedia discussions helps originating concepts manually. In contrast, other metadata might require the use of computational methods, such as clustering, keyphrase extraction, and textual entailment.

Unlike previous approaches to the modeling of discussions on Wikipedia, our model decouples the three principle dimensions of discussions: *discourse acts*, *argumentative relations*, and *frames*. We argue that the distinction of these dimensions is key to develop tool support for discussion participants, for example, for recommending the best possible move in an ongoing discussion.

Also, our model helps analyzing the influence of user interaction and behavior on the effectiveness of discussion decisions. For example, some Wikipedia users focus on the frame 'well written' while ignoring others, which may negatively affect the accuracy of an article's content. Also, users often attack other turns, instead of considering neutral acts such as clarifications of misunderstandings.

Many categories in our model will apply to deliberative discussions in general, particularly the discourse acts and argumentative relations. While the found frames are more Wikipedia-specific, similar play a role on collaborative writing platforms. For example, when writing a scientific paper, possible frames are the 'writing quality' or the 'verifiability of content and citations'.

Besides the model, we created two large-scale corpora: The *Webis-WikiDiscussions-18* corpus, including the entire set of Wikipedia discussions (at the time of parsing) with annotated discussion structure and metadata, and the *Webis-WikiDebate-18* corpus, where turns are labeled for their discourse acts, argumentative relations, and frames. We believe that these corpora will help foster research on tasks such as argument mining, among others.

Finally, we operationalized our Wikipedia discussion model in three support vector machine classifiers with tailored features. Our experiment results confirm that categories of our model can be predicted successfully. In future work, we plan to study how to distinguish effective from ineffective discussions based on our model as well as how to learn from the strategies used in successful discussions, in order to predict the best next deliberative move in an ongoing discussion.

Venice, CA 90291
{piyushsharma,dingnan,seabass,rsoricut}@google.com

Abstract

We present a new dataset of image caption annotations, Conceptual Captions, which contains an order of magnitude more images than the MS-COCO dataset (Lin et al., 2014) and represents a wider variety of both images and image caption styles. We achieve this by extracting and filtering image caption annotations from billions of webpages. We also present quantitative evaluations of a number of image captioning models and show that a model architecture based on Inception-ResNet-v2 (Szegedy et al., 2016) for image-feature extraction and Transformer (Vaswani et al., 2017) for sequence modeling achieves the best performance when trained on the Conceptual Captions dataset.

Conceptual Captions: pop artist performs at the festival in a city.

Figure 1: Examples of images and image descriptions from the Conceptual Captions dataset; we start from existing alt-text descriptions, and automatically process them into Conceptual Captions with a balance of cleanliness, informativeness, fluency, and learnability.

1 Introduction

Automatic image description is the task of producing a natural-language utterance (usually a sentence) which correctly reflects the visual content of an image. This task has seen an explosion in proposed solutions based on deep learning architectures (Bengio, 2009), starting with the winners of the 2015 COCO challenge (Vinyals et al., 2015a; Fang et al., 2015), and continuing with a variety of improvements (see e.g. Bernardi et al. (2016) for a review). Practical applications of automatic image description systems include leveraging descriptions for image indexing or retrieval, and helping those with visual impairments by transforming visual signals into information that can be communicated via text-to-speech technology. The scientific challenge is seen as aligning, exploiting, and pushing further the latest improvements at the intersection of Computer Vision and Natural Language Processing.

There are two main categories of advances responsible for increased interest in this task. The first is the availability of large amounts of annotated data. Relevant datasets include the ImageNet dataset (Deng et al., 2009), with over 14 million images and 1 million bounding-box annotations, and the MS-COCO dataset (Lin et al., 2014), with 120,000 images and 5-way image-caption annotations. The second is the availability of powerful modeling mechanisms such as modern Convolutional Neural Networks (e.g. Krizhevsky et al. (2012)), which are capable of converting image pixels into high-level features with no manual feature-engineering.

In this paper, we make contributions to both the data and modeling categories. First, we present a new dataset of caption annotations[*], Conceptual Captions (Fig. 1), which has an order of magnitude more images than the COCO

[*]https://github.com/google-research-datasets/conceptual-captions

dataset. Conceptual Captions consists of about 3.3M $\langle image, description \rangle$ pairs. In contrast with the curated style of the COCO images, Conceptual Captions images and their raw descriptions are harvested from the web, and therefore represent a wider variety of styles. The raw descriptions are harvested from the Alt-text HTML attribute[†] associated with web images. We developed an automatic pipeline (Fig. 2) that extracts, filters, and transforms candidate image/caption pairs, with the goal of achieving a balance of cleanliness, informativeness, fluency, and learnability of the resulting captions.

As a contribution to the modeling category, we evaluate several image-captioning models. Based on the findings of Huang et al. (2016), we use Inception-ResNet-v2 (Szegedy et al., 2016) for image-feature extraction, which confers optimization benefits via residual connections and computationally efficient Inception units. For caption generation, we use both RNN-based (Hochreiter and Schmidhuber, 1997) and Transformer-based (Vaswani et al., 2017) models. Our results indicate that Transformer-based models achieve higher output accuracy; combined with the reports of Vaswani et al. (2017) regarding the reduced number of parameters and FLOPs required for training & serving (compared with RNNs), models such as T2T8x8 (Section 4) push forward the performance on image-captioning and deserve further attention.

2 Related Work

Automatic image captioning has a long history (Hodosh et al., 2013; Donahue et al., 2014; Karpathy and Fei-Fei, 2015; Kiros et al., 2015). It has accelerated with the success of Deep Neural Networks (Bengio, 2009) and the availability of annotated data as offered by datasets such as Flickr30K (Young et al., 2014) and MS-COCO (Lin et al., 2014).

The COCO dataset is not large (order of 10^6 images), given the training needs of DNNs. In spite of that, it has been very popular, in part because it offers annotations for images with non-iconic views, or non-canonical perspectives of objects, and therefore reflects the composition of everyday scenes (the same is true about Flickr30K (Young et al., 2014)). COCO annotations–category labeling, instance spotting, and instance segmentation–are done for all objects in an image, including those in the background, in a cluttered environment, or partially occluded. Its images are also annotated with captions, i.e. sentences produced by human annotators to reflect the visual content of the images in terms of objects and their actions or relations.

A large number of DNN models for image caption generation have been trained and evaluated using COCO captions (Vinyals et al., 2015a; Fang et al., 2015; Xu et al., 2015; Ranzato et al., 2015; Yang et al., 2016; Liu et al., 2017; Ding and Soricut, 2017). These models are inspired by sequence-to-sequence models (Sutskever et al., 2014; Bahdanau et al., 2015) but use CNN-based encodings instead of RNNs (Hochreiter and Schmidhuber, 1997; Chung et al., 2014). Recently, the Transformer architecture (Vaswani et al., 2017) has been shown to be a viable alternative to RNNs (and CNNs) for sequence modeling. In this work, we evaluate the impact of the Conceptual Captions dataset on the image captioning task using models that combine CNN, RNN, and Transformer layers.

Also related to this work is the Pinterest image and sentence-description dataset (Mao et al., 2016). It is a large dataset (order of 10^8 examples), but its text descriptions do not strictly reflect the visual content of the associated image, and therefore cannot be used directly for training image-captioning models.

3 Conceptual Captions Dataset Creation

The Conceptual Captions dataset is programmatically created using a Flume (Chambers et al., 2010) pipeline. This pipeline processes billions of Internet webpages in parallel. From these webpages, it extracts, filters, and processes candidate $\langle image, caption \rangle$ pairs. The filtering and processing steps are described in detail in the following sections.

Image-based Filtering The first filtering stage, image-based filtering, discards images based on encoding format, size, aspect ratio, and offensive content. It only keeps JPEG images where both dimensions are greater than 400 pixels, and the ratio of larger to smaller dimension is no more than 2. It excludes images that trigger pornography or profanity detectors. These filters discard more than 65% of the candidates.

Text-based Filtering The second filtering stage, text-based filtering, harvests Alt-text from HTML webpages. Alt-text generally accompanies images,

"pop rock artist wearing a black gown and sandals at awards"

Figure 2: Conceptual Captions pipeline steps with examples and final output.

and intends to describe the nature or the content of the image. Because these Alt-text values are not in any way restricted or enforced to be good image descriptions, many of them have to be discarded, e.g., search engine optimization (SEO) terms, or Twitter hash-tag terms.

We analyze candidate Alt-text using the Google Cloud Natural Language APIs, specifically part-of-speech (POS), sentiment/polarity, and pornography/profanity annotations. On top of these annotations, we have the following heuristics:

- a well-formed caption should have a high unique word ratio covering various POS tags; candidates with no determiner, no noun, or no preposition are discarded; candidates with a high noun ratio are also discarded;

- candidates with a high rate of token repetition are discarded;

- capitalization is a good indicator of well-composed sentences; candidates where the first word is not capitalized, or with too high capitalized-word ratio are discarded;

- highly unlikely tokens are a good indicator of not desirable text; we use a vocabulary V_W of 1B token types, appearing at least 5 times in the English Wikipedia, and discard candidates that contain tokens that are not found in this vocabulary.

- candidates that score too high or too low on the polarity annotations, or trigger the pornography/profanity detectors, are discarded;

- predefined boiler-plate prefix/suffix sequences matching the text are cropped, e.g. "click to enlarge picture", "stock photo"; we also drop text which begins/ends in certain patterns, e.g. "embedded image permalink", "profile photo".

These filters only allow around 3% of the incoming candidates to pass to the later stages.

Image&Text-based Filtering In addition to the separate filtering based on image and text content, we filter out candidates for which none of the text tokens can be mapped to the content of the image. To this end, we use classifiers available via the Google Cloud Vision APIs to assign class labels to images, using an image classifier with a large number of labels (order of magnitude of 10^5). Notably, these labels are also 100% covered by the V_w token types.

Images are generally assigned between 5 to 20 labels, though the exact number depends on the

Original Alt-text	Harrison Ford and Calista Flockhart attend the premiere of 'Hollywood Homicide' at the 29th American Film Festival September 5, 2003 in Deauville, France.

Conceptual Captions	sculptures by person adorn trees outside the derelict offices
what-happened	object count (e.g. "Two") dropped; proper noun-phrase hypernymized to "person"; proper-noun modifiers dropped; location dropped; boilerplate removed.

Table 1: Examples of Conceptual Captions as derived from their original Alt-text versions.

image. We match these labels against the candidate text, taking into account morphology-based stemming as provided by the text annotation. Candidate $\langle image, caption\rangle$ pairs with no overlap are discarded. This filter discards around 60% of the incoming candidates.

Text Transformation with Hypernymization In the current version of the dataset, we considered over 5 billion images from about 1 billion English webpages. The filtering criteria above are designed to be high-precision (which comes with potentially low recall). From the original input candidates, only 0.2% $\langle image, caption\rangle$ pairs pass the filtering criteria described above.

While the remaining candidate captions tend to be appropriate Alt-text image descriptions (see Alt-text in Fig. 1), a majority of these candidate captions contain proper names (people, venues, locations, etc.), which would be extremely difficult to learn as part of the image captioning task. To give an idea of what would happen in such cases, we train an RNN-based captioning model (see Section 4) on non-hypernymized Alt-text data and present an output example in Fig. 3. If automatic determination of person identity, location, etc. is needed, it should be attempted as a separate task and would need to leverage image meta-information about the image (e.g. location).

Using the Google Cloud Natural Language APIs, we obtain named-entity and syntactic-dependency annotations. We then use the Google Knowledge Graph (KG) Search API to match the named-entities to KG entries and exploit the associated hypernym terms. For instance, both "Harrison Ford" and "Calista Flockhart" identify as named-entities,

Alt-text (groundtruth): Jimmy Barnes performs at the Sydney Entertainment Centre

Model output: Singer Justin Bieber performs onstage during the Billboard Music Awards at the MGM

Figure 3: Example of model output trained on clean, non-hypernymized Alt-text data.

so we match them to their corresponding KG entries. These KG entries have "actor" as their hypernym, so we replace the original surface tokens with that hypernym.

The following steps are applied to achieve text transformations:

- noun modifiers of certain types (proper nouns, numbers, units) are removed;
- dates, durations, and preposition-based locations (e.g., "in Los Angeles") are removed;
- named-entities are identified, matched against the KG entries, and substitute with their hypernym;
- resulting coordination noun-phrases with the same head (e.g., "actor and actor") are resolved into a single-head, pluralized form (e.g., "actors");

Around 20% of samples are discarded during this transformation because it can leave sentences too short or inconsistent.

Finally, we perform another round of text analysis and entity resolution to identify concepts with low-count. We cluster all resolved entities (e.g., "actor", "dog", "neighborhood", etc.) and keep only the candidates for which all detected types have a count of over 100 (around 55% of the candidates). These remaining $\langle image, caption \rangle$ pairs contain around 16,000 entity types, guaranteed to be well represented in terms of number of examples. Table 1 contains several examples of before/after-transformation pairs.

Conceptual Captions Quality To evaluate the precision of our pipeline, we consider a random sample of 4K examples extracted from the test split of the Conceptual Captions dataset. We perform a human evaluation on this sample, using the same methodology described in Section 5.4.

	GOOD (out of 3)		
	1+	2+	3
Conceptual Captions	96.9%	90.3%	78.5%

Table 2: Human evaluation results on a sample from Conceptual Captions.

The results are presented in Table 2 and show that, out of 3 annotations, over 90% of the captions receive a majority (2+) of GOOD judgments. This indicates that the Conceptual Captions pipeline, though involving extensive algorithmic processing, produces high-quality image captions.

	Examples	Unique Tokens	Tokens/Caption		
			Mean	StdDev	Median
Train	3,318,333	51,201	10.3	4.5	9.0
Valid.	28,355	13,063	10.3	4.6	9.0
Test	22,530	11,731	10.1	4.5	9.0

Table 3: Statistics over Train/Validation/Test splits for Conceptual Captions.

We present in Table 3 statistics over the Train/Validation/Test splits for the Conceptual Captions dataset. The training set consists of slightly over 3.3M examples, while there are slightly over 28K examples in the validation set and 22.5K examples in the test set. The size of the training set vocabulary (unique tokens) is 51,201. Note that the test set has been cleaned using human judgements (2+ GOOD), while both the training and validation splits contain all the data, as produced by our automatic pipeline. The mean/stddev/median statistics for tokens-per-caption over the data splits are consistent with each other, at around 10.3/4.5/9.0, respectively.

4 Image Captioning Models

In order to assess the impact of the Conceptual Captions dataset, we consider several image captioning models previously proposed in the literature. These models can be understood using the illustration in Fig. 4, as they mainly differ in the way in which they instantiate some of these components.

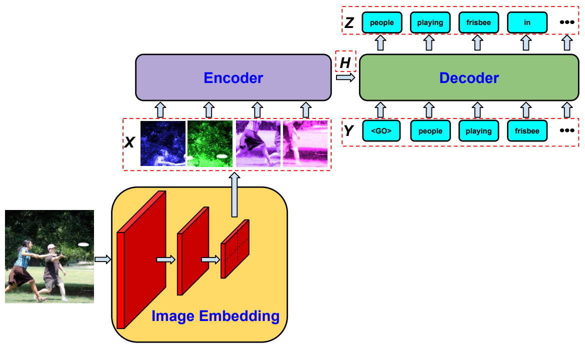

Figure 4: The main model components.

There are three main components to this architecture:

- A deep CNN that takes a (preprocessed) image and outputs a vector of image embeddings $\mathbf{X} = (\mathbf{x}_1, \mathbf{x}_2, ..., \mathbf{x}_L)$.
- An Encoder module that takes the image embeddings and encodes them into a tensor $\mathbf{H} = f_{\text{enc}}(\mathbf{X})$.
- A Decoder model that generates outputs $\mathbf{z}_t = f_{\text{dec}}(\mathbf{Y}_{1:t}, \mathbf{H})$ at each step t, conditioned on $\mathbf{H}$ as well as the decoder inputs $\mathbf{Y}_{1:t}$.

We explore two main instantiations of this architecture. One uses RNNs with LSTM cells (Hochreiter and Schmidhuber, 1997) to implement the f_{enc} and f_{dec} functions, corresponding to the Show-And-Tell (Vinyals et al., 2015b) model. The other uses Transformer self-attention networks (Vaswani et al., 2017) to implement f_{enc} and f_{dec}. All models in this paper use Inception-ResNet-v2 as the CNN component (Szegedy et al., 2016).

4.1 RNN-based Models

Our instantiation of the RNN-based model is close to the Show-And-Tell (Vinyals et al., 2015b) model.

$$\mathbf{h}_l \triangleq \text{RNN}_{enc}(\mathbf{x}_l, \mathbf{h}_{l-1}), \text{ and } \mathbf{H} = \mathbf{h}_L,$$
$$\mathbf{z}_t \triangleq \text{RNN}_{dec}(\mathbf{y}_t, \mathbf{z}_{t-1}), \text{ where } \mathbf{z}_0 = \mathbf{H}.$$

In the original Show-And-Tell model, a single image embedding of the entire image is fed to the first cell of an RNN, which is also used for text generation. In our model, a single image embedding is fed to an RNN$_{enc}$ with only one cell, and then a different RNN$_{dec}$ is used for text generation. We tried both single image (1x1) embeddings and 8x8 partitions of the image, where each partition has its own embedding. In the 8x8 case, image embeddings are fed in a sequence to the RNN$_{enc}$. In both cases, we apply plain RNNs without cross attention, same as the Show-And-Tell model. RNNs with cross attention were used in the Show-Attend-Tell model (Xu et al., 2015), but we find its performance to be inferior to the Show-And-Tell model.

4.2 Transformer Model

In the Transformer-based models, both the encoder and the decoder contain a stack of N layers. We denote the n-th layer in the encoder by $\mathbf{X}_n = \{\mathbf{x}_{n,1}, \ldots, \mathbf{x}_{n,L}\}$, and $\mathbf{X}_0 = \mathbf{X}$, $\mathbf{H} = \mathbf{X}_N$. Each of these layers contains two sub-layers: a multi-head self-attention layer ATTN, and a position-wise feedforward network FFN:

$$\begin{aligned}\mathbf{x}'_{n,j} &= \text{ATTN}(\mathbf{x}_{n,j}, \mathbf{X}_n; \mathbf{W}^e_q, \mathbf{W}^e_k, \mathbf{W}^e_v) \\ &\triangleq \text{softmax}(\langle \mathbf{x}_{n,j}\, \mathbf{W}^e_q, \mathbf{X}_n\, \mathbf{W}^e_k \rangle)\, \mathbf{X}_n\, \mathbf{W}^e_v \\ \mathbf{x}_{(n+1),j} &= \text{FFN}(\mathbf{x}'_{n,j}; \mathbf{W}^e_f)\end{aligned}$$

where $\mathbf{W}^e_q$, $\mathbf{W}^e_k$, and $\mathbf{W}^e_v$ are the encoder weight matrices for query, key, and value transformation in the self-attention sub-layer; and $\mathbf{W}^e_f$ denotes the encoder weight matrix of the feedforward sub-layer. Similar to the RNN-based model, we consider using a single image embedding (1x1) and a vector of 8x8 image embeddings.

In the decoder, we denote the n-th layer by $\mathbf{Z}_n = \{\mathbf{z}_{n,1}, \ldots, \mathbf{z}_{n,T}\}$ and $\mathbf{Z}_0 = \mathbf{Y}$. There are two main differences between the decoder and encoder layers. First, the self-attention sub-layer in the decoder is masked to the right, in order to prevent attending to "future" positions (i.e. $\mathbf{z}_{n,j}$ does not attend to $\mathbf{z}_{n,(j+1)}, \ldots, \mathbf{z}_{n,T}$). Second, in between the self-attention layer and the feedforward layer, the decoder adds a third cross-attention layer that connects $\mathbf{z}_{n,j}$ to the top-layer encoder representation $\mathbf{H} = \mathbf{X}_N$.

$$\begin{aligned}\mathbf{z}'_{n,j} &= \text{ATTN}(\mathbf{z}_{n,j}, \mathbf{Z}_{n,1:j}; \mathbf{W}^d_q, \mathbf{W}^d_k, \mathbf{W}^d_v) \\ \mathbf{z}''_{n,j} &= \text{ATTN}(\mathbf{z}'_{n,j}, \mathbf{H}; \mathbf{W}^c_q, \mathbf{W}^c_k, \mathbf{W}^c_v) \\ \mathbf{z}_{(n+1),j} &= \text{FFN}(\mathbf{z}''_{n,j}; \mathbf{W}^d_f)\end{aligned}$$

where $\mathbf{W}^d_q$, $\mathbf{W}^d_k$, and $\mathbf{W}^d_v$ are the weight matrices for query, key, and value transformation in the decoder self-attention sub-layer; $\mathbf{W}^c_q$, $\mathbf{W}^c_k$, $\mathbf{W}^c_v$ are the corresponding decoder weight matrices in the cross-attention sub-layer; and $\mathbf{W}^d_f$ is the decoder weight matrix of the feedforward sub-layer.

The Transformer-based models utilize position information at the embedding layer. In the 8x8 case, the 64 embedding vectors are serialized to a 1D sequence with positions from $[0, \ldots, 63]$. The position information is modeled by applying sine and cosine functions at each position and with different frequencies for each embedding dimension, as in (Vaswani et al., 2017), and subsequently added to the embedding representations.

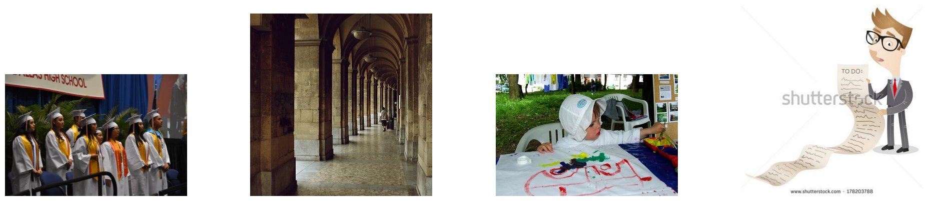
5 Experimental Results

In this section, we evaluate the impact of using the Conceptual Captions dataset (referred to as 'Conceptual' in what follows) for training image captioning models. To this end, we train the models described in Section 4 under two experimental conditions: using the training & development sets provided by the COCO dataset (Lin et al., 2014), versus training & development sets using the Conceptual dataset. We quantitatively evaluate the resulting models using three different test sets: the blind COCO-C40 test set (in-domain for COCO-trained models, out-of-domain for Conceptual-trained models); the Conceptual test set (out-of-domain for COCO-trained models, in-domain for Conceptual-trained models); and the Flickr (Young et al., 2014) 1K test set (out-of-domain for both COCO-trained models and Conceptual-trained models).

5.1 Dataset Details

COCO Image Captions The COCO image captioning dataset is normally divided into 82K images for training, and 40K images for validation. Each of these images comes with at least 5 groundtruth captions. Following standard practice, we combine the training set with most of the validation dataset for training our model, and only hold out a subset of 4K images for validation.

Conceptual Captions The Conceptual Captions dataset contains around 3.3M images for training, 28K for validation and 22.5K for the test set. For more detailed statistics, see Table 3.



COCO-trained				
RNN8x8	a group of men standing in front of a building	a couple of people walking down a walkway	a child sitting at a table with a cake on it	a close up of a stuffed animal on a table
T2T8x8	a group of men in uniform and ties are talking	a narrow hallway with a clock and two doors	a woman cutting a birthday cake at a party	a picture of a fish on the side of a car
Conceptual-trained				
RNN8x8	graduates line up for the commencement ceremony	a view of the nave	a child 's drawing at a birthday party	a cartoon businessman thinking about something
T2T8x8	graduates line up to receive their diplomas	the cloister of the cathedral	learning about the arts and crafts	a cartoon businessman asking for help

Figure 5: Side by side comparison of model outputs under two training conditions. Conceptual-based models (lower half) tend to hallucinate less, are more expressive, and handle well a larger variety of images. The two images in the middle are from Flickr; the other two are from Conceptual Captions.

5.2 Experimental Setup

Image Preprocessing Each input image is first preprocessed by random distortion and cropping (using a random ratio from 50%∼100%). This prevents models from overfitting individual pixels of the training images.

Encoder-Decoder For RNN-based models, we use a 1-layer, 512-dim LSTM as the RNN cell. For the Transformer-based models, we use the default setup from (Vaswani et al., 2017), with $N = 6$ encoder and decoder layers, a hidden-layer size of 512, and 8 attention heads.

Text Handling Training captions are truncated to maximum 15 tokens. We use a token type min-count of 4, which results in around 9,000 token types for the COCO dataset, and around 25,000 token types for the Conceptual Captions dataset. All other tokens are replaced with special token ⟨UNK⟩. The word embedding matrix has size 512 and is tied to the output projection matrix.

Optimization All models are trained using MLE loss and optimized using Adagrad (Duchi et al., 2011) with learning rate 0.01. Mini-batch size is 25. All model parameters are trained for a total number of 5M steps, with batch updates asynchronously distributed across 40 workers. The final model is selected based on the best CIDEr score on the development set for the given training condition.

Inference During inference, the decoder prediction of the previous position is fed to the input of the next position. We use a beam search of beam size 4 to compute the most likely output sequence.

5.3 Qualitative Results

Before we present the numerical results for our experiments, we discuss briefly the patterns that we have observed.

One difference between COCO-trained models and Conceptual-trained models is their ability to use the appropriate natural language terms for the entities in an image. For the left-most image in Fig. 5, COCO-trained models use "group of men" to refer to the people in the image; Conceptual-based models use the more appropriate and informative term "graduates". The second image, from the Flickr test set, makes this even more clear. The Conceptual-trained T2T8x8 model is perfectly rendering the image content as "the cloister of the cathedral". None of the other models come close to producing such an accurate description.

A second difference is that COCO-trained models often seem to hallucinate objects. For instance, they hallucinate "front of building" for the first image, "clock and two doors" for the second, and "birthday cake" for the third image. In contrast, Conceptual-trained models do not seem to have this problem. We hypothesize that the hallucination issue for COCO-based models comes from the high correlations present in the COCO data (e.g., if there is a kid at a table, there is also cake). This high degree of correlation in the data does not allow the captioning model to correctly disentangle and learn representations at the right level of granularity.

Model	Training	1+	2+	3+
RNN8x8	COCO	0.390	0.276	0.173
T2T8x8	COCO	0.478	0.362	0.275
RNN8x8	Conceptual	0.571	0.418	0.277
T2T8x8	Conceptual	0.659	0.506	0.355

Table 4: Human eval results on Flickr 1K Test.

A third difference is the resilience to a large spectrum of image types. COCO only contains natural images, and therefore a cartoon image like the fourth one results in massive hallucination effects for COCO-trained models (“stuffed animal”, “fish”, “side of car”). In contrast, Conceptual-trained models handle such images with ease.

5.4 Quantitative Results

In this section, we present quantitative results on the quality of the outputs produced by several image captioning models. We present both automatic evaluation results and human evaluation results.

5.4.1 Human Evaluation Results

For human evaluations, we use a pool of professional raters (tens of raters), with a double-blind evaluation condition. Raters are asked to assign a GOOD or BAD label to a given $\langle image, caption \rangle$ input, using just common-sense judgment. This approximates the reaction of a typical user, who normally would not accept predefined notions of GOOD vs. BAD. We ask 3 separate raters to rate each input pair and report the percentage of pairs that receive k or more (k+) GOOD annotations.

In Table 4, we report the results on the Flickr 1K test set. This evaluation is out-of-domain for both training conditions, so all models are on relatively equal footing. The results indicate that the Conceptual-based models are superior. In 50.6% (for the T2T8x8 model) of cases, a majority of annotators (2+) assigned a GOOD label. The results also indicate that the Transformer-based models are superior to the RNN-based models by a good margin, by over 8-points (for 2+) under both COCO and Conceptual training conditions.

Model	Training	CIDEr	ROUGE-L	METEOR
RNN1x1	COCO	1.021	0.694	0.348
RNN8x8	COCO	1.044	0.698	0.354
T2T1x1	COCO	1.032	0.700	0.358
T2T8x8	COCO	1.032	0.700	0.356
RNN1x1	Conceptual	0.403	0.445	0.191
RNN8x8	Conceptual	0.410	0.437	0.189
T2T1x1	Conceptual	0.348	0.403	0.171
T2T8x8	Conceptual	0.345	0.400	0.170

T2T8x8	Conceptual	0.227	0.277	0.066

Table 7: Auto metrics on the Flickr 1K Test.

5.4.2 Automatic Evaluation Results

In this section, we report automatic evaluation results, using established image captioning metrics.

For the COCO C40 test set (Fig. 5), we report the numerical values returned by the COCO online evaluation server[‡], using the CIDEr (Vedantam et al., 2015), ROUGE-L (Lin and Och, 2004), and METEOR (Banerjee and Lavie, 2005) metrics. For Conceptual Captions (Fig. 6) and Flickr (Fig. 7) test sets, we report numerical values for the CIDEr, ROUGE-L, and SPICE (Anderson et al., 2016)[§]. For all metrics, higher number means closer distance between the candidates and the groundtruth captions.

The automatic metrics are good at detecting in- vs out-of-domain situations. For COCO-models tested on COCO, the results in Fig. 5 show CIDEr scores in the 1.02-1.04 range, for both RNN- and Transformer-based models; the scores drop in the 0.35-0.41 range (CIDEr) for the Conceptual-based models tested against COCO groundtruth. For Conceptual-models tested on the Conceptual Captions test set, the results in Fig. 6 show scores as high as 1.468 CIDEr for the T2T8x8 model, which corroborates the human-eval results for the Transformer-based models being superior to the RNN-based models; the scores for the COCO-based models tested against Conceptual Captions groundtruth are all below 0.2 CIDEr.

The automatic metrics fail to corroborate the

[‡]http://mscoco.org/dataset/#captions-eval.

[§]https://github.com/tylin/coco-caption.

human evaluation results. According to the automatic metrics, the COCO-trained models are superior to the Conceptual-trained models (CIDEr scores in the mid-0.3 for the COCO-trained condition, versus mid-0.2 for the Conceptual-trained condition), and the RNN-based models are superior to Transformer-based models. Notably, these are the same metrics which score humans lower than the methods that won the COCO 2015 challenge (Vinyals et al., 2015a; Fang et al., 2015), despite the fact that humans are still much better at this task. The failure of these metrics to align with the human evaluation results casts again grave doubts on their ability to drive progress in this field. A significant weakness of these metrics is that hallucination effects are under-penalized (a small precision penalty for tokens with no correspondent in the reference), compared to human judgments that tend to dive dramatically in the presence of hallucinations.

6 Conclusions

We present a new image captioning dataset, Conceptual Captions, which has several key characteristics: it has around 3.3M examples, an order of magnitude larger than the COCO image-captioning dataset; it consists of a wide variety of images, including natural images, product images, professional photos, cartoons, drawings, etc.; and, its captions are based on descriptions taken from original Alt-text attributes, automatically transformed to achieve a balance between cleanliness, informativeness, and learnability.

We evaluate both the quality of the resulting image/caption pairs, as well as the performance of several image-captioning models when trained on the Conceptual Captions data. The results indicate that such models achieve better performance, and avoid some of the pitfalls seen with COCO-trained models, such as object hallucination. We hope that the availability of the Conceptual Captions dataset will foster considerable progress on the automatic image-captioning task.

Abstract

We conduct the most comprehensive study to date into translating words via images. To facilitate research on the task, we introduce a large-scale multilingual corpus of images, each labeled with the word it represents. Past datasets have been limited to only a few high-resource languages and unrealistically easy translation settings. In contrast, we have collected by far the largest available dataset for this task, with images for approximately 10,000 words in each of 100 languages. We run experiments on a dozen high resource languages and 20 low resources languages, demonstrating the effect of word concreteness and part-of-speech on translation quality. To improve image-based translation, we introduce a novel method of predicting word concreteness from images, which improves on a previous state-of-the-art unsupervised technique. This allows us to predict when image-based translation may be effective, enabling consistent improvements to a state-of-the-art text-based word translation system. Our code and the Massively Multilingual Image Dataset (MMID) are available at http://multilingual-images.org/.

1 Introduction

Learning the translations of words is important for machine translation and other tasks in natural language processing. Typically this learning is done using sentence-aligned bilingual parallel texts. However, for many languages, there are not sufficiently large parallel texts to effectively learn translations. In this paper, we explore the question of whether it is possible to learn translations with images. We systematically explore an idea originally proposed by Bergsma and Van Durme (2011): translations can be identified via images associated with words in different languages that have a high degree of visual similarity. This is illustrated in Figure 1.

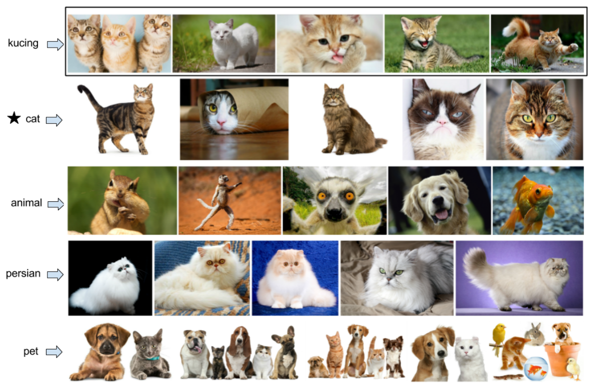

Figure 1: Our dataset and approach allow translations to be discovered by comparing the images associated with foreign and English words. Shown here are five images for the Indonesian word *kucing*, a word with high predicted concreteness, along with its top 4 ranked translations using CNN features.

Most previous image datasets compiled for the task of learning translations were limited to the translation of nouns in a few high-resource languages. In this work, we present a new large-scale dataset that contains images for 100 languages, and is not restricted by part-of-speech. We collected images using Google Image Search for up to 10,000 words in each of 100 foreign languages, and their English translations. For each word, we collected up to 100 images and the text on images' corresponding web pages.

We conduct a broad range of experiments to evaluate the utility of image features across a number of factors:

*These authors contributed equally; listed alphabetically.

- We evaluate on 12 high-resource and 20 low-resource languages.
- We evaluate translation quality stratified by part-of-speech, finding that nouns and adjectives are translated with much higher accuracy than adverbs and verbs.
- We present a novel method for predicting word concreteness from image features that better correlates with human perception than existing methods. We show that choosing concrete subsets of words to translate results in higher accuracy.
- We augment a state-of-the-art text-based word translation system with image feature scores and find consistent improvements to the text-only system, ranging from 3.12% absolute top-1 accuracy improvement at 10% recall to 1.30% absolute improvement at 100% recall.

A further contribution of this paper is our dataset, which is the largest of its kind and should be a standard for future work in learning translations from images. The dataset may facilitate research into multilingual, multimodal models, and translation of low-resource languages.

2 Related Work

The task of learning translations without sentence-aligned bilingual parallel texts is often called bilingual lexicon induction (Rapp, 1999; Fung and Yee, 1998). Most work in bilingual lexicon induction has focused on text-based methods. Some researchers have used similar spellings across related languages to find potential translations (Koehn and Knight, 2002; Haghighi et al., 2008). Others have exploited temporal similarity of word frequencies to induce translation pairs (Schafer and Yarowsky, 2002; Klementiev and Roth, 2006). Irvine and Callison-Burch (2017) provide a systematic study of different text-based features used for bilingual lexicon induction. Recent work has focused on building joint distributional word embedding spaces for multiple languages, leveraging a range of levels of language supervision from bilingual dictionaries to comparable texts (Vulić and Korhonen, 2016; Wijaya et al., 2017).

The most closely related work to ours is research into bilingual lexicon induction using image similarity by Bergsma and Van Durme (2011) and Kiela et al. (2015). Their work differs from ours in that they focused more narrowly on the translation of nouns for a limited number of high resource languages. Bergsma and Van Durme (2011) compiled datasets for Dutch, English, French, German, Italian, and Spanish by downloading 20 images for up to 500 concrete nouns in each of the foreign languages, and 20,000 English words.

Another dataset was generated by Vulic and Moens (2013) who collected images for 1,000 words in Spanish, Italian, and Dutch, along with the English translations for each. Their dataset also consists of only nouns, but includes abstract nouns. Our corpus will allow researchers to explore image similarity for bilingual lexicon induction on a much wider range of languages and parts of speech, which is especially desirable given the potential utility of the method for improving translation between languages with little parallel text.

The ability of images to usefully represent a word is strongly dependent on how concrete or abstract the word is. The terms *abstractness* and *concreteness* are used in the psycholinguistics and cognitive psychology literature. *Concrete* words directly reference a sense experience (Paivio et al., 1968), while abstract words can denote ideas, emotions, feelings, qualities or other abstract or intangible concepts. Concreteness ratings are closely correlated with *imagery* ratings, defined as the ease with which a word arouses a mental image (Gilhooly and Logie, 1980; Friendly et al., 1982). Intuitively, concrete words are easier to represent visually, so a measure of a word's concreteness ought to be able to predict the effectiveness of using images to translate the word.

Kiela et al. (2014) defines an unsupervised method called *image dispersion* that approximates a word's concreteness by taking the average pairwise cosine distance of a set of image representations of the word. Kiela et al. (2015) show that image dispersion helps predict the usefulness of image representations for translation. In this paper, we introduce novel supervised approaches for predicting word concreteness from image and textual features. We make use of a dataset created by Brysbaert et al. (2014) containing human evaluations of concreteness for 39,954 English words.

Concurrently with our work, Hartmann and Søgaard (2017) released an unpublished arXiv draft challenging the efficacy of using images for translation. Their work presents several difficulties of using image features for translation, difficulties which our methods address. They find that image features are only useful in translating simple nouns. While we did indeed find that nouns perform better than other parts of speech, we do not find that images are only effective in translating simple words. Instead, we show a gradual degradation in performance as words become more abstract. Their dataset is restricted to six high-resource languages and a small vocabulary of 557 English words. In contrast, we present results for over 260,000 English words and 32 foreign languages.

Recent research in the NLP and computer vision communities has been enabled by large collections of images associated with words or longer texts. Object recognition has seen dramatic gains in part due to the ImageNet database (Deng et al., 2009), which contains 500-1000 images associated with 80,000 synsets in WordNet. Ferraro et al. (2015) surveys existing corpora that are used in vision and language research. Other NLP+Vision tasks that have been enabled by the availability of large datasets include caption generation for images, action recognition in videos, visual question answering, and others.

Most existing work on multilingual NLP+Vision relies on having a corpus of images manually annotated with captions in several languages, as in the Multi30K dataset (Elliott et al., 2016). Several works have proposed using image features to improve sentence level translations or to translate image captions (Gella et al., 2017; Hitschler and Riezler, 2016; Miyazaki and Shimizu, 2016). Funaki and Nakayama (2015) show that automatically scraped data from websites in English and Japanese can be used to effectively perform zero-shot learning for the task of cross-lingual document retrieval. Since collecting multilingual annotations is difficult at a large-scale or for low-resource languages, our approach relies only on data scraped automatically from the web.

3 Corpus Construction

We present a new dataset for image-based word translation that is more expansive than any previous ones, encompassing all parts-of-speech, the gamut of abstract to concrete, and both low- and high-resource languages.

3.1 Dictionaries

We collect images for words in 100 bilingual dictionaries created by Pavlick et al. (2014). They selected the 10,000 most frequent words on Wikipedia pages in the foreign language, and then collected their translations into English via crowdsourcing. We will denote these dictionaries as CROWDTRANS. The superset of English translations for all foreign words consists of 263,102 translations. The English portion of their data tends to be much noisier than the foreign portion due to its crowdsourced nature (e.g. misspellings, or definition included with translations.)

We computed part-of-speech for entries in each dictionary. We found that while nouns are the most common, other parts-of-speech are reasonably represented (Section 5.1).

3.2 Method

For each English and foreign word, we query Google Image Search to collect 100 images associated with the word. A potential criticism of our use of Google Image Search is that it may be using a bilingual dictionary to translate queries into English (or other high resource languages) and returning images associated with the translated queries (Kilgarriff, 2007). We take steps (Section 3.3) to filter out images that did not appear on pages written in the language that we are gathering images for. After assembling the collection of images associated with words, we construct low-dimensional vector representations of the images using convolutional neural networks (CNNs). We also save the text from each web page that an image appeared on. Further detail on our corpus construction pipeline can be found in Section 2 of the supplemental materials.

3.3 Filtering by Web Page Language

We used the following heuristic to filter images: if text could be extracted from an image's web page, and the expected language was in the top-3 most likely languages output by the CLD2[1] language detection system then we kept the image; otherwise it was discarded. This does not filter all images from webpages with English text; instead it acknowledges the presence of English in the multilingual web and keeps images from pages with some target-language presence. An average of approximately 42% of images for each foreign language remained after the language-filtering step.

[1]`https://github.com/CLD2Owners/cld2`

Language	Concreteness Ratings				Overall
	1-2	2-3	3-4	4-5	
English	.804	.814	.855	.913	.857
French	.622	.653	.706	.828	.721
Indonesian	.505	.569	.665	.785	.661
Uzbek	.568	.530	.594	.683	.601
All	.628	.649	.713	.810	.717
# Words	77	292	292	302	963

Table 1: The proportion of images determined to be good representations of their corresponding word. In columns 2-5, we bucket the results by the word's ground-truth concreteness, while column 6 shows the results over all words. The last row shows the number of words in each bucket of concreteness, and the number of words overall for each language.

3.4 Manual Evaluation of Images

By using a dataset scraped from the web, we expect some fraction of the images for each word to be incorrectly labeled. To confirm the overall quality of our dataset, we asked human evaluators on Amazon Mechanical Turk to label a subset of the images returned by queries in four languages: our target language, English; a representative high-resource language, French; and two low-resource languages, Indonesian and Uzbek. In total, we collected 36,050 judgments of whether the images returned by Google Image Search were a good match for the keyword. Details on the experimental setup can be found in Section 1 of the Supplemental Materials.

Table 1 shows the fraction of images that were judged to be good representations of the search word. It also demonstrates that as the concreteness of a word increases, the proportion of good images associated with that word increases as well. We further discuss the role of concreteness in Section 6.1. Overall, 85% of the English images, 72% of French, 66% of Indonesian, and 60% of Uzbek were judged to be good.

4 Finding Translations Using Images

Can images help us learn translations for low-resource languages? In this section we replicate prior work in high-resource languages, and then evaluate on a wide array of low-resource languages.

Although we scraped images and text for 100 languages, we have selected a representative set of 32 for evaluation. Kiela et al. (2015) established that CNN features are superior to the SIFT plus color histogram features used by Bergsma and Van Durme (2011), and so we restrict all analysis to the former.

4.1 Translation Prediction with AvgMax

To learn the English translation of each foreign word, we rank the English words as candidate translations based on their visual similarity with the foreign words. We take the cosine similarity score for each image i_f associated the foreign word w_f with each of image i_e for the English word w_e, and then compute the average maximum similarity as

$$\textsc{AvgMax}(w_f, w_e) = \frac{1}{|w_f|} \sum_{i_f \in w_f} \max_{i_e \in w_e}(cosine(i_f, i_e))$$

Each image is represented by a 4096-dimensional vector from the fully connected 7th (FC7) layer of a CNN trained on ImageNet (Krizhevsky et al., 2012). AvgMax is the best-performing method described by Bergsma and Van Durme (2011) on images created with SIFT and color histogram features. It was later validated on CNN features by Kiela et al. (2015).

The number of candidate English words is the number of entries in the bilingual dictionary after filtering out dictionary entries where the English word and foreign word are identical. In order to compare with Kiela et al. (2015), we evaluate the models' rankings using Mean Reciprocal Rank (MRR), top-1, top-5 and top-20 accuracy. We prefer the more interpretable top-k accuracy in our subsequent experiments. We choose to follow Wijaya et al. (2017) in standardizing to $k = 10$, and we report top-1 accuracy only when it is particularly informative.

4.2 Replication of Prior Work

We evaluate on the five languages–Dutch, French, German, Italian, and Spanish–which have been the focus of prior work. Table 2 shows the results reported by Kiela et al. (2015) on the BERGSMA500 dataset, along with results using our image crawl method (Section 3.2) on BERGSMA500's vocabulary.

On all five languages, our dataset performs better than that of Kiela et al. (2015). We attribute this to improvements in image search since they collected images. We additionally note that in the BERGSMA500 vocabularies, approximately 11% of the translation pairs are string-identical, like *film* $\leftrightarrow$ *film*. In all subsequent experiments, we remove trivial translation pairs like this.

We also evaluate the identical model on our full data set, which contains 8,500 words, covering all parts of speech and the full range of concreteness ratings. The top-1 accuracy of the model is 23% on our more realistic and challenging data set, versus 68% on the easier concrete nouns set.

4.3 High- and Low-resource Languages

To determine whether image-based translation is effective for low resource languages, we sample 12 high-resource languages (HIGHRES), and 20 low-resource languages (LOWRES). Table 3 reports the top-10 accuracy across all 32 languages.

For each language, we predict a translation for each foreign word in the language's CROWDTRANS dictionary. This comes to approximately 7,000 to 10,000 foreign words per language. We find that high-resource languages' image features are more predictive of translation than those of low-resource languages. Top-10 accuracy is 29% averaged across high-resource languages, but only 16% for low-resource languages. This may be due to the quality of image search in each language, and the number of websites in each language indexed by Google, as suggested by Table 1. The difficulty of the translation task is dependent on the size of the English vocabulary used, as distinguishing between $5,000$ English candidates as in Slovak is not as difficult as distinguishing between $10,000$ words as in Tamil.

4.4 Large Target Vocabulary

How does increasing the number of candidate translations affect accuracy? Prior work used an English vocabulary of 500 or 1,000 words, where the correct English translation is guaranteed to appear. This is unrealistic for many tasks such as machine translation, where the target language vocabulary is likely to be large. To evaluate a more realistic scenario, we take the union of the English vocabulary of every dictionary in CROWDTRANS, and run the same translation experiments as before. We call this large common vocabulary LARGEENG.

Confirming our intuition, experiments with LARGEENG give significantly lower top-10 accuracies across parts of speech, but still provide discriminative power. We find .181 average top-10 accuracy using LARGEENG, whereas on the same languages, average accuracy on the CROWDTRANS vocabularies was .260. The full results for these experiments are reported in Table 4.

5 Evaluation by Part-of-speech

Can images be used to translate words other than nouns? This section presents our methods for de-

dataset	BERGSMA500	BERGSMA500	all
	Kiela et al. (2015)	(ours)	(ours)
# words	500	500	8,500
MRR	0.658	0.704	0.277
Top 1	0.567	0.679	0.229
Top 5	0.692	0.763	0.326
Top 20	0.774	0.811	0.385

Table 2: Our results are consistently better than those reported by Kiela et al. (2015), averaged over Dutch, French, German, Italian, and Spanish on a similar set of 500 concrete nouns. The rightmost column shows the added challenge with our larger, more realistic dataset.

HIGHRES	All	VB	RB	JJ	NN	#
Spanish	.417	.144	.157	.329	.593	9.9k

LARGEENG *Avg*	*.181*	*.041*	*.055*	*.118*	*.244*
SMALL *Avg*	*.260*	*.089*	*.078*	*.210*	*.392*

Table 4: Top-10 accuracy on the expanded English dictionary task. For each experiment, 263,102 English words were used as candidate translations for each foreign word. The SMALL average is given for reference, averaging the results from Table 3 across the same 10 languages.

termining part-of-speech for foreign words even in low-resource languages, and presents our image-based translation results across part-of-speech.

5.1 Assigning POS Labels

To show the performance of our translation method for each particular POS, we first assign a POS tag to each foreign word. Since we evaluate on high- and low-resource languages, many of which do not have POS taggers, we POS tag English words, and transfer the tag to their translations. We scraped the text on the web pages associated with the images of each English word, and collected the sentences that contained each query (English) word. We chose to tag words in sentential context, rather than simply collecting parts of speech from a dictionary, because many words have multiple senses, often with different parts of speech.

We assign universal POS tags (Petrov et al., 2012) using spaCy[2], giving each word its majority tag. We gathered part-of-speech tags for 42% of the English words in our translations. Of the remaining untagged English entries, 40% were multi-word expressions, and 18% were not found in the text of the web pages that we scraped.

When transferring POS tags to foreign words, we only considered foreign words where every English translation had the same POS. Across all 32 languages, on average, we found that, after filtering, 65% of foreign words were nouns, 14% were verbs, 14% were adjectives, 3% were adverbs, and 3% were other (i.e. they were labeled a different POS).

[2]https://spacy.io

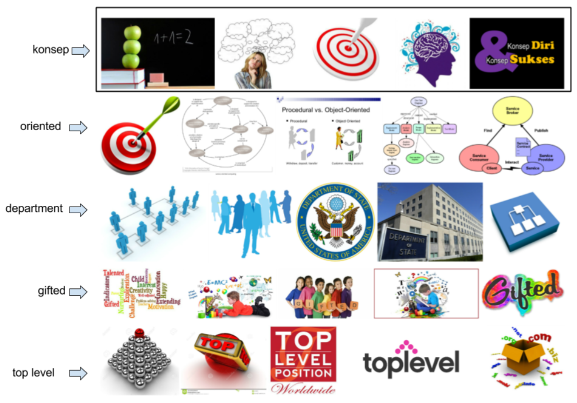

Figure 2: Shown here are five images for the abstract Indonesian word *konsep*, along with its top 4 ranked translations using CNN features. The actual translation, *concept*, was ranked 3,465.

5.2 Accuracy by Part-of-speech

As we see in the results in Table 3, the highest translation performance is obtained for nouns, which confirms the observation by Hartmann and Søgaard (2017). However, we see considerable signal in translating adjectives as well, with top-10 accuracies roughly half that of nouns. This trend extends to low-resource languages. We also see that translation quality is relatively poor for adverbs and verbs. There is higher variation in our performance on adverbs across languages, because there were relatively few adverbs (3% of all words.) From these results, it is clear that one can achieve higher accuracy by choosing to translate only nouns and adjectives.

Analysis by part-of-speech only indirectly addresses the question of when translation with images is useful. For example, Figure 2 shows that nouns like *concept* translate incorrectly because of a lack of consistent visual representation. However, verbs like *walk* may have concrete visual representation. Thus, one might perform better overall at translation on *concrete* words, regardless of part-of-speech.

6 Evaluation by Concreteness

Can we effectively predict the concreteness of words in a variety of languages? If so, can these predictions be used to determine when translation via images is helpful? In this section, we answer both of these questions in the affirmative.

6.1 Predicting Word Concreteness

Previous work has used *image dispersion* as a measure of word concreteness (Kiela et al., 2014). We introduce a novel supervised method for predicting word concreteness that more strongly correlates with human judgements of concreteness.

To train our model, we took Brysbaert et al. (2014)'s dataset, which provides human judgments for about 40k words, each with a 1-5 abstractness-to-concreteness score, and scraped 100 images from English Google Image Search for each word. We then trained a two-layer perceptron with one hidden layer of 32 units, to predict word concreteness. The inputs to the network were the element-wise mean and standard deviation (concatenated into a 8094-dimensional vector)of the CNN features for each of the images corresponding to a word. To better assess this image-only approach, we also experimented with using the distributional word embeddings of Salle et al. (2016) as input. We used these 300-dimensional vectors either seperately or concatentated with the image-based features. Our final network was trained with a cross-entropy loss, although an L2 loss performed nearly as well. We randomly selected 39,000 words as our training set. Results on the remaining held-out validation set are visualized in Figure 3.

Although the concatenated image and word embedding features performed the best, we do not expect to have high-quality word embeddings for words in low-resource languages. Therefore, for the evaluation in Section 6.2, we used the image-embeddings-only model to predict concreteness for every English and foreign word in our dataset.

6.2 Accuracy by Predicted Concreteness

It has already been shown that the images of more abstract words provide a weaker signal for translation (Kiela et al., 2015). Using our method for predicting concreteness, we determine which images sets are most concrete, and thereby estimate the likelihood that we will obtain a high quality translation.

Figure 4 shows the reduction in translation accuracy as increasingly abstract words are included in the set. The concreteness model can be used to establish recall thresholds. For the 25% of foreign words we predict to be most concrete, (25% recall,) AVGMAX achieves top-10 accuracy of 47.0% for high-resource languages and 32.8% for low-resource languages. At a 50% most-concrete recall treshold, top-10 translation accuracies are 25.0% and 37.8% for low- and high-resource languages respectively, compared to 18.6% and 29.3% at 100% recall.

7 Translation with Images and Text

Translation via image features performs worse than state-of-the-art distributional similarity-based methods. For example, Wijaya et al. (2017) demonstrate top-10 accuracies in range of above 85% on the VULIC1000 a 1,000-word dataset, whereas with only image features, Kiela et al. (2015) report top-10 accuracies below 60%. However, there may be utility in combining the two methods, as it is likely that visual and textual distributional representations are contributing different information, and fail in different cases.

We test this intuition by combining image scores with the current state-of-the-art system of Wijaya et al. (2017), which uses Bayesian Personalized Ranking (BPR). In their arXiv draft, Hartmann and Søgaard (2017) presented a negative result when directly combining image representations with distributional representations into a single system. Here, we present a positive result by formalizing the problem as a reranking task. Our intuition is that we hope to guide BPR, clearly the stronger system, with aid from image features and a predicted concreteness value, instead of joining them as equals and potentially washing out the stronger signal.

7.1 Reranking Model

For each foreign word w_f and each English word w_e, we have multiple scores for the pair $p_{f,e} = (w_f, w_e)$, used to rank w_e against all other $w_{e'} \in E$, where E is the English dictionary used in the experiment. Specifically, we have $\textsc{Txt}(p_{f,e})$ and $\textsc{Image}(p_{f,e})$ for all pairs. For each foreign word, we also have the concreteness score, $\textsc{Cnc}(w_f)$, predicted from its image set by the method described in Section 6.1.

We use a small bilingual dictionary, taking all pairs $p_{f,e}$ and labeling them $\{\pm 1\}$, with 1 denoting the words are translations. We construct training data out of the dictionary, treating each labeled pair as an independent observation. We then train a 2-layer perceptron (MLP), with 1 hidden layer of 4 units, to predict translations from the individual scores, minimizing the squared loss.[3]

$$\text{MLP}(p_{f,e}) = \\ \text{MLP}\big([\textsc{Txt}(p_{f,e}); \textsc{Image}(p_{f,e}); \textsc{Cnc}(w_f)]\big) = \{\pm 1\}$$

[3]We use DyNet (Neubig et al., 2017) for constructing and training our network with the Adam optimization method (Kingma and Ba, 2014).

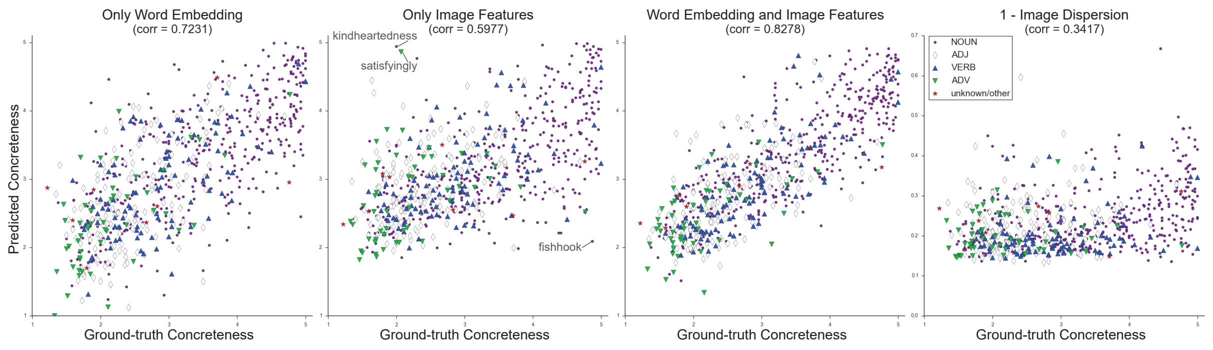

Figure 3: Plots visualizing the distribution of concreteness predictions on the validation set for our three trained models and for image dispersion. Spearman correlation coefficients are shown. For the model trained only on images, the three worst failure cases are annotated. False positives tend to occur when one concrete meaning of an abstract word dominates the search results (i.e. many photos of "satisfyingly" show food). False negatives often stem from related proper nouns or an overabundance of clipart, as is the case for "fishhook."

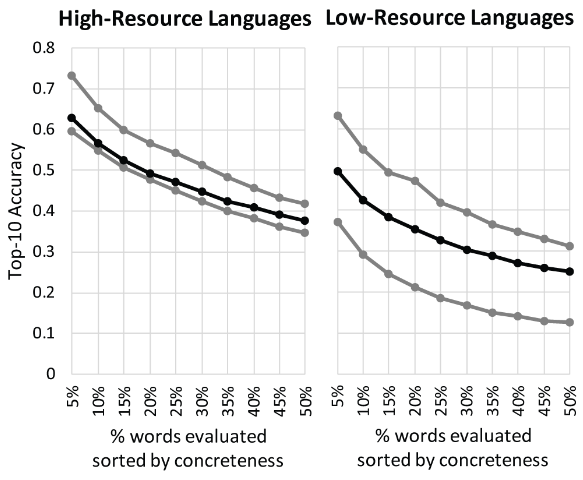

Figure 4: The black curve shows mean top-10 accuracy over the HIGHRES and LOWRES sets sorted by predicted concreteness. The gray curves show the 25th and 75th percentiles.

Once the model is trained, we fix each foreign word w_f, and score all pairs $(w_f, w_{e'})$ for all $e' \in E$, using the learned model MLP$(p_{f,e'})$. Using these scores, we sort E for each w_f.

7.2 Evaluation

We evaluate our text-based and image-based combination method by translating Bosnian, Dutch, French, Indonesian, Italian, and Spanish into English. For each language, we split our bilingual dictionary (of 8,673 entries, on average) into 2,000 entries for a testing set, 20% for training the text-based BPR system, 35% for training the reranking MLP, and the rest for a development set. We filtered out multi-word phrases, and translations where w_f and w_e are string identical.

We compare three models: TXT is Wijaya et al. (2017)'s text-based state-of-the-art model. TXT+IMG is our MLP-learned combination of the two features. TXT+IMG+CNC uses our predicted concreteness of the foreign word as well. We evaluate all models on varying percents of testing data sorted by predicted concreteness, as in Section 6.2. As shown in Figure 5, both image-augmented methods beat TXT across concreteness thresholds on the top-1 accuracy metric.

Results across the 6 languages are reported in Table 5. Confirming our intuition, images are useful at high concreteness, improving the SOA text-based method 3.21% at 10% recall. At 100% recall our method with images still improves the SOA by 1.3%. For example, the text-only system translates the Bosnian word *košarkaški* incorrectly as *football*, whereas the image+text system produces the correct *basketball*.

Further, gains are more pronounced for low-resource languages than for high-resource languages. Concreteness scores are useful for high-resource languages, for example Spanish, where TXT+IMG falls below TXT alone on more abstract words, but TXT+IMG+CNC remains an improvement. Finally, we note that the text-only system also performs better on concrete words than abstract words, indicating a general trend of ease in translating concrete words regardless of method.

8 Summary

We have introduced a large-scale multilingual image resource, and used it to conduct the most comprehensive study to date on using images to learn translations. Our Massively Multilingual Image Dataset will serve as a standard for future work in image-based translation due to its size and generality, covering 100 languages, hundreds of thousands

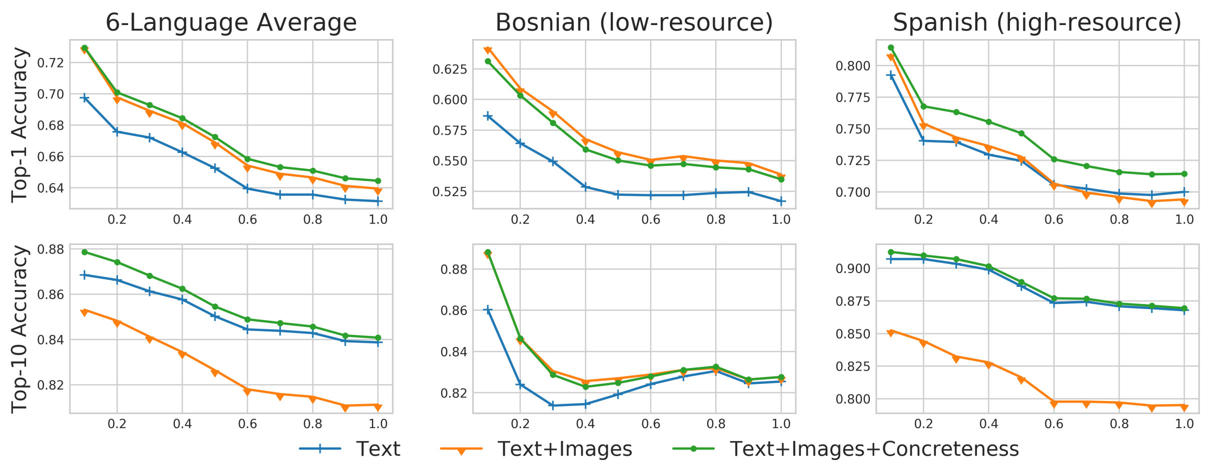

Figure 5: Reranking top-1 and top-10 accuracies of our image+text combination sytems compared to the text-only Bayesian Personalized Ranking system. The X-axis shows percent of foreign words evaluated on, sorted by decreasing predicted concreteness.

	Method	% words evaluated 10%	50%	100%
High-Res	TXT	.746	.696	.673
	TXT+IMG	**.771**	.708	.678
	TXT+IMG+Cnc	**.773**	**.714**	**.685**
Low-Res	TXT	.601	.565	.549
	TXT+IMG	**.646**	**.590**	**.562**
	TXT+IMG+Cnc	**.643**	**.589**	**.563**

Table 5: Top-1 accuracy results across high-resource (Dutch, French, Italian, Spanish) and low-resource (Bosnian, Indonesian) languages. Words evaluated on are again sorted by concreteness for the sake of analysis. The best result on each % of test data is bolded.

of words, and a broad range of parts of speech. Using this corpus, we demonstrated the substantial utility in supervised prediction of word concreteness when using image features, improving over the unsupervised state-of-the-art and finding that image-based translation is much more accurate for concrete words. Because of the text we collected with our corpus, we were also able to collect part-of-speech information and demonstrate that image features are useful in translating adjectives and nouns. Finally, we demonstrate a promising path forward, showing that incorporating images can improve a state-of-the-art text-based word translation system.

9 Dataset and Code

The MMID will be distributed both in raw form and for a subset of languages in memory compact featurized versions from `http://multilingual-images.org` along with code we used in our experiments. Additional details are given in our Supplemental Materials document, which also describes our manual image annotation setup, and gives numerous illustrative examples of our system's predictions.

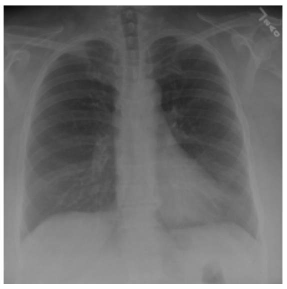
Abstract

Medical imaging is widely used in clinical practice for diagnosis and treatment. Report-writing can be error-prone for unexperienced physicians, and time-consuming and tedious for experienced physicians. To address these issues, we study the automatic generation of medical imaging reports. This task presents several challenges. First, a complete report contains multiple heterogeneous forms of information, including *findings* and *tags*. Second, abnormal regions in medical images are difficult to identify. Third, the reports are typically long, containing multiple sentences. To cope with these challenges, we (1) build a multi-task learning framework which jointly performs the prediction of tags and the generation of paragraphs, (2) propose a co-attention mechanism to localize regions containing abnormalities and generate narrations for them, (3) develop a hierarchical LSTM model to generate long paragraphs. We demonstrate the effectiveness of the proposed methods on two publicly available datasets.

1 Introduction

Medical images, such as radiology and pathology images, are widely used in hospitals for the diagnosis and treatment of many diseases, such as pneumonia and pneumothorax. The reading and interpretation of medical images are usually conducted by specialized medical professionals. For example, radiology images are read by radiologists. They write textual reports (Figure 1) to narrate the findings regarding each area of the body examined in the imaging study, specifically whether each area was found to be normal, abnormal or potentially abnormal.



Impression: No acute cardiopulmonary abnormality.

Findings: There are no focal areas of consolidation. No suspicious pulmonary opacities. Heart size within normal limits. No pleural effusions. There is no evidence of pneumothorax. Degenerative changes of the thoracic spine.

MTI Tags: degenerative change

Figure 1: An exemplar chest x-ray report. In the *impression* section, the radiologist provides a diagnosis. The *findings* section lists the radiology observations regarding each area of the body examined in the imaging study. The *tags* section lists the keywords which represent the critical information in the findings. These keywords are identified using the Medical Text Indexer (MTI).

For less-experienced radiologists and pathologists, especially those working in the rural area where the quality of healthcare is relatively low, writing medical-imaging reports is demanding. For instance, to correctly read a chest x-ray image, the following skills are needed (Delrue et al., 2011): (1) thorough knowledge of the normal anatomy of the thorax, and the basic physiology of chest diseases; (2) skills of analyzing the radiograph through a fixed pattern; (3) ability of evaluating the evolution over time; (4) knowledge of clinical presentation and history; (5) knowledge of the correlation with other diagnostic results (laboratory results, electrocardiogram, and respiratory function tests).

For experienced radiologists and pathologists, writing imaging reports is tedious and time-consuming. In nations with large population such as China, a radiologist may need to read hundreds of radiology images per day. Typing the findings of each image into computer takes about 5-10 minutes, which occupies most of their working time. In sum, for both unexperienced and experienced medical professionals, writing imaging reports is unpleasant.

This motivates us to investigate whether it is possible to automatically generate medical image reports. Several challenges need to be addressed. First, a complete diagnostic report is comprised of multiple heterogeneous forms of information. As shown in Figure 1, the report for a chest x-ray contains *impression* which is a sentence, *findings* which are a paragraph, and *tags* which are a list of keywords. Generating this heterogeneous information in a unified framework is technically demanding. We address this problem by building a multi-task framework, which treats the prediction of tags as a multi-label classification task, and treats the generation of long descriptions as a text generation task.

Second, how to localize image-regions and attach the right description to them are challenging. We solve these problems by introducing a co-attention mechanism, which simultaneously attends to images and predicted tags and explores the synergistic effects of visual and semantic information.

Third, the descriptions in imaging reports are usually long, containing multiple sentences. Generating such long text is highly nontrivial. Rather than adopting a single-layer LSTM (Hochreiter and Schmidhuber, 1997), which is less capable of modeling long word sequences, we leverage the compositional nature of the report and adopt a hierarchical LSTM to produce long texts. Combined with the co-attention mechanism, the hierarchical LSTM first generates high-level topics, and then produces fine-grained descriptions according to the topics.

Overall, the main contributions of our work are:

- We propose a multi-task learning framework which can simultaneously predict the tags and generate the text descriptions.
- We introduce a co-attention mechanism for localizing sub-regions in the image and generating the corresponding descriptions.
- We build a hierarchical LSTM to generate long paragraphs.
- We perform extensive experiments to show the effectiveness of the proposed methods.

The rest of the paper is organized as follows. Section 2 reviews related works. Section 3 introduces the method. Section 4 present the experimental results and Section 5 concludes the paper.

2 Related Works

Textual labeling of medical images There have been several works aiming at attaching "texts" to medical images. In their settings, the target "texts" are either fully-structured or semi-structured (e.g. tags, templates), rather than natural texts. Kisilev et al. (2015) build a pipeline to predict the attributes of medical images. Shin et al. (2016) adopt a CNN-RNN based framework to predict tags (e.g. locations, severities) of chest x-ray images. The work closest to ours is recently contributed by (Zhang et al., 2017), which aims at generating semi-structured pathology reports, whose contents are restricted to 5 predefined topics.

However, in the real-world, different physicians usually have different writing habits and different x-ray images will represent different abnormalities. Therefore, collecting semi-structured reports is less practical and thus it is important to build models to learn from natural reports. To the best of our knowledge, our work represents the first one that generates truly natural reports written by physicians, which are usually long and cover diverse topics.

Image captioning with deep learning Image captioning aims at automatically generating text descriptions for given images. Most recent image captioning models are based on a CNN-RNN framework (Vinyals et al., 2015; Fang et al., 2015; Karpathy and Fei-Fei, 2015; Xu et al., 2015; You et al., 2016; Krause et al., 2017).

Recently, attention mechanisms have been shown to be useful for image captioning (Xu et al., 2015; You et al., 2016). Xu et al. (2015) introduce a spatial-visual attention mechanism over image features extracted from intermediate layers of the CNN. You et al. (2016) propose a semantic attention mechanism over tags of given images. To better leverage both the visual features and semantic tags, we propose a co-attention mechanism for report generation.

Instead of only generating one-sentence caption

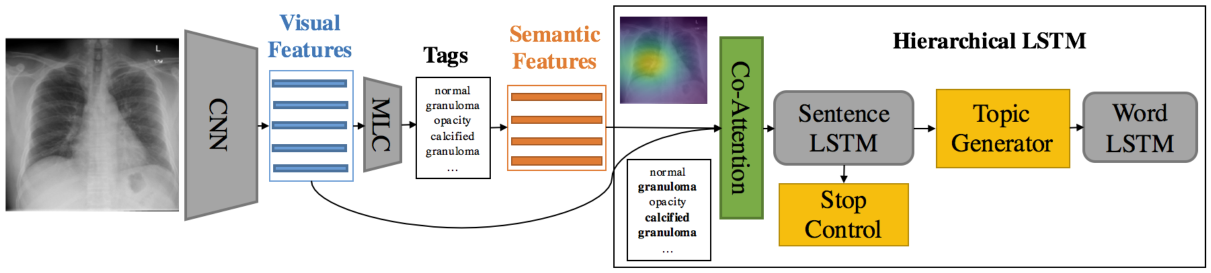


Figure 2: Illustration of the proposed model. MLC denotes a *multi-label classification* network. Semantic features are the word embeddings of the predicted tags. The boldfaced tags "calcified granuloma" and "granuloma" are attended by the co-attention network.

for images, Krause et al. (2017) and Liang et al. (2017) generate paragraph captions using a hierarchical LSTM. Our method also adopts a hierarchical LSTM for paragraph generation, but unlike Krause et al. (2017), we use a co-attention network to generate topics.

3 Methods

3.1 Overview

A complete diagnostic report for a medical image is comprised of both text descriptions (long paragraphs) and lists of tags, as shown in Figure 1. We propose a *multi-task hierarchical model with co-attention* for automatically predicting keywords and generating long paragraphs. Given an image which is divided into regions, we use a CNN to learn visual features for these patches. Then these visual features are fed into a *multi-label classification* (MLC) network to predict the relevant tags. In the tag vocabulary, each tag is represented by a word-embedding vector. Given the predicted tags for a specific image, their word-embedding vectors serve as the semantic features of this image. Then the visual features and semantic features are fed into a *co-attention* model to generate a context vector that simultaneously captures the visual and semantic information of this image. As of now, the encoding process is completed.

Next, starting from the context vector, the decoding process generates the text descriptions. The description of a medical image usually contains multiple sentences, and each sentence focuses on one specific topic. Our model leverages this compositional structure to generate reports in a hierarchical way: it first generates a sequence of high-level topic vectors representing sentences, then generates a sentence from each topic vector. Specifically, the context vector is inputted into a *sentence LSTM*, which unrolls for a few steps and produces a topic vector at each step. A topic vector represents the semantics of a sentence to be generated. Given a topic vector, the *word LSTM* takes it as input and generates a sequence of words to form a sentence. The termination of the unrolling process is controlled by the sentence LSTM.

3.2 Tag Prediction

The first task of our model is predicting the tags of the given image. We treat the tag prediction task as a multi-label classification task. Specifically, given an image I, we first extract its features $\{\mathbf{v}_n\}_{n=1}^{N} \in \mathbb{R}^D$ from an intermediate layer of a CNN, and then feed $\{\mathbf{v}_n\}_{n=1}^{N}$ into a *multi-label classification* (MLC) network to generate a distribution over all of the L tags:

$$\mathbf{p}_{l,pred}(\mathbf{l}_i = 1 | \{\mathbf{v}_n\}_{n=1}^{N}) \propto \exp(\text{MLC}_i(\{\mathbf{v}_n\}_{n=1}^{N})) \quad (1)$$

where $\mathbf{l} \in \mathbb{R}^L$ is a tag vector, $\mathbf{l}_i = 1/0$ denote the presence and absence of the i-th tag respectively, and MLC_i means the i-th output of the MLC network.

For simplicity, we extract visual features from the last convolutional layer of the VGG-19 model (Simonyan and Zisserman, 2014) and use the last two fully connected layers of VGG-19 for MLC.

Finally, the embeddings of the M most likely tags $\{\mathbf{a}_m\}_{m=1}^{M} \in \mathbb{R}^E$ are used as semantic features for topic generation.

3.3 Co-Attention

Previous works have shown that visual attention alone can perform fairly well for localizing objects (Ba et al., 2015) and aiding caption generation (Xu et al., 2015). However, visual attention does not provide sufficient high level semantic information. For example, only looking at the right lower region of the chest x-ray image (Figure 1) without accounting for other areas, we might not be able to recognize what we are looking at, not to even mention detecting the abnormalities. In contrast, the tags can always provide the needed high level information. To this end, we propose a co-attention mechanism which can simultaneously attend to visual and semantic modalities.

In the sentence LSTM at time step s, the joint context vector $\mathbf{ctx}^{(s)} \in \mathbb{R}^C$ is generated by a co-attention network $f_{co_{att}}(\{\mathbf{v}_n\}_{n=1}^N, \{\mathbf{a}_m\}_{m=1}^M, \mathbf{h}_{sent}^{(s-1)})$, where $\mathbf{h}_{sent}^{(s-1)} \in \mathbb{R}^H$ is the sentence LSTM hidden state at time step $s-1$. The co-attention network $f_{co_{att}}$ uses a single layer feed-forward network to compute the soft visual attentions and soft semantic attentions over input image features and tags:

$$\alpha_{\mathbf{v},n} \propto \exp(\mathbf{W}_{\mathbf{v}_{att}} \tanh(\mathbf{W}_{\mathbf{v}}\mathbf{v}_n + \mathbf{W}_{\mathbf{v},\mathbf{h}}\mathbf{h}_{sent}^{(s-1)})) \quad (2)$$

$$\alpha_{\mathbf{a},m} \propto \exp(\mathbf{W}_{\mathbf{a}_{att}} \tanh(\mathbf{W}_{\mathbf{a}}\mathbf{a}_m + \mathbf{W}_{\mathbf{a},\mathbf{h}}\mathbf{h}_{sent}^{(s-1)})) \quad (3)$$

where $\mathbf{W}_{\mathbf{v}}$, $\mathbf{W}_{\mathbf{v},\mathbf{h}}$, and $\mathbf{W}_{\mathbf{v}_{att}}$ are parameter matrices of the visual attention network. $\mathbf{W}_{\mathbf{a}}$, $\mathbf{W}_{\mathbf{a},\mathbf{h}}$, and $\mathbf{W}_{\mathbf{a}_{att}}$ are parameter matrices of the semantic attention network.

The visual and semantic context vectors are computed as:

$$\mathbf{v}_{att}^{(s)} = \sum_{n=1}^{N} \alpha_{\mathbf{v},n}\mathbf{v}_n, \quad \mathbf{a}_{att}^{(s)} = \sum_{m=1}^{M} \alpha_{\mathbf{a},m}\mathbf{a}_m.$$

There are many ways to combine the visual and semantic context vectors such as concatenation and element-wise operations. In this paper, we first concatenate these two vectors as $[\mathbf{v}_{att}^{(s)}; \mathbf{a}_{att}^{(s)}]$, and then use a fully connected layer $\mathbf{W}_{fc}$ to obtain a joint context vector:

$$\mathbf{ctx}^{(s)} = \mathbf{W}_{fc}[\mathbf{v}_{att}^{(s)}; \mathbf{a}_{att}^{(s)}]. \quad (4)$$

3.4 Sentence LSTM

The sentence LSTM is a single-layer LSTM that takes the joint context vector $\mathbf{ctx} \in \mathbb{R}^C$ as its input, and generates topic vector $\mathbf{t} \in \mathbb{R}^K$ for word LSTM through topic generator and determines whether to continue or stop generating captions by a stop control component.

Topic generator We use a deep output layer (Pascanu et al., 2014) to strengthen the context information in topic vector $\mathbf{t}^{(s)}$, by combining the hidden state $\mathbf{h}_{sent}^{(s)}$ and the joint context vector $\mathbf{ctx}^{(s)}$ of the current step:

$$\mathbf{t}^{(s)} = \tanh(\mathbf{W}_{\mathbf{t},\mathbf{h}_{sent}}\mathbf{h}_{sent}^{(s)} + \mathbf{W}_{\mathbf{t},\mathbf{ctx}}\mathbf{ctx}^{(s)}) \quad (5)$$

where $\mathbf{W}_{\mathbf{t},\mathbf{h}_{sent}}$ and $\mathbf{W}_{\mathbf{t},\mathbf{ctx}}$ are weight parameters.

Stop control We also apply a deep output layer to control the continuation of the sentence LSTM. The layer takes the previous and current hidden state $\mathbf{h}_{sent}^{(s-1)}$, $\mathbf{h}_{sent}^{(s)}$ as input and produces a distribution over {*STOP*=1, *CONTINUE*=0}:

$$p(STOP|\mathbf{h}_{sent}^{(s-1)}, \mathbf{h}_{sent}^{(s)}) \propto \exp\{\mathbf{W}_{stop} \tanh(\mathbf{W}_{stop,s-1}\mathbf{h}_{sent}^{(s-1)} + \mathbf{W}_{stop,s}\mathbf{h}_{sent}^{(s)})\} \quad (6)$$

where $\mathbf{W}_{stop}$, $\mathbf{W}_{stop,s-1}$ and $\mathbf{W}_{stop,s}$ are parameter matrices. If $p(STOP|\mathbf{h}_{sent}^{(s-1)}, \mathbf{h}_{sent}^{(s)})$ is greater than a predefined threshold (e.g. 0.5), then the sentence LSTM will stop producing new topic vectors and the word LSTM will also stop producing words.

3.5 Word LSTM

The words of each sentence are generated by a word LSTM. Similar to (Krause et al., 2017), the topic vector $\mathbf{t}$ produced by the sentence LSTM and the special *START* token are used as the first and second input of the word LSTM, and the subsequent inputs are the word sequence.

The hidden state $\mathbf{h}_{word} \in \mathbb{R}^H$ of the word LSTM is directly used to predict the distribution over words:

$$p(word|\mathbf{h}_{word}) \propto \exp(\mathbf{W}_{out}\mathbf{h}_{word}) \quad (7)$$

where $\mathbf{W}_{out}$ is the parameter matrix. After each word-LSTM has generated its word sequences, the final report is simply the concatenation of all the generated sequences.

3.6 Parameter Learning

Each training example is a tuple (I, $\mathbf{l}$, $\mathbf{w}$) where I is an image, $\mathbf{l}$ denotes the ground-truth tag vector, and $\mathbf{w}$ is the diagnostic paragraph, which is comprised of S sentences and each sentence consists of T_s words.

Given a training example (I, $\mathbf{l}$, $\mathbf{w}$), our model first performs multi-label classification on I and produces a distribution $\mathbf{p}_{\mathbf{l},pred}$ over all tags. Note that $\mathbf{l}$ is a binary vector which encodes the presence and absence of tags. We can obtain the ground-truth tag distribution by normalizing $\mathbf{l}$: $\mathbf{p}_{\mathbf{l}} = \mathbf{l}/||\mathbf{l}||_1$. The training loss of this step is a cross-entropy loss ℓ_{tag} between $\mathbf{p}_{\mathbf{l}}$ and $\mathbf{p}_{\mathbf{l},pred}$.

Next, the sentence LSTM is unrolled for S steps to produce topic vectors and also distributions over $\{STOP, CONTINUE\}$: p^s_{stop}. Finally, the S topic vectors are fed into the word LSTM to generate words $\mathbf{w}_{s,t}$. The training loss of caption generation is the combination of two cross-entropy losses: ℓ_{sent} over stop distributions p^s_{stop} and ℓ_{word} over word distributions $p_{s,t}$. Combining the pieces together, we obtain the overall training loss:

$$\begin{aligned} \ell(I, \mathbf{l}, \mathbf{w}) = & \lambda_{tag}\ell_{tag} \\ & + \lambda_{sent} \sum_{s=1}^{S} \ell_{sent}(p^s_{stop}, I\{s = S\}) \\ & + \lambda_{word} \sum_{s=1}^{S} \sum_{t=1}^{T_s} \ell_{word}(p_{s,t}, w_{s,t}) \end{aligned} \quad (8)$$

In addition to the above training loss, there is also a regularization term for visual and semantic attentions. Similar to (Xu et al., 2015), let $\boldsymbol{\alpha} \in \mathbb{R}^{N\times S}$ and $\boldsymbol{\beta} \in \mathbb{R}^{M\times S}$ be the matrices of visual and semantic attentions respectively, then the regularization loss over $\boldsymbol{\alpha}$ and $\boldsymbol{\beta}$ is:

$$\ell_{reg} = \lambda_{reg}[\sum_{n}^{N}(1-\sum_{s}^{S}\alpha_{n,s})^2 + \sum_{m}^{M}(1-\sum_{s}^{S}\beta_{m,s})^2] \quad (9)$$

Such regularization encourages the model to pay equal attention over different image regions and different tags.

4 Experiments

In this section, we evaluate the proposed model with extensive quantitative and qualitative experiments.

4.1 Datasets

We used two publicly available medical image datasets to evaluate our proposed model.

IU X-Ray The Indiana University Chest X-Ray Collection (IU X-Ray) (Demner-Fushman et al., 2015) is a set of chest x-ray images paired with their corresponding diagnostic reports. The dataset contains 7,470 pairs of images and reports. Each report consists of the following sections: *impression*, *findings*, *tags*[1], *comparison*, and *indication*. In this paper, we treat the contents in *impression* and *findings* as the target captions[2] to be generated and the Medical Text Indexer (MTI) annotated tags as the target tags to be predicted (Figure 1 provides an example).

We preprocessed the data by converting all tokens to lowercases, removing all of non-alpha tokens, which resulting in 572 unique tags and 1915 unique words. On average, each image is associated with 2.2 tags, 5.7 sentences, and each sentence contains 6.5 words. Besides, we find that top 1,000 words cover 99.0% word occurrences in the dataset, therefore we only included top 1,000 words in the dictionary. Finally, we randomly selected 500 images for validation and 500 images for testing.

PEIR Gross The Pathology Education Informational Resource (PEIR) digital library[3] is a public medical image library for medical education. We collected the images together with their descriptions in the Gross sub-collection, resulting in the PEIR Gross dataset that contains 7,442 image-caption pairs from 21 different sub-categories. Different from the IU X-Ray dataset, each caption in PEIR Gross contains only one sentence. We used this dataset to evaluate our model's ability of generating single-sentence report.

For PEIR Gross, we applied the same preprocessing as IU X-Ray, which yields 4,452 unique words. On average, each image contains 12.0 words. Besides, for each caption, we selected 5 words with the highest tf-idf scores as tags.

4.2 Implementation Details

We used the full VGG-19 model (Simonyan and Zisserman, 2014) for tag prediction. As for the training loss of the multi-label classification (MLC) task, since the number of tags for semantic attention is fixed as 10, we treat MLC as a multi-label retrieval task and adopt a softmax cross-entropy loss (a multi-label ranking loss), similar to (Gong et al., 2013; Guillaumin et al., 2009).

[1]There are two types of tags: manually generated (MeSH) and Medical Text Indexer (MTI) generated.

[2]The *impression* and *findings* sections are concatenated together as a long paragraph, since *impression* can be viewed as a conclusion or topic sentence of the report.

[3]PEIR is ©University of Alabama at Birmingham, Department of Pathology. (http://peir.path.uab.edu/library/)

Table 1: Main results for paragraph generation on the IU X-Ray dataset (upper part), and single sentence generation on the PEIR Gross dataset (lower part). BLUE-n denotes the BLEU score that uses up to n-grams.

In paragraph generation, we set the dimensions of all hidden states and word embeddings as 512. For words and tags, different embedding matrices were used since a tag might contain multiple words. We utilized the embeddings of the 10 most likely tags as the semantic feature vectors $\{\mathbf{a}_m\}_{m=1}^{M=10}$. We extracted the visual features from the last convolutional layer of the VGG-19 network, which yields a $14 \times 14 \times 512$ feature map.

We used the Adam (Kingma and Ba, 2014) optimizer for parameter learning. The learning rates for the CNN (VGG-19) and the hierarchical LSTM were 1e-5 and 5e-4 respectively. The weights (λ_{tag}, λ_{sent}, λ_{word} and λ_{reg}) of different losses were set to 1.0. The threshold for stop control was 0.5. Early stopping was used to prevent over-fitting.

4.3 Baselines

We compared our method with several state-of-the-art image captioning models: CNN-RNN (Vinyals et al., 2015), LRCN (Donahue et al., 2015), Soft ATT (Xu et al., 2015), and ATT-RK (You et al., 2016). We re-implemented all of these models and adopt VGG-19 (Simonyan and Zisserman, 2014) as the CNN encoder. Considering these models are built for single sentence captions and to better show the effectiveness of the hierarchical LSTM and the attention mechanism for paragraph generation, we also implemented a hierarchical model without any attention: Ours-no-Attention. The input of Ours-no-Attention is the overall image feature of VGG-19, which has a dimension of 4096. Ours-no-Attention can be viewed as a CNN-RNN (Vinyals et al., 2015) equipped with a hierarchical LSTM decoder. To further show the effectiveness of the proposed co-attention mechanism, we also implemented two ablated versions of our model: Ours-Semantic-only and Ours-Visual-only, which takes solely the semantic attention or visual attention context vector to produce topic vectors.

4.4 Quantitative Results

We report the paragraph generation (upper part of Table 1) and one sentence generation (lower part of Table 1) results using the standard image captioning evaluation tool [4] which provides evaluation on the following metrics: BLEU (Papineni et al., 2002), METEOR (Denkowski and Lavie, 2014), ROUGE (Lin, 2004), and CIDER (Vedantam et al., 2015).

For paragraph generation, as shown in the upper part of Table 1, it is clear that models with a single LSTM decoder perform much worse than those with a hierarchical LSTM decoder. Note that the only difference between Ours-no-Attention and CNN-RNN (Vinyals et al., 2015) is that Ours-no-Attention adopts a hierarchical LSTM decoder while CNN-RNN (Vinyals et al., 2015) adopts a single-layer LSTM. The comparison between these two models directly demonstrates the effectiveness of the hierarchical LSTM. This result is not surprising since it is well-known that a single-layer LSTM cannot effectively model long sequences (Liu et al., 2015; Martin and Cundy, 2018). Additionally, employing semantic attention alone (Ours-Semantic-only) or visual attention alone (Ours-Visual-only) to generate topic vectors does not seem to help caption generation a lot. The potential reason might be that visual at-

Visualized osseous structures of the thorax are without acute abnormality.
	No evidence of active disease. The lungs are clear. There is no focal airspace consolidation. No pleural effusion or pneumothorax. Heart size and mediastinal contour are within normal limits. There are multilevel degenerative changes of the spine.	No acute cardiopulmonary findings. Heart size is not enlarged. No focal airspace consolidation suspicious pulmonary opacity large pleural effusion or pneumothorax. No focal areas of consolidation. Degenerative changes of the spine. This is moderate exam of the hydropneumothorax. Lungs are clear. There is no focal airspace consolidation pleural effusion or pneumothorax.	The lungs are clear bilaterally. The are grossly normal. No pleural effusion. The heart is normal in size and contour. The lungs are clear. There are no acute bony findings.	No acute cardiopulmonary abnormality. The lungs are clear bilaterally. There is no pleural effusion or pneumothorax. The heart and mediastinum are normal. There is no focal air space opacity to suggest a pneumonia.
	No acute cardiopulmonary abnormality. Normal heart size mediastinal contours. Eventration of the right hemidiaphragm. No focal airspace consolidation. No pleural effusion or pneumothorax.	No acute cardiopulmonary abnormality. Stable appearance of the thoracic aorta. The right lateral lower lobe is noted in the right lower right midlung. No large pleural effusion or focal airspace disease. Mild interstitial opacities. Atherosclerotic calcifications bony structures bilaterally. There is no pleural effusion or pneumothorax developed in the right lower lobe.	The lungs are clear bilaterally. The are grossly normal. No acute bony abnormality. The lungs are otherwise clear. No acute osseous abnormality. No acute osseous abnormality. The heart and mediastinum are normal. There is no focal air space opacity.	No acute cardiopulmonary abnormality. The lungs are clear bilaterally. There is no focal airspace consolidation. No pleural effusion or pneumothorax. Heart size and pulmonary vascularity appear within normal limits.
	No acute cardiopulmonary abnormality. Heart size appears within normal limits . Pulmonary vasculature appears within normal limits. Overlying the middle cardiac silhouette representing a hiatal hernia. No focal consolidation pleural effusion or pneumothorax. No acute bony abnormality.	No active disease. The heart and lungs have in the interval. Nipple and lateral lucency in the lungs suggestive of focal airspace disease. The lungs are hyperexpanded consistent with emphysema in the left lower lobe. This is most at the upper lobes. This may indicate hypoventilated irregularities or effusions. The lungs are otherwise grossly clear. Resolution of by normal pleural effusion.	No acute cardiopulmonary abnormality. The lungs are clear bilaterally. The are grossly normal. No focal airspace consolidation. No pneumothorax or pleural effusion. Heart size and pulmonary vascularity within normal limits. There is no pneumothorax or pleural effusion.	No acute cardiopulmonary abnormality. There is no focal airspace consolidation. No pneumothorax or pleural effusion. No acute bony abnormality. Heart size is normal .

Figure 3: Illustration of paragraph generated by Ours-CoAttention, Ours-no-Attention, and Soft Attention models. The underlined sentences are the descriptions of detected abnormalities. The second image is a lateral x-ray image. Top two images are positive results, the third one is a partial failure case and the bottom one is failure case. These images are from test dataset.

tention can only capture the visual information of sub-regions of the image and is unable to correctly capture the semantics of the entire image. Semantic attention is inadequate of localizing small abnormal image-regions. Finally, our full model (Ours-CoAttention) achieves the best results on all of the evaluation metrics, which demonstrates the effectiveness of the proposed co-attention mechanism.

For the single-sentence generation results (shown in the lower part of Table 1), the ablated versions of our model (Ours-Semantic-only and Ours-Visual-only) achieve competitive scores compared with the state-of-the-art methods. Our full model (Ours-CoAttention) outperforms all of the baseline, which indicates the effectiveness of the proposed co-attention mechanism.

4.5 Qualitative Results

4.5.1 Paragraph Generation

An illustration of paragraph generation by three models (Ours-CoAttention, Ours-no-Attention and Soft Attention models) is shown in Figure 3. We can find that different sentences have different topics. The first sentence is usually a high level description of the image, while each of the following sentences is associated with one area of the image (e.g. "lung", "heart"). Soft Attention and Ours-no-Attention models detect only a few abnormalities of the images and the detected abnormalities are incorrect. In contrast, Ours-CoAttention model is able to correctly describe many true abnormalities (as shown in top three images). This comparison demonstrates that co-attention is better at capturing abnormalities.

For the third image, Ours-CoAttention model successfully detects the area ("right lower lobe") which is abnormal ("eventration"), however, it fails to precisely describe this abnormality. In addition, the model also finds abnormalities about "interstitial opacities" and "atheroscalerotic calcification", which are not considered as true abnormality by human experts. The potential reason for this mis-description might be that this x-ray image is darker (compared with the above images), and our model might be very sensitive to this change.

normal	normal; **calcified granuloma; granulomatous disease; granuloma;** scarring; opacity; degenerative change; sternotomy; thoracic aorta; nodule	**normal;** calcified granuloma; granulomatous disease; granuloma; scarring; opacity; **degenerative change;** sternotomy; thoracic aorta; **nodule**	**normal;** calcified granuloma; granulomatous disease; granuloma; scarring; opacity; **degenerative change;** sternotomy; thoracic aorta; **nodule**	**normal;** calcified granuloma; granulomatous disease; granuloma; scarring; opacity; **degenerative change; sternotomy;** thoracic aorta; nodule	**normal;** calcified granuloma; granulomatous disease; granuloma; scarring; opacity; **degenerative change; sternotomy;** thoracic aorta; nodule	normal; **calcified granuloma; granulomatous disease;** granuloma; scarring; opacity; degenerative change; **sternotomy;** thoracic aorta; nodule
	Right upper lobe infiltrate.	Lungs are clear .	Stable heart size and aortic contours.	No acute displaced rib fractures.	No focal airspace opacities or consolidation.	No visualized of pneumothorax.
No acute cardiopulmonary abnormality identified. The examination consists of frontal and lateral radiographs of the chest. The cardio mediastinal contours are within normal limits. Pulmonary vascularity is within normal limits. No focal consolidation pleural effusion or pneumothorax identified. The visualized osseous structures and upper abdomen are unremarkable.						

Figure 4: Visualization of co-attention for three examples. Each example is comprised of four things: (1) image and visual attentions; (2) ground truth tags and semantic attention on predicted tags; (3) generated descriptions; (4) ground truth descriptions. For the semantic attention, three tags with highest attention scores are highlighted. The underlined tags are those appearing in the ground truth.

The image at the bottom is a failure case of Ours-CoAttention. However, even though the model makes the wrong judgment about the major abnormalities in the image, it does find some unusual regions: "lateral lucency" and "left lower lobe".

To further understand models' ability of detecting abnormalities, we present the portion of sentences which describe the normalities and abnormalities in Table 2. We consider sentences which contain "no", "normal", "clear", "stable" as sentences describing normalities. It is clear that Ours-CoAttention best approximates the ground truth distribution over normality and abnormality.

Method	Normality	Abnormality	Total
Soft Attention	0.510	0.490	1.0
Ours-no-Attention	0.753	0.247	1.0
Ours-CoAttention	0.471	0.529	1.0
Ground Truth	0.385	0.615	1.0

Table 2: Portion of sentences which describe the normalities and abnormalities in the image.

4.5.2 Co-Attention Learning

Figure 4 presents visualizations of co-attention. The first property shown by Figure 4 is that the sentence LSTM can generate different topics at different time steps since the model focuses on different image regions and tags for different sentences. The next finding is that visual attention can guide our model to concentrate on relevant regions of the image. For example, the third sentence of the first example is about "cardio", and the visual attention concentrates on regions near the heart. Similar behavior can also be found for semantic attention: for the last sentence in the first example, our model correctly concentrates on "degenerative change" which is the topic of the sentence. Finally, the first sentence of the last example presents a mis-description caused by incorrect semantic attention over tags. Such incorrect attention can be reduced by building a better tag prediction module.

5 Conclusion

In this paper, we study how to automatically generate textual reports for medical images, with the goal to help medical professionals produce reports more accurately and efficiently. Our proposed methods address three major challenges: (1) how to generate multiple heterogeneous forms of information within a unified framework, (2) how to localize abnormal regions and produce accurate descriptions for them, (3) how to generate long texts that contain multiple sentences or even paragraphs. To cope with these challenges, we propose a multi-task learning framework which jointly predicts tags and generates descriptions. We introduce a co-attention mechanism that can simultaneously explore visual and semantic information to accurately localize and describe abnormal regions. We develop a hierarchical LSTM network that can more effectively capture long-range semantics and produce high quality long texts. On two medical datasets containing radiology and pathology images, we demonstrate the effectiveness of the proposed methods through quantitative and qualitative studies.

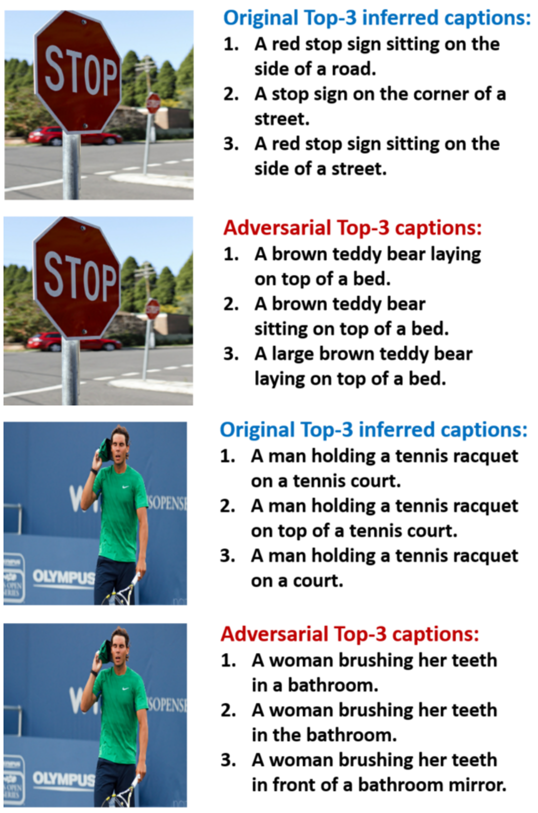
Abstract

Visual language grounding is widely studied in modern neural image captioning systems, which typically adopts an encoder-decoder framework consisting of two principal components: a convolutional neural network (CNN) for image feature extraction and a recurrent neural network (RNN) for language caption generation. To study the robustness of language grounding to adversarial perturbations in machine vision and perception, we propose **Show-and-Fool**, a novel algorithm for crafting adversarial examples in neural image captioning. The proposed algorithm provides two evaluation approaches, which check whether neural image captioning systems can be mislead to output some randomly chosen captions or keywords. Our extensive experiments show that our algorithm can successfully craft visually-similar adversarial examples with randomly targeted captions or keywords, and the adversarial examples can be made highly transferable to other image captioning systems. Consequently, our approach leads to new robustness implications of neural image captioning and novel insights in visual language grounding.

1 Introduction

In recent years, language understanding grounded in machine vision and perception has made remarkable progress in natural language processing (NLP) and artificial intelligence (AI), such as image captioning and visual question answering. Image captioning is a multimodal learning task and has been used to study the interaction between language and vision models (Shekhar et al., 2017). It takes an image as an input and generates a language caption that best describes its visual contents, and has many important applications such as developing image search engines with complex natural language queries, building AI agents that can see and talk, and promoting equal web access for people who are blind or visually impaired. Modern image captioning systems typically adopt an encoder-decoder framework composed of two principal modules: a convolutional neural network (CNN) as an encoder for image feature extraction and a recurrent neural network (RNN) as a decoder for caption generation. This CNN+RNN architecture includes popular image captioning models such as Show-and-Tell (Vinyals et al., 2015), Show-Attend-and-Tell (Xu et al., 2015) and NeuralTalk (Karpathy and Li, 2015).

Recent studies have highlighted the vulnerability of CNN-based image classifiers to adversarial examples: adversarial perturbations to benign images can be easily crafted to mislead a well-trained classifier, leading to visually indistinguishable adversarial examples to human (Szegedy et al., 2014; Goodfellow et al., 2015). In this study, we investigate a more challenging problem in visual language grounding domain that evaluates the robustness of multimodal RNN in the form of a CNN+RNN architecture, and use neural image captioning as a case study. Note that crafting adversarial examples in image captioning tasks is strictly harder than in well-studied image classification tasks, due to the following reasons: (i) class attack v.s. caption attack: unlike classification tasks where the class labels are well defined, the output of image captioning is a set of top-ranked captions. Simply treating different captions as distinct classes will result in an enormous number of classes that can even precede the number of training images. In addition, semantically similar



Original Top-3 inferred captions:

1. A red stop sign sitting on the side of a road.
2. A stop sign on the corner of a street.
3. A red stop sign sitting on the side of a street.

Adversarial Top-3 captions:

1. A brown teddy bear laying on top of a bed.
2. A brown teddy bear sitting on top of a bed.
3. A large brown teddy bear laying on top of a bed.

Original Top-3 inferred captions:

2. A man holding a tennis racquet on top of a tennis court.
3. A man holding a tennis racquet on a court.

Adversarial Top-3 captions:

1. A woman brushing her teeth in a bathroom.
2. A woman brushing her teeth in the bathroom.
3. A woman brushing her teeth in front of a bathroom mirror.

Figure 1: Adversarial examples crafted by Show-and-Fool using the targeted caption method. The target captioning model is Show-and-Tell (Vinyals et al., 2015), the original images are selected from the MSCOCO validation set, and the targeted captions are randomly selected from the top-1 inferred caption of other validation images.

captions can be expressed in different ways and hence should not be viewed as different classes; and (ii) CNN v.s. CNN+RNN: attacking RNN models is significantly less well-studied than attacking CNN models. The CNN+RNN architecture is unique and beyond the scope of adversarial examples in CNN-based image classifiers.

In this paper, we tackle the aforementioned challenges by proposing a novel algorithm called *Show-and-Fool*. We formulate the process of crafting adversarial examples in neural image captioning systems as optimization problems with novel objective functions designed to adopt the CNN+RNN architecture. Specifically, our objective function is a linear combination of the distortion between benign and adversarial examples as well as some carefully designed loss functions. The proposed Show-and-Fool algorithm provides two approaches to craft adversarial examples in neural image captioning under different scenarios:

1. **Targeted caption method:** Given a targeted caption, craft adversarial perturbations to any image such that its generated caption matches the targeted caption.
2. **Targeted keyword method:** Given a set of keywords, craft adversarial perturbations to any image such that its generated caption contains the specified keywords. The captioning model has the freedom to make sentences with target keywords *in any order*.

As an illustration, Figure 1 shows an adversarial example crafted by Show-and-Fool using the targeted caption method. The adversarial perturbations are visually imperceptible while can successfully mislead Show-and-Tell to generate the targeted captions. Interestingly and perhaps surprisingly, our results pinpoint the Achilles heel of the language and vision models used in the tested image captioning systems. Moreover, the adversarial examples in neural image captioning highlight the inconsistency in visual language grounding between humans and machines, suggesting a possible weakness of current machine vision and perception machinery. Below we highlight our major contributions:

- We propose *Show-and-Fool*, a novel optimization based approach to crafting adversarial examples in image captioning. We provide two types of adversarial examples, targeted caption and targeted keyword, to analyze the robustness of neural image captioners. To the best of our knowledge, this is the very first work on crafting adversarial examples for image captioning.
- We propose powerful and generic loss functions that can craft adversarial examples and evaluate the robustness of the encoder-decoder pipelines in the form of a CNN+RNN architecture. In particular, our loss designed for targeted keyword attack only requires the adversarial caption to contain a few specified keywords; and we allow the neural network to *make meaningful sentences with these keywords on its own*.
- We conduct extensive experiments on the MSCOCO dataset. Experimental results show that our targeted caption method attains a 95.8% attack success rate when crafting adversarial examples with randomly assigned captions. In addition, our targeted keyword attack yields an even higher success rate. We also show that attacking CNN+RNN models is inherently different and more challenging than only attacking

CNN models.

- We also show that Show-and-Fool can produce highly transferable adversarial examples: an adversarial image generated for fooling Show-and-Tell can also fool other image captioning models, leading to new robustness implications of neural image captioning systems.

2 Related Work

In this section, we review the existing work on visual language grounding, with a focus on neural image captioning. We also review related work on adversarial attacks on CNN-based image classifiers. Due to space limitations, we defer the second part to the supplementary material.

Visual language grounding represents a family of multimodal tasks that bridge visual and natural language understanding. Typical examples include image and video captioning (Karpathy and Li, 2015; Vinyals et al., 2015; Donahue et al., 2015b; Pasunuru and Bansal, 2017; Venugopalan et al., 2015), visual dialog (Das et al., 2017; De Vries et al., 2017), visual question answering (Antol et al., 2015; Fukui et al., 2016; Lu et al., 2016; Zhu et al., 2017), visual storytelling (Huang et al., 2016), natural question generation (Mostafazadeh et al., 2017, 2016), and image generation from captions (Mansimov et al., 2016; Reed et al., 2016). In this paper, we focus on studying the robustness of neural image captioning models, and believe that the proposed method also sheds lights on robustness evaluation for other visual language grounding tasks using a similar multimodal RNN architecture.

Many image captioning methods based on deep neural networks (DNNs) adopt a multimodal RNN framework that first uses a CNN model as the encoder to extract a visual feature vector, followed by a RNN model as the decoder for caption generation. Representative works under this framework include (Chen and Zitnick, 2015; Devlin et al., 2015; Donahue et al., 2015a; Karpathy and Li, 2015; Mao et al., 2015; Vinyals et al., 2015; Xu et al., 2015; Yang et al., 2016; Liu et al., 2017a,b), which are mainly differed by the underlying CNN and RNN architectures, and whether or not the attention mechanisms are considered. Other lines of research generate image captions using semantic information or via a compositional approach (Fang et al., 2015; Gan et al., 2017; Tran et al., 2016; Jia et al., 2015; Wu et al., 2016; You et al., 2016).

The recent work in (Shekhar et al., 2017) touched upon the robustness of neural image captioning for language grounding by showing its insensitivity to one-word (foil word) changes in the language caption, which corresponds to the *untargeted attack* category in adversarial examples. In this paper, we focus on the more challenging *targeted attack* setting that requires to fool the captioning models and enforce them to generate pre-specified captions or keywords.

3 Methodology of Show-and-Fool

3.1 Overview of the Objective Functions

We now formally introduce our approaches to crafting adversarial examples for neural image captioning. The problem of finding an adversarial example for a given image I can be cast as the following optimization problem:

$$\begin{aligned} \min_{\delta} \quad & c \cdot \text{loss}(I+\delta) + \|\delta\|_2^2 \\ \text{s.t.} \quad & I+\delta \in [-1,1]^n. \end{aligned} \tag{1}$$

Here δ denotes the adversarial perturbation to I. $\|\delta\|_2^2 = \|(I+\delta) - I\|_2^2$ is an ℓ_2 distance metric between the original image and the adversarial image. $\text{loss}(\cdot)$ is an attack loss function which takes different forms in different attacking settings. We will provide the explicit expressions in Sections 3.2 and 3.3. The term $c > 0$ is a pre-specified regularization constant. Intuitively, with larger c, the attack is more likely to succeed but at the price of higher distortion on δ. In our algorithm, we use a binary search strategy to select c. The box constraint on the image $I \in [-1,1]^n$ ensures that the adversarial example $I+\delta \in [-1,1]^n$ lies within a valid image space.

For the purpose of efficient optimization, we convert the constrained minimization problem in (1) into an unconstrained minimization problem by introducing two new variables $y \in \mathbb{R}^n$ and $w \in \mathbb{R}^n$ such that

$$y = \text{arctanh}(I) \quad \text{and} \quad w = \text{arctanh}(I+\delta) - y,$$

where arctanh denotes the inverse hyperbolic tangent function and is applied element-wisely. Since $\tanh(y_i + w_i) \in [-1,1]$, the transformation will automatically satisfy the box constraint. Consequently, the constrained optimization problem in

(1) is equivalent to

$$\min_{w\in\mathbb{R}^n} \quad c \cdot \text{loss}(\tanh(w+y)) \\ +\|\tanh(w+y)-\tanh(y)\|_2^2. \tag{2}$$

In the following sections, we present our designed loss functions for different attack settings.

3.2 Targeted Caption Method

Note that a targeted caption is denoted by

$$S = (S_1,\ S_2,\ ...,\ S_t,\ ...,\ S_N),$$

where S_t indicates the index of the t-th word in the vocabulary list $\mathcal{V}$, S_1 is a start symbol and S_N indicates the end symbol. N is the length of caption S, which is not fixed but does not exceed a predefined maximum caption length. To encourage the neural image captioning system to output the targeted caption S, one needs to ensure the log probability of the caption S conditioned on the image $I+\delta$ attains the maximum value among all possible captions, that is,

$$\log P(S|I+\delta) = \max_{S'\in\Omega} \log P(S'|I+\delta), \tag{3}$$

where Ω is the set of all possible captions. It is also common to apply the chain rule to the joint probability and we have

$$\log P(S'|I+\delta) = \sum_{t=2}^{N} \log P(S'_t|I+\delta, S'_1, ..., S'_{t-1}).$$

In neural image captioning networks, $p(S'_t|I+\delta, S'_1, ..., S'_{t-1})$ is usually computed by a RNN/LSTM cell f, with its hidden state h_{t-1} and input S'_{t-1}:

$$z_t = f(h_{t-1}, S'_{t-1}) \text{ and } p_t = \text{softmax}(z_t), \tag{4}$$

where $z_t := [z_t^{(1)}, z_t^{(2)}, ..., z_t^{(|\mathcal{V}|)}] \in \mathbb{R}^{|\mathcal{V}|}$ is a vector of the *logits* (unnormalized probabilities) for each possible word in the vocabulary. The vector p_t represents a probability distribution on $\mathcal{V}$ with each coordinate $p_t^{(i)}$ defined as:

$$p_t^{(i)} := P(S'_t = i|I+\delta, S'_1, ..., S'_{t-1}).$$

Following the definition of softmax function:

$$P(S'_t|I+\delta, S'_1, ..., S'_{t-1}) = \exp(z_t^{(S'_t)}) / \sum_{i\in\mathcal{V}} \exp(z_t^{(i)}).$$

Intuitively, to maximize the targeted caption's probability, we can directly use its negative log probability (5) as a loss function. The inputs of the RNN are the first $N-1$ words of the targeted caption $(S_1, S_2, ..., S_{N-1})$.

$$\begin{aligned}\text{loss}_{S,\text{log-prob}}(I+\delta) &= -\log P(S|I+\delta) \\ &= -\sum_{t=2}^{N} \log P(S_t|I+\delta, S_1, ..., S_{t-1}).\end{aligned} \tag{5}$$

Applying (5) to (2), the formulation of targeted caption method given a targeted caption S is:

$$\min_{w\in\mathbb{R}^n} c \cdot \text{loss}_{S,\text{log prob}}(\tanh(w+y)) \\ + \ \|\tanh(w+y)-\tanh(y)\|_2^2.$$

Alternatively, using the definition of the softmax function,

$$\begin{aligned}\log P(S'|I+\delta) &= \sum_{t=2}^{N} [z_t^{(S'_t)} - \log(\sum_{i\in\mathcal{V}} \exp(z_t^{(i)}))] \\ &= \sum_{t=2}^{N} z_t^{(S'_t)} - \text{constant},\end{aligned} \tag{6}$$

(3) can be simplified as

$$\log P(S|I+\delta) \propto \sum_{t=2}^{N} z_t^{(S_t)} = \max_{S'\in\Omega} \sum_{t=2}^{N} z_t^{(S'_t)}.$$

Instead of making each $z_t^{(S_t)}$ as large as possible, it is sufficient to require the target word S_t to attain the largest (top-1) logit (or probability) among all the words in the vocabulary at position t. In other words, we aim to minimize the difference between the maximum logit except S_t, denoted by $\max_{k\in\mathcal{V},k\neq S_t}\{z_t^{(k)}\}$, and the logit of S_t, denoted by $z_t^{(S_t)}$. We also propose a ramp function on top of this difference as the final loss function:

$$\text{loss}_{S,\text{logits}}(I+\delta) = \sum_{t=2}^{N-1} \max\{-\epsilon, \max_{k\neq S_t}\{z_t^{(k)}\} - z_t^{(S_t)}\}, \tag{7}$$

where $\epsilon > 0$ is a confidence level accounting for the gap between $\max_{k\neq S_t}\{z_t^{(k)}\}$ and $z_t^{(S_t)}$. When $z_t^{(S_t)} > \max_{k\neq S_t}\{z_t^{(k)}\} + \epsilon$, the corresponding term in the summation will be kept at $-\epsilon$ and does not contribute to the gradient of the loss function, encouraging the optimizer to focus on minimizing other terms where $z_t^{(S_t)}$ is not large enough.

Applying the loss (7) to (1), the final formulation of targeted caption method given a targeted caption S is

$$\min_{w \in \mathbb{R}^n} c \cdot \sum_{t=2}^{N-1} \max\{-\epsilon, \max_{k \neq S_t}\{z_t^{(k)}\} - z_t^{(S_t)}\} + \| \tanh(w+y) - \tanh(y) \|_2^2.$$

We note that (Carlini and Wagner, 2017) has reported that in CNN-based image classification, using logits in the attack loss function can produce better adversarial examples than using probabilities, especially when the target network deploys some gradient masking schemes such as defensive distillation (Papernot et al., 2016b). Therefore, we provide both logit-based and probability-based attack loss functions for neural image captioning.

3.3 Targeted Keyword Method

In addition to generating an exact targeted caption by perturbing the input image, we offer an intermediate option that aims at generating captions with specific keywords, denoted by $\mathcal{K} := \{K_1, \cdots, K_M\} \subset \mathcal{V}$. Intuitively, finding an adversarial image generating a caption with specific keywords might be easier than generating an exact caption, as we allow more degree of freedom in caption generation. However, as we need to ensure a valid and meaningful inferred caption, finding an adversarial example with specific keywords in its caption is difficult in an optimization perspective. Our target keyword method can be used to investigate the generalization capability of a neural captioning system given only a few keywords.

In our method, we do not require a target keyword K_j, $j \in [M]$ to appear at a particular position. Instead, we want a loss function that allows K_j to become the top-1 prediction (plus a confidence margin ϵ) at any position. Therefore, we propose to use the minimum of the hinge-like loss terms over all $t \in [N]$ as an indication of K_j appearing at any position as the top-1 prediction, leading to the following loss function:

$$\text{loss}_{K,\text{logits}} = \sum_{j=1}^{M} \min_{t \in [N]} \{\max\{-\epsilon, \max_{k \neq K_j}\{z_t^{(k)}\} - z_t^{(K_j)}\}\}. \tag{8}$$

We note that the loss functions in (4) and (5) require an input S'_{t-1} to predict z_t for each $t \in \{2, \ldots, N\}$. For the targeted caption method, we use the targeted caption S as the input of RNN. In contrast, for the targeted keyword method we no longer know the exact targeted sentence, but only require the presence of specified keywords in the final caption. To bridge the gap, we use the originally inferred caption $S^0 = (S_1^0, \cdots, S_N^0)$ from the benign image as the initial input to RNN. Specifically, after minimizing (8) for T iterations, we run inference on $I + \delta$ and set the RNN's input S^1 as its current top-1 prediction, and continue this process. With this iterative optimization process, the desired keywords are expected to gradually appear in top-1 prediction.

Another challenge arises in targeted keyword method is the problem of "keyword collision". When the number of keywords $M \geq 2$, more than one keywords may have large values of $\max_{k \neq K_j}\{z_t^{(k)}\} - z_t^{(K_j)}$ at a same position t. For example, if `dog` and `cat` are top-2 predictions for the second word in a caption, the caption can either start with "A dog ..." or "A cat ...". In this case, despite the loss (8) being very small, a caption with both `dog` and `cat` can hardly be generated, since only one word is allowed to appear at the same position. To alleviate this problem, we define a gate function $g_{t,j}(x)$ which masks off all the other keywords when a keyword becomes top-1 at position t:

$$g_{t,j}(x) = \begin{cases} A, \text{ if } \arg\max_{i \in \mathcal{V}} z_t^{(i)} \in \mathcal{K} \setminus \{K_j\} \\ x, \text{ otherwise,} \end{cases}$$

where A is a predefined value that is significantly larger than common logits values. Then (8) becomes:

$$\sum_{j=1}^{M} \min_{t \in [N]} \{g_{t,j}(\max\{-\epsilon, \max_{k \neq K_j}\{z_t^{(k)}\} - z_t^{(K_j)}\})\}. \tag{9}$$

The log-prob loss for targeted keyword method is discussed in the Supplementary Material.

4 Experiments

4.1 Experimental Setup and Algorithms

We performed extensive experiments to test the effectiveness of our Show-and-Fool algorithm and study the robustness of image captioning systems under different problem settings. In our experiments[1], we use the pre-trained TensorFlow implementation[2] of Show-and-Tell (Vinyals et al., 2015)

[1]Our source code is available at: https://github.com/huanzhang12/ImageCaptioningAttack

[2]https://github.com/tensorflow/models/tree/master/research/im2txt

with Inception-v3 as the CNN for visual feature extraction. Our testbed is Microsoft COCO (Lin et al., 2014) (MSCOCO) data set. Although some more recent neural image captioning systems can achieve better performance than Show-and-Tell, they share a similar framework that uses CNN for feature extraction and RNN for caption generation, and Show-and-Tell is the vanilla version of this CNN+RNN architecture. Indeed, we find that the adversarial examples on Show-and-Tell are transferable to other image captioning models such as Show-Attend-and-Tell (Xu et al., 2015) and NeuralTalk2[3], suggesting that the attention mechanism and the choice of CNN and RNN architectures do not significantly affect the robustness. We also note that since Show-and-Fool is the first work on crafting adversarial examples for neural image captioning, to the best of our knowledge, there is no other method for comparison.

We use ADAM to minimize our loss functions and set the learning rate to 0.005. The number of iterations is set to $1,000$. All the experiments are performed on a single Nvidia GTX 1080 Ti GPU. For targeted caption and targeted keyword methods, we perform a binary search for 5 times to find the best c: initially $c = 1$, and c will be increased by 10 times until a successful adversarial example is found. Then, we choose a new c to be the average of the largest c where an adversarial example can be found and the smallest c where an adversarial example cannot be found. We fix $\epsilon = 1$ except for transferability experiments. For each experiment, we randomly select 1,000 images from the MSCOCO validation set. We use BLEU-1 (Papineni et al., 2002), BLEU-2, BLEU-3, BLEU-4, ROUGE (Lin, 2004) and METEOR (Lavie and Agarwal, 2005) scores to evaluate the correlations between the inferred captions and the targeted captions. These scores are widely used in NLP community and are adopted by image captioning systems for quality assessment. Throughout this section, we use the *logits loss* (7)(9). The results of using the *log-prob loss* (5) are similar and are reported in the supplementary material.

4.2 Targeted Caption Results

Unlike the image classification task where all possible labels are predefined, the space of possible captions in a captioning system is almost infinite. However, the captioning system is only able to output relevant captions learned from the training set. For instance, the captioning model cannot generate a passive-voice sentence if the model was never trained on such sentences. Therefore, we need to ensure that the targeted caption lies in the space where the captioning system can possibly generate. To address this issue, we use the generated caption of a randomly selected image (other than the image under investigation) from MSCOCO validation set as the targeted caption S. The use of a generated caption as the targeted caption excludes the effect of out-of-domain captioning, and ensures that the target caption is within the output space of the captioning network.

Here we use the logits loss (7) plus a ℓ_2 distortion term (as in (2)) as our objective function. A successful adversarial example is found if the inferred caption after adding the adversarial perturbation δ is *exactly the same* as the targeted caption. In our setting, 1,000 ADAM iterations take about 38 seconds for one image. The overall success rate and average distortion of adversarial perturbation δ are shown in Table 1. Among all the tested images, our method attains 95.8% attack success

[3]https://github.com/karpathy/neuraltalk2

Table 1: Summary of targeted caption method (Section 3.2) and targeted keyword method (Section 3.3) using logits loss. The ℓ_2 distortion of adversarial noise $\|\delta\|_2$ is averaged over successful adversarial examples. For comparison, we also include CNN based attack methods (Section 4.5).

Experiments	Success Rate	Avg. $\|\delta\|_2$
targeted caption	95.8%	2.213
1-keyword	97.1%	1.589
2-keyword	97.5%	2.363
3-keyword	96.0%	2.626
C&W on CNN	22.4%	2.870
I-FGSM on CNN	34.5%	15.596

Table 2: Statistics of the 4.2% failed adversarial examples using the targeted caption method and logits loss (7). All correlation scores are computed using the top-5 inferred captions of an adversarial image and the targeted caption (higher score means better targeted attack performance).

c	1	10	10^2	10^3	10^4
ℓ_2 Distortion	1.726	3.400	7.690	16.03	23.31
BLEU-1	.567	.725	.679	.701	.723
BLEU-2	.420	.614	.559	.585	.616
BLEU-3	.320	.509	.445	.484	.514
BLEU-4	.252	.415	.361	.402	.417
ROUGE	.502	.664	.629	.638	.672
METEOR	.258	.407	.375	.403	.399

rate. Moreover, our adversarial examples have small ℓ_2 distortions and are visually identical to the original images, as displayed in Figure 1. We also examine the failed adversarial examples and summarize their statistics in Table 2. We find that their generated captions, albeit not entirely identical to the targeted caption, are in fact highly correlated to the desired one. Overall, the high success rate and low ℓ_2 distortion of adversarial examples clearly show that Show-and-Tell is not robust to targeted adversarial perturbations.

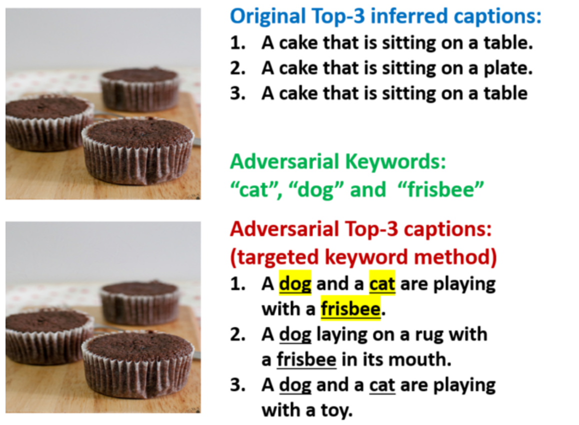
4.3 Targeted Keyword Results

In this task, we use (9) as our loss function, and choose the number of keywords $M = \{1, 2, 3\}$. We run an inference step on $I + \delta$ every $T = 5$ iterations, and use the top-1 caption as the input of RNN/LSTMs. Similar to Section 4.2, for each image the targeted keywords are selected from the caption generated by a randomly selected validation set image. To exclude common words like "a", "the", "and", we look up each word in the targeted sentence and only select nouns, verbs, adjectives or adverbs. We say an adversarial image is successful when its caption contains *all* specified keywords. The overall success rate and average distortion are shown in Table 1. When compared to the targeted caption method, targeted keyword method achieves an even higher success rate (at least 96% for 3-keyword case and at least 97% for 1-keyword and 2-keyword cases). Figure 2 shows an adversarial example crafted from our targeted keyword method with three keywords - "dog", "cat" and "frisbee". Using Show-and-Fool, the top-1 caption of a cake image becomes "A dog and a cat are playing with a frisbee" while the adversarial image remains visually indistinguishable to the original one. When $M = 2$ and 3, even if we cannot find an adversarial image yielding all specified keywords, we might end up with a caption that contains some of the keywords (partial success). For example, when $M = 3$, Table 3 shows the number of keywords appeared in the captions (M') for those *failed* examples (not all 3 targeted keywords are found). These results clearly show that the 4% failed examples are still partially successful: the generated captions contain about 1.5 targeted keywords on average.

4.4 Transferability of Adversarial Examples

It has been shown that in image classification tasks, adversarial examples found for one machine learning model may also be effective against another model, even if the two models have different architectures (Papernot et al., 2016a; Liu et al., 2017c). However, unlike image classification where correct labels are made explicit, two different image captioning systems may generate quite different, yet semantically similar, captions for the same benign image. In image captioning, we say an adversarial example is *transferable* when the adversarial image found on model A with a target sentence S_A can generate a similar (rather than exact) sentence S_B on model B.

In our setting, model A is Show-and-Tell, and we choose Show-Attend-and-Tell (Xu et al., 2015) as model B. The major differences between Show-and-Tell and Show-Attend-and-Tell are the addition of attention units in LSTM network for caption generation, and the use of last convolutional layer (rather than the last fully-connected layer) feature maps for feature extraction. We use Inception-v3 as the CNN architecture for both models and train them on the MSCOCO 2014 data set. However, their CNN parameters are different due to the fine-tuning process.



Original Top-3 inferred captions:
1. A cake that is sitting on a table.
2. A cake that is sitting on a plate.
3. A cake that is sitting on a table

Adversarial Keywords:
"cat", "dog" and "frisbee"

Adversarial Top-3 captions:
(targeted keyword method)
1. A dog and a cat are playing with a frisbee.
2. A dog laying on a rug with a frisbee in its mouth.
3. A dog and a cat are playing with a toy.

Figure 2: An adversarial example ($\|\delta\|_2 = 1.284$) of an cake image crafted by the Show-and-Fool targeted keyword method with three keywords - "dog", "cat" and "frisbee".

Table 3: Percentage of partial success with different c in the 4.0% failed images that do not contain all the 3 targeted keywords.

c	Avg. $\|\delta\|_2$	$M' \geq 1$	$M' = 2$	Avg. M'
1	2.49	72.4%	34.5%	1.07
10	5.40	82.7%	37.9%	1.21
10^2	12.95	93.1%	58.6%	1.52
10^3	24.77	96.5%	51.7%	1.48
10^4	29.37	100.0%	58.6%	1.59

Table 4: Transferability of adversarial examples from Show-and-Tell to Show-Attend-and-Tell, using different ϵ and c. **ori** indicates the scores between the generated captions of the *original* images and the transferred adversarial images on Show-Attend-and-Tell. **tgt** indicates the scores between the *targeted* captions on Show-and-Tell and the generated captions of transferred adversarial images on Show-Attend-and-Tell. A smaller **ori** or a larger **tgt** value indicates better transferability. **mis** measures the differences between captions generated by the two models given the same benign image (*model mismatch*). When $C = 1000$, $\epsilon = 10$, **tgt** is close to **mis**, indicating the discrepancy between adversarial captions on the two models is mostly bounded by model mismatch, and the adversarial perturbation is highly transferable.

	$\epsilon=1$						$\epsilon=5$						$\epsilon=10$						
	C=10		C=100		C=1000		C=10		C=100		C=1000		C=10		C=100		C=1000		
	ori	**tgt**	**ori**	**tgt**	**ori**	**tgt**	**ori**	**tgt**	**ori**	**tgt**	**ori**	**tgt**	**ori**	**tgt**	**ori**	**tgt**	**ori**	**tgt**	**mis**

Original Top-1 inferred caption:
Show-and-Tell: A bathroom with a sink and a mirror
Show-Attend-and-Tell: A bathroom with a sink and a mirror.
Adversarial Top-1 caption:
Show-and-Tell (targeted caption method): A man riding a wave on top of a surfboard.
Show-Attend-and-Tell (transferred example): A man on a surfboard in the air.

Figure 3: A highly transferable adversarial example ($\|\delta\|_2 = 15.226$) crafted by Show-and-Tell targeted caption method, transfers to Show-Attend-and-Tell, yielding similar adversarial captions.

To investigate the transferability of adversarial examples in image captioning, we first use the targeted caption method to find adversarial examples for 1,000 images in model A with different c and ϵ, and then transfer successful adversarial examples (which generate the exact target captions on model A) to model B. The generated captions by model B are recorded for transferability analysis. The transferability of adversarial examples depends on two factors: the intrinsic difference between two models even when the same benign image is used as the input, i.e., *model mismatch*, and the transferability of adversarial perturbations.

To measure the mismatch between Show-and-Tell and Show-Attend-and-Tell, we generate captions of the same set of 1,000 original images from both models, and report their mutual BLEU, ROUGE and METEOR scores in Table 4 under the **mis** column. To evaluate the effectiveness of transferred adversarial examples, we measure the scores for two set of captions: (i) the captions of original images and the captions of transferred adversarial images, both generated by Show-Attend-and-Tell (shown under column **ori** in Table 4); and (ii) the targeted captions for generating adversarial examples on Show-and-Tell, and the captions of the transferred adversarial image on Show-Attend-and-Tell (shown under column **tgt** in Table 4). Small values of **ori** suggest that the adversarial images on Show-Attend-and-Tell generate significantly different captions from original images' captions. Large values of **tgt** suggest that the adversarial images on Show-Attend-and-Tell generate similar adversarial captions as on the Show-and-Tell model. We find that increasing c or ϵ helps to enhance transferability at the cost of larger (but still acceptable) distortion. When $C = 1{,}000$ and $\epsilon = 10$, Show-and-Fool achieves the best transferability results: **tgt** is close to **mis**, indicating that the discrepancy between adversarial captions on the two models is mostly bounded by the intrinsic model mismatch rather than the transferability of adversarial perturbations, and implying that the adversarial perturbations are easily transferable. In addition, the adversarial examples generated by our method can also fool NeuralTalk2. When $c = 10^4, \epsilon = 10$, the average ℓ_2 distortion, BLEU-4 and METEOR scores between the original and transferred adversarial captions are 38.01, 0.440 and 0.473, respectively. The high transferability of adversarial examples crafted by Show-

and-Fool also indicates the problem of common robustness leakage between different neural image captioning models.

4.5 Attacking Image Captioning v.s. Attacking Image Classification

In this section we show that attacking image captioning models is inherently more challenging than attacking image classification models. In the classification task, a targeted attack usually becomes harder when the number of labels increases, since an attack method needs to change the classification prediction to a specific label over all the possible labels. In the targeted attack on image captioning, if we treat each caption as a label, we need to change the original label to a specific one over an almost infinite number of possible labels, corresponding to a nearly zero volume in the search space. This constraint forces us to develop non-trivial methods that are significantly different from the ones designed for attacking image classification models.

To verify that the two tasks are inherently different, we conducted additional experiments on attacking *only* the CNN module using two state-of-the-art image classification attacks on ImageNet dataset. Our experiment setup is as follows. Each selected ImageNet image has a label corresponding to a WordNet synset ID. We randomly selected 800 images from ImageNet dataset such that their synsets have at least one word in common with Show-and-Tell's vocabulary, while ensuring the Inception-v3 CNN (Show-and-Tell's CNN) classify them correctly. Then, we perform Iterative Fast Gradient Sign Method (I-FGSM) (Kurakin et al., 2017) and Carlini and Wagner's (C&W) attack (Carlini and Wagner, 2017) on these images. The attack target labels are randomly chosen and their synsets also have at least one word in common with Show-and-Tell's vocabulary. Both I-FGSM and C&W achieve 100% targeted attack success rate on the Inception-v3 CNN. These adversarial examples were further employed to attack Show-and-Tell model. An attack is considered successful if *any* word in the targeted label's synset or its hypernyms up to 5 levels is presented in the resulting caption. For example, for the chain of hypernyms 'broccoli'⇒'cruciferous vegetable'⇒'vegetable, veggie, veg'⇒'produce, green goods, green groceries, garden truck'⇒'food, solid food', we include 'broccoli','cruciferous','vegetable','veggie' and all other following words. Note that this criterion of success is much weaker than the criterion we use in the targeted caption method, since a caption with the targeted image's hypernyms does not necessarily leads to similar meaning of the targeted image's captions. To achieve higher attack success rates, we allow relatively larger distortions and set $\epsilon_\infty = 0.3$ (maximum ℓ_∞ distortion) in I-FGSM and $\kappa = 10$, $C = 100$ in C&W. However, as shown in Table 1, the attack success rates are only 34.5% for I-FGSM and 22.4% for C&W, respectively, which are much lower than the success rates of our methods despite larger distortions. This result further confirms that performing targeted attacks on neural image captioning requires a careful design (as proposed in this paper), and attacking image captioning systems is not a trivial extension to attacking image classifiers.

5 Conclusion

In this paper, we proposed a novel algorithm, **Show-and-Fool**, for crafting adversarial examples and providing robustness evaluation of neural image captioning. Our extensive experiments show that the proposed targeted caption and keyword methods yield high attack success rates while the adversarial perturbations are still imperceptible to human eyes. We further demonstrate that Show-and-Fool can generate highly transferable adversarial examples. The high-quality and transferable adversarial examples in neural image captioning crafted by Show-and-Fool highlight the inconsistency in visual language grounding between humans and machines, suggesting a possible weakness of current machine vision and perception machinery. We also show that attacking neural image captioning systems are inherently different from attacking CNN-based image classifiers.

Our method stands out from the well-studied adversarial learning on image classifiers and CNN models. To the best of our knowledge, this is the very first work on crafting adversarial examples for neural image captioning systems. Indeed, our Show-and-Fool algorithm[1] can be easily extended to other applications with RNN or CNN+RNN architectures. We believe this paper provides potential means to evaluate and possibly improve the robustness (for example, by adversarial training or data augmentation) of a wide range of visual language grounding and other NLP models.

Abstract

In this paper, we study the problem of geometric reasoning in the context of question-answering. We introduce Dynamic Spatial Memory Network (DSMN), a new deep network architecture designed for answering questions that admit latent visual representations. DSMN learns to generate and reason over such representations. Further, we propose two synthetic benchmarks, FloorPlanQA and ShapeIntersection, to evaluate the geometric reasoning capability of QA systems. Experimental results validate the effectiveness of our proposed DSMN for visual thinking tasks[1].

1 Introduction

The ability to reason is a hallmark of intelligence and a requirement for building question-answering (QA) systems. In AI research, reasoning has been strongly associated with logic and symbol manipulation, as epitomized by work in automated theorem proving (Fitting, 2012). But for humans, reasoning involves not only symbols and logic, but also images and shapes. Einstein famously wrote: "The psychical entities which seem to serve as elements in thought are certain signs and more or less clear images which can be 'voluntarily' reproduced and combined... Conventional words or other signs have to be sought for laboriously only in a secondary state..." And the history of science abounds with discoveries from visual thinking, from the Benzene ring to the structure of DNA (Pinker, 2003).

There are also plenty of ordinary examples of human visual thinking. Consider a square room with a door in the middle of its southern wall. Suppose you are standing in the room such that the eastern wall of the room is behind you. Where is the door with respect to you? The answer is 'to your left.' Note that in this case both the question and answer are just text. But in order to answer the question, it is natural to construct a mental picture of the room and use it in the process of reasoning. Similar to humans, the ability to 'think visually' is desirable for AI agents like household robots. An example could be to construct a rough map and navigation plan for an unknown environment from verbal descriptions and instructions.

In this paper, we investigate how to model geometric reasoning (a form of visual reasoning) using deep neural networks (DNN). Specifically, we address the task of answering questions through geometric reasoning—both the question and answer are expressed in symbols or words, but a geometric representation is created and used as part of the reasoning process.

In order to focus on geometric reasoning, we do away with natural language by designing two synthetic QA datasets, FloorPlanQA and ShapeIntersection. In FloorPlanQA, we provide the blueprint of a house in words and ask questions about location and orientation of objects in it. For ShapeIntersection, we give a symbolic representation of various shapes and ask how many places they intersect. In both datasets, a reference visual representation is provided for each sample.

Further, we propose Dynamic Spatial Memory Network (DSMN), a novel DNN that uses virtual imagery for QA. DSMN is similar to existing memory networks (Kumar et al., 2016; Sukhbaatar et al., 2015; Henaff et al., 2016) in that it uses vector embeddings of questions and memory modules to perform reasoning. The main novelty of DSMN is that it creates virtual images for the input question and uses a spatial memory to aid the reasoning

[1] Code and datasets: `https://github.com/umich-vl/think_visually`

process.

We show through experiments that with the aid of an internal visual representation and a spatial memory, DSMN outperforms strong baselines on both FloorPlanQA and ShapeIntersection. We also demonstrate that explicitly learning to create visual representations further improves performance. Finally, we show that DSMN is substantially better than the baselines even when visual supervision is provided for only a small proportion of the samples.

It's important to note that our proposed datasets consist of synthetic questions as opposed to natural texts. Such a setup allows us to sidestep difficulties in parsing natural language and instead focus on geometric reasoning. However, synthetic data lacks the complexity and diversity of natural text. For example, spatial terms used in natural language have various ambiguities that need to resolved by context (e.g. how far is "far" and whether "to the left" is relative to the speaker or the listener) (Shariff, 1998; Landau and Jackendoff, 1993), but our synthetic data lacks such complexities. Therefore, our method and results do not automatically generalize to real-life tasks involving natural language. Additional research is needed to extend and validate our approach on natural data.

Our contributions are three-fold: First, we present Dynamic Spatial Memory Network (DSMN), a novel DNN that performs geometric reasoning for QA. Second, we introduce two synthetic datasets that evaluate a system's visual thinking ability. Third, we demonstrate that on synthetic data, DSMN achieves superior performance for answering questions that require visual thinking.

2 Related Work

Natural language datasets for QA: Several natural language QA datasets have been proposed to test AI systems on various reasoning abilities (Levesque et al., 2011; Richardson et al., 2013). Our work differs from them in two key aspects: first, we use synthetic data instead of natural data; and second, we specialize in geometrical reasoning instead of general language understanding. Using synthetic data helps us simplify language parsing and thereby focus on geometric reasoning. However, additional research is necessary to generalize our work to natural data.

Synthetic datasets for QA: Recently, synthetic datasets for QA are also becoming crucial in AI. In particular, bAbI (Weston et al., 2015) has driven the development of several recent DNN-based QA systems (Kumar et al., 2016; Sukhbaatar et al., 2015; Henaff et al., 2016). bAbI consists of 20 tasks to evaluate different reasoning abilities. Two tasks, Positional Reasoning (PR) and Path Finding (PF), are related to geometric reasoning. However, each Positional Reasoning question contains only two sentences, and can be solved through simple logical deduction such as 'A is left of B implies B is right of A'. Similarly, Path Finding involves a search problem that requires simple spatial deductions such as 'A is east of B implies B is west of A'. In contrast, the questions in our datasets involve longer descriptions, more entities, and more relations; they are thus harder to answer with simple deductions. We also provide reference visual representation for each sample, which is not available in bAbI.

Mental Imagery and Visual Reasoning: The importance of visual reasoning has been long recognized in AI (Forbus et al., 1991; Lathrop and Laird, 2007). Prior works in NLP (Seo et al., 2015; Lin and Parikh, 2015) have also studied visual reasoning. Our work is different from them as we use synthetic language instead of natural language. Our synthetic language is easier to parse, allowing our evaluation to mainly reflect the performance of geometric reasoning. On the other hand, while our method and conclusions can potentially apply to natural text, this remains to be validated and involves nontrivial future work. There are other differences to prior works as well. Specifically, (Seo et al., 2015) combined information from textual questions and diagrams to build a model for solving SAT geometry questions. However, our task is different as diagrams are not provided as part of the input, but are generated from the words/symbols themselves. Also, (Lin and Parikh, 2015) take advantage of synthetic images to gather semantic common sense knowledge (visual common sense) and use it to perform fill-in-the-blank (FITB) and visual paraphrasing tasks. Similar to us, they also form 'mental images'. However, there are two differences (apart from natural vs synthetic language): first, their benchmark tests higher level semantic knowledge (like "Mike is having lunch when he sees a bear." $\Longrightarrow$ "Mike tries to hide."), while ours is more focused on geometric reasoning. Second, their model is based on hand-crafted features while we use a DNN.

Spatial language for Human-Robot Interaction: Our work is also related to prior work on making robots understand spatial commands (e.g. “put that box here”, “move closer to the box”) and complete tasks such as navigation and assembly. Earlier work (Müller et al., 2000; Gribble et al., 1998; Zelek, 1997) in this domain used template-based commands, whereas more recent work (Skubic et al., 2004) tried to make the commands more natural. This line of work differs from ours in that the robot has visual perception of its environment that allows grounding of the textual commands, whereas in our case the agent has no visual perception, and an environment needs to be imagined.

Image Generation: Our work is related to image generation using DNNs which has a large body of literature, with diverse approaches (Reed et al., 2016; Gregor et al., 2015). We also generate an image from the input. But in our task, image generation is in the service of reasoning rather than an end goal in itself—as a result, photorealism or artistic style of generated images is irrelevant and not considered.

Visual Question Answering: Our work is also related to visual QA (VQA) (Johnson et al., 2016; Antol et al., 2015; Lu et al., 2016). Our task is different from VQA because our questions are in terms of words/symbols whereas in VQA the questions are visual, consisting of both text descriptions and images. The images involved in our task are internal and virtual, and are not part of the input or output.

Memory and Attention: Memory and attention have been increasingly incorporated into DNNs, especially for tasks involving algorithmic inference and/or natural language (Graves et al., 2014; Vaswani et al., 2017). For QA tasks, memory and attention play an important role in state-of-the-art (SOTA) approaches. (Sukhbaatar et al., 2015) introduced End-To-End Memory Network (MemN2N), a DNN with memory and recurrent attention mechanism, which can be trained end-to-end for diverse tasks like textual QA and language modeling. Concurrently, (Kumar et al., 2016) introduced Dynamic Memory Network (DMN), which also uses attention and memory. (Xiong et al., 2016) proposed DMN+, with several improvements over the previous version of DMN and achieved SOTA results on VQA (Antol et al., 2015) and bAbI (Weston et al., 2015). Our proposed DSMN is a strict generalization of DMN+ (see Sec. 4.1). On removing the images and spatial memory from DSMN, it reduces to DMN+. Recently (Gupta et al., 2017) also used spatial memory in their deep learning system, but for visual navigation. We are using spatial memory for QA.

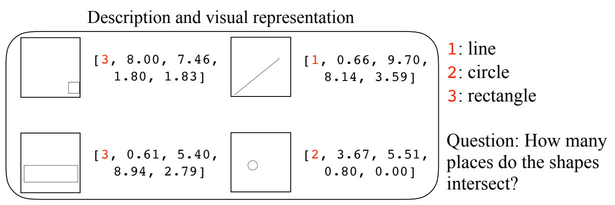

Figure 1: An example in the ShapeIntersection dataset.

3 Datasets

We introduce two synthetically-generated QA datasets to evaluate a system’s goemetrical reasoning ability: FloorPlanQA and ShapeIntersection. These datasets are not meant to test natural language understanding, but instead focus on geometrical reasoning. Owing to their synthetic nature, they are easy to parse, but nevertheless they are still challenging for DNNs like DMN+ (Xiong et al., 2016) and MemN2N (Sukhbaatar et al., 2015) that achieved SOTA results on existing QA datasets (see Table 2a).

The proposed datasets are similar in spirit to bAbI (Weston et al., 2015), which is also synthetic. In spite of its synthetic nature, bAbI has proved to be a crucial benchmark for the development of new models like MemN2N, DMN+, variants of which have proved successful in various natural domains (Kumar et al., 2016; Perez and Liu, 2016). Our proposed dataset is first to explicitly test ‘visual thinking’, and its synthetic nature helps us avoid the expensive and tedious task of collecting human annotations. Meanwhile, it is important to note that conclusions drawn from synthetic data do not automatically translate to natural data, and methods developed on synthetic benchmarks need additional validation on natural domains.

The proposed datasets also contain visual representations of the questions. Each of them has 38,400 questions, evenly split into a training set, a validation set and a test set (12,800 each).

The door for this room is located in its {*n-er, s-er, n-wr, s-wr, n-er, s-er, n-wr, s-wr*} side, such that it opens towards {*n, s, e, w*}. This room's door is located in its {*n-er, s-er, n-wr, s-wr, n-er, s-er, n-wr, s-wr*} side, such that it opens towards {*n, s, e, w*}.
Small room	Room {1, 2, 3} is small in size and it is located in the {*n, s, e, w, c, n-e, s-e, n-w, s-w*} of the house. Room {1, 2, 3} is located in the {*n, s, e, w, c, n-e, s-e, n-w, s-w*} of the house and is small in size.
Medium room	Room {1, 2, 3} is medium in size and it extends from the {*n, s, e, w, c, n-e, s-e, n-w, s-w*} to the {*n, s, e, w, c, n-e, s-e, n-w, s-w*} of the house. Room {1, 2, 3} extends from the {*n, s, e, w, c, n-e, s-e, n-w, s-w*} to the {*n, s, e, w, c, n-e, s-e, n-w, s-w*} of the house and is medium in size.
Large room	Room {1, 2, 3} is large in size and it stretches along the {*n-s, e-w*}direction in the {*n, s, e, w, c*} of the house. Room {1, 2, 3} stretches along the {*n-s, e-w*} direction in the {*n, s, e, w, c*} of the house and is large in size.
Object	A {*cu, cd, sp, co*} is located in the middle of the {*nr, sr, er, wr*} part of the house. A {*cu, cd, sp, co*} is located in the {*n-er, s-er, n-wr, s-wr, n-er, s-er, n-wr, s-wr, cr*} part of the house. A {*cu, cd, sp, co*} is located in the middle of the {*nr, sr, er, wr*} part of this room. A {*cu, cd, sp, co*} is located in the {*n-er, s-er, n-wr, s-wr, n-er, s-er, n-wr, s-wr, cr*} part of this room.

Table 1: Templates used by the description generator for FloorPlanQA. For compactness we used the following notations, *n* - north, *s* - south, *e* - east, *w* - west, *c* - center, *nr* - northern, *sr* - southern, *er* - eastern, *wr* - western, *cr* - central, *cu* - cube, *cd* - cuboid, *sp* - sphere and *co* - cone.

FloorPlanQA: Each sample in FloorPlanQA involves the layout of a house that has multiple rooms (max 3). The rooms are either small, medium or large. All the rooms and the house have a door. Additionally, each room and empty-space in the house (i.e. the space in the house that is not part of any room) might also contain an object (either a cube, cuboid, sphere, or cone).

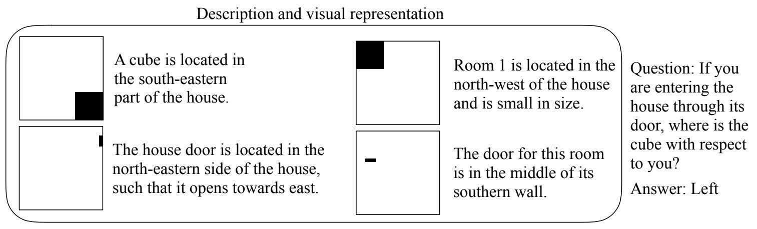
Each sample has four components, *a description, a question, an answer*, and *a visual representation*. Each sentence in the description describes either a room, a door or an object. A question is of the following template: *Suppose you are entering the* {*house, room 1, room 2, room 3*}, *where is the* {*house door, room 1 door, room 2 door, room 3 door, cube, cuboid, sphere, cone*} *with respect to you?*. The answer is either of *left, right, front,* or *back*. Other characteristics of FloorPlanQA are summarized in Fig. 2.

The visual representation of a sample consists of an ordered set of image channels, one per sentence in the description. An image channel pictorially represents the location and/or orientation of the described item (room, door, object) w.r.t. the house. An example is shown in Fig. 2.

To generate samples for FloorPlanQA, we define a probabilistic generative process which produces tree structures representing layouts of houses, similar to scene graphs used in computer graphics. The root node of a tree represents an entire house, and the leaf nodes represent rooms. We use a description and visual generator to produce respectively the description and visual representation from the tree structure. The templates used by the description generator are described in Table 1. Furthermore, the order of sentences in a description is randomized while making sure that the description still makes sense. For example, in some sample, the description of room 1 can appear before that of the house-door, while in another sample, it could be reversed. Similarly, for a room, the sentence describing the room's door could appear before or after the sentence describing the object in the room (if the room contains one). We perform rejection sampling to ensure that all the answers are equally likely, and thus removing bias.

ShapeIntersection: As the name suggests, ShapeIntersection is concerned with counting the number of intersection points between shapes. In this dataset, the description consists of symbols representing various shapes, and the question is always "how many points of intersection are there among these shapes?"

There are three types of shapes in ShapeIntersection: rectangles, circles, and lines. The description of shapes is provided in the form of a sequence of 1D vectors, each vector representing one shape. A vector in ShapeIntersection is analogous to a sentence in FloorPlanQA. Hence,



Description and visual representation
A cube is located in the south-eastern part of the house.
The house door is located in the north-eastern side of the house, such that it opens towards east.
Room 1 is located in the north-west of the house and is small in size.
The door for this room is in the middle of its southern wall.
Question: If you are entering the house through its door, where is the cube with respect to you?
Answer: Left

vocabulary size	66
# unique sentences	264
# unique descriptions	38093
# unique questions	32
# unique question-description pairs	38228
Avg. # words per sentence	15
Avg. # sentences per description	6.61

Figure 2: An example and characteristics of FloorPlanQA (when considering all the 38,400 samples i.e. training, validation and test sets combined).

for ShapeIntersection, the term 'sentence' actually refers to a vector. Each sentence describing a shape consists of 5 real numbers. The first number stands for the type of shape: 1 - line, 2 - circle, and 3 - rectangle. The subsequent four numbers specify the size and location of the shape. For example, in case of a rectangle, they represent its height, its width, and coordinates of its bottom-left corner. Note that one can also describe the shapes using a sentence, e.g. "there is a rectangle at (5, 5), with a height of 2 cm and width of 8 cm." However, as our focus is to evaluate 'visual thinking', we work directly with the symbolic encoding.

In a given description, there are 6.5 shapes on average, and at most 6 lines, 3 rectangles and 3 circles. All the shapes in the dataset are unique and lie on a 10×10 canvas. While generating the dataset, we do rejection sampling to ensure that the number of intersections is uniformly distributed from 0 to the maximum possible number of intersections, regardless of the number of lines, rectangles, and circles. This ensures that the number of intersections cannot be estimated from the number of lines, circles or rectangles.

Similar to FloorPlanQA, the visual representation for a sample in this dataset is an ordered set of image channels. Each channel is associated with a sentence, and it plots the described shape. An example is shown in Figure 1.

4 Dynamic Spatial Memory Network

We propose Dynamic Spatial Memory Network (DSMN), a novel DNN designed for QA with geometric reasoning. What differentiates DSMN from other QA DNNs is that it forms an internal visual representation of the input. It then uses a spatial memory to reason over this visual representation.

A DSMN can be divided into five modules: *the input module, visual representation module, question module, spatial memory module*, and *answer module*. The input module generates an embedding for each sentence in the description. The visual representation module uses these embeddings to produce an intermediate visual representation for each sentence. In parallel, the question module produces an embedding for the question. The spatial memory module then goes over the question embedding, the sentence embeddings, and the visual representation multiple times to update the spatial memory. Finally, the answer module uses the spatial memory to output the answer. Fig. 3 illustrates the overall architecture of DSMN.

Input Module: This module produces an embedding for each sentence in the description. It is therefore customized based on how the descriptions are provided in a dataset. Since the descriptions are in words for FloorPlanQA, a position encoding (PE) layer is used to produce the initial sentence embeddings. This is done to ensure a fair comparison with DMN+ (Xiong et al., 2016) and MemN2N (Sukhbaatar et al., 2015), which also use a PE layer. A PE layer combines the word-embeddings to encode the position of words in a sentence (Please see (Sukhbaatar et al., 2015) for more information). For ShapeIntersection, the description is given as a sequence of vectors. Therefore, two FC layers (with ReLU in between) are used to obtain the initial sentence embeddings.

These initial sentence embeddings are then fed into a bidirectional Gated Recurrent Unit (GRU) (Cho et al., 2014) to propagate the information across sentences. Let $\overrightarrow{s_i}$ and $\overleftarrow{s_i}$ be the respective output of the forward and backward GRU at i^{th} step. Then, the final sentence embedding for the i^{th} sentence is given by $s_i = \overrightarrow{s_i} + \overleftarrow{s_i}$.

Question Module: This module produces an embedding for the question. It is also customized to the dataset. For FloorPlanQA, the embeddings of the words in the question are fed to a GRU, and the final hidden state of the GRU is used as the question embedding. For ShapeIntersection, the question is always fixed, so we use an all-zero vector as the question embedding.

Visual Representation Module: This module generates a visual representation for each sentence in the description. It consists of two subcomponents: an attention network and an encoder-decoder network. The attention network gathers information from previous sentences that is important to produce the visual representation for the current sentence. For example, suppose the current sentence describes the location of an object with respect to a room. Then in order to infer the location of the object with respect to the house, one needs the location of the room with respect to the house, which is described in some previous sentence.

The encoder-decoder network encodes the visual information gathered by the attention network, combines it with the current sentence embedding, and decodes the visual representation of the current sentence. An encoder ($En(.)$) takes an image as input and produces an embedding, while a decoder ($De(.)$) takes an embedding as input and produces an image. An encoder is composed of series of convolution layers and a decoder is composed of series of deconvolution layers.

Suppose we are currently processing the sentence $\boldsymbol{s_t}$. This means we have already processed the sentences $\boldsymbol{s_1}, \boldsymbol{s_2}, \ldots, \boldsymbol{s_{t-1}}$ and produced the corresponding visual representations $\boldsymbol{S_1}, \boldsymbol{S_2}, \ldots, \boldsymbol{S_{t-1}}$. We also add $\boldsymbol{s_0}$ and $\boldsymbol{S_0}$, which are all-zero vectors to represent the null sentence. The attention network produces a scalar attention weight a_i for the i^{th} sentence which is given by $a_i = \text{Softmax}(\boldsymbol{w_s}^t \boldsymbol{z_i} + b_s)$ where $\boldsymbol{z_i} = [|\boldsymbol{s_i} - \boldsymbol{s_t}|; \boldsymbol{s_i} \circ \boldsymbol{s_t}]$. Here, $\boldsymbol{w_s}$ is a vector, b_s is a scalar, $\circ$ represents element-wise multiplication, $|.|$ represents element-wise absolute value, and $[\boldsymbol{v1}; \boldsymbol{v2}]$ represents the concatenation of vectors $\boldsymbol{v1}$ and $\boldsymbol{v2}$.

The gathered visual information is $\bar{\boldsymbol{S_t}} = \sum_{i=0}^{t-1} a_i \boldsymbol{S_i}$. It is fed into the encoder-decoder network. The visual representation for $\boldsymbol{s_t}$ is given by $\boldsymbol{S_t} = De_s\Big([\boldsymbol{s_t}; En_s(\bar{\boldsymbol{S_t}})]\Big)$. The parameters of $En_s(.)$, $De_s()$, $\boldsymbol{w_s}$, and b_s are shared across multiple iterations.

In the proposed model, we make the simplifying assumption that the visual representation of the current sentence does not depend on future sentences. In other words, it can be completely determined from the previous sentences in the description. Both FloorPlanQA and ShapeIntersection satisfy this assumption.

Spatial Memory Module: This module gathers relevant information from the description and updates memory accordingly. Similar to DMN+ and MemN2N, it collects information and updates memory multiple times to perform transitive reasoning. One iteration of information collection and memory update is referred as a 'hop'.

The memory consists of two components: a 2D spatial memory and a tag vector. The 2D spatial memory can be thought of as a visual scratch pad on which the network 'sketches' out the visual information. The tag vector is meant to represent what is 'sketched' on the 2D spatial memory. For example, the network can sketch the location of room 1 on its 2D spatial memory, and store the fact that it has sketched room 1 in the tag vector.

As mentioned earlier, each step of the spatial memory module involves gathering of relevant information and updating of memory. Suppose we are in step t. Let $\boldsymbol{M^{(t-1)}}$ represent the 2D spatial memory and $\boldsymbol{m^{(t-1)}}$ represent the tag vector after step $t-1$. The network gathers the relevant information by calculating the attention value for each sentence based on the question and the current memory. For sentence $\boldsymbol{s_i}$, the scalar attention value $g_i^{(t)}$ equal to $\text{Softmax}(\boldsymbol{w_y^t p_i^{(t)}} + b_y)$, where $\boldsymbol{p_i^{(t)}}$ is given as

$$\begin{aligned} \boldsymbol{p_i^{(t)}} = \big[&|\boldsymbol{m^{(t-1)}} - \boldsymbol{s_i}|;\ \boldsymbol{m^{(t-1)}} \circ \boldsymbol{s_i};\ |\boldsymbol{q} - \boldsymbol{s_i}|; \\ &\boldsymbol{q} \circ \boldsymbol{s_i};\ En_{p_1}^{(t)}(|\boldsymbol{M^{(t-1)}} - \boldsymbol{S_i}|); \\ &En_{p_2}^{(t)}(\boldsymbol{M^{(t-1)}} \circ \boldsymbol{S_i})\big] \end{aligned} \quad (1)$$

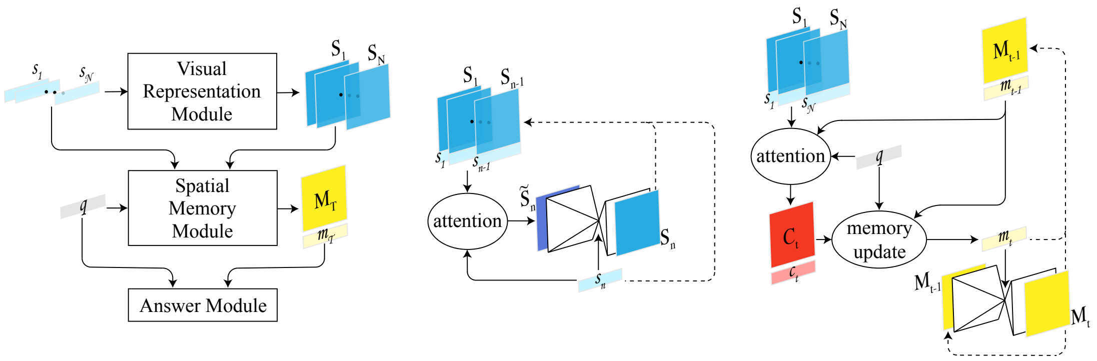
$\boldsymbol{M^{(0)}}$ and $\boldsymbol{m^{(0)}}$ represent initial blank memory, and their elements are all zero. Then, gathered information is represented as a context tag vector, $\boldsymbol{c^{(t)}} = \text{AttGRU}(g_i{}^{(t)}\boldsymbol{s_i})$ and 2D context, $\boldsymbol{C^{(t)}} = \sum_{i=0}^{n} g_i{}^{(t)} \boldsymbol{S_i}$. Please refer to (Xiong et al., 2016) for information about AttGRU(.). Finally, we use the 2D context and context tag vector to update the memory as follows:

$$\begin{aligned} \boldsymbol{m^{(t)}} = \text{ReLU}\Big(&\boldsymbol{W}_m{}^{(t)}\big[\boldsymbol{m^{(t-1)}};\ \boldsymbol{q};\ \boldsymbol{c^{(t)}}; \\ &En_c(\boldsymbol{C^{(t)}})\big] + \boldsymbol{b_m}{}^{(t)}\Big) \end{aligned} \quad (2)$$

$$\boldsymbol{M^{(t)}} = De_m^{(t)}\Big(\big[\boldsymbol{m^{(t)}};\ En_m^{(t)}(\boldsymbol{M^{(t-1)}})\big]\Big) \quad (3)$$

Answer Module: This module uses the final memory and question embedding to generate the output. The feature vector used for predicting the answer is given by $\boldsymbol{f}$, where $\boldsymbol{M^{(T)}}$ and $\boldsymbol{m^{(T)}}$ represent the final memory.

$$\boldsymbol{f} = [En_f(\boldsymbol{M^{(T)}});\ \boldsymbol{m^{(T)}};\ \boldsymbol{q}] \quad (4)$$



(a) Overall architecture (b) Visual represenation module (c) Spatial memory module

Figure 3: The architecture of the proposed Dynamic Spatial Memory Network (DSMN).

To obtain the output, an FC layer is applied to $\boldsymbol{f}$ in case of regression, while the FC layer is followed by softmax in case of classification. To keep DSMN similar to DMN+, we apply a dropout layer on sentence encodings ($\boldsymbol{s_i}$) and $\boldsymbol{f}$.

4.1 DSMN as a strict generalization of DMN

DSMN is a strict generalization of a DMN+. If we remove the visual representation of the input along with the 2D spatial memory, and just use vector representations with memory tags, then a DSMN reduces to DMN+. This ensures that comparison with DMN+ is fair.

4.2 DSMN with or without intermediate visual supervision

As described in previous sections, a DSMN forms an intermediate visual representation of the input. Therefore, if we have a 'ground-truth' visual representation for the training data, we could use it to train our network better. This leads to two different ways for training a DSMN, one with intermediate visual supervision and one without it. Without intermediate visual supervision, we train the network in an end-to-end fashion by using a loss (L_{w/o_vi}) that compares the predicted answer with the ground truth. With intermediate visual supervision, we train our network using an additional visual representation loss (L_{vi}) that measures how close the generated visual representation is to the ground-truth representation. Thus, the loss used for training with intermediate supervision is given by $L_{w\_vi} = \lambda_{vi} L_{vi} + (1 - \lambda_{vi}) L_{w/o\_vi}$, where λ_{vi} is a hyperparameter which can be tuned for each dataset. Note that in neither case do we need any visual input once the network is trained. During testing, the only input to the network is the description and question.

Also note that we can provide intermediate visual supervision to DSMN even when the visual representations for only a portion of samples in the training data are available. This can be useful when obtaining visual representation is expensive and time-consuming.

5 Experiments

Baselines: LSTM (Hochreiter and Schmidhuber, 1997) is a popular neural network for sequence processing tasks. We use two versions of LSTM-based baselines. LSTM-1 is a common version that is used as a baseline for textual QA (Sukhbaatar et al., 2015; Graves et al., 2016). In LSTM-1, we concatenate all the sentences and the question to a single string. For FloorPlanQA, we do word embedding look-up, while for ShapeIntersection, we project each real number into higher dimension via a series of FC layers. The sequence of vectors is fed into an LSTM. The final output vector of the LSTM is then used for prediction.

We develop another version of LSTM that we call LSTM-2, in which the question is concatenated to the description. We use a two-level hierarchy to embed the description. We first extract an embedding for each sentence. For FloorPlanQA, we use an LSTM to get the sentence embeddings, and for ShapeIntersection, we use a series of FC layers. We then feed the sentence embeddings into an LSTM, whose output is used for prediction.

Further, we compare our model to DMN+ (Xiong et al., 2016) and MemN2N (Sukhbaatar et al., 2015), which achieved state-of-the-art results on bAbI (Weston et al., 2015). In particular, we compare the 3-hop versions of DSMN, DMN+, and MemN2N.

Training Details: We used ADAM (Kingma and Ba, 2014) to train all models, and the learning rate

MODEL	FloorPlanQA (accuracy in %)	ShapeIntersection (rmse)
LSTM-1	41.36	3.28
LSTM-2	50.69	2.99
MemN2N	45.92	3.51
DMN+	60.29	2.98
DSMN	68.01	2.84
DSMN*	**97.73**	**2.14**

(a) The test set performance of different models on FloorPlanQA and ShapeIntersection. DSMN* refers to the model with intermediate supervision.

MODEL	$\boldsymbol{f}$ in Eqn. 4	FloorPlanQA (accuracy in %)
DSMN	$[\boldsymbol{m}^{(\boldsymbol{T})}; \boldsymbol{q}]$	67.65
DSMN	$[En_f(\boldsymbol{M}^{(\boldsymbol{T})}); \boldsymbol{q}]$	43.90
DSMN	$[En_f(\boldsymbol{M}^{(\boldsymbol{T})}); \boldsymbol{m}^{(\boldsymbol{T})}; \boldsymbol{q}]$	68.12
DSMN*	$[\boldsymbol{m}^{(\boldsymbol{T})}; \boldsymbol{q}]$	97.24
DSMN*	$[En_f(\boldsymbol{M}^{(\boldsymbol{T})}); \boldsymbol{q}]$	95.17
DSMN*	$[En_f(\boldsymbol{M}^{(\boldsymbol{T})}); \boldsymbol{m}^{(\boldsymbol{T})}; \boldsymbol{q}]$	98.08

(b) The validation set performances for the ablation study on the usefulness of tag ($\boldsymbol{m}^{(\boldsymbol{T})}$) and 2D spatial memory ($\boldsymbol{M}^{(\boldsymbol{T})}$) in the answer feature vector for $\boldsymbol{f}$.

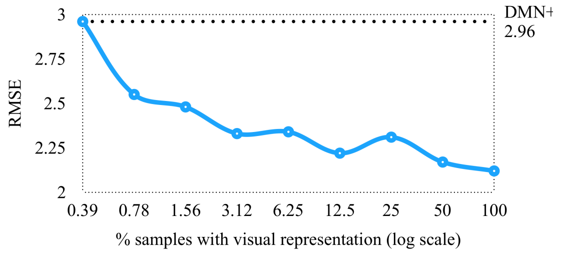
MODEL	FloorPlanQA (accuracy in %)
1-Hop DSMN	63.32
2-Hop DSMN	65.59
3-Hop DSMN	68.12
1-Hop DSMN*	90.09
2-Hop DSMN*	97.45
3-Hop DSMN*	98.08

(c) The validation set performance for the ablation study on variation in performance with hops.

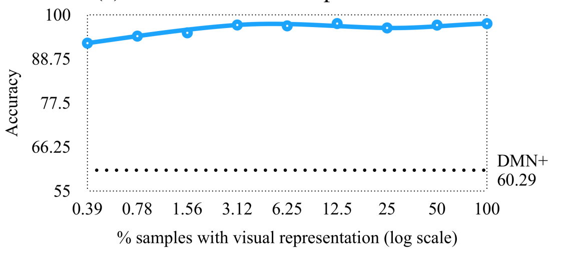
Table 2: Experimental results showing comparison with baselines, and ablation study of DSMN

for each model is tuned for each dataset. We tune the embedding size and l_2 regularization weight for each model and dataset pair separately. For reproducibility, the value of the best-tuned hyperparameters is mentioned in the supplementary material. As reported by (Sukhbaatar et al., 2015; Kumar et al., 2016; Henaff et al., 2016), we also observe that the results of memory networks are unstable across multiple runs. Therefore for each hyperparameter choice, we run all the models 10 times and select the run with the best performance on the validation set. For FloorPlanQA, all models are trained up to a maximum of 1600 epochs, with early stopping after 80 epochs if the validation accuracy did not increase. The maximum number of epochs for ShapeIntersection is 800 epochs, with early stopping after 80 epochs. Additionally, we modify the input module and question module of DMN+ and MemN2N to be same as ours for the ShapeIntersection dataset.

For MemN2N, we use the publicly available im-



(a) Test set rmse on ShapeIntersection.



(b) Test set accuracy on FloorPlanQA.

Figure 4: Performance of DSMN* with varying percentage of intermediate visual supervision.

plementation[2] and train it exactly as all other models (same optimizer, total epochs, and early stopping criteria) for fairness. While the reported best result for MemN2N is on the version with position encoding, linear start training, and random-injection of time index noise (Sukhbaatar et al., 2015), the version we use has only position encoding. Note that the comparison is still meaningful because linear start training and time index noise are not used in DMN+ (and as a result, neither in our proposed DSMN).

Results: The results for FloorPlanQA and ShapeIntersection are summarized in Table 2a. For brevity, we will refer to the DSMN model trained without intermediate visual supervision as DSMN, and the one with intermediate visual supervision as DSMN*. We see that DSMN (i.e the one without intermediate supervision) outperforms DMN+, MemN2N and the LSTM baselines on both datasets. However, we consider DSMN to be only slightly better than DMN+ because both are observed to be unstable across multiple runs and so the gap between the two has a large variance. Finally, DSMN* outperforms all other approaches by a large margin on both datasets, which demonstrates the utility of visual supervision in proposed tasks. While the variation can be significant across runs, if we run each model 10 times and choose the best run, we observe consistent results. We visualized the intermediate visual representations, but when no visual supervision is pro-

[2]`https://github.com/domluna/memn2n`

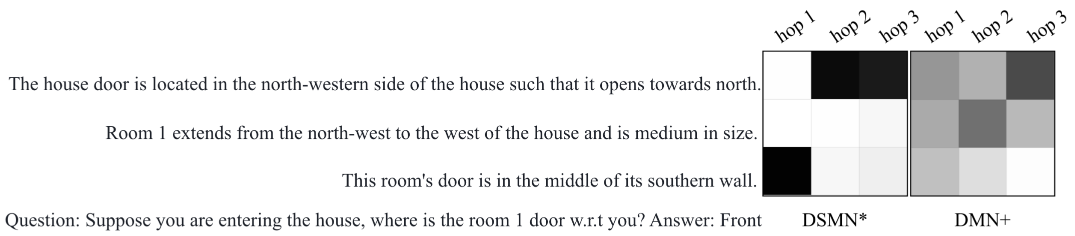


Figure 5: Attention values on each sentence during different memory 'hops' for a sample from FloorPlanQA. Darker color indicates more attention. To answer, one needs the location of room 1's door and the house door. To infer the location of room 1's door, DSMN* directly jumps to sent. 3. Since DMN+ does not form a visual representation, it tries to infer the location of room 1's door w.r.t the house by finding the location of the room's door w.r.t the room (sent. 3) and the location of the room w.r.t the house (sent. 2). Both DSMN* and DMN+ use one hop to infer the location of the house door (sent. 1).

vided, they were not interpretable (sometimes they looked like random noise, sometimes blank). In the case when visual supervision is provided, the intermediate visual representation is well-formed and similar to the ground-truth.

We further investigate how DSMN* performs when intermediate visual supervision is available for only a portion of training samples. As shown in Fig. 4, DSMN* outperforms DMN+ by a large margin, even when intermediate visual supervision is provided for only 1% of the training samples. This can be useful when obtaining visual representations is expensive and time-consuming. One possible justification for why visual supervision (even in a small amount) helps a lot is that it constrains the high-dimensional space of possible intermediate visual representations. With limited data and no explicit supervision, automatically learning these high-dimensional representations can be difficult.

Additonally, we performed ablation study (see Table 2b) on the usefulness of final memory tag vector ($\boldsymbol{m^{(T)}}$) and 2D spatial memory ($\boldsymbol{M^{(T)}}$) in the answer feature vector $\boldsymbol{f}$ (see Eqn. 4). We removed each of them one at a time, and retrained (with hyperparameter tuning) the DSMN and DSMN* models. Note that they are removed only from the final feature vector $\boldsymbol{f}$, and both of them are still coupled. The model with both tag and 2D spatial memory ($\boldsymbol{f} = \big[En_f(\boldsymbol{M^{(T)}}); \boldsymbol{m^{(T)}}; \boldsymbol{q}\big]$) performs slightly better than the only tag vector model ($\boldsymbol{f} = \big[\boldsymbol{m^{(T)}}; \boldsymbol{q}\big]$). Also, as expected the only 2D spatial memory model ($\boldsymbol{f} = \big[En_f(\boldsymbol{M^{(T)}}); \boldsymbol{q}\big]$) performs much better for DSMN* than DSMN becuase of the intermdiate supervision.

Further, Table 2c shows the effect of varying the number of memory 'hops' for DSMN and DSMN* on FloorPlanQA. The performance of both DSMN and DSMN* increases with the number of 'hops'. Note that even the 1-hop DSMN* performs well (better than baselines). Also, note that the difference in performance between 2-hop DSMN* and 3-hop DSMN* is not much. A possible justification for why DSMN* performs well even with fewer memory 'hops' is that DSMN* completes some 'hops of reasoning' in the visual representation module itself. Suppose one needs to find the location of an object placed in a room, w.r.t. the house. To do so, one first needs to find the location of the room w.r.t. the house, and then the location of the object w.r.t. the room. However, if one has already 'sketched' out the location of the object in the house, one can directly fetch it. It is during sketching the object's location that one has completed a 'hop of reasoning'. For a sample from FloorPlanQA, we visualize the attention maps in the memory module of 3-hop DMN+ and 3-hop DSMN* in Fig. 5. To infer the location of room 1's door, DSMN* directly fetches sentence 3, while DMN+ tries to do so by fetching two sentences (one for the room's door location w.r.t the room and one for the room's location w.r.t the house).

Conclusion: We have investigated how to use DNNs for modeling visual thinking. We have introduced two synthetic QA datasets, FloorPlanQA and ShapeIntersection, that test a system's ability to think visually. We have developed DSMN, a novel DNN that reasons in the visual space for answering questions. Experimental results have demonstrated the effectiveness of DSMN for geometric reasoning on synthetic data.

Abstract

Building intelligent agents that can communicate with and learn from humans in natural language is of great value. Supervised language learning is limited by the ability of capturing mainly the statistics of training data, and is hardly adaptive to new scenarios or flexible for acquiring new knowledge without inefficient retraining or catastrophic forgetting. We highlight the perspective that conversational interaction serves as a natural interface both for language learning and for novel knowledge acquisition and propose a joint imitation and reinforcement approach for grounded language learning through an interactive conversational game. The agent trained with this approach is able to actively acquire information by asking questions about novel objects and use the just-learned knowledge in subsequent conversations in a one-shot fashion. Results compared with other methods verified the effectiveness of the proposed approach.

1 Introduction

Language is one of the most natural forms of communication for human and is typically viewed as fundamental to human intelligence; therefore it is crucial for an intelligent agent to be able to use language to communicate with human as well. While supervised training with deep neural networks has led to encouraging progress in language learning, it suffers from the problem of capturing mainly the statistics of training data, and from a lack of adaptiveness to new scenarios and being flexible for acquiring new knowledge without inefficient retraining or catastrophic forgetting. Moreover, supervised training of deep neural network models needs a large number of training samples while many interesting applications require rapid learning from a small amount of data, which poses an even greater challenge to the supervised setting.

In contrast, humans learn in a way very different from the supervised setting (Skinner, 1957; Kuhl, 2004). First, humans act upon the world and learn from the consequences of their actions (Skinner, 1957; Kuhl, 2004; Petursdottir and Mellor, 2016). While for mechanical actions such as movement, the consequences mainly follow geometrical and mechanical principles, for language, humans act by speaking, and the consequence is typically a response in the form of verbal and other behavioral feedback (*e.g.*, nodding) from the conversation partner (*i.e.*, teacher). These types of feedback typically contain informative signals on how to improve language skills in subsequent conversations and play an important role in humans' language acquisition process (Kuhl, 2004; Petursdottir and Mellor, 2016). Second, humans have shown a celebrated ability to learn new concepts from small amount of data (Borovsky et al., 2003). From even just one example, children seem to be able to make inferences and draw plausible boundaries between concepts, demonstrating the ability of one-shot learning (Lake et al., 2011).

The language acquisition process and the one-shot learning ability of human beings are both impressive as a manifestation of human intelligence, and are inspiring for designing novel settings and algorithms for computational language learning. In this paper, we leverage conversation as both an interactive environment for language learning (Skinner, 1957) and a natural interface for acquiring new knowledge (Baker et al., 2002). We propose an approach for interactive language acquisition with one-shot concept learning ability. The proposed approach allows an agent to learn grounded language from scratch, acquire the transferable skill of actively seeking and memorizing information about novel objects, and develop the one-shot learning ability, purely through conversational interaction with a teacher.

2 Related Work

Supervised Language Learning. Deep neural network-based language learning has seen great success on many applications, including machine translation (Cho et al., 2014b), dialogue generation (Wen et al., 2015; Serban et al., 2016), image captioning and visual question answering (**?**Antol et al., 2015). For training, a large amount of labeled data is needed, requiring significant efforts to collect. Moreover, this setting essentially captures the statistics of training data and does not respect the interactive nature of language learning, rendering it less flexible for acquiring new knowledge without retraining or forgetting (Stent and Bangalore, 2014).

Reinforcement Learning for Sequences. Some recent studies used reinforcement learning (RL) to tune the performance of a pre-trained language model according to certain metrics (Ranzato et al., 2016; Bahdanau et al., 2017; Li et al., 2016; Yu et al., 2017). Our work is also related to RL in natural language action space (He et al., 2016) and shares a similar motivation with Weston (2016) and Li et al. (2017), which explored language learning through pure textual dialogues. However, in these works (He et al., 2016; Weston, 2016; Li et al., 2017), a set of candidate sequences is provided and the action is to select one from the set. Our main focus is rather on learning language from scratch: the agent has to learn to *generate* a sequence action rather than to simply *select* one from a provided candidate set.

Communication and Emergence of Language. Recent studies have examined learning to communicate (Foerster et al., 2016; Sukhbaatar et al., 2016) and invent language (Lazaridou et al., 2017; Mordatch and Abbeel, 2018). The emerged language needs to be interpreted by humans via post-processing (Mordatch and Abbeel, 2018). We, however, aim to achieve language learning from the dual perspectives of understanding and generation, and the speaking action of the agent is readily understandable without any post-processing. Some studies on language learning have used a guesser-responder setting in which the guesser tries to achieve the final goal (*e.g.*, classification) by collecting additional information through asking the responder questions (Strub et al., 2017; Das et al., 2017). These works try to optimize the question being asked to help the guesser achieve the final goal, while we focus on transferable speaking and one-shot ability.

One-shot Learning and Active Learning. One-shot learning has been investigated in some recent works (Lake et al., 2011; Santoro et al., 2016; Woodward and Finn, 2016). The memory-augmented network (Santoro et al., 2016) stores visual representations mixed with ground truth class labels in an external memory for one-shot learning. A class label is always provided following the presentation of an image; thus the agent receives information from the teacher in a passive way. Woodward and Finn (2016) present efforts toward active learning, using a vanilla recurrent neural network (RNN) without an external memory. Both lines of study focus on image classification only, meaning the class label is directly provided for memorization. In contrast, we target language and one-shot learning via conversational interaction, and the learner has to learn to extract important information from the teacher's sentences for memorization.

3 The Conversational Game

We construct a conversational game inspired by experiments on language development in infants from cognitive science (Waxman, 2004). The game is implemented with the XWORLD simulator (Yu et al., 2018; Zhang et al., 2017) and is publicly available online.[1] It provides an environment for the agent[2] to learn language and develop the one-shot learning ability. One-shot learning here means that during test sessions, no further training happens to the agent and it has to answer teacher's questions correctly about novel images of never-before-seen classes after being taught only once by the teacher, as illustrated in Figure 1. To succeed in this game, the agent has to learn to 1) speak by generating sentences, 2) extract and memorize useful information with only one exposure and use it in subsequent conversations, and 3) behave adaptively according to context and its own knowledge (*e.g.*, asking questions about unknown objects and answering questions about something known), all achieved through interacting with the

[1] `https://github.com/PaddlePaddle/XWorld`

[2] We use the term *agent* interchangeably with *learner*.

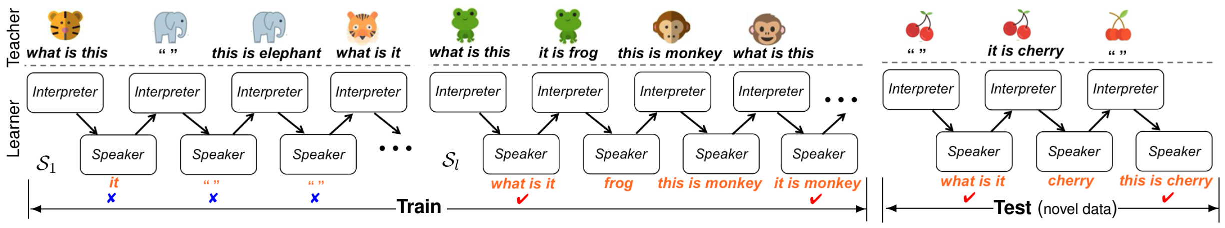

Figure 1: **Interactive language and one-shot concept learning.** Within a session $\mathcal{S}_l$, the teacher may ask questions, answer learner's questions, make statements, or say nothing. The teacher also provides reward feedback based on learner's responses as (dis-)encouragement. The learner alternates between interpreting teacher's sentences and generating a response through *interpreter* and *speaker*. **Left:** Initially, the learner can barely say anything meaningful. **Middle:** Later it can produce meaningful responses for interaction. **Right:** After training, when confronted with an image of *cherry*, which is a novel class that the learner never saw before during training, the learner can ask a question about it ("*what is it*") and generate a correct statement ("*this is cherry*") for another instance of cherry after only being taught once.

teacher. This makes our game distinct from other seemingly relevant games, in which the agent cannot speak (Wang et al., 2016) or "speaks" by *selecting* a candidate from a provided set (He et al., 2016; Weston, 2016; Li et al., 2017) rather than *generating* sentences by itself, or games mainly focus on slow learning (Das et al., 2017; Strub et al., 2017) and falls short on one-shot learning.

In this game, sessions ($\mathcal{S}_l$) are randomly instantiated during interaction. Testing sessions are constructed with a separate dataset with concepts that never appear before during training to evaluate the language and one-shot learning ability. Within a session, the teacher randomly selects an object and interacts with the learner about the object by randomly 1) posing a question (*e.g.*, "*what is this*"), 2) saying nothing (*i.e.*, "") or 3) making a statement (*e.g.*, "*this is monkey*"). When the teacher asks a question or says nothing, i) if the learner raises a question, the teacher will provide a statement about the object asked (*e.g.*, "*it is frog*") with a *question-asking reward* (+0.1); ii) if the learner says nothing, the teacher will still provide an answer (*e.g.*, "*this is elephant*") but with an *incorrect-reply reward* (−1) to discourage the learner from remaining silent; iii) for all other incorrect responses from the learner, the teacher will provide an *incorrect-reply reward* and move on to the next random object for interaction. When the teacher generates a statement, the learner will receive no reward if a correct statement is generated otherwise an *incorrect-reply reward* will be given. The session ends if the learner answers the teacher's question correctly, generates a correct statement when the teacher says nothing (receiving a *correct-answer reward* +1), or when the maximum number of steps is reached. The sentence from teacher at each time step is generated using a context-free grammar as shown in Table 1.

A success is reached if the learner behaves correctly during the whole session: asking questions about novel objects, generating answers when asked, and making statements when the teacher says nothing about objects that have been taught within the session. Otherwise it is a failure.

4 Interactive Language Acquisition via Joint Imitation and Reinforcement

Motivation. The goal is to *learn to converse and develop the one-shot learning ability by conversing with a teacher and improving from teacher's feedback*. We propose to use a *joint imitation and reinforce* approach to achieve this goal. *Imitation* helps the agent to develop the basic ability to generate sensible sentences. As learning is done by observing the teacher's behaviors during conversion, the agent essentially imitates the teacher from a *third-person perspective* (Stadie et al., 2017) rather than imitating an expert agent who is conversing with the teacher (Das et al., 2017; Strub et al., 2017). During conversations, the agent perceives sentences and images without any explicit labeling of ground truth answers, and it has to learn to make sense of raw perceptions, extract useful information, and save it for later use when generating an answer to teacher's question. While it is tempting to purely imitate the teacher, the agent trained this way only develops *echoic behavior* (Skinner, 1957), *i.e.*, mimicry. *Reinforce* leverages confirmative feedback from the teacher for learning to converse adaptively beyond mimicry by adjusting the action policy. It enables the learner to use the acquired speaking ability and adapt it according to reward feedback. This is analogous to some views on the babies' language-learning process that babies use the acquired speaking skills by trial and error with parents and improve according to the consequences of speaking actions (Skinner, 1957; Petursdottir and Mellor, 2016). The fact that babies don't fully develop the speaking capabilities without the ability to hear (Houston and Miyamoto, 2011), and that it is hard to make a meaningful conversation with a trained parrot signifies the importance of both imitation and reinforcement in language learning.

Formulation. The agent's response can be modeled as a sample from a probability distribution over the possible sequences. Specifically, for one session, given the visual input $\mathbf{v}^t$ and conversation history $\mathcal{H}^t = \{\mathbf{w}^1, \mathbf{a}^1, \cdots, \mathbf{w}^t\}$, the agent's response $\mathbf{a}^t$ can be generated by sampling from a distribution of the speaking action $\mathbf{a}^t \sim p_\theta^{\mathrm{S}}(\mathbf{a}|\mathcal{H}^t, \mathbf{v}^t)$. The agent interacts with the teacher by outputting the utterance $\mathbf{a}^t$ and receives feedback from the teacher in the next step, with $\mathbf{w}^{t+1}$ a sentence as verbal feedback and r^{t+1} reward feedback (with positive values as encouragement while negative values as discouragement, according to $\mathbf{a}^t$, as described in Section 3). Central to the goal is learning $p_\theta^{\mathrm{S}}(\cdot)$. We formulate the problem as the minimization of a cost function as:

$$\mathcal{L}_\theta = \underbrace{\mathbb{E}_{\mathcal{W}}\left[-\textstyle\sum_t \log p_\theta^{\mathrm{I}}(\mathbf{w}^t|\cdot)\right]}_{\text{Imitation } \mathcal{L}_\theta^{\mathrm{I}}} + \underbrace{\mathbb{E}_{p_\theta^{\mathrm{S}}}\left[-\textstyle\sum_t [\gamma]^{t-1} \cdot r^t\right]}_{\text{Reinforce } \mathcal{L}_\theta^{\mathrm{R}}}$$

where $\mathbb{E}_{\mathcal{W}}(\cdot)$ is the expectation over all the sentences $\mathcal{W}$ from teacher, γ is a reward discount factor, and $[\gamma]^t$ denotes the exponentiation over γ. While the imitation term learns directly the predictive distribution $p_\theta^{\mathrm{I}}(\mathbf{w}^t|\mathcal{H}^{t-1}, \mathbf{a}^t)$, it contributes to $p_\theta^{\mathrm{S}}(\cdot)$ through *parameter sharing* between them.

Architecture. The learner comprises four major components: *external memory*, *interpreter*, *speaker*, and *controller*, as shown in Figure 2. *External memory* is flexible for storing and retrieving information (Graves et al., 2014; Santoro et al., 2016), making it a natural component of our network for one-shot learning. The *interpreter* is responsible for interpreting the teacher's sentences, extracting information from the perceived signals, and saving it to the external memory. The *speaker* is in charge of generating sentence responses with reading access to the external memory. The response could be a question asking for information or a statement answering a teacher's question, leveraging the information stored in the external memory. The *controller* modulates the behavior of the speaker to generate responses according to context (*e.g.*, the learner's knowledge status).

At time step t, the *interpreter* uses an interpreter-RNN to encode the input sentence $\mathbf{w}^t$ from the teacher as well as historical conversational information into a state vector $\mathbf{h}_{\mathrm{I}}^t$. $\mathbf{h}_{\mathrm{I}}^t$ is then passed through a residue-structured network, which is an identity mapping augmented with a learnable controller $f(\cdot)$ implemented with fully connected layers for producing $\mathbf{c}^t$. Finally, $\mathbf{c}^t$ is used as the initial state of the speaker-RNN for generating the response $\mathbf{a}^t$. The final state $\mathbf{h}_{\mathrm{last}}^t$ of the speaker-RNN will be used as the initial state of the interpreter-RNN at the next time step.

4.1 Imitation with Memory Augmented Neural Network for Echoic Behavior

The teacher's way of speaking provides a source for the agent to imitate. For example, the syntax for composing a sentence is a useful skill the agent can learn from the teacher's sentences, which could benefit both *interpreter* and *speaker*. Imitation is achieved by predicting teacher's future sentences with *interpreter* and parameter sharing between *interpreter* and *speaker*. For prediction, we can represent the probability of the next sentence $\mathbf{w}^t$ conditioned on the image $\mathbf{v}^t$ as well as previous sentences from both the teacher and the

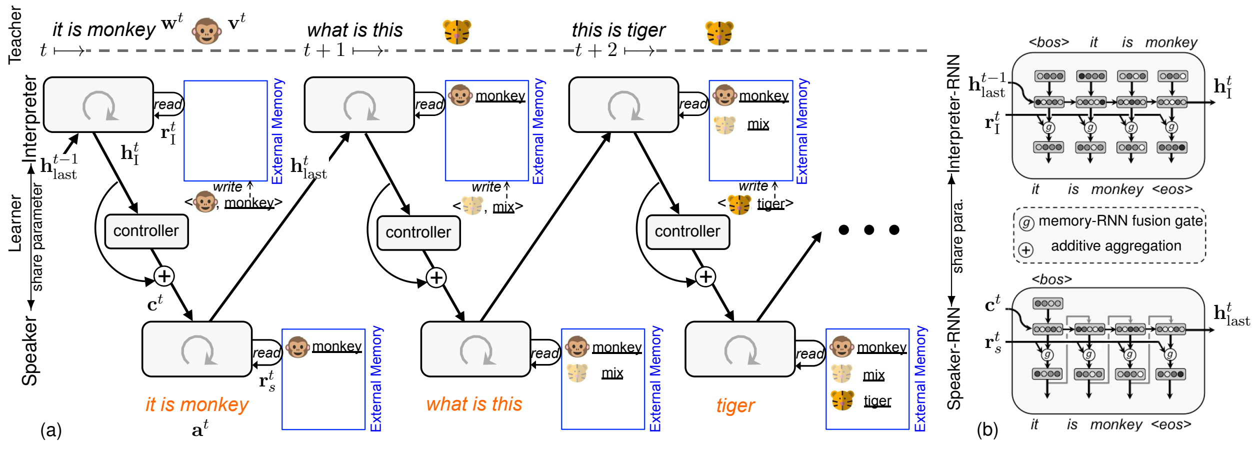

Figure 2: **Network structure.** (a) Illustration of the overall architecture. At each time step, the learner uses the interpreter module to encode the teacher's sentence. The visual perception is also encoded and used as a key to retrieve information from the external memory. The last state of the interpreter-RNN will be passed through a controller. The controller's output will be added to the input and used as the initial state of the speaker-RNN. The interpreter-RNN will update the external memory with an importance (illustrated with transparency) weighted information extracted from the perception input. 'Mix' denotes a mixture of word embedding vectors. (b) The structures of the interpreter-RNN (top) and the speaker-RNN (bottom). The interpreter-RNN and speaker-RNN share parameters.

learner $\{\mathbf{w}^1, \mathbf{a}^1, \cdots, \mathbf{w}^{t-1}, \mathbf{a}^{t-1}\}$ as

$$\begin{aligned} & p^{\mathrm{I}}_{\theta}(\mathbf{w}^t|\mathcal{H}^{t-1}, \mathbf{a}^{t-1}, \mathbf{v}^t) \\ & = \textstyle\prod_i p^{\mathrm{I}}_{\theta}(w^t_i|w^t_{1:i-1}, \mathbf{h}^{t-1}_{\text{last}}, \mathbf{v}^t), \end{aligned} \tag{1}$$

where $\mathbf{h}^{t-1}_{\text{last}}$ is the last state of the RNN at time step t–1 as the summarization of $\{\mathcal{H}^{t-1}, \mathbf{a}^{t-1}\}$ (*c.f.*, Figure 2), and i indexes words within a sentence.

It is natural to model the probability of the i-th word in the t-th sentence with an RNN, where the sentences up to t and words up to i within the t-th sentence are captured by a fixed-length state vector $\mathbf{h}^t_i = \text{RNN}(\mathbf{h}^t_{i-1}, w^t_i)$. To incorporate knowledge learned and stored in the external memory, the generation of the next word is *adaptively* based on i) the predictive distribution of the next word from the state of the RNN to capture the *syntactic structure of sentences*, and ii) the information from the external memory to represent the previously learned knowledge, via a fusion gate g:

$$p^{\mathrm{I}}_{\theta}(w^t_i|\mathbf{h}^t_i, \mathbf{v}^t) = (1-g)\cdot p_{\mathbf{h}} + g\cdot p_{\mathbf{r}}, \tag{2}$$

where $p_{\mathbf{h}} = \text{softmax}\big(\mathbf{E}^{\mathsf{T}} f_{\text{MLP}}(\mathbf{h}^t_i)\big)$ and $p_{\mathbf{r}} = \text{softmax}\big(\mathbf{E}^{\mathsf{T}}\mathbf{r}\big)$. $\mathbf{E}\in\mathbb{R}^{d\times k}$ is the word embedding table, with d the embedding dimension and k the vocabulary size. $\mathbf{r}$ is a vector read out from the external memory using a visual key as detailed in the next section. $f_{\text{MLP}}(\cdot)$ is a multi-layer Multi-Layer Perceptron (MLP) for bridging the semantic gap between the RNN state space and the word embedding space. The fusion gate g is computed as $g = f(\mathbf{h}^t_i, c)$, where c is the confidence score $c = \max(\mathbf{E}^{\mathsf{T}}\mathbf{r})$, and a well-learned concept should have a large score by design (Appendix A.2).

Multimodal Associative Memory. We use a multimodal memory for storing visual (v) and sentence (s) features with each modality while preserving the correspondence between them (Baddeley, 1992). Information organization is more structured than the single modality memory as used in Santoro et al. (2016) and cross modality retrieval is straightforward under this design. A visual encoder implemented as a convolutional neural network followed by fully connected layers is used to encode the visual image $\mathbf{v}$ into a visual key $\mathbf{k}_v$, and then the corresponding sentence feature can be retrieved from the memory as:

$$\mathbf{r} \leftarrow \textsc{Read}(\mathbf{k}_v, \mathbf{M}_v, \mathbf{M}_s). \tag{3}$$

$\mathbf{M}_v$ and $\mathbf{M}_s$ are memories for visual and sentence modalities with the same number of slots (columns). Memory read is implemented as $\mathbf{r} = \mathbf{M}_s\boldsymbol{\alpha}$ with $\boldsymbol{\alpha}$ a soft reading weight obtained through the visual modality by calculating the cosine similarities between $\mathbf{k}_v$ and slots of $\mathbf{M}_v$.

Memory write is similar to Neural Turing Machine (Graves et al., 2014), but with a content importance gate g_{mem} to adaptively control whether the content $\mathbf{c}$ should be written into memory:

$$\mathbf{M}_m \leftarrow \textsc{Write}(\mathbf{M}_m, \mathbf{c}_m, g_{\text{mem}}),\ m\in\{v, s\}.$$

For the visual modality $\mathbf{c}_v \triangleq \mathbf{k}_v$. For the sentence modality, $\mathbf{c}_s$ has to be selectively extracted from the sentence generated by the teacher. We use an attention mechanism to achieve this by $\mathbf{c}_s = \mathbf{W}\boldsymbol{\eta}$, where $\mathbf{W}$ denotes the matrix with columns being the embedding vectors of all the words in the sentence. $\boldsymbol{\eta}$ is a normalized attention vector representing the relative importance of each word in the sentence as measured by the cosine similarity between the sentence representation vector and each word's context vector, computed using a bidirectional-RNN. The scalar-valued content importance gate g_{mem} is computed as a function of the sentence from the teacher, meaning that the importance of the content to be written into memory depends on the content itself (*c.f.*, Appendix A.3 for more details). The memory write is achieved with an erase and an add operation:

$$\tilde{\mathbf{M}}_m = \mathbf{M}_m - \mathbf{M}_m \odot (g_{\text{mem}} \cdot \mathbf{1} \cdot \boldsymbol{\beta}^{\mathsf{T}}),$$
$$\mathbf{M}_m = \tilde{\mathbf{M}}_m + g_{\text{mem}} \cdot \mathbf{c}_m \cdot \boldsymbol{\beta}^{\mathsf{T}}, \ m \in \{v, s\}.$$

$\odot$ denotes Hadamard product and the write location $\boldsymbol{\beta}$ is determined with a Least Recently Used Access mechanism (Santoro et al., 2016).

4.2 Context-adaptive Behavior Shaping through Reinforcement Learning

Imitation fosters the basic language ability for generating echoic behavior (Skinner, 1957), but it is not enough for conversing adaptively with the teacher according to context and the knowledge state of the learner. Thus we leverage reward feedback to shape the behavior of the agent by optimizing the policy using RL. The agent's response $\mathbf{a}^t$ is generated by the *speaker*, which can be modeled as a sample from a distribution over all possible sequences, given the conversation history $\mathcal{H}^t = \{\mathbf{w}^1, \mathbf{a}^1, \cdots, \mathbf{w}^t\}$ and visual input $\mathbf{v}^t$:

$$\mathbf{a}^t \sim p_\theta^{\mathrm{S}}(\mathbf{a}|\mathcal{H}^t, \mathbf{v}^t). \qquad (4)$$

As $\mathcal{H}^t$ can be encoded by the interpreter-RNN as $\mathbf{h}_{\mathrm{I}}^t$, the action policy can be represented as $p_\theta^{\mathrm{S}}(\mathbf{a}|\mathbf{h}_{\mathrm{I}}^t, \mathbf{v}^t)$. To leverage the language skill that is learned via imitation through the *interpreter*, we can generate the sentence by implementing the *speaker* with an RNN, sharing parameters with the interpreter-RNN, but with a conditional signal modulated by a controller network (Figure 2):

$$p_\theta^{\mathrm{S}}(\mathbf{a}^t|\mathbf{h}_{\mathrm{I}}^t, \mathbf{v}^t) = p_\theta^{\mathrm{I}}(\mathbf{a}^t|\mathbf{h}_{\mathrm{I}}^t + f(\mathbf{h}_{\mathrm{I}}^t, c), \mathbf{v}^t). \qquad (5)$$

The reason for using a controller $f(\cdot)$ for modulation is that the basic language model only offers the learner the echoic ability to generate a sentence, but not necessarily the adaptive behavior according to context (*e.g.* asking questions when facing novel objects and providing an answer for a previously learned object according to its own knowledge state). Without any additional module or learning signals, the agent's behaviors would be the same as those of the teacher because of parameter sharing; thus, it is difficult for the agent to learn to speak in an adaptive manner.

To learn from consequences of speaking actions, the policy $p_\theta^{\mathrm{S}}(\cdot)$ is adjusted by maximizing expected future reward as represented by $\mathcal{L}_\theta^{\mathrm{R}}$. As a non-differentiable sampling operation is involved in Eqn.(4), policy gradient theorem (Sutton and Barto, 1998) is used to derive the gradient for updating $p_\theta^{\mathrm{S}}(\cdot)$ in the reinforce module:

$$\nabla_\theta \mathcal{L}_\theta^{\mathrm{R}} = \mathbb{E}_{p_\theta^{\mathrm{S}}}\left[\textstyle\sum_t A^t \cdot \nabla_\theta \log p_\theta^{\mathrm{S}}(\mathbf{a}^t|\mathbf{c}^t)\right], \qquad (6)$$

where $A^t = V(\mathbf{h}_{\mathrm{I}}^t, c^t) - r^{t+1} - \gamma V(\mathbf{h}_{\mathrm{I}}^{t+1}, c^{t+1})$ is the advantage (Sutton and Barto, 1998) estimated using a value network $V(\cdot)$. The imitation module contributes by implementing $\mathcal{L}_\theta^{\mathrm{I}}$ with a cross-entropy loss (Ranzato et al., 2016) and minimizing it with respect to the parameters in $p_\theta^{\mathrm{I}}(\cdot)$, which are shared with $p_\theta^{\mathrm{S}}(\cdot)$. The training signal from imitation takes the shortcut connection without going through the controller. More details on $f(\cdot)$, $V(\cdot)$ are provided in Appendix A.2.

5 Experiments

We conduct experiments with comparison to baseline approaches. We first experiment with a word-level task in which the teacher and the learner communicate a single word each time. We then investigate the impact of image variations on concept learning. We further perform evaluation on the more challenging sentence-level task in which the teacher and the agent communicate in the form of sentences with varying lengths.

Setup. To evaluate the performance in learning a transferable ability, rather than the ability of fitting a particular dataset, we use an Animal dataset for training and test the trained models on a Fruit dataset (Figure 1). More details on the datasets are provided in Appendix A.1. Each session consists of two randomly sampled classes, and the maximum number of interaction steps is six.

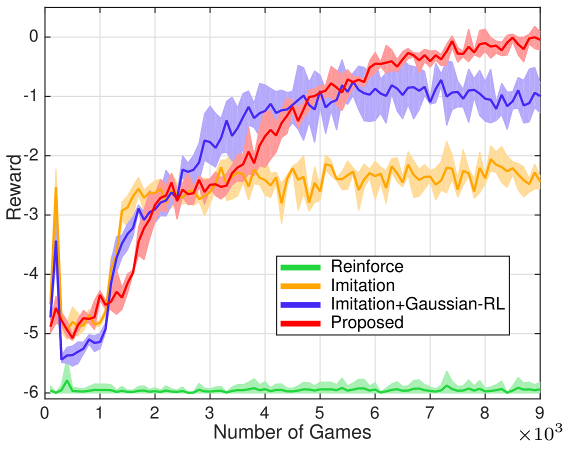

Figure 3: **Evolution of reward** during training for the word-level task without image variations.

Baselines. The following methods are compared:

- **Reinforce**: a baseline model with the same network structure as the proposed model and trained using RL only, *i.e.* minimizing $\mathcal{L}_{\theta}^{\mathrm{R}}$;
- **Imitation**: a recurrent encoder decoder (Serban et al., 2016) model with the same structure as ours and trained via imitation (minimizing $\mathcal{L}_{\theta}^{\mathrm{I}}$);
- **Imitation+Gaussian-RL**: a joint imitation and reinforcement method using a Gaussian policy (Duan et al., 2016) in the latent space of the control vector $\mathbf{c}^t$ (Zhang et al., 2017). The policy is changed by modifying the control vector $\mathbf{c}^t$ the action policy depends upon.

Training Details. The training algorithm is implemented with the deep learning platform PaddlePaddle.[3] The whole network is trained from scratch in an end-to-end fashion. The network is randomly initialized without any pre-training and is trained with decayed Adagrad (Duchi et al., 2011). We use a batch size of 16, a learning rate of 1×10^{-5} and a weight decay rate of 1.6×10^{-3}. We also exploit experience replay (Wang et al., 2017; Yu et al., 2018). The reward discount factor γ is 0.99, the word embedding dimension d is 1024 and the dictionary size k is 80. The visual image size is 32×32, the maximum length of generated sentence is 6 and the memory size is 10. Word embedding vectors are initialized as random vectors and remain fixed during training. A sampling operation is used for sentence generation during training for exploration while a max operation is used during testing both for **Proposed** and for **Reinforce** baseline. The max operation is used in both training and testing for **Imitation** and **Imitation+Gaussian-RL** baselines.

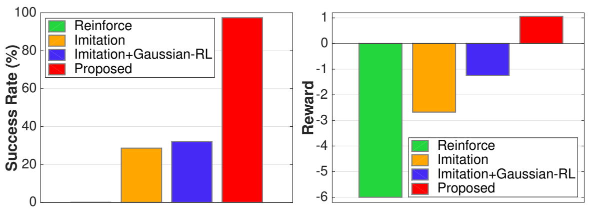

Figure 4: **Test performance** for the word-level task without image variations. Models are trained on the Animal dataset and tested on the Fruit dataset.

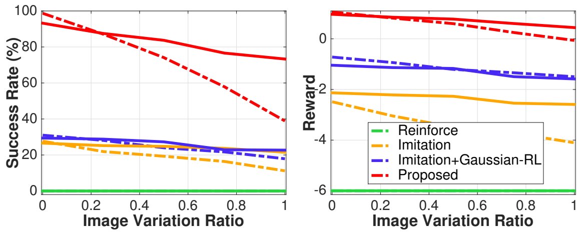

Figure 5: **Test success rate and reward** for the word-level task on the Fruit dataset under different test image variation ratios for models trained on the Animal dataset with a variation ratio of 0.5 (solid lines) and without variation (dashed lines).

5.1 Word-Level Task

In this experiment, we focus on a word-level task, which offers an opportunity to analyze and understand the underlying behavior of different algorithms while being free from distracting factors. Note that although the teacher speaks a word each time, the learner still has to learn to generate a full-sentence ended with an end-of-sentence symbol.

Figure 3 shows the evolution curves of the rewards during training for different approaches. It is observed that **Reinforce** makes very little progress, mainly due to the difficulty of exploration in the large space of sequence actions. **Imitation** obtains higher rewards than **Reinforce** during training, as it can avoid some penalty by generating sensible sentences such as questions. **Imitation+Gaussian-RL** gets higher rewards than both **Imitation** and **Reinforce**, indicating that the RL component reshapes the action policy toward higher rewards. However, as the Gaussian policy optimizes the action policy indirectly in a latent feature space, it is less efficient for exploration and learning. **Proposed** achieves the highest final reward during training.

We train the models using the Animal dataset and evaluate them on the Fruit dataset; Figure 4 sum-

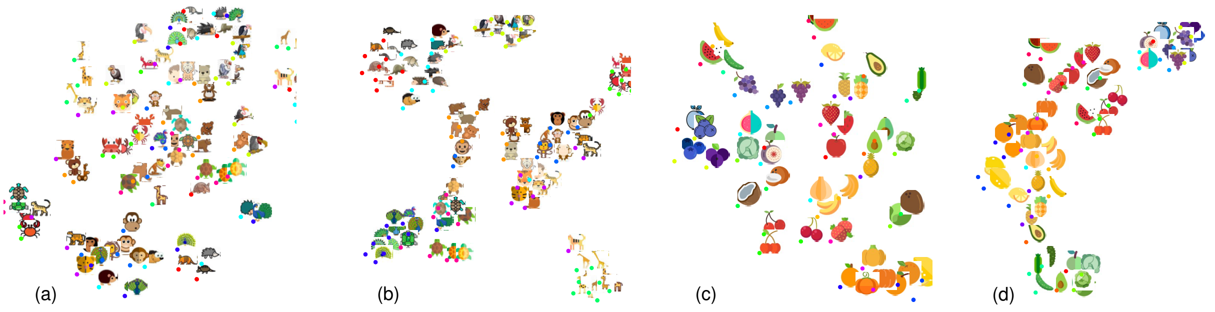

Figure 6: **Visualization of the CNN features** with t-SNE. Ten classes randomly sampled from **(a-b)** the Animal dataset and **(c-d)** the Fruit dataset, with features extracted using the visual encoder trained without (a, c) and with (b, d) image variations on the the Animal dataset.

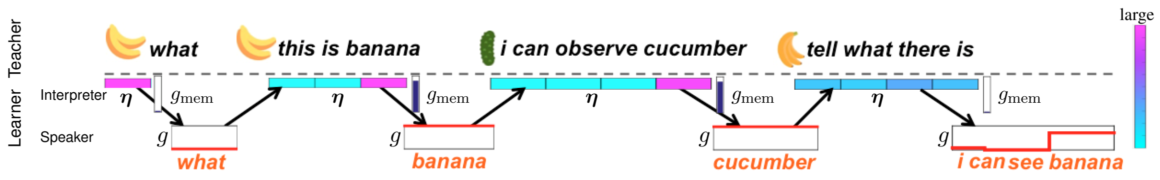

Figure 7: **Example results** of the proposed approach on novel classes. The learner can ask about the new class and use the interpreter to extract useful information from the teacher's sentence via word-level attention $\boldsymbol{\eta}$ and content importance g_{mem} jointly. The speaker uses the fusion gate g to adaptively switch between signals from RNN (small g) and external memory (large g) to generate sentence responses.

marizes the success rate and average reward over 1K testing sessions. As can be observed, **Reinforce** achieves the lowest success rate (0.0%) and reward (-6.0) due to its inherent inefficiency in learning. **Imitation** performs better than **Reinforce** in terms of both its success rate (28.6%) and reward value (-2.7). **Imitation+Gaussian-RL** achieves a higher reward (-1.2) during testing, but its success rate (32.1%) is similar to that of **Imitation**, mainly due to the rigorous criteria for success. **Proposed** reaches the highest success rate (97.4%) and average reward ($+1.1$)[4], outperforming all baseline methods by a large margin. From this experiment, it is clear that imitation with a proper usage of reinforcement is crucial for achieving adaptive behaviors (*e.g.*, asking questions about novel objects and generating answers or statements about learned objects proactively).

5.2 Learning with Image Variations

To evaluate the impact of within-class image variations on one-shot concept learning, we train models with and without image variations, and during testing compare their performance under different image variation ratios (the chance of a novel image instance being present within a session) as shown in Figure 5. It is observed that the performance of the model trained without image variations drops significantly as the variation ratio increases. We also evaluate the performance of models trained under a variation ratio of 0.5. Figure 5 clearly shows that although there is also a performance drop, which is expected, the performance degrades more gradually, indicating the importance of image variation for learning one-shot concepts. Figure 6 visualizes sampled training and testing images represented by their corresponding features extracted using the visual encoder trained without and with image variations. Clusters of visually similar concepts emerge in the feature space when trained with image variations, indicating that a more discriminative visual encoder was obtained for learning generalizable concepts.

5.3 Sentence-Level Task

We further evaluate the model on sentence-level tasks. Teacher's sentences are generated using the grammar as shown in Table 1 and have a number of variations with sentence lengths ranging from one to five. Example sentences from the teacher are presented in Appendix A.1. This task is more challenging than the word-level task in two ways: i) information processing is more difficult as the learner has to learn to extract useful information which could appear at different locations of the sentence; ii) the sentence generation is also more

[4]The testing reward is higher than the training reward mainly due to the action sampling in training for exploration.

difficult than the word-level task and the learner has to adaptively fuse information from RNN and external memory to generate a complete sentence. Comparison of different approaches in terms of their success rates and average rewards on the novel test set are shown in Figure 8. As can be observed from the figure, **Proposed** again outperforms all other compared methods in terms of both success rate (82.8%) and average reward (+0.8), demonstrating its effectiveness even for the more complex sentence-level task.

We also visualize the information extraction and the adaptive sentence composing process of the proposed approach when applied to a test set. As shown in Figure 7, the agent learns to extract useful information from the teacher's sentence and use the content importance gate to control what content is written into the external memory. Concretely, sentences containing object names have a larger g_{mem} value, and the word corresponding to object name has a larger value in the attention vector $\boldsymbol{\eta}$ compared to other words in the sentence. The combined effect of $\boldsymbol{\eta}$ and g_{mem} suggests that words corresponding to object names have higher likelihoods of being written into the external memory. The agent also successfully learns to use the external memory for storing the information extracted from the teacher's sentence, to fuse it adaptively with the signal from the RNN (capturing the syntactic structure) and to generate a complete sentence with the new concept included. The value of the fusion gate g is small when generating words like "*what*,", "*i*," "*can*," and "*see*," meaning it mainly relies on the signal from the RNN for generation (*c.f.*, Eqn.(2) and Figure 7). In contrast, when generating object names (*e.g.*, "*banana*," and "*cucumber*"), the fusion gate g has a large value, meaning that there is more emphasis on the signal from the external memory. This experiment showed that the proposed approach is applicable to the more complex sentence-level task for language learning and one-shot learning. More interestingly, it learns an interpretable operational process, which can be easily understood. More results including example dialogues from different approaches are presented in Appendix A.4.

6 Discussion

We have presented an approach for grounded language acquisition with one-shot visual concept learning in this work. This is achieved by purely

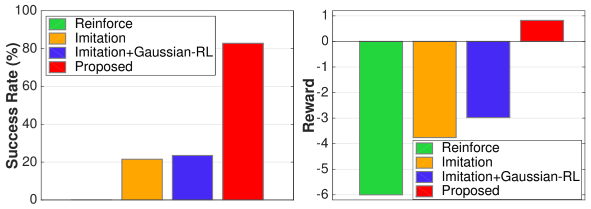

Figure 8: **Test performance** for sentence-level task with image variations (variation ratio=0.5).

interacting with a teacher and learning from feedback arising naturally during interaction through joint imitation and reinforcement learning, with a memory augmented neural network. Experimental results show that the proposed approach is effective for language acquisition with one-shot visual concept learning across several different settings compared with several baseline approaches.

In the current work, we have designed and used a computer game (synthetic task with synthetic language) for training the agent. This is mainly due to the fact that there is no existing dataset to the best of our knowledge that is adequate for developing our addressed interactive language learning and one-shot learning problem. For our current design, although it is an artificial game, there is a reasonable amount of variations both within and across sessions, *e.g.*, the object classes to be learned within a session, the presentation order of the selected classes, the sentence patterns and image instances to be used etc. All these factors contribute to the increased complexity of the learning task, making it non-trivial and already very challenging to existing approaches as shown by the experimental results. While offering flexibility in training, one downside of using a synthetic task is its limited amount of variation compared with real-world scenarios with natural languages. Although it might be non-trivial to extend the proposed approach to real natural language directly, we regard this work as an initial step towards this ultimate ambitious goal and our game might shed some light on designing more advanced games or performing real-world data collection. We plan to investigate the generalization and application of the proposed approach to more realistic environments with more diverse tasks in future work.

Abstract

Recently, there has been growing interest in multi-speaker speech recognition, where the utterances of multiple speakers are recognized from their mixture. Promising techniques have been proposed for this task, but earlier works have required additional training data such as isolated source signals or senone alignments for effective learning. In this paper, we propose a new sequence-to-sequence framework to directly decode multiple label sequences from a single speech sequence by unifying source separation and speech recognition functions in an end-to-end manner. We further propose a new objective function to improve the contrast between the hidden vectors to avoid generating similar hypotheses. Experimental results show that the model is directly able to learn a mapping from a speech mixture to multiple label sequences, achieving 83.1% relative improvement compared to a model trained without the proposed objective. Interestingly, the results are comparable to those produced by previous end-to-end works featuring explicit separation and recognition modules.

1 Introduction

Conventional automatic speech recognition (ASR) systems recognize a single utterance given a speech signal, in a one-to-one transformation. However, restricting the use of ASR systems to situations with only a single speaker limits their applicability. Recently, there has been growing interest in single-channel multi-speaker speech recognition, which aims at generating multiple transcriptions from a single-channel mixture of multiple speakers' speech (Cooke et al., 2009).

To achieve this goal, several previous works have considered a two-step procedure in which the mixed speech is first separated, and recognition is then performed on each separated speech signal (Hershey et al., 2016; Isik et al., 2016; Yu et al., 2017; Chen et al., 2017). Dramatic advances have recently been made in speech separation, via the *deep clustering* framework (Hershey et al., 2016; Isik et al., 2016), hereafter referred to as DPCL. DPCL trains a deep neural network to map each time-frequency (T-F) unit to a high-dimensional embedding vector such that the embeddings for the T-F unit pairs dominated by the same speaker are close to each other, while those for pairs dominated by different speakers are farther away. The speaker assignment of each T-F unit can thus be inferred from the embeddings by simple clustering algorithms, to produce masks that isolate each speaker. The original method using k-means clustering (Hershey et al., 2016) was extended to allow end-to-end training by unfolding the clustering steps using a permutation-free mask inference objective (Isik et al., 2016). An alternative approach is to perform *direct mask inference* using the permutation-free objective function with networks that directly estimate the labels for a fixed number of sources. Direct mask inference was first used in Hershey et al. (2016) as a baseline method, but without showing good performance. This approach was revisited in Yu et al. (2017) and Kolbaek et al. (2017) under the name permutation-invariant training (PIT). Combination of such single-channel speaker-independent multi-speaker speech separation systems with ASR was first considered in Isik et al. (2016) using a conventional Gaussian Mixture Model/Hidden Markov Model

*This work was done while H. Seki, Ph.D. candidate at Toyohashi University of Technology, Japan, was an intern at MERL.

(GMM/HMM) system. Combination with an end-to-end ASR system was recently proposed in (Settle et al., 2018). Both these approaches either trained or pre-trained the source separation and ASR networks separately, making use of mixtures and their corresponding isolated clean source references. While the latter approach could in principle be trained without references for the isolated speech signals, the authors found it difficult to train from scratch in that case. This ability can nonetheless be used when adapting a pre-trained network to new data without such references.

In contrast with this two-stage approach, Qian et al. (2017) considered direct optimization of a deep-learning-based ASR recognizer without an explicit separation module. The network is optimized based on a permutation-free objective defined using the cross-entropy between the system's hypotheses and reference labels. The best permutation between hypotheses and reference labels in terms of cross-entropy is selected and used for backpropagation. However, this method still requires reference labels in the form of senone alignments, which have to be obtained on the clean isolated sources using a single-speaker ASR system. As a result, this approach still requires the original separated sources. As a general caveat, generation of multiple hypotheses in such a system requires the number of speakers handled by the neural network architecture to be determined before training. However, Qian et al. (2017) reported that the recognition of two-speaker mixtures using a model trained for three-speaker mixtures showed almost identical performance with that of a model trained on two-speaker mixtures. Therefore, it may be possible in practice to determine an upper bound on the number of speakers.

Chen et al. (2018) proposed a progressive training procedure for a hybrid system with explicit separation motivated by curriculum learning. They also proposed self-transfer learning and multi-output sequence discriminative training methods for fully exploiting pairwise speech and preventing competing hypotheses, respectively.

In this paper, we propose to circumvent the need for the corresponding isolated speech sources when training on a set of mixtures, by using an end-to-end multi-speaker speech recognition without an explicit speech separation stage. In separation based systems, the spectrogram is segmented into complementary regions according to sources, which generally ensures that different utterances are recognized for each speaker. Without this complementarity constraint, our direct multi-speaker recognition system could be susceptible to redundant recognition of the same utterance. In order to prevent degenerate solutions in which the generated hypotheses are similar to each other, we introduce a new objective function that enhances contrast between the network's representations of each source. We also propose a training procedure to provide permutation invariance with low computational cost, by taking advantage of the joint CTC/attention-based encoder-decoder network architecture proposed in (Hori et al., 2017a). Experimental results show that the proposed model is able to directly convert an input speech mixture into multiple label sequences without requiring any explicit intermediate representations. In particular no frame-level training labels, such as phonetic alignments or corresponding unmixed speech, are required. We evaluate our model on spontaneous English and Japanese tasks and obtain comparable results to the DPCL based method with explicit separation (Settle et al., 2018).

2 Single-speaker end-to-end ASR

2.1 Attention-based encoder-decoder network

An attention-based encoder-decoder network (Bahdanau et al., 2016) predicts a target label sequence $Y = (y_1, \dots, y_N)$ without requiring intermediate representation from a T-frame sequence of D-dimensional input feature vectors, $O = (o_t \in \mathbb{R}^D | t = 1, \dots, T)$, and the past label history. The probability of the n-th label y_n is computed by conditioning on the past history $y_{1:n-1}$:

$$p_{\text{att}}(Y|O) = \prod_{n=1}^{N} p_{\text{att}}(y_n|O, y_{1:n-1}). \qquad (1)$$

The model is composed of two main sub-modules, an encoder network and a decoder network. The encoder network transforms the input feature vector sequence into a high-level representation $H = (h_l \in \mathbb{R}^C | l = 1, \dots, L)$. The decoder network emits labels based on the label history y and a context vector c calculated using an attention mechanism which weights and sums the C-dimensional sequence of representation H with attention weight a. A hidden state e of the decoder is updated based on the previous state, the previous context vector, and the emitted label. This mechanism is summarized as follows:

$$H = \mathrm{Encoder}(O), \quad (2)$$

$$y_n \sim \mathrm{Decoder}(c_n, y_{n-1}), \quad (3)$$

$$c_n, a_n = \mathrm{Attention}(a_{n-1}, e_n, H), \quad (4)$$

$$e_n = \mathrm{Update}(e_{n-1}, c_{n-1}, y_{n-1}). \quad (5)$$

At inference time, the previously emitted labels are used. At training time, they are replaced by the reference label sequence $R = (r_1, \ldots, r_N)$ in a *teacher-forcing* fashion, leading to conditional probability $p_{\text{att}}(Y_R|O)$, where Y_R denotes the output label sequence variable in this condition. The detailed definitions of Attention and Update are described in Section A of the supplementary material. The encoder and decoder networks are trained to maximize the conditional probability of the reference label sequence R using backpropagation:

$$\mathcal{L}_{\text{att}} = \mathrm{Loss}_{\text{att}}(Y_R, R) \triangleq -\log p_{\text{att}}(Y_R = R|O), \quad (6)$$

where $\mathrm{Loss}_{\text{att}}$ is the cross-entropy loss function.

2.2 Joint CTC/attention-based encoder-decoder network

The joint CTC/attention approach (Kim et al., 2017; Hori et al., 2017a), uses the connectionist temporal classification (CTC) objective function (Graves et al., 2006) as an auxiliary task to train the network. CTC formulates the conditional probability by introducing a framewise label sequence Z consisting of a label set $\mathcal{U}$ and an additional blank symbol defined as $Z = \{z_l \in \mathcal{U} \cup \{\texttt{'blank'}\} | l = 1, \cdots, L\}$:

$$p_{\text{ctc}}(Y|O) = \sum_{Z} \prod_{l=1}^{L} p(z_l|z_{l-1}, Y) p(z_l|O), \quad (7)$$

where $p(z_l|z_{l-1}, Y)$ represents monotonic alignment constraints in CTC and $p(z_l|O)$ is the frame-level label probability computed by

$$p(z_l|O) = \mathrm{Softmax}(\mathrm{Linear}(h_l)), \quad (8)$$

where h_l is the hidden representation generated by an encoder network, here taken to be the encoder of the attention-based encoder-decoder network defined in Eq. (2), and $\mathrm{Linear}(\cdot)$ is the final linear layer of the CTC to match the number of labels. Unlike the attention model, the forward-backward algorithm of CTC enforces monotonic alignment between the input speech and the output label sequences during training and decoding. We adopt the joint CTC/attention-based encoder-decoder network as the monotonic alignment helps the separation and extraction of high-level representation. The CTC loss is calculated as:

$$\mathcal{L}_{\text{ctc}} = \mathrm{Loss}_{\text{ctc}}(Y, R) \triangleq -\log p_{\text{ctc}}(Y = R|O). \quad (9)$$

The CTC loss and the attention-based encoder-decoder loss are combined with an interpolation weight $\lambda \in [0, 1]$:

$$\mathcal{L}_{\text{mtl}} = \lambda \mathcal{L}_{\text{ctc}} + (1 - \lambda) \mathcal{L}_{\text{att}}. \quad (10)$$

Both CTC and encoder-decoder networks are also used in the inference step. The final hypothesis is a sequence that maximizes a weighted conditional probability of CTC in Eq. (7) and attention-based encoder decoder network in Eq. (1):

$$\hat{Y} = \arg\max_{Y} \{\gamma \log p_{\text{ctc}}(Y|O) + (1 - \gamma) \log p_{\text{att}}(Y|O)\}, \quad (11)$$

where $\gamma \in [0, 1]$ is an interpolation weight.

3 Multi-speaker end-to-end ASR

3.1 Permutation-free training

In situations where the correspondence between the outputs of an algorithm and the references is an arbitrary permutation, neural network training faces a *permutation problem*. This problem was first addressed by deep clustering (Hershey et al., 2016), which circumvented it in the case of source separation by comparing the relationships between pairs of network outputs to those between pairs of labels. As a baseline for deep clustering, Hershey et al. (2016) also proposed another approach to address the permutation problem, based on an objective which considers all permutations of references when computing the error with the network estimates. This objective was later used in Isik et al. (2016) and Yu et al. (2017). In the latter, it was referred to as permutation-invariant training.

This permutation-free training scheme extends the usual one-to-one mapping of outputs and labels for backpropagation to one-to-many by selecting the proper permutation of hypotheses and references, thus allowing the network to generate multiple independent hypotheses from a single-channel speech mixture. When a speech mixture contains speech uttered by S speakers simultaneously, the network generates S label sequence variables $Y^s = (y_1^s, \dots, y_{N_s}^s)$ with N_s labels from the T-frame sequence of D-dimensional input feature vectors, $O = (o_t \in \mathbb{R}^D | t = 1, \dots, T)$:

$$Y^s \sim g^s(O),\ s = 1, \dots, S, \tag{12}$$

where the transformations g^s are implemented as neural networks which typically share some components with each other. In the training stage, all possible permutations of the S sequences $R^s = (r_1^s, \dots, r_{N_s'}^s)$ of N_s' reference labels are considered (considering permutations on the hypotheses would be equivalent), and the one leading to minimum loss is adopted for backpropagation. Let $\mathcal{P}$ denote the set of permutations on $\{1, \dots, S\}$. The final loss $\mathcal{L}$ is defined as

$$\mathcal{L} = \min_{\pi \in \mathcal{P}} \sum_{s=1}^{S} \mathrm{Loss}(Y^s, R^{\pi(s)}), \tag{13}$$

where $\pi(s)$ is the s-th element of a permutation π. For example, for two speakers, $\mathcal{P}$ includes two permutations $(1, 2)$ and $(2, 1)$, and the loss is defined as:

$$\begin{aligned}\mathcal{L} = \min(&\mathrm{Loss}(Y^1, R^1) + \mathrm{Loss}(Y^2, R^2),\\ &\mathrm{Loss}(Y^1, R^2) + \mathrm{Loss}(Y^2, R^1)).\end{aligned} \tag{14}$$

Figure 1 shows an overview of the proposed end-to-end multi-speaker ASR system. In the following Section 3.2, we describe an extension of encoder network for the generation of multiple hidden representations. We further introduce a permutation assignment mechanism for reducing the computation cost in Section 3.3, and an additional loss function $\mathcal{L}_{KL}$ for promoting the difference between hidden representations in Section 3.4.

3.2 End-to-end permutation-free training

To make the network output multiple hypotheses, we consider a stacked architecture that combines both shared and unshared (or specific) neural network modules. The particular architecture we consider in this paper splits the encoder network into three stages: the first stage, also referred to as mixture encoder, processes the input mixture and

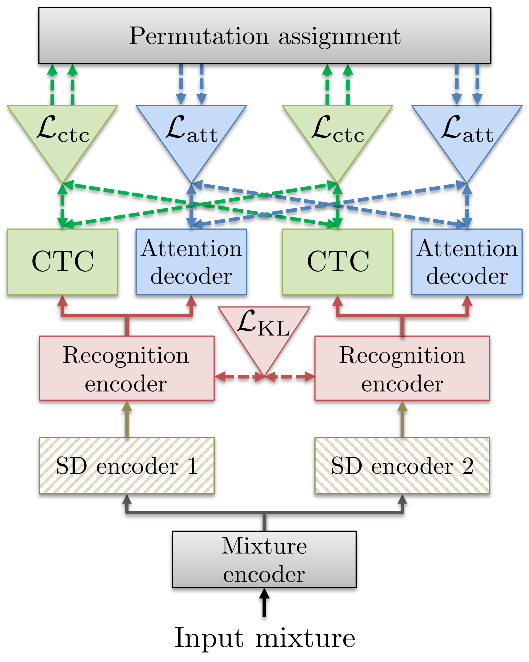

Figure 1: End-to-end multi-speaker speech recognition. We propose to use the permutation-free training for CTC and attention loss functions $\mathrm{Loss}_{\mathrm{ctc}}$ and $\mathrm{Loss}_{\mathrm{att}}$, respectively.

outputs an intermediate feature sequence H; that sequence is then processed by S independent encoder sub-networks which do not share parameters, also referred to as speaker-differentiating (SD) encoders, leading to S feature sequences H^s; at the last stage, each feature sequence H^s is independently processed by the same network, also referred to as recognition encoder, leading to S final high-level representations G^s.

Let $u \in \{1 \dots, S\}$ denote an output index (corresponding to the transcription of the speech by one of the speakers), and $v \in \{1 \dots, S\}$ denote a reference index. Denoting by $\mathrm{Encoder}_{\mathrm{Mix}}$ the mixture encoder, $\mathrm{Encoder}_{\mathrm{SD}}^{\mathrm{u}}$ the u-th speaker-differentiating encoder, and $\mathrm{Encoder}_{\mathrm{Rec}}$ the recognition encoder, an input sequence O corresponding to an input mixture can be processed by the encoder network as follows:

$$H = \mathrm{Encoder}_{\mathrm{Mix}}(O), \tag{15}$$
$$H^u = \mathrm{Encoder}_{\mathrm{SD}}^{\mathrm{u}}(\mathrm{H}), \tag{16}$$
$$G^u = \mathrm{Encoder}_{\mathrm{Rec}}(H^u). \tag{17}$$

The motivation for designing such an architecture can be explained as follows, following analogies with the architectures in (Isik et al., 2016) and (Settle et al., 2018) where separation and recognition are performed explicitly in separate steps: the first stage in Eq. (15) corresponds to a speech separation module which creates embedding vectors that can be used to distinguish between the multiple sources; the speaker-differentiating second stage in Eq. (16) uses the first stage's output to disentangle each speaker's speech content from the mixture, and prepare it for recognition; the final stage in Eq. (17) corresponds to an acoustic model that encodes the single-speaker speech for final decoding.

The decoder network computes the conditional probabilities for each speaker from the S outputs of the encoder network. In general, the decoder network uses the reference label R as a history to generate the attention weights during training, in a teacher-forcing fashion. However, in the above permutation-free training scheme, the reference label to be attributed to a particular output is not determined until the loss function is computed, so we here need to run the attention decoder for all reference labels. We thus need to consider the conditional probability of the decoder output variable $Y^{u,v}$ for each output G^u of the encoder network under the assumption that the reference label for that output is R^v:

$$p_{\text{att}}(Y^{u,v}|O) = \prod_n p_{\text{att}}(y_n^{u,v}|O, y_{1:n-1}^{u,v}), \quad (18)$$

$$c_n^{u,v}, a_n^{u,v} = \text{Attention}(a_{n-1}^{u,v}, e_n^{u,v}, G^u), \quad (19)$$

$$e_n^{u,v} = \text{Update}(e_{n-1}^{u,v}, c_{n-1}^{u,v}, r_{n-1}^{v}), \quad (20)$$

$$y_n^{u,v} \sim \text{Decoder}(c_n^{u,v}, r_{n-1}^{v}). \quad (21)$$

The final loss is then calculated by considering all permutations of the reference labels as follows:

$$\mathcal{L}_{\text{att}} = \min_{\pi \in \mathcal{P}} \sum_s \text{Loss}_{\text{att}}(Y^{s,\pi(s)}, R^{\pi(s)}). \quad (22)$$

3.3 Reduction of permutation cost

In order to reduce the computational cost, we fixed the permutation of the reference labels based on the minimization of the CTC loss alone, and used the same permutation for the attention mechanism as well. This is an advantage of using a joint CTC/attention based end-to-end speech recognition. Permutation is performed only for the CTC loss by assuming synchronous output where the permutation is decided by the output of CTC:

$$\hat{\pi} = \arg\min_{\pi \in \mathcal{P}} \sum_s \text{Loss}_{\text{ctc}}(Y^s, R^{\pi(s)}), \quad (23)$$

where Y^u is the output sequence variable corresponding to encoder output G^u. Attention-based decoding is then performed on the same hidden representations G^u, using teacher forcing with the labels determined by the permutation $\hat{\pi}$ that minimizes the CTC loss:

$$p_{\text{att}}(Y^{u,\hat{\pi}(u)}|O) = \prod_n p_{\text{att}}(y_n^{u,\hat{\pi}(u)}|O, y_{1:n-1}^{u,\hat{\pi}(u)}),$$

$$c_n^{u,\hat{\pi}(u)}, a_n^{u,\hat{\pi}(u)} = \text{Attention}(a_{n-1}^{u,\hat{\pi}(u)}, e_n^{u,\hat{\pi}(u)}, G^u),$$

$$e_n^{u,\hat{\pi}(u)} = \text{Update}(e_{n-1}^{u,\hat{\pi}(u)}, c_{n-1}^{u,\hat{\pi}(u)}, r_{n-1}^{\hat{\pi}(u)}),$$

$$y_n^{u,\hat{\pi}(u)} \sim \text{Decoder}(c_n^{u,\hat{\pi}(u)}, r_{n-1}^{\hat{\pi}(u)}).$$

This corresponds to the "permutation assignment" in Fig. 1. In contrast with Eq. (18), we only need to run the attention-based decoding once for each output G^u of the encoder network. The final loss is defined as the sum of two objective functions with interpolation λ:

$$\mathcal{L}_{\text{mtl}} = \lambda \mathcal{L}_{\text{ctc}} + (1-\lambda)\mathcal{L}_{\text{att}}, \quad (24)$$

$$\mathcal{L}_{\text{ctc}} = \sum_s \text{Loss}_{\text{ctc}}(Y^s, R^{\hat{\pi}(s)}), \quad (25)$$

$$\mathcal{L}_{\text{att}} = \sum_s \text{Loss}_{\text{att}}(Y^{s,\hat{\pi}(s)}, R^{\hat{\pi}(s)}). \quad (26)$$

At inference time, because both CTC and attention-based decoding are performed on the same encoder output G^u and should thus pertain to the same speaker, their scores can be incorporated as follows:

$$\hat{Y}^u = \arg\max_{Y^u} \{\gamma \log p_{\text{ctc}}(Y^u|G^u) + (1-\gamma)\log p_{\text{att}}(Y^u|G^u)\}, \quad (27)$$

where $p_{\text{ctc}}(Y^u|G^u)$ and $p_{\text{att}}(Y^u|G^u)$ are obtained with the same encoder output G^u.

3.4 Promoting separation of hidden vectors

A single decoder network is used to output multiple label sequences by independently decoding the multiple hidden vectors generated by the encoder network. In order for the decoder to generate multiple different label sequences the encoder needs to generate sufficiently differentiated hidden vector sequences for each speaker. We propose to encourage this contrast among hidden vectors by introducing in the objective function a new term based on the negative symmetric Kullback-Leibler

(KL) divergence. In the particular case of two-speaker mixtures, we consider the following additional loss function:

$$\mathcal{L}_{\mathrm{KL}} = -\eta \sum_{l} \{\mathrm{KL}(\bar{G}^1(l) \,||\, \bar{G}^2(l)) + \mathrm{KL}(\bar{G}^2(l) \,||\, \bar{G}^1(l))\}, \quad (28)$$

where η is a small constant value, and $\bar{G}^u = (\mathrm{softmax}(G^u(l)) \mid l = 1, \dots, L)$ is obtained from the hidden vector sequence G^u at the output of the recognition encoder $\mathrm{Encoder}_{\mathrm{Rec}}$ as in Fig. 1 by applying an additional frame-wise softmax operation in order to obtain a quantity amenable to a probability distribution.

3.5 Split of hidden vector for multiple hypotheses

Since the network maps acoustic features to label sequences directly, we consider various architectures to perform implicit separation and recognition effectively. As a baseline system, we use the concatenation of a VGG-motivated CNN network (Simonyan and Zisserman, 2014) (referred to as VGG) and a bi-directional long short-term memory (BLSTM) network as the encoder network. For the splitting point in the hidden vector computation, we consider two architectural variations as follows:

- Split by BLSTM: The hidden vector is split at the level of the BLSTM network. 1) the VGG network generates a single hidden vector H; 2) H is fed into S independent BLSTMs whose parameters are not shared with each other; 3) the output of each independent BLSTM $H^u, u = 1, \dots, S$, is further separately fed into a unique BLSTM, the same for all outputs. Each step corresponds to Eqs. (15), (16), and (17).

- Split by VGG: The hidden vector is split at the level of the VGG network. The number of filters at the last convolution layer is multiplied by the number of mixtures S in order to split the output into S hidden vectors (as in Eq. (16)). The layers prior to the last VGG layer correspond to the network in Eq. (15), while the subsequent BLSTM layers implement the network in (17).

4 Experiments

4.1 Experimental setup

We used English and Japanese speech corpora, WSJ (Wall street journal) (Consortium, 1994; Garofalo et al., 2007) and CSJ (Corpus of spontaneous Japanese) (Maekawa, 2003). To show the effectiveness of the proposed models, we generated mixed speech signals from these corpora to simulate single-channel overlapped multi-speaker recording, and evaluated the recognition performance using the mixed speech data. For WSJ, we used WSJ1 SI284 for training, Dev93 for development, and Eval92 for evaluation. For CSJ, we followed the Kaldi recipe (Moriya et al., 2015) and used the full set of academic and simulated presentations for training, and the standard test sets 1, 2, and 3 for evaluation.

Table 1: Duration (hours) of unmixed and mixed corpora. The mixed corpora are generated by Algorithm 1 in Section B of the supplementary material, using the training, development, and evaluation set respectively.

	TRAIN	DEV.	EVAL
WSJ (UNMIXED)	81.5	1.1	0.7
WSJ (MIXED)	98.5	1.3	0.8
CSJ (UNMIXED)	583.8	6.6	5.2
CSJ (MIXED)	826.9	9.1	7.5

We created new corpora by mixing two utterances with different speakers sampled from existing corpora. The detailed algorithm is presented in Section B of the supplementary material. The sampled pairs of two utterances are mixed at various signal-to-noise ratios (SNR) between 0 dB and 5 dB with a random starting point for the overlap. Duration of original unmixed and generated mixed corpora are summarized in Table 1.

4.1.1 Network architecture

As input feature, we used 80-dimensional log Mel filterbank coefficients with pitch features and their delta and delta delta features ($83 \times 3 = 249$-dimension) extracted using Kaldi tools (Povey et al., 2011). The input feature is normalized to zero mean and unit variance. As a baseline system, we used a stack of a 6-layer VGG network and a 7-layer BLSTM as the encoder network. Each BLSTM layer has 320 cells in each direction, and is followed by a linear projection layer with 320 units to combine the forward and backward LSTM outputs. The decoder network has an 1-layer LSTM with 320 cells. As described in Section 3.5, we adopted two types of encoder architectures for multi-speaker speech recognition. The network architectures are summarized in Table 2. The split-by-VGG network had speaker differentiating encoders with a convolution layer

Table 2: Network architectures for the encoder network. The number of layers is indicated in parentheses. $\mathrm{Encoder}_{\mathrm{Mix}}$, $\mathrm{Encoder}^{\mathrm{u}}_{\mathrm{SD}}$, and $\mathrm{Encoder}_{\mathrm{Rec}}$ correspond to Eqs. (15), (16), and (17).

SPLIT BY	$\mathrm{Encoder}_{\mathrm{Mix}}$	$\mathrm{Encoder}^{\mathrm{u}}_{\mathrm{SD}}$	$\mathrm{Encoder}_{\mathrm{Rec}}$
NO	VGG (6)	—	BLSTM (7)
VGG	VGG (4)	VGG (2)	BLSTM (7)
BLSTM	VGG (6)	BLSTM (2)	BLSTM (5)

(and the following maxpooling layer). The split-by-BLSTM network had speaker differentiating encoders with two BLSTM layers. The architectures were adjusted to have the same number of layers. We used characters as output labels. The number of characters for WSJ was set to 49 including alphabets and special tokens (e.g., characters for space and unknown). The number of characters for CSJ was set to 3,315 including Japanese Kanji/Hiragana/Katakana characters and special tokens.

4.1.2 Optimization

The network was initialized randomly from uniform distribution in the range -0.1 to 0.1. We used the AdaDelta algorithm (Zeiler, 2012) with gradient clipping (Pascanu et al., 2013) for optimization. We initialized the AdaDelta hyperparameters as $\rho = 0.95$ and $\epsilon = 1^{-8}$. ϵ is decayed by half when the loss on the development set degrades. The networks were implemented with Chainer (Tokui et al., 2015) and ChainerMN (Akiba et al., 2017). The optimization of the networks was done by synchronous data parallelism with 4 GPUs for WSJ and 8 GPUs for CSJ.

The networks were first trained on single-speaker speech, and then retrained with mixed speech. When training on unmixed speech, only one side of the network only (with a single speaker differentiating encoder) is optimized to output the label sequence of the single speaker. Note that only character labels are used, and there is no need for clean source reference corresponding to the mixed speech. When moving to mixed speech, the other speaker-differentiating encoders are initialized using the already trained one by copying the parameters with random perturbation, $w' = w \times (1 + \mathrm{Uniform}(-0.1, 0.1))$ for each parameter w. The interpolation value λ for the multiple objectives in Eqs. (10) and (24) was set to 0.1 for WSJ and to 0.5 for CSJ. Lastly, the model is retrained with the additional negative KL divergence loss in Eq. (28) with $\eta = 0.1$.

Table 3: Evaluation of unmixed speech without multi-speaker training.

TASK	AVG.
WSJ	2.6
CSJ	7.8

4.1.3 Decoding

In the inference stage, we combined a pre-trained RNNLM (recurrent neural network language model) in parallel with the CTC and decoder network. Their label probabilities were linearly combined in the log domain during beam search to find the most likely hypothesis. For the WSJ task, we used both character and word level RNNLMs (Hori et al., 2017b), where the character model had a 1-layer LSTM with 800 cells and an output layer for 49 characters. The word model had a 1-layer LSTM with 1000 cells and an output layer for 20,000 words, i.e., the vocabulary size was 20,000. Both models were trained with the WSJ text corpus. For the CSJ task, we used a character level RNNLM (Hori et al., 2017c), which had a 1-layer LSTM with 1000 cells and an output layer for 3,315 characters. The model parameters were trained with the transcript of the training set in CSJ. We added language model probabilities with an interpolation factor of 0.6 for character-level RNNLM and 1.2 for word-level RNNLM.

The beam width for decoding was set to 20 in all the experiments. Interpolation γ in Eqs. (11) and (27) was set to 0.4 for WSJ and 0.5 for CSJ.

4.2 Results

4.2.1 Evaluation of unmixed speech

First, we examined the performance of the baseline joint CTC/attention-based encoder-decoder network with the original unmixed speech data. Table 3 shows the character error rates (CERs), where the baseline model showed 2.6% on WSJ and 7.8% on CSJ. Since the model was trained and evaluated with unmixed speech data, these CERs are considered lower bounds for the CERs in the succeeding experiments with mixed speech data.

4.2.2 Evaluation of mixed speech

Table 4 shows the CERs of the generated mixed speech from the WSJ corpus. The first column indicates the position of split as mentioned in Section 3.5. The second, third and forth columns indicate CERs of the high energy speaker (HIGH E. SPK.), the low energy speaker (LOW E. SPK.), and the average (AVG.), respectively. The baseline model has very high CERs because

Table 4: CER (%) of mixed speech for WSJ.

Split	High E. spk.	Low E. spk.	Avg.
no (baseline)	86.4	79.5	83.0
VGG	17.4	15.6	16.5
BLSTM	14.6	**13.3**	14.0
+ KL loss	**14.0**	**13.3**	**13.7**

Table 5: CER (%) of mixed speech for CSJ.

Split	High E. spk.	Low E. spk.	Avg.
no (baseline)	93.3	92.1	92.7
BLSTM	**11.0**	**18.8**	**14.9**

it was trained as a single-speaker speech recognizer without permutation-free training, and it can only output one hypothesis for each mixed speech. In this case, the CERs were calculated by duplicating the generated hypothesis and comparing the duplicated hypotheses with the corresponding references. The proposed models, i.e., split-by-VGG and split-by-BLSTM networks, obtained significantly lower CERs than the baseline CERs, the split-by-BLSTM model in particular achieving 14.0% CER. This is an 83.1% relative reduction from the baseline model. The CER was further reduced to 13.7% by retraining the split-by-BLSTM model with the negative KL loss, a 2.1% relative reduction from the network without retraining. This result implies that the proposed negative KL loss provides better separation by actively improving the contrast between the hidden vectors of each speaker. Examples of recognition results are shown in Section C of the supplementary material. Finally, we profiled the computation time for the permutations based on the decoder network and on CTC. Permutation based on CTC was 16.3 times faster than that based on the decoder network, in terms of the time required to determine the best match permutation given the encoder network's output in Eq. (17).

Table 5 shows the CERs for the mixed speech from the CSJ corpus. Similarly to the WSJ experiments, our proposed model significantly reduced the CER from the baseline, where the average CER was 14.9% and the reduction ratio from the baseline was 83.9%.

4.2.3 Visualization of hidden vectors

We show a visualization of the encoder networks outputs in Fig. 2 to illustrate the effect of the negative KL loss function. Principal component analysis (PCA) was applied to the hidden vectors on the vertical axis. Figures 2(a) and 2(b) show the hidden vectors generated by the split-by-BLSTM model without the negative KL divergence loss for an example mixture of two speakers. We can observe different activation patterns showing that the hidden vectors were successfully separated to the individual utterances in the mixed speech, although some activity from one speaker can be seen as leaking into the other. Figures 2(c) and 2(d) show the hidden vectors generated after retraining with the negative KL divergence loss. We can more clearly observe the different patterns and boundaries of activation and deactivation of hidden vectors. The negative KL loss appears to regularize the separation process, and even seems to help in finding the end-points of the speech.

4.2.4 Comparison with earlier work

We first compared the recognition performance with a hybrid (non end-to-end) system including DPCL-based speech separation and a Kaldi-based ASR system. It was evaluated under the same evaluation data and metric as in (Isik et al., 2016) based on the WSJ corpus. However, there are differences in the size of training data and the options in decoding step. Therefore, it is not a fully matched condition. Results are shown in Table 6. The word error rate (WER) reported in (Isik et al., 2016) is 30.8%, which was obtained with jointly trained DPCL and second-stage speech enhancement networks. The proposed end-to-end ASR gives an 8.4% relative reduction in WER even though our model does not require any explicit frame-level labels such as phonetic alignment, or clean signal reference, and does not use a phonetic lexicon for training. Although this is an unfair comparison, our purely end-to-end system outperformed a hybrid system for multi-speaker speech recognition.

Next, we compared our method with an end-to-end explicit separation and recognition network (Settle et al., 2018). We retrained our model previously trained on our WSJ-based corpus using the training data generated by Settle et al. (2018), because the direct optimization from scratch on their data caused poor recognition performance due to data size. Other experimental conditions are shared with the earlier work. Interestingly, our method showed comparable performance to the end-to-end explicit separation and recognition network, without having to pre-train using clean signal training references. It remains to be seen if this parity of performance holds in other tasks and conditions.

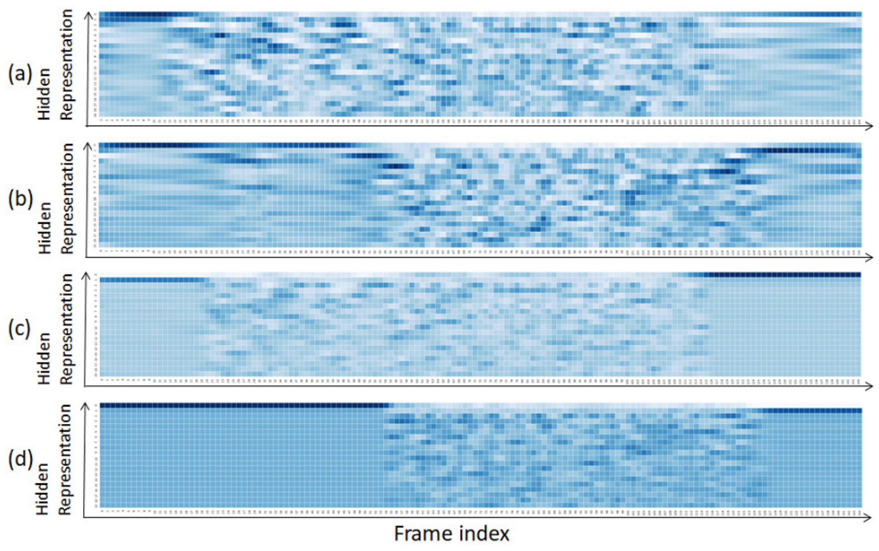

Figure 2: Visualization of the two hidden vector sequences at the output of the split-by-BLSTM encoder on a two-speaker mixture. (a,b): Generated by the model without the negative KL loss. (c,d): Generated by the model with the negative KL loss.

Table 6: Comparison with conventional approaches

METHOD	WER (%)
DPCL + ASR (ISIK ET AL., 2016)	30.8
Proposed end-to-end ASR	**28.2**
METHOD	CER (%)
END-TO-END DPCL + ASR (CHAR LM) (SETTLE ET AL., 2018)	**13.2**
Proposed end-to-end ASR (char LM)	14.0

5 Related work

Several previous works have considered an explicit two-step procedure (Hershey et al., 2016; Isik et al., 2016; Yu et al., 2017; Chen et al., 2017, 2018). In contrast with our work which uses a single objective function for ASR, they introduced an objective function to guide the separation of mixed speech.

Qian et al. (2017) trained a multi-speaker speech recognizer using permutation-free training without explicit objective function for separation. In contrast with our work which uses an end-to-end architecture, their objective function relies on a senone posterior probability obtained by aligning unmixed speech and text using a model trained as a recognizer for single-speaker speech. Compared with (Qian et al., 2017), our method directly maps a speech mixture to multiple character sequences and eliminates the need for the corresponding isolated speech sources for training.

6 Conclusions

In this paper, we proposed an end-to-end multi-speaker speech recognizer based on permutation-free training and a new objective function promoting the separation of hidden vectors in order to generate multiple hypotheses. In an encoder-decoder network framework, teacher forcing at the decoder network under multiple references increases computational cost if implemented naively. We avoided this problem by employing a joint CTC/attention-based encoder-decoder network.

Experimental results showed that the model is able to directly convert an input speech mixture into multiple label sequences under the end-to-end framework without the need for any explicit intermediate representation including phonetic alignment information or pairwise unmixed speech. We also compared our model with a method based on explicit separation using deep clustering, and showed comparable result. Future work includes data collection and evaluation in a real world scenario since the data used in our experiments are simulated mixed speech, which is already extremely challenging but still leaves some acoustic aspects, such as Lombard effects and real room impulse responses, that need to be alleviated for further performance improvement. In addition, further study is required in terms of increasing the number of speakers that can be simultaneously recognized, and further comparison with the separation-based approach.

A Structured Variational Autoencoder for Contextual Morphological Inflection

Abstract

Statistical morphological inflectors are typically trained on fully supervised, type-level data. One remaining open research question is the following: How can we effectively exploit raw, token-level data to improve their performance? To this end, we introduce a novel generative latent-variable model for the semi-supervised learning of inflection generation. To enable posterior inference over the latent variables, we derive an efficient variational inference procedure based on the wake-sleep algorithm. We experiment on 23 languages, using the Universal Dependencies corpora in a simulated low-resource setting, and find improvements of over 10% absolute accuracy in some cases.

1 Introduction

The majority of the world's languages overtly encodes syntactic information on the word form itself, a phenomenon termed inflectional morphology (Dryer et al., 2005). In English, for example, the verbal lexeme with lemma talk has the four forms: talk, talks, talked and talking. Other languages, such as Archi (Kibrik, 1998), distinguish more than a thousand verbal forms. Despite the cornucopia of unique variants a single lexeme may mutate into, native speakers can flawlessly predict the correct variant that the lexeme's syntactic context dictates. Thus, in computational linguistics, a natural question is the following: Can we estimate a probability model that can do the same?

The topic of inflection generation has been the focus of a flurry of individual attention of late and, moreover, has been the subject of two shared tasks

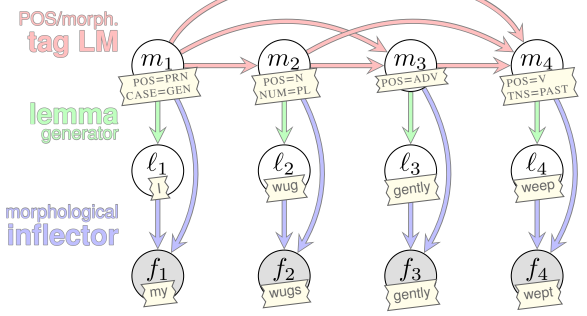

Figure 1: A length-4 example of our generative model factorized as in Eq. (1) and overlayed with example values of the random variables in the sequence. We highlight that all the conditionals in the Bayesian network are recurrent neural networks, e.g., we note that m_i depends on $\boldsymbol{m}_{<i}$ because we employ a recurrent neural network to model the morphological tag sequence.

(Cotterell et al., 2016, 2017). Most work, however, has focused on the fully supervised case—a source lemma and the morpho-syntactic properties are fed into a model, which is asked to produce the desired inflection. In contrast, our work focuses on the semi-supervised case, where we wish to make use of unannotated raw text, i.e., a sequence of inflected tokens.

Concretely, we develop a generative directed graphical model of inflected forms *in context*. A contextual inflection model works as follows: Rather than just generating the proper inflection for a single given word form *out of context* (for example *walking* as the gerund of *walk*), our generative model is actually a fully-fledged language model. In other words, it generates *sequences* of inflected words. The graphical model is displayed in Fig. 1 and examples of words it may generate are pasted on top of the graphical model notation. That our model is a language model enables it to exploit both inflected lexicons and unlabeled raw text in a principled semi-supervised way. In order to train using

raw-text corpora (which is useful when we have less annotated data), we marginalize out the unobserved lemmata and morpho-syntactic annotation from unlabeled data. In terms of Fig. 1, this refers to marginalizing out $m_1, \ldots, m_4$ and $\ell_1, \ldots, \ell_4$. As this marginalization is intractable, we derive a variational inference procedure that allows for efficient approximate inference. Specifically, we modify the wake-sleep procedure of Hinton et al. (1995). It is the inclusion of raw text in this fashion that makes our model *token level*, a novelty in the camp of inflection generation, as much recent work in inflection generation (Dreyer et al., 2008; Durrett and DeNero, 2013; Nicolai et al., 2015; Ahlberg et al., 2015; Faruqui et al., 2016), trains a model on *type-level* lexicons.

We offer empirical validation of our model's utility with experiments on 23 languages from the Universal Dependencies corpus in a simulated low-resource setting.[1] Our semi-supervised scheme improves inflection generation by over 10% absolute accuracy in some cases.

2 Background: Morphological Inflection

2.1 Inflectional Morphology

To properly discuss models of inflectional morphology, we require a formalization. We adopt the framework of word-based morphology (Aronoff, 1976; Spencer, 1991). Note in the present paper, we omit derivational morphology.

We define an **inflected lexicon** as a set of 4-tuples consisting of a part-of-speech tag, a lexeme, an inflectional slot, and a surface form. A **lexeme** is a discrete object that indexes the word's core meaning and part of speech. In place of such an abstract lexeme, lexicographers will often use a **lemma**, denoted by ℓ, which is a designated[2] surface form of the lexeme (such as the infinitive). For the remainder of this paper, we will use the lemma as a proxy for the lexeme, wherever convenient, although we note that lemmata may be ambiguous: bank is the lemma for at least two distinct nouns and two distinct verbs. For inflection, this ambiguity will rarely[3] play a role—for instance, all senses of bank inflect in the same fashion.

A **part-of-speech (POS) tag**, denoted t, is a coarse syntactic category such as VERB. Each POS tag allows some set of lexemes, and also allows some set of inflectional **slots**, denoted as σ, such as $\left[\text{TNS=PAST}, \text{PERSON=3}\right]$. Each allowed $\langle$tag, lexeme, slot$\rangle$ triple is realized—in only one way—as an inflected **surface form**, a string over a fixed phonological or orthographic alphabet Σ. (In this work, we take Σ to be an orthographic alphabet.) Additionally, we will define the term **morphological tag**, denoted by m, which we take to be the POS-slot pair $m = \langle t, \sigma \rangle$. We will further define $\mathcal{T}$ as the set of all POS tags and $\mathcal{M}$ as the set of all morphological tags.

A **paradigm** $\pi(t, \ell)$ is the mapping from tag t's slots to the surface forms that "fill" those slots for lexeme/lemma ℓ. For example, in the English paradigm $\pi(\text{VERB}, \text{talk})$, the past-tense slot is said to be filled by talked, meaning that the lexicon contains the tuple $\langle \text{VERB}, \text{talk}, \text{PAST}, \text{talked} \rangle$.

A cheat sheet for the notation is provided in Tab. 2.

We will specifically work with the UniMorph annotation scheme (Sylak-Glassman, 2016). Here, each slot specifies a morpho-syntactic bundle of inflectional features such as tense, mood, person, number, and gender. For example, the German surface form Wörtern is listed in the lexicon with tag NOUN, lemma Wort, and a slot specifying the feature bundle $\left[\text{NUM=PL}, \text{CASE=DAT}\right]$. The full paradigms $\pi(\text{NOUN}, \text{Wort})$ and $\pi(\text{NOUN}, \text{Herr})$ are found in Tab. 1.

2.2 Morphological Inflection

Now, we formulate the task of context-free **morphological inflection** using the notation developed in §2. Given a set of N form-tag-lemma triples $\{\langle f_i, m_i, \ell_i \rangle\}_{i=1}^{N}$, the goal of morphological inflection is to map the pair $\langle m_i, \ell_i \rangle$ to the form f_i. As

[1]We make our code and data available at: https://github.com/lwolfsonkin/morph-svae.

[2]A specific slot of the paradigm is chosen, depending on the part-of-speech tag – all these terms are defined next.

[3]One example of a paradigm where the lexeme, rather than the lemma, may influence inflection is hang. If one chooses the lexeme that licenses animate objects, the proper past tense is hanged, whereas it is hung for the lexeme that licenses inanimate objects.

object	symbol	example
form	f	talking
lemma	ℓ	talk
POS	t	VERB
slot	σ	[TNS=GERUND]
morph. tag	m	[POS=V, TNS=GERUND]

Table 2: Notational cheat sheet for the paper.

the definition above indicates, the task is traditionally performed at the *type level*. In this work, however, we focus on a generalization of the task to the *token level*—we seek to map a bisequence of lemma-tag pairs to the sequence of inflected forms in context. Formally, we will denote the lemma-morphological tag bisequence as $\langle \boldsymbol{\ell}, \boldsymbol{m} \rangle$ and the form sequence as $\boldsymbol{f}$. Foreshadowing, the primary motivation for this generalization is to enable the use of raw-text in a semi-supervised setting.

3 Generating Sequences of Inflections

The primary contribution of this paper is a novel generative model over sequences of inflected words in their sentential context. Following the notation laid out in §2.2, we seek to jointly learn a distribution over sequences of forms $\boldsymbol{f}$, lemmata $\boldsymbol{\ell}$, and morphological tags $\boldsymbol{m}$. The generative procedure is as follows: First, we sample a sequence of tags $\boldsymbol{m}$, each morphological tag coming from a language model over morphological tags: $m_i \sim p_{\boldsymbol{\theta}}(\cdot \mid \boldsymbol{m}_{<i})$. Next, we sample the sequence of lemmata $\boldsymbol{\ell}$ given the previously sampled sequence of tags $\boldsymbol{m}$— these are sampled conditioned only on the corresponding morphological tag: $\ell_i \sim p_{\boldsymbol{\theta}}(\cdot \mid m_i)$. Finally, we sample the sequence of inflected words $\boldsymbol{f}$, where, again, each word is chosen conditionally independent of other elements of the sequence: $f_i \sim p_{\boldsymbol{\theta}}(\cdot \mid \ell_i, m_i)$.[4] This yields the factorized joint distribution:

$$p_{\boldsymbol{\theta}}(\boldsymbol{f}, \boldsymbol{\ell}, \boldsymbol{m}) = \tag{1}$$
$$\left(\prod_{i=1}^{|\boldsymbol{f}|} \underbrace{p_{\boldsymbol{\theta}}(f_i \mid \ell_i, m_i)}_{\substack{\textit{morphological inflector} \\ \textcircled{3}}} \cdot \underbrace{p_{\boldsymbol{\theta}}(\ell_i \mid m_i)}_{\substack{\textit{lemma generator} \\ \textcircled{2}}} \right) \cdot \underbrace{p_{\boldsymbol{\theta}}(\boldsymbol{m})}_{\substack{\textit{m-tag LM} \\ \textcircled{1}}}$$

We depict the corresponding directed graphical model in Fig. 1.

[4]Note that we denote all three distributions as $p_{\boldsymbol{\theta}}$ to simplify notation and emphasize the joint modeling aspect; context will always resolve the ambiguity in this paper. We will discuss their parameterization in §4.

Relation to Other Models in NLP. As the graphical model drawn in Fig. 1 shows, our model is quite similar to a Hidden Markov Model (HMM) (Rabiner, 1989). There are two primary differences. First, we remark that an HMM directly emits a form f_i conditioned on the tag m_i. Our model, in contrast, emits a lemma ℓ_i conditioned on the morphological tag m_i and, then, conditioned on both the lemma ℓ_i and the tag m_i, we emit the inflected form f_i. In this sense, our model resembles the hierarchical HMM of Fine et al. (1998) with the difference that we do not have interdependence between the lemmata ℓ_i. The second difference is that our model is non-Markovian: we sample the i^{th} morphological tag m_i from a distribution that depends on *all* previous tags, using an LSTM language model (§4.1). This yields richer interactions among the tags, which may be necessary for modeling long-distance agreement phenomena.

Why a Generative Model? What is our interest in a generative model of inflected forms? Eq. (1) is a syntax-only language model in that it only allows for interdependencies between the morpho-syntactic tags in $p_{\boldsymbol{\theta}}(\boldsymbol{m})$. However, given a tag sequence $\boldsymbol{m}$, the individual lemmata and forms are *conditionally independent*. This prevents the model from learning notions such as semantic frames and topicality. So what is this model good for? Our chief interest is the ability to *train a morphological inflector on unlabeled data*, which is a boon in a low-resource setting. As the model is generative, we may consider the latent-variable model:

$$p_{\boldsymbol{\theta}}(\boldsymbol{f}) = \sum_{\langle \boldsymbol{\ell}, \boldsymbol{m} \rangle} p_{\boldsymbol{\theta}}(\boldsymbol{f}, \boldsymbol{\ell}, \boldsymbol{m}), \tag{2}$$

where we marginalize out the latent lemmata and morphological tags from raw text. The sum in Eq. (2) is unabashedly intractable—given a sequence $\boldsymbol{f}$, it involves consideration of an exponential (in $|\boldsymbol{f}|$) number of tag sequences and an *infinite* number of lemmata sequences. Thus, we will fall back on an approximation scheme (see §5).

4 Recurrent Neural Parameterization

The graphical model from §3 specifies a family of models that obey the conditional independence assumptions dictated by the graph in Fig. 1. In this section we define a specific parameterization using long short-term memory (LSTM) recurrent neural network (Hochreiter and Schmidhuber, 1997) language models (Sundermeyer et al., 2012).

4.1 LSTM Language Models

Before proceeding, we review the modeling of sequences with LSTM language models. Given some alphabet Δ, the distribution over sequences $\mathbf{x} \in \Delta^*$ can be defined as follows:

$$p(\mathbf{x}) = \prod_{j=1}^{|\mathbf{x}|} p(x_j \mid \mathbf{x}_{<j}), \tag{3}$$

where $\mathbf{x}_{<j} = x_1, \ldots, x_{j-1}$. The prediction at time step j of a single element x_j is then parametrized by a neural network:

$$p(x_j \mid \mathbf{x}_{<j}) = \text{softmax}\left(\mathbf{W} \cdot \mathbf{h}_j + \mathbf{b}\right), \tag{4}$$

where $\mathbf{W} \in \mathbb{R}^{|\Delta| \times d}$ and $\mathbf{b} \in \mathbb{R}^{|\Delta|}$ are learned parameters (for some number of hidden units d) and the hidden state $\mathbf{h}_j \in \mathbb{R}^d$ is defined through the recurrence given by Hochreiter and Schmidhuber (1997) from the previous hidden state and an embedding of the previous character (assuming some learned embedding function $\mathbf{e}\colon \Delta \to \mathbb{R}^c$ for some number of dimensions c):

$$\mathbf{h}_j = \text{LSTM}\big(\mathbf{h}_{j-1},\, \mathbf{e}(x_{j-1})\big) \tag{5}$$

4.2 Our Conditional Distributions

We discuss each of the factors in Eq. (1) in turn.

① **Morphological Tag Language Model: $p_{\boldsymbol{\theta}}(\boldsymbol{m})$.** We define $p_{\boldsymbol{\theta}}(\boldsymbol{m})$ as an LSTM language model, as defined in §4.1, where we take $\Delta = \mathcal{M}$, i.e., the elements of the sequence that are to be predicted are tags like $\left[\text{POS=V, TNS=GERUND}\right]$. Note that the embedding function $\mathbf{e}$ does not treat them as atomic units, but breaks them up into individual attribute-value pairs that are embedded individually and then summed to yield the final vector representation. To be precise, each tag is first encoded by a multi-hot vector, where each component corresponds to a attribute-value pair in the slot, and then this multi-hot vector is multiplied with an embedding matrix.

② **Lemma Generator: $p_{\boldsymbol{\theta}}(\ell_i \mid m_i)$.** The next distribution in our model is a lemma generator which we define to be a *conditional* LSTM language model over characters (we take $\Delta = \Sigma$), i.e., each x_i is a single (orthographic) character. The language model is conditioned on t_i (the part-of-speech information contained in the morphological tag $m_i = \langle t_i, \sigma_i \rangle$), which we embed into a low-dimensional space and feed to the LSTM by concatenating its embedding with that of the current character. Thusly, we obtain the new recurrence relation for the hidden state:

$$\mathbf{h}_j = \text{LSTM}\Big(\mathbf{h}_{j-1},\, \Big[\,\mathbf{e}\big([\ell_i]_{j-1}\big)\,;\,\mathbf{e}'\big(t_i\big)\,\Big]\Big), \tag{6}$$

where $[\ell_i]_j$ denotes the j^{th} character of the generated lemma ℓ_i and $\mathbf{e}' : \mathcal{T} \to \mathbb{R}^{c'}$ for some c' is a learned embedding function for POS tags. Note that we embed only the POS tag, rather than the entire morphological tag, as we assume the lemma depends on the part of speech exclusively.

③ **Morphological Inflector: $p_{\boldsymbol{\theta}}(f_i \mid \ell_i, m_i)$.** The final conditional in our model is a morphological inflector, which we parameterize as a neural recurrent sequence-to-sequence model (Sutskever et al., 2014) with Luong dot-style attention (Luong et al., 2015). Our particular model uses a single encoder-decoder architecture (Kann and Schütze, 2016) for all tag pairs within a language and we refer to reader to that paper for further details. Concretely, the encoder runs over a string consisting of the desired slot and all characters of the lemma that is to be inflected (e.g. `<w> V PST t a l k </w>`), one LSTM running left-to-right, the other right-to-left. Concatenating the hidden states of both RNNs at each time step results in hidden states $\mathbf{h}_j^{(enc)}$. The decoder, again, takes the form of an LSTM language model (we take $\Delta = \Sigma$), producing the inflected form character by character, but at each time step not only the previous hidden state and the previously generated token are considered, but attention (a convex combination) over all encoder hidden states $\mathbf{h}_j^{(\text{enc})}$, with the distribution given by another neural network; see Luong et al. (2015).

5 Semi-Supervised Wake-Sleep

We train the model with the wake-sleep procedure, which requires us to perform posterior inference over the latent variables. However, the exact computation in the model is intractable—it involves a sum over all possible lemmatizations and taggings of the sentence, as shown in Eq. (2). Thus, we fall back on a variational approximation (Jordan et al., 1999). We train an **inference network** $q_{\boldsymbol{\phi}}(\boldsymbol{\ell}, \boldsymbol{m} \mid \boldsymbol{f})$ that approximates the true posterior over the latent variables $p_{\boldsymbol{\theta}}(\boldsymbol{\ell}, \boldsymbol{m} \mid \boldsymbol{f})$.[5] The variational family we choose in this work will be

[5]Inference networks are also known as **stochastic inverses** (Stuhlmüller et al., 2013) or **recognition models** (Dayan et al., 1995).

detailed in §5.5. We fit the distribution q_{ϕ} using a semi-supervised extension of the wake-sleep algorithm (Hinton et al., 1995; Dayan et al., 1995; Bornschein and Bengio, 2014). We derive the algorithm in the following subsections and provide pseudo-code in Alg. 1.

Note that the wake-sleep algorithm shows structural similarities to the expectation-maximization (EM) algorithm (Dempster et al., 1977), and, presaging the exposition, we note that the wake-sleep procedure is a type of variational EM (Beal, 2003). The key difference is that the E-step minimizes an inclusive KL divergence, rather than the exclusive one typically found in variational EM.

5.1 Data Requirements of Wake-Sleep

We emphasize again that we will train our model in a semi-supervised fashion. Thus, we will assume a set of labeled sentences, $\mathcal{D}_{labeled}$, represented as a set of triples $\langle \boldsymbol{f}, \boldsymbol{\ell}, \boldsymbol{m} \rangle$, and a set of unlabeled sentences, $\mathcal{D}_{unlabeled}$, represented as a set of surface form sequences $\boldsymbol{f}$.

5.2 The Sleep Phase

Wake-sleep first dictates that we find an approximate posterior distribution q_{ϕ} that minimizes the KL divergences for all form sequences:

$$D_{KL}\Big(\underbrace{p_{\boldsymbol{\theta}}(\cdot,\cdot,\cdot)}_{\textit{full joint: Eq. (1)}} \;||\; \underbrace{q_{\phi}(\cdot,\cdot\mid\cdot)}_{\textit{variational approximation}} \Big) \quad (7)$$

with respect to the parameters ϕ, which control the variational approximation q_{ϕ}. Because q_{ϕ} is trained to be a variational approximation for *any* input $\boldsymbol{f}$, it is called an inference network. In other words, it will return an approximate posterior over the latent variables for any observed sequence. Importantly, note that computation of Eq. (7) is still hard—it requires us to normalize the distribution $p_{\boldsymbol{\theta}}$, which, in turn, involves a sum over all lemmatizations and taggings. However, it does lend itself to an efficient Monte Carlo approximation. As our model is fully generative and directed, we may easily take samples from the complete joint. Specifically, we will take K samples $\langle \tilde{\boldsymbol{f}}, \tilde{\boldsymbol{\ell}}, \tilde{\boldsymbol{m}} \rangle \sim p_{\boldsymbol{\theta}}(\cdot,\cdot,\cdot)$ by forward sampling and define them as $\widetilde{\mathcal{D}}_{sleep}$. We remark that we use a tilde to indicate that a form, lemmata or tag is sampled, rather than human annotated. Using K samples, we obtain the objective

$$\mathcal{S}_{unsup} = {}^{1}\!/_{K} \cdot \sum_{\langle \tilde{\boldsymbol{f}}, \tilde{\boldsymbol{\ell}}, \tilde{\boldsymbol{m}} \rangle \in \widetilde{\mathcal{D}}_{sleep}} \log q_{\phi}(\tilde{\boldsymbol{\ell}}, \tilde{\boldsymbol{m}} \mid \tilde{\boldsymbol{f}}), \quad (8)$$

which we could maximize by fitting the model q_{ϕ} through backpropagation (Rumelhart et al., 1986), as one would during maximum likelihood estimation.

5.3 The Wake Phase

Now, given our approximate posterior $q_{\phi}(\boldsymbol{\ell}, \boldsymbol{m} \mid \boldsymbol{f})$, we are in a position to re-estimate the parameters of the generative model $p_{\boldsymbol{\theta}}(\boldsymbol{f}, \boldsymbol{\ell}, \boldsymbol{m})$. Given a set of unannotated sentences $\mathcal{D}_{unlabeled}$, we again first consider the objective

$$\mathcal{W}_{unsup} = {}^{1}\!/_{M} \cdot \sum_{\langle \boldsymbol{f}, \tilde{\boldsymbol{\ell}}, \tilde{\boldsymbol{m}} \rangle \in \widetilde{\mathcal{D}}_{wake}} \log p_{\boldsymbol{\theta}}(\boldsymbol{f}, \tilde{\boldsymbol{\ell}}, \tilde{\boldsymbol{m}}) \quad (9)$$

where $\widetilde{\mathcal{D}}_{wake}$ is a set of triples $\langle \boldsymbol{f}, \tilde{\boldsymbol{\ell}}, \tilde{\boldsymbol{m}} \rangle$ with $\boldsymbol{f} \in \mathcal{D}_{unlabeled}$ and $\langle \tilde{\boldsymbol{\ell}}, \tilde{\boldsymbol{m}} \rangle \sim q_{\phi}(\cdot,\cdot \mid \boldsymbol{f})$, maximizing with respect to the parameters $\boldsymbol{\theta}$ (we may stochastically backprop through the expectation simply by backpropagating through this sum). Note that Eq. (9) is a Monte Carlo approximation of the inclusive divergence of the data distribution of $\mathcal{D}_{unlabeled}$ times q_{ϕ} with $p_{\boldsymbol{\theta}}$.

5.4 Adding Supervision to Wake-Sleep

So far we presented a purely unsupervised training method that makes no assumptions about the latent lemmata and morphological tags. In our case, however, we have a very clear idea what the latent variables should look like. For instance, we are quite certain that the lemma of talking is talk and that it is in fact a GERUND. And, indeed, we have access to annotated examples $\mathcal{D}_{labeled}$ in the form of an annotated corpus. In the presence of these data, we optimize the supervised sleep phase objective,

$$\mathcal{S}_{sup} = {}^{1}\!/_{N} \cdot \sum_{\langle \boldsymbol{f}, \boldsymbol{\ell}, \boldsymbol{m} \rangle \in \mathcal{D}_{labeled}} \log q_{\phi}(\boldsymbol{\ell}, \boldsymbol{m} \mid \boldsymbol{f}). \quad (10)$$

which is a Monte Carlo approximation of $D_{KL}(\mathcal{D}_{labeled} \mid\mid q_{\phi})$. Thus, when fitting our variational approximation q_{ϕ}, we will optimize a joint objective $\mathcal{S} = \mathcal{S}_{sup} + \gamma_{sleep} \cdot \mathcal{S}_{unsup}$, where $\mathcal{S}_{sup}$, to repeat, uses actual annotated lemmata and morphological tags; we balance the two parts of the objective with a scaling parameter γ_{sleep}. Note that on the first sleep phase iteration, we set $\gamma_{sleep} = 0$ since taking samples from an untrained $p_{\boldsymbol{\theta}}(\cdot,\cdot,\cdot)$ when we have available labeled data is of little utility. We will discuss the provenance of our data in §7.2.

Likewise, in the wake phase we can neglect the approximation q_{ϕ} in favor of the annotated latent

Algorithm 1 semi-supervised wake-sleep

```
1: input $\mathcal{D}_{labeled}$                    ▷ labeled training data
2: input $\mathcal{D}_{unlabeled}$                  ▷ unlabeled training data
3: for $i = 1$ to $I$ do
4:     $\widetilde{\mathcal{D}}_{sleep} \leftarrow \emptyset$
5:     if $i > 1$ then
6:         for $k = 1$ to $K$ do
7:             $\langle \tilde{\boldsymbol{f}}, \tilde{\boldsymbol{\ell}}, \tilde{\boldsymbol{m}} \rangle \sim p_{\boldsymbol{\theta}}(\cdot, \cdot, \cdot)$
8:             $\widetilde{\mathcal{D}}_{sleep} \leftarrow \widetilde{\mathcal{D}}_{sleep} \cup \{\langle \tilde{\boldsymbol{f}}, \tilde{\boldsymbol{\ell}}, \tilde{\boldsymbol{m}} \rangle\}$
9:     maximize $\log q_{\boldsymbol{\phi}}$ on $\mathcal{D}_{labeled} \cup \widetilde{\mathcal{D}}_{sleep}$
                                  ▷ this corresponds to Eq. (10) + Eq. (8)
10:    $\widetilde{\mathcal{D}}_{wake} \leftarrow \emptyset$
11:    for $\boldsymbol{f} \in \mathcal{D}_{unlabeled}$ do
12:        $\langle \tilde{\boldsymbol{\ell}}, \tilde{\boldsymbol{m}} \rangle \sim q_{\boldsymbol{\phi}}(\cdot, \cdot \mid \boldsymbol{f})$
13:        $\widetilde{\mathcal{D}}_{wake} \leftarrow \widetilde{\mathcal{D}}_{wake} \cup \{\langle \boldsymbol{f}, \tilde{\boldsymbol{\ell}}, \tilde{\boldsymbol{m}} \rangle\}$
14:    maximize $\log p_{\boldsymbol{\theta}}$ on $\mathcal{D}_{labeled} \cup \widetilde{\mathcal{D}}_{wake}$
                                  ▷ this corresponds to Eq. (11) + Eq. (9)
```

variables found in $\mathcal{D}_{labeled}$; this leads to the following supervised objective

$$\mathcal{W}_{sup} = {}^{1}\!/\!{}_{N} \cdot \sum_{\langle \boldsymbol{f}, \boldsymbol{\ell}, \boldsymbol{m} \rangle \in \mathcal{D}_{labeled}} \log p_{\boldsymbol{\theta}}(\boldsymbol{f}, \boldsymbol{\ell}, \boldsymbol{m}), \qquad (11)$$

which is a Monte Carlo approximation of $D_{KL}(\mathcal{D}_{labeled} \mid\mid p_{\boldsymbol{\theta}})$. As in the sleep phase, we will maximize $\mathcal{W} = \mathcal{W}_{sup} + \gamma_{wake} \cdot \mathcal{W}_{unsup}$, where γ_{wake} is, again, a scaling parameter.

5.5 Our Variational Family

How do we choose the variational family $q_{\boldsymbol{\phi}}$? In terms of NLP nomenclature, $q_{\boldsymbol{\phi}}$ represents a joint morphological tagger and lemmatizer. The open-source tool LEMMING (Müller et al., 2015) represents such an object. LEMMING is a higher-order linear-chain conditional random field (CRF; Lafferty et al., 2001), that is an extension of the morphological tagger of Müller et al. (2013). Interestingly, LEMMING is a linear model that makes use of simple character n-gram feature templates. On both the tasks of morphological tagging and lemmatization, neural models have supplanted linear models in terms of performance in the high-resource case (Heigold et al., 2017). However, we are interested in producing an accurate approximation to the posterior in the presence of minimal annotated examples and potentially noisy samples produced during the sleep phase, where linear models still outperform non-linear approaches (Cotterell and Heigold, 2017). We note that our variational approximation is compatible with any family.

5.6 Interpretation as an Autoencoder

We may also view our model as an autoencoder, following Kingma and Welling (2013), who saw that a variational approximation to any generative model naturally has this interpretation. The crucial difference between Kingma and Welling (2013) and this work is that our model is a **structured** variational autoencoder in the sense that the space of our latent code is structured: the inference network encodes a sentence into a pair of lemmata and morphological tags $\langle \boldsymbol{\ell}, \boldsymbol{m} \rangle$. This bisequence is then decoded back into the sequence of forms $\boldsymbol{f}$ through a morphological inflector. The reason the model is called an autoencoder is that we arrive at an auto-encoding-like objective if we combine the $p_{\boldsymbol{\theta}}$ and $q_{\boldsymbol{\phi}}$ as so:

$$p(\boldsymbol{f} \mid \hat{\boldsymbol{f}}) = \sum_{\langle \boldsymbol{\ell}, \boldsymbol{m} \rangle} p_{\boldsymbol{\theta}}(\boldsymbol{f} \mid \boldsymbol{\ell}, \boldsymbol{m}) \cdot q_{\boldsymbol{\phi}}(\boldsymbol{\ell}, \boldsymbol{m} \mid \hat{\boldsymbol{f}}) \qquad (12)$$

where $\hat{\boldsymbol{f}}$ is a copy of the original sentence $\boldsymbol{f}$.

Note that this choice of latent space sadly precludes us from making use of the *reparametrization trick* that makes inference in VAEs particularly efficient. In fact, our whole inference procedure is quite different as we do not perform gradient descent on both $q_{\boldsymbol{\phi}}$ and $p_{\boldsymbol{\theta}}$ jointly but alternatingly optimize both (using wake-sleep). We nevertheless call our model a VAE to uphold the distinction between the VAE as a model (essentially a specific Helmholtz machine (Dayan et al., 1995), justified by variational inference) and the end-to-end inference procedure that is commonly used.

Another way of viewing this model is that it tries to force the words in the corpus through a syntactic bottleneck. Spiritually, our work is close to the conditional random field autoencoder of Ammar et al. (2014).

We remark that many other structured NLP tasks can be “autoencoded” in this way and, thus, trained by a similar wake-sleep procedure. For instance, any two tasks that effectively function as inverses, e.g., translation and backtranslation, or language generation and parsing, can be treated with a similar variational autoencoder. While this work only focuses on the creation of an improved morphological inflector $p_{\boldsymbol{\theta}}(\boldsymbol{f} \mid \boldsymbol{\ell}, \boldsymbol{m})$, one could imagine a situation where the encoder was also a task of interest. That is, the goal would be to improve both the decoder (the generation model) *and* the encoder (the variational approximation).

6 Related Work

Closest to our work is Zhou and Neubig (2017), who describe an unstructured variational autoencoder. However, the exact use case of our respective models is distinct. Our method models the syntactic dynamics with an LSTM language model over morphological tags. Thus, in the semi-supervised setting, we require token-level annotation. Additionally, our latent variables are interpretable as they correspond to well-understood linguistic quantities. In contrast, Zhou and Neubig (2017) infer latent lemmata as real vectors. To the best of our knowledge, we are only the second attempt, after Zhou and Neubig (2017), to attempt to perform semi-supervised learning for a neural inflection generator. Other non-neural attempts at semi-supervised learning of morphological inflectors include Hulden et al. (2014). Models in this vein are non-neural and often focus on exploiting corpus statistics, e.g., token frequency, rather than explicitly modeling the forms in context. All of these approaches are designed to learn from a type-level lexicon, rendering direct comparison difficult.

7 Experiments

While we estimate all the parameters in the generative model, the purpose of this work is to improve the performance of morphological inflectors through semi-supervised learning with the incorporation of unlabeled data.

7.1 Low-Resource Inflection Generation

The development of our method was primarily aimed at the low-resource scenario, where we observe a limited number of annotated data points. Why low-resource? When we have access to a preponderance of data, morphological inflection is close to being a solved problem, as evinced in SIGMORPHON's 2016 shared task. However, the CoNLL-SIGMORPHON 2017 shared task showed there is much progress to be made in the low-resource case. Semi-supervision is a clear avenue.

7.2 Data

As our model requires *token-level* morphological annotation, we perform our experiments on the Universal Dependencies (UD) dataset (Nivre et al., 2017). As this stands in contrast to most work on morphological inflection (which has used the UniMorph (Sylak-Glassman et al., 2015)[6] datasets), we use a converted version of UD data, in which the UD morphological tags have been deterministically converted into UniMorph tags.

For each of the treebanks in the UD dataset, we divide the training portion into three chunks consisting of the first 500, 1000 and 5000 tokens, respectively. These *labeled* chunks will constitute three unique sets $\mathcal{D}_{labeled}$. The remaining sentences in the training portion will be used as *unlabeled* data $\mathcal{D}_{unlabeled}$ for each language, i.e., we will discard those labels. The development and test portions will be left untouched.

Languages. We explore a typologically diverse set of languages of various stocks: Indo-European, Afro-Asiatic, Turkic and Finno-Ugric, as well as the language isolate Basque. We have organized our experimental languages in Tab. 3 by genetic grouping, highlighting sub-families where possible. The Indo-European languages mostly exhibit fusional morphologies of varying degrees of complexity. The Basque, Turkic, and Finno-Ugric languages are agglutinative. Both of the Afro-Asiatic languages, Arabic and Hebrew, are Semitic and have templatic morphology with fusional affixes.

7.3 Evaluation

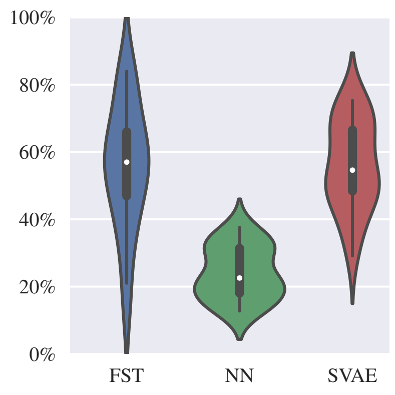
The end product of our procedure is a morphological inflector, whose performance is to be improved through the incorporation of unlabeled data. Thus, we evaluate using the standard metric accuracy. We will evaluate at the *type level*, as is traditional in the morphological inflection literature, even though the UD treebanks on which we evaluate are *token-level* resources. Concretely, we compile an incomplete type-level morphological lexicon from the token-level resource. To create this resource, we gather all unique form-lemma-tag triples $\langle f, \ell, m\rangle$ present in the UD test data.[7]

7.4 Baselines

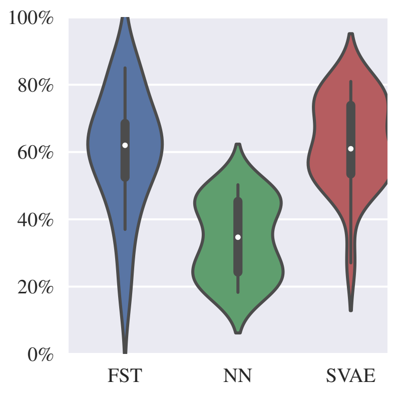
As mentioned before, most work on morphological inflection has considered the task of estimating statistical inflectors from type-level lexicons. Here, in

[6]The two annotation schemes are similar. For a discussion, we refer the reader to `http://universaldependencies.org/v2/features.html`; sadly there are differences that render all numbers reported in this work incomparable with previous work, see §7.4.

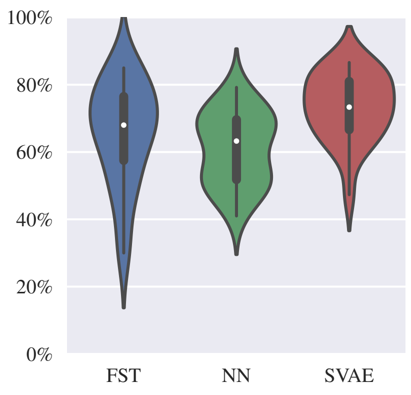
[7]Some of these form-lemma-tag triples will overlap with those seen in the training data.



(a) 500 training tokens



(b) 1000 training tokens



(c) 5000 training tokens

Figure 2: Violin plots showing the distribution over accuracies. The structured variational autoencoder (SVAE) always outperforms the neural network (NN), but only outperformed the FST-based approach when trained on 5000 annotated tokens. Thus, while semi-supervised training helps neural models reduce their sample complexity, roughly 5000 annotated tokens are still required to boost their performance above more symbolic baselines.

contrast, we require token-level annotation to estimate our model. For this reason, there is neither a competing approach whose numbers we can make a fair comparison to nor is there an open-source system we could easily run in the token-level setting. This is why we treat our token-level data as a list of "types"[8] and then use two simple type-based baselines.

First, we consider the probabilistic finite-state transducer used as the baseline for the CoNLL-SIGMORPHON 2017 shared task.[9] We consider this a relatively strong baseline, as we seek to generalize from a minimal amount of data. As described by Cotterell et al. (2017), the baseline performed quite competitively in the task's low-resource setting. Note that the finite-state machine is created by heuristically extracting prefixes and suffixes from the word forms, based on an unsupervised alignment step. The second baseline is our neural inflector $p(f \mid \ell, m)$ given in §4 *without* the semi-supervision; this model is state-of-the-art on the high-resource version of the task.

We will refer to our baselines as follows: **FST** is the probabilistic transducer, **NN** is the neural sequence-to-sequence model *without* semi-supervision, and **SVAE** is the structured variational autoencoder, which is equivalent to **NN** but also trained using wake-sleep and unlabeled data.

[8]Typical type-based inflection lexicons are likely not i.i.d. samples from natural utterances, but we have no other choice if we want to make use of only our token-level data and not additional resources like frequency and regularity of forms.

7.5 Results

We ran the three models on 23 languages with the hyperparameters and experimental details described in App. A. We present our results in Fig. 2 and in Tab. 3. We also provide sample output of the generative model created using the dream step in App. B. The high-level take-away is that on almost all languages we are able to exploit the unlabeled data to improve the sequence-to-sequence model using unlabeled data, i.e., SVAE outperforms the NN model on *all* languages across *all* training scenarios. However, in many cases, the FST model is a better choice—the FST can sometimes generalize better from a handful of supervised examples than the neural network, even with semi-supervision (SVAE). We highlight three finer-grained observations below.

Observation 1: FST Good in Low-Resource. As clearly evinced in Fig. 2, the baseline FST is still competitive with the NN, or even our SVAE when data is extremely scarce. Our neural architecture is quite general, and lacks the prior knowledge and inductive biases of the rule-based system, which become more pertinent in low-resource scenarios. Even though our semi-supervised strategy clearly improves the performance of NN, we cannot always recommend SVAE for the case when we only have 500 annotated tokens, but on average it does slightly better. The SVAE surpasses the FST when moving up to 1000 annotated tokens, becoming even more pronounced at 5000 annotated tokens.

		500 tokens					1000 tokens					5000 tokens

Table 3: Type-level morphological inflection accuracy across different models, training scenarios, and languages

Observation 2: Agglutinative Languages. The next trend we remark upon is that languages of an agglutinating nature tend to benefit more from the semi-supervised learning. Why should this be? Since in our experimental set-up, every language sees the *same number of tokens*, it is naturally harder to generalize on languages that have more distinct morphological variants. Also, by the nature of agglutinative languages, relevant morphemes could be arbitrarily far from the edges of the string, making the (NN and) SVAE's ability to learn more generic rules even more valuable.

Observation 3: Non-concatenative Morphology. One interesting advantage that the neural models have over the FSTs is the ability to learn non-concatenative phenomena. The FST model is based on prefix and suffix rewrite rules and, naturally, struggles when the correctly reinflected form is more than the concatenation of these parts. Thus we see that for the two semitic language, the SVAE is the best method across all resource settings.

8 Conclusion

We have presented a novel generative model for morphological inflection generation in context. The model allows us to exploit unlabeled data in the training of morphological inflectors. As the model's rich parameterization prevents tractable inference, we craft a variational inference procedure, based on the wake-sleep algorithm, to marginalize out the latent variables. Experimentally, we provide empirical validation on 23 languages. We find that, especially in the lower-resource conditions, our model improves by large margins over the baselines.

Morphosyntactic Tagging with a Meta-BiLSTM Model over Context Sensitive Token Encodings

Abstract

The rise of neural networks, and particularly recurrent neural networks, has produced significant advances in part-of-speech tagging accuracy (Zeman et al., 2017). One characteristic common among these models is the presence of rich initial word encodings. These encodings typically are composed of a recurrent character-based representation with learned and pre-trained word embeddings. However, these encodings do not consider a context wider than a single word and it is only through subsequent recurrent layers that word or sub-word information interacts. In this paper, we investigate models that use recurrent neural networks with sentence-level context for initial character and word-based representations. In particular we show that optimal results are obtained by integrating these context sensitive representations through synchronized training with a meta-model that learns to combine their states. We present results on part-of-speech and morphological tagging with state-of-the-art performance on a number of languages.

1 Introduction

Morphosyntactic tagging accuracy has seen dramatic improvements through the adoption of recurrent neural networks—specifically BiLSTMs (Schuster and Paliwal, 1997; Graves and Schmidhuber, 2005) to create sentence-level context sensitive encodings of words. A successful recipe is to first create an initial context insensitive word representation, which usually has three main parts: 1) A dynamically trained word embedding; 2) a fixed pre-trained word-embedding, induced from a large corpus; and 3) a sub-word character model, which itself is usually the final state of a recurrent model that ingests one character at a time. Such word/sub-word models originated with Plank et al. (2016). Recently, Dozat et al. (2017) used precisely such a context insensitive word representation as input to a BiLSTM in order to obtain context sensitive word encodings used to predict part-of-speech tags. The Dozat et al. model had the highest accuracy of all participating systems in the CoNLL 2017 shared task (Zeman et al., 2017).

In such a model, sub-word character-based representations only interact indirectly via subsequent recurrent layers. For example, consider the sentence *I had shingles, which is a painful disease*. Context insensitive character and word representations may have learned that for unknown or infrequent words like ‘shingles’, ‘s’ and more so ‘es’ is a common way to end a plural noun. It is up to the subsequent BiLSTM layer to override this once it sees the singular verb is to the right. Note that this differs from traditional linear models where word and sub-word representations are directly concatenated with similar features in the surrounding context (Giménez and Marquez, 2004).

In this paper we aim to investigate to what extent having initial sub-word and word context insensitive representations affects performance. We propose a novel model where we learn context sensitive initial character and word representations through two separate sentence-level recurrent models. These are then combined via a meta-BiLSTM model that builds a unified representation of each word that is then used for syntactic tagging. Critically, while each of these three models—character, word and meta—are trained synchronously, they are ultimately separate models using different network configurations, training hyperparameters and loss functions. Empirically, we found this optimal as it allowed control over the fact that each representation has a different learning capacity.

We tested the system on the 2017 CoNLL shared task data sets and gain improvements compared to the top performing systems for the majority of languages for part-of-speech and morphological tagging. As we will see, a pattern emerged where gains were largest for morphologically rich languages, especially those in the Slavic family group. We also applied the approach to the benchmark English PTB data, where our model achieved 97.9 using the standard train/dev/test split, which constitutes a relative reduction in error of 12% over the previous best system.

2 Related Work

While sub-word representations are often attributed to the advent of deep learning in NLP, it was, in fact, commonplace for linear featurized machine learning methods to incorporate such representations. While the literature is too large to enumerate, Giménez and Marquez (2004) is a good example of an accurate linear model that uses both word and sub-word features. Specifically, like most systems of the time, they use n-gram affix features, which were made context sensitive via manually constructed conjunctions with features from other words in a fixed window.

Collobert and Weston (2008) was perhaps the first modern neural network for tagging. While this first study used only word embeddings, a subsequent model extended the representation to include suffix embeddings (Collobert et al., 2011).

The seminal dependency parsing paper of Chen and Manning (2014) led to a number of tagging papers that used their basic architecture of highly featurized (and embedded) feed-forward neural networks. Botha et al. (2017), for example, studied this architecture in a low resource setting using word, sub-word (prefix/suffix) and induced cluster features to obtain competitive accuracy with the state-of-the-art. Zhou et al. (2015), Alberti et al. (2015) and Andor et al. (2016) extended the work of Chen et al. to a structured prediction setting, the later two use again a mix of word and sub-word features.

The idea of using a recurrent layer over characters to induce a complementary view of a word has occurred in numerous papers. Perhaps the earliest is Santos and Zadrozny (2014) who compare character-based LSTM encodings to traditional word-based embeddings. Ling et al. (2015) take this a step further and combine the word embeddings with a recurrent character encoding of the word—instead of just relying on one or the other. Alberti et al. (2017) use characters encodings for parsing. Peters et al. (2018) show that contextual embeddings using character convolutions improve accuracy for number of NLP tasks. Plank et al. (2016) is probably the jumping-off point for most current architectures for tagging models with recurrent neural networks. Specifically, they used a combined word embedding and recurrent character encoding as the initial input to a BiLSTM that generated context sensitive word encodings. Though, like most previous studies, these initial encodings were context insensitive and relied on subsequent layers to encode sentence-level interactions.

Finally, Dozat et al. (2017) showed that subword/word combination representations lead to state-of-the-art morphosyntactic tagging accuracy across a number of languages in the CoNLL 2017 shared task (Zeman et al., 2017). Their word representation consisted of three parts: 1) A dynamically trained word embedding; 2) a fixed pretrained word embedding; 3) a character LSTM encoding that summed the final state of the recurrent model with vector constructed using an attention mechanism over all character states. Again, the initial representations are all context insensitive. As this model is currently the state-of-the-art in morphosyntactic tagging, it will serve as a baseline during our discussion and experiments.

3 Models

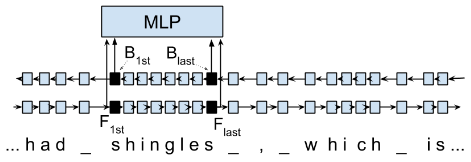
In this section, we introduce models that we investigate and experiment with in §4.

3.1 Sentence-based Character Model

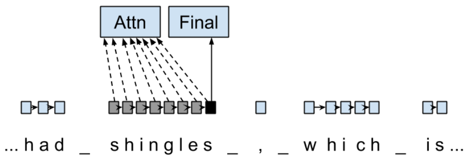
The feature that distinguishes our model most from previous work is that we apply a bidirectional recurrent layer (LSTM) on all characters of a sentence to induce fully context sensitive initial word encodings. That is, we do not restrict the context of this layer to the words themselves (as in Figure 1b). Figure 1a shows the sentence-based character model applied to an example token in context.

The character model uses, as input, sentences split into UTF8 characters. We include the spaces between the tokens[1] in the input and map each

[1]As input, we assume the sentence has been tok-



(a) Sentence-based Character Model. The representation for the token *shingles* is the concatenation of the four shaded boxes. Note the surrounding sentence context affects the representation.



(b) Token-based Character Model[a]. The token is represented by the concatenation of attention over the lightly shaded boxes with the final cell (dark shaded box). The rest of the sentence has no impact on the representation.

[a]This is specifically the model of Dozat et al. (2017).

Figure 1: Token representations are sensitive to the context in the sentence-based character model (§3.1) and are context-independent in the token-based character model (§3.2).

character to a dynamically learned embedding.

Next, a forward LSTM reads the characters from left to right and a backward LSTM reads sentences from right to left, in standard BiLSTM fashion.

More formally, for an n-character sentence, we apply for each character embedding $(e_1^{char}, ..., e_n^{char})$ a BiLSTM:

$$f_{c,i}^0, b_{c,i}^0 \quad = \quad \text{BiLSTM}(r_0, (e_1^{char}, ..., e_n^{char}))_i$$

As is also typical, we can have multiple such layers (l) that feed into each other through the concatenation of previous layer encodings. The last layer l has both forward $(f_{c,1}^l, ..., f_{c,n}^l)$ and backward $(b_{c,1}^l, ..., b_{c,n}^l)$ output vectors for each character.

To create word encodings, we need to combine a relevant subset of these context sensitive character encodings. These word encodings can then be used in a model that assigns morphosyntactic tags to each word directly or via subsequent layers. To accomplish this, the model concatenates up to four character output vectors: the {*forward*, *backward*} output of the {*first*, *last*} character in the token $(F_{1st}(w), F_{last}(w), B_{1st}(w), B_{last}(w))$. In Figure 1a, the four shaded boxes indicate these four outputs for the example token. Thus, the proposed model concatenates all four of these and passes it as input to an multilayer perceptron (MLP):

$$\begin{aligned} g_i \quad &= \quad \text{concat}(F_{1st}(w), F_{last}(w), \\ &\qquad B_{1st}(w), B_{last}(w)) \qquad (1) \\ m_i^{chars} \quad &= \quad \text{MLP}(g_i) \end{aligned}$$

A tag can then be predicted with a linear classifier that takes as input the output of the MLP m_i^{chars}, applies a softmax function and chooses for each word the tag with highest probability. Table 8 investigates the empirical impact of alternative definitions of g_i that concatenate only subsets of $\{F_{1st}(w), F_{last}(w), B_{1st}(w), B_{last}(w)\}$.

enized/segmented.

3.2 Word-based Character Model

To investigate whether a sentence sensitive character model is better than a character model where the context is restricted to the characters of a word, we reimplemented the word-based character model of Dozat et al. (2017) as shown in Figure 1a. This model uses the final state of a unidirectional LSTM over the characters of the word, combined with the attention mechanism of Cao and Rei (2016) over all characters. We refer the reader to those works for more details. Critically, however, all the information fed to this representation comes from the word itself, and not a wider sentence-level context.

3.3 Sentence-based Word Model

We used a similar setup for our context sensitive word encodings as the character encodings. There are a few differences. Obviously, the inputs are the words of the sentence. For each of the words, we use pretrained word embeddings $(p_1^{word}, ..., p_n^{word})$ summed with a dynamically learned word embedding for each word in the corpus $(e_1^{word}, ..., e_n^{word})$:

$$in_i^{word} = e_i^{word} + p_i^{word}$$

The summed embeddings in_i are passed as input to one or more BiLSTM layers whose output $f_{w,i}^l, b_{w,i}^l$ is concatenated and used as the final encoding, which is then passed to an MLP

$$o_i^{word} = \text{concat}(f_{w,i}^l, b_{w,i}^l)$$
$$m_i^{word} = \text{MLP}(o_i^{word})$$

It should be noted, that the output of this BiLSTM is essentially the Dozat et al. model before tag prediction, with the exception that the word-based character encodings are excluded.

3.4 Meta-BiLSTM: Model Combination

Given initial word encodings, both character and word-based, a common strategy is to pass these through a sentence-level BiLSTM to create context sensitive encodings, e.g., this is precisely what Plank et al. (2016) and Dozat et al. (2017) do. However, we found that if we trained each of the character-based and word-based encodings with their own loss, and combined them using an additional meta-BiLSTM model, we obtained optimal performance. In the meta-BiLSTM model, we concatenate the output, for each word, of its context sensitive character and word-based encodings, and put this through another BiLSTM to create an additional combined context sensitive encoding. This is followed by a final MLP whose output is passed to a linear layer for tag prediction.

$$\begin{aligned} cw_i &= \text{concat}(m_i^{char}, m_i^{word}) \\ f_{m,i}^l, b_{m,i}^l &= \text{BiLSTM}(r_0, (cw_0, ..., cw_n))_i \\ m_i^{comb} &= \text{MLP}(\text{concat}(f_{m,i}^l, b_{m,i}^l)) \end{aligned}$$

With this setup, each of the models can be optimized independently which we describe in more detail in §3.5. Figure 2b depicts the architecture of the combined system and contrasts it with that of the Dozat et al. model (Figure 2a).

3.5 Training Schema

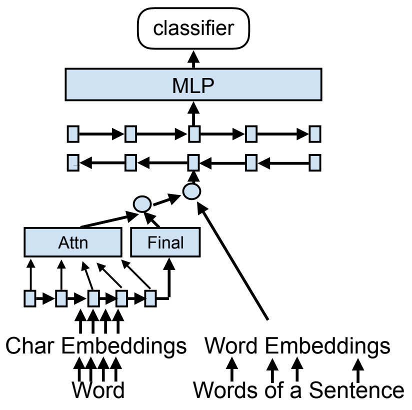
As mentioned in the previous section, the character and word-based encoding models have their own tagging loss functions, which are trained independently and joined via the meta-BiLSTM. I.e., the loss of each model is minimized independently by separate optimizers with their own hyperparameters. Thus, it is in some sense a multi-task learning model and we must define a schedule in which individual models are updated. We opted for a simple synchronous schedule outline in Algorithm 1. Here, during each epoch, we update each of the models in sequence—character, word and meta—using the entire training data.

In terms of model selection, after each epoch, the algorithm evaluates the tagging accuracy of the development set and keeps the parameters of the best model. Accuracy is measured using the meta-BiLSTM tagging layer, which requires a forward pass through all three models. Though we use all three losses to update the models, only the meta-BiLSTM layer is used for model selection and test-time prediction.

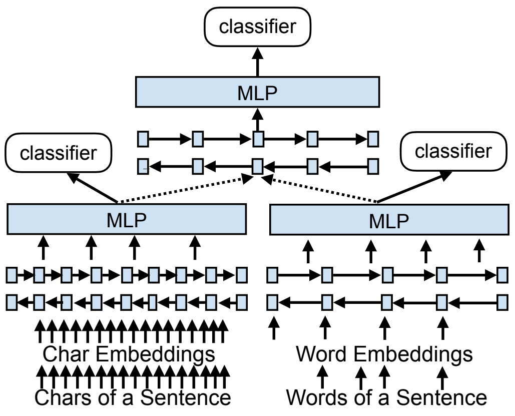
```
Data: train-corpus, dev-corpus
/* The following models are defined
   in §3.  */
Input: char-model, word-model, meta-model
/* Model optimizers */
Input: char-opt, word-opt, meta-opt
/* Results are parameter sets for
   each model.  */
Result: best-char, best-word, best-meta
/* Initialize parameter sets (cf.
   Table 1) */
Initialize($pa_c, pa_w, pa_m$)
/* Iteration on over training
   corpus.  */
for epoch = 1 to MAX do
    /* Update character model.  */
    char-logits, char-preds =
      char-model(train-corpus, $pa_c$)
    $pa_c$ = char-opt.update(char-preds, train-data)
    /* Update word model.  */
    word-logits, word-preds =
      word-model(train-corpus, $pa_w$)
    $pa_w$ = word-opt.update(char-preds, train-data)
    /* Update Meta-BiLSTM model.  */
    meta-preds = meta-model(train-corpus,
      $pa_c, pa_w, pa_m$)
    $pa_m$ = meta-opt.update(train-corpus,
      meta-preds)
    /* Evaluate model due to dev set
       accuracy.  */
    F1 = DevEval($par_c, par_w, par_m$)
    /* Keep the best model.  */
    if F1 > best-F1 then
        best-char = $pa_c$; best-word = $pa_w$
        best-meta = $pa_m$; best-F1 = F1
    end
end
```

Algorithm 1: Training procedure for learning initial character and word-based context sensitive encodings synchronously with meta-BiLSTM.

While each of the three models—character, word and meta—are trained with their own loss functions, it should be emphasized that training is synchronous in the sense that the meta-BiLSTM model is trained in tandem with the two encoding models, and not after those models have converged. Since accuracy from the meta-BiLSTM model on the development set determines the best parameters, training is not completely independent. We found this to improve accuracy overall. Crucially, when we allowed the meta-BiLSTM to back-propagate through the whole network, performance degraded regardless of whether one or multiple loss functions were used.



(a) The overall architecture of Dozat et al. (2017)



(b) The overall architecture of the system. The data flows along the arrows. The optimizers minimizes the loss of the classifiers independently and backpropagates along the bold arrows.

Figure 2: Tagging architectures. (a) Dozat et al. (2017); (b) Meta-BiLSTM architecture of this work.

Each language could in theory use separate hyperparameters, optimized for highest accuracy. However, for our main experiments we use identical settings for each language which worked well for large corpora and simplified things. We provide an overview of the selected hyperparameters in §4.1. We explored more settings for selected individual languages with a grid search and ablation experiments and present the results in §5.

4 Experiments and Results

In this section, we present the experimental setup and the selected hyperparameter for the main experiments where we use the CoNLL Shared Task 2017 treebanks and compare with the best systems of the shared task.

4.1 Experimental Setup

For our main results, we selected one network configuration and set of the hyperparameters. These settings are not optimal for all languages. However, since hyperparameter exploration is computationally demanding due to the number of languages we optimized these hyperparameters on initial development data experiments over a few languages. Table 1 shows an overview of the architecture, hyperparameters and the initialization settings of the network. The word embeddings are initialized with zero values and the pre-trained embeddings are not updated during training. The dropout used on the embeddings is achieved by a single dropout mask and we use dropout on the input and the states of the LSTM.

Architecture		
Model	**Parameter**	**Value**
Chr, Wrd	BiLSTM layers	3
Mt	BiLSTM layers	1
Chr, Wrd, Mt	BiLSTM size	400
Chr, Wrd, Mt	Dropout LSTMs	0.33
Chr, Wrd, Mt	Dropout MLP	0.33
Wrd	Dropout embeddings	0.33
Chr	Dropout embeddings	0.05
Chr, Wrd, Mt	Nonlinear act. (MLP)	ELU
Initialization		
Model	**Parameter**	**Value**
Wrd	embeddings	Zero
Chr	embeddings	Gaussian
Chr, Wrd, Mt	MLP	Gaussian
Training		
Model	**Parameter**	**Value**
Chr, Wrd, Mt	Optimizer	Adam
Chr, Wrd, Mt	Loss	Cross entropy
Chr, Wrd, Mt	Learning rate	0.002
Chr, Wrd, Mt	Decay	0.999994
Chr, Wrd, Mt	Adam epsilon	1e-08
Chr, Wrd, Mt	beta1	0.9
Chr, Wrd, Mt	beta2	0.999

Table 1: Selected hyperparameters and initialization of parameters for our models. *Chr*, *Wrd*, and *Mt* are used to indicate the character, word, and meta models respectively. The Gaussian distribution is used with a mean of 0 and variance of 1 to generate the random values.

As is standard, model selection was done measuring development accuracy/F1 score after each epoch and taking the model with maximum value on the development set.

4.2 Data Sets

For the experiments, we use the data sets as provided by the CoNLL Shared Task 2017 (Zeman et al., 2017). For training, we use the training sets which were denoted as big treebanks [2].

We followed the same methodology used in the CoNLL Shared Task. We use the training treebank for training only and the development sets for hyperparameter tuning and early stopping. To keep our results comparable with the Shared Task, we use the provided precomputed word embeddings. We excluded Gothic from our experiments as the available downloadable content did not include embeddings for this language.

As input to our system—for both part-of-speech tagging and morphological tagging—we use the output of the UDPipe-base baseline system (Straka and Straková, 2017) which provides segmentation. The segmentation differs from the gold segmentation and impacts accuracy negatively for a number of languages. Most of the top performing systems for part-of-speech tagging used as input UDPipe to obtain the segmentation for the input data. For morphology, the top system for most languages (IMS) used its own segmentation (Björkelund et al., 2017). For the evaluation, we used the official evaluation script (Zeman et al., 2017).

4.3 Part-of-Speech Tagging Results

In this section, we present the results of the application of our model to part-of-speech tagging. In our first experiment, we used our model in the setting of the CoNLL 2017 Shared Task to annotate words with XPOS[3] tags (Zeman et al., 2017). We compare our results against the top systems of the CoNLL 2017 Shared Task. Table 2 contains the results of this task for the large treebanks.

Because Dozat et al. (2017) won the challenge for the majority of the languages, we first compare our results with the performance of their system. Our model outperforms Dozat et al. (2017) in 32 of the 54 treebanks with 13 ties. These ties correspond mostly to languages where XPOS tagging anyhow obtains accuracies above 99%. Our model tends to produce better results, especially for morphologically rich languages (e.g. Slavic

[2]In the CONLL 2017 Shared Task, a big treebank is one that contains a development set. In total, there are 55 out of the 64 UD treebanks which are considered big treebanks.

[3]These are the language specific fine-grained part-of-speech tags from the Universal Dependency Treebanks.

Dozat et al. (2017)	97.41
ours	**97.96**

Table 3: Results on WSJ test set.

languages), whereas Dozat et al. (2017) showed higher performance in 10 languages in particular English, Greek, Brazilian Portuguese and Estonian.

4.4 Part-of-Speech Tagging on WSJ

We also performed experiments on the Penn Treebank with the usual split in train, development and test set. Table 3 shows the results of our model in comparison to the results reported in state-of-the-art literature. Our model significantly outperforms these systems, with an absolute difference of 0.32% in accuracy, which corresponds to a RRIE of 12%.

4.5 Morphological Tagging Results

In addition to the XPOS tagging experiments, we performed experiments with morphological tagging. This annotation was part of the CONLL 2017 Shared Task and the objective was to predict a bundle of morphological features for each token in the text. Our model treats the morphological bundle as one tag making the problem equivalent to a sequential tagging problem. Table 4 shows the results.

Our models tend to produce significantly better results than the winners of the CoNLL 2017 Shared Task (i.e., 1.8% absolute improvement on average, corresponding to a RRIE of 21.20%). The only cases for which this is not true are again languages that require significant segmentation efforts (i.e., Hebrew, Chinese, Vietnamese and Japanese) or when the task was trivial.

Given the fact that Dozat et al. (2017) obtained the best results in part-of-speech tagging by a significant margin in the CoNLL 2017 Shared Task, it would be expected that their model would also perform significantly well in morphological tagging since the tasks are very similar. Since they did not participate in this particular challenge, we decided to reimplement their system to serve

Table 4: Results for morphological features. The column **CoNLL Winner** shows the top system of the ST 17, the **DQM Reimpl.** shows our reimplementation of Dozat et al. (2017), the column **ours** shows our system with a sentence-based character model; **RRIE** gives the relative reduction in error between the Reimpl. DQM and sentence-based character system. Our system outperforms the CoNLL Winner by 48 out of 54 treebanks and the reimplementation of DQM, by 43 of 54 treebanks, with 6 ties.

as a strong baseline. As expected, our reimplementation of Dozat et al. (2017) tends to significantly outperform the winners of the CONLL 2017 Shared Task. However, in general, our models still obtain better results, outperforming Dozat et al. on 43 of the 54 treebanks, with an absolute difference of 0.42% on average.

5 Ablation Study

The model proposed in this paper of a Meta-BiLSTM with a sentence-based character model differs from prior work in multiple aspects. In this section, we perform ablations to determine the relative impact of each modeling decision.

For the experimental setup of the ablation experiments, we report accuracy scores for the development sets. We split off 5% of the sentences from each training corpus and we use this part for early stopping. Ablation experiments are either performed on a few selected treebanks to show individual language results or averaged across all treebanks for which tagging is non-trivial.

Impact of the Training Schema We first compare jointly training the three model components (Meta-BiLSTM, character model, word model) to training each separately. Table 5 shows that separately optimized models are significantly more accurate on average than jointly optimized models. Separate optimization leads to better accuracy for 34 out of 40 treebanks for the morphological features task and for 30 out of 39 treebanks for xpos tagging. Separate optimization outperformed joint optimization by up to 2.1 percent absolute, while joint never out-performed separate by more than 0.5% absolute. We hypothesize that separately training the models forces each submodel (word and character) to be strong enough to make high accuracy predictions and in some sense serves as a regularizer in the same way that dropout does for individual neurons.

Impact of the Sentence-based Character Model We compared the setup with sentence-based character context (Figure 1a) to word-based character context (Figure 1b). We selected for these experiments a number of morphological rich languages. The results are shown in Table 6. The accuracy of the word-based character model joint with a word-based model were significantly lower than a sentence-based character model. We conclude also from these results and comparing with results of the reimplementation of DQM that early integration of the word-based character model performs much better as late integration via Meta-BiLSTM for a word-based character model.

Optimization	Avg. F1 Score morphology	Avg. F1 Score xpos
separate	**94.57**	**94.85**
jointly	94.15	94.48

Table 5: Comparison of optimization methods: Separate optimization of the word, character and meta model is more accurate on average than full back-propagation using a single loss function.The results are statistically significant with two-tailed paired t-test for xpos with p<0.001 and for morphology with p <0.0001.

Table 7: F1 score for the character, word and joint models. The standard deviation of 10 random restarts of each model is show in the last three columns. The differences in means are all statistically significant at $p < 0.001$ (paired t-test).

Impact of the Meta-BiLSTM Model Combination The proposed model trains word and character models independently while training a joint model on top. Here we investigate the part-of-speech tagging performance of the joint model compared with the word and character models on their own (using hyperparameters from in 4.1).

Table 5 shows, for selected languages, the results averaged over 10 runs in order to measure standard deviation. The examples show that the combined model has significantly higher accuracy compared with either the character and word models individually.

dev. set. lang.	F_{last} B_{1st}	F_{1st} B_{last}	F_{last} B_{last}	F_{1st} B_{1st}	DQM	|xpos|

Table 8: F1 score of char models and their performance on the dev. set for selected languages with different gather strategies, concatenate to g_i (Equation 1). DQM shows results for our reimplementation of Dozat et al. (2017) (cf. §3.2), where we feed in only the characters. The final column shows the number of xpos tags in the training set.

Concatenation Strategies for the Context-Sensitive Character Encodings The proposed model bases a token encoding on both the forward and the backward character representations of both the first and last character in the token (see Equation 1). Table 8 reports, for a few morphological rich languages, the part-of-speech tagging performance of different strategies to gather the characters when creating initial word encodings. The strategies were defined in §3.1. The Table also contains a column with results for our reimplementation of Dozat et al. (2017). We removed, for all systems, the word model in order to assess each strategy in isolation. The performance is quite different per language. E.g., for Latin, the outputs of the forward and backward LSTMs of the last character scored highest.

Sensitivity to Hyperparameter Search We picked Vietnamese for a more in-depth analysis since it did not perform well and investigated the influence of the sizes of LSTMs for the word and character model on the accuracy of development set. With larger network sizes, the capacity of the network increases, however, on the other hand it is prune to overfitting. We fixed all the hyperparameters except those for the network size of the character model and the word model, and ran a grid search over dimension sizes from 200 to 500 in steps of 50. The surface plot in 3 shows that the grid peaks with more moderate settings around 350 LSTM cells which might lead to a higher accuracy. For all of the network sizes in the grid search, we still observed during training that the accuracy reach a high value and degrades with more iterations for the character and word model. This suggests that future variants of this model might benefit from higher regularization.

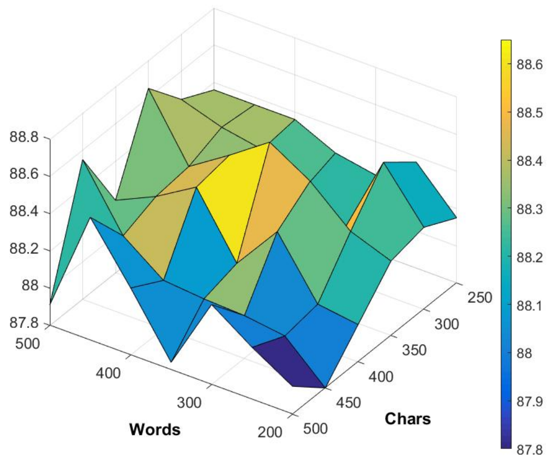

Figure 3: 3D surface plot for development set accuracy for XPOS (y-axis) depending on LSTM size of the character and word model for the Vietnamese treebank. The snapshot is take after 195 training epochs and we average the values of neighboring epochs.

Discussion Generally, the fact that different techniques for creating word encodings from character encodings and different network sizes can lead to different accuracies per language suggests that it should be possible to increase the accuracy of our model on a per language basis via a grid search over all possibilities. In fact, there are many variations on the models we presented in this work (e.g., how the character and word models are combined with the meta-BiLSTM). Since we are using separate losses, we could also change our training schema. For example, one could use methods like stack-propagation (Zhang and Weiss, 2016) where we burn-in the character and word models and then train the meta-BiLSTM backpropagating throughout the entire network.

6 Conclusions

We presented an approach to morphosyntactic tagging that combines context-sensitive initial character and word encodings with a meta-BiLSTM layer to obtain state-of-the art accuracies for a wide variety of languages.

Neural Factor Graph Models for Cross-lingual Morphological Tagging

Abstract

Morphological analysis involves predicting the syntactic traits of a word (e.g. {*POS: Noun, Case: Acc, Gender: Fem*}). Previous work in morphological tagging improves performance for low-resource languages (LRLs) through cross-lingual training with a high-resource language (HRL) from the same family, but is limited by the strict—often false—assumption that tag sets exactly overlap between the HRL and LRL. In this paper we propose a method for cross-lingual morphological tagging that aims to improve information sharing between languages by relaxing this assumption. The proposed model uses factorial conditional random fields with neural network potentials, making it possible to (1) utilize the expressive power of neural network representations to smooth over superficial differences in the surface forms, (2) model pairwise and transitive relationships between tags, and (3) accurately generate tag sets that are unseen or rare in the training data. Experiments on four languages from the Universal Dependencies Treebank (Nivre et al., 2017) demonstrate superior tagging accuracies over existing cross-lingual approaches.[1]

1 Introduction

Morphological analysis (Hajič and Hladká (1998), Oflazer and Kuruöz (1994), *inter alia*) is the task of predicting fine-grained annotations about the syntactic properties of tokens in a language such as part-of-speech, case, or tense. For instance, in Figure 1, the given Portuguese sentence is labeled with the respective morphological tags such as Gender and its label value Masculine.

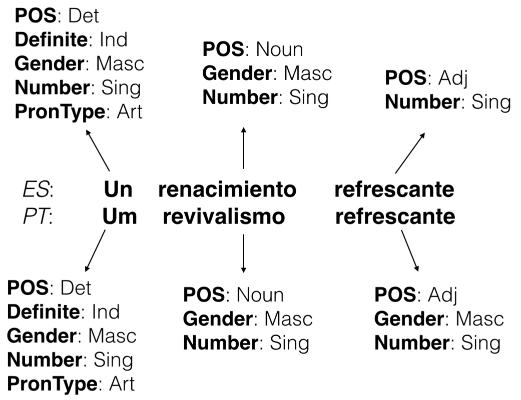

Figure 1: Morphological tags for a UD sentence in Portuguese and a translation in Spanish

The accuracy of morphological analyzers is paramount, because their results are often a first step in the NLP pipeline for tasks such as translation (Vylomova et al., 2017; Tsarfaty et al., 2010) and parsing (Tsarfaty et al., 2013), and errors in the upstream analysis may cascade to the downstream tasks. One difficulty, however, in creating these taggers is that only a limited amount of annotated data is available for a majority of the world's languages to learn these morphological taggers. Fortunately, recent efforts in morphological annotation follow a standard annotation schema for these morphological tags across languages, and now the Universal Dependencies Treebank (Nivre et al., 2017) has tags according to this schema in 60 languages.

Cotterell and Heigold (2017) have recently shown that combining this shared schema with cross-lingual training on a related high-resource language (HRL) gives improved performance

[1]Our code and data is publicly available at www.github.com/chaitanyamalaviya/NeuralFactorGraph.

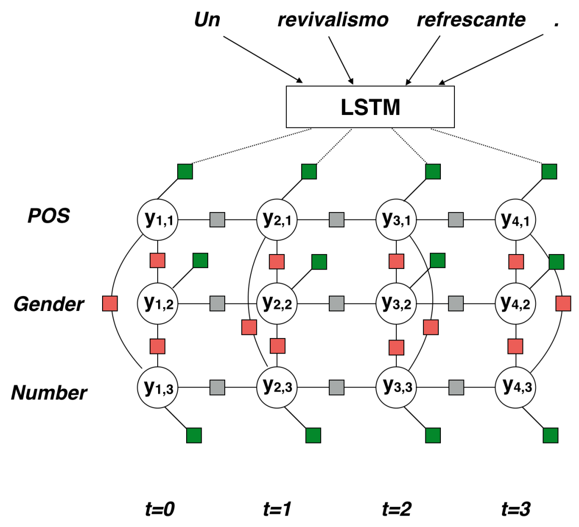

Figure 2: FCRF-LSTM Model for morphological tagging

on tagging accuracy for low-resource languages (LRLs). The output space of this model consists of tag sets such as {*POS: Adj, Gender: Masc, Number: Sing*}, which are predicted for a token at each time step. However, this model relies heavily on the fact that *the entire space of tag sets* for the LRL must match those of the HRL, which is often not the case, either due to linguistic divergence or small differences in the annotation schemes between the two languages.[2] For instance, in Figure 1 "refrescante" is assigned a gender in the Portuguese UD treebank, but not in the Spanish UD treebank.

In this paper, we propose a method that instead of predicting full tag sets, makes predictions over single tags separately but ties together each decision by modeling variable dependencies between tags over time steps (e.g. capturing the fact that nouns frequently occur after determiners) and pairwise dependencies between all tags at a single time step (e.g. capturing the fact that infinitive verb forms don't have tense). The specific model is shown in Figure 2, consisting of a factorial conditional random field (FCRF; Sutton et al. (2007)) with neural network potentials calculated by long short-term memory (LSTM; (Hochreiter and Schmidhuber, 1997)) at every variable node (§3). Learning and inference in the model is made tractable through belief propagation over the possible tag combinations, allowing the model to consider an exponential label space in polynomial time (§3.5).

This model has several advantages:

- The model is able to generate tag sets unseen in training data, and share information between similar tag sets, alleviating the main disadvantage of previous work cited above.
- Our model is empirically strong, as validated in our main experimental results: it consistently outperforms previous work in cross-lingual low-resource scenarios in experiments.
- Our model is more interpretable, as we can probe the model parameters to understand which variable dependencies are more likely to occur in a language, as we demonstrate in our analysis.

In the following sections, we describe the model and these results in more detail.

2 Problem Formulation and Baselines

2.1 Problem Formulation

Formally, we define the problem of morphological analysis as the task of mapping a length-T string of tokens $\mathbf{x} = x_1, \ldots, x_T$ into the target morphological tag sets for each token $\mathbf{y} = \mathbf{y}_1, \ldots, \mathbf{y}_T$. For the tth token, the target label $\mathbf{y}_t = y_{t,1}, \ldots, y_{t,m}$ defines a set of tags (e.g. {*Gender: Masc, Number: Sing, POS: Verb*}). An annotation schema defines a set $\mathcal{S}$ of M possible tag types and with the mth type (e.g. *Gender*) defining its set of possible labels $\mathcal{Y}_m$ (e.g. {*Masc, Fem, Neu*}) such that $y_{t,m} \in \mathcal{Y}_m$. We must note that not all tags or attributes need to be specified for a token; usually, a subset of $\mathcal{S}$ is specified for a token and the remaining tags can be treated as mapping to a `NULL` $\in \mathcal{Y}_m$ value. Let $\mathcal{Y} = \{(y_1, \ldots, y_M) : y_1 \in \mathcal{Y}_1, \ldots, y_M \in \mathcal{Y}_M\}$ denote the set of all possible tag sets.

2.2 Baseline: Tag Set Prediction

Data-driven models for morphological analysis are constructed using training data $\mathcal{D} = \{(\mathbf{x}^{(i)}, \mathbf{y}^{(i)})\}_{i=1}^{N}$ consisting of N training examples. The baseline model (Cotterell and Heigold, 2017) we compare with regards the output space of the model as a subset $\tilde{\mathcal{Y}} \subset \mathcal{Y}$ where $\tilde{\mathcal{Y}}$ is the

[2]In particular, the latter is common because many UD resources were created by full or semi-automatic conversion from treebanks with less comprehensive annotation schemes than UD. Our model can generate label values for these tags too, which could possibly aid the enhancement of UD annotations, although we do not examine this directly in our work.

set of all tag sets seen in this training data. Specifically, they solve the task as a multi-class classification problem where the classes are individual tag sets. In low-resource scenarios, this indicates that $|\tilde{\mathcal{Y}}| << |\mathcal{Y}|$ and even for those tag sets existing in $\tilde{\mathcal{Y}}$ we may have seen very few training examples. The conditional probability of a sequence of tag sets given the sentence is formulated as a 0th order CRF.

$$p(\mathbf{y}|\mathbf{x}) = \prod_{t=1}^{T} p(\mathbf{y}_t|\mathbf{x}) \tag{1}$$

Instead, we would like to be able to generate any combination of tags from the set $\mathcal{Y}$, and share statistical strength among similar tag sets.

2.3 A Relaxation: Tag-wise Prediction

As an alternative, we could consider a model that performs prediction for each tag's label $y_{t,m}$ independently.

$$p(\mathbf{y}|\mathbf{x}) = \prod_{t=1}^{T} \prod_{m=1}^{M} p(y_{t,m}|\mathbf{x}) \tag{2}$$

This formulation has an advantage: the tag-predictions within a single time step are now independent, it is now easy to generate any combination of tags from $\mathcal{Y}$. On the other hand, now it is difficult to model the interdependencies between tags in the same tag set $\mathbf{y}_i$, a major disadvantage over the previous model. In the next section, we describe our proposed neural factor graph model, which can model not only dependencies within tags for a single token, but also dependencies across time steps while still maintaining the flexibility to generate any combination of tags from $\mathcal{Y}$.

3 Neural Factor Graph Model

Due to the correlations between the syntactic properties that are represented by morphological tags, we can imagine that capturing the relationships between these tags through pairwise dependencies can inform the predictions of our model. These dependencies exist both among tags for the same token (intra-token pairwise dependencies), and across tokens in the sentence (inter-token transition dependencies). For instance, knowing that a token's POS tag is a Noun, would strongly suggest that this token would have a `NULL` label for the tag Tense, with very few exceptions (Nordlinger and Sadler, 2004). In a language where nouns follow adjectives, a tag set prediction {*POS: Adj, Gender: Fem*} might inform the model that the next token is likely to be a noun and have the same gender. The baseline model can not explicitly model such interactions given their factorization in equation 1.

To incorporate the dependencies discussed above, we define a factorial CRF (Sutton et al., 2007), with pairwise links between cotemporal variables and transition links between the same types of tags. This model defines a distribution over the tag-set sequence $\mathbf{y}$ given the input sentence $\mathbf{x}$ as,

$$p(\mathbf{y}|\mathbf{x}) = \frac{1}{Z(\mathbf{x})} \prod_{t=1}^{T} \prod_{\alpha \in \mathcal{C}} \psi_\alpha(\mathbf{y}_\alpha, \mathbf{x}, t) \tag{3}$$

where $\mathcal{C}$ is the set of factors in the factor graph (as shown in Figure 2), α is one such factor, and $\mathbf{y}_\alpha$ is the assignment to the subset of variables neighboring factor α. We define three types of potential functions: neural ψ_{NN}, pairwise ψ_P, and transition ψ_T, described in detail below.

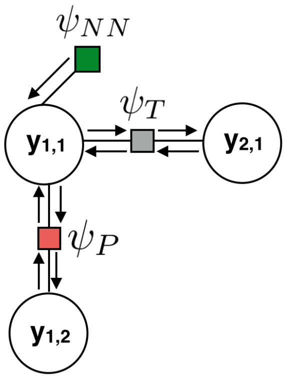

Figure 3: Factors in the Neural Factor Graph model (red: Pairwise, grey: Transition, green: Neural Network)

3.1 Neural Factors

The flexibility of our formulation allows us to include any form of custom-designed potentials in our model. Those for the neural factors have a fairly standard log-linear form,

$$\psi_{NN,i}(y_{t,m}) = \exp\left\{\sum_k \lambda_{\text{nn},k} f_{\text{nn},k}(\mathbf{x}, t)\right\} \tag{4}$$

except that the features $f_{\text{nn},k}$ are themselves given by a neural network. There is one such factor per variable. We obtain our neural factors using a biLSTM over the input sequence $\mathbf{x}$, where the input word embedding for each token is obtained from a character-level biLSTM embedder. This component of our model is similar to the model proposed by Cotterell and Heigold (2017). Given an input token $\mathbf{x}_t = c_1...c_n$, we compute an input embedding v_t as,

$$v_t = [\text{cLSTM}(c_1...c_n); \text{cLSTM}(c_n...c_1)] \quad (5)$$

Here, cLSTM is a character-level LSTM function that returns the last hidden state. This input embedding v_t is then used in the biLSTM tagger to compute an output representation e_t. Finally, the scores $f_{\text{nn}}(\mathbf{x}, t)$ are obtained as,

$$f_{\text{nn}}(\mathbf{x}, t) = W_l e_t + b_l \quad (6)$$

We use a language-specific linear layer with weights W_l and bias b_l.

3.2 Pairwise Factors

As discussed previously, the pairwise factors are crucial for modeling correlations between tags. The pairwise factor potential for a tag i and tag j at timestep t is given in equation 7. Here, the dimension of f_p is $(|\mathcal{Y}_i|, |\mathcal{Y}_j|)$. These scores are used to define the neural factors as,

$$\psi_{P_{i,j}}(y_{t,i}, y_{t,j}) = \exp\left\{\sum_k \lambda_{\text{p},k} f_{\text{p},k}(y_{t,i}, y_{t,j})\right\} \quad (7)$$

3.3 Transition Factors

Previous work has experimented with the use of a linear chain CRF with factors from a neural network (Huang et al., 2015) for sequence tagging tasks. We hypothesize that modeling transition factors in a similar manner can allow the model to utilize information about neighboring tags and capture word order features of the language. The transition factor for tag i and timestep t is given below for variables $y_{t,i}$ and $y_{t+1,i}$. The dimension of f_T is $(|\mathcal{Y}_i|, |\mathcal{Y}_i|)$.

$$\psi_{T_{i,t}}(y_{t,i}, y_{t+1,i}) = \exp\left\{\sum_k \lambda_{\text{T},k} f_{\text{T},k}(y_{t,i}, y_{t+1,i})\right\} \quad (8)$$

In our experiments, $f_{\text{p},k}$ and $f_{\text{T},k}$ are simple indicator features for the values of tag variables with no dependence on $\mathbf{x}$.

3.4 Language-Specific Weights

As an enhancement to the information encoded in the transition and pairwise factors, we experiment with training general and language-specific parameters for the transition and the pairwise weights. We define the weight matrix λ_{gen} to learn the general trends that hold across both languages, and the weights λ_{lang} to learn the exceptions to these trends. In our model, we sum both these parameter matrices before calculating the transition and pairwise factors. For instance, the transition weights λ_T are calculated as $\lambda_T = \lambda_{\text{T, gen}} + \lambda_{\text{T, lang}}$.

3.5 Loopy Belief Propagation

Since the graph from Figure 2 is a loopy graph, performing exact inference can be expensive. Hence, we use loopy belief propagation (Murphy et al., 1999; Ihler et al., 2005) for computation of approximate variable and factor marginals. Loopy BP is an iterative message passing algorithm that sends messages between variables and factors in a factor graph. The message updates from variable v_i, with neighboring factors $N(i)$, to factor α is

$$\mu_{i\to\alpha}(v_i) = \prod_{\alpha \in N(i)\setminus\alpha} \mu_{\alpha\to i}(v_i) \quad (9)$$

The message from factor α to variable v_i is

$$\mu_{\alpha\to i}(v_i) = \sum_{\mathbf{v}_\alpha : \mathbf{v}_\alpha[i]=v_i} \psi_\alpha(\mathbf{v}_\alpha) \prod_{j\in N(\alpha)\setminus i} \mu_{j\to\alpha}(\mathbf{v}_\alpha[i]) \quad (10)$$

where $\mathbf{v}_\alpha$ denote an assignment to the subset of variables adjacent to factor α, and $\mathbf{v}_\alpha[i]$ is the assignment for variable v_i. Message updates are performed asynchronously in our model. Our message passing schedule was similar to that of foward-backward: the forward pass sends all messages from the first time step in the direction of the last. Messages to/from pairwise factors are included in this forward pass. The backward pass sends messages in the direction from the last time step back to the first. This process is repeated until convergence. We say that BP has converged when the maximum residual error (Sutton and McCallum, 2007) over all messages is below some threshold. Upon convergence, we obtain the belief values of variables and factors as,

$$b_i(v_i) = \frac{1}{\kappa_i} \prod_{\alpha\in N(i)} \mu_{\alpha\to i}(v_i) \quad (11)$$

$$b_\alpha(v_\alpha) = \frac{1}{\kappa_\alpha} \psi_\alpha(v_\alpha) \prod_{i\in N(\alpha)} \mu_{i\to\alpha}(v_\alpha[i]) \quad (12)$$

where κ_i and κ_α are normalization constants ensuring that the beliefs for a variable i and factor α sum-to-one. In this way, we can use the beliefs as approximate marginal probabilities.

3.6 Learning and Decoding

We perform end-to-end training of the neural factor graph by following the (approximate) gradient of the log-likelihood $\sum_{i=1}^{N} \log p(\mathbf{y}^{(i)}|\mathbf{x}^{(i)})$. The true gradient requires access to the marginal probabilities for each factor, e.g. $p(\mathbf{y}_\alpha|\mathbf{x})$ where $\mathbf{y}_\alpha$ denotes the subset of variables in factor α. For example, if α is a transition factor for tag m at timestep t, then $\mathbf{y}_\alpha$ would be $y_{t,m}$ and $y_{t+1,m}$. Following (Sutton et al., 2007), we replace these marginals with the beliefs $b_\alpha(\mathbf{y}_\alpha)$ from loopy belief propagation.[3] Consider the log-likelihood of a single example $\ell^{(i)} = \log p(\mathbf{y}^{(i)}|\mathbf{x}^{(i)})$. The partial derivative with respect to parameter $\lambda_{g,k}$ for each type of factor $g \in \{NN, T, P\}$ is the difference of the observed features with the expected features under the model's (approximate) distribution as represented by the beliefs:

$$\frac{\partial \ell^{(i)}}{\partial \lambda_{g,k}} = \sum_{\alpha \in \mathcal{C}_g} \left(f_{g,k}(\mathbf{y}_\alpha^{(i)}) - \sum_{\mathbf{y}_\alpha} b_\alpha(\mathbf{y}_\alpha) f_{g,k}(\mathbf{y}_\alpha) \right)$$

where $\mathcal{C}_g$ denotes all the factors of type g, and we have omitted any dependence on $\mathbf{x}^{(i)}$ and t for brevity—t is accessible through the factor index α. For the neural network factors, the features are given by a biLSTM. We backpropagate through to the biLSTM parameters using the partial derivative below,

$$\frac{\partial \ell^{(i)}}{\partial f_{NN,k}(y_{t,m}^{(i)}, t)} = \lambda_{NN,k} - \sum_{y_{t,m}} b_{t,m}(y_{t,m}) \lambda_{NN,k}$$

where $b_{t,m}(\cdot)$ is the variable belief corresponding to variable $y_{t,m}$.

To predict a sequence of tag sets $\hat{\mathbf{y}}$ at test time, we use minimum Bayes risk (MBR) decoding (Bickel and Doksum, 1977; Goodman, 1996) for Hamming loss over tags. For a variable $y_{t,m}$ representing tag m at timestep t, we take

$$\hat{y}_{t,m} = \operatorname*{arg\,max}_{l \in \mathcal{Y}_m} b_{t,m}(l). \tag{13}$$

where l ranges over the possible labels for tag m.

Language Pair	HRL Train	Dev	Test
DA/SV	4,383	504	1219

ES/PT	19	451

Table 2: Tag Set Sizes with tgt_size=100

4 Experimental Setup

4.1 Dataset

We used the Universal Dependencies Treebank UD v2.1 (Nivre et al., 2017) for our experiments. We picked four low-resource/high-resource language pairs, each from a different family: Danish/Swedish (DA/SV), Russian/Bulgarian (RU/BG), Finnish/Hungarian (FI/HU), Spanish/Portuguese (ES/PT). Picking languages from different families would ensure that we obtain results that are on average consistent across languages.

The sizes of the training and evaluation sets are specified in Table 1. In order to simulate low-resource settings, we follow the experimental procedure from Cotterell and Heigold (2017). We restrict the number of sentences of the target language (tgt_size) in the training set to 100 or 1000 sentences. We also augment the tag sets in our training data by adding a `NULL` label for all tags that are not seen for a token. It is expected that our model will learn which tags are unlikely to occur given the variable dependencies in the factor graph. The dev set and test set are only in the target language. From Table 2, we can see there is also considerable variance in the number of unique tags and tag sets found in each of these language pairs.

[3]Using this approximate gradient is akin to the *surrogate likelihood* training of (Wainwright, 2006).

Language	Model	tgt_size = 100			tgt_size=1000		
		Accuracy	F1-Micro	F1-Macro	Accuracy	F1-Macro	F1-Micro

Table 3: Token-wise accuracy and F1 scores on mono-lingual experiments

4.2 Baseline Tagger

As the baseline tagger model, we re-implement the SPECIFIC model from Cotterell and Heigold (2017) that uses a language-specific softmax layer. Their model architecture uses a character biLSTM embedder to obtain a vector representation for each token, which is used as input in a word-level biLSTM. The output space of their model is all the tag sets seen in the training data. This work achieves strong performance on several languages from UD on the task of morphological tagging and is a strong baseline.

4.3 Training Regimen

We followed the parameter settings from Cotterell and Heigold (2017) for the baseline tagger and the neural component of the FCRF-LSTM model. For both models, we set the input embedding and linear layer dimension to 128. We used 2 hidden layers for the LSTM where the hidden layer dimension was set to 256 and a dropout (Srivastava et al., 2014) of 0.2 was enforced during training. All our models were implemented in the PyTorch toolkit (Paszke et al., 2017). The parameters of the character biLSTM and the word biLSTM were initialized randomly. We trained the baseline models and the neural factor graph model with SGD and Adam respectively for 10 epochs each, in batches of 64 sentences. These optimizers gave the best performances for the respective models.

For the FCRF, we initialized transition and pairwise parameters with zero weights, which was important to ensure stable training. We considered BP to have reached convergence when the maximum residual error was below 0.05 or if the maximum number of iterations was reached (set to 40 in our experiments). We found that in cross-lingual experiments, when $tgt\_size = 100$, the relatively large amount of data in the HRL was causing our model to overfit on the HRL and not generalize well to the LRL. As a solution to this, we upsampled the LRL data by a factor of 10 when $tgt\_size = 100$ for both the baseline and the proposed model.

Evaluation: Previous work on morphological analysis (Cotterell and Heigold, 2017; Buys and Botha, 2016) has reported scores on average token-level accuracy and F1 measure. The average token level accuracy counts a tag set prediction as correct only it is an exact match with the gold tag set. On the other hand, F1 measure is measured on a tag-by-tag basis, which allows it to give partial credit to partially correct tag sets. Based on the characteristics of each evaluation measure, Accuracy will favor tag-set prediction models (like the baseline), and F1 measure will favor tag-wise prediction models (like our proposed method). Given the nature of the task, it seems reasonable to prefer getting some of the tags correct (e.g. Noun+Masc+Sing becomes Noun+Fem+Sing), instead of missing all of them (e.g. Noun+Masc+Sing becomes Adj+Fem+Plur). F-score gives partial credit for getting some of the tags correct, while tagset-level accuracy will treat these two mistakes equally. Based on this, we believe that F-score is intuitively a better metric. However, we report both scores for completeness.

5 Results and Analysis

5.1 Main Results

First, we report the results in the case of monolingual training in Table 3. The first row for each language pair reports the results for our reimple-

Language	Model	tgt_size = 100			tgt_size=1000		
		Accuracy	F1-Micro	F1-Macro	Accuracy	F1-Macro	F1-Micro
DA/SV	Baseline	**66.06**	73.95	74.37	**82.26**	**87.88**	**87.91**
	Ours	63.22	**78.75**	**78.72**	77.43	87.56	87.52
RU/BG	Baseline	**52.76**	58.41	58.23	**71.90**	77.89	77.97
	Ours	46.89	**64.46**	**64.75**	67.56	**82.06**	**82.11**
FI/HU	Baseline	**51.74**	68.15	66.82	61.80	75.96	76.16
	Ours	45.41	**68.63**	**68.07**	**63.93**	**85.06**	**84.12**
ES/PT	Baseline	**79.40**	86.03	86.14	**85.85**	91.91	91.93
	Ours	77.75	**88.42**	**88.44**	85.02	**92.35**	**92.37**

Table 4: Token-wise accuracy and F1 scores on cross-lingual experiments

mentation of Cotterell and Heigold (2017), and the second for our full model. From these results, we can see that we obtain improvements on the F-measure over the baseline method in most experimental settings except BG with $tgt\_size = 1000$. In a few more cases, the baseline model sometimes obtains higher accuracy scores for the reason described in 4.3.

In our cross-lingual experiments shown in Table 4, we also note F-measure improvements over the baseline model with the exception of DA/SV when $tgt\_size = 1000$. We observe that the improvements are on average stronger when $tgt\_size = 100$. This suggests that our model performs well with very little data due to its flexibility to generate any tag set, including those not observed in the training data. The strongest improvements are observed for FI/HU. This is likely because the number of unique tags is the highest in this language pair and our method scales well with the number of tags due to its ability to make use of correlations between the tags in different tag sets.

Language	Transition	Pairwise	F1-Macro
HU	×	×	69.87
	✓	×	73.21
	×	✓	73.68
	✓	✓	74.05
FI/HU	×	×	79.57
	✓	×	84.41
	×	✓	84.73
	✓	✓	85.06

Table 5: Ablation Experiments (tgt_size=1000)

To examine the utility of our transition and pairwise factors, we also report results on ablation experiments by removing transition and pairwise factors completely from the model in Table 5. Ablation experiments for each factor showed decreases in scores relative to the model where both factors are present, but the decrease attributed to the pairwise factors is larger, in both the monolingual and cross-lingual cases. Removing both factors from our proposed model results in a further decrease in the scores. These differences were found to be more significant in the case when $tgt\_size = 100$.

Upon looking at the tag set predictions made by our model, we found instances where our model utilizes variable dependencies to predict correct labels. For instance, for a specific phrase in Portuguese (*um estado*), the baseline model predicted $\{$*POS: Det, Gender: Masc, Number: Sing*$\}_t$, $\{$*POS: Noun, Gender: Fem (X), Number: Sing*$\}_{t+1}$, whereas our model was able to get the gender correct because of the transition factors in our model.

5.2 What is the Model Learning?

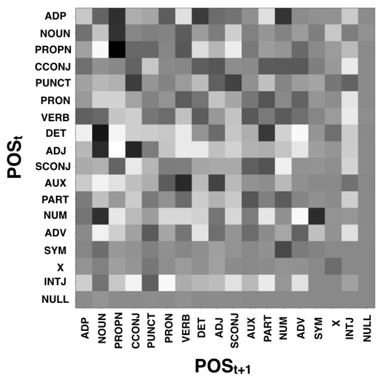

Figure 4: Generic transition weights for POS from the RU/BG model

One of the major advantages of our model is

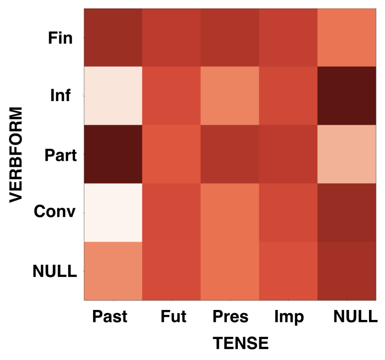

Figure 5: Generic pairwise weights between `Verbform` and `Tense` from the RU/BG model

the ability to interpret what the model has learned by looking at the trained parameter weights. We investigated both language-generic and language-specific patterns learned by our parameters:

- **Language-Generic**: We found evidence for several syntactic properties learned by the model parameters. For instance, in Figure 4, we visualize the generic ($\lambda_{\mathrm{T,\,gen}}$) transition weights of the POS tags in RU/BG. Several universal trends such as determiners and adjectives followed by nouns can be seen. In Figure 5, we also observed that infinitive has a strong correlation for `NULL` tense, which follows the universal phenomena that infinitives don't have tense.

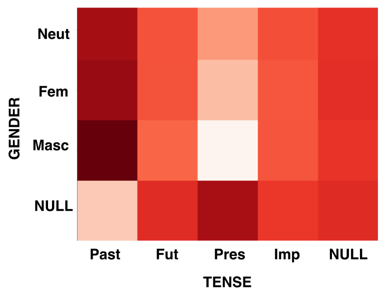

Figure 6: Language-specific pairwise weights for RU between `Gender` and `Tense` from the RU/BG model

- **Language Specific Trends**: We visualized the learnt language-specific weights and looked for evidence of patterns corresponding to linguistic phenomenas observed in a language of interest. For instance, in Russian, verbs are gender-specific in past tense but not in other tenses. To analyze this, we plotted pairwise weights for Gender/Tense in Figure 6 and verified strong correlations between the past tense and all gender labels.

6 Related Work

There exist several variations of the task of prediction of morphological information from annotated data: paradigm completion (Durrett and DeNero, 2013; Cotterell et al., 2017b), morphological reinflection (Cotterell et al., 2017a), segmentation (Creutz et al., 2005; Cotterell et al., 2016) and tagging. Work on morphological tagging has broadly focused on structured prediction models such as CRFs, and neural network models. Amongst structured prediction approaches, Müller et al. (2013); Müller and Schütze (2015) proposed the use of a higher-order CRF that is approximated using coarse-to-fine decoding. (Müller et al., 2015) proposed joint lemmatization and tagging using this framework. (Hajič, 2000) was the first work that performed experiments on multilingual morphological tagging. They proposed an exponential model and the use of a morphological dictionary. Buys and Botha (2016); Kirov et al. (2017) proposed a model that used tag projection of type and token constraints from a resource-rich language to a low-resource language for tagging.

Most recent work has focused on character-based neural models (Heigold et al., 2017), that can handle rare words and are hence more useful to model morphology than word-based models. These models first obtain a character-level representation of a token from a biLSTM or CNN, which is provided to a word-level biLSTM tagger. Heigold et al. (2017, 2016) compared several neural architectures to obtain these character-based representations and found the effect of the neural network architecture to be minimal given the networks are carefully tuned. Cross-lingual transfer learning has previously boosted performance on tasks such as translation (Johnson et al., 2016) and POS tagging (Snyder et al., 2008; Plank et al., 2016). Cotterell and Heigold (2017) proposed a cross-lingual character-level neural morphological tagger. They experimented with different strategies to facilitate cross-lingual training: a language ID for each token, a language-specific softmax and a joint language identification and tagging model. We have used this work as a baseline model for comparing with our proposed method.

In contrast to earlier work on morphological tagging, we use a hybrid of neural and graphical model approaches. This combination has several advantages: we can make use of expressive feature representations from neural models while ensuring that our model is interpretable. Our work is similar in spirit to Huang et al. (2015) and Ma and Hovy (2016), who proposed models that use a CRF with features from neural models. For our graphical model component, we used a factorial CRF (Sutton et al., 2007), which is a generalization of a linear chain CRF with additional pairwise factors between cotemporal variables.

7 Conclusion and Future Work

In this work, we proposed a novel framework for sequence tagging that combines neural networks and graphical models, and showed its effectiveness on the task of morphological tagging. We believe this framework can be extended to other sequence labeling tasks in NLP such as semantic role labeling. Due to the robustness of the model across languages, we believe it can also be scaled to perform morphological tagging for multiple languages together.

Abstract

Shi, Huang, and Lee (2017a) obtained state-of-the-art results for English and Chinese dependency parsing by combining dynamic-programming implementations of transition-based dependency parsers with a minimal set of bidirectional LSTM features. However, their results were limited to projective parsing. In this paper, we extend their approach to support non-projectivity by providing the first practical implementation of the MH_4 algorithm, an $O(n^4)$ mildly non-projective dynamic-programming parser with very high coverage on non-projective treebanks. To make MH_4 compatible with minimal transition-based feature sets, we introduce a transition-based interpretation of it in which parser items are mapped to sequences of transitions. We thus obtain the first implementation of global decoding for non-projective transition-based parsing, and demonstrate empirically that it is more effective than its projective counterpart in parsing a number of highly non-projective languages.

1 Introduction

Transition-based dependency parsers are a popular approach to natural language parsing, as they achieve good results in terms of accuracy and efficiency (Yamada and Matsumoto, 2003; Nivre and Scholz, 2004; Zhang and Nivre, 2011; Chen and Manning, 2014; Dyer et al., 2015; Andor et al., 2016; Kiperwasser and Goldberg, 2016). Until very recently, practical implementations of transition-based parsing were limited to approximate inference, mainly in the form of greedy search or beam search. While cubic-time exact inference algorithms for several well-known projective transition systems had been known since the work of Huang and Sagae (2010) and Kuhlmann et al. (2011), they had been considered of theoretical interest only due to their incompatibility with rich feature models: incorporation of complex features resulted in jumps in asymptotic runtime complexity to impractical levels.

However, the recent popularization of bidirectional long-short term memory networks (bi-LSTMs; Hochreiter and Schmidhuber, 1997) to derive feature representations for parsing, given their capacity to capture long-range information, has demonstrated that one may not need to use complex feature models to obtain good accuracy (Kiperwasser and Goldberg, 2016; Cross and Huang, 2016). In this context, Shi et al. (2017a) presented an implementation of the exact inference algorithms of Kuhlmann et al. (2011) with a minimal set of only two bi-LSTM-based feature vectors. This not only kept the complexity cubic, but also obtained state-of-the-art results in English and Chinese parsing.

While their approach provides both accurate parsing and the flexibility to use any of greedy, beam, or exact decoding with the same underlying transition systems, it does not support non-projectivity. Trees with crossing dependencies make up a significant portion of many treebanks, going as high as 63% for the Ancient Greek treebank in the Universal Dependencies[1] (UD) dataset version 2.0 and averaging around 12% over all languages in UD 2.0. In this paper, we extend Shi et al.'s (2017a) approach to mildly non-projective parsing in what, to our knowledge, is the first implementation of exact decoding for a non-projective transition-based parser.

As in the projective case, a mildly non-

[1]http://universaldependencies.org/

projective decoder has been known for several years (Cohen et al., 2011), corresponding to a variant of the transition-based parser of Attardi (2006). However, its $O(n^7)$ runtime — or the $O(n^6)$ of a recently introduced improved-coverage variant (Shi et al., 2018) — is still prohibitively costly in practice. Instead, we seek a more efficient algorithm to adapt, and thus develop a transition-based interpretation of Gómez-Rodríguez et al.'s (2011) MH_4 dynamic programming parser, which has been shown to provide very good non-projective coverage in $O(n^4)$ time (Gómez-Rodríguez, 2016). While the MH_4 parser was originally presented as a non-projective generalization of the dynamic program that later led to the arc-hybrid transition system (Gómez-Rodríguez et al., 2008; Kuhlmann et al., 2011), its own relation to transition-based parsing was not known. Here, we show that MH_4 can be interpreted as exploring a subset of the search space of a transition-based parser that generalizes the arc-hybrid system, under a mapping that differs from the "push computation" paradigm used by the previously-known dynamic-programming decoders for transition systems. This allows us to extend Shi et al. (2017a)'s work to non-projective parsing, by implementing MH_4 with a minimal set of transition-based features.

Experimental results show that our approach outperforms the projective approach of Shi et al. (2017a) and maximum-spanning-tree non-projective parsing on the most highly non-projective languages in the CoNLL 2017 shared-task data that have a single treebank. We also compare with the third-order 1-Endpoint-Crossing (1EC) parser of Pitler (2014), the only other practical implementation of an exact mildly non-projective decoder that we know of, which also runs in $O(n^4)$ but without a transition-based interpretation. We obtain comparable results for these two algorithms, in spite of the fact that the MH_4 algorithm is notably simpler than 1EC. The MH_4 parser remains effective in parsing projective treebanks, while our baseline parser, the fully non-projective maximum spanning tree algorithm, falls behind due to its unnecessarily large search space in parsing these languages. Our code, including our re-implementation of the third-order 1EC parser with neural scoring, is available at `https://github.com/tzshi/mh4-parser-acl18`.

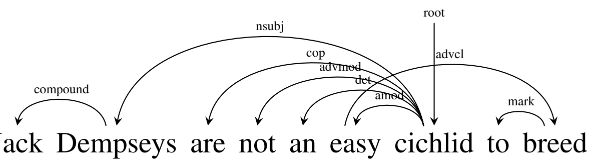

Figure 1: A non-projective dependency parse from the UD 2.0 English treebank.

2 Non-projective Dependency Parsing

In dependency grammar, syntactic structures are modeled as word-word asymmetrical subordinate relations among lexical entries (Kübler et al., 2009). These relations can be represented in a graph. For a sentence $w = w_1, ..., w_n$, we first define a corresponding set of nodes $\{0, 1, 2, ..., n\}$, where 0 is an artificial node denoting the root of the sentence. Dependency relations are encoded by edges of the form (h, m), where h is the head and m the modifier of the bilexical subordinate relation.[2]

As is conventional, we assume two more properties on dependency structures. First, each word has exactly one syntactic head, and second, the structure is acyclic. As a consequence, the edges form a directed tree rooted at node 0.

We say that a dependency structure is *projective* if it has no crossing edges. While in the CoNLL and Stanford conversions of the English Penn Treebank, over 99% of the sentences are projective (Chen and Manning, 2014) — see Fig. 1 for a non-projective English example — for other languages' treebanks, non-projectivity is a common occurrence (see Table 3 for some statistics). This paper is targeted at learning parsers that can handle non-projective dependency trees.

3 MH_4 Deduction System and Its Underlying Transition System

3.1 The MH_4 Deduction System

The MH_4 parser is the instantiation for $k = 4$ of Gómez-Rodríguez et al.'s (2011) more general MH_k parser. MH_k stands for "multi-headed with at most k heads per item": items in its deduction system take the form $[h_1, \ldots, h_p]$ for $p \leqslant k$, indicating the existence of a forest of p dependency subtrees headed by $h_1, \ldots, h_p$ such that their yields are disjoint and the union of their

[2] To simplify exposition here, we only consider the unlabeled case. We use a separately-trained labeling module to obtain labeled parsing results in §5.

$$\begin{array}{llll}
\textit{Axiom:} & \textsc{Shift}: \dfrac{[h_1,\ldots,h_m]}{[h_m,h_m+1]}\ (h_m \leqslant n) & \textsc{Combine}: \dfrac{[h_1,\ldots,h_m] \qquad [h_m,h_{m+1},\ldots,h_p]}{[h_1,\ldots,h_p]}\ (p \leqslant k) \\
{[0,1]} & & \\
\textit{Goal:} & \textsc{Link}: \dfrac{[h_1,\ldots,h_m]}{[h_1,\ldots,h_{j-1},h_{j+1},\ldots,h_m]}\ h_i \rightarrow h_j (1 \leqslant i \leqslant m \wedge 1 < j < m \wedge j \neq i) & \\
{[0,n+1]} & &
\end{array}$$

Figure 2: MH_k's deduction steps.

yields is the contiguous substring $h_1 \ldots h_p$ of the input. Deduction steps, shown in Figure 2, can be used to join two such forests that have an endpoint in common via graph union (COMBINE); or to add a dependency arc to a forest that attaches an interior head as a dependent of any of the other heads (LINK).

In the original formulation by Gómez-Rodríguez et al. (2011), all valid items of the form $[i, i+1]$ are considered to be axioms. In contrast, we follow Kuhlmann et al.'s (2011) treatment of MH_3: we consider $[0,1]$ as the only axiom and include an extra SHIFT step to generate the rest of the items of that form. Both formulations are equivalent, but including this SHIFT rule facilitates giving the parser a transition-based interpretation.

Higher values of k provide wider coverage of non-projective structures at an asymptotic runtime complexity of $O(n^k)$. When k is at its minimum value of 3, the parser covers exactly the set of projective trees, and in fact, it can be seen as a transformation[3] of the deduction system described in Gómez-Rodríguez et al. (2008) that gave rise to the projective arc-hybrid parser (Kuhlmann et al., 2011). For $k \geqslant 4$, the parser covers an increasingly larger set of non-projective structures. While a simple characterization of these sets has been lacking[4], empirical evaluation on a large number of treebanks (Gómez-Rodríguez, 2016) has shown MH_k to provide the best known tradeoff between asymptotic complexity and efficiency for $k > 4$. When $k = 4$, its coverage is second only to the 1-Endpoint-Crossing parser of Pitler et al. (2013). Both parsers fully cover well over 80% of the non-projective trees observed in the studied treebanks.

[3]Formally, it is a step refinement; see Gómez-Rodríguez et al. (2011).

[4]This is a common issue with parsers based on the general idea of arcs between non-contiguous heads, such as those deriving from Attardi (2006).

3.2 The MH_4 Transition System

Kuhlmann et al. (2011) show how the items of a variant of MH_3 can be given a transition-based interpretation under the "push computation" framework, yielding the arc-hybrid projective transition system. However, such a derivation has not been made for the non-projective case ($k > 3$), and the known techniques used to derive previous associations between tabular and transition-based parsers do not seem to be applicable in this case. The specific issue is that the deduction systems of Kuhlmann et al. (2011) and Cohen et al. (2011) have in common that the structure of their derivations is similar to that of a Dyck (or balanced-brackets) language, where steps corresponding to shift transitions are balanced with those corresponding to reduce transitions. This makes it possible to group derivation subtrees, and the transition sequences that they yield, into "push computations" that increase the length of the stack by a constant amount. However, this does not seem possible in MH_4.

Instead, we derive a transition-based interpretation of MH_4 by a generalization of that of MH_3 that departs from push computations.

To do so, we start with the MH_3 interpretation of an item $[i, j]$ given by Kuhlmann et al. (2011). This item represents a set of computations (transition sequences) that start from a configuration of the form $(\sigma, i|\beta, A)$ (where σ is the stack and $i|\beta$ is the buffer, with i being the first buffer node) and take the parser to a configuration of the form $(\sigma|i, j|\beta', A)$. That is, the computation has the net effect of placing node i on top of the previous contents of the stack, and it ends in a state where the first buffer element is j.

Under this item semantics, the COMBINE deduction step of the MH_3 parser (i.e., the instantiation of the one in Fig. 2 for $k = 3$) simply concatenates transition sequences. The SHIFT step generates a sequence with a single arc-hybrid sh transition:

$$\mathsf{sh} : (\sigma, h_m|\beta, A) \vdash (\sigma|h_m, \beta, A)$$

and the two possible instantiations of the COMBINE step when $k = 3$ take the antecedent transition sequence and add a transition to it, namely, one of the two arc-hybrid reduce transitions. Written in the context of the node indexes used in Figure 2, these are the following:

$$(\sigma|h_1|h_2, h_3|\beta, A) \vdash (\sigma|h_1, h_3|\beta, A \cup \{h_3 \rightarrow h_2\})$$
$$(\sigma|h_1|h_2, h_3|\beta, A) \vdash (\sigma|h_1, h_3|\beta, A \cup \{h_1 \rightarrow h_2\})$$

where h_1 and h_3 respectively can be simplified out to obtain the well-known arc-hybrid transitions:

$$\mathsf{la} : (\sigma|h_2, h_3|\beta, A) \vdash (\sigma, h_3|\beta, A \cup \{h_3 \rightarrow h_2\})$$
$$\mathsf{ra} : (\sigma|h_1|h_2, \beta, A) \vdash (\sigma|h_1, \beta, A \cup \{h_1 \rightarrow h_2\})$$

Now, we assume the following generalization of the item semantics: an item $[h_1, \ldots, h_m]$ represents a set of computations that start from a configuration of the form $(\sigma, h_1|\beta, A)$ and lead to a configuration of the form $(\sigma|h_1|\ldots|h_{m-1}, h_m|\beta', A)$. Note that this generalization no longer follows the "push computation" paradigm of Kuhlmann et al. (2011) and Cohen et al. (2011) because the number of nodes pushed onto the stack depends on the value of m.

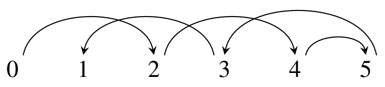
Under this item semantics, the SHIFT and COMBINE steps have the same interpretation as for MH_3. In the case of the LINK step, following the same reasoning as for the MH_3 case, we obtain the following transitions:

$$\mathsf{la} : (\sigma|h_3, h_4|\beta, A) \vdash (\sigma, h_4|\beta, A \cup \{h_4 \rightarrow h_3\})$$
$$\mathsf{ra} : (\sigma|h_2|h_3, \beta, A) \vdash (\sigma|h_2, \beta, A \cup \{h_2 \rightarrow h_3\})$$
$$\mathsf{la}' : (\sigma|h_2|h_3, h_4|\beta, A) \vdash (\sigma|h_3, h_4|\beta, A \cup \{h_3 \rightarrow h_2\})$$
$$\mathsf{ra}' : (\sigma|h_1|h_2|h_3, \beta, A) \vdash (\sigma|h_1|h_3, \beta, A \cup \{h_1 \rightarrow h_2\})$$
$$\mathsf{la}_2 : (\sigma|h_2|h_3, h_4|\beta, A) \vdash (\sigma|h_3, h_4|\beta, A \cup \{h_4 \rightarrow h_2\})$$
$$\mathsf{ra}_2 : (\sigma|h_1|h_2|h_3, \beta, A) \vdash (\sigma|h_1|h_2, \beta, A \cup \{h_1 \rightarrow h_3\})$$

These transitions give us the MH_4 transition system: a parser with four projective reduce transitions (la,ra,la′,ra′) and two Attardi-like, non-adjacent-arc reduce transitions (la$_2$ and ra$_2$).

It is worth mentioning that this MH_4 transition system we have obtained is the same as one of the variants of Attardi's algorithm introduced by Shi et al. (2018), there called ALLs_0s_1. However, in that paper they show that it can be tabularized in $O(n^6)$ using the push computation framework. Here, we have derived it as an interpretation of the $O(n^4)$ MH_4 parser.

However, in this case the dynamic programming algorithm does not cover the full search space of the transition system: while each item in the MH_4 parser can be mapped into a computation of this MH_4 transition-based parser, the opposite is not true. This tree:



can be parsed by the transition system using the computation

$\mathsf{sh}(0); \mathsf{sh}(1); \mathsf{sh}(2); \mathsf{la}_2(3 \rightarrow 1); \mathsf{sh}(3); \mathsf{sh}(4);$
$\mathsf{la}_2(5 \rightarrow 3); \mathsf{sh}(5); \mathsf{ra}(4 \rightarrow 5); \mathsf{ra}(2 \rightarrow 4); \mathsf{ra}(0 \rightarrow 2)$

but it is not covered by the dynamic programming algorithm, as no deduction sequence will yield an item representing this transition sequence. As we will see, this issue will not prevent us from implementing a dynamic-programming parser with transition-based scoring functions, or from achieving good practical accuracy.

4 Model

Given the transition-based interpretation of the MH_4 system, the learning objective becomes to find a computation that gives the gold-standard parse. For each sentence $w_1, \ldots, w_n$, we train parsers to produce the transition sequence $\mathbf{t}^*$ that corresponds to the annotated dependency structure. Thus, the model consists of two components: a parameterized scorer $S(\mathbf{t})$, and a decoder that finds a sequence $\hat{\mathbf{t}}$ as prediction based on the scoring.

As discussed by Shi et al. (2017a), there exists some tension between rich-feature scoring models and choices of decoders. Ideally, a globally-optimal decoder finds the maximum-scoring transition sequence $\hat{\mathbf{t}}$ without brute-force searching the exponentially-large output space. To keep the runtime of our exact decoder at a practical low-order polynomial, we want its feature set to be

Features	$\{\mathbf{s}_0, \mathbf{b}_0\}$	$\{\mathbf{s}_1, \mathbf{s}_0, \mathbf{b}_0\}$	$\{\mathbf{s}_2, \mathbf{s}_1, \mathbf{s}_0, \mathbf{b}_0\}$
UAS	49.83	85.17	85.27

Table 1: Performance of *local* parsing models with varying number of features. We report average UAS over 10 languages on UD 2.0.

Features	$\{\mathbf{s}_0, \mathbf{b}_0\}$	Hybrid
UAS	86.79	87.27

Table 2: Performance of *global* parsing models with varying number of features.

minimal, consulting as few stack and buffer positions as possible. In what follows, we use s_0 and s_1 to denote the top two stack items and b_0 and b_1 to denote the first two buffer items.

4.1 Scoring and Minimal Features

This section empirically explores the lower limit on the number of necessary positional features. We experiment with both *local* and *global* decoding strategies. The parsers take features extracted from parser configuration c, and score each valid transition t with $S(t; c)$. The *local* parsers greedily take transitions with the highest score until termination, while the *global* parsers use the scores to find the globally-optimal solutions $\hat{\mathbf{t}} = \arg\max_{\mathbf{t}} S(\mathbf{t})$, where $S(\mathbf{t})$ is the sum of scores for the component transitions.

Following prior work, we employ bi-LSTMs for compact feature representation. A bi-LSTM runs in both directions on the input sentence, and assigns a context-sensitive vector encoding to each token in the sentence: $\mathbf{w}_1, \ldots, \mathbf{w}_n$. When we need to extract features, say, $\mathbf{s}_0$, from a particular stack or buffer position, say s_0, we directly use the bi-LSTM vector $\mathbf{w}_{i_{s_0}}$, where i_{s_0} gives the index of the subroot of s_0 into the sentence.

Shi et al. (2017a) showed that feature vectors $\{\mathbf{s}_0, \mathbf{b}_0\}$ suffice for MH_3. Table 1 and Table 2 show the use of small feature sets for MH_4, for *local* and *global* parsing models, respectively. For a *local* parser to exhibit decent performance, we need at least $\{\mathbf{s}_1, \mathbf{s}_0, \mathbf{b}_0\}$, but adding $\mathbf{s}_2$ on top of that does not show any significant impact on the performance. Interestingly, in the case of *global* models, the two-vector feature set $\{\mathbf{s}_0, \mathbf{b}_0\}$ already suffices. Adding $\mathbf{s}_1$ to the global setting (column "Hybrid" in Table 2) seems attractive, but entails resolving a technical challenge that we discuss in the following section.

4.2 Global Decoder

In our transition-system interpretation of MH_k, sh transitions correspond to SHIFT and reduce transitions reflect the LINK steps. Since the SHIFT conclusions lose the contexts needed to score the transitions, we set the scores for all SHIFT rules to zero and delegate the scoring of the sh transitions to the COMBINE steps, as as in Shi et al. (2017a); for example,

$$\frac{[h_1, h_2] : v_1 \quad [h_2, h_3, h_4] : v_2}{[h_1, h_2, h_3, h_4] : v_1 + v_2 + S(\mathsf{sh}; \{\mathbf{h}_1, \mathbf{h}_2\})}$$

Here the transition sequence denoted by $[h_2, h_3, h_4]$ starts from a sh, with h_1 and h_2 taking the s_0 and b_0 positions. If we further wish to access s_1, such information is not readily available in the deduction step, apparently requiring extra bookkeeping that pushes the space and time complexity to an impractical $O(n^4)$ and $O(n^5)$, respectively. But, consider the scoring for the reduce transitions in the LINK steps:

$$\frac{[h_1, h_2, h_3, h_4] : v}{[h_1, h_2, h_4] : v + S(\mathsf{la}; \{\mathbf{h}_2, \mathbf{h}_3, \mathbf{h}_4\})}$$

$$\frac{[h_1, h_2, h_3] : v}{[h_1, h_3] : v + S(\mathsf{la}; \{\mathbf{h}_1, \mathbf{h}_2, \mathbf{h}_3\})}$$

The deduction steps *already* keep indices for s_1 (h_2 in the first rule, h_1 in the second) and thus provide direct access without any modification. To resolve the conflict between including s_1 for richer representations and the unavailability of s_1 in scoring the sh transitions in the COMBINE steps, we propose a hybrid scoring approach — we use features $\{\mathbf{s}_0, \mathbf{b}_0\}$ when scoring a sh transition, and features $\{\mathbf{s}_1, \mathbf{s}_0, \mathbf{b}_0\}$ for consideration of reduce transitions. We call this method MH_4-hybrid, in contrast to MH_4-two, where we simply take $\{\mathbf{s}_0, \mathbf{b}_0\}$ for scoring all transitions.

4.3 Large-Margin Training

We train the greedy parsers with hinge loss, and the global parsers with its structured version (Taskar et al., 2005). The loss function for each sentence is formally defined as:

$$\max_{\hat{\mathbf{t}}} \left(S(\hat{\mathbf{t}}) + \mathit{cost}(\mathbf{t}^*, \hat{\mathbf{t}}) - S(\mathbf{t}^*) \right)$$

where the margin $cost(\mathbf{t}^*, \hat{\mathbf{t}})$ counts the number of mis-attached nodes for taking sequence $\hat{\mathbf{t}}$ instead of $\mathbf{t}^*$. Minimizing this loss can be thought of as optimizing for the attachment scores.

The calculation of the above loss function can be solved as efficiently as the deduction system if the *cost* function decomposes into the dynamic program. We achieve this by replacing the scoring of each reduce step by its cost-augmented version:

$$\frac{[h_1, h_2, h_3, h_4] : v}{[h_1, h_2, h_4] : v + S(\mathsf{la}_2; \{\mathbf{h}_2, \mathbf{h}_3, \mathbf{h}_4\}) + \Delta}$$

where $\Delta = \mathbf{1}(head(w_{h_3}) \neq w_{h_4})$. This loss function encourages the model to give higher contrast between gold-standard and wrong predictions, yielding better generalization results.

5 Experiments

Data and Evaluation We experiment with the Universal Dependencies (UD) 2.0 dataset used for the CoNLL 2017 shared task (Zeman et al., 2017). We restrict our choice of languages to be those with only one training treebank, for a better comparison with the shared task results.[5] Among these languages, we pick the top 10 most non-projective languages. Their basic statistics are listed in Table 3. For all development-set results, we assume gold-standard tokenization and sentence delimitation. When comparing to the shared task results on test sets, we use the provided baseline UDPipe (Straka et al., 2016) segmentation. Our models do not use part-of-speech tags or morphological tags as features, but rather leverage such information via stack propagation (Zhang and Weiss, 2016), i.e., we learn to predict them as a secondary training objective. We report unlabeled attachment F1-scores (UAS) on the development sets for better focus on comparing our (unlabeled) parsing modules. We report its labeled variant (LAS), the main metric of the shared task, on the test sets. For each experiment setting, we ran the model with 5 different random initializations, and report the mean and standard deviation. We detail the implementation details in the supplementary material.

Baseline Systems For comparison, we include three baseline systems with the same underlying feature representations and scoring paradigm. All the following baseline systems are trained with the cost-augmented large-margin loss function.

The MH_3 *parser* is the projective instantiation of the MH_k parser family. This corresponds to the global version of the arc-hybrid transition system (Kuhlmann et al., 2011). We adopt the minimal feature representation $\{\mathbf{s}_0, \mathbf{b}_0\}$, following Shi et al. (2017a). For this model, we also implement a greedy incremental version.

The *edge-factored non-projective maximal spanning tree (MST) parser* allows arbitrary non-projective structures. This decoding approach has been shown to be very competitive in parsing non-projective treebanks (McDonald et al., 2005), and was deployed in the top-performing system at the CoNLL 2017 shared task (Dozat et al., 2017). We score each edge individually, with the features being the bi-LSTM vectors $\{\mathbf{h}, \mathbf{m}\}$, where h is the head, and m the modifier of the edge.

The *crossing-sensitive third-order 1EC parser* provides a hybrid dynamic program for parsing 1-Endpoint-Crossing non-projective dependency trees with higher-order factorization (Pitler, 2014). Depending on whether an edge is crossed, we can access the modifier's grandparent g, head h, and sibling si. We take their corresponding bi-LSTM features $\{\mathbf{g}, \mathbf{h}, \mathbf{m}, \mathbf{si}\}$ for scoring each edge. This is a re-implementation of Pitler (2014) with neural scoring functions.

Main Results Table 4 shows the development-set performance of our models as compared with baseline systems. MST considers non-projective structures, and thus enjoys a theoretical advantage over projective MH_3, especially for the most non-projective languages. However, it has a vastly larger output space, making the selection of correct structures difficult. Further, the scoring is edge-factored, and does not take any structural contexts into consideration. This tradeoff leads to the similar performance of MST comparing to MH_3. In comparison, both 1EC and MH_4 are mildly non-projective parsing algorithms, limiting the size of the output space. 1EC includes higher-order features that look at tree-structural contexts; MH_4 derives its features from parsing configurations of a transition system, hence leveraging contexts within transition sequences. These considerations explain their significant improvements over MST. We also observe that MH_4 recovers more short dependencies than 1EC, while 1EC is better at longer-distance ones.

[5]When multiple treebanks are available, one can develop domain transfer strategies, which is not the focus of this work.

Table 4: Experiment results (UAS, %) on the UD 2.0 development set. Bold: best result per language.

In comparison to MH_4-two, the richer feature representation of MH_4-hybrid helps in all our languages.

Interestingly, MH_4 and MH_3 react differently to switching from global to greedy models. MH_4 covers more structures than MH_3, and is naturally more capable in the global case, even when the feature functions are the same (MH_4-two). However, its greedy version is outperformed by MH_3. We conjecture that this is because MH_4 explores only the same number of configurations as MH_3, despite the fact that introducing non-projectivity expands the search space dramatically.

Comparison with CoNLL Shared Task Results (Table 5) We compare our models on the test sets, along with the best single model (#1; Dozat et al., 2017) and the best ensemble model (#2; Shi et al., 2017b) from the CoNLL 2017 shared task. MH_4 outperforms 1EC in 7 out of the 10 languages. Additionally, we take our non-projective parsing models (MST, MH_4-hybrid, 1EC) and combine them into an ensemble. The average result is competitive with the best CoNLL submissions. Interestingly, Dozat et al. (2017) uses fully non-projective parsing algorithms (MST), and our ensemble system sees larger gains in the more non-projective languages, confirming the potential benefit of global mildly non-projective parsing.

Results on Projective Languages (Table 6) For completeness, we also test our models on the 10 most projective languages that have a single treebank. MH_4 remains the most effective, but by a much smaller margin. Interestingly, MH_3, which is strictly projective, matches the performance of 1EC; both outperform the fully non-projective MST by half a point.

6 Related Work

Exact inference for dependency parsing can be achieved in cubic time if the model is restricted to projective trees (Eisner, 1996). However, non-projectivity is needed for natural language parsers to satisfactorily deal with linguistic phenomena like topicalization, scrambling and extraposition, which cause crossing dependencies. In UD 2.0, 68 out of 70 treebanks were reported to contain

non-projectivity (Wang et al., 2017).

However, exact inference has been shown to be intractable for models that support arbitrary non-projectivity, except under strong independence assumptions (McDonald and Satta, 2007). Thus, exact inference parsers that support unrestricted non-projectivity are limited to edge-factored models (McDonald et al., 2005; Dozat et al., 2017). Alternatives include treebank transformation and pseudo-projective parsing (Kahane et al., 1998; Nivre and Nilsson, 2005), approximate inference (e.g. McDonald and Pereira (2006); Attardi (2006); Nivre (2009); Fernández-González and Gómez-Rodríguez (2017)) or focusing on sets of dependency trees that allow only restricted forms of non-projectivity. A number of such sets, called mildly non-projective classes of trees, have been identified that both exhibit good empirical coverage of the non-projective phenomena found in natural languages and are known to have polynomial-time exact parsing algorithms; see Gómez-Rodríguez (2016) for a survey.

However, most of these algorithms have not been implemented in practice due to their prohibitive complexity. For example, Corro et al. (2016) report an implementation of the WG_1 parser, a $O(n^7)$ mildly non-projective parser introduced in Gómez-Rodríguez et al. (2009), but it could not be run for real sentences of length greater than 20. On the other hand, Pitler et al. (2012) provide an implementation of an $O(n^5)$ parser for a mildly non-projective class of structures called gap-minding trees, but they need to resort to aggressive pruning to make it practical, exploring only a part of the search space in $O(n^4)$ time.

To the best of our knowledge, the only practical system that actually implements exact inference for mildly non-projective parsing is the 1-Endpoint-Crossing (1EC) parser of Pitler (2013; 2014), which runs in $O(n^4)$ worst-case time like the MH_4 algorithm used in this paper. Thus, the system presented here is the second practical implementation of exact mildly non-projective parsing that has successfully been executed on real corpora.[6]

Comparing with Pitler (2014)'s 1EC, our parser has the following disadvantages: (-1) It has slightly lower coverage, at least on the treebanks considered by Gómez-Rodríguez (2016). (-2) The set of trees covered by MH_4 has not been characterized with a non-operational definition, while the set of 1-Endpoint-Crossing trees can be simply defined.

However, it also has the following advantages: (+1) It can be given a transition-based interpretation, allowing us to use transition-based scoring functions and to implement the analogous algorithm with greedy or beam search apart from exact inference. No transition-based interpretation is known for 1EC. While a transition-based algorithm has been defined for a strict subset of 1-Endpoint-Crossing trees, called 2-Crossing Interval trees (Pitler and McDonald, 2015), this is a separate algorithm with no known mapping or relation to 1EC or any other dynamic programming model. Thus, we provide the first exact inference algorithm for a non-projective transition-based parser with practical complexity. (+2) It is conceptually much simpler, with one kind of item and two deduction steps, while the 1-Endpoint-Crossing parser has five classes of items and several dozen distinct deduction steps. It is also a purely bottom-up parser, whereas the 1-Endpoint-Crossing parser does not have the bottom-up property. This property is necessary for models that involve compositional representations of subtrees (Dyer et al., 2015), and facilitates parallelization and partial parsing. (+3) It can be easily generalized to MH_k for $k > 4$, providing higher coverage, with time complexity $O(n^k)$. Out of the mildly non-projective parsers studied in Gómez-Rodríguez (2016), MH_4 provides the maximum coverage with respect to its complexity for $k > 4$. (+4) As shown in §5, MH_4 obtains slightly higher accuracy than 1EC on average, albeit not by a conclusive margin.

It is worth noting that 1EC has recently been extended to graph parsing by Kurtz and Kuhlmann (2017), Kummerfeld and Klein (2017), and Cao et al. (2017a,b), with the latter providing a practical implementation of a parser for 1-Endpoint-Crossing, pagenumber-2 graphs.

[6]Corro et al. (2016) describe a parser that enforces mildly non-projective constraints (bounded block degree and well-nestedness), but it is an arc-factored model, so it is subject to the same strong independence assumptions as maximum-spanning-tree parsers like McDonald et al. (2005) and does not support the greater flexibility in scoring that is the main advantage of mildly non-projective parsers over these. Instead, mild non-projectivity is exclusively used as a criterion to discard nonconforming trees.

7 Conclusion

We have extended the parsing architecture of Shi et al. (2017a) to non-projective dependency parsing by implementing the MH_4 parser, a mildly non-projective $O(n^4)$ chart parsing algorithm, using a minimal set of transition-based bi-LSTM features. For this purpose, we have established a mapping between MH_4 items and transition sequences of an underlying non-projective transition-based parser.

To our knowledge, this is the first practical implementation of exact inference for non-projective transition-based parsing. Empirical results on a collection of highly non-projective datasets from Universal Dependencies show improvements in accuracy over the projective approach of Shi et al. (2017a), as well as edge-factored maximum-spanning-tree parsing. The results are on par with the 1-Endpoint-Crossing parser of Pitler (2014) (re-implemented under the same neural framework), but our algorithm is notably simpler and has additional desirable properties: it is purely bottom-up, generalizable to higher coverage, and compatible with transition-based semantics.

Constituency Parsing with a Self-Attentive Encoder

Nikita Kitaev and **Dan Klein**

{kitaev, klein}@cs.berkeley.edu

Abstract

We demonstrate that replacing an LSTM encoder with a self-attentive architecture can lead to improvements to a state-of-the-art discriminative constituency parser. The use of attention makes explicit the manner in which information is propagated between different locations in the sentence, which we use to both analyze our model and propose potential improvements. For example, we find that separating positional and content information in the encoder can lead to improved parsing accuracy. Additionally, we evaluate different approaches for lexical representation. Our parser achieves new state-of-the-art results for single models trained on the Penn Treebank: 93.55 F1 without the use of any external data, and 95.13 F1 when using pre-trained word representations. Our parser also outperforms the previous best-published accuracy figures on 8 of the 9 languages in the SPMRL dataset.

1 Introduction

In recent years, neural network approaches have led to improvements in constituency parsing (Dyer et al., 2016; Cross and Huang, 2016; Choe and Charniak, 2016; Stern et al., 2017a; Fried et al., 2017). Many of these parsers can broadly be characterized as following an encoder-decoder design: an encoder reads the input sentence and summarizes it into a vector or set of vectors (e.g. one for each word or span in the sentence), and then a decoder uses these vector summaries to incrementally build up a labeled parse tree. In contrast to the large variety of decoder architectures investigated in recent work, the encoders in recent parsers have predominantly been built using recurrent neural networks (RNNs), and in particular Long Short-Term Memory networks (LSTMs).

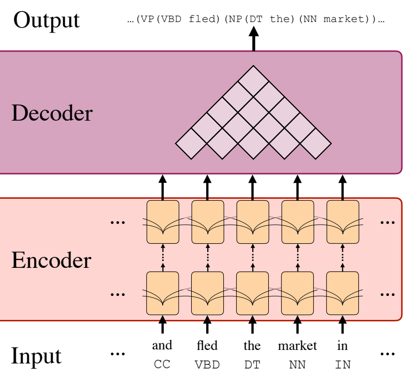

Figure 1: Our parser combines a chart decoder with a sentence encoder based on self-attention.

RNNs have largely replaced approaches such as the fixed-window-size feed-forward networks of Durrett and Klein (2015) in part due to their ability to capture global context. However, RNNs are not the only architecture capable of summarizing large global contexts: recent work by Vaswani et al. (2017) presented a new state-of-the-art approach to machine translation with an architecture that entirely eliminates recurrent connections and relies instead on a repeated neural attention mechanism. In this paper, we introduce a parser that combines an encoder built using this kind of self-attentive architecture with a decoder customized for parsing (Figure 1). In Section 2 of this paper, we describe the architecture and present our finding that self-attention can outperform an LSTM-based approach.

A neural attention mechanism makes explicit the manner in which information is transferred between different locations in the sentence, which we can use to study the relative importance of different kinds of context to the parsing task. Different locations in the sentence can attend to each other based on their positions, but also based on their contents (i.e. based on the words at or around those positions). In Section 3 we present our finding that when our parser learns to make an implicit trade-off between these two types of attention, it predominantly makes use of position-based attention, and show that explicitly factoring the two types of attention can noticeably improve parsing accuracy. In Section 4, we study our model's use of attention and reaffirm the conventional wisdom that sentence-wide global context is important for parsing decisions.

Like in most neural parsers, we find morphological (or at least sub-word) features to be important to achieving good results, particularly on unseen words or inflections. In Section 5.1, we demonstrate that a simple scheme based on concatenating character embeddings of word prefixes/suffixes can outperform using part-of-speech tags from an external system. We also present a version of our model that uses a character LSTM, which performs better than other lexical representations – even if word embeddings are removed from the model. In Section 5.2, we explore an alternative approach for lexical representations that makes use of pre-training on a large unsupervised corpus. We find that using the deep contextualized representations proposed by Peters et al. (2018) can boost parsing accuracy.

Our parser achieves 93.55 F1 on the Penn Treebank WSJ test set when not using external word representations, outperforming all previous single-system constituency parsers trained only on the WSJ training set. The addition of pre-trained word representations following Peters et al. (2018) increases parsing accuracy to 95.13 F1, a new state-of-the-art for this dataset. Our model also outperforms previous best published results on 8 of the 9 languages in the SPMRL 2013/2014 shared tasks. Code and trained English models are publicly available.[1]

2 Base Model

Our parser follows an encoder-decoder architecture, as shown in Figure 1. The decoder, described in Section 2.1, is borrowed from the chart parser of Stern et al. (2017a) with additional modifications from Gaddy et al. (2018). Their parser is architecturally streamlined yet achieves the highest performance among discriminative single-system parsers trained on WSJ data only, which is why we selected it as the starting point for our experiments with encoder variations. Sections 2.2 and 2.3 describe the base version of our encoder, where the self-attentive architecture described in Section 2.2 is adapted from Vaswani et al. (2017).

2.1 Tree Scores and Chart Decoder

Our parser assigns a real-valued score $s(T)$ to each tree T, which decomposes as

$$s(T) = \sum_{(i,j,l)\in T} s(i,j,l) \tag{1}$$

Here $s(i,j,l)$ is a real-valued score for a constituent that is located between fencepost positions i and j in a sentence and has label l. To handle unary chains, the set of labels includes a collapsed entry for each unary chain in the training set. The model handles n-ary trees by binarizing them and introducing a dummy label $\varnothing$ to nodes created during binarization, with the property that $\forall i,j : s(i,j,\varnothing) = 0$. Enforcing that scores associated with the dummy labels are always zero ensures that (1) continues to hold for all possible binarizations of an n-ary tree.

At test time, the model-optimal tree

$$\hat{T} = \arg\max_T s(T)$$

can be found efficiently using a CKY-style inference algorithm. Given the correct tree $T^\star$, the model is trained to satisfy the margin constraints

$$s(T^\star) \geq s(T) + \Delta(T, T^\star)$$

for all trees T by minimizing the hinge loss

$$\max\left(0, \max_{T\neq T^\star}\left[s(T) + \Delta(T,T^\star)\right] - s(T^\star)\right)$$

Here Δ is the Hamming loss on labeled spans, and the tree corresponding to the most-violated constraint can be found using a slight modification of the inference algorithm used at test time.

For further details, see Gaddy et al. (2018). The remainder of this paper concerns itself with the functional form of $s(i,j,l)$, which is calculated using a neural network for all $l \neq \varnothing$.

2.2 Context-Aware Word Representations

The encoder portion of our model is split into two parts: a word-based portion that assigns a context-aware vector representation y_t to each position t in the sentence (described in this section), and a chart portion that combines the vectors y_t to generate span scores $s(i,j,l)$ (Section 2.3). The architecture for generating the vectors y_t is adapted from Vaswani et al. (2017).

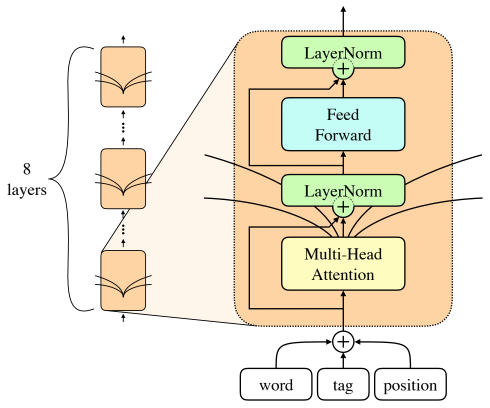

Figure 2: An overview of our encoder, which produces a context-aware summary vector for each word in the sentence. The multi-headed attention mechanism is the only means by which information may propagate between different positions in the sentence.

The encoder takes as input a sequence of word embeddings $[w_1, w_2, \ldots, w_T]$, where the first and last embeddings are of special *start* and *stop* tokens. All word embeddings are learned jointly with other parts of the model. To better generalize to words that are not seen during training, the encoder also receives a sequence of part-of-speech tag embeddings $[m_1, m_2, \ldots, m_T]$ based on the output of an external tagger (alternative lexical representations are discussed in Section 5). Additionally, the encoder stores a learned table of position embeddings, where every number $i \in 1, 2, \ldots$ (up to some maximum sentence length) is associated with a vector p_i. All embeddings have the same dimensionality, which we call d_{model}, and are added together at the input of the encoder: $z_t = w_t + m_t + p_t$.

The vectors $[z_1, z_2, \ldots, z_T]$ are transformed by a stack of 8 identical layers, as shown in Figure 2. Each layer consists of two stacked sublayers: a multi-headed attention mechanism and a position-wise feed-forward sublayer. The output of each sublayer given an input x is $\text{LayerNorm}(x + \text{SubLayer}(x))$, i.e. each sublayer is followed by a residual connection and a Layer Normalization (Ba et al., 2016) step. As a result, all sublayer outputs, including final outputs y_t, are of size d_{model}.

2.2.1 Self-Attention

The first sublayer in each of our 8 layers is a multi-headed self-attention mechanism, which is the only means by which information may propagate between positions in the sentence. The input

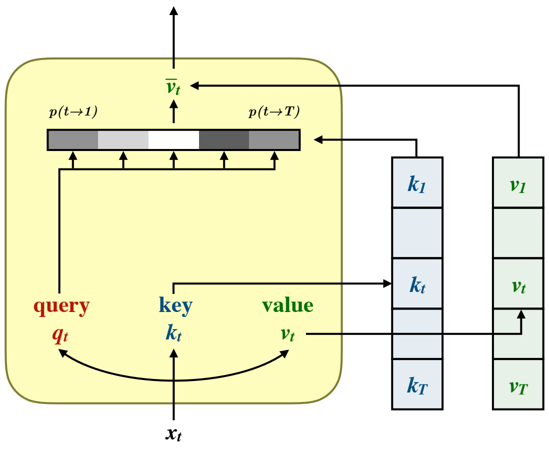

Figure 3: A single attention head. An input x_t is split into three vectors that participate in the attention mechanism: a query q_t, a key k_t, and a value v_t. The query q_t is compared with all keys to form a probability distribution $p(t \to \cdot)$, which is then used to retrieve an average value $\bar{v}_t$.

to the attention mechanism is a $T \times d_{model}$ matrix X, where each row vector x_t corresponds to word t in the sentence.

We first consider a single attention head, as illustrated in Figure 3. Learned parameter matrices W_Q, W_K, and W_V are used to map an input x_t to three vectors: a query $q_t = W_Q^\top x_t$, a key $k_t = W_K^\top x_t$, and a value $v_t = W_V^\top x_t$. Query and key vectors have the same number of dimensions, which we call d_k. The probability that word i attends to word j is then calculated as $p(i \to j) \propto \exp(\frac{q_i \cdot k_j}{\sqrt{d_k}})$. The values v_j for all words that have been attended to are aggregated to form an average value $\bar{v}_i = \sum_j p(i \to j) v_j$, which is projected back to size d_{model} using a learned matrix W_O. In matrix form, the behavior of a single attention head is:

$$\text{SingleHead}(X) = \left[\text{Softmax}\left(\frac{QK^\top}{\sqrt{d_k}}\right) V\right] W_O$$
$$\text{where } Q = XW_Q;\ K = XW_K;\ V = XW_V$$

Rather than using a single head, our model sums together the outputs from multiple heads:

$$\text{MultiHead}(X) = \sum_{n=1}^{8} \text{SingleHead}^{(n)}(X)$$

Each of the 8 heads has its own trainable parameters $W_Q^{(n)}$, $W_K^{(n)}$, $W_V^{(n)}$, and $W_O^{(n)}$. This allows a word to gather information from up to 8 remote locations in the sentence at each attention sublayer.

2.2.2 Position-Wise Feed-Forward Sublayer

We use the same form as Vaswani et al. (2017):

$$\text{FeedForward}(x) = W_2\text{relu}(W_1 x + b_1) + b_2$$

Here *relu* denotes the Rectified Linear Unit nonlinearity, and distinct sets of learned parameters are used at each of the 8 instances of the feed-forward sublayer in our model.

The input and output dimensions are the same because of the use of residual connections throughout the model, but we can vary the number of parameters by adjusting the size of the intermediate vector that the nonlinearity is applied to.

2.3 Span Scores

The outputs y_t from the word-based encoder portion described in the previous section are combined to form span scores $s(i, j, \cdot)$ following the method of Stern et al. (2017a). Concretely,

$$s(i, j, \cdot) = M_2\text{relu}(\text{LayerNorm}(M_1 v + c_1)) + c_2$$

where LayerNorm denotes Layer Normalization, *relu* is the Rectified Linear Unit nonlinearity, and $v = [\overrightarrow{y}_j - \overrightarrow{y}_i; \overleftarrow{y}_{j+1} - \overleftarrow{y}_{i+1}]$ combines summary vectors for relevant positions in the sentence. A span endpoint to the right of the word potentially requires different information from the endpoint to the left, so a word at a position k is associated with *two* annotation vectors ($\overrightarrow{y}_k$ and $\overleftarrow{y}_k$).

Stern et al. (2017a) define $\overrightarrow{y}_k$ and $\overleftarrow{y}_k$ in terms of the output of the forward and backward portions, respectively, of their BiLSTM encoder; we instead construct each of $\overrightarrow{y}_k$ and $\overleftarrow{y}_k$ by splitting in half[2] the outputs y_k from Section 2.2. We also introduce a Layer Normalization step to match the use of Layer Normalization throughout our model.

2.4 Results

The model presented above achieves a score of 92.67 F1 on the Penn Treebank WSJ development set. Details regarding hyperparameter choice and optimizer settings are presented in the supplementary material. For comparison, a model that uses the same decode procedure with an LSTM-based encoder achieves a development set score of 92.24 (Gaddy et al., 2018). These results demonstrate that an RNN-based encoder is not required for building a good parser; in fact, self-attention can achieve better results.

[2]To avoid an adverse interaction with material described in Section 3, when a vector y_k is split in half the even coordinates contribute to $\overrightarrow{y}_k$ and the odd coordinates contribute to $\overleftarrow{y}_k$.

3 Content vs. Position Attention

The primary mechanism for information transfer throughout our encoder is self-attention, where words can attend to each other using both content features and position information. In Section 2, we described an encoder that takes as input a component-wise addition between a word, tag, and position embedding for each word in the sentence. Content and position information are intermingled throughout the network. While ideally the network would learn to balance the different types of information, in practice it does not. In this section we show that factoring the model to explicitly separate content and position information results in increased parsing accuracy.

To help gauge the relative importance of the two types of attention, we trained a modified version of our model that was only allowed to use position attention. This constraint was enforced by making the query and key vectors used for the attention mechanism be linear transformations of the corresponding word's position embedding: $Q^{(n)} = PW_Q^{(n)}$ and $K^{(n)} = PW_K^{(n)}$. The per-head weight matrices now multiply a matrix P containing the same position embeddings that are used at the input to the encoder, rather than the layer input X (as in Section 2.2.1). However, value vectors $V^{(n)} = XW_V^{(n)}$ remain unchanged and continue to carry content-related information.

We expected our parser to still achieve reasonable performance when restricted to only use positional attention because the resulting architecture can be viewed as a generalization of a multi-layer convolutional neural network. The 8 attention heads at each layer of our model can mimic the behavior of a size-8 convolutional filter, but can also determine their attention targets dynamically and need not respect any translation-invariance properties. Disabling content-based attention throughout all 8 layers of the network results in a development-set accuracy decrease of only 0.27 F1. While we expected reasonable parsing performance in this setting, it seems strange that content-based attention benefits our model to such a small degree.

We next investigate the possibility that intermingling content and position information in a single vector can cause one type of attention to dominate over the other and compromise the network's ability to find the optimal balance of the two. To do this we propose a factored version of our model that explicitly separates content and position information.

A first step is to replace the component-wise addition $z_t = w_t + m_t + p_t$ (where w_t, m_t, and p_t represent word, tag, and position embeddings, respectively) with a concatenation $z_t = [w_t + m_t; p_t]$. We preserve the size of the vector z_t by cutting the dimensionality of embeddings in half for the concatenative scheme. However, simply isolating the position-related components of the input vectors in this manner does not improve the performance of our network: the concatenative network achieves a development-set F1 of 92.60 (not much different from 92.67 F1 using the model in Section 2).

The issue with intermingling information is not the component-wise addition per se. In fact, concatenation and addition often perform similarly in high dimensions (especially when the resulting vector is immediately multiplied by a matrix that intermingles the two sources of information). On that note, we can examine how the mixed vectors are used later in the network, and in particular in the query-key dot products for the attention mechanism. If we have a query-key dot product $q \cdot k$ (see Section 2.2.1) where we imagine q decomposing into content and positional information as $q = q^{(c)} + q^{(p)}$ (and likewise for k), we have $q \cdot k = (q^{(c)} + q^{(p)}) \cdot (k^{(c)} + k^{(p)})$. This formulation includes cross-terms such as $q^{(c)} \cdot k^{(p)}$; for example it is possible to learn a network where the word *the* always attends to the *5th position* in the sentence. Such cross-attention seems of limited use compared to the potential for overfitting that it introduces.

To complete our factored model, we find all cases where a vector $x = [x^{(c)}; x^{(p)}]$ is multiplied by a parameter matrix, and replace the matrix multiplication $c = Wx$ with a split form $c = [c^{(c)}; c^{(p)}] = [W^{(c)}x^{(c)}; W^{(p)}x^{(p)}]$. This causes a number of intermediate quantities in our model to be factored, including all query and key vectors. Query-key dot products now decompose as $q \cdot k = q^{(c)} \cdot k^{(c)} + q^{(p)} \cdot k^{(p)}$. The result of factoring a single attention head, shown in Figure 4, can also be viewed as separately applying attention to $x^{(c)}$ and $x^{(p)}$, except that the log-probabilities in the two halves are added together prior to value lookup. The feed-forward sublayers in our model (Section 2.2.2) are likewise split into two independent portions that operate on position and content information.

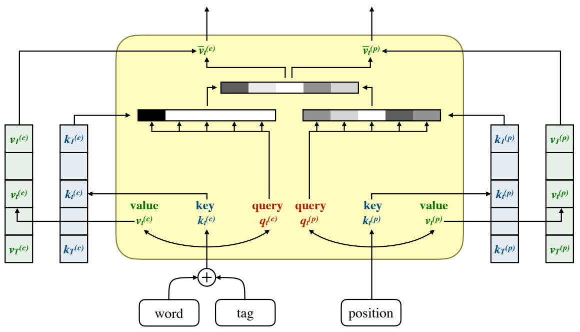

Figure 4: A single attention head, after factoring content and position information. Attention probabilities are calculated separately for the two types of information, and a combined probability distribution is then applied to both types of input information.

Alternatively, factoring can be seen as enforcing the block-sparsity constraint

$$W = \begin{bmatrix} W^{(c)} & 0 \\ 0 & W^{(p)} \end{bmatrix}$$

on parameter matrices throughout our model. We maintain the same vector sizes as in Section 2, which means that factoring strictly reduces the number of trainable parameters. For simplicity, we split each vector into equal halves that contain position and content information, cutting the number of model parameters roughly in half. This factored scheme is able to achieve 93.15 development-set F1, an improvement of almost 0.5 F1 over the unfactored model.

These results suggest that factoring different types of information leads to a better parser, but there is in principle a confound: perhaps by making all matrices block-sparse we've stumbled across a better hyperparameter configuration. For example, these gains could be due to a difference in the number of trainable parameters alone. To control for this confound we also evaluated a version of our model that enforces block-sparsity throughout, but retains the use of component-wise addition at the inputs. This model achieves 92.63 F1 (not much different from the unfactored model), which supports our hypothesis that true factoring of information is important.

Attention		
Content	Position	F1
All 8 layers	All 8 layers	93.15
All 8 layers	Disabled	72.45
Disabled	All 8 layers	90.84
First 4 layers only	All 8 layers	91.77
Last 4 layers only	All 8 layers	92.82
First 6 layers only	All 8 layers	92.42
Last 6 layers only	All 8 layers	92.90

Table 1: Development-set F1 scores when content and/or position attention is selectively disabled *at test-time only* for a subset of the layers in our model. Position attention is the most important contributor to our model, but content attention is also helpful (especially at the final layers of the encoder).

Distance	F1 (strict)	F1 (relaxed)
5	81.65	89.82
10	89.83	92.20
15	91.72	92.78
20	92.48	92.91
30	93.01	93.09
40	93.04	93.12
∞	93.15	

Table 2: Development-set F1 scores when attention is constrained to not exceed a particular distance in the sentence *at test time only*. In the *relaxed* setting, the first and last two tokens of the sentence can attend to any word and be attended to by any word, to allow for sentence-wide pooling of information.

4 Analysis of our Model

The defining feature of our encoder is the use of self-attention, which is the only mechanism for transfer of information between different locations throughout a sentence. The attention is further factored into types: content-based attention and position-based attention. In this section, we analyze the manner in which our model uses this attention mechanism to make its predictions.

4.1 Content vs. Position Attention

To examine the relative utilization of content-based vs. position-based attention in our architecture, we perturb a trained model at test-time by selectively zeroing out the contribution of either the content or the position component to any attention mechanism. This can be done independently at different layers; the results of this experiment are shown in Table 1.

We can see that our model learns to use a combination of the two attention types, with position-based attention being the most important. We also see that content-based attention is more useful at later layers in the network, which is consistent with the idea that the initial layers of our model act similarly to a dilated convolutional network while the upper layers have a greater balance between the two attention types.

4.2 Windowed Attention

We can also examine our model's use of long-distance context information by applying windowing to the attention mechanism. We begin by taking our trained model and windowing the attention mechanism at test-time only. As shown in Table 2, strict windowing yields poor results: even a window of size 40 causes a loss in parsing accuracy compared to the original model. When we began to investigate *how* the model makes use of long-distance attention, we immediately found that there are particular attention heads at some layers in our model that almost always attend to the start token. This suggests that the start token is being used as the location for some sentence-wide pooling/processing, or perhaps as a dummy target location when a head fails to find the particular phenomenon that it's learned to search for. In light of this observation, we introduce a *relaxed* variation on the windowing scheme, where the start token, first word, last word, and stop token can participate in all possible uses of attention, but pairs of other words in the sentence can only attend to each other if they are within a given window. We include three other positions in addition to the start token to do our best to cover possible locations for global pooling by our model. Results for relaxed windowing at test-time only are also shown in Table 2. Even when we allow global processing to take place at designated locations such as the start token, our model is able to make use of long-distance dependencies at up to length 40.

Next, we examine whether the parser's use of long-distance dependencies is actually essential to performing the task by retraining our model subject to windowing. To evaluate the role of global

Distance	F1 (strict)	F1 (relaxed)
5	92.74	92.94
10	92.92	93.00
20	93.06	93.17
∞	93.15	

Table 3: Development-set F1 scores when attention is constrained to not exceed a particular distance in the sentence *during training and at test time*. In the *relaxed* setting, the first and last two tokens of the sentence can attend to any word and be attended to by any word, to allow for sentence-wide pooling of information.

computation, we consider both strict and relaxed windowing. In principle we could have replaced relaxed windowing at training time with explicit provisions for global computation, but for analysis purposes we choose to minimize departures from our original architecture.

The results, shown in Table 3, demonstrate that long-distance dependencies continue to be essential for achieving maximum parsing accuracy using our model. Note that when a window of size 10 was imposed at training time, this was *per-layer* and the series of 8 layers actually had an effective context size of around *80* – which was still insufficient to recover the performance of our full parser (with either approach to windowing). The side-by-side comparison of strict and relaxed windowing shows that the ability to pool global information, using the designated locations that are always available in the relaxed scheme, consistently translates to accuracy gains but is insufficient to compensate for small window sizes. This suggests that not only must the information signal from long-distance tokens be available in principle, but that it also helps to have this information be directly accessible without an intermediate bottleneck.

5 Lexical Models

The models described in previous sections all rely on pretagged input sentences, where the tags are predicted using the Stanford tagger. We use the same pretagged dataset as Cross and Huang (2016). In this section we explore two alternative classes of lexical models: those that use no external systems or data of any kind, as well as word vectors that are pretrained in an unsupervised manner.

	Word embeddings	
	✓	✗
None	92.20	–
Tags	93.15	–
CharLSTM	93.40	93.61
CharConcat	93.32	93.35

Table 4: Development-set F1 scores for different approaches to handling morphology, with and without the addition of learned word embeddings.

5.1 Models with Subword Features

If tag embeddings are removed from our model and only word embeddings remain (where word embeddings are learned jointly with other model parameters), performance suffers by around 1 F1. To restore performance without introducing any dependencies on an external system, we explore incorporating lexical features directly into our model. The results for different approaches we describe in this section are shown in Table 4.

We first evaluate an approach (CharLSTM) that independently runs a bidirectional LSTM over the characters in each word and uses the LSTM outputs in place of part-of-speech tag embeddings. We find that this approach performs better than using predicted part-of-speech tags. We can further remove the word embeddings (leaving the character LSTMs only), which does not seem to hurt and can actually help increase parsing accuracy.

Next we examine the importance of recurrent connections by constructing and evaluating a simpler alternative. Our approach (CharConcat) is inspired by Hall et al. (2014), who found it effective to replace words with frequently-occurring suffixes, and the observation that our original tag embeddings are rather high-dimensional. To represent a word, we extract its first 8 letters and last 8 letters, embed each letter, and concatenate the results. If we use 32-dimensional embeddings, the 16 letters can be packed into a 512-dimensional vector – the same size as the inputs to our model. This size for the inputs in our model was chosen to simplify the use of residual connections (by matching vector dimensions), even though the inputs themselves could have been encoded in a smaller vector. This allows us to directly replace tag embeddings with the 16-letter prefix/suffix concatenation. For short words, embeddings of a padding token are inserted as needed. Words longer than 16 letters are represented in a lossy manner by this concatenative approach, but we hypothesize that prefix/suffix information is enough for our task. We find this simple scheme remarkably effective: it is able to outperform pretagging and can operate even in the absence of word embeddings. However, its performance is ultimately not quite as good as using a character LSTM.

Given the effectiveness of the self-attentive encoder at the sentence level, it is aesthetically appealing to consider it as a sub-word architecture as well. However, it was empirically much slower, did not parallelize better than a character-level LSTM (because words tend to be short), and initial results underperformed the LSTM. One explanation is that in a lexical model, one only wants to compute a single vector per word, whereas the self-attentive architecture is better adapted for producing context-aware summaries at multiple positions in a sequence.

5.2 External Embeddings

Next, we consider a version of our model that uses external embeddings. Recent work by Peters et al. (2018) has achieved state-of-the-art performance across a range of NLP tasks by augmenting existing models with a new technique for word representation called ELMo (Embeddings from Language Models). Their approach is able to capture both subword information and contextual clues: the embeddings are produced by a network that takes characters as input and then uses an LSTM to capture contextual information when producing a vector representation for each word in a sentence.

We evaluate a version of our model that uses ELMo as the sole lexical representation, using publicly available ELMo weights. These pre-trained word representations are 1024-dimensional, whereas all of our factored models thus far have 512-dimensional content representations; we found that the most effective way to address this mismatch is to project the ELMo vectors to the required dimensionality using a learned weight matrix. With the addition of contextualized word representations, we hypothesized that a full 8 layers of self-attention would no longer be necessary. This proved true in practice: our best development set result of 95.21 F1 was obtained with a 4-layer encoder.

Encoder Architecture	F1 (dev)	Δ
LSTM (Gaddy et al., 2018)	92.24	-0.43
Self-attentive (Section 2)	92.67	0.00
+ Factored (Section 3)	93.15	0.48
+ CharLSTM (Section 5.1)	93.61	0.94
+ ELMo (Section 5.2)	95.21	2.54

Table 6: Comparison of F1 scores on the WSJ test set.

6 Results

6.1 English (WSJ)

The development set scores of the parser variations presented in previous sections are summarized in Table 5. Our best-performing parser used a factored self-attentive encoder over ELMo word representations.

The results of evaluating our model on the test set are shown in Table 6. The test score of 93.55 F1 for our CharLSTM parser exceeds the previous best numbers for single-system parsers trained on the Penn Treebank (without the use of any external data, such as pre-trained word embeddings). When our parser is augmented with ELMo word representations, it achieves a new state-of-the-art score of 95.13 F1 on the WSJ test set.

Our WSJ-only parser took 18 hours to train using a single Tesla K80 GPU and can parse the

Table 7: Results on the SPMRL dataset. All values are F1 scores calculated using the version of `evalb` distributed with the shared task. [a]Björkelund et al. (2013) [b]Uses character LSTM, whereas other results from Coavoux and Crabbé (2017) use predicted part-of-speech tags.

1,700-sentence WSJ development set in 8 seconds. When using ELMo embeddings, training time was 13 hours (not including the time needed to pre-train the word embeddings) and parsing the development set takes 24 seconds. Training and inference times are dominated by neural network computations; our single-threaded Cython implementation of the chart decoder (Section 2.1) consumes a negligible fraction of total running time.

6.2 Multilingual (SPMRL)

We tested our model's ability to generalize across languages by training it on the nine languages represented in the SPMRL 2013/2014 shared tasks (Seddah et al., 2013). To verify that our lexical representations can function for morphologically-rich languages and smaller treebanks, we restricted ourselves to running a subset of the exact models that we evaluated on English. In particular, we evaluated the model that uses a character-level LSTM, with and without the addition of learned word embeddings. We did not evaluate ELMo in the multilingual setting because pre-trained ELMo weights were only available for English. Hyper-parameters were unchanged compared to the English model with the exception of the learning rate, which we adjusted for some of the smaller datasets in the SPMRL task (see Table 9 in the supplementary material). Results are shown in Table 7.

Development set results show that the addition of word embeddings to a model that uses a character LSTM has a mixed effect: it improves performance for some languages, but hurts for others. For each language, we selected the trained model that performed better on the development set and evaluated it on the test set. On 8 of the 9 languages, our test set result exceeds the previous best-published numbers from any system we are aware of. The exception is Swedish, where the model of Björkelund et al. (2014) continues to be state-of-the-art despite a number of approaches proposed in the intervening years that have achieved better performance on other languages. We note that their model uses ensembling (via product grammars) and a reranking step, whereas our model was only evaluated in the single-system condition.

7 Conclusion

In this paper, we show that the choice of encoder can have a substantial effect on parser performance. In particular, we demonstrate state-of-the-art parsing results with a novel encoder based on factored self-attention. The gains we see come not only from incorporating *more* information (such as subword features or externally-trained word representations), but also from structuring the architecture to *separate* different kinds of information from each other. Our results suggest that further research into different ways of encoding utterances can lead to additional improvements in both parsing and other natural language processing tasks.

Abstract

Motivated by the positive impact of empty categories on syntactic parsing, we study neural models for pre- and in-parsing detection of empty categories, which has not previously been investigated. We find several non-obvious facts: (a) BiLSTM can capture non-local contextual information which is essential for detecting empty categories, (b) even with a BiLSTM, syntactic information is still able to enhance the detection, and (c) automatic detection of empty categories improves parsing quality for overt words. Our neural ECD models outperform the prior state-of-the-art by significant margins.

1 Introduction

Encoding unpronounced nominal elements, such as dropped pronouns and traces of dislocated elements, the empty category is an important piece of machinery in representing the (deep) syntactic structure of a sentence (Carnie, 2012). Figure 1 shows an example. In linguistic theory, e.g. Government and Binding (GB; Chomsky, 1981), empty category is a key concept bridging S-Structure and D-Structure, due to its possible contribution to trace *movements*. In practical treebanking, empty categories have been used to indicate long-distance dependencies, discontinuous constituents, and certain dropped elements (Marcus et al., 1993; Xue et al., 2005). Recently, there has been an increasing interest in automatic empty category detection (ECD; Johnson, 2002; Seeker et al., 2012; Xue and Yang, 2013; Wang et al., 2015). And it has been shown that ECD is able to improve the linear model-based dependency parsing (Zhang et al., 2017b).

There are two key dimensions of approaches for ECD: the relationship with parsing and statistical disambiguation. Considering the relationship with parsing, we can divide ECD models into three types: (1) Pre-parsing approach (e.g. Dienes and Dubey (2003)) where empty categories are identified without using syntactic analysis, (2) In-parsing approach (e.g. Cai et al. (2011); Zhang et al. (2017b)) where detection is integrated into a parsing model, and (3) Post-parsing approach (e.g. Johnson (2002); Wang et al. (2015)) where parser outputs are utilized as clues to determine the existence of empty categories. For disambiguation, while early work on dependency parsing focused on linear models, recent work started exploring deep learning techniques for the post-parsing approach (Wang et al., 2015). From the above two dimensions, we show all existing systems for ECD in Table 1. Neural models for pre- and in-parsing ECD have not been studied yet. In this paper, we fill this gap in the literature.

	Pre-Parsing	In-Parsing	Post-Parsing
Linear	✔	✔	✔
Neural	✘	✘	✔

Table 1: ECD approaches that have been investigated.

It is obvious that empty categories are highly related to surface syntactic analysis. To determine the existence of empty elements between two overt words relies on not only the *sequential contexts* but also the *hierarchical contexts*. Traditional linear structured prediction models, e.g. conditional random fields (CRF), for sequence structures are rather weak to capture hierarchical contextual information which is essentially *non-local* for their architectures. Accordingly, pre-parsing models based on linear disambiguation techniques fail to produce comparable accuracy to the other two models. In striking contrast, RNN based se-

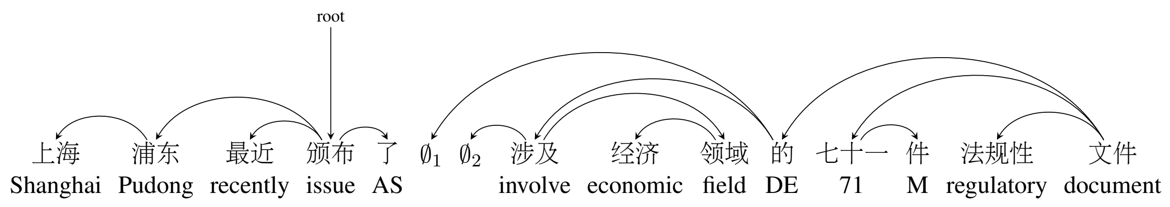

Figure 1: An example from CTB: *Shanghai Pudong recently enacted 71 regulatory documents involving the economic fields*. The dependency structure is according to Xue (2007). "$\emptyset_1$" indicates a null operator that represents empty relative pronouns. "$\emptyset_2$" indicates a trace left by relativization.

quence labeling models have been shown very powerful to capture non-local information, and therefore have great potential to advance the pre-parsing approach for ECD. In this paper, we propose a new bidirectional LSTM (BiLSTM) model for pre-parsing ECD using information about contextual words.

Previous studies highlight the usefulness of syntactic analysis for ECD. Furthermore, syntactic parsing of overt words can benefit from detection of empty elements and vice versa (Zhang et al., 2017b). In this paper, we follow Zhang et al.'s encouraging results obtained with linear models and study first- and second-order neural models for in-parsing ECD. The main challenge for neural in-parsing ECD is to encode empty element candidates and integrate the corresponding embeddings into a parsing model. We focus on the state-of-the-art parsing architecture developed by Kiperwasser and Goldberg (2016) and Dozat and Manning (2016), which use BiLSTMs to extract features from contexts followed by a nonlinear transformation to perform local scoring.

To evaluate the effectiveness of deep learning techniques for ECD, we conduct experiments on a pro-drop language, i.e. Chinese. The empirical evaluation indicates some non-obvious facts:

1. Neural ECD models outperform the prior state-of-the-art by significant margins. Even a pre-parsing model without any syntactic information outperforms the best existing linear in-parsing and post-parsing ECD models.

2. Incorporating empty elements can help neural dependency parsing. This parallels Zhang et al.'s investigation on linear models.

3. Our in-parsing neural models obtain better predictions than the pre-parsing model.

The implementation of all models is available at `https://github.com/draplater/empty-parser`.

2 Pre-Parsing Detection

2.1 Context of Empty Categories

Sequential Context Perhaps, it is the most intuitive idea to view a natural language sentence as a word-by-word sequence. Analyzing contextual information by modeling neighboring words according to this sequential structure is a very basic view for dealing with a large number of NLP tasks, e.g. POS tagging and syntactic parsing. It is also important to consider sequential contexts for ECD to derive the horizontal features that exploit the lexical context of the current pending point, presented as one or more preceding and following word tokens, as well as their part-of-speech tags (POS).

Hierarchical Context The detection of ECs requires broad contextual knowledge. Besides one-dimensional representation, vertical features are equally essential to express the empty element. The hierarchical structure is a compact reflection of the syntactic content. By integrating the hierarchical context, we can analyze the regular distributional pattern of ECs in a syntactic tree. More specifically, it means considering the head information of the EC and relevant dependencies to augment the prediction.

Both *sequential* and *hierarchical* contexts are essential to determine the existence of empty elements between two overt words. Even words close to each other in a hierarchical structure may appear far apart in sequential representations, which makes it hard for linear sequential tagging models to catch the hierarchical contextual information. RNN based sequence models have been proven very powerful to capture non-local features. In this paper, we show that LSTM is able to advance the pre-parsing ECD significantly.

Interspace:	@@ 颁布(issue)	@@ 了(AS)	@@ 涉及(involve)	@@ 经济(economic)
	O VV	O AS	*OP**T* VV	O NN

Prepost:	颁布(issue)	了(AS)	涉及(involve)	经济(economic)
	VV	AS#post=*OP*	VV#pre1=*T*	NN

Figure 2: An example of four kinds of annotations. The phrase is cut out from the sentence in Figure 1. "@@" means interspaces between words.

2.2 A Sequence-Oriented Model

In the sequence-oriented model, we formulate ECD as a sequence labeling problem. In general, we attach ECs to surrounding overt tokens to represent their identifications, i.e. their locations and types. We explore four sets of annotation specifications, denoted as *Interspace*, *Pre2*, *Pre3* and *Prepost*, respectively. Following is the detailed descriptions.

Interspace We convert ECs' information into different tags of the interspaces between words. The assigned tag is the concatenation of ECs between the two words. If there is no EC, we just tag the interspace as *O*. Specially, according to our observation that only one EC occurs at the end of the sentence in our data set, we simply count on the heading space of sentences instead of the one standing at the end. Assume that there are n words in a given sentence, then there will be $2 * n$ items (n words and n interspaces) to tag.

Pre2 and Pre3 We stick ECs to words following them. In experiments using POS information, ECs are attached to the POS of the next word, while the normal words are just tagged with their POS. In experiments without POS information, ECs are straightly regarded as the label of the following words. Words without ECs ahead are consistently tagged using an empty marker. Similar to *Interspace*, linearly consecutive ECs are concatenated as a whole. *Pre2* means that at most two preceding consecutive ECs are considered while *Pre3* limits the considered continuous length to three. The determination of window lengths are grounded in the distribution of ECs' continuous lengths as shown in Table 2.

Prepost Considering that it may be a challenge to capture long-distance features, we introduce another labeling rule called *Prepost*. Different from *Pre2* and *Pre3*, the responsibility for presenting ECs will be shared by both the preceding and the following words. Whereas, tags heading sentences will remain unchanged. Particularly, if the amount of consecutive ECs in the current position is an odd number, we choose to attach the extra EC to the following word for consistency and clarity.

	1	2	3	4
Train	7499	3702	142	5
Dev	530	233	10	0
Test	900	433	19	0

Table 2: The distribution of ECs' continuous lengths in training, development and test data.

Take part of the sentence in Figure 1 as an example. As described above, the four kinds of representations are depicted in Figure 2. To investigate the effect of POS in the tagging process, we also conduct experiments by integrating POS to the tagging process. For *Interspace*, POS tags are individual output labels, while for other representations, the POS information is used to divide an empty category integrated tag into subtypes.

2.3 Tagging Based on LSTM-CRF

In order to capture long-range syntactic information for accurate disambiguation in pre-parsing phase, we build a LSTM-CRF model inspired by the neural network proposed in Ma and Hovy (2016). A BiLSTM layer is set up on character embeddings for extracting character-level representations of each word, which is concatenated with the pre-trained word embedding before feeding into another BiLSTM layer to capture contextual information. Thus we have obtained dense and continuous representations of the words in given sentences. The last part is to decode with linear chain CRF which can optimize the output sequence by factoring in local characteristics. Dropout layers both before and after the sentence-level network serve to prevent over-fitting.

3 In-Parsing Detection

Zhang et al. (2017b) designs novel algorithms to produce dependency trees in which empty elements are allowed. Their results show that integrating empty categories can augment the parsing of overt tokens when structured perceptron, a global linear model, is applied for disambiguation. From a different perspective, by jointing ECD and dependency parsing, we can utilize full syntactic information in the process of detecting ECs. Parallel to their work, we explore the effect of ECD on the neural dependency based parsing in this section.

3.1 Joint ECD and Dependency Parsing

To perform ECD and dependency parsing in a unified framework, we formulate the issue as an optimization problem. Assume that we are given a sentence s with n normal words. We use an index set $\mathcal{I}_o = \{(i,j)|i,j \in \{1,\cdots,n\}\}$ to denote all possible overt dependency edges, and use $\mathcal{I}_c = \{(i,\phi_j)|i,j \in \{1,\cdots,n\}\}$ to denote all possible covert dependency edges. ϕ_j denotes an empty node that precede the jth word. Then a dependency parse with empty nodes can be represented as a vector:

$$\boldsymbol{z} = \{z(i,j) : (i,j) \in \mathcal{I}_o \cup \mathcal{I}_c\}.$$

Let $\mathcal{Z}$ denote the set of all possible $\boldsymbol{z}$, and $\textsc{Part}(\boldsymbol{z})$ denote the factors in the dependency tree, including edges (and edge siblings in the second-order model). Then parsing with ECD can be defined as a search for the highest-scored $\boldsymbol{z}^*(s)$ in all compatible analyses, just like parsing without empty elements:

$$\begin{aligned}\boldsymbol{z}^*(s) &= \arg\max_{\boldsymbol{z}\in\mathcal{Z}(s)} \textsc{Score}(s,\boldsymbol{z}) \\ &= \arg\max_{\boldsymbol{z}\in\mathcal{Z}(s)} \sum_{p\in\textsc{Part}(\boldsymbol{z})} \textsc{ScorePart}(s,p)\end{aligned}$$

The graph-based parsing algorithms proposed by Zhang et al. are based on two properties: ECs can only serve as dependents and the number of successive ECs is limited. The latter trait makes it reasonable to treat consecutive ECs governed by the same head as one *word*. We also follow this set-up.

3.2 Scoring Based on BiLSTM

Kiperwasser and Goldberg (2016) proposed a simple yet effective architecture to implement neural dependency parsers. In particular, a BiLSTM is utilized as a powerful *feature extractor* to assist a dependency parser. Mainstream data-driven dependency parsers, including both transition- and graph-based ones, can apply useful word vectors provided by a BiLSTM to conduct the disambiguation. Following Kiperwasser and Goldberg (2016)'s experience on graph-based dependency parser, we implement such a parser to recover empty categories and to evaluate the impact of empty categories on surface parsing.

Figure 3: The neural network structure when parsing sentence "It wasn't Black Monday." 5 MLPs is used for overt edges (i,j), covert edges (i,ϕ_j), overt-both siblings (i,j,k), covert-inside siblings (i,ϕ_j,k) and covert-outside siblings (i,j,ϕ_k) respectively, and 3 of them are shown in the graph.

Here we present details of the design of our parser. A vector is associated with each word or POS-tag to transform them into continuous and dense representations. We use pre-trained word embeddings and random initialized POS-tag embeddings.

The concatenation of the word embedding and the POS-tag embedding of each word in a specific sentence is used as the input of BiLSTMs to extract context related feature vectors r_i.

$$\boldsymbol{r}_{1:n} = \text{BiLSTM}(s; 1:n)$$

The context related feature vectors are fed into a non-linear transformation to perform scoring.

3.3 A First-Order Model

In the first-order model, we only consider the head and the dependent of the possible dependency arc. The two feature vectors of each word pair is scored with a non-linear transformation g as the first-order score. When words i and j are overt words, we define the score function in sentence s as follows,

$$\begin{aligned}&\textsc{ScoreDep}(s,i,j)\\&=\boldsymbol{W}_2\cdot g(\boldsymbol{W}_{1,1}\cdot\boldsymbol{r}_i+\boldsymbol{W}_{1,2}\cdot\boldsymbol{r}_j+\boldsymbol{b})\end{aligned}$$

$\boldsymbol{W}_2$, $\boldsymbol{W}_{1,1}$ and $\boldsymbol{W}_{1,2}$ denote the weight matrices in linear transformations. The score of covert edge from word i to word ϕ_j is calculated in a similar way with different parameters:

$$\begin{aligned}&\textsc{ScoreEmpty}(s,i,\phi_j)\\&=\boldsymbol{W}_2'\cdot g(\boldsymbol{W}_{1,1}'\cdot\boldsymbol{r}_i+\boldsymbol{W}_{1,2}'\cdot\boldsymbol{r}_j+\boldsymbol{b}')\end{aligned}$$

These non-linear transformations are also known as Multiple Layer Perceptrons(MLPs). The total score in our first-order model is defined as follows,

$$\begin{aligned}\textsc{Score}(s,\boldsymbol{z})=&\sum_{(i,j)\in\textsc{Dep}(\boldsymbol{z})}\textsc{ScoreDep}(s,i,j)\\&+\sum_{(i,\phi_j)\in\textsc{DepEmpty}(\boldsymbol{z})}\textsc{ScoreEmpty}(s,i,\phi_j)\end{aligned}$$

$\textsc{Dep}(\boldsymbol{z})$ and $\textsc{DepEmpty}(\boldsymbol{z})$ denote all overt and covert edges in $\boldsymbol{z}$ respectively. Because each overt and covert edge is selected independently of the others, the decoding process can be seen as calculating the maximum subtree from overt edges(we use Eisner Algorithm in our experiments) and appending each covert edge (i,ϕ_j) when $\textsc{ScoreEmpty}(i,\phi_j)>0$.

3.4 A Second-Order Model

In the second-order model, we also consider sibling arcs. We extend the neural network in section 3.3 to perform the second-order parsing. We calculate second-order scores(scores defined over sibling arcs) in a similar way. Each pair of overt sibling arcs, for example, (i,j) and (i,k) $(j<k)$, is denoted as (i,j,k) and scored with a non-linear transformation.

$$\begin{aligned}&\textsc{ScoreOvertBoth}(s,i,j,k)=\\&\boldsymbol{W}_2''\cdot g(\boldsymbol{W}_{1,1}''\cdot\boldsymbol{r}_i+\boldsymbol{W}_{1,2}''\cdot\boldsymbol{r}_j+\boldsymbol{W}_{1,3}''\cdot\boldsymbol{r}_k+\boldsymbol{b}'')\end{aligned}$$

Zhang et al. (2017b) defines two kinds of second-order scores to describe the interaction between concrete nodes and empty categories: the covert-inside sibling (i,ϕ_j,k) and covert-outside sibling (i,j,ϕ_k). Their scores can be calculated in a similar way with different parameters.

And finally, the score function over the whole syntactic analysis is defined as:

$$\begin{aligned}\textsc{Score}(s,\boldsymbol{z})=&\sum_{(i,j)\in\textsc{Dep}(\boldsymbol{z})}\textsc{ScoreDep}(s,i,j)\\&+\sum_{(i,\phi_j)\in\textsc{DepEmpty}(\boldsymbol{z})}\textsc{ScoreEmpty}(s,i,\phi_j)\\&+\sum_{(i,j,k)\in\textsc{OvertBoth}(\boldsymbol{z})}\textsc{ScoreOvertBoth}(s,i,j,k)\\&+\sum_{(i,\phi_j,k)\in\textsc{CovertIn}(\boldsymbol{z})}\textsc{ScoreCovertIn}(s,i,\phi_j,k)\\&+\sum_{(i,j,\phi_k)\in\textsc{CovertOut}(\boldsymbol{z})}\textsc{ScoreCovertOut}(s,i,j,\phi_k)\end{aligned}$$

$\textsc{OvertBoth}(\boldsymbol{z})$, $\textsc{CovertIn}(\boldsymbol{z})$ and $\textsc{CovertOut}(\boldsymbol{z})$ denotes overt-both, covert-inside and covert-outside siblings of $\boldsymbol{z}$ respectively. Totally 5 MLPs are used to calculate the 5 types of scores. The network structure is shown in Figure 3.

Labeled Parsing Similar to Kiperwasser and Goldberg (2016) and Zhang et al. (2017a), we use a two-step process to perform labeled parsing: conduct an unlabeled parsing and assign labels to each dependency edge. The labels are determined with the nonlinear classification. We use different nonlinear classifiers for edges between concrete nodes and empty categories.

Training In order to update graphs which have high model scores but are very wrong, we use a margin-based approach to compute loss from the gold tree T^* and the best prediction $\hat{T}$ under the current model.

We define the *loss* term as:

$$\max(0,\Delta(T^*,\hat{T})-\textsc{Score}(T^*)+\textsc{Score}(\hat{T}))$$

The margin objective Δ measures the similarity between the gold tree T^* and the prediction $\hat{T}$. Following Kiperwasser and Goldberg (2016)'s experience of loss augmented inference, we define Δ as the count of dependency edges in prediction results but not belonging to the gold tree.

3.5 Structure Regularization

ECD significantly increases the search space for parsing. This results in a side effect for practical parsing. Given the limit of available annotations for training, searching for more complex structures in a larger space is harmful to the generalization ability in structured prediction (Sun, 2014). To control structure-based overfitting, we train a normal dependency parser, namely parser for overt words only, and use its first- and second-order scores to augment the corresponding score functions in the joint parsing and ECD model. At the training phase, the two parsers are trained separately, while at the test phase, the scores are calculated by individual models and added for decoding.

4 Experiments

4.1 Experimental Setup

4.1.1 Data

We conduct experiments on a subset of Penn Chinese Treebank (CTB; Xue et al., 2005) 9.0. As a pro-drop language, the empty category is a very useful method for representing the (deep) syntactic analysis in Chinese language. Empty categories in CTB is divided into six classes: *pro*, *PRO*, *OP*, *T*, *RNR* and *, which were described in detail in Xue and Yang (2013); Wang et al. (2015). For comparability with the state-of-the-art, the division of training, development and testing data is coincident with the previous work (Xue and Yang, 2013).

Our experiments can be divided into two groups. The first group is conducted on the linear conditional random field (Linear-CRF) model and LSTM-CRF tagging model to evaluate gains from the introduction of neural structures. The second group is designed for the dependency-based in-parsing models.

4.1.2 Evaluation Metrics

We adopt two kinds of metrics for the evaluation of our experiments. The first one focuses on EC's position and type, in accordance with the *labeled empty elements* measure proposed by Cai et al. (2011), which can be implemented on all models in our experiments. The second one is stricter. Besides position and type, it also checks EC's head information. An EC is considered to be correct, only when all the three parts are the same as the corresponding gold standard. Thus only models involved in dependency structures can be evaluated according to the latter metric. Based on above measures of the two degrees, we evaluate our neural pre- and in-parsing models regarding each type of EC as well as overall performance.

Besides, to compare different models' abilities to capture non-local information, we design *Dependency Distance* to indicate the number of words from one EC to its head, not counting other ECs on the path. Taking the two ECs in Figure 1 as an example, $\emptyset_2$ has a *Dependency Distance* of 0 while $\emptyset_1$'s *Dependency Distance* is 3. We calculate labeled recall scores for enumerated *Dependency Distance*. A higher score means greater capability to catch and to represent long-distance details.

4.2 Results of Pre-Parsing Models

Table 3 shows overall performances of the two sequential models on development data. From the results, we can clearly see that the introduction of neural structure pushes up the scores exceptionally. The reason is that our LSTM-CRF model not only benefits from the linear weighted combination of local characteristics like ordinary CRF models, but also has the ability to integrate more contextual information, especially long-distance information. It confirms LSTM-based models' great superiority in sequence labeling problems.

Further more, we find that the difference among the four kinds of representations is not so obvious. The most performing one with LSTM-CRF model is *Interspace*, but the advantage is narrow. *Pre3* uses a larger window length to incorporate richer contextual tokens, but at the same time, the searching space for decoding grows larger. It explains that the performance drops slightly with increasing window length. In general, experiments with POS tags show higher scores as more syntactic clues are incorporated.

We compare LSTM-CRF with other state-of-the-art systems in Table 4[1]. We can see that a simple neural pre-parsing model outperforms state-of-the-art linear in-parsing systems. Analysis about results on different EC types as displayed in Table 5 shows that the sequence-oriented pre-parsing model is good at detecting *pro* compared with previous systems, which is used widely in pro-drop languages. Additionally, the model succeeds in detecting seven * EC tokens in evaluating process. * indicates trace left by passivization as well as raising, and is very rare in training data. Previous models usually cannot identify any *. This detail reflects that the LSTM-CRF model can make the most of limited training data compared with existing systems.

[1] Wang et al. (2015) reported an overall F-score of 71.7. But their result is based on the gold standard syntactic analysis.

Table 6: The performances of the first- and second-order in-parsing models on test data.

4.3 Results of In-Parsing Models

Table 6 presents detailed results of the in-parsing models on test data. Compared with the state-of-the-art, the first-order model performs a little worse while the second-order model achieves a remarkable score. The first-order parsing model only constrains the dependencies of both the covert and overt tokens to make up a tree. Due to the loose scoring constraint of the first-order model, the prediction of empty nodes is affected little from the prediction of dependencies of overt words. The four bold numbers in the table intuitively elicits the conclusion that integrating an *empty* edge and its sibling *overt edges* is necessary to boost the performance. It makes sense because empty categories are highly related to syntactic analysis. When we conduct ECD and dependency parsing simultaneously, we can leverage more hierarchical contextual information. Comparing results regarding EC types, we can find that *OP* and *T* benefit most from the parsing information, the F_1 score increasing by about ten points, more markedly than other types.

4.4 Results on Dependency Parsing

Table 7 shows the impact of automatic detection of empty categories on parsing overt words. We compare the results of both steps in labeled parsing. We can clearly see that integrating empty elements into dependency parsing can improve the neural parsing accuracy of overt words. Besides, when jointing parsing models both without and with ECs together, we can push up the performance further. These results confirm the conclusion in Zhang et al. (2017b) that empty elements help parse the overt words. The main reason lies in that the existence of ECs provides extra structural information which can reduce approximation

	-EC	+EC	-+EC
Unlabeled	87.6	88.9	89.6
Labeled	84.6	85.9	86.6

Table 7: Accuracies of both unlabeled and labeled parsing on development data. -EC indicates parsing without empty categories. +EC indicates the second-order in-parsing models. -+EC indicates jointing parsing models both without and with ECs together.

errors in a structured prediction problem.

According to above analysis, we can draw a conclusion that ECD and syntactic parsing can promote each other mutually. That partially explains why in-parsing models can outperform pre-parsing models. Meanwhile, it provides a new approach to improving the dependency parsing quality in a unified framework.

4.5 Impact of Dependency Distance

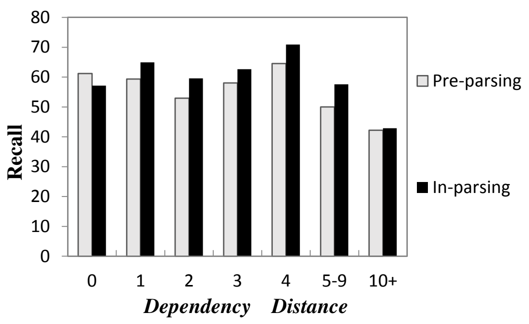

Figure 4: Recall scores of different models regarding *Dependency Distance*. ”Pre-parsing” and ”In-parsing” refer to the LSTM-CRF model and the dependency-based in-parsing model respectively.

We compare pre- and in-parsing models regarding *Dependency Distance*. The former refers to the LSTM-CRF model while the latter means the dependency-based in-parsing model. Figure 4 shows the results. The abscissa value ranges from 0 to 26, with the longest dependency arc spanning 26 non-EC word tokens. We can see that long-distance disambiguation is a challenge shared by both models. When the value of *Dependency Distance* exceeds four, the recall score drops gradually with abscissa increasing. Based on the comparison of two sets of data, we can find that in-parsing model performs better on ECs which are close to their heads. However, as for ECs which are far apart from their heads, two models have performed almost exactly alike. It demonstrates that LSTM structure is capable of capturing non-local features, making up for no exposure to parsing information.

4.6 Challenges

On the whole, the most challenging EC type is *pro*. We assume that it is because that pro-drop situations are complicated and diverse in Chinese language. According to Chinese linguistic theory, pronouns are dropped as a result of continuing from the preceding discourse or just idiomatic rules, such as the ellipsis of the first person pronoun “我/I” in the subject position. To fill this gap, we may need to extract more deep structural features.

Another difficulty is the detection of consecutive ECs. In the result of our experiments, in-parsing dependency-based model can only accurately detect up to two consecutive ECs. Too many empty elements in the same sentence conceal too much syntactic information, making it hard to disclose the original structure.

Moreover, in view of the fact that ECs play an essential role in syntactic analysis, the current detection accuracy of ECs is far from enough. We still have a long way to go.

5 Related Work

The detection of empty categories is an essential ground for many downstream tasks. For example, Chung and Gildea (2010) has proved that automatic empty category detection has a positive impact on machine translation. Zhang et al. (2017b) shows that ECD can benefit linear syntactic parsing of overt words. To accurately distinguish empty elements in sentences, there are generally three approaches. The first method is to build pre-processors before syntactic parsing. Dienes and Dubey (2003) proposed a shallow *trace tagger* which can detect discontinuities. And it can be combined with unlexicalized PCFG parsers to implement deep syntactic processing. Due to the lack of phrase structure information, it did not acquire remarkable results. The second method is to integrate ECD into parsing, as shown in Schmid (2006) and Cai et al. (2011), which involved empty elements in the process of generating parse trees. Another in-parsing system is proposed in Zhang et al. (2017b). Zhang et al. (2017b) designed algorithms to produce dependency trees in which empty elements are allowed. To add empty elements into dependency structures, they extend Eisner's first-order DP algorithm for parsing to second- and third-order algorithms. The last approach to recognizing empty elements is post-parsing methods. Johnson (2002) proposed a simple pattern-matching algorithm for recovering empty nodes in phrase structure trees while Campbell (2004) presented a rule-based algorithm. Xue and Yang (2013) conducted ECD based on dependency trees. Their methods can leverage richer syntactic information, thus have achieved more satisfying scores.

As neural networks have been demonstrated to have a great ability to capture complex features, it has been applied in multiple NLP tasks (Bengio and Schwenk, 2006; Collobert et al., 2011). Neural methods have also explored in distinguishing empty elements. For example, Wang et al. (2015) described a novel ECD solution using distributed word representations and achieved the state-of-the-art performance. Based on above work, we explore neural pre- and in-parsing models for ECD.

6 Conclusion

Neural networks have played a big role in multiple NLP tasks recently owing to its nonlinear mapping ability and the avoidance of human-engineered features. It should be a well-justified solution to identify empty categories as well as to integrate empty categories into syntactic analysis. In this paper, we study neural models to detect empty categories. We observe three facts: (1) BiLSTM significantly advances the pre-parsing ECD. (2) Automatic ECD improves the neural dependency parsing quality for overt words. (3) Even with a BiLSTM, syntactic information can enhance the detection further. Experiments on Chinese language show that our neural model for ECD exceptionally boosts the state-of-the-art detection accuracy.

Composing Finite State Transducers on GPUs

Arturo Argueta and **David Chiang**
Department of Computer Science and Engineering
University of Notre Dame
{aargueta,dchiang}@nd.edu

Abstract

Weighted finite state transducers (FSTs) are frequently used in language processing to handle tasks such as part-of-speech tagging and speech recognition. There has been previous work using multiple CPU cores to accelerate finite state algorithms, but limited attention has been given to parallel graphics processing unit (GPU) implementations. In this paper, we introduce the first (to our knowledge) GPU implementation of the FST composition operation, and we also discuss the optimizations used to achieve the best performance on this architecture. We show that our approach obtains speedups of up to 6× over our serial implementation and 4.5× over OpenFST.

1 Introduction

Finite-state transducers (FSTs) and their algorithms (Mohri, 2009) are widely used in speech and language processing for problems such as grapheme-to-phoneme conversion, morphological analysis, part-of-speech tagging, chunking, named entity recognition, and others (Mohri et al., 2002; Mohri, 1997). Hidden Markov models (Baum et al., 1970), conditional random fields (Lafferty et al., 2001) and connectionist temporal classification (Graves et al., 2006) can also be thought of as finite-state transducers.

Composition is one of the most important operations on FSTs, because it allows complex FSTs to be built up from many simpler building blocks, but it is also one of the most expensive. Much work has been done on speeding up composition on a single CPU processor (Pereira and Riley, 1997; Hori and Nakamura, 2005; Dixon et al., 2007; Allauzen and Mohri, 2008; Allauzen et al., 2009; Ladner and Fischer, 1980; Cheng et al., 2007). Methods such as on-the-fly composition, shared data structures, and composition filters have been used to improve time and space efficiency.

There has also been some successful work on speeding up composition using multiple CPU cores (Jurish and Würzner, 2013; Mytkowicz et al., 2014; Jung et al., 2017). This is a challenge because many of the algorithms used in NLP do not parallelize in a straightforward way and previous work using multi-core implementations do not handle the reduction of identical edges generated during the composition. The problem becomes more acute on the graphics processing units (GPUs) architecture, which have thousands of cores but limited memory available. Another problem with the composition algorithm is that techniques used on previous work (such as composition filters and methods to expand or gather transitions using dictionaries or hash tables) do not translate well to the GPU architecture given the hardware limitations and communication overheads.

In this paper, we parallelize the FST composition task across multiple GPU cores. To our knowledge, this is the first successful attempt to do so. Our approach treats the composed FST as a sparse graph and uses some techniques from the work of Merrill et al. (2012); Jung et al. (2017) to explore the graph and generate the composed edges during the search. We obtain a speedup of 4.5× against OpenFST's implementation and 6× against our own serial implementation.

2 Finite State Transducers

In this section, we introduce the notation that will be used throughout the paper for the composition task. A weighted FST is a tuple $M = (Q, \Sigma, \Gamma, s, F, \delta)$, where

- Q is a finite set of states.
- Σ is a finite input alphabet.
- Γ is a finite output alphabet.
- $s \in Q$ is the start state.
- $F \subseteq Q$ are the accept states.
- $\delta : Q \times \Sigma \times \Gamma \times Q \to \mathbb{R}$ is the transition function. If $\delta(q, a, b, r) = p$, we write

$$q \xrightarrow{a:b/p} r.$$

Note that we don't currently allow epsilon transitions; this would require implementation of composition filters (Allauzen et al., 2009), which is not a trivial task on the GPU architecture given the data structures and memory needed. Hence, we leave this for future work.

For the composition task, we are given two weighted FSTs:

$$M_1 = (Q_1, \Sigma, \Gamma, s_1, F_1, \delta_1)$$
$$M_2 = (Q_2, \Gamma, \Delta, s_2, F_2, \delta_2).$$

Call Γ, the alphabet shared between the two transducers, the *inner* alphabet, and let $m = |\Gamma|$. Call Σ and Δ, the input alphabet of M_1 and the output alphabet of M_2, the *outer* alphabets.

The composition of M_1 and M_2 is the weighted FST

$$M_1 \circ M_2 = (Q_1 \times Q_2, \Sigma, \Delta, s_1 s_2, F_1 \times F_2, \delta)$$

where

$$\delta(q_1 q_2, a, b, r_1 r_2) = \sum_{b \in \Gamma} \delta_1(q_1, a, c, r_1) \cdot \delta_2(q_2, c, b, r_2).$$

That is, for each pair of transitions with the same inner symbol,

$$q_1 \xrightarrow{a:b/p_1} r_1$$
$$q_2 \xrightarrow{b:c/p_2} r_2,$$

the composed transducer has a transition

$$q_1 q_2 \xrightarrow{a:c/p_1 p_2} r_1 r_2.$$

Transitions with the same source, target, input, and output symbols are merged, adding their weights.

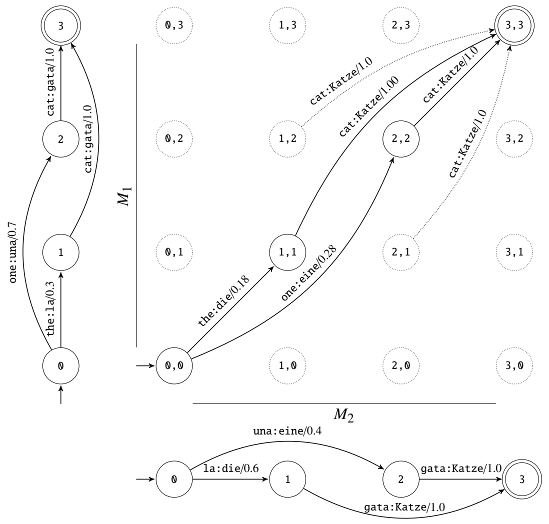

Figure 1: Example composition of two finite state transducers: M_1 translates English to Spanish, M_2 translates Spanish to German. The center of the image contains the composition of the two input transducers. This new transducer translates English to German. The dotted states and transitions are those that cannot be reached from the start state.

3 Method

In this section, we describe our composition method and its implementation.

3.1 Motivation

If implemented naïvely, the above operation is inefficient. Even if M_1 and M_2 are trim (have no states that are unreachable from the start state or cannot reach the accept state), their composition may have many unreachable states. Figure 1 shows a clear example where the transducers used for composition are trim, yet several states (drawn as dotted circles) on the output transducers cannot be reached from the start state. The example also shows composed transitions that originate from unreachable states. As a result, a large amount of time and memory may be spent creating states and composing transitions that will not be reachable nor needed in practice. One solution to avoid the problem is to compose only the edges and states that are reachable from the start state on the output transducer to avoid unnecessary computations and reduce the overall memory footprint.

We expect this problem to be more serious when the FSTs to be composed are sparse, that is, when there are many pairs of states without a transition between them. And we expect that FSTs used in

	Data	Transitions	Nonzero	% Nonzero
1k	de-en	21.7M	16.5k	0.076%
	en-de	12.3M	15.4k	0.125%
	en-es	12.5M	15.5k	0.124%
	en-it	13.1M	16.3k	0.124%
10k	de-en	394M	114k	0.029%
	en-de	138M	93.9k	0.067%
	en-es	135M	93.3k	0.068%
	en-it	143M	97.2k	0.067%
15k	de-en	634M	158k	0.025%
	en-de	201M	126k	0.062%
	en-es	195M	125k	0.064%
	en-it	209M	131k	0.062%

Table 1: FSTs used in our experiments. Key: Data = language pair used to generate the transducers; Transitions = maximum possible number of transitions; Nonzero = number of transitions with nonzero weight; % Nonzero = percent of possible transitions with nonzero weight. The left column indicates the number of parallel sentences used to generate the transducers used for testing.

natural language processing, whether they are constructed by hand or induced from data, will often be sparse.

For example, below (Section 4.1), we will describe some FSTs induced from parallel text that we will use in our experiments. We measured the sparsity of these FSTs, shown in Table 1. These FSTs contain very few non-zero connections between their states, suggesting that the output of the composition will have a large number of unreachable states and transitions. The percentage of non-zero transitions found in the transducers used for testing decreases as the transducer gets larger. Therefore, when composing FSTs, we want to construct only reachable states, using a traversal scheme similar to breadth-first search to avoid the storage and computation of irrelevant elements.

3.2 Serial composition

We first present a serial composition algorithm (Algorithm 2). This algorithm performs a breadth-first search (BFS) of the composed FST beginning from the start state, so as to avoid creating inaccessible states. As is standard, the BFS uses two data structures, a frontier queue (A) and a visited set (Q), which is always a superset of A. For each state q_1q_2 popped from A, the algorithm composes all transitions from q_1 with all transitions from q_2 that have the same inner symbol. The composed edges are added to the final transducer, and the corresponding target states q_1q_2 are pushed into A for future expansion. The search finishes once A runs out of states to expand.

Algorithm 1 Serial composition algorithm.

```
Input Transducers: $M_1 = (Q_1, \Sigma, \Gamma, s_1, F_1, \delta_1)$
                   $M_2 = (Q_2, \Gamma, \Delta, s_2, F_2, \delta_2)$
Output Transducer: $M_1 \circ M_2$
 1: $A \leftarrow \{s_1 s_2\}$                ▷ Queue of states to process
 2: $Q \leftarrow \{s_1 s_2\}$                ▷ Set of states created so far
 3: $\delta \leftarrow \emptyset$                       ▷ Transition function
 4: while $|A| > 0$ do
 5:     $q_1 q_2 \leftarrow \text{pop}(A)$
 6:     for $q_1 \xrightarrow{a:b/p_1} r_1 \in \delta_1$ do
 7:         for $q_2 \xrightarrow{b:c/p_2} r_2 \in \delta_2$ do
 8:             $\delta(q_1 q_2, a, c, r_1 r_2) \mathrel{+}= p_1 p_2$
 9:             if $r_1 r_2 \notin Q$ then
10:                 $Q \leftarrow Q \cup \{r_1 r_2\}$
11:                 push$(A, r_1 r_2)$
12: return $(Q, \Sigma, \Delta, s_1 s_2, F_1 \times F_2, \delta)$
```

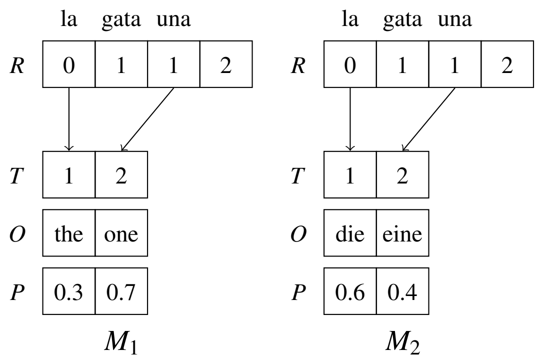

Figure 2: Example CSR-like representation of state 0 for transducers M_1 and M_2 from Figure 1.

3.3 Transducer representation

Our GPU implementation stores FST transition functions in a format similar to compressed sparse row (CSR) format, as introduced by our previous work Argueta and Chiang (2017). For the composition task we use a slightly different representation. An example of the adaptation is shown in Figure 2. The transition function δ for the result is stored in a similar fashion. The storage method is defined as follows:

- z is the number of transitions with nonzero weight.
- R is an array of length $|Q|m + 1$ containing offsets into the arrays T, O, and P. If the states are numbered $0, \dots, |Q| - 1$ and the inner symbols are numbered $0, \dots m - 1$, then state q's outgoing transitions on inner symbol b can be found starting at the offset stored in $R[qm + b]$. The last offset index, $R[|Q|m + 1]$, must equal z.
- $T[k]$ is the target state of the kth transition.
- $O[k]$ is the outer symbol of the kth transition.
- $P[k]$ is the weight of the kth transition.

Similarly to several toolkits (such as OpenFST), we require the edges in T, O, P to be sorted by their inner symbols before executing the algorithm, which allows faster indexing and simpler parallelization.

3.4 Parallel composition

Our parallel composition implementation has the same overall structure as the serial algorithm, and is shown in Algorithm 2. The two transducers to be composed are stored on the GPU in global memory, in the format described in Section 3.3. Both transducers are sorted according to their inner symbol on the CPU and copied to the device. The memory requirements for a large transducer complicates the storage of the result on the GPU global memory. If the memory of states and edges generated by both inputs does not fit on the GPU, then the composition cannot be computed using only device memory. The execution time will also be affected if the result lives on the device and there is a limited amount of memory available for temporary variables created during the execution. Therefore, the output transducer must be stored on the host using page-locked memory, with the edge transitions unsorted.

Page-locked, or pinned, memory is memory that will not get paged out by the operating system. Since this memory cannot be paged out, the amount of RAM available to other applications will be reduced. This enables the GPU to access the host memory quickly. Pinned memory provides better transfer speeds since the GPU creates different mappings to speed up `cudaMemcpy` operations on host memory. Allocating pinned memory consumes more time than a regular `malloc`,

Algorithm 2 Parallel composition algorithm.

```
Input Transducers: $M_1 = (Q_1, \Sigma, \Gamma, s_1, F_1, \delta_1)$
                   $M_2 = (Q_2, \Gamma, \Delta, s_2, F_2, \delta_2)$
Output Transducer: $M_1 \circ M_2$
 1: $A \leftarrow \{s_1 s_2\}$                          ▷ Queue of states to process
 2: $Q \leftarrow \{s_1 s_2\}$                          ▷ Set of states visited
 3: $\delta \leftarrow []$                              ▷ List of transitions
 4: while $|A| > 0$ do
 5:     $q_1 q_2 \leftarrow \text{pop}(A)$
 6:     $\delta_d \leftarrow []$
 7:     $A_d \leftarrow \emptyset$
 8:     $H \leftarrow \emptyset$
 9:     $red \leftarrow$ false
10:     parfor $b \in \Gamma$ do                        ▷ kernels
11:         parfor $q_1 \xrightarrow{a:b/p_1} r_1$ do    ▷ threads
12:             parfor $q_2 \xrightarrow{b:c/p_2} r_2$ do    ▷ threads
13:                 append $q_1 q_2 \xrightarrow{a:c/p_1 p_2} r_1 r_2$ to $\delta_d$
14:                 if $h(a, c, r_1 r_2) \in H$ then
15:                     $red \leftarrow$ true
16:                 else
17:                     add $h(a, c, r_1 r_2)$ to $H$
18:                 if $r_1 r_2 \notin Q$ then
19:                     $A_d \leftarrow A_d \cup \{r_1 r_2\}$
20:                     $Q \leftarrow Q \cup \{r_1 r_2\}$
21:     concatenate $\delta_d$ to $\delta$
22:     for $q \in A_d$ do push$(A, q)$
23:     if $red$ then
24:         sort $\delta[q_1 q_2]$
25:         reduce $\delta[q_1 q_2]$
26: return $(Q, \Sigma, \Delta, s_1 s_2, F_1 \times F_2, \delta)$
```

therefore it should be done sporadically. In this work, pinned memory is allocated only once at start time and released once the composition has been completed. Using page-locked memory on the host side as well as pre-allocating memory on the device decreases the time to both copy the results back from the GPU, and the time to reuse device structures used on different kernel methods.

Generating transitions The frontier queue A is stored on the host. For each state $q_1 q_2$ popped from A, we need to compose all outgoing transitions of q_1 and q_2 obtained from M_1 and M_2 respectively. Following previous work (Merrill et al., 2012; Jurish and Würzner, 2013), we create these in parallel, using the three **parfor** loops in lines 10–12. Although these three loops are written the same way in pseudocode for simplicity, in actuality they use two different parallelization schemes in the actual implementation of the algorithm.

The outer loop launches a CUDA kernel for each inner symbol $b \in \Gamma$. For example, to compose the start states in Figure 1, three kernels will be launched (one for *la*, *gata*, and *una*). Each of these kernels composes all outgoing transitions of q_1 with output b with all outgoing transitions of q_2 with input b. Each of these kernels is executed in a unique stream, so that a higher parallelization can be achieved. Streams are used in CUDA programming to minimize the number of idle cores during execution. A stream is a group of commands that execute in-order on the GPU. What makes streams useful in CUDA is the ability to execute several asynchronously. If more than one kernel can run asynchronously without any interdependence, the assignment of kernel calls to different streams will allow a higher speedup by minimizing the amount of idling cores during execution. All kernel calls using streams are asynchronous to the host making synchronization between several different streams necessary if there exist data dependencies between different parts of the execution pipeline. Asynchronous memory transactions can also benefit from streams, if these operations do not have any data dependencies.

We choose a kernel block size of 32 for the kernel calls since this is the amount of threads that run in parallel on all GPU streaming multiprocessors at any given time. If the number of threads required to compose a tuple of states is not divisible by 32, the number of threads is rounded up to the closest multiple. When several input tuples generate less than 32 edges, multiple cores will remain idle during execution. Our approach obtains better speedups when the input transducers are able to generate a large amount of edges for each symbol b and each state tuple on the result. In general, the kernels may take widely varying lengths of time based on the amount of composed edges; using streams enables the scheduler to minimize the number of idle cores.

The two inner loops represent the threads of the kernel; each composes a pair of transitions sharing an inner symbol b. Because these transitions are stored contiguously (Figure 2), the reads can be coalesced, meaning that the memory reads from the parallel threads can be combined into one transaction for greater efficiency. Figure 2 shows how the edges for a transducer are stored in global memory to achieve coalesced memory operations each time the edges of a symbol b associated with a state tuple q_1,q_2 need to be composed.

Figure 2 shows how the edges leaving the start state tuple for transducers M_1 and M_2 are stored. As mentioned above, three kernels will be launched to compose the transitions leaving the start states, but only two will be executed (because there are no transitions on *gata* for both start states). For $R[\texttt{la}]$ on machine M_1, only one edge can output `la` given $R[\texttt{la} + 1] - R[\texttt{la}] = 1$, and machine M_2 has one edge that reads *la* given $R[\texttt{la} + 1] - R[\texttt{la}] = 1$. For this example, $R[\texttt{la}]$ points to index 0 on T, O, P for both states. This means that only one edge will be generated from the composition $(0, 0 \xrightarrow{\texttt{the:die/0.18}} 1, 1)$. For symbol `gata`, no edges can be composed given $R[\texttt{gata} + 1] - R[\texttt{gata}] = 0$ on both machines, meaning that no edges read or output that symbol. Finally, for $R[\texttt{una}]$ on machine M_1 and M_2, one edge can be generated $(0, 0 \xrightarrow{\texttt{one:eine/0.28}} 2, 2)$ given the offsets in R for both input FSTs. If n_1 edges can be composed for a symbol b on one machine and n_2 from the other one, the kernel will generate $n_1 n_2$ edges.

The composed transitions are first appended to a pre-allocated buffer δ_d on the GPU. After processing the valid compositions leaving $q_1 q_2$, all the transitions added in δ_d are appended in bulk to δ on the host.

Updating frontier and visited set Each destination state $r_1 r_2$, if previously unvisited, needs to be added to both A and Q. Instead of adding it directly to A (which is stored on the host), we add it to a buffer A_d stored on the device to minimize the communication overhead between the host and the device. After processing $q_1 q_2$ and synchronizing all streams, A_d is appended in bulk to A using a single `cudaMemcpy` operation.

The visited set Q is stored on the GPU device as a lookup table of length $|Q_1||Q_2|$. Merrill et al. (2012) perform BFS using two stages to obtain the states and edges needed for future expansion. Similarly, our method performs the edge expansion using two steps by using the lookup table Q. The first step of the kernel updates Q and all visited states that need to be added to A_d. The second step appends all the composed edges to δ in parallel. Since several threads check the table in parallel, an atomic operation (`atomicOr`) is used to check and update each value on the table in a consistent fashion. Q also functions as a map to convert the state tuple q_1q_2 into a single integer. Each time a tuple is not in Q, the structure gets updated with the total number of states generated plus one for a specific pair of states.

Reduction Composed edges with the same source, target, input, and output labels must be merged, summing their probabilities. This is done in lines 23–25, which first sort the transitions and then merge and sum them. To do this, we pack the transitions into an array of keys and an array of values. Each key is a tuple (a, c, r_1r_2) packed into a 64-bit integer. We then use the sort-by-key and reduce-by-key operations provided by the Thrust library. The mapping of tuples to integers is required for the sort operation since the comparisons required for the sorting can be made faster than using custom data structures with a custom comparison operator. [1]

Because the above reduction step is rather expensive, lines 14–17 use a heuristic to avoid it if possible. H is a set of transitions represented as a hash table without collision resolution, so that lookups can yield false positives. If *red* is false, then there were no collisions, so the reduction step can be skipped. The hash function is simply $h(a, c, r_1r_2) = a + c|\Sigma|$. In more detail, H actually maps from hashes to integers. Clearing H (line 8) actually just increments a counter i; storing a hash k is implemented as $H[k] \leftarrow i$, so we can test whether k is a member by testing whether $H[k] = i$. An atomic operation (`atomicExch`) is used to consistently check H since several threads update this variable asynchronously.

4 Experiments

We tested the performance of our implementation by constructing several FSTs of varying sizes and comparing our implementation against other baselines.

4.1 Setup

In our previous work (Argueta and Chiang, 2017), we created transducers for a toy translation task. We trained a bigram language model (as in Figure 3a) and a one-state translation model (as in Figure 3) with probabilities estimated from GIZA++ Viterbi word alignments. Both were trained on the Europarl corpus. We then precomposed them using the Carmel toolkit (Graehl, 1997).

We used the resulting FSTs to test our parallel composition algorithm, composing a German-to-English transducer with a English-to-t transducer to translate German to language t, where t is German, Spanish, or Italian.

Our experiments were tested using two different architectures. The serial code was measured using a 16-core Intel Xeon CPU E5-2650 v2, and the parallel implementation was executed on a system with a GeForce GTX 1080 Ti GPU connected to a 24-core Intel Xeon E5-2650 v4 processor.

4.2 Baselines

In this work, OpenFST (Allauzen et al., 2007) and our serial implementation (Algorithm 1) were used as a baseline for comparison. OpenFST is a toolkit developed by Google as a successor of the AT&T Finite State Machine library. For consistency, all implementations use the OpenFST text file format to read and process the transducers.

4.3 Results

OpenFST's composition operation can potentially create multiple transitions (that is, two or more transitions with the same source state, destination state, input label, and output label); a separate function (`ArcSumMapper`) must be applied to merge multiple transitions and sum their weights. Previous work also requires an additional step if identical edges need to be merged. For this reason,

Table 2: This table shows how the total running time of our GPU implementation compares against all other methods. Times (in seconds) are for composing two transducers using English as the shared input/output vocabulary and German as the source language of the first transducer (de-en,en-*). Ratios are relative to our parallel algorithm on the GeForce GTX 1080 Ti.

we compare our implementation against OpenFST both with and without the reduction of transitions with an identical source,target,input, and output. We analyzed the time to compose all possible edges without performing any reductions (Algorithm 1, line 8). The second setup analyzes the time it takes to compute the composition and the arc summing of identical edges generated during the process.

Table 2 shows the performance of the parallel implementation and the baselines without reducing identical edges. For the smallest transducers, our parallel implementation is slower than the baselines (0.72× compared to OpenFST and 0.30× compared to our serial version). With larger transducers, the speedups increase up to 4.38× against OpenFST and 2.02× against our serial implementation. Larger speedups are obtained for larger transducers because the GPU can utilize the streaming multiprocessors more fully. On the other hand, the overhead created by CUDA calls, device synchronization, and memory transfers between the host CPU and the device might be too expensive when the inputs are too small.

Table 3 shows the performance of all implementations with the reduction operation. Again, for the smallest transducers we can see a similar behavior, our parallel implementation is slower (0.30× against OpenFST and 0.39× against our serial version). Speedups improve with the larger transducers, eventually achieving a 4.52× speedup over OpenFST and a 6.26× speedup over our serial implementation of the composition algorithm.

4.4 Discussion

One comparison missing above is a comparison against a multicore processor. We attempted to compare against a parallel implementation using OpenMP on a single 16-core processor, but it did not yield any meaningful speedup, and even slowdowns of up to 10%. We think the reason for this is that because the BFS-like traversal of the FST makes it impractical to process states in parallel, the best strategy is to process and compose transitions in parallel. This very fine-grained parallelism does not seem suitable for OpenMP, as the overhead due to thread initialization and synchronization is higher than the time to execute the parallel sections of the code where the actual composition is calculated. According to our measurements, the average time to compose two transitions is 7.4 nanoseconds, while the average time to create an OpenMP thread is 10.2 nanoseconds. By contrast, the overhead for creating a CUDA thread seems to be around 0.4 nanoseconds. While a different parallelization strategy may exist for multicore architectures, at present, our finding is that GPUs, or other architectures with a low cost to create and destroy threads, are much more suitable for the fine grained operations used for the composition task.

			Training size (lines)					
			1000		10000		15000	
Method	Hardware	Target	Time	Ratio	Time	Ratio	Time	Ratio

Table 3: This table shows how the total running time of our GPU implementation compares against all other methods. Times (in seconds) are for composing two transducers and performing edge reduction using English as the shared input/output vocabulary and German as the source language of the first transducer (de-en,en-*). Ratios are relative to our parallel algorithm on the GeForce GTX 1080 Ti.

5 Future Work

For future work, other potential bottlenecks could be addressed. The largest bottleneck is the queue used on the host to keep track of the edges to expand on the GPU. Using a similar data structure on the GPU to keep track of the states to expand would yield higher speedups. The only challenge of using such a data structure is the memory consumption on the GPU. If the two input transducers contain a large number of states and transitions, the amount of memory needed to track all the states and edges generated will grow significantly. Previous work (Harish and Narayanan, 2007) has shown that state queues on the GPU cause a large memory overhead. Therefore, if state expansion is moved to the GPU, the structures used to keep track of the states must be compressed or occupy the least amount of memory possible on the device in order to allocate all structures required on the device. The queue will also require a mechanism to avoid inserting duplicate tuples into the queue.

For the reduction step, speedups can be achieved if the sort and reduce operations can be merged with the edge expansion part of the method. The challenge of merging identical edges during expansion is the auxiliary memory that will be required to store and index intermediate probabilities. It can be doable if the transducers used for the composition are small. In that case, the reduce operation might not yield significant speedups given the fact that the overhead to compose small transducers is too high when using a GPU architecture.

6 Conclusion

This is the first work, to our knowledge, to deliver a parallel GPU implementation of the FST composition algorithm. We were able to obtain speedups of up to 4.5× over a serial OpenFST baseline and 6× over the serial implementation of our method. This parallel method considers several factors, such as host to device communication using page-locked memory, storage formats on the device, thread configuration, duplicate edge detection, and duplicate edge reduction. Our implementation is available as open-source software.[2]

Abstract

Treebank conversion is a straightforward and effective way to exploit various heterogeneous treebanks for boosting parsing accuracy. However, previous work mainly focuses on unsupervised treebank conversion and makes little progress due to the lack of manually labeled data where each sentence has two syntactic trees complying with two different guidelines at the same time, referred as *bi-tree aligned data.*

In this work, we for the first time propose the task of *supervised treebank conversion*. First, we manually construct a bi-tree aligned dataset containing over ten thousand sentences. Then, we propose two simple yet effective treebank conversion approaches (pattern embedding and treeLSTM) based on the state-of-the-art deep biaffine parser. Experimental results show that 1) the two approaches achieve comparable *conversion accuracy*, and 2) treebank conversion is superior to the widely used multi-task learning framework in multiple treebank exploitation and leads to significantly higher *parsing accuracy*.

1 Introduction

During the past few years, neural network based dependency parsing has achieved significant progress and outperformed the traditional discrete-feature based parsing (Chen and Manning, 2014; Dyer et al., 2015; Zhou et al., 2015; Andor et al., 2016). Most remarkably, Dozat and Manning (2017) propose a simple yet effective deep biaffine parser that further advances the state-of-the-art accuracy by large margin. As reported, their parser outperforms the state-of-the-art discrete-feature based parser of Bohnet and Nivre (2012) by 0.97 (93.76% − 92.79%) on the English WSJ data and 6.87 (85.38% − 78.51%) on the Chinese CoNLL-2009 data, respectively. Kindly note that all these results are obtained by training parsers on a single treebank.

Treebanks	#Tok	Grammar
Sinica (Chen et al., 2003)	0.36M	Case grammar
CTB (Xue et al., 2005)	1.62M	Phrase structure
TCT (Zhou, 2004)	1.00M	Phrase structure
PCT (Zhan, 2012)	0.90M	Phrase structure
HIT-CDT (Che et al., 2012)	0.90M	Dependency structure
PKU-CDT (Qiu et al., 2014)	1.40M	Dependency structure

Table 1: Large-scale Chinese treebanks (token number in million).

Meanwhile, motivated by different syntactic theories and practices, major languages in the world often possess multiple large-scale heterogeneous treebanks, e.g., Tiger (Brants et al., 2002) and TüBa-D/Z (Telljohann et al., 2004) treebanks for German, Talbanken (Einarsson, 1976) and Syntag (Järborg, 1986) treebanks for Swedish, ISST (Montemagni et al., 2003) and TUT[1] treebanks for Italian, etc. Table 1 lists several large-scale Chinese treebanks. In this work, we take HIT-CDT as a case study. Our next-step plan is to annotate bi-tree aligned data for PKU-CDT and then convert PKU-CDT to our guideline. For non-dependency treebanks, the straight-

* The first two (student) authors make equal contributions to this work. Zhenghua is the correspondence author.

[1] `http://www.di.unito.it/~tutreeb/`

forward choice is to convert such treebanks to dependency treebanks based on heuristic head-finding rules. The second choice is to directly extend our proposed approaches by adapting the patterns and treeLSTMs for non-dependency structures, which should be straightforward as well.

Considering the high cost of treebank construction, it has always been an interesting and attractive research direction to exploit various heterogeneous treebanks for boosting parsing performance. Though under different linguistic theories or annotation guidelines, the treebanks are painstakingly developed to capture the syntactic structures of the same language, thereby having a great deal of common grounds.

Previous researchers have proposed two approaches for multi-treebank exploitation. On the one hand, the *guiding-feature* method projects the knowledge of the source-side treebank into the target-side treebank, and utilizes extra pattern-based features as guidance for the target-side parsing, mainly for the traditional discrete-feature based parsing (Li et al., 2012). On the other hand, the *multi-task learning* method simultaneously trains two parsers on two treebanks and uses shared neural network parameters for representing common-ground syntactic knowledge (Guo et al., 2016).[2] Regardless of their effectiveness, while the guiding-feature method fails to directly use the source-side treebank as extra training data, the multi-task learning method is incapable of explicitly capturing the structural correspondences between two guidelines. In this sense, we consider both of them as *indirect exploitation* approaches.

Compared with the indirect approaches, treebank conversion aims to directly convert a source-side treebank into the target-side guideline, and uses the converted treebank as extra labeled data for training the target-side model. Taking the example in Figure 1, the goal of this work is to convert the under tree that follows the HIT-CDT guideline (Che et al., 2012) into the upper one that follows our new guideline. However, due to the lack

[2] Johansson (2013) applies the feature-sharing approach of Daumé III (2007) for multiple treebank exploitation, which can be regarded as a simple discrete-feature variant of multi-task learning.

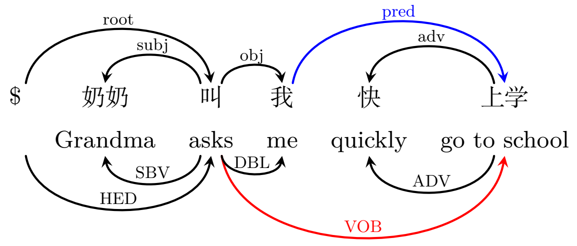

Figure 1: Example of treebank conversion from the source-side HIT-CDT tree (under) to the target-side our-CDT tree (upper).

of *bi-tree aligned data*, in which each sentence has two syntactic trees following the source-side and target-side guidelines respectively, most previous studies are based on unsupervised treebank conversion (Niu et al., 2009) or pseudo bi-tree aligned data (Zhu et al., 2011; Li et al., 2013), making very limited progress.

In this work, we for the first time propose the task of supervised treebank conversion. *The key motivation is to better utilize a large-scale source-side treebank by constructing a small-scale bi-tree aligned data.* In summary, we make the following contributions.

(1) We have manually annotated a high-quality bi-tree aligned data containing over ten thousand sentences, by re-annotating the HIT-CDT treebank according to a new guideline.

(2) We propose a pattern embedding conversion approach by retrofitting the indirect guiding-feature method of Li et al. (2012) to the direct conversion scenario, with several substantial extensions.

(3) We propose a treeLSTM conversion approach that encodes the source-side tree at a deeper level than the shallow pattern embedding approach.

Experimental results show that 1) the two conversion approaches achieve nearly the same conversion accuracy, and 2) direct treebank conversion is superior to indirect multi-task learning in exploiting multiple treebanks in methodology simplicity and performance, yet with the cost of manual annotation. We release the annotation guideline and the newly annotated data in http://hlt.suda.edu.cn/index.php/SUCDT.

2 Annotation of Bi-tree Aligned Data

The key issue for treebank conversion is that sentences in the source-side and target-side treebanks are non-overlapping. In other words, there lacks a bi-tree aligned data in which each sentence has two syntactic trees complying with two guidelines as shown in Figure 1. Consequently, we cannot train a supervised conversion model to directly learn the structural correspondences between the two guidelines. To overcome this obstacle, we construct a bi-tree aligned data of over ten thousand sentences by re-annotating the publicly available dependency-structure HIT-CDT treebank according to a new annotation guideline.

2.1 Data Annotation

Annotation guideline. Unlike phrase-structure treebank construction with very detailed and systematic guidelines (Xue et al., 2005; Zhou, 2004), previous works on Chinese dependency-structure annotation only briefly describe each relation label with a few concrete examples. For example, the HIT-CDT guideline contains 14 relation labels and illustrates them in a 14-page document.

The UD (universal dependencies) project[3] releases a more detailed language-generic guideline to facilitate cross-linguistically consistent annotation, containing 37 relation labels. However, after in-depth study, we find that the UD guideline is very useful and comprehensive, but may not be completely compact for realistic annotation of Chinese-specific syntax. After many months' investigation and trial, we have developed a systematic and detailed annotation guideline for Chinese dependency treebank construction. Our 60-page guideline employs 20 relation labels and gives detailed illustrations for annotation, in order to improve consistency and quality.

Please refer to Guo et al. (2018) for the details of our guideline, including detailed discussions on the correspondences and differences between the UD guideline and ours.

[3]http://universaldependencies.org

Partial annotation. To save annotation effort, we adopt the idea of Li et al. (2016) and only annotate the most uncertain (difficult) words in a sentence. For simplicity, we directly use their released parser and produce the uncertainty results of all HLT-CDT sentences via two-fold jack-knifing. First, we select $2,000$ most difficult sentences of lengths $[5, 10]$ for full annotation[4]. Then, we select $3,000$ most difficult sentences of lengths $[10, 20]$ from the remaining data for 50% annotation. Finally, we select $6,000$ most difficult sentences of lengths $[5, 25]$ for 20% annotation from the remaining data. The difficulty of a sentence is computed as the averaged difficulty of its selected words.

Annotation platform. To guarantee annotation consistency and data quality, we build an online annotation platform to support *strict double annotation* and subsequent inconsistency handling. Each sentence is distributed to two random annotators. If the two submissions are not the same (inconsistent dependency or relation label), a third expert annotator will compare them and decide a single answer.

Annotation process. We employ about 20 students in our university as part-time annotators. Before real annotation, we first give a detailed talk on the guideline for about two hours. Then, the annotators spend several days on systematically studying our guideline. Finally, they are required to annotate 50 testing sentences on the platform. If the submission is different from the correct answer, the annotator receives an instant feedback for self-improvement. Based on their performance, about 10 capable annotators are chosen as experts to deal with inconsistent submissions.

2.2 Statistics and Analysis

Consistency statistics. Compared with the final answers, the overall accuracy of all annotators is 87.6%. Although the overall inter-annotator dependency-wise consistency rate is 76.5%, the sentence-wise consistency rate is only 43.7%. In other words, 56.3% $(100 - 43.7)$ sentences are further checked by a third expert annotator. This shows how

[4] Punctuation marks are ruled out and unannotated.

difficult it is to annotate syntactic structures and how important it is to employ strict double annotation to guarantee data quality.

Annotation time analysis. As shown in Table 2, the averaged sentence length is 15.4 words in our annotated data, among which 4.7 words (30%) are partially annotated with their heads. According to the records of our annotation platform, each sentence requires about 3 minutes in average, including the annotation time spent by two annotators and a possible expert. The total cost of our data annotation is about 550 person-hours, which can be completed by 20 full-time annotators within 4 days. The most cost is spent on quality control via two-independent annotation and inconsistency handling by experts. This is in order to obtain very high-quality data. The cost is reduced to about 150 person-hours without such strict quality control.

Heterogeneity analysis. In order to understand the heterogeneity between our guideline and the HIT-CDT guideline, we analyze the $36,348$ words with both-side heads in the `train` data, as shown in Table 2. The consistency ratio of the two guidelines is 81.69% (UAS), without considering relation labels. By mapping each relation label in HIT-CDT (14 in total) to a single label of our guideline (20 in total), the maximum consistency ratio is 73.79% (LAS). The statistics are similar for the `dev`/`test` data.

3 Indirect Multi-task Learning

Basic parser. In this work, we build all the approaches over the state-of-the-art deep biaffine parser proposed by Dozat and Manning (2017). As a graph-based dependency parser, it employs a deep biaffine neural network to compute the scores of all dependencies, and uses viterbi decoding to find the highest-scoring tree. Figure 2 shows how to score a dependency $i \leftarrow j$.[5]

First, the biaffine parser applies multi-layer bidirectional sequential LSTMs (biSeqLSTM) to encode the input sentence. The word/tag embeddings $\mathbf{e}^{w_k}$ and $\mathbf{e}^{t_k}$ are concatenated as the input vector at w_k.

[5] The score computation of the relation labels is analogous, but due to space limitation, we refer readers to Dozat and Manning (2017) for more details.

Then, the output vector of the top-layer biSeqLSTM at w_k, denoted as $\mathbf{h}_k^{seq}$, is fed into two separate MLPs to get two lower-dimensional representation vectors.

$$\begin{aligned} \mathbf{r}_k^{\mathrm{H}} &= \mathrm{MLP}^{\mathrm{H}}\left(\mathbf{h}_k^{seq}\right) \\ \mathbf{r}_k^{\mathrm{D}} &= \mathrm{MLP}^{\mathrm{D}}\left(\mathbf{h}_k^{seq}\right) \end{aligned} \tag{1}$$

where $\mathbf{r}_k^{\mathrm{H}}$ is the representation vector of w_k as a head word, and $\mathbf{r}_k^{\mathrm{D}}$ as a dependent.

Finally, the score of the dependency $i \leftarrow j$ is computed via a biaffine operation.

$$\texttt{score}(i \leftarrow j) = \begin{bmatrix} \mathbf{r}_i^{\mathrm{D}} \\ 1 \end{bmatrix}^{\mathrm{T}} \mathbf{W}^b \mathbf{r}_j^{\mathrm{H}} \tag{2}$$

During training, the original biaffine parser uses the local softmax loss. For each w_i and its head w_j, its loss is defined as $-\log \frac{e^{\texttt{score}(i \leftarrow j)}}{\sum_k e^{\texttt{score}(i \leftarrow k)}}$. Since our training data is partially annotated, we follow Li et al. (2016) and employ the global CRF loss (Ma and Hovy, 2017) for better utilization of the data, leading to consistent accuracy gain.

Multi-task learning aims to incorporate labeled data of multiple related tasks for improving performance (Collobert and Weston, 2008). Guo et al. (2016) apply multi-task learning to multi-treebank exploitation based on the neural transition-based parser of Dyer et al. (2015), and achieve higher improvement than the guiding-feature approach of Li et al. (2012).

Based on the state-of-the-art biaffine parser, this work makes a straightforward extension to realize multi-task learning. We treat the source-side and target-side parsing as two individual tasks. The two tasks use shared parameters for word/tag embeddings and multi-layer biSeqLSTMs to learn common-ground syntactic knowledge, use separate parameters for the MLP and biaffine layers to learn task-specific information.

4 Direct Treebank Conversion

Task definition. As shown in Figure 1, given an input sentence $\mathbf{x}$, treebank conversion aims to convert the under source-side tree $\mathbf{d}^{src}$ to the upper target-side tree $\mathbf{d}^{tgt}$. Therefore, the main challenge is how to make full use of the given $\mathbf{d}^{src}$ to guide the construction of $\mathbf{d}^{tgt}$. Specifically, under the biaffine parser framework, the key is to utilize $\mathbf{d}^{src}$ as guidance for better scoring an arbitrary target-side dependency $i \leftarrow j$.

In this paper, we try to encode the structural information of i and j in $\mathbf{d}^{src}$ as a dense vector from two representation levels, thus leading to two approaches, i.e., the shallow pattern embedding approach and the deep treeLSTM approach. The dense vectors are then used as extra inputs of the MLP layer to obtain better word representations, as shown in Figure 2.

4.1 The Pattern Embedding Approach

In this subsection, we propose the pattern embedding conversion approach by retrofitting the indirect guiding-feature method of Li et al. (2012) to the direct conversion scenario, with several substantial extensions.

The basic idea of Li et al. (2012) is to use extra guiding features produced by the source-side parser. First, they train the source parser $Parser^{src}$ on the source-side treebank. Then, they use $Parser^{src}$ to parse the target-side treebank, leading to *pseudo* bi-tree aligned data. Finally, they use the predictions of $Parser^{src}$ as extra pattern-based guiding features and build a better target-side parser $Parser^{tgt}$.

The original method of Li et al. (2012) is proposed for traditional discrete-feature based parsing, and does not consider the relation labels in $\mathbf{d}^{src}$. In this work, we make a few useful extensions for more effective utilization of $\mathbf{d}^{src}$.

- We further subdivide their "else" pattern into four cases according to the length of the path from w_i to w_j in $\mathbf{d}^{src}$. The left part of Figure 2 shows all 9 patterns.
- We use the labels of w_i and w_j in $\mathbf{d}^{src}$, denoted as l_i and l_j.
- Inspired by the treeLSTM approach, we also consider the label of w_a, the lowest common ancestor (LCA) of w_i and w_j, denoted as l_a.

Our pattern embedding approach works as follows. Given $i \leftarrow j$, we first decide its pattern type according to the structural relationship between w_i and w_j in $\mathbf{d}^{src}$, denoted as $p_{i\leftarrow j}$. For example, if w_i and w_j are both the children of a third word w_k in $\mathbf{d}^{src}$, then $p_{i\leftarrow j} =$ "*sibling*". Figure 2 shows all 9 patterns.

Then, we embed $p_{i\leftarrow j}$ into a dense vector $\mathbf{e}^{p_{i\leftarrow j}}$ through a lookup operation in order to fit into the biaffine parser. Similarly, the three labels are also embedded into three dense vectors, i.e., $\mathbf{e}^{l_i}$, $\mathbf{e}^{l_j}$, $\mathbf{e}^{l_a}$.

The four embeddings are combined as $\mathbf{r}^{pat}_{i\leftarrow j}$ to represent the structural information of w_i and w_j in $\mathbf{d}^{src}$.

$$\mathbf{r}^{pat}_{i\leftarrow j} = \mathbf{e}^{p_{i\leftarrow j}} \oplus \mathbf{e}^{l_i} \oplus \mathbf{e}^{l_j} \oplus \mathbf{e}^{l_a} \qquad (3)$$

Finally, the representation vector $\mathbf{r}^{pat}_{i\leftarrow j}$ and the top-layer biSeqLSTM outputs are concatenated as the inputs of the MLP layer.

$$\begin{aligned} \mathbf{r}^{\mathrm{D}}_{i,i\leftarrow j} &= \mathrm{MLP}^{\mathrm{D}}\left(\mathbf{r}^{seq}_i \oplus \mathbf{r}^{pat}_{i\leftarrow j}\right) \\ \mathbf{r}^{\mathrm{H}}_{j,i\leftarrow j} &= \mathrm{MLP}^{\mathrm{H}}\left(\mathbf{r}^{seq}_j \oplus \mathbf{r}^{pat}_{i\leftarrow j}\right) \end{aligned} \qquad (4)$$

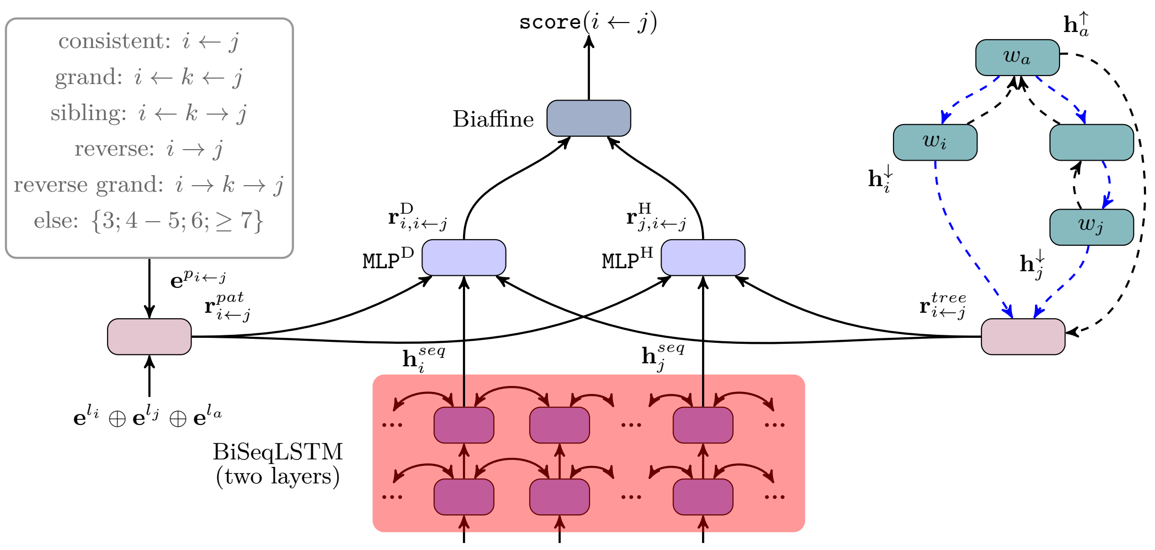
Through $\mathbf{r}^{pat}_{i\leftarrow j}$, the extended word representations, i.e., $\mathbf{r}^{\mathrm{D}}_{i,i\leftarrow j}$ and $\mathbf{r}^{\mathrm{H}}_{j,i\leftarrow j}$, now contain the structural information of w_i and w_j in $\mathbf{d}^{src}$.

The remaining parts of the biaffine parser is unchanged. The extended $\mathbf{r}^{\mathrm{D}}_{i,i\leftarrow j}$ and $\mathbf{r}^{\mathrm{H}}_{j,i\leftarrow j}$ are fed into the biaffine layer to compute a more reliable score of the dependency $i \leftarrow j$, with the help of the guidance of $\mathbf{d}^{src}$.

4.2 The TreeLSTM Approach

Compared with the pattern embedding approach, our second conversion approach employs treeLSTM to obtain a deeper representation of $i \leftarrow j$ in the source-side tree $\mathbf{d}^{src}$. Tai et al. (2015) first propose treeLSTM as a generalization of seqLSTM for encoding tree-structured inputs, and show that treeLSTM is more effective than seqLSTM on the semantic relatedness and sentiment classification tasks. Miwa and Bansal (2016) compare three treeLSTM variants on the relation extraction task and show that the SP-tree (shortest path) treeLSTM is superior to the full-tree and subtree treeLSTMs.

In this work, we employ the SP-tree treeLSTM of Miwa and Bansal (2016) for our treebank conversion task. Our preliminary experiments also show the SP-tree treeLSTM outperforms the full-tree treeLSTM, which is consistent with Miwa and Bansal. We did not implement the in-between subtree treeLSTM.



consistent: $i \leftarrow j$
grand: $i \leftarrow k \leftarrow j$
sibling: $i \leftarrow k \rightarrow j$
reverse: $i \rightarrow j$
reverse grand: $i \rightarrow k \rightarrow j$
else: $\{3; 4-5; 6; \geq 7\}$

$\mathbf{r}^{\mathrm{H}}_{j,i\leftarrow j}$
MLP$^{\mathrm{D}}$
MLP$^{\mathrm{H}}$
$\mathbf{e}^{p_{i\leftarrow j}}$
$\mathbf{r}^{pat}_{i\leftarrow j}$
$\mathbf{h}^{seq}_i$
$\mathbf{h}^{seq}_j$
$\mathbf{e}^{l_i} \oplus \mathbf{e}^{l_j} \oplus \mathbf{e}^{l_a}$
BiSeqLSTM (two layers)
$\mathbf{h}^{\uparrow}_a$
w_a
w_i
$\mathbf{h}^{\downarrow}_i$
w_j
$\mathbf{h}^{\downarrow}_j$
$\mathbf{r}^{tree}_{i\leftarrow j}$

Figure 2: Computation of $\texttt{score}(i \leftarrow j)$ in our proposed conversion approaches. Without the source-side tree $\mathbf{d}^{src}$, the baseline uses the basic $\mathbf{r}^{\mathrm{D}}_i$ and $\mathbf{r}^{\mathrm{H}}_j$ (instead of $\mathbf{r}^{\mathrm{D}}_{i,i\leftarrow j}$ and $\mathbf{r}^{\mathrm{H}}_{j,i\leftarrow j}$).

Given w_i and w_j and their LCA w_a, the SP-tree is composed of two paths, i.e., the path from w_a to w_i and the path from w_a to w_j, as shown in the right part of Figure 2.

Different from the shallow pattern embedding approach, the treeLSTM approach runs a bidirectional treeLSTM through the SP-tree, in order to encode the structural information of w_i and w_j in $\mathbf{d}^{src}$ at a deeper level. The top-down treeLSTM starts from w_a and accumulates information until w_i and w_j, whereas the bottom-up treeLSTM propagates information in the opposite direction.

Following Miwa and Bansal (2016), we stack our treeLSTM on top of the biSeqLSTM layer of the basic biaffine parser, instead of directly using word/tag embeddings as inputs. For example, the input vector for w_k in the treeLSTM is $\mathbf{x}_k = \mathbf{h}^{seq}_k \oplus \mathbf{e}^{l_k}$, where $\mathbf{h}^{seq}_k$ is the top-level biSeqLSTM output vector at w_k, and l_k is the label between w_k and its head word in $\mathbf{d}^{src}$, and $\mathbf{e}^{l_k}$ is the label embedding.

In the bottom-up treeLSTM, an LSTM node computes a hidden vector based on the combination of the input vector and the hidden vectors of its children in the SP-tree. The right part of Figure 2 and Eq. (5) illustrate the computation at w_a.

$$\begin{aligned}
\tilde{\mathbf{h}}_a &= \sum_{k \in \mathcal{C}(a)} \mathbf{h}_k \\
\mathbf{i}_a &= \sigma\left(\mathbf{U}^{(i)}\mathbf{x}_a + \mathbf{V}^{(i)}\tilde{\mathbf{h}}_a + \mathbf{b}^{(i)}\right) \\
\mathbf{f}_{a,k} &= \sigma\left(\mathbf{U}^{(f)}\mathbf{x}_a + \mathbf{V}^{(f)}\mathbf{h}_k + \mathbf{b}^{(f)}\right) \\
\mathbf{o}_a &= \sigma\left(\mathbf{U}^{(o)}\mathbf{x}_a + \mathbf{V}^{(o)}\tilde{\mathbf{h}}_a + \mathbf{b}^{(o)}\right) \\
\mathbf{u}_a &= \tanh\left(\mathbf{U}^{(u)}\mathbf{x}_a + \mathbf{V}^{(u)}\tilde{\mathbf{h}}_a + \mathbf{b}^{(u)}\right) \\
\mathbf{c}_a &= \mathbf{i}_a \odot \mathbf{u}_a + \sum_{k \in \mathcal{C}(a)} \mathbf{f}_{a,k} \odot \mathbf{c}_k \\
\mathbf{h}_a &= \mathbf{o}_a \odot \tanh\left(\mathbf{c}_a\right)
\end{aligned} \tag{5}$$

where $\mathcal{C}(a)$ means the children of w_a in the SP-tree, and $\mathbf{f}_{a,k}$ is the forget vector for w_a's child w_k.

The top-down treeLSTM sends information from the root w_a to the leaves w_i and w_j. An LSTM node computes a hidden vector based on the combination of its input vector and the hidden vector of its single preceding (father) node in the SP-tree.

After performing the biTreeLSTM, we follow Miwa and Bansal (2016) and use the combination of three output vectors to represent the structural information of w_i and w_j in $\mathbf{d}^{src}$, i.e., the output vectors of w_i and w_j in the top-down treeLSTM, and the output vector of w_a

	#Sent	#Tok (HIT)	#Tok (our)
`train`	7,768	119,707	36,348
`dev`	998	14,863	4,839
`test`	1,995	29,975	9,679
`train-HIT`	52,450	980,791	36,348

Table 2: Data statistics. Kindly note that sentences in `train` are also in `train-HIT`.

in the bottom-up treeLSTM.

$$\mathbf{r}_{i \leftarrow j}^{tree} = \mathbf{h}_i^{\downarrow} \oplus \mathbf{h}_j^{\downarrow} \oplus \mathbf{h}_a^{\uparrow} \tag{6}$$

Similar to Eq. (4) for the pattern embedding approach, we concatenate $\mathbf{r}_{i \leftarrow j}^{tree}$ with the output vectors of the top-layer biSeqLSTM, and feed them into MLP$^{\text{H/D}}$.

5 Experiments

5.1 Experiment Settings

Data. We randomly select $1,000/2,000$ sentences from our newly annotated data as the `dev/test` datasets, and the remaining as `train`. Table 2 shows the data statistics after removing some broken sentences (ungrammatical or wrongly segmented) discovered during annotation. The "#tok (our)" column shows the number of tokens annotated according to our guideline. `Train-HIT` contains all sentences in HIT-CDT except those in `dev/test`, among which most sentences only have the HIT-CDT annotations.

Evaluation. We use the standard labeled attachment score (LAS, UAS for unlabeled) to measure the parsing and conversion accuracy.

Implementation. In order to more flexibly realize our ideas, we re-implement the baseline biaffine parser in C++ based on the lightweight neural network library of Zhang et al. (2016). On the Chinese CoNLL-2009 data, our parser achieves 85.80% in LAS, whereas the original tensorflow-based parser[6] achieves 85.54% (85.38% reported in their paper) under the same parameter settings and external word embedding.

Hyper-parameters. We follow most parameter settings of Dozat and Manning (2017). The external word embedding dictionary is trained on Chinese Gigaword (LDC2003T09) with GloVe (Pennington et al., 2014). For efficiency, we use two biSeqLSTM layers instead of three, and reduce the biSeqLSTM output dimension (300) and the MLP output dimension (200).

[6]`https://github.com/tdozat/Parser-v1`

	Training data	UAS	LAS
Multi-task	`train & train-HIT`	79.29	74.51
Pattern	`train`	86.66	82.03
TreeLSTM	`train`	**86.69**	**82.09**
Combined	`train`	86.66	81.82

Table 3: Conversion accuracy on `test` data.

For the conversion approaches, the source-side pattern/label embedding dimensions are 50 (thus $|\mathbf{r}_{i \leftarrow j}^{pat}| = 200$), and the treeLSTM output dimension is 100 (thus $|\mathbf{r}_{i \leftarrow j}^{tree}| = 300$).

During training, we use 200 sentences as a data batch, and evaluate the model on the `dev` data every 50 batches (as an epoch). Training stops after the peak LAS on `dev` does not increase in 50 consecutive epochs.

For the multi-task learning approach, we randomly sample 100 `train` sentences and 100 `train-HIT` sentences to compose a data batch, for the purpose of corpus weighting.

To fully utilize `train-HIT` for the conversion task, the conversion models are built upon multi-task learning, and directly reuse the embeddings and biSeqLSTMs of the multi-task trained model without fine-tuning.

5.2 Results: Treebank Conversion

Table 3 shows the conversion accuracy on the `test` data. As a strong baseline for the conversion task, the multi-task trained target-side parser ("multi-task") does not use $\mathbf{d}^{src}$ during both training and evaluation. In contrast, the conversion approaches use both the sentence $\mathbf{x}$ and $\mathbf{d}^{src}$ as inputs.

Compared with "multi-task", the two proposed conversion approaches achieve nearly the same accuracy, and are able to dramatically improve the accuracy with the extra guidance of $\mathbf{d}^{src}$. The gain is 7.58 (82.09 − 74.51) in LAS for the treeLSTM approach.

It is straightforward to combine the two conversion approaches. We simply concatenate $\mathbf{h}_{i/j}^{seq}$ with both $\mathbf{r}_{i \leftarrow j}^{pat}$ and $\mathbf{r}_{i \leftarrow j}^{tree}$ before feeding into MLP$^{\text{H/D}}$. However, the "combined" model leads to no further improvement. This indicates that although the two approaches try

	on `dev`		on `test`	
	UAS	LAS	UAS	LAS
Pattern (full)	86.73	81.93	86.66	82.03
w/o distance	86.73	81.75	86.57	81.94
w/o l_i	86.47	80.55	86.47	81.15
w/o l_j	86.55	81.69	86.45	81.76
w/o l_a	86.24	81.66	86.17	81.51

w/o labels	86.55	80.32	86.20	80.56

Table 4: Feature ablation for the conversion approaches.

to encode the structural information of w_i and w_j in $\mathbf{d}^{src}$ from different perspectives, the resulted representations are actually overlapping instead of complementary, which is contrary to our intuition that the treeLSTM approach should give better and deeper representations than the shallow pattern embedding approach. We have also tried several straightforward modifications to the standard treeLSTM in Eq. (5), but found no further improvement. We leave further exploration of better treeLSTMs and model combination approaches as future work.

Feature ablation results are presented in Table 4 to gain more insights on the two proposed conversion approaches. In each experiment, we remove a single component from the full model to learn its individual contribution.

For the pattern embedding approach, all proposed extensions to the basic pattern-based approach of Li et al. (2012) are useful. Among the three labels, the embedding of l_i is the most useful and its removal leads to the highest LAS drop of 0.88 (82.03 − 81.15). This is reasonable considering that 81.69% dependencies are consistent in the two guidelines, as discussed in the heterogeneity analysis of Section 2.2. Removing all three labels decreases UAS by 0.73 (86.66−85.93) and LAS by 1.95 (82.03 − 80.08), demonstrating that the source-side labels are highly correlative with the target-side labels, and therefore very helpful for improving LAS.

For the treeLSTM approach, the source-side labels in $\mathbf{d}^{src}$ are also very useful, improving UAS by 0.49 (86.69 − 86.20) and LAS by 1.53 (82.09 − 80.56).

5.3 Results: Utilizing Converted Data

Another important question to be answered is whether treebank conversion can lead to higher parsing accuracy than multi-task learning. In terms of model simplicity, treebank conversion is better because eventually the target-side parser is trained directly on an enlarged homogeneous treebank unlike the multi-task learning approach that needs to simultaneously train two parsers on two heterogeneous treebanks.

Table 5 shows the empirical results. Please kindly note that the parsing accuracy looks very low, because the `test` data is partially annotated and only about 30% most uncertain (difficult) words are manually labeled with their heads according to our guideline, as discussed in Section 2.1.

The first-row, "single" is the baseline target-side parser trained on the `train` data.

The second-row "single (hetero)" refers to the source-side heterogeneous parser trained on `train-HIT` and evaluated on the target-side `test` data. Since the similarity between the two guidelines is high, as discussed in Section 2.2, the source-side parser achieves even higher UAS by 0.21 (76.20 − 75.99) than the baseline target-side parser trained on the small-scale `train` data. The LAS is obtained by mapping the HIT-CDT labels to ours (Section 2.2).

In the third row, "multi-task" is the target-side parser trained on `train & train-HIT` with the multi-task learning approach. It significantly outperforms the baseline parser by 4.30 (74.51 − 70.21) in LAS. This shows that the multi-task learning approach can effectively utilize the large-scale `train-HIT` to help the target-side parsing.

In the fourth row, "single (large)" is the basic parser trained on the large-scale `converted train-HIT` (homogeneous). We employ the treeLSTM approach to convert all sentences in train-HIT into our guideline.[7] We can see that

[7] For each sentence in `train`, which is already partially annotated, the conversion model actually completes the partial target-side tree into a full tree via constrained decoding. As shown by the results in Li et al. (2016), since the most difficult dependencies are known and given to the model, the parsing accuracy will be much higher than the traditional parsing without constraints.

	Training data	UAS	LAS
Single	`train`	75.99	70.95
Single (hetero)	`train-HIT`	76.20	68.43
Multi-task	`train & train-HIT`	79.29	74.51
Single (large)	`converted train-HIT`	**80.45**	**75.83**

Table 5: Parsing accuracy on `test` data. LAS difference between any two systems is statistically significant ($p < 0.005$) according to Dan Bikel' s randomized parsing evaluation comparer for significance test Noreen (1989).

Task	Training data	UAS	LAS
Conversion	`train`	93.42	90.49
Parsing (baseline)	`train`	89.66	86.41
Parsing (ours)	`converted train-HIT`	91.16	88.07

Table 6: Results on the fully annotated 372 sentences of the `test` data.

the single parser trained on the converted data significantly outperforms the parser in the multi-task learning approach by 1.32 (75.83 – 74.51) in LAS.

In summary, we can conclude that *treebank conversion is superior to multi-task learning in multi-treebank exploitation for its simplicity and better performance.*

5.4 Results on fully annotated data

We randomly divided the newly annotated data into train/dev/test, so the test set has a mix of 100%, 50% and 20% annotated sentences. To gain a rough estimation of the performance of different approaches on fully annotated data, we give the results in Table 6. We can see that all the models achieve much higher accuracy on the portion of fully annotated data than on the whole test data as shown in Table 3 and 5, since the dependencies to be evaluated are the most difficult ones in a sentence for the portion of partially annotated data. Moreover, the conversion model can achieve over 90% LAS thanks to the guidance of the source-side HIT-CDT tree. Please also note that there would still be a slight bias, because those fully annotated sentences are chosen as the most difficult ones according to the parsing model but are also very short ($[5, 10]$).

6 Conclusions and Future Work

In this work, we for the first time propose the task of supervised treebank conversion by constructing a bi-tree aligned data of over ten thousand sentences. We design two simple yet effective conversion approaches based on the state-of-the-art deep biaffine parser. Results show that 1) the two approaches achieves nearly the same conversion accuracy; 2) relation labels in the source-side tree are very helpful for both approaches; 3) treebank conversion is more effective in multi-treebank exploitation than multi-task learning, and achieves significantly higher parsing accuracy.

In future, we would like to advance this work in two directions: 1) proposing more effective conversion approaches, especially by exploring the potential of treeLSTMs; 2) constructing bi-tree aligned data for other treebanks and exploiting all available single-tree and bi-tree labeled data for better conversion.

Acknowledgments

The authors would like to thank the anonymous reviewers for the helpful comments. We are greatly grateful to all participants in data annotation for their hard work. We also thank Guodong Zhou and Wenliang Chen for the helpful discussions, and Meishan Zhang for his help on the re-implementation of the Biaffine Parser. Object-oriented Neural Programming (OONP) for Document Understanding

Abstract

We propose Object-oriented Neural Programming (OONP), a framework for semantically parsing documents in specific domains. Basically, OONP reads a document and parses it into a predesigned object-oriented data structure that reflects the domain-specific semantics of the document. An OONP parser models semantic parsing as a decision process: a neural net-based Reader sequentially goes through the document, and builds and updates an intermediate ontology during the process to summarize its partial understanding of the text. OONP supports a big variety of forms (both symbolic and differentiable) for representing the state and the document, and a rich family of operations to compose the representation. An OONP parser can be trained with supervision of different forms and strength, including supervised learning (SL) , reinforcement learning (RL) and hybrid of the two. Our experiments on both synthetic and real-world document parsing tasks have shown that OONP can learn to handle fairly complicated ontology with training data of modest sizes.

1 Introduction

Mapping a document into a structured "machine readable" form is a canonical and probably the most effective way for document understanding. There are quite some recent efforts on designing neural net-based learning machines for this purpose, which can be roughly categorized into two groups: 1) sequence-to-sequence model with the

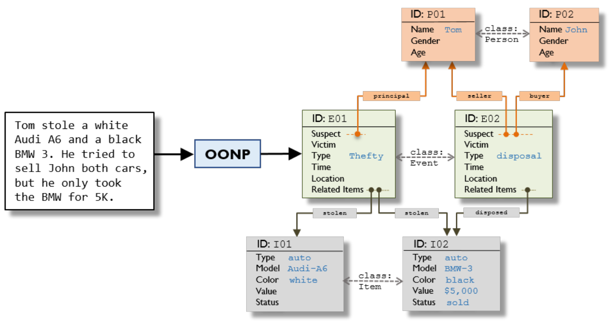

Figure 1: Illustration of OONP on a parsing task.

neural net as the black box (Liang et al., 2017), and 2) neural net as a component in a pre-designed statistical model (Zeng et al., 2014). Both categories are hindered in tackling document with complicated structures, by either the lack of effective representation of knowledge or the flexibility in fusing them in the model.

Towards solving this problem, we proposed Object-oriented Neural Programming (OONP), a framework for semantically parsing in-domain documents (illustrated in Figure 1). OONP maintains an object-oriented data structure, where objects from different classes are to represent entities (people, events, items etc) which are connected through links with varying types. Each object encapsulates internal properties (both symbolic and differentiable), allowing both neural and symbolic reasoning over complex structures and hence making it possible to represent rich semantics of documents. An OONP parser is neural net-based, but it has sophisticated architecture and mechanism designed for taking and yielding discrete structures, hence nicely combining symbolism (for interpretability and formal reasoning) and connectionism (for flexibility and learnability).

For parsing, OONP reads a document and parses it into this object-oriented data structure through a series of discrete actions along reading the document sequentially. OONP supports a rich fam-

* The work was done when these authors worked as interns at DeeplyCurious.ai.

ily of operations for composing the ontology, and flexible hybrid forms for knowledge representation. An OONP parser can be trained with supervised learning (SL), reinforcement learning (RL) and hybrid of the two.

OONP in a nutshell The key properties of OONP can be summarized as follows

1. OONP models parsing as a decision process: as the "reading and comprehension" agent goes through the text it gradually forms the ontology as the representation of the text through its action;
2. OONP uses a symbolic memory with graph structure as part of the state of the parsing process. This memory will be created and updated through the sequential actions of the decision process, and will be used as the semantic representation of the text at the end
3. OONP can blend supervised learning (SL) and reinforcement learning (RL) in tuning its parameters to suit the supervision signal in different forms and strength.

2 Related Works

2.1 Semantic Parsing

Semantic parsing is concerned with translating language utterances into executable logical forms and plays a key role in building conversational interfaces (Jonathan and Percy, 2014). Different from common tasks of semantic parsings, such as parsing the sentence to dependency structure (Buys and Blunsom, 2017) and executable commands (Herzig and Berant, 2017), OONP parses documents into a predesigned object-oriented data structure which is easily readable for both human and machine. It is related to semantic web (Berners-Lee et al., 2001) as well as frame semantics (Charles J, 1982) in the way semantics is represented, so in a sense, OONP can be viewed as a neural-symbolic implementation of semantic parsing with similar semantic representation.

2.2 State Tracking

OONP is inspired by Daumé III et al. (2009) on modeling parsing as a decision process, and the work on state-tracking models in dialogue system (Henderson et al., 2014) for the mixture of symbolic and probabilistic representations of dialogue state. For modeling a document with entities, Yang et al. (2017) use coreference links to recover entity clusters, though they only model entity mentions as containing a single word. However, entities whose names consist of multiple words are not considered. Entity Networks (Henaff et al., 2017) and EntityNLM (Ji et al., 2017) have addressed above problem and are the pioneers to model on tracking entities, but they have not considered the properties of the entities. In fact, explicitly modeling the entities both with their properties and contents is important to understand a document, especially a complex document. For example, if there are two persons named 'Avery', it is vital to know their genders or last names to avoid confusion. Therefore, we propose OONP to sketch objects and their relationships by building a structured graph for document parsing.

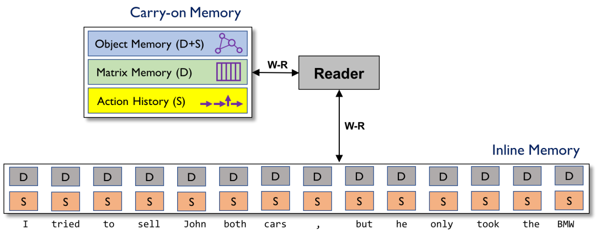

Figure 2: The overall diagram of OONP, where S stands for symbolic representation, D for distributed representation, and S+D for a hybrid of symbolic and distributed parts.

3 OONP: Overview

An OONP parser (illustrated in Figure 2) consists of a Reader equipped with read/write heads, Inline Memory that represents the document, and Carry-on Memory that summarizes the current understanding of the document at each time step. For each document to parse, OONP first preprocesses it and puts it into the Inline Memory, and then Reader controls the read-heads to sequentially go through the Inline Memory and at the same time update the Carry-on Memory. We will give a more detailed description of the major components below.

3.1 Memory

we have two types of memory, Carry-on Memory and Inline Memory. Carry-on Memory is designed to save the state in the decision process and summarize current understanding of the document based on the text that has been "read", while Inline Memory is designed to save location-specific information about the document. In a sense, the information in Inline Memory is low-level and unstructured, waiting for Reader to fuse and integrate into more structured representation.

Carry-on Memory has three compartments:

- Object Memory: denoted M_{obj}, the object-oriented data structure constructed during the parsing process;
- Matrix Memory: denoted M_{mat}, a matrix-type memory with fixed size, for differentiable read/write by the controlling neural net (Graves et al., 2014). In the simplest case, it could be just a vector as the hidden state of conventional RNN;
- Action History: symbolic memory to save the entire history of actions made during the parsing process.

Intuitively, Object Memory stores the extracted knowledge of the document with defined structure and strong evidence, while Matrix Memory keeps the knowledge that is fuzzy, uncertain or incomplete, waiting for further information to confirm, complete or clarify.

Object Memory

Object Memory stores an object-oriented representation of document, as illustrated in Figure 3. Each object is an instance of a particular class[*], which specifies the innate structure of the object, including internal properties, operations, and how this object can be connected with others. The internal properties can be of different types, for example string or category, which usually correspond to different actions in specifying them: the string-type property is usually "copied" from the original text in Inline Memory, while the category properties need to be rendered by a classifier. The links are in general directional and typed, resembling a special property viewing from the "source object". In Figure 3, there are six "linked" objects of three classes (namely, PERSON, EVENT, and ITEM) . Taking ITEM-object `I02` for example, it has five internal properties (`Type`, `Model`, `Color`, `Value`, `Status`), and is linked with two EVENT-objects through `stolen` and `disposed` link respectively.

In addition to the symbolic properties and links, each object had also its *object-embedding* as the distributed interface with Reader. For description simplicity, we will refer to the symbolic part of this hybrid representation of objects as the Ontology, with some slight abuse of this word. Object-embedding is complementary to the symbolic part

[*]We only consider flat structure of classes, but it is possible to have a hierarchy of classes with different levels of abstractness, and to allow an object to go from abstract class to its child during parsing with more information obtained.

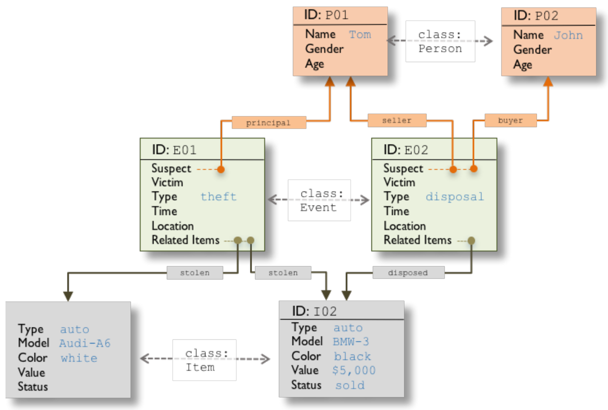

Figure 3: An example of objects of three classes.

of the object, recording all the relevant information associated with it but not represented in the Ontology, e.g., the contextual information when the object is created. Both Ontology and the object embeddings will be updated in time by the class-dependent operations driven by the actions issued by the Policy-net in Reader.

According to the way the Ontology evolves with time, the parsing task can be roughly classified into two categories: 1) **Stationary:** there is a final ground truth that does not change with time, and 2) **Dynamical:** the truth changes with time. For stationary Ontology, see Section 5.2 and 5.3 for example, and for dynamical Ontology, please see Section 5.1.

Inline Memory

Inline Memory stores the relatively raw representation of the document with the sequential structure. Basically, Inline Memory is an array of memory cells, each corresponding to a pre-defined language unit (e.g., word) in the same order as they are in the original text. Each cell can have distributed part and symbolic part, designed to save the result of preprocessing of text, e.g., plain word embedding, hidden states of RNN, or some symbolic processing.

Inline Memory provides a way to represent locally encoded "low level" knowledge of the text, which will be read, evaluated and combined with the global semantic representation in Carry-on Memory by Reader. One particular advantage of this setting is that it allows us to incorporate the local decisions of some other models, including "higher order" ones like local relations across multiple language units, as illustrated in Figure 4.

3.2 Reader

Reader is the control center of OONP, coordinating and managing all the operations of OONP. More

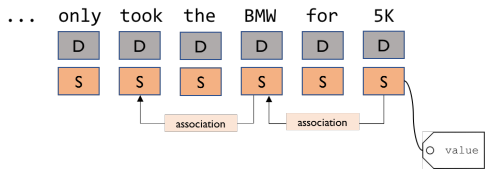

Figure 4: Inline Memory with symbolic knowledge.

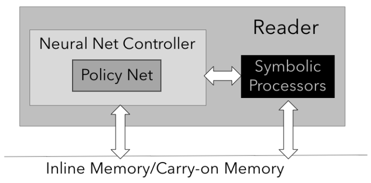

Figure 5: The overall digram of OONP

specifically, it takes the input of different forms (reading), processes it (thinking), and updates the memory (writing). As shown in Figure 5, Reader contains Neural Net Controller (NNC) and multiple symbolic processors, and NNC also has Policy-net as its sub-component. Similar to the controller in Neural Turing Machine (Graves et al., 2014), NNC is equipped with multiple read-heads and write-heads for differentiable read/write over Matrix Memory and (the distributed part of) Inline Memory, with a variety of addressing strategies (Graves et al., 2014). Policy-net however issues discrete outputs (i.e., *actions*), which gradually builds and updates the Object Memory in time. The symbolic processors are designed to handle information in symbolic form from Object Memory, Inline Memory, Action History, and Policy-net, while that from Inline Memory and Action History is eventually generated by Policy-net. In Appendix.A[†], we give a particular implementation of Reader with more details.

4 OONP: Actions

The actions issued by Policy-net can be generally categorized as the following

- `New-Assign` : determine whether to create an new object for the information at hand or assign it to a certain existed object;
- `Update.X` : determine which internal property or link of the selected object to update;
- `Update2what` : determine the content of the updating, which could be about string, category or links;

The typical order of actions is `New-Assign` $\rightarrow$ `Update.X` $\rightarrow$ `Update2what`, but it is common to have `New-Assign` action followed by nothing, when, for example, an object is mentioned but no substantial information is provided. As shown in Figure 6, we give an example of the entire episode of OONP parsing on the short text given in Figure 1, to show that a sequence of actions gradually forms the complete representation of the document.

[†]The appendix is also available at `https://arxiv.org/abs/1709.08853`

5 An examples of actions

5.1 `New-Assign`

With any information at hand (denoted as $\mathcal{S}_t$) at time t, the choices of `New-Assign` include the following three categories of actions: 1) creating (`New`) an object of a certain type, 2) assigning $\mathcal{S}_t$ to an existed object, and 3) doing nothing for $\mathcal{S}_t$ and moving on. For Policy-net, the stochastic policy is to determine the following probabilities:

$$\begin{aligned} \mathsf{prob}(c, \mathsf{new}|\mathcal{S}_t), &\quad c = 1, 2, \cdots, |\mathcal{C}| \\ \mathsf{prob}(c, k|\mathcal{S}_t), &\quad \text{for } \mathcal{O}_t^{c,k} \in \mathsf{M}_{\mathsf{obj}}^t \\ \mathsf{prob}(\mathtt{none}|\mathcal{S}_t) & \end{aligned}$$

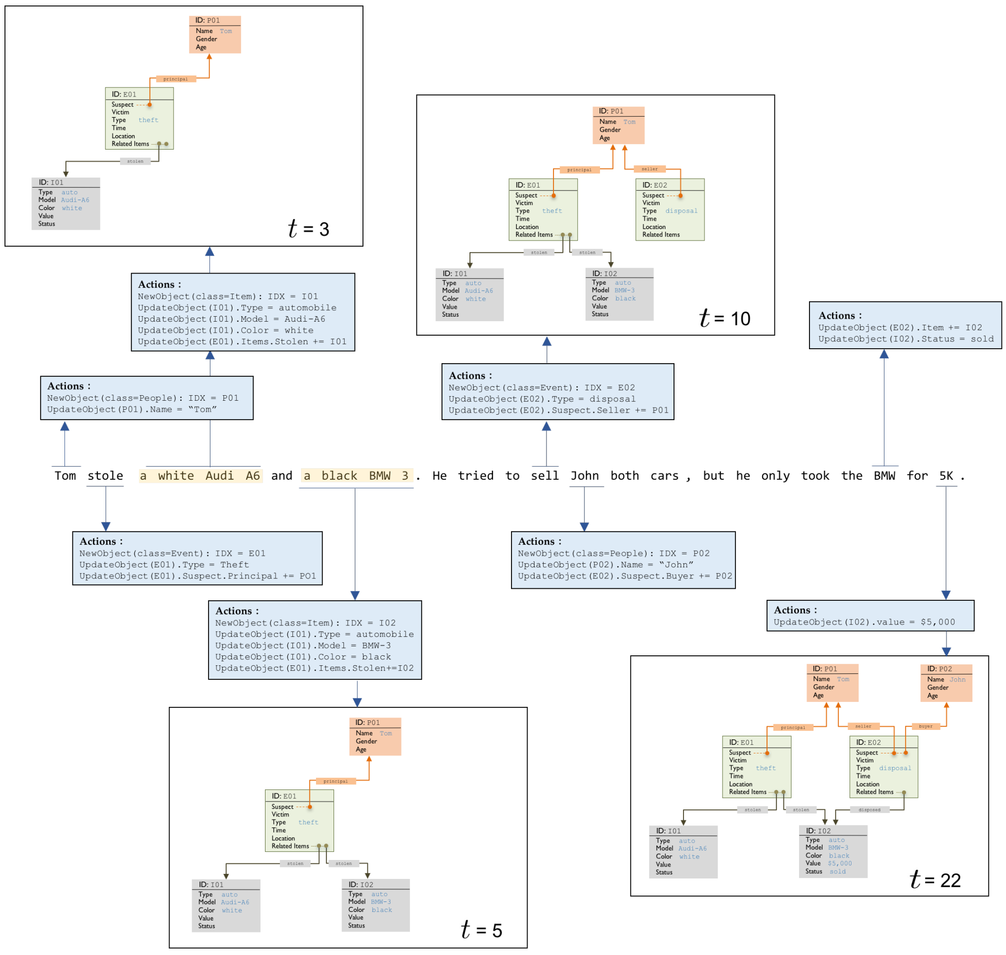
where $|\mathcal{C}|$ stands for the number of classes, $\mathcal{O}_t^{c,k}$ stands for the k^{th} object of class c at time t. Determining whether to new an object always relies on the following two signals

1. The information at hand cannot be contained by any existed objects;
2. Linguistic hints that suggest whether a new object is introduced.

Based on those intuitions, we take a score-based approach to determine the above-mentioned probability. More specifically, for a given $\mathcal{S}_t$, Reader forms a "temporary" object with its own structure (denoted $\hat{\mathcal{O}}_t$) with both symbolic and distributed sections. We also have a virtual object for the New action for each class c, denoted $\mathcal{O}_t^{c,\mathsf{new}}$, which is typically a time-dependent vector formed by Reader based on information in Matrix Memory. For a given $\hat{\mathcal{O}}_t$, we can then define the following $|\mathcal{C}| + |\mathsf{M}_{\mathsf{obj}}^t| + 1$ types of score functions:

$$\begin{aligned} \mathtt{New:}\ & \mathsf{score}_{\mathsf{new}}^{(c)}(\mathcal{O}_t^{c,\mathsf{new}}, \hat{\mathcal{O}}_t; \theta_{\mathsf{new}}^{(c)}),\ c = 1, 2, \cdots, |\mathcal{C}| \\ \mathtt{Assign:}\ & \mathsf{score}_{\mathsf{assign}}^{(c)}(\mathcal{O}_t^{c,k}, \hat{\mathcal{O}}_t; \theta_{\mathsf{assign}}^{(c)}),\ \text{for } \mathcal{O}_t^{c,k} \in \mathsf{M}_{\mathsf{obj}}^t \\ \mathtt{Do\ nothing:}\ & \mathsf{score}_{\mathsf{none}}(\hat{\mathcal{O}}_t; \theta_{\mathsf{none}}). \end{aligned}$$

to measure the level of matching between the information at hand and existed objects, as well as the likeliness for creating an object or doing nothing. This process is pictorially illustrated in Figure 7. We therefore can define the following probability for the stochastic policy



```
Tom stole a white Audi A6 and a black BMW 3 . He tried to sell John both cars , but he only took the BMW for 5K .
```

```
Actions :
NewObject(class=People): IDX = P01
UpdateObject(P01).Name = "Tom"
```

```
Actions :
NewObject(class=Item): IDX = I01
UpdateObject(I01).Type = automobile
UpdateObject(I01).Model = Audi-A6
UpdateObject(I01).Color = white
UpdateObject(E01).Items.Stolen += I01
```

```
Actions :
NewObject(class=Event): IDX = E01
UpdateObject(E01).Type = Theft
UpdateObject(E01).Suspect.Principal += P01
```

```
Actions :
NewObject(class=Item): IDX = I02
UpdateObject(I01).Type = automobile
UpdateObject(I01).Model = BMW-3
UpdateObject(I01).Color = black
UpdateObject(E01).Items.Stolen+=I02
```

```
Actions :
NewObject(class=Event): IDX = E02
UpdateObject(E02).Type = disposal
UpdateObject(E02).Suspect.Seller += P01
```

```
Actions :
NewObject(class=People): IDX = P02
UpdateObject(P02).Name = "John"
UpdateObject(E02).Suspect.Buyer += P02
```

```
Actions :
UpdateObject(E02).Item += I02
UpdateObject(I02).Status = sold
```

```
Actions :
UpdateObject(I02).value = $5,000
```

Figure 6: A pictorial illustration of a full episode of OONP parsing, where we assume the description of cars (highlighted with shadow) are segmented in preprocessing.

$$\text{prob}(c, \text{new}|\mathcal{S}_t) = \frac{e^{\text{score}^{(c)}_{\text{new}}(\mathcal{O}^{c,\text{new}}_t, \hat{\mathcal{O}}_t; \theta^{(c)}_{\text{new}})}}{Z(t)} \quad (1)$$

$$\text{prob}(c, k|\mathcal{S}_t) = \frac{e^{\text{score}^{(c)}_{\text{assign}}(\mathcal{O}^{c,k}_t, \hat{\mathcal{O}}_t; \theta^{(c)}_{\text{assign}})}}{Z(t)} \quad (2)$$

$$\text{prob}(\text{none}|\mathcal{S}_t) = \frac{e^{\text{score}_{\text{none}}(\hat{\mathcal{O}}_t; \theta_{\text{none}})}}{Z(t)} \quad (3)$$

where $Z(t) = \sum_{c' \in \mathcal{C}} e^{\text{score}^{(c')}_{\text{new}}(\mathcal{O}^{c',\text{new}}_t, \hat{\mathcal{O}}_t; \theta^{(c')}_{\text{new}})} + \sum_{(c'',k') \in \text{idx}(\mathbf{M}^t_{\text{obj}})} e^{\text{score}^{(c'')}_{\text{assign}}(\mathcal{O}^{c'',k}_t, \hat{\mathcal{O}}_t; \theta^{(c'')}_{\text{assign}})} + e^{\text{score}_{\text{none}}(\hat{\mathcal{O}}_t; \theta_{\text{none}})}$ is the normalizing factor.

5.2 Updating Objects

In `Update.X` step, Policy-net needs to choose the property or external link (or none) to update for the selected object determined by `New-Assign` step. If `Update.X` chooses to update an external link, Policy-net needs to further determine which object it links to. After that, `Update2what` updates the chosen property or links. In task with static Ontology, most internal properties and links will be "locked" after they are updated for the first time, with some exception on a few semi-structured properties (e.g., the `Description` property in the experiment in Section 7.2). For dynamical Ontology, on the contrary, some properties and links are always subject to changes.

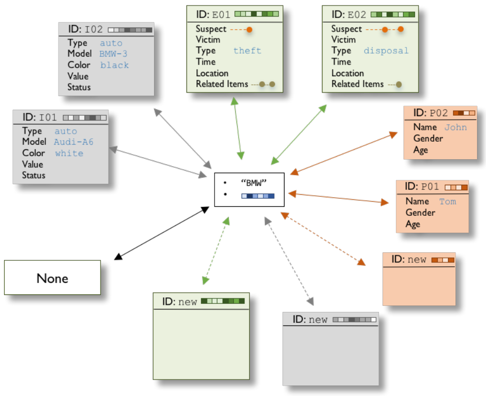


Figure 7: A pictorial illustration of what the Reader sees in determining whether to `New` an object and the relevant object when the read-head on Inline Memory reaches the last word in the text in Figure 2. The color of the arrow line stands for different matching functions for object classes, where the dashed lines are for the new object.

6 Learning

The parameters of OONP models (denoted Θ) include that for all operations and that for composing the distributed sections in Inline Memory. They can be trained with supervised learning (SL) , reinforcement learning (RL), and a hybrid of the two in different ways. With pure SL, the oracle gives the ground truth about the "right action" at each time step during the entire decision process, with which the parameter can be tuned to maximize the likelihood of the truth, with the following objective function

$$\mathcal{J}_{\text{SL}}(\Theta) = -\frac{1}{N}\sum_{i}^{N}\sum_{t=1}^{T_i}\log(\pi_t^{(i)}[a_t^\star]) \tag{4}$$

where N stands for the number of instances, T_i stands for the number of steps in decision process for the i^{th} instance, $\pi_t^{(i)}[\cdot]$ stands for the probabilities of the actions at t from the stochastic policy, and $a_t^\star$ stands for the ground truth action in step t.

With RL, the supervision is given as rewards during the decision process, for which an extreme case is to give the final reward at the end of the decision process by comparing the generated Ontology and the ground truth, e.g.,

$$r_t^{(i)} = \begin{cases} 0, & \text{if } t \neq T_i \\ \mathsf{match}(\mathsf{M}_{\text{obj}}^{T_i}, \mathcal{G}_i), & \text{if } t = T_i \end{cases} \tag{5}$$

where the $\mathsf{match}(\mathsf{M}_{\text{obj}}^{T_i}, \mathcal{G}_i)$ measures the consistency between the Ontology of in the Object Memory $\mathsf{M}_{\text{obj}}^{T_i}$ and the ground truth $\mathcal{G}^\star$. We can use policy search algorithm to maximize the expected total reward, e.g. the commonly used REINFORCE (Williams, 1992) for training, with the gradient

$$\nabla_\Theta \mathcal{J}_{\text{RL}}(\Theta) = -\mathbb{E}_{\pi_\theta}\left[\nabla_\Theta \log \pi_\Theta\left(a_t^i|s_t^i\right) r_{t:T}^{(i)}\right] \tag{6}$$

$$\approx -\frac{1}{NT_i}\sum_{i}^{N}\sum_{t=1}^{T}\nabla_\Theta \log \pi_\Theta\left(a_t^i|s_t^i\right) r_{t:T_i}^{(i)}. \tag{7}$$

When OONP is applied to real-world tasks, there is often quite natural supervision signals for both SL and RL. More specifically, for static Ontology one can infer some actions from the final ontology based on some basic assumption, e.g.,

- the system should `New` an object the first time it is mentioned;
- the system should put an extracted string (say, that for `Name`) into the right property of right object at the end of the string.

For those that can not be fully inferred, say the categorical properties of an object (e.g., `Type` for event objects), we have to resort to RL to determine the *time* of decision, while we also need SL to train Policy-net on the *content* of the decision. Fortunately it is quite straightforward to combine the two learning paradigms in optimization. More specifically, we maximize this combined objective

$$\mathcal{J}(\Theta) = \mathcal{J}_{\text{SL}}(\Theta) + \lambda\mathcal{J}_{\text{RL}}(\Theta), \tag{8}$$

where $\mathcal{J}_{\text{SL}}$ and $\mathcal{J}_{RL}$ are over the parameters within their own supervision mode and λ coordinates the weight of the two learning mode on the parameters they share. Equation (8) actually indicates a deep coupling of supervised learning and reinforcement learning, since for any episode the samples of actions related to RL might affect the inputs to the models under supervised learning.

For dynamical Ontology (see Section 7.1 for example), it is impossible to derive most of the decisions from the final Ontology since they may change over time. For those we have to rely mostly on the supervision at the time step to train the action (supervised mode) or count on OONP to learn the dynamics of the ontology evolution by fitting the final ground truth. Both scenarios are discussed in Section 7.1 on a synthetic task.

7 Experiments

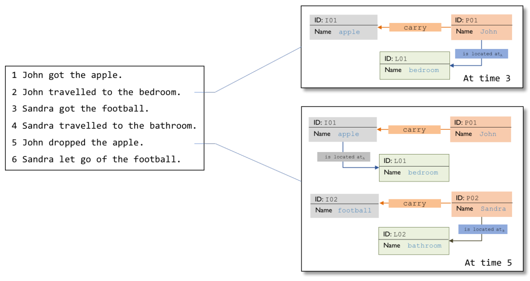
We applied OONP on three document parsing tasks, to verify its efficacy on parsing documents with different characteristics and investigate different components of OONP.

7.1 Task-I: bAbI Task

Data and Task

We implemented OONP on enriched version of bAbI tasks (Johnson, 2017) with intermediate representation for history of arbitrary length. In this experiment, we considered only the original bAbi task-2 (Weston et al., 2015), with an instance shown in the left panel Figure 8. The ontology has three types of objects: PERSON-object, ITEM-object, and LOCATION-object, and three types of links specifying relations between them (see Figure 8 for an illustration). All three types of objects have `Name` as the only internal property.

The task for OONP is to read an episode of story and recover the trajectory of the evolving ontology. We choose bAbI for its dynamical ontology that evolves with time and ground truth given for each snapshot. Comparing with the real-world tasks we will present later, bAbi has almost trivial internal properties but relatively rich opportunities for links, considering that any two objects of different types could potentially have a link.



```
1 John got the apple.
2 John travelled to the bedroom.
3 Sandra got the football.
4 Sandra travelled to the bathroom.
5 John dropped the apple.
6 Sandra let go of the football.
```

Figure 8: One instance of bAbI (6-sentence episode) and the ontology of two snapshots.

Action	Description
`NewObject`(c)	New an object of class-c.
`AssignObject`(c,k)	Assign the current information to existed object (c,k)
`Update`(c,k)`.AddLink`(c',k',ℓ)	Add an link of type-ℓ from object-(c,k) to object-(c',k')
`Update`(c,k)`.DelLink`(c',k',ℓ)	Delete the link of type-ℓ from object-(c,k) to object-(c',k')

Table 1: Actions for bAbI.

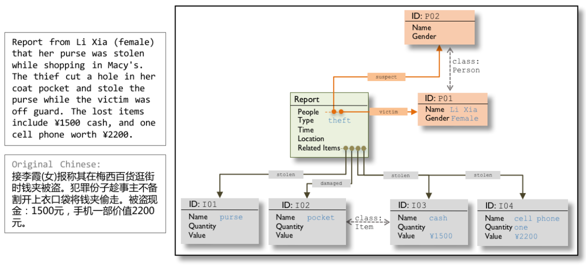
Implementation Details

For preprocessing, we have a trivial NER to find the names of people, items and locations (saved in the symbolic part of Inline Memory) and word-level bi-directional GRU for the distributed representations of Inline Memory. In the parsing process, Reader goes through the inline word-by-word in the temporal order of the original text, makes `New-Assign` action at every word, leaving `Update.X` and `Update2what` actions to the time steps when the read-head on Inline Memory reaches a punctuation (see more details of actions in Table 1). For this simple task, we use an almost fully neural Reader (with MLPs for Policy-net) and a vector for Matrix Memory, with however a Symbolic Reasoner to maintain the logical consistency after updating the relations with the actions (see Appendx.B for more details).

Results and Analysis

For training, we use 1,000 episodes with length evenly distributed from one to six. We use just REINFORCE with only the final reward defined as the overlap between the generated ontology and the ground truth, while step-by-step supervision on actions yields almost perfect result (result omitted). For evaluation, we use the F1 (Rijsbergen, 1979) between the generated links and the ground truth averaged over all snapshots of all test instances, since the links are sparse compared with all the possible pairwise relations between objects, with which we get F1= 94.80% without Symbolic Reasoner and F1= 95.30% with it.

Clearly OONP can learn fairly well on recovering the evolving ontology with such a small training set and weak supervision (RL with the final reward), showing that the credit assignment over to earlier snapshots does not cause much difficulty in the learning of OONP even with a generic policy search algorithm. It is not so surprising to observe that Symbolic Reasoner helps to improve the results on discovering the links, while it does not improve the performance on identifying the objects although it is taken within the learning.



```
Report from Li Xia (female)
that her purse was stolen
while shopping in Macy's.
The thief cut a hole in her
coat pocket and stole the
purse while the victim was
off guard. The lost items
include ¥1500 cash, and one
cell phone worth ¥2200.
```

Figure 9: Example of police report & its ontology.

7.2 Task-II: Parsing Police Report

Data & Task

We implement OONP for parsing Chinese police report (brief description of criminal cases written by policeman), as illustrated in the left panel of Figure 9. We consider a corpus of 5,500 cases with a variety of crime categories, including theft, robbery, drug dealing and others. Although the language is reasonably formal, the corpus covers a big variety of topics and language styles, and has a high proportion of typos. The ontology we designed for this task mainly consists of a number of PERSON-objects and ITEM-objects connected through an EVENT-object with several types of relations, as illustrated in the right panel of Figure 9. A PERSON-object has three internal properties: `Name` (string), `Gender` (categorical) and `Age` (number), and two types of external links (`suspect` and `victim`) to an EVENT-object. An ITEM-object has three internal properties: `Name` (string), `Quantity` (string) and `Value` (string), and six types of external links (`stolen`, `drug`, `robbed`, `swindled`, `damaged`, and `other`) to an EVENT-object. On average, a sample has 95.24 Chinese words and the ontology has 3.35 objects, 3.47 mentions and 5.02 relationships. Compared with bAbI in Section 7.1, the police report ontology has less pairwise links but much richer internal properties for objects of all three objects.

Implementation Details

The OONP model is to generate the ontology as illustrated in Figure 9 through a decision process with actions in Table 2. As pre-processing, we performed third party NER algorithm to find people names, locations, item etc. For the distributed part of Inline Memory, we used dilated CNN with different choices of depth and kernel size (Yu and Koltun, 2016), all of which will be jointly learned during training. In updating objects with its string-type properties (e.g., `Name` for a PERSON-object), we use Copy-Paste strategy for extracted string (whose NER tag already specifies which property in an object it goes to) as Reader sees it. For undetermined category properties in existed objects, Policy-net will determine the object to update (a `New-Assign` action without `New` option), its property to update (an `Update.X` action), and the updating operation (an `Update2what` action) at milestones of the decision process , e.g., when reaching an punctuation. For this task, since all the relations are between the single by-default EVENT-object and other objects, the relations can be reduced to category-type properties of the corresponding objects in practice. For category-type properties, we cannot recover `New-Assign` and `Update.X` actions from the label (the final ontology), so we resort RL for learning to determine that part, which is mixed with the supervised learning for `Update2what` and other actions for string-type properties.

Action	Description
`NewObject`(c)	New an object of class-c.
`AssignObject`(c,k)	Assign the current information to existed object (c,k)
`UpdateObject`(c,k)`.Name`	Set the name of object-(c,k) with the extracted string.
`UpdateObject`(PERSON,k)`.Gender`	Set the name of a PERSON-object indexed k with the extracted string.
`UpdateObject`(ITEM,k)`.Quantity`	Set the quantity of an ITEM-object indexed k with the extracted string.
`UpdateObject`(ITEM,k)`.Value`	Set the value of an ITEM-object indexed k with the extracted string.
`UpdateObject`(EVENT,1)`.Items.x`	Set the link between the EVENT-object and an ITEM-object, where `x` ∈{`stolen`, `drug`, `robbed`, `swindled`, `damaged`, `other`}
`UpdateObject`(EVENT,1)`.Persons.x`	Set the link between the EVENT-object and an PERSON-object, and `x` ∈{`victim`, `suspect`}

Table 2: Actions for parsing police report.

Results & Discussion

We use 4,250 cases for training, 750 for validation an held-out 750 for test. We consider the following four metrics in comparing the performance of different models:

Assignment Accuracy	the accuracy on `New-Assign` actions made by the model
Category Accuracy	the accuracy of predicting the category properties of all the objects
Ontology Accuracy	the proportion of instances for which the generated Objects is exactly the same as the ground truth
Ontology Accuracy-95	the proportion of instances for which the generated Objects achieves 95% consistency with the ground truth

which measures the accuracy of the model in making discrete decisions as well as generating the final ontology.

Model	Assign Acc. (%)	Type Acc. (%)	Ont. Acc. (%)	Ont. Acc-95 (%)
Bi-LSTM (baseline)	73.2 ± 0.58	-	36.4± 1.56	59.8 ± 0.83
ENTITYNLM (baseline)	87.6 ± 0.50	84.3 ± 0.80	59.6 ± 0.85	72.3 ± 1.37
OONP (neural)	88.5 ± 0.44	84.3 ± 0.58	61.4 ± 1.26	75.2 ± 1.35
OONP (structured)	91.2 ± 0.62	87.0 ± 0.40	65.4 ± 1.42	79.9 ± 1.28
OONP (RL)	**91.4** ± 0.38	**87.8** ± 0.75	**66.7** ± 0.95	**80.7** ± 0.82

Table 3: OONP on parsing police reports.

We empirically investigated two competing models, Bi-LSTM and EntityNLM , as baselines. Both models can be viewed as simplified versions of OONP. Bi-LSTM consists of a bi-directional LSTM as Inline Memory encoder and a two-layer MLP on top of that as Policy-net. Bi-LSTM does not support categorical prediction for objects due to the lack of explicit object representation, which will only be trained to perform `New-Assign` actions and evaluated on them (with the relevant metrics modified for it). EntityNLM, on the other hand, has some modest capability for modeling entities with the original purpose of predicting entity mentions (Ji et al., 2017) which has been adapted and re-implemented for this scenario. For OONP , we consider three variants:

- OONP (neural): simple version of OONP with only distributed representation in Reader;
- OONP (structured): OONP that considers the matching between two structured objects in `New-Assign` actions;
- OONP (RL): another version of OONP (structured) that uses RL[‡] to determine the time for predicting the category properties, while OONP (neural) and OONP (structured) use a rule-based approach to determine the time.

The experimental results are given in Table 3. As shown in Table 3, Bi-LSTM struggles to achieve around 73% Assignment Accuracy on test set, while OONP (neural) can boost the performance to 88.5%. Arguably, this difference in performance is due to the fact that Bi-LSTM lacks Object Memory, so all relevant information has to be stored in the Bi-LSTM hidden states along the reading process. When we start putting symbolic representation and operation into Reader, as shown in the result of OONP (structure), the performance is again significantly improved on all four metrics.

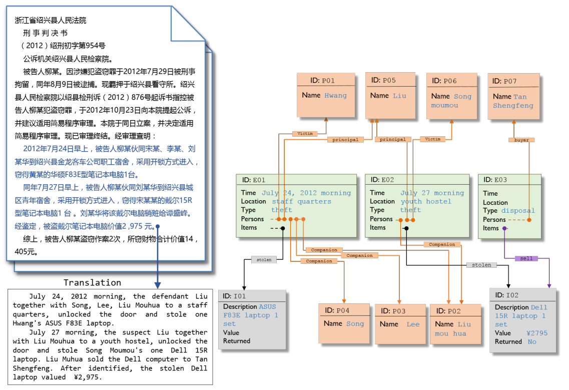
From the result of OONP (RL), RL improves not only the prediction of categorical property (and hence the overall ontology accuracy) but also tasks trained with purely SL (i.e., learning the `New-Assign` actions). This indicates there might be some deep entanglement between SL and RL through the obvious interaction between features in parsing and/or sharing of parameters.

7.3 Task-III: Parsing court judgment docs

Data and Task

Comparing with Task-II, court judgements are typically much longer, containing multiple events

[‡] A more detailed exposition of this idea can be found in (Liu et al., 2018), where RL is used for training a multi-label classifier of text



浙江省绍兴县人民法院
刑 事 判 决 书
（2012）绍刑初字第954号
公诉机关绍兴县人民检察院。
被告人柳某。因涉嫌犯盗窃罪于2012年7月29日被刑事拘留，同年8月9日被逮捕。现羁押于绍兴县看守所。绍兴县人民检察院以绍县检刑诉（2012）876号起诉书指控被告人柳某犯盗窃罪，于2012年10月23日向本院提起公诉，并建议适用简易程序审理。本院于同日立案，并决定适用简易程序审理。现已审理终结。经审理查明：
2012年7月24日早上，被告人柳某伙同宋某、李某、刘某华到绍兴县金龙客车公司职工宿舍，采用开锁方式进入，窃得黄某的华硕F83E型笔记本电脑1台。
同年7月27日早上，被告人柳某伙同刘某华到绍兴县城区青年宿舍，采用开锁方式进入，窃得宋某某的戴尔15R型笔记本电脑1 台 。刘某华将该戴尔电脑销赃给谭盛峰。经鉴定，被盗戴尔笔记本电脑价值2 ,975 元。
综上，被告人柳某盗窃作案2次，所窃财物合计价值14，405元。

Translation

July 24, 2012 morning, the defendant Liu together with Song, Lee, Liu Mouhua to a staff quarters, unlocked the door and stole one Hwang's ASUS F83E laptop.
July 27 morning, the suspect Liu together with Liu Mouhua to a youth hostel, unlocked the door and stole Song Moumou's one Dell 15R laptop. Liu Muhua sold the Dell computer to Tan Shengfeng. After identified, the stolen Dell laptop valued ¥2,975.

Figure 10: Left: the judgement document with highlighted part being the description the facts of crime; right: the corresponding ontology

of different types and large amount of irrelevant text. The dataset contains 4056 Chinese judgement documents, divided into training/dev/testing set 3256/400/400 respectively. The ontology for this task mainly consists of a number of PERSON-objects and ITEM-objects connected through a number EVENT-object with several types of links. An EVENT-object has three internal properties: `Time` (string), `Location` (string), and `Type` (category, ∈{`theft`, `restitution`, `disposal`}), four types of external links to PERSON-objects (namely, `principal`, `companion`, `buyer`, `victim`) and four types of external links to ITEM-objects (`stolen`, `damaged`, `restituted`, `disposed`). In addition to the external links to EVENT-objects , a PERSON-object has only the `Name` (string) as the internal property. An ITEM-object has three internal properties: `Description` (array of strings), `Value` (string) and `Returned`(binary) in addition to its external links to EVENT-objects , where `Description` consists of the words describing the corresponding item, which could come from multiple segments across the document. An object could be linked to more than one EVENT-object, for example a person could be the principal suspect in event A and also a companion in event B. An illustration of the judgement document and the corresponding ontology can be found in Figure 10.

Implementation Details

We use a model configuration similar to that in Section 7.2, with event-based segmentation of text given by third-party extraction algorithm (Yan et al., 2017) in Inline Memory, which enables OONP to trivially `New` EVENT-objectwith rules. OONP reads the Inline Memory, fills the EVENT-objects, creates and fills PERSON-objects and ITEM-objects, and specifies the links between them, with the actions summarized in Table 4. When an object is created during a certain event, it will be given an extra feature (not an internal property) indicating this connection, which will be used in deciding links between this object and event object, as well as in determining the future `New-Assign` actions.

Action for 2nd-round	Description
`NewObject`(c)	New an object of class-c.
`AssignObject`(c, k)	Assign the current information to existed object (c, k)
`UpdateObject`(PERSON, k)`.Name`	Set the name of the k^{th} PERSON-object with the extracted string.
`UpdateObject`(ITEM, k)`.Description`	Add to the description of an k^{th} ITEM-object with the extracted string.
`UpdateObject`(ITEM, k)`.Value`	Set the value of an k^{th} ITEM-object with the extracted string.
`UpdateObject`(EVENT, k)`.Time`	Set the time of an k^{th} EVENT-object with the extracted string.
`UpdateObject`(EVENT, k)`.Location`	Set the location of an k^{th} EVENT-object with the extracted string.
`UpdateObject`(EVENT, k)`.Type`	Set the type of the k^{th} EVENT-object among {`theft`, `disposal`, `restitution`}
`UpdateObject`(EVENT, k)`.Items.x`	Set the link between the k^{th} EVENT-object and an ITEM-object, where `x` ∈ {`stolen`, `damaged`, `restituted`, `disposed` }
`UpdateObject`(EVENT, k)`.Persons.x`	Set the link between the k^{th} EVENT-object and an PERSON-object, and `x` ∈ {`principal`, `companion`, `buyer`, `victim`}

Table 4: Actions for parsing court judgements.

Results and Analysis

We use the same metric as in Section 7.2, and compare two OONP variants, OONP (neural) and OONP (structured), with two baselines EntityNLM and Bi-LSTM. The two baselines will be tested only on the second-round reading, while both OONP variants are tested on a two-round reading. The results are shown in Table 5. OONP parsers attain accuracy significantly higher than Bi-LSTM. Among, OONP (structure) achieves over 71% accuracy on getting the entire ontology right and over 77% accuracy on getting 95% consistency with the ground truth. We omitted the RL results since the model RL model chooses to predict the type properties same as the simple rules.

Model	Assign Acc. (%)	Type Acc. (%)	Ont. Acc. (%)	Ont. Acc-95 (%)
Bi-LSTM (baseline)	84.66 ± 0.20	-	18.20 ± 0.74	36.88 ± 1.01
ENTITYNLM (baseline)	90.50 ± 0.21	96.33 ± 0.39	39.85 ± 0.20	48.29 ± 1.96
OONP (neural)	94.50 ± 0.24	97.73 ± 0.12	53.29 ± 0.26	72.22 ± 1.01
OONP (structured)	**96.90** ± 0.22	**98.80** ± 0.08	**71.11** ± 0.54	**77.27** ± 1.05

Table 5: OONP on judgement documents.

8 Conclusion

We proposed Object-oriented Neural Programming (OONP), a framework for semantically parsing in-domain documents. OONP is neural net-based, but equipped with sophisticated architecture and mechanism for document understanding, therefore nicely combining interpretability and learnability. Experiments on both synthetic and real-world datasets have shown that OONP outperforms several strong baselines by a large margin on parsing fairly complicated ontology.

Abstract

Recurrent neural network grammars (RNNGs) are generative models of (tree, string) pairs that rely on neural networks to evaluate derivational choices. Parsing with them using beam search yields a variety of incremental complexity metrics such as word surprisal and parser action count. When used as regressors against human electrophysiological responses to naturalistic text, they derive two amplitude effects: an early peak and a P600-like later peak. By contrast, a non-syntactic neural language model yields no reliable effects. Model comparisons attribute the early peak to syntactic composition within the RNNG. This pattern of results recommends the RNNG+beam search combination as a mechanistic model of the syntactic processing that occurs during normal human language comprehension.

1 Introduction

Computational psycholinguistics has "always been...the thing that computational linguistics stood the greatest chance of providing to humanity" (Kay, 2005). Within this broad area, cognitively-plausible parsing models are of particular interest. They are mechanistic computational models that, at some level, do the same task people do in the course of ordinary language comprehension. As such, they offer a way to gain insight into the operation of the human sentence processing mechanism (for a review see Hale, 2017).

As Keller (2010) suggests, a promising place to look for such insights is at the intersection of (a) incremental processing, (b) broad coverage, and (c) neural signals from the human brain.

The contribution of the present paper is situated precisely at this intersection. It combines a probabilistic generative grammar (RNNG; Dyer et al., 2016) with a parsing procedure that uses this grammar to manage a collection of syntactic derivations as it advances from one word to the next (Stern et al., 2017, cf. Roark, 2004). Via well-known complexity metrics, the intermediate states of this procedure yield quantitative predictions about language comprehension difficulty. Juxtaposing these predictions against data from human encephalography (EEG), we find that they reliably derive several amplitude effects including the P600, which is known to be associated with syntactic processing (e.g. Osterhout and Holcomb, 1992).

Comparison with language models based on long short term memory networks (LSTM, e.g. Hochreiter and Schmidhuber, 1997; Mikolov, 2012; Graves, 2012) shows that these effects are specific to the RNNG. A further analysis pinpoints one of these effects to RNNGs' syntactic composition mechanism. These positive findings reframe earlier null results regarding the syntax-sensitivity of human processing (Frank et al., 2015). They extend work with eyetracking (e.g. Roark et al., 2009; Demberg et al., 2013) and neuroimaging (Brennan et al., 2016; Bachrach, 2008) to higher temporal resolution.[1] Perhaps most significantly, they establish a general correspondence between a computational model and electrophysiological responses to naturalistic language.

Following this Introduction, section 2 presents recurrent neural network grammars, emphasizing their suitability for incremental parsing. Sections 3 then reviews a previously-proposed

[1]Magnetoencephalography also offers high temporal resolution and as such this work fits into a tradition that includes Wehbe et al. (2014), van Schijndel et al. (2015), Wingfield et al. (2017) and Brennan and Pylkkänen (2017).

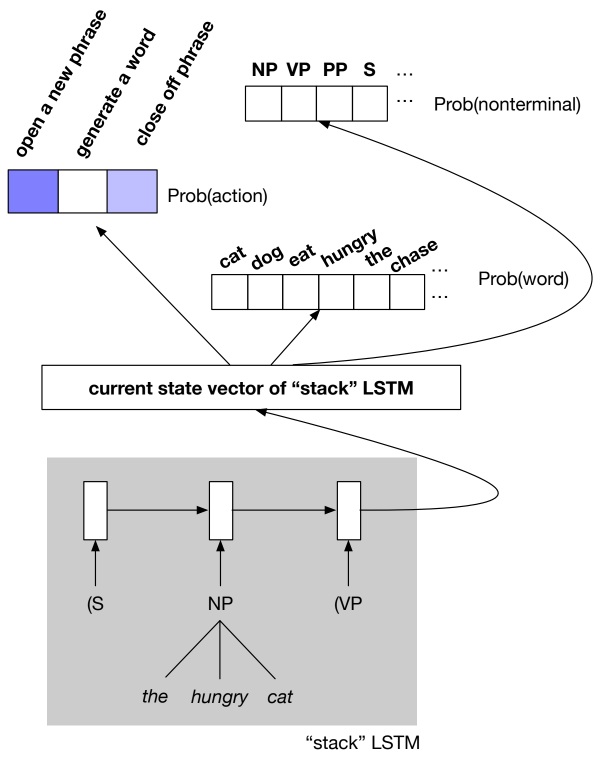

Figure 1: Recurrent neural network grammar configuration used in this paper. The absence of a lookahead buffer is significant, because it forces parsing to be incremental. Completed constituents such as [$_{\mathrm{NP}}$ the hungry cat] are represented on the stack by numerical vectors that are the output of the syntactic composition function depicted in Figure 2.

beam search procedure for them. Section 4 goes on to introduce the novel application of this procedure to human data via incremental complexity metrics. Section 5 explains how these theoretical predictions are specifically brought to bear on EEG data using regression. Sections 6 and 7 elaborate on the model comparison mentioned above and report the results in a way that isolates the operative element. Section 8 discusses these results in relation to established computational models. The conclusion, to anticipate section 9, is that syntactic processing can be found in naturalistic speech stimuli if ambiguity resolution is modeled as beam search.

2 Recurrent neural network grammars for incremental processing

Recurrent neural network grammars (henceforth: RNNGs Kuncoro et al., 2017; Dyer et al.,

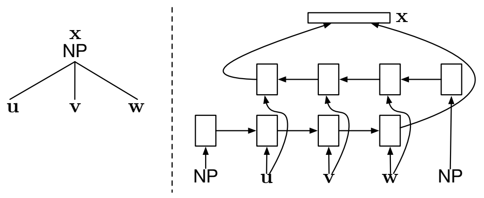

Figure 2: RNNG composition function traverses daughter embeddings $\mathbf{u}$, $\mathbf{v}$ and $\mathbf{w}$, representing the entire tree with a single vector $\mathbf{x}$. This Figure is reproduced from (Dyer et al., 2016).

2016) are probabilistic models that generate trees. The probability of a tree is decomposed via the chain rule in terms of derivational action-probabilities that are conditioned upon previous actions i.e. they are history-based grammars (Black et al., 1993). In the vanilla version of RNNG, these steps follow a depth-first traversal of the developing phrase structure tree. This entails that daughters are announced bottom-up one by one as they are completed, rather than being predicted at the same time as the mother.

Each step of this generative story depends on the state of a stack, depicted inside the gray box in Figure 1. This stack is "neuralized" such that each stack entry corresponds to a numerical vector. At each stage of derivation, a single vector summarizing the entire stack is available in the form of the final state of a neural sequence model. This is implemented using the stack LSTMs of Dyer et al. (2015). These stack-summary vectors (central rectangle in Figure 1) allow RNNGs to be sensitive to aspects of the left context that would be masked by independence assumptions in a probabilistic context-free grammar. In the present paper, these stack-summaries serve as input to a multi-layer perceptron whose output is converted via softmax into a categorical distribution over three possible parser actions: open a new constituent, close off the latest constituent, or generate a word. A hard decision is made, and if the first or last option is selected, then the same vector-valued stack–summary is again used, via multilayer perceptrons, to decide which specific nonterminal to open, or which specific word to generate.

Phrase-closing actions trigger a syntactic composition function (depicted in Figure 2) which squeezes a sequence of subtree vectors into one single vector. This happens by applying a bidirectional LSTM to the list of daughter vectors, prepended with the vector for the mother category following §4.1 of Dyer et al. (2016).

The parameters of all these components are adaptively adjusted using backpropagation at training time, minimizing the cross entropy relative to a corpus of trees. At testing time, we parse incrementally using beam search as described below in section 3.

3 Word-synchronous beam search

Beam search is one way of addressing the search problem that arises with generative grammars — constructive accounts of language that are sometimes said to "strongly generate" sentences. Strong generation in this sense simply means that they derive both an observable word-string as well as a hidden tree structure. Probabilistic grammars are joint models of these two aspects. By contrast, parsers are programs intended to infer a good tree from a given word-string. In incremental parsing with history-based models this inference task is particularly challenging, because a decision that looks wise at one point may end up looking foolish in light of future words. Beam search addresses this challenge by retaining a collection called the "beam" of parser states at each word. These states are rated by a score that is related to the probability of a partial derivation, allowing an incremental parser to hedge its bets against temporary ambiguity. If the score of one analysis suddenly plummets after seeing some word, there may still be others within the beam that are not so drastically affected. This idea of ranked parallelism has become central in psycholinguistic modeling (see e.g. Gibson, 1991; Narayanan and Jurafsky, 1998; Boston et al., 2011).

As Stern et al. (2017) observe, the most straightforward application of beam search to generative models like RNNG does not perform well. This is because lexical actions, which advance the analysis onwards to successive words, are assigned such low probabilities compared to structural actions which do not advance to the next word. This imbalance is inevitable in a probability model that strongly generates sentences, and it causes naive beam-searchers to get bogged down, proposing more and more phrase structure rather than moving on through the sentence. To address it, Stern et al. (2017) propose a word-synchronous variant of beam search. This variant keeps searching through structural actions until "enough" high-scoring parser states finally take a lexical action, arriving in synchrony at the next word of the sentence. Their procedure is written out as Algorithm 1.

Algorithm 1 Word-synchronous beam search with fast-tracking. After Stern et al. (2017)

```
1:  thisword ← input beam
2:  nextword ← ∅
3:  while |nextword| < k do
4:      fringe ← successors of all states
                 s ∈ thisword via any
                 parsing action
5:      prune fringe to top k
6:      thisword ← ∅
7:      for each parser state s ∈ fringe do
8:          if s came via a lexical action then
9:              add s to nextword
10:         else            ▷ must have been structural
11:             add s to thisword
12:         end if
13:     end for
14: end while
15: return nextword pruned to top $k_{\text{word}} \ll k$
```

In Algorithm 1 the beam is held in a set-valued variable called *nextword*. Beam search continues until this set's cardinality exceeds the designated action beam size, k. If the beam still isn't large enough (line 3) then the search process explores one more action by going around the while-loop again. Each time through the loop, lexical actions compete against structural actions for a place among the top k (line 5). The imbalance mentioned above makes this competition fierce, and on many loop iterations *nextword* may not grow by much. Once there are enough parser states, another threshold called the word beam k_{word} kicks in (line 15). This other threshold sets the number of analyses that are handed off to the next invocation of the algorithm. In the study reported here the word beam remains at the default setting suggested by Stern and colleagues, $k/10$.

Stern et al. (2017) go on to offer a modification of the basic procedure called "fast tracking" which improves performance, particularly when the action beam k is small. Under fast tracking, an additional step is added between lines 4 and 5 of

	k=100	k=200	k=400	k=600	k=800	k=1000	k=2000
Fried et al. (2017) RNNG ppl unknown, −fast track	74.1	80.1	85.3	87.5	88.7	89.6	not reported
this paper ppl=141, −fast track	71.5	78.81	84.15	86.42	87.34	88.16	89.81
this paper ppl=141, $k_{ft} = k/100$	87.1	88.96	90.48	90.64	90.84	90.96	91.25

Table 1: Penn Treebank development section bracketing accuracies (F1) under Word-Synchronous beam search. These figures show that an incremental parser for RNNG can perform well on a standard benchmark. "ppl" indicates the perplexity of over both trees and strings for the trained model on the development set, averaged over words In all cases the word beam is set to a tenth of the action beam, i.e. $k_{\text{word}} = k/10$.

Algorithm 1 such that some small number k_{ft} of parser states are promoted directly into *nextword*. These states are required to come via a lexical action, but in the absence of fast tracking they quite possibly would have failed the thresholding step in line 5.

Table 1 shows Penn Treebank accuracies for this word-synchronous beam search procedure, as applied to RNNG. As expected, accuracy goes up as the parser considers more and more analyses. Above $k = 200$, the RNNG+beam search combination outperforms a conditional model based on greedy decoding (88.9). This demonstration re-emphasizes the point, made by Brants and Crocker (2000) among others, that cognitively-plausible incremental processing can be achieved without loss of parsing performance.

4 Complexity metrics

In order to relate computational models to measured human responses, some sort of auxiliary hypothesis or linking rule is required. In the domain of language, these are traditionally referred to as complexity metrics because of the way they quantify the "processing complexity" of particular sentences. When a metric offers a prediction on each successive word, it is an *incremental* complexity metric.

Table 2 characterizes four incremental complexity metrics that are all obtained from intermediate states of Algorithm 1. The metric denoted DISTANCE is the most classic; it is inspired by the count of "transitions made or attempted" in Kaplan (1972). It quantifies syntactic work by counting the number of parser actions explored by Algorithm 1 between each word i.e. the number of times around the while-loop on line 3. The information theoretical quantities SURPRISAL and ENTROPY came into more widespread use later. They quantify unexpectedness and uncertainty, respectively, about alternative syntactic analyses at a given point within a sentence. Hale (2016) reviews their applicability across many different languages, psycholinguistic measurement techniques and grammatical models. Recent work proposes possible relationships between these two metrics, at the empirical as well as theoretical level (van Schijndel and Schuler, 2017; Cho et al., 2018).

metric	characterization
DISTANCE	count of actions required to synchronize k analyses at the next word
SURPRISAL	log-ratio of summed forward probabilities for analyses in the beam
ENTROPY	average uncertainty of analyses in the beam
ENTROPY Δ	difference between previous and current entropy value

Table 2: Complexity Metrics

The SURPRISAL metric was computed over the word beam i.e. the k_{word} highest-scoring partial syntactic analyses at each successive word. In an attempt to obtain a more faithful estimate, ENTROPY and its first-difference are computed over *nextword* itself, whose size varies but is typically much larger than k_{word}.

5 Regression models of naturalistic EEG

Electroencephalography (EEG) is an experimental technique that measures very small voltage fluctuations on the scalp. For a review emphasizing its implications vis-á-vis computational models, see Murphy et al. (2018).

We analyzed EEG recordings from 33 participants as they passively listened to a spoken recitation of the first chapter of Alice's Adventures in Wonderland.[2] This auditory stimulus was delivered via earphones in an isolated booth. All participants scored significantly better than chance on a post-session 8-question comprehension quiz. An additional ten datasets were excluded for not meeting this behavioral criterion, six due to excessive noise, and three due to experimenter error. All participants provided written informed consent under the oversight of the University of Michigan HSBS Institutional Review Board (#HUM00081060) and were compensated \$15/h.[3]

Data were recorded at 500 Hz from 61 active electrodes (impedences < 25 kΩ) and divided into 2129 epochs, spanning -0.3–1 s around the onset of each word in the story. Ocular artifacts were removed using ICA, and remaining epochs with excessive noise were excluded. The data were filtered from 0.5–40 Hz, baseline corrected against a 100 ms pre-word interval, and separated into epochs for content words and epochs for function words because of interactions between parsing variables of interest and word-class (Roark et al., 2009).

Linear regression was used per-participant, at each time-point and electrode, to identify content-word EEG amplitudes that correlate with complexity metrics derived from the RNNG+beam search combination via the complexity metrics in Table 2. We refer to these time series as Target predictors.

Each Target predictor was included in its own model, along with several Control predictors that are known to influence sentence processing: sentence order, word-order in sentence, log word frequency (Lund and Burgess, 1996), frequency of the previous and subsequent word, and acoustic sound power averaged over the first 50 ms of the epoch.

All predictors were mean-centered. We also constructed null regression models in which the rows of the design matrix were randomly permuted.[4] β coefficients for each effect were tested against these null models at the group level across all electrodes from 0–1 seconds post-onset, using a non-parametric cluster-based permutation test to correct for multiple comparisons across electrodes and time-points (Maris and Oostenveld, 2007).

6 Language models for literary stimuli

We compare the fit against EEG data for models that are trained on the same amount of textual data but differ in the explicitness of their syntactic representations.

At the low end of this scale is the LSTM language model. Models of this type treat sentences as a sequence of words, leaving it up to backpropagation to decide whether or not to encode syntactic properties in a learned history vector (Linzen et al., 2016). We use SURPRISAL from the LSTM as a baseline.

RNNGs are higher on this scale because they explicitly build a phrase structure tree using a symbolic stack. We consider as well a degraded version, RNNG$_{-\mathrm{comp}}$ which lacks the composition mechanism shown in Figure 2. This degraded version replaces the stack with initial substrings of bracket expressions, following Choe and Charniak (2016); Vinyals et al. (2015). An example would be the length 7 string shown below

$$\text{(S} \mid \text{(NP} \mid \text{the} \mid \text{hungry} \mid \text{cat} \mid)_{NP} \mid \text{(VP}$$

Here, vertical lines separate symbols whose vector encoding would be considered separately by RNNG$_{-\mathrm{comp}}$. In this degraded representation, the noun phrase is not composed explicitly. It takes up five symbols rather than one. The balanced parentheses (NP and)$_{\mathrm{NP}}$ are rather like instructions for some subsequent agent who might later perform the kind of syntactic composition that occurs online in RNNGs, albeit in an implicit manner.

In all cases, these language models were trained on chapters 2–12 of Alice's Adventures in Wonderland. This comprises 24941 words. The stimulus that participants saw during EEG data collection, for which the metrics in Table 2 are calculated, was chapter 1 of the same book, comprising 2169 words.

RNNGs were trained to match the output trees provided by the Stanford parser (Klein and Manning, 2003). These trees conform to the Penn Treebank annotation standard but do not explicitly mark long-distance dependency or include any empty categories. They seem to adequately represent basic syntactic properties such

[2] `https://tinyurl.com/alicedata`

[3] A separate analysis of these data appears in Brennan and Hale (2018); datasets are available from JRB.

[4] Temporal auto-correlation across epochs could impact model fits. Content-words are spaced 1 s apart on average and a spot-check of the residuals from these linear models indicates that they do not show temporal auto-correlation: AR(1) < 0.1 across subjects, time-points, and electrodes.

as clausal embedding and direct objecthood; nevertheless we did not undertake any manual correction.

During RNNG training, the first chapter was used as a development set, proceeding until the per-word perplexity over all parser actions on this set reached a minimum, 180. This performance was obtained with a RNNG whose state vector was 170 units wide. The corresponding LSTM language model state vector had 256 units; it reached a per-word perplexity of 90.2. Of course the RNNG estimates the joint probability of both trees *and* words, so these two perplexity levels are not directly comparable. Hyperparameter settings were determined by grid search in a region near the one which yielded good performance on the Penn Treebank benchmark reported on Table 1.

7 Results

To explore the suitability of the RNNG + beam search combination as a cognitive model of language processing difficulty, we fitted regression models as described above in section 5 for each of the metrics in Table 2. We considered six beam sizes $k = \{100, 200, 400, 600, 800, 1000\}$. Table 3 summarizes statistical significance levels reached by these Target predictors; no other combinations reached statistical significance.

LSTM		not significant
SURPRISAL	$k = 100$	$p_{cluster} = 0.027$
DISTANCE	$k = 200$	$p_{cluster} = 0.012$
SURPRISAL	$k = 200$	$p_{cluster} = 0.003$
DISTANCE	$k = 400$	$p_{cluster} = 0.002$
SURPRISAL	$k = 400$	$p_{cluster} = 0.049$
ENTROPY Δ	$k = 400$	$p_{cluster} = 0.026$
DISTANCE	$k = 600$	$p_{cluster} = 0.012$
ENTROPY	$k = 600$	$p_{cluster} = 0.014$

Table 3: Statistical significance of fitted Target predictors in Whole-Head analysis. $p_{cluster}$ values are minima for each Target with respect to a Monte Carlo cluster-based permutation test (Maris and Oostenveld, 2007).

7.1 Whole-Head analysis

Surprisal from the LSTM sequence model did not reliably predict EEG amplitude at any timepoint or electrode. The DISTANCE predictor did derive a central positivity around 600 ms post-word onset as shown in Figure 3a. SURPRISAL predicted an early frontal positivity around 250 ms, shown in Figure 3b. ENTROPY and ENTROPY Δ seemed to drive effects that were similarly early and frontal, although negative-going (not depicted); the effect for ENTROPY Δ localized to just the left side.

7.2 Region of Interest analysis

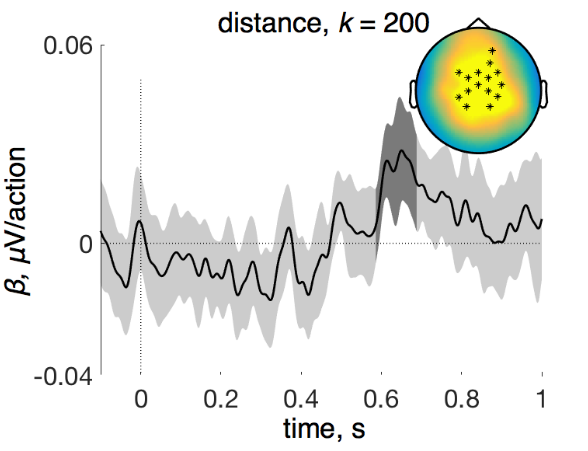
We compared RNNG to its degraded cousin, RNNG$_{-\text{comp}}$, in three regions of interest shown in Figure 4. These regions are defined by a selection of electrodes and a time window whose zero-point corresponds to the onset of the spoken word in the naturalistic speech stimulus. Regions "N400" and "P600" are well-known in EEG research, while "ANT" is motivated by findings with a PCFG baseline reported by Brennan and Hale (2018).

Single-trial data were averaged across electrodes and time-points within each region and fit with a linear mixed-effects model with fixed effects as described below and random intercepts by-subjects (Alday et al., 2017). We used a stepwise likelihood-ratio test to evaluate whether individual Target predictors from the RNNG significantly improved over RNNG$_{-\text{comp}}$, and whether a RNNG$_{-\text{comp}}$ model significantly improve a baseline regression model. The baseline regression model, denoted $\emptyset$, contains the Control predictors described in section 5 and SURPRISAL from the LSTM sequence model. Targets represent each of the eight reliable whole-head effects detailed in Table 3. These 24 tests (eight effects by three regions) motivate a Bonferroni correction of $\alpha = 0.002 = 0.05/24$.

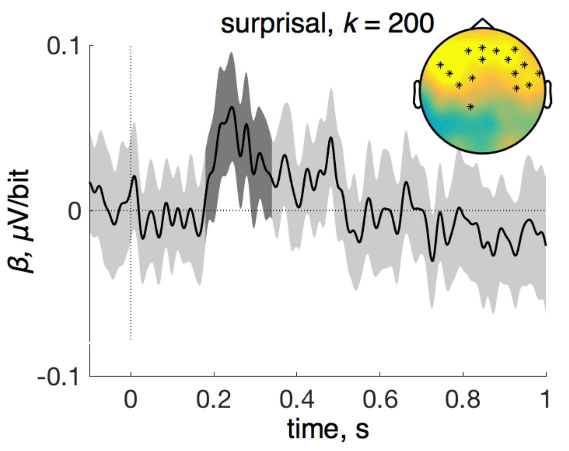
Statistically significant results obtained for DISTANCE from RNNG$_{-\text{comp}}$ in the P600 region and for SURPRISAL for RNNG in the ANT region. No significant results were observed in the N400 region. These results are detailed in Table 4.

8 Discussion

Since beam search explores analyses in descending order of probability, DISTANCE and SURPRISAL ought to be yoked, and indeed they are correlated at $r = 0.33$ or greater across all of the beam sizes k that we considered in this study. However they are reliably associated with different EEG effects. SURPRISAL manifests at anterior electrodes relatively early. This seems to be a different effect from that observed by Frank et al. (2015). Frank and colleagues relate N400 ampli-



(a) DISTANCE derives a P600 at $k = 200$.



(b) SURPRISAL derives an early response at $k = 200$.

Figure 3: Plotted values are fitted regression coefficients and 95% confidence intervals, statistically significant in the dark-shaded region with respect to a permutation test following Maris and Oostenveld (2007). The zero point represents the onset of a spoken word. Insets show electrodes with significant effects along with grand-averaged coefficient values across the significant time intervals. The diagram averages over all content words in the first chapter of Alice's Adventures in Wonderland.

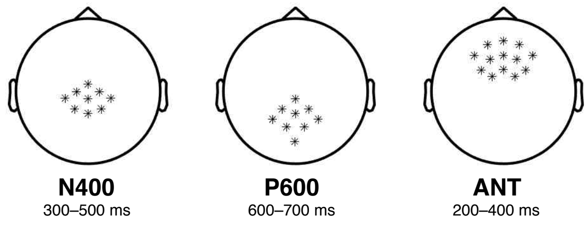


Figure 4: Regions of interest. The first region on the left, named "N400", comprises central-posterior electrodes during a time window 300–500 ms post-onset. The middle region, "P600" includes posterior electrodes 600–700 ms post-onset. The rightmost region "ANT" consists of just anterior electrodes 200-400 ms post-onset.

tude to word surprisals from an Elman-net, analogous to the LSTM sequence model evaluated in this work. Their study found no effects of syntax-based predictors over and above sequential ones. In particular, no effects emerged in the 500–700 ms window, where one might have expected a P600. The present results, by contrast, show that an explicitly syntactic model can derive the P600 quite generally via DISTANCE. The absence of an N400 effect in this analysis could be attributable to the choice of electrodes, or perhaps the modality of the stimulus narrative, i.e. spoken versus read.

The model comparisons in Table 4 indicate that the early peak, but not the later one, is attributable to the RNNG's composition function. Choe and Charniak's (2016) "parsing as language modeling" scheme potentially could explain the P600-like wave, but it would not account for the earlier peak. This earlier peak is the one derived by the RNNG under SURPRISAL, but only when the RNNG includes the composition mechanism depicted in Figure 2.

This pattern of results suggests an approach to the overall modeling task. In this approach, both grammar and processing strategy remain the same, and alternative complexity metrics, such as SURPRISAL and DISTANCE, serve to interpret the unified model at different times or places within the brain. This inverts the approach of Brouwer et al. (2017) and Wehbe et al. (2014) who interpret different *layers* of the same neural net using the same complexity metric.

9 Conclusion

Recurrent neural net grammars indeed learn something about natural language syntax, and what they learn corresponds to indices of human language processing difficulty that are manifested in electroencephalography. This correspondence, between computational model and human electrophysiological response, follows from a system that lacks an initial stage of purely string-based processing. Previous work was "two-stage" in the sense that the generative model served to

	RNNG$_{-\text{comp}} > \emptyset$			RNNG $>$ RNNG$_{-\text{comp}}$		
	χ^2	df	p	χ^2	df	p
DISTANCE, "P600" region						
$k = 200$	13.409	1	**0.00025**	4.198	1	0.04047
$k = 400$	15.842	1	**<0.0001**	3.853	1	0.04966
$k = 600$	13.955	1	**0.00019**	3.371	1	0.06635
SURPRISAL, "ANT" region						
$k = 100$	3.671	1	0.05537	13.167	1	**0.00028**
$k = 200$	3.993	1	0.04570	10.860	1	**0.00098**
$k = 400$	3.902	1	0.04824	10.189	1	**0.00141**
ENTROPY Δ, "ANT" region						
$k = 400$	10.141	1	**0.00145**	5.273	1	0.02165

Table 4: Likelihood-ratio tests indicate that regression models with predictors derived from RNNGs with syntactic composition (see Figure 2) do a better job than their degraded counterparts in accounting for the early peak in region "ANT" (right-hand columns). Similar comparisons in the "P600" region show that the model improves, but the improvement does not reach the $\alpha = 0.002$ significance threshold imposed by our Bonferroni correction (bold-faced text). RNNGs lacking syntactic composition do improve over a baseline model ($\emptyset$) containing lexical predictors and an LSTM baseline (left-hand columns).

rerank proposals from a conditional model (Dyer et al., 2016). If this one-stage model is cognitively plausible, then its simplicity undercuts arguments for string-based perceptual strategies such as the Noun-Verb-Noun heuristic (for a textbook presentation see Townsend and Bever, 2001). Perhaps, as Phillips (2013) suggests, these are unnecessary in an adequate cognitive model. Certainly, the road is now open for more fine-grained investigations of the order and timing of individual parsing operations within the human sentence processing mechanism.

Learning to Ask Good Questions: Ranking Clarification Questions using Neural Expected Value of Perfect Information

Abstract

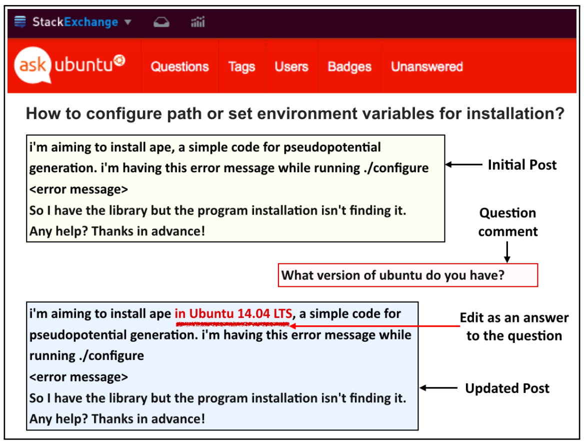
Inquiry is fundamental to communication, and machines cannot effectively collaborate with humans unless they can ask questions. In this work, we build a neural network model for the task of ranking clarification questions. Our model is inspired by the idea of expected value of perfect information: a good question is one whose expected answer will be useful. We study this problem using data from StackExchange, a plentiful online resource in which people routinely ask clarifying questions to posts so that they can better offer assistance to the original poster. We create a dataset of clarification questions consisting of ∼77K posts paired with a clarification question (and answer) from three domains of StackExchange: `askubuntu`, `unix` and `superuser`. We evaluate our model on 500 samples of this dataset against expert human judgments and demonstrate significant improvements over controlled baselines.

1 Introduction

A principle goal of asking questions is to fill information gaps, typically through clarification questions.[1] We take the perspective that a good question is the one whose *likely answer* will be useful. Consider the exchange in Figure 1, in which an initial poster (who we call "Terry") asks for help configuring environment variables. This post is underspecified and a responder ("Parker") asks a clarifying question (a) below, but could alternatively have asked (b) or (c):

(a) What version of Ubuntu do you have?

[1]We define 'clarification question' as a question that asks for some information that is currently missing from the given context.



How to configure path or set environment variables for installation?

i'm aiming to install ape, a simple code for pseudopotential generation. i'm having this error message while running ./configure
<error message>
So I have the library but the program installation isn't finding it.
Any help? Thanks in advance!

What version of ubuntu do you have?

i'm aiming to install ape in Ubuntu 14.04 LTS, a simple code for pseudopotential generation. i'm having this error message while running ./configure
<error message>
So I have the library but the program installation isn't finding it.
Any help? Thanks in advance!

Figure 1: A post on an online Q & A forum "askubuntu.com" is updated to fill the missing information pointed out by the question comment.

(b) What is the make of your wifi card?

(c) Are you running Ubuntu 14.10 kernel 4.4.0-59-generic on an x86_64 architecture?

Parker should not ask (b) because an answer is unlikely to be useful; they should not ask (c) because it is too specific and an answer like "No" or "I do not know" gives little help. Parker's question (a) is much better: it is both likely to be useful, and is plausibly answerable by Terry.

In this work, we design a model to rank a candidate set of clarification questions by their usefulness to the given post. We imagine a use case (more discussion in § 7) in which, while Terry is writing their post, a system suggests a shortlist of questions asking for information that it thinks people like Parker might need to provide a solution, thus enabling Terry to immediately clarify their post, potentially leading to a much quicker resolution. Our model is based on the decision theoretic framework of the Expected Value of Perfect Information (EVPI) (Avriel and Williams, 1970), a measure of the value of gathering additional information. In our setting, we use EVPI to calculate which questions are most likely to elicit an answer that would make the post more informative.

Figure 2: The behavior of our model during test time: Given a post p, we retrieve 10 posts similar to post p using Lucene. The questions asked to those 10 posts are our question candidates Q and the edits made to the posts in response to the questions are our answer candidates A. For each question candidate q_i, we generate an answer representation $F(p, q_i)$ and calculate how close is the answer candidate a_j to our answer representation $F(p, q_i)$. We then calculate the utility of the post p if it were updated with the answer a_j. Finally, we rank the candidate questions Q by their expected utility given the post p (Eq 1).

Our work has two main contributions:

1. A novel neural-network model for addressing the task of ranking clarification question built on the framework of expected value of perfect information (§2).
2. A novel dataset, derived from StackExchange[2], that enables us to learn a model to ask clarifying questions by looking at the types of questions people ask (§3).

We formulate this task as a ranking problem on a set of potential clarification questions. We evaluate models both on the task of returning the original clarification question and also on the task of picking any of the candidate clarification questions marked as good by experts (§4). We find that our EVPI model outperforms the baseline models when evaluated against expert human annotations. We include a few examples of human annotations along with our model performance on them in the supplementary material. We have released our dataset of ∼77K (p, q, a) triples and the expert annotations on 500 triples to help facilitate further research in this task.[3]

2 Model description

We build a neural network model inspired by the theory of expected value of perfect information (EVPI). EVPI is a measurement of: if I were to acquire information X, how useful would that be to me? However, because we haven't acquired X yet, we have to take this quantity in expectation over all possible X, weighted by each X's likelihood. In our setting, for any given question q_i that we can ask, there is a set A of possible answers that could be given. For each possible answer $a_j \in A$, there is some probability of getting that answer, and some utility if that were the answer we got. The value of this question q_i is the expected utility, over all possible answers:

$$\text{EVPI}(q_i|p) = \sum_{a_j \in A} \mathbb{P}[a_j|p, q_i]\mathbb{U}(p + a_j) \qquad (1)$$

In Eq 1, p is the post, q_i is a potential question from a set of candidate questions Q and a_j is a potential answer from a set of candidate answers A. Here, $\mathbb{P}[a_j|p, q_i]$ measures the probability of getting an answer a_j given an initial post p and a clarifying question q_i, and $\mathbb{U}(p + a_j)$ is a utility function that measures how much more complete p would be if it were augmented with answer a_j. The modeling question then is how to model:

1. The probability distribution $\mathbb{P}[a_j|p, q_i]$ and
2. The utility function $\mathbb{U}(p + a_j)$.

In our work, we represent both using neural networks over the appropriate inputs. We train the parameters of the two models jointly to minimize a joint loss defined such that an answer that has a higher potential of increasing the utility of a post gets a higher probability.

Figure 2 describes the behavior of our model during test time. Given a post p, we generate a set of candidate questions and a set of candidate

Figure 3: Training of our answer generator. Given a post p_i and its question q_i, we generate an answer representation that is not only close to its original answer a_i, but also close to one of its candidate answers a_j if the candidate question q_j is close to the original question q_i.

answers (§2.1). Given a post p and a question candidate q_i, we calculate how likely is this question to be answered using one of our answer candidates a_j (§2.2). Given a post p and an answer candidate a_j, we calculate the utility of the updated post i.e. $\mathbb{U}(p + a_j)$ (§2.3). We compose these modules into a joint neural network that we optimize end-to-end over our data (§2.4).

2.1 Question & answer candidate generator

Given a post p, our first step is to generate a set of question and answer candidates. One way that humans learn to ask questions is by looking at how others ask questions in a similar situation. Using this intuition we generate question candidates for a given post by identifying posts similar to the given post and then looking at the questions asked to those posts. For identifying similar posts, we use Lucene[4], a software extensively used in information retrieval for extracting documents relevant to a given query from a pool of documents. Lucene implements a variant of the term frequency-inverse document frequency (TF-IDF) model to score the extracted documents according to their relevance to the query. We use Lucene to find the top 10 posts most similar to a given post from our dataset (§ 3). We consider the questions asked to these 10 posts as our set of question candidates Q and the edits made to the posts in response to the questions as our set of answer candidates A. Since the top-most similar candidate extracted by Lucene is always the original post itself, the original question and answer paired with the post is always one of the candidates in Q and A. §3 describes in detail the process of extracting the (*post, question, answer*) triples from the StackExchange datadump.

2.2 Answer modeling

Given a post p and a question candidate q_i, our second step is to calculate how likely is this question to be answered using one of our answer candidates a_j. We first generate an answer representation by combining the neural representations of the post and the question using a function $F_{ans}(\bar{p}, \bar{q}_i)$ (details in §2.4). Given such a representation, we measure the distance between this answer representation and one of the answer candidates a_j using the function below:

$$dist(F_{ans}(\bar{p},\ \bar{q}_i),\ \hat{a}_j) = 1 - cos\_sim(F_{ans}(\bar{p},\ \bar{q}_i),\ \hat{a}_j)$$

The likelihood of an answer candidate a_j being the answer to a question q_i on post p is finally calculated by combining this distance with the cosine similarity between the question q_i and the question q_j paired with the answer candidate a_j:

$$\mathbb{P}[a_j|p, q_i] = \exp^{-dist(F_{ans}(\bar{p},\ \bar{q}_i),\ \hat{a}_j)} * cos\_sim(\hat{q}_i,\ \hat{q}_j) \tag{2}$$

where $\hat{a}_j$, $\hat{q}_i$ and $\hat{q}_j$ are the average word vector of a_j, q_i and q_j respectively (details in § 2.4) and cos_sim is the cosine similarity between the two input vectors.

We model our answer generator using the following intuition: a question can be asked in several different ways. For e.g. in Figure 1, the question "What version of Ubuntu do you have?" can be asked in other ways like "What version of operating system are you using?", "Version of OS?", etc. Additionally, for a given post and a question, there can be

[4]https://lucene.apache.org/

several different answers to that question. For instance, “Ubuntu 14.04 LTS”, “Ubuntu 12.0”, “Ubuntu 9.0”, are all valid answers. To generate an answer representation capturing these generalizations, we train our answer generator on our triples dataset (§3) using the loss function below:

$$\text{loss}_{\text{ans}}(p_i, q_i, a_i, Q_i) = dist(F_{ans}(\bar{p}_i, \bar{q}_i),\ \hat{a}_i) + \sum_{j \in Q} \Big(dist(F_{ans}(\bar{p}_i, \bar{q}_i),\ \hat{a}_j) * cos\_sim(\hat{q}_i,\ \hat{q}_j) \Big) \quad (3)$$

where, $\hat{a}$ and $\hat{q}$ is the average word vectors of a and q respectively (details in §2.4), cos_sim is the cosine similarity between the two input vectors.

This loss function can be explained using the example in Figure 3. Question q_i is the question paired with the given post p_i. In Eq 3, the first term forces the function $F_{ans}(\bar{p}_i, \bar{q}_i)$ to generate an answer representation as close as possible to the correct answer a_i. Now, a question can be asked in several different ways. Let Q_i be the set of candidate questions for post p_i, retrieved from the dataset using Lucene (§ 2.1). Suppose a question candidate q_j is very similar to the correct question q_i (i.e. $cos\_sim(\hat{q}_i,\ \hat{q}_j)$ is near zero). Then the second term forces the answer representation $F_{ans}(\bar{p}_i, \bar{q}_i)$ to be close to the answer a_j corresponding to the question q_j as well. Thus in Figure 3, the answer representation will be close to a_j (since q_j is similar to q_i), but may not be necessarily close to a_k (since q_k is dissimilar to q_i).

2.3 Utility calculator

Given a post p and an answer candidate a_j, the third step is to calculate the utility of the updated post i.e. $\mathbb{U}(p + a_j)$. As expressed in Eq 1, this utility function measures how useful it would be if a given post p were augmented with an answer a_j paired with a different question q_j in the candidate set. Although theoretically, the utility of the updated post can be calculated only using the given post (p) and the candidate answer (a_j), empirically we find that our neural EVPI model performs better when the candidate question (q_j) paired with the candidate answer is a part of the utility function. We attribute this to the fact that much information about whether an answer increases the utility of a post is also contained in the question asked to the post. We train our utility calculator using our dataset of (p, q, a) triples (§3). We label all the (p_i, q_i, a_i) pairs from our triples dataset with label $y = 1$. To get negative samples, we make use of the answer candidates generated using Lucene as described in §2.1. For each $a_j \in A_i$, where A_i is the set of answer candidates for post p_i, we label the pair (p_i, q_j, a_j) with label $y = 0$, except for when $a_j = a_i$. Thus, for each post p_i in our triples dataset, we have one positive sample and nine negative samples. It should be noted that this is a noisy labelling scheme since a question not paired with the original question in our dataset can often times be a *good* question to ask to the post (§ 4). However, since we do not have annotations for such other good questions at train time, we assume such a labelling.

Given a post p_i and an answer a_j paired with the question q_j, we combine their neural representations using a function $F_{util}(\bar{p}_i, \bar{q}_j, \bar{a}_j)$ (details in § 2.4). The utility of the updated post is then defined as $\mathbb{U}(p_i + a_j) = \sigma(F_{util}(\bar{p}_i, \bar{q}_j, \bar{a}_j))$[5]. We want this utility to be close to 1 for all the positively labelled (p, q, a) triples and close to 0 for all the negatively labelled (p, q, a) triples. We therefore define our loss using the binary cross-entropy formulation below:

$$\text{loss}_{\text{util}}(y_i, \bar{p}_i, \bar{q}_j, \bar{a}_j) = y_i \log(\sigma(F_{util}(\bar{p}_i, \bar{q}_j, \bar{a}_j))) \quad (4)$$

2.4 Our joint neural network model

Our fundamental representation is based on recurrent neural networks over word embeddings. We obtain the word embeddings using the GloVe (Pennington et al., 2014) model trained on the entire datadump of StackExchange.[6]. In Eq 2 and Eq 3, the average word vector representations $\hat{q}$ and $\hat{a}$ are obtained by averaging the GloVe word embeddings for all words in the question and the answer respectively. Given an initial post p, we generate a post neural representation $\bar{p}$ using a post LSTM (long short-term memory architecture) (Hochreiter and Schmidhuber, 1997). The input layer consists of word embeddings of the words in the post which is fed into a single hidden layer. The output of each of the hidden states is averaged together to get our neural representation $\bar{p}$. Similarly, given a question q and an answer a, we generate the neural representations $\bar{q}$ and $\bar{a}$ using a question LSTM and an answer LSTM respectively. We define the function F_{ans} in our answer model as a feedforward neural network with five hidden layers on the inputs $\bar{p}$ and $\bar{q}$. Likewise, we

[5] σ is the sigmoid function.

[6] Details in the supplementary material.

define the function F_{util} in our utility calculator as a feedforward neural network with five hidden layers on the inputs $\bar{p}$, $\bar{q}$ and $\bar{a}$. We train the parameters of the three LSTMs corresponding to p, q and a, and the parameters of the two feedforward neural networks jointly to minimize the sum of the loss of our answer model (Eq 3) and our utility calculator (Eq 4) over our entire dataset:

$$\sum_i \sum_j \text{loss}_{\text{ans}}(\bar{p}_i, \bar{q}_i, \bar{a}_i, Q_i) + \text{loss}_{\text{util}}(y_i, \bar{p}_i, \bar{q}_j, \bar{a}_j) \tag{5}$$

Given such an estimate $\mathbb{P}[a_j|p, q_i]$ of an answer and a utility $\mathbb{U}(p + a_j)$ of the updated post, we rank the candidate questions by their value as calculated using Eq 1. The remaining question, then, is how to get data that enables us to train our answer model and our utility calculator. Given data, the training becomes a multitask learning problem, where we learn simultaneously to predict utility and to estimate the probability of answers.

3 Dataset creation

StackExchange is a network of online question answering websites about varied topics like academia, ubuntu operating system, latex, etc. The data dump of StackExchange contains timestamped information about the posts, comments on the post and the history of the revisions made to the post. We use this data dump to create our dataset of (*post, question, answer*) triples: where the *post* is the initial unedited post, the *question* is the comment containing a question and the *answer* is either the edit made to the post after the question or the author's response to the question in the comments section.

Extract posts: We use the post histories to identify posts that have been updated by its author. We use the timestamp information to retrieve the initial unedited version of the post.

Extract questions: For each such initial version of the post, we use the timestamp information of its comments to identify the first question comment made to the post. We truncate the comment till its question mark '?' to retrieve the question part of the comment. We find that about 7% of these are rhetoric questions that indirectly suggest a solution to the post. For e.g. *"have you considered installing X?"*. We do a manual analysis of these non-clarification questions and hand-crafted a few rules to remove them. [7]

	Train	Tune	Test
`askubuntu`	19,944	2493	2493
`unix`	10,882	1360	1360
`superuser`	30,852	3857	3856

Table 1: Table above shows the sizes of the train, tune and test split of our dataset for three domains.

Extract answers: We extract the answer to a clarification question in the following two ways:
(a) Edited post: Authors tend to respond to a clarification question by editing their original post and adding the missing information. In order to account for edits made for other reasons like stylistic updates and grammatical corrections, we consider only those edits that are longer than four words. Authors can make multiple edits to a post in response to multiple clarification questions.[8] To identify the edit made corresponding to the given question comment, we choose the edit closest in time following the question.
(b) Response to the question: Authors also respond to clarification questions as subsequent comments in the comment section. We extract the first comment by the author following the clarification question as the answer to the question.

In cases where both the methods above yield an answer, we pick the one that is the most semantically similar to the question, where the measure of similarity is the cosine distance between the average word embeddings of the question and the answer.

We extract a total of 77,097 (*post, question, answer*) triples across three domains in StackExchange (Table 1). We will release this dataset along with the the nine question and answer candidates per triple that we generate using lucene (§ 2.1). We include an analysis of our dataset in the supplementary material.

4 Evaluation design

We define our task as given a post p, and a set of candidate clarification questions Q, rank the questions according to their usefulness to the post.

[7] Details in the supplementary material.

[8] On analysis, we find that 35%-40% of the posts get asked multiple clarification questions. We include only the first clarification question to a post in our dataset since identifying if the following questions are clarifications or a part of a dialogue is non-trivial.

Since the candidate set includes the original question q that was asked to the post p, one possible approach to evaluation would be to look at how often the original question is ranked higher up in the ranking predicted by a model. However, there are two problems to this approach: 1) Our dataset creation process is noisy. The original question paired with the post may not be a useful question. For e.g. *"are you seriously asking this question?"*, *"do you mind making that an answer?"*[9]. 2) The nine other questions in the candidate set are obtained by looking at questions asked to posts that are similar to the given post.[10] This greatly increases the possibility of some other question(s) being more useful than the original question paired with the post. This motivates an evaluation design that does not rely solely on the original question but also uses human judgments. We randomly choose a total of 500 examples from the test sets of the three domains proportional to their train set sizes (`askubuntu:160`, `unix:90` and `superuser:250`) to construct our evaluation set.

4.1 Annotation scheme

Due to the technical nature of the posts in our dataset, identifying useful questions requires technical experts. We recruit 10 such experts on Upwork[11] who have prior experience in unix based operating system administration.[12] We provide the annotators with a post and a randomized list of the ten question candidates obtained using Lucene (§2.1) and ask them to select a *single* "best" (B) question to ask, and additionally mark as "valid" (V) other questions that they thought would be okay to ask in the context of the original post. We enforce that the "best" question be always marked as a "valid" question. We group the 10 annotators into 5 pairs and assign the same 100 examples to the two annotators in a pair.

4.2 Annotation analysis

We calculate the inter-annotator agreement on the "best" and the "valid" annotations using Cohen's Kappa measurement. When calculating the agreement on the "best" in the strict sense, we get a low

[9]Data analysis included in the supplementary material suggests 9% of the questions are not useful.

[10]Note that this setting is different from the distractor-based setting popularly used in dialogue (Lowe et al., 2015) where the distractor candidates are chosen randomly from the corpus.

[11]https://upwork.com

[12]Details in the supplementary material.

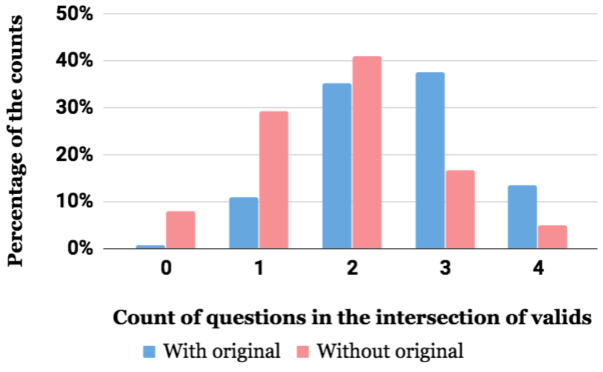

Figure 4: Distribution of the count of questions in the intersection of the "valid" annotations.

agreement of 0.15. However, when we relax this to a case where the question marked as"best" by one annotator is marked as "valid" by another, we get an agreement of 0.87. The agreement on the "valid" annotations, on the other hand, was higher: 0.58. We calculate this agreement on the binary judgment of whether a question was marked as valid by the annotator.

Given these annotations, we calculate how often is the original question marked as "best" or "valid" by the two annotators. We find that 72% of the time one of the annotators mark the original as the "best", whereas only 20% of the time both annotators mark it as the "best" suggesting against an evaluation solely based on the original question. On the other hand, 88% of the time one of the two annotators mark it as a "valid" question confirming the noise in our training data.[13]

Figure 4 shows the distribution of the counts of questions in the intersection of "valid" annotations (blue legend). We see that about 85% of the posts have more than 2 valid questions and 50% have more than 3 valid questions. The figure also shows the distribution of the counts when the original question is removed from the intersection (red legend). Even in this set, we find that about 60% of the posts have more than two valid questions. These numbers suggests that the candidate set of questions retrieved using Lucene (§2.1) very often contains useful clarification questions.

5 Experimental results

Our primary research questions that we evaluate experimentally are:

1. Does a neural network architecture improve upon non-neural baselines?

[13]76% of the time both the annotators mark it as a "valid".

Bag-of-ngrams	19.4	19.4	18.7	34.4	25.6	27.6	27.5	42.7	10.7
Community QA	23.1	21.2	20.0	40.2	33.6	30.8	29.1	47.0	18.5
Neural (p, q)	21.9	20.9	19.5	39.2	31.6	30.0	28.9	45.5	15.4
Neural (p, a)	24.1	**23.5**	20.6	41.4	32.3	**31.5**	29.0	46.5	18.8
Neural (p, q, a)	25.2	**22.7**	**21.3**	42.5	34.4	**31.8**	**30.1**	47.7	20.5
EVPI	**27.7**	**23.4**	**21.5**	**43.6**	**36.1**	**32.2**	**30.5**	**49.2**	**21.4**

Table 2: Model performances on 500 samples when evaluated against the union of the "best" annotations ($B1 \cup B2$), intersection of the "valid" annotations ($V1 \cap V2$) and the original question paired with the post in the dataset. The difference between the bold and the non-bold numbers is statistically significant with $p < 0.05$ as calculated using bootstrap test. p@k is the precision of the k questions ranked highest by the model and MAP is the mean average precision of the ranking predicted by the model.

2. Does the EVPI formalism provide leverage over a similarly expressive feedforward network?
3. Are answers useful in identifying the right question?
4. How do the models perform when evaluated on the candidate questions excluding the original?

5.1 Baseline methods

We compare our model with following baselines:

Random: Given a post, we randomly permute its set of 10 candidate questions uniformly.[14]

Bag-of-ngrams: Given a post and a set of 10 question and answer candidates, we construct a bag-of-ngrams representation for the post, question and answer. We train the baseline on all the positive and negative candidate triples (same as in our utility calculator (§2.3)) to minimize hinge loss on misclassification error using cross-product features between each of (*p, q*), (*q, a*) and (*p, a*). We tune the ngram length and choose n=3 which performs best on the tune set. The question candidates are finally ranked according to their predictions for the positive label.

Community QA: The recent SemEval2017 Community Question-Answering (CQA) (Nakov et al., 2017) included a subtask for ranking a set of comments according to their relevance to a given post in the Qatar Living[15] forum. Nandi et al. (2017), winners of this subtask, developed a logistic regression model using features based on string similarity, word embeddings, etc. We train this model on all the positively and negatively labelled (p, q) pairs in our dataset (same as in our utility calculator (§2.3), but without a). We use a subset of their features relevant to our task.[16]

Neural baselines: We construct the following neural baselines based on the LSTM representation of their inputs (as described in §2.4):
1. **Neural(p, q):** Input is concatenation of $\bar{p}$ and $\bar{q}$.
2. **Neural(p, a):** Input is concatenation of $\bar{p}$ and $\bar{a}$.
3. **Neural(p, q, a):** Input is concatenation of $\bar{p}$, $\bar{q}$ and $\bar{a}$.

Given these inputs, we construct a fully connected feedforward neural network with 10 hidden layers and train it to minimize the binary cross entropy across all positive and negative candidate triples (same as in our utility calculator (§ 2.3)). The major difference between the neural baselines and our EVPI model is in the loss function: the EVPI model is trained to minimize the joint loss between the answer model (defined on $F_{ans}(p, q)$ in Eq 3) and the utility calculator (defined on $F_{util}(p, q, a)$ in Eq 4) whereas the neural baselines are trained to minimize the loss directly on $F(p, q)$, $F(p, a)$ or $F(p, q, a)$. We include the implementation details of all our neural models in the supplementary material.

5.2 Results

5.2.1 Evaluating against expert annotations

We first describe the results of the different models when evaluated against the expert annotations we collect on 500 samples (§4). Since the annotators

[14]We take the average over 1000 random permutations.
[15]http://www.qatarliving.com/forum

[16]Details in the supplementary material.

had a low agreement on a single best, we evaluate against the union of the "best" annotations ($B1 \cup B2$ in Table 2) and against the intersection of the "valid" annotations ($V1 \cap V2$ in Table 2).

Among non-neural baselines, we find that the bag-of-ngrams baseline performs slightly better than random but worse than all the other models. The Community QA baseline, on the other hand, performs better than the neural baseline (Neural (p, q)), both of which are trained without using the answers. The neural baselines with answers (Neural(p, q, a) and Neural(p, a)) outperform the neural baseline without answers (Neural(p, q)), showing that answer helps in selecting the right question.

More importantly, EVPI outperforms the Neural (p, q, a) baseline across most metrics. Both models use the same information regarding the true question and answer and are trained using the same number of model parameters.[17] However, the EVPI model, unlike the neural baseline, additionally makes use of alternate question and answer candidates to compute its loss function. This shows that when the candidate set consists of questions similar to the original question, summing over their utilities gives us a boost.

5.2.2 Evaluating against the original question

The last column in Table 2 shows the results when evaluated against the original question paired with the post. The bag-of-ngrams baseline performs similar to random, unlike when evaluated against human judgments. The Community QA baseline again outperforms Neural(p, q) model and comes very close to the Neural (p, a) model.

As before, the neural baselines that make use of the answer outperform the one that does not use the answer and the EVPI model performs significantly better than Neural(p, q, a).

5.2.3 Excluding the original question

In the preceding analysis, we considered a setting in which the "ground truth" original question was in the candidate set Q. While this is a common evaluation framework in dialog response selection (Lowe et al., 2015), it is overly optimistic. We, therefore, evaluate against the "best" and the "valid" annotations on the nine other question candidates. We find that the neural models beat the non-neural baselines. However, the differences between all the neural models are statistically insignificant.[18]

6 Related work

Most prior work on question generation has focused on generating reading comprehension questions: given text, write questions that one might find on a standardized test (Vanderwende, 2008; Heilman, 2011; Rus et al., 2011; Olney et al., 2012). Comprehension questions, by definition, are answerable from the provided text. Clarification questions–our interest–are not.

Outside reading comprehension questions, Labutov et al. (2015) generate high-level question templates by crowdsourcing which leads to significantly less data than we collect using our method. Liu et al. (2010) use template question generation to help authors write better related work sections. Mostafazadeh et al. (2016) introduce a Visual Question Generation task where the goal is to generate natural questions that are not about what is present in the image rather about what can be inferred given the image, somewhat analogous to clarification questions. Penas and Hovy (2010) identify the notion of missing information similar to us, but they fill the knowledge gaps in a text with the help of external knowledge bases, whereas we instead ask clarification questions. Artzi and Zettlemoyer (2011) use human-generated clarification questions to drive a semantic parser where the clarification questions are aimed towards simplifying a user query; whereas we generate clarification questions aimed at identifying missing information in a text.

Among works that use community question answer forums, the keywords to questions (K2Q) system (Zheng et al., 2011) generates a list of candidate questions and refinement words, given a set of input keywords, to help a user ask a better question. Figueroa and Neumann (2013) rank different paraphrases of query for effective search on forums. (Romeo et al., 2016) develop a neural network based model for ranking questions on forums with the intent of retrieving similar other question. The recent SemEval-2017 Community Question-Answering (CQA) (Nakov et al., 2017) task included a subtask to rank the comments according to their relevance to the post. Our task primarily differs from this task in that we want to identify a

[17]We use 10 hidden layers in the feedforward network of the neural baseline and five hidden layers each in the two feedforward networks F_{ans} and F_{util} of the EVPI model.

[18]Results included in the supplementary material.

question comment which is not only relevant to the post but will also elicit useful information missing from the post. Hoogeveen et al. (2015) created the CQADupStack dataset using StackExchange forums for the task of duplicate question retrieval. Our dataset, on the other hand, is designed for the task of ranking clarification questions asked as comments to a post.

7 Conclusion

We have constructed a new dataset for learning to rank clarification questions, and proposed a novel model for solving this task. Our model integrates well-known deep network architectures with the classic notion of expected value of perfect information, which effectively models a pragmatic choice on the part of the questioner: how do I *imagine* the other party would answer if I were to ask this question. Such pragmatic principles have recently been shown to be useful in other tasks as well (Golland et al., 2010; Smith et al., 2013; Orita et al., 2015; Andreas and Klein, 2016). One can naturally extend our EVPI approach to a full reinforcement learning approach to handle multi-turn conversations.

Our results shows that the EVPI model is a promising formalism for the question generation task. In order to move to a full system that can help users like Terry write better posts, there are three interesting lines of future work. First, we need it to be able to generalize: for instance by constructing templates of the form “What version of ___ are you running?” into which the system would need to fill a variable. Second, in order to move from question ranking to question generation, one could consider sequence-to-sequence based neural network models that have recently proven to be effective for several language generation tasks (Sutskever et al., 2014; Serban et al., 2016; Yin et al., 2016). Third is in evaluation: given that this task requires expert human annotations and also given that there are multiple possible good questions to ask, how can we automatically measure performance at this task?, a question faced in dialog and generation more broadly (Paek, 2001; Lowe et al., 2015; Liu et al., 2016).

Abstract

We introduce the task of predicting adverbial presupposition triggers such as *also* and *again*. Solving such a task requires detecting recurring or similar events in the discourse context, and has applications in natural language generation tasks such as summarization and dialogue systems. We create two new datasets for the task, derived from the Penn Treebank and the Annotated English Gigaword corpora, as well as a novel attention mechanism tailored to this task. Our attention mechanism augments a baseline recurrent neural network without the need for additional trainable parameters, minimizing the added computational cost of our mechanism. We demonstrate that our model statistically outperforms a number of baselines, including an LSTM-based language model.

1 Introduction

In pragmatics, presuppositions are assumptions or beliefs in the common ground between discourse participants when an utterance is made (Frege, 1892; Strawson, 1950; Stalnaker, 1973, 1998), and are ubiquitous in naturally occurring discourses (Beaver and Geurts, 2014). Presuppositions underly spoken statements and written sentences and understanding them facilitates smooth communication. We refer to expressions that indicate the presence of presuppositions as *presupposition triggers*. These include definite descriptions, factive verbs and certain adverbs, among others. For example, consider the following statements:

(1) John is going to the restaurant *again*.

(2) John has been to the restaurant.

(1) is only appropriate in the context where (2) is held to be true because of the presence of the presupposition trigger *again*. One distinguishing characteristic of presupposition is that it is unaffected by negation of the presupposing context, unlike other semantic phenomena such as entailment and implicature. The negation of (1), *John is not going to the restaurant again.*, also presupposes (2).

Our focus in this paper is on adverbial presupposition triggers such as *again, also* and *still*. Adverbial presupposition triggers indicate the recurrence, continuation, or termination of an event in the discourse context, or the presence of a similar event. In one study of presuppositional triggers in English journalistic texts (Khaleel, 2010), adverbial triggers were found to be the most commonly occurring presupposition triggers after existential triggers.[1] Despite their frequency, there has been little work on these triggers in the computational literature from a statistical, corpus-driven perspective.

As a first step towards language technology systems capable of understanding and using presuppositions, we propose to investigate the detection of contexts in which these triggers can be used. This task constitutes an interesting testing ground for pragmatic reasoning, because the cues that are indicative of contexts containing recurring or similar events are complex and often span more than one sentence, as illustrated in Sentences (1) and (2). Moreover, such a task has immediate practical consequences. For example, in language generation applications such as summarization and dialogue systems, adding presuppositional triggers in contextually appropriate loca-

[*] Authors (listed in alphabetical order) contributed equally.

[1] Presupposition of existence are triggered by possessive constructions, names or definite noun phrases.

tions can improve the readability and coherence of the generated output.

We create two datasets based on the Penn Treebank corpus (Marcus et al., 1993) and the English Gigaword corpus (Graff et al., 2007), extracting contexts that include presupposition triggers as well as other similar contexts that do not, in order to form a binary classification task. In creating our datasets, we consider a set of five target adverbs: *too, again, also, still*, and *yet*. We focus on these adverbs in our investigation because these triggers are well known in the existing linguistic literature and commonly triggering presuppositions. We control for a number of potential confounding factors, such as class balance, and the syntactic governor of the triggering adverb, so that models cannot exploit these correlating factors without any actual understanding of the presuppositional properties of the context.

We test a number of standard baseline classifiers on these datasets, including a logistic regression model and deep learning methods based on recurrent neural networks (RNN) and convolutional neural networks (CNN).

In addition, we investigate the potential of attention-based deep learning models for detecting adverbial triggers. Attention is a promising approach to this task because it allows a model to weigh information from multiple points in the previous context and infer long-range dependencies in the data (Bahdanau et al., 2015). For example, the model could learn to detect multiple instances involving *John* and *restaurants*, which would be a good indication that *again* is appropriate in that context. Also, an attention-based RNN has achieved success in predicting article definiteness, which involves another class of presupposition triggers (Kabbara et al., 2016).

As another contribution, we introduce a new weighted pooling attention mechanism designed for predicting adverbial presupposition triggers. Our attention mechanism allows for a weighted averaging of our RNN hidden states where the weights are informed by the inputs, as opposed to a simple unweighted averaging. Our model uses a form of self-attention (Paulus et al., 2018; Vaswani et al., 2017), where the input sequence acts as both the attention mechanism's query and key/value. Unlike other attention models, instead of simply averaging the scores to be weighted, our approach aggregates (learned) attention scores by learning a reweighting scheme of those scores through another level (dimension) of attention. Additionally, our mechanism does not introduce any new parameters when compared to our LSTM baseline, reducing its computational impact.

We compare our model using the novel attention mechanism against the baseline classifiers in terms of prediction accuracy. Our model outperforms these baselines for most of the triggers on the two datasets, achieving 82.42% accuracy on predicting the adverb "also" on the Gigaword dataset.

The contributions of this work are as follows:

1. We introduce the task of predicting adverbial presupposition triggers.

2. We present new datasets for the task of detecting adverbial presupposition triggers, with a data extraction method that can be applied to other similar pre-processing tasks.

3. We develop a new attention mechanism in an RNN architecture that is appropriate for the prediction of adverbial presupposition triggers, and show that its use results in better prediction performance over a number of baselines without introducing additional parameters.

2 Related Work

2.1 Presupposition and pragmatic reasoning

The discussion of presupposition can be traced back to Frege's work on the philosophy of language (Frege, 1892), which later leads to the most commonly accepted view of presupposition called the Frege-Strawson theory (Kaplan, 1970; Strawson, 1950). In this view, presuppositions are preconditions for sentences/statements to be true or false. To the best of our knowledge, there is no previous computational work that directly investigates adverbial presupposition. However in the fields of semantics and pragmatics, there exist linguistic studies on presupposition that involve adverbs such as "too" and "again" (e.g., (Blutner et al., 2003), (Kang, 2012)) as a pragmatic presupposition trigger. Also relevant to our work is (Kabbara et al., 2016), which proposes using an attention-based LSTM network to predict noun phrase definiteness in English. Their work demonstrates the ability of these attention-based models to pick up on contextual cues for pragmatic reasoning.

Many different classes of construction can trigger presupposition in an utterance, this includes but is not limited to stressed constituents, factive verbs, and implicative verbs (Zare et al., 2012). In this work, we focus on the class of adverbial presupposition triggers.

Our task setup resembles the Cloze test used in psychology (Taylor, 1953; E. B. Coleman, 1968; Earl F. Rankin, 1969) and machine comprehension (Riloff and Thelen, 2000), which tests text comprehension via a fill-in-the-blanks task. We similarly pre-process our samples such that they are roughly the same length, and have equal numbers of negative samples as positive ones. However, we avoid replacing the deleted words with a blank, so that our model has no clue regarding the exact position of the possibly missing trigger. Another related work on the Children's Book Test (Hill et al., 2015) notes that memories that encode sub-sentential chunks (windows) of informative text seem to be most useful to neural networks when interpreting and modelling language. Their finding inspires us to run initial experiments with different context windows and tune the size of chunks according to the Logistic Regression results on the development set.

2.2 Attention

In the context of encoder-decoder models, attention weights are usually based on an energy measure of the previous decoder hidden state and encoder hidden states. Many variations on attention computation exist. Sukhbaatar et al. (2015) propose an attention mechanism conditioned on a query and applied to a document. To generate summaries, Paulus et al. (2018) add an attention mechanism in the prediction layer, as opposed to the hidden states. Vaswani et al. (2017) suggest a model which learns an input representation by self-attending over inputs. While these methods are all tailored to their specific tasks, they all inspire our choice of a self-attending mechanism.

3 Datasets

3.1 Corpora

We extract datasets from two corpora, namely the Penn Treebank (PTB) corpus (Marcus et al., 1993) and a subset (sections 000-760) of the third edition of the English Gigaword corpus (Graff et al., 2007). For the PTB dataset, we use sections 22 and 23 for testing. For the Gigaword corpus, we use sections 700-760 for testing. For the remaining data, we randomly chose 10% of them for development, and the other 90% for training.

```
('still',
['The', 'Old', 'Granary', .../* 46
    tokens omitted */...,'has', '@@@@',
    'included', 'Bertrand', 'Russell',
    .../* 6 tokens omitted */... 'Morris
    '],
['DT', 'NNP', 'NNP', .../* 46 tokens
    omitted */..., 'VBZ', '@@@@', 'VBN',
     'NNP', 'NNP', .../* 6 tokens
    omitted */... 'NNP'])
```

Figure 1: An example of an instance containing a presuppositional trigger from our dataset.

For each dataset, we consider a set of five target adverbs: *too, again, also, still*, and *yet*. We choose these five because they are commonly used adverbs that trigger presupposition. Since we are concerned with investigating the capacity of attentional deep neural networks in predicting the presuppositional effects in general, we frame the learning problem as a binary classification for predicting the presence of an adverbial presupposition (as opposed to the identity of the adverb).

On the Gigaword corpus, we consider each adverb separately, resulting in five binary classification tasks. This was not feasible for PTB because of its small size.

Finally, because of the commonalities between the adverbs in presupposing similar events, we create a dataset that unifies all instances of the five adverbs found in the Gigaword corpus, with a label "1" indicating the presence of any of these adverbs.

3.2 Data extraction process

We define a sample in our dataset as a 3-tuple, consisting of a label (representing the target adverb, or 'none' for a negative sample), a list of tokens we extract (before/after the adverb), and a list of corresponding POS tags (Klein and Manning, 2002). In each sample, we also add a special token "@@@@" right before the head word and the corresponding POS tag of the head word, both in positive and negative cases. We add such special tokens to identify the candidate context in the passage to the model. Figure 1 shows a single positive sample in our dataset.

We first extract positive contexts that contain a triggering adverb, then extract negative contexts that do not, controlling for a number of potential confounds. Our positive data consist of cases where the target adverb triggers presupposition by modifying a certain head word which, in most cases, is a verb. We define such head word as a *governor* of the target adverb.

When extracting positive data, we scan through all the documents, searching for target adverbs. For each occurrence of a target adverb, we store the location and the governor of the adverb. Taking each occurrence of a governor as a pivot, we extract the 50 unlemmatized tokens preceding it, together with the tokens right after it up to the end of the sentence (where the adverb is)–with the adverb itself being removed. If there are less than 50 tokens before the adverb, we simply extract all of these tokens. In preliminary testing using a logistic regression classifier, we found that limiting the size to 50 tokens had higher accuracy than 25 or 100 tokens. As some head words themselves are stopwords, in the list of tokens, we do not remove any stopwords from the sample; otherwise, we would lose many important samples.

We filter out the governors of "too" that have POS tags "JJ" and "RB" (adjectives and adverbs), because such cases corresponds to a different sense of "too" which indicates excess quantity and does not trigger presupposition (e.g., "rely too heavily on", "it's too far from").

After extracting the positive cases, we then use the governor information of positive cases to extract negative data. In particular, we extract sentences containing the same governors but not any of the target adverbs as negatives. In this way, models cannot rely on the identity of the governor alone to predict the class. This procedure also roughly balances the number of samples in the positive and negative classes.

For each governor in a positive sample, we locate a corresponding context in the corpus where the governor occurs without being modified by any of the target adverbs. We then extract the surrounding tokens in the same fashion as above. Moreover, we try to control position-related confounding factors by two randomization approaches: 1) randomize the order of documents to be scanned, and 2) within each document, start scanning from a random location in the document. Note that the number of negative cases might not be exactly equal to the number of negative cases in all datasets because some governors appearing in positive cases are rare words, and we're unable to find any (or only few) occurrences that match them for the negative cases.

4 Learning Model

In this section, we introduce our attention-based model. At a high level, our model extends a bidirectional LSTM model by computing correlations between the hidden states at each timestep, then applying an attention mechanism over these correlations. Our proposed weighted-pooling (WP) neural network architecture is shown in Figure 2.

The input sequence $u = \{u_1, u_2, \ldots, u_T\}$ consists of a sequence, of time length T, of one-hot encoded word tokens, where the original tokens are those such as in Listing 1. Each token u_t is embedded with pretrained embedding matrix $W_e \in \mathbb{R}^{|V| \times d}$, where $|V|$ corresponds to the number of tokens in vocabulary V, and d defines the size of the word embeddings. The embedded token vector $x_t \in \mathbb{R}^d$ is retrieved simply with $x_t = u_t W_e$. Optionally, x_t may also include the token's POS tag. In such instances, the embedded token at time step t is concatenated with the POS tag's one-hot encoding p_t: $x_t = u_t W_e || p_t$, where $||$ denotes the vector concatenation operator.

At each input time step t, a bi-directional LSTM (Hochreiter and Schmidhuber, 1997) encodes x_t into hidden state $h_t \in \mathbb{R}^s$:

$$h_t = \left[\overrightarrow{h_t} || \overleftarrow{h_t}\right] \tag{1}$$

where $\overrightarrow{h_t} = f(x_t, h_{t-1})$ is computed by the forward LSTM, and $\overleftarrow{h_t} = f(x_t, h_{t+1})$ is computed by the backward LSTM. Concatenated vector h_t is of size $2s$, where s is a hyperparameter determining the size of the LSTM hidden states. Let matrix $H \in \mathbb{R}^{2s \times T}$ correspond to the concatenation of all hidden state vectors:

$$H = [h_1 || h_2 || \ldots || h_T]. \tag{2}$$

Our model uses a form of self-attention (Paulus et al., 2018; Vaswani et al., 2017), where the input sequence acts as both the attention mechanism's query and key/value. Since the location of a presupposition trigger can greatly vary from one sample to another, and because dependencies can be long range or short range, we model all possible word-pair interactions within a sequence. We calculate the energy between all input tokens with a

	Training set			Test set

Table 1: Number of training samples in each dataset.

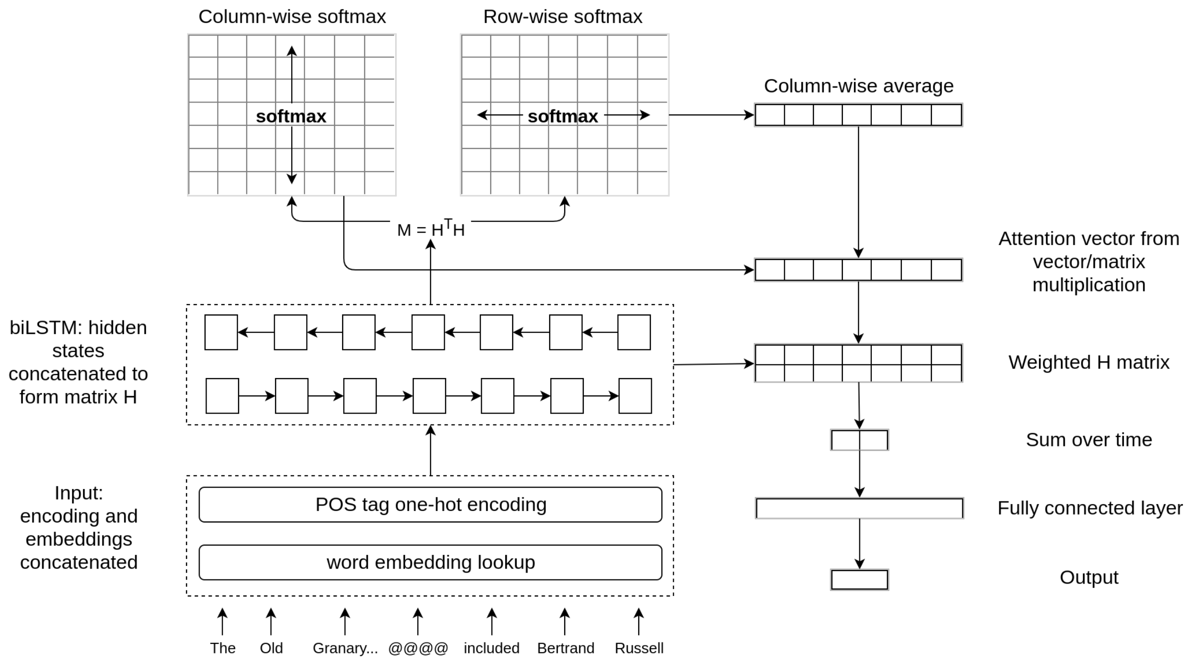

Figure 2: Our weighted-pooling neural network architecture (WP). The tokenized input is embedded with pretrained word embeddings and possibly concatenated with one-hot encoded POS tags. The input is then encoded with a bi-directional LSTM, followed by our attention mechanism. The computed attention scores are then used as weights to average the encoded states, in turn connected to a fully connected layer to predict presupposition triggering.

pair-wise matching matrix:

$$M = H^{\top}H \tag{3}$$

where M is a square matrix $\in \mathbb{R}^{T\times T}$. To get a single attention weight per time step, we adopt the attention-over-attention method (Cui et al., 2017). With matrix M, we first compute row-wise attention score M^r_{ij} over M:

$$M^r_{ij} = \frac{exp(e_{ij})}{\sum_{t=1}^{T} exp(e_{it})} \tag{4}$$

where $e_{ij} = M_{ij}$. M^r can be interpreted as a word-level attention distribution over all other words. Since we would like a single weight per word, we need an additional step to aggregate these attention scores. Instead of simply averaging the scores, we follow (Cui et al., 2017)'s approach which learns the aggregation by an additional attention mechanism. We compute column-wise softmax M^c_{ij} over M:

$$M^c_{ij} = \frac{exp(e_{ij})}{\sum_{t=1}^{T} exp(e_{tj})} \tag{5}$$

The columns of M^r are then averaged, forming vector $\beta \in \mathbb{R}^T$. Finally, β is multiplied with the column-wise softmax matrix M^c to get attention vector α:

$$\alpha = M^{r\top}\beta. \tag{6}$$

Note Equations (2) to (6) have described how we derived an attention score over our input without the introduction of any new parameters, potentially minimizing the computational effect of our attention mechanism.

As a last layer to their neural network, Cui et al. (2017) sum over α to extract the most relevant input. However, we use α as weights to combine all of our hidden states h_t:

$$c = \sum_{t=1}^{T} \alpha_t h_t \tag{7}$$

where $c \in \mathbb{R}^s$. We follow the pooling with a dense layer $z = \sigma(W_z c + b_z)$, where σ is a non-linear function, matrix $W_z \in \mathbb{R}^{64 \times s}$ and vector $b_z \in \mathbb{R}^{64}$ are learned parameters. The presupposition trigger probability is computed with an affine transform followed by a softmax:

$$\hat{y} = \text{softmax}(W_o z + b_o) \tag{8}$$

where matrix $W_o \in \mathbb{R}^{2 \times 64}$ and vector $b_o \in \mathbb{R}^2$ are learned parameters. The training objective minimizes:

$$J(\theta) = \frac{1}{m} \sum_{t=1}^{m} E(\hat{y}, y) \tag{9}$$

where $E(\cdot\,,\cdot)$ is the standard cross-entropy.

5 Experiments

We compare the performance of our WP model against several models which we describe in this section. We carry out the experiments on both datasets described in Section 3. We also investigate the impact of POS tags and attention mechanism on the models' prediction accuracy.

5.1 Baselines

We compare our learning model against the following systems. The first is the most-frequent-class baseline **(MFC)** which simply labels all samples with the most frequent class of 1. The second is a logistic regression classifier **(LogReg)**, in which the probabilities describing the possible outcomes of a single input x is modeled using a logistic function. We implement this baseline classifier with the scikit-learn package (Pedregosa et al., 2011), with a CountVectorizer including bi-gram features. All of the other hyperparameters are set to default weights.

The third is a variant LSTM recurrent neural network as introduced in (Graves, 2013). The input is encoded by a bidirectional LSTM like the WP model detailed in Section 4. Instead of a self-attention mechanism, we simply mean-pool matrix H, the concatenation of all LSTM hidden states, across all time steps. This is followed by a fully connected layer and softmax function for the binary classification. Our WP model uses the same bidirectional LSTM as this baseline LSTM, and has the same number of parameters, allowing for a fair comparison of the two models. Such a standard LSTM model represents a state-of-the-art language model, as it outperforms more recent models on language modeling tasks when the number of model parameters is controlled for (Melis et al., 2017).

For the last model, we use a slight variant of the CNN sentence classification model of (Kim, 2014) based on the Britz tensorflow implementation[2].

5.2 Hyperparameters & Additional Features

After tuning, we found the following hyperparameters to work best: 64 units in fully connected layers and 40 units for POS embeddings. We used dropout with probability 0.5 and mini-batch size of 64.

For all models, we initialize word embeddings with word2vec (Mikolov et al., 2013) pretrained embeddings of size 300. Unknown words are randomly initialized to the same size as the word2vec embeddings. In early tests on the development datasets, we found that our neural networks would consistently perform better when fixing the word embeddings. All neural network performance reported in this paper use fixed embeddings.

Fully connected layers in the LSTM, CNN and WP model are regularized with dropout (Srivastava et al., 2014). The model parameters for these neural networks are fine-tuned with the Adam algorithm (Kingma and Ba, 2015). To stabilize the RNN training gradients (Pascanu et al., 2013), we perform gradient clipping for gradients below threshold value -1, or above 1. To reduce overfitting, we stop training if the development set does not improve in accuracy for 10 epochs. All performance on the test set is reported using the best trained model as measured on the development set.

In addition, we use the CoreNLP Part-of-

	- POS	**74.84**	**58.87**	**81.64**	**59.03**	58.49	**68.37**	**56.68**

Table 2: Performance of various models, including our weighted-pooled LSTM (WP). MFC refers to the most-frequent-class baseline, LogReg is the logistic regression baseline. LSTM and CNN correspond to strong neural network baselines. Note that we bold the performance numbers for the best performing model for each of the "+ POS" case and the "- POS" case.

Speech (POS) tagger (Manning et al., 2014) to get corresponding POS features for extracted tokens. In all of our models, we limit the maximum length of samples and POS tags to 60 tokens. For the CNN, sequences shorter than 60 tokens are zero-padded.

6 Results

Table 2 shows the performance obtained by the different models with and without POS tags. Overall, our attention model WP outperforms all other models in 10 out of 14 scenarios (combinations of datasets and whether or not POS tags are used). Importantly, our model outperforms the regular LSTM model without introducing additional parameters to the model, which highlights the advantage of WP's attention-based pooling method. For all models listed in Table 2, we find that including POS tags benefits the detection of adverbial presupposition triggers in Gigaword and PTB datasets. Note that, in Table 2, we bolded accuracy figures that were within 0.1% of the best performing WP model as McNemar's test did not show that WP significantly outperformed the other model in these cases (p value > 0.05).

Table 3 shows the confusion matrix for the best performing model (WP,+POS). The small differences in the off-diagonal entries inform us that the model misclassifications are not particularly skewed towards the presence or absence of presupposition triggers.

		Predicted	
		Absence	Presence
Actual	Absence	54,658	11,961
	Presence	11,776	55,006

Table 4: Contingency table for correct (cor.) and incorrect (inc.) predictions between the LSTM baseline and the attention model (WP) on the Giga_also dataset.

The contingency table, shown in Table 4, shows the distribution of agreed and disagreed classification.

7 Analysis

Consider the following pair of samples that we randomly choose from the PTB dataset (shortened for readability):

1. ...Taped just as the market closed yesterday , it offers Ms. Farrell advising , " We view

the market here as going through a relatively normal cycle ... . We **continue** to feel that the stock market is the @@@@ place to be for long-term appreciation

2. ...More people are remaining independent longer presumably because they are better off physically and financially . Careers count most for the well-to-do many affluent people @@@@ place personal success and money above family

In both cases, the head word is *place*. In Example 1, the word *continue* (emphasized in the above text) suggests that adverb *still* could be used to modify head word *place* (i.e., ... *the stock market is still the place* ...). Further, it is also easy to see that *place* refers to *stock market*, which has occurred in the previous context. Our model correctly predicts this sample as containing a presupposition, this despite the complexity of the coreference across the text.

In the second case of the usage of the same main head word *place* in Example 2, our model falsely predicts the presence of a presupposition. However, even a human could read the sentence as "many people still place personal success and money above family". This underlies the subtlety and difficulty of the task at hand. The long-range dependencies and interactions within sentences seen in these examples are what motivate the use of the various deep non-linear models presented in this work, which are useful in detecting these coreferences, particularly in the case of attention mechanisms.

8 Conclusion

In this work, we have investigated the task of predicting adverbial presupposition triggers and introduced several datasets for the task. Additionally, we have presented a novel weighted-pooling attention mechanism which is incorporated into a recurrent neural network model for predicting the presence of an adverbial presuppositional trigger. Our results show that the model outperforms the CNN and LSTM, and does not add any additional parameters over the standard LSTM model. This shows its promise in classification tasks involving capturing and combining relevant information from multiple points in the previous context.

In future work, we would like to focus more on designing models that can deal with and be optimized for scenarios with severe data imbalance. We would like to also explore various applications of presupposition trigger prediction in language generation applications, as well as additional attention-based neural network architectures.
