Message from the General Chair

It is an honor to write the initial words of this proceedings as General Chair of the 56th Annual Meeting of the Association for Computational Linguistics! This is only the second time that an ACL conference has been held in Australia — the first time was for the joint COLING/ACL conference in June of 2006 in Sydney, and I was one of its Program Chairs. For ACL 2018 we have tried to maintain the welcoming and intimate spirit and the relaxed and genial character of the much smaller ACL conferences of the past in spite of the ever-growing number of researchers in the field and participants in our conferences.

It is my pleasure here to express gratitude to all those without whom this conference would not exist. My biggest thanks go to the Program Chairs Iryna Gurevych and Yusuke Miyao, as well as to Local Chairs Tim Baldwin, Trevor Cohn and Karin Verspoor. They have done a tremendous job to manage the submission and review process, and the local arrangement details, respectively.

I also want to thank all of the other chairs for their very hard work: Workshops Chairs Brendan O'Connor and Eva Maria Vecchi; Tutorials Chairs Yoav Artzi and Jacob Eisenstein; Demo Chairs Fei Liu and Thamar Solorio; Student Research Workshop Organizers Vered Shwartz, Jeniya Tabassum and Rob Voigt; Faculty Advisors to the Student Research Workshop Marie-Catherine de Marneffe, Wanxiang Che and Malvina Nissim; Publications Chairs Shay Cohen, Kevin Gimpel and Wei Lu; Exhibits Coordinator Karin Vespoor; Student Volunteer Coordinator Karin Vespoor; Conference Handbook Chairs Jey Han Lau and Trevor Cohn; Publicity Chair Sarvnaz Karimi; Local Sponsorship Chair Cecile Paris; Webmaster Andrew MacKinlay; and Priscilla Rasmussen, giver of advice and wisdom to all of us as ACL Business Manager.

I also warmly thank the ACL Executive Committee for its guidance and advice on many important issues and concerns as they arose.

I am also extremely grateful to all the sponsors for their great support to the conference.

Many thanks to the area chairs, the reviewers, the invited speakers, the authors of the various papers, posters and presentations.

And, finally, many many thanks to all the participants who will put the final touches on making ACL 2018 an exciting, stimulating and inspiring event!

Claire Cardie
ACL 2018 General Chair
July 2018

Message from the Program Committee Co-Chairs

Welcome to the 56th Annual Meeting of the Association for Computational Linguistics 2018 – or ACL 2018 for short.

In September 2017, Program Committee Co-Chairs (PCs) posted the call for nominations of Area Chairs (AC), Reviewers and Invited Speakers. We received 752 responses in total. Overall, out of 388 valid nominations for area chairs, 299 unique persons were suggested; 110 persons were self-nominations. About 70% of the 56 selected area chairs (later expanded to 61 area chairs due to the high number of submissions) were nominated by the community. For the reviewers, we collected 936 valid nominations. At the PhD level, 139 persons were self-nominations and 129 were nominated by others. At the Postdoc/Ass.Prof. level, 160 were self-nominated, 112 nominated by others. At the Prof. level, 221 persons were self-nominated, 175 nominated by others.

We received 138 unique nominations for invited speakers, from which two invited speakers of the conference were selected:

- Carolyn Penstein Rosé, Language Technologies Institute at Carnegie Mellon University, USA
- Anton van den Hengel, Australian Centre for Visual Technologies at University of Adelaide, Australia

Our community is steadily growing: in total, 1621 submissions were received right after the submission deadline: 1045 long, 576 short papers. 13 erroneous submissions were deleted or withdrawn in the preliminary checks by PCs. 25 papers were rejected without review (16 long, 9 short); the reasons are the violation of the ACL 2018 style and dual submission guidelines. 32 papers were withdrawn before the review period started; the main reason was that the papers have been accepted as the short papers at NAACL HLT 2018. In total, 1551 papers went into the reviewing phase: 1021 long, 530 short papers. 1610 reviewers (1473 primary and 137 secondary reviewers) were involved in the reviewing process; each reviewer has reviewed about 3 papers on average. 3 long and 4 short papers were withdrawn during the reviewing period, and finally 1018 long and 526 short papers were considered during the acceptance decision phase.

The assignment of papers to areas and reviewers has been done in multiple rounds. First round: Initial assignments of papers to areas were determined automatically with the help of the authors' input, while PCs went through all submissions and moved papers to other areas, considering COI and the topical fit. PCs assigned one AC as a meta-reviewer to each paper using Toronto Paper Matching System (TPMS) scores. Second round: ACs looked into the papers in their area, and adjusted meta-reviewer assignments. ACs sent a report to PCs if they found any problems. Third round: PCs made the final decision, considering the workload balance, possible COIs and the topical fit. Fourth round: ACs decided which reviewers would review each paper, based on AC's knowledge about the reviewers, TPMS scores, reviewers' bids, and COI.

We have introduced several innovations to the reviewing process. One of them is an argument-based review form. The reviewers were asked to provide arguments for and against the paper. This has been tremendously helpful for ACs and PCs to analyze the reviews and come up with final recommendations. The authors were asked to respond to the con arguments during the rebuttal. In coordination with the NAACL HLT 2018 PCs, we plan to do some analytics on anonymized reviews and rebuttal statements, with the consent of the reviewers and authors. Our purpose is to improve the quality of the review process. The data will be compiled into a unique corpus for NLP, and will be made available to the research community after appropriate anonymization checks, at the earliest in 2 years after ACL 2018.

We hope to provide data on *how to review* to younger researchers, and to improve the transparency of the reviewing process in general.

The ACL 2018 conference is super-competitive: We accepted 256 out of 1018 submitted long papers and 125 out of 526 short papers, with an overall acceptance rate of 24.7%. The details of the review process are available at the conference homepage. Criteria of acceptance were mainly:

- strengths/weaknesses raised by reviewers and their significance;
- the result of discussions and author responses;
- contribution to CL as the science of language: whether the paper advances (or contributes to) our understanding of language in any way;
- diversity: we do not want to fill ACL with similar papers like achieving 1% improvement on a well-known task.

We also considered the balance of paper types, topics and contributions and re-considered the acceptance when reviewers reported any problem in preliminary checks (*Appropriateness* to *Handling of Human Participants*).

Continuing the tradition, ACL 2018 will feature 20 papers which were accepted for publication in the Transactions of the Association for Computational Linguistics (TACL). The TACL papers were split into 10 oral presentations and 10 poster presentations.

There are many people to thank for who have worked diligently to make ACL 2018 possible. All names are listed in the Program Committee section of the Front Matter.

Since the conference size continues to grow and the organizational complexity increases, we have introduced the role of Program Committee Co-Chair Assistants. In total, 5 senior researchers have supported the PCs during most intensive work phases to handle the communication in a timely manner, draft various documents and effectively prepare decisions.

Thanks to our area chairs for their hard work on recruiting reviewers, managing reviews, leading discussions, and making recommendations.

This program certainly would not be possible without the help of the 1610 reviewers. In particular, 192 reviewers from this list were recognized by the area chairs as outstanding reviewers who have turned in exceptionally well-written and constructive reviews and who have actively engaged themselves in the post-rebuttal discussions.

We are also deeply indebted to the best paper selection committee which consists of 22 members. They had to additionally review 6-8 papers according to the best paper criteria on short notice. Their time and effort in recommending the best paper awards is much appreciated.

We also would like to thank many colleagues for generously sharing their experience in organizing prior ACL conferences and for their advice. We are grateful for the guidance and the support of the ACL presidents Joakim Nivre and Marti Hearst, and the ACL board. We also would like to thank the publication co-chairs Shay Cohen, Kevin Gimpel and Wei Lu (Advisory) and the handbook chair Jey Han Lau for putting together the proceedings and the conference handbook; and Rich Gerber from Softconf for always being responsive to our requests. We would like to thank the ACL Business Manager Priscilla Rasmussen for helping us to sort important things out. Finally, this conference could not have happened without the efforts of the general chair, Claire Cardie. We thank her for the leadership and advice, especially when matters got complicated.

We hope you will enjoy ACL 2018 and contribute to the future success of our community!

ACL 2018 Program Committee Co-Chairs
Iryna Gurevych, TU Darmstadt, Germany
Yusuke Miyao, National Institute of Informatics, Japan

The process for selecting best papers and honourable mentions

The Program Committee Co-Chairs (PCs) have defined a multi-step process. Area Chairs (ACs) were asked to select a number of top papers in their areas satisfying as many as possible of the following criteria:

- high quality
- nominated for the award by at least one primary reviewer
- bringing disruptive ground-breaking innovation as compared to the current mainstream

ACs re-read their finalists and discussed among themselves the merits of the nominee's work with the help of the primary reviews. ACs then submitted the papers to the PCs along with their selection decisions. PCs balanced ACs' nominations for diversity and representativeness among areas and the review consistency. They prepared the papers in Softconf for best-paper reviewing and selection. There were 52 best paper candidates.

In parallel, PCs formed the best paper selection committee (BPC) from 22 experts in the field with a mix of expertise and backgrounds and at a good seniority level. In case of COIs, the BPC member was excluded from the further evaluation process. BPC members reviewed 6-8 papers each and provided a short review with respect to the best paper criteria.

Based on BPC recommendations, there were about 20 papers left in the pool. PCs then re-read those papers and discussed their particular merits. Finally, 6 long papers and 2 short papers were selected as honourable mentions. For the best papers, 3 long papers and 2 short papers were selected for presentation in the closing conference session.

The selected honourable mentions and best papers emphasize the diversity of the ACL in terms of research questions, methods, and interdisciplinarity.

Best Long Papers

- *Finding syntax in human encephalography with beam search.* John Hale, Chris Dyer, Adhiguna Kuncoro and Jonathan Brennan.
- *Learning to Ask Good Questions: Ranking Clarification Questions using Neural Expected Value of Perfect Information.* Sudha Rao and Hal Daumé III.
- *Let's do it "again": A First Computational Approach to Detecting Adverbial Presupposition Triggers.* Andre Cianflone, Yulan Feng, Jad Kabbara and Jackie Chi Kit Cheung.

Best Short Papers

- *Know What You Don't Know: Unanswerable Questions for SQuAD.* Pranav Rajpurkar, Robin Jia and Percy Liang.
- *'Lighter' Can Still Be Dark: Modeling Comparative Color Descriptions.* Olivia Winn and Smaranda Muresan.

Invited Talk: Deep Neural Networks, and what they're not very good at

Anton van den Hengel
Professor, School of Computer Science, University of Adelaide

Abstract: Deep Neural Networks have had an incredible impact in a variety of areas within machine learning, including computer vision and natural language processing. Deep Neural Networks use implicit representations that are very high-dimensional, however, and are thus particularly well suited to problems that can be solved by associative recall of previous solutions. They are ill-suited to problems that require human-interpretable representations, explicit manipulation of symbols, or reasoning. The dependency of Deep Neural Networks on large volumes of training data, also means that they are typically only applicable when the problem itself, and the nature of the test data, are predictable long in advance.

The application of Deep Neural Networks to Visual Question Answering has achieved results that would have been thought impossible only a few years ago. It has also thrown a spotlight on the shortcomings of current Deep Nets in solving problems that require explicit reasoning, the use of a knowledge base, or the ability to learn on the fly. In this talk I will illustrate some of the steps being taken to address these problems, and a new learning-to-learn approach that we hope will combine the power of Deep Learning with the significant benefits of explicit-reasoning-based methods.

Bio: Anton van den Hengel is a Professor in the School of Computer Science at the University of Adelaide, the Director of the Australian Institute for Machine Learning, and a Chief Investigator of the Australian Centre for Robotic Vision. Prof. van den Hengel has been a CI on over $60m in external research funding from sources including Google, Canon, BHP Billiton and the ARC, and has won a number of awards, including the Pearcey Foundation Entrepreneur Award, the SA Science Excellence Award for Research Collaboration, and the CVPR Best Paper prize in 2010. He has authored over 300 publications, had 8 patents commercialised, formed 2 start-ups, and has recently had a medical technology achieve first-in-class FDA approval. Current research interests include Deep Learning, vison and language problems, interactive image-based modelling, large-scale video surveillance, and learning from large image databases.

Invited Talk: Who is the Bridge Between the What and the How

Carolyn Penstein Rosé
Professor, School of Computer Science, Carnegie Mellon University

Abstract: This talk reports on over a decade of research where theoretical foundations motivate computational models that produce real world impact in online spaces. Both the earliest philosophers of language and the most recent researchers in computational approaches to social media analysis have acknowledged the distinction between the what of language, namely its propositional content, and the how of language, or its form, style, or framing. What bridges between these realms are social processes that motivate the linguistic choices that result in specific realizations of propositional content situated within social interactions, designed to achieve social goals. These insights allow researchers to make sense of the connection between discussion processes and outcomes from those discussions. These findings motivate on the one hand design of computational approaches to real time monitoring of discussion processes and on the other hand the design of interventions that support interactions in online spaces with the goal of increasing desired outcomes, including learning, health, and wellbeing.

As an example, in this talk we probe into a specific quality of discussion referred to as Transactivity. Transactivity is the extent to which a contribution articulates the reasoning of the speaker, that of an interlocutor, and the relation between them. In different contexts, and within very distinct theoretical frameworks, this construct has been associated with solidarity, influence, expertise transfer, and learning. Within the construct of Transactivity, the cognitive and social underpinnings are inextricably linked such that modeling the who enables prediction of the connection between the what and the how.

Bio: Dr. Carolyn Rosé is a Professor of Language Technologies and Human-Computer Interaction in the School of Computer Science at Carnegie Mellon University. Her research program is focused on better understanding the social and pragmatic nature of conversation, and using this understanding to build computational systems that can improve the efficacy of conversation between people, and between people and computers. In order to pursue these goals, she invokes approaches from computational discourse analysis and text mining, conversational agents, and computer supported collaborative learning. Her research group's highly interdisciplinary work, published in 200 peer reviewed publications, is represented in the top venues in 5 fields: namely, Language Technologies, Learning Sciences, Cognitive Science, Educational Technology, and Human-Computer Interaction, with awards in 3 of these fields. She serves as Past President and Inaugural Fellow of the International Society of the Learning Sciences, Chair of the International Alliance to Advance Learning in the Digital Era, and Executive Editor of the International Journal of Computer-Supported Collaborative Learning.

Organising Committee

General Chair:

Claire Cardie, Cornell University

Program Chairs:

Iryna Gurevych, TU Darmstadt
Yusuke Miyao, National Institute of Informatics

Workshop Chairs:

Brendan O'Connor, University of Massachusetts Amherst
Eva Maria Vecchi, University of Cambridge

Tutorial Chairs:

Yoav Artzi, Cornell University
Jacob Eisenstein, Georgia Institute of Technology

Demo Chairs:

Fei Liu, University of Central Florida
Thamar Solorio, University of Houston

Publications Chairs:

Shay Cohen, University of Edinburgh
Kevin Gimpel, Toyota Technological Institute at Chicago
Wei Lu, Singapore University of Technology and Design (Advisory)

Exhibits Coordinator:

Karin Verspoor, University of Melbourne

Conference Handbook Chairs:

Jey Han Lau, IBM Research
Trevor Cohn, University of Melbourne

Publicity Chair:

Sarvnaz Karimi, CSIRO

Local Sponsorship Chair:

Cecile Paris, CSIRO

Local Chairs:

Tim Baldwin, University of Melbourne
Karin Verspoor, University of Melbourne
Trevor Cohn, University of Melbourne

Table of Contents

Conference Program

Monday, July 16, 2018

9:00–10:00 ***Welcome Session & Presidential Address***

10:00–10:30 ***Coffee Break***

Session 1A: Word Semantics 1

10:30–10:55 *Probabilistic FastText for Multi-Sense Word Embeddings*
Ben Athiwaratkun, Andrew Wilson and Anima Anandkumar

10:55–11:20 *A La Carte Embedding: Cheap but Effective Induction of Semantic Feature Vectors*
Mikhail Khodak, Nikunj Saunshi, Yingyu Liang, Tengyu Ma, Brandon Stewart and Sanjeev Arora

11:20–11:45 *Unsupervised Learning of Distributional Relation Vectors*
Shoaib Jameel, Zied Bouraoui and Steven Schockaert

11:45–12:10 *Explicit Retrofitting of Distributional Word Vectors*
Goran Glavaš and Ivan Vulić

Session 1B: Machine Translation 1

10:30–10:55 *Unsupervised Neural Machine Translation with Weight Sharing*
Zhen Yang, Wei Chen, Feng Wang and Bo Xu

10:55–11:20 *Triangular Architecture for Rare Language Translation*
Shuo Ren, Wenhu Chen, Shujie Liu, Mu Li, Ming Zhou and Shuai Ma

11:20–11:45 *Subword Regularization: Improving Neural Network Translation Models with Multiple Subword Candidates*
Taku Kudo

11:45–12:10 *The Best of Both Worlds: Combining Recent Advances in Neural Machine Translation*
Mia Xu Chen, Orhan Firat, Ankur Bapna, Melvin Johnson, Wolfgang Macherey, George Foster, Llion Jones, Mike Schuster, Noam Shazeer, Niki Parmar, Ashish Vaswani, Jakob Uszkoreit, Lukasz Kaiser, Zhifeng Chen, Yonghui Wu and Macduff Hughes

Monday, July 16, 2018 (continued)

Session 1E: Resource, Annotation

10:30–10:55	*Obtaining Reliable Human Ratings of Valence, Arousal, and Dominance for 20,000 English Words* Saif Mohammad
10:55–11:20	*Comprehensive Supersense Disambiguation of English Prepositions and Possessives* Nathan Schneider, Jena D. Hwang, Vivek Srikumar, Jakob Prange, Austin Blodgett, Sarah R. Moeller, Aviram Stern, Adi Bitan and Omri Abend
11:20–11:45	*A Corpus with Multi-Level Annotations of Patients, Interventions and Outcomes to Support Language Processing for Medical Literature* Benjamin Nye, Junyi Jessy Li, Roma Patel, Yinfei Yang, Iain Marshall, Ani Nenkova and Byron Wallace
11:45–12:10	*Efficient Online Scalar Annotation with Bounded Support* Keisuke Sakaguchi and Benjamin Van Durme

Session 1F: Argument Mining

10:30–10:55	*Neural Argument Generation Augmented with Externally Retrieved Evidence* Xinyu Hua and Lu Wang
10:55–11:20	*A Stylometric Inquiry into Hyperpartisan and Fake News* Martin Potthast, Johannes Kiesel, Kevin Reinartz, Janek Bevendorff and Benno Stein
11:20–11:45	*Retrieval of the Best Counterargument without Prior Topic Knowledge* Henning Wachsmuth, Shahbaz Syed and Benno Stein

12:10–12:30 ***Short Break***

12:30–14:00 ***Poster Session 1A: Machine Learning***

LinkNBed: Multi-Graph Representation Learning with Entity Linkage
Rakshit Trivedi, Bunyamin Sisman, Xin Luna Dong, Christos Faloutsos, Jun Ma and Hongyuan Zha

Monday, July 16, 2018 (continued)

Monday, July 16, 2018 (continued)

Session 2E: Vision

14:00–14:25	*No Metrics Are Perfect: Adversarial Reward Learning for Visual Storytelling* Xin Wang, Wenhu Chen, Yuan-Fang Wang and William Yang Wang
14:25–14:50	*Bridging Languages through Images with Deep Partial Canonical Correlation Analysis* Guy Rotman, Ivan Vulić and Roi Reichart
14:50–15:15	*Illustrative Language Understanding: Large-Scale Visual Grounding with Image Search* Jamie Kiros, William Chan and Geoffrey Hinton
15:15–15:40	*What Action Causes This? Towards Naive Physical Action-Effect Prediction* Qiaozi Gao, Shaohua Yang, Joyce Chai and Lucy Vanderwende

Session 2F: Sentiment

14:00–14:25	*Transformation Networks for Target-Oriented Sentiment Classification* Xin Li, Lidong Bing, Wai Lam and Bei Shi
14:25–14:50	*Target-Sensitive Memory Networks for Aspect Sentiment Classification* Shuai Wang, Sahisnu Mazumder, Bing Liu, Mianwei Zhou and Yi Chang
14:50–15:15	*Identifying Transferable Information Across Domains for Cross-domain Sentiment Classification* Raksha Sharma, Pushpak Bhattacharyya, Sandipan Dandapat and Himanshu Sharad Bhatt
15:15–15:40	*Unpaired Sentiment-to-Sentiment Translation: A Cycled Reinforcement Learning Approach* Jingjing Xu, Xu SUN, Qi Zeng, Xiaodong Zhang, Xuancheng Ren, Houfeng Wang and Wenjie Li

15:40–16:10 ***Coffee Break***

Tuesday, July 17, 2018 (continued)

Session 4E: Evaluation

Tuesday, July 17, 2018 (continued)

Tuesday, July 17, 2018 (continued)

Wednesday, July 18, 2018 (continued)

Probabilistic FastText for Multi-Sense Word Embeddings

Abstract

We introduce *Probabilistic FastText*, a new model for word embeddings that can capture multiple word senses, sub-word structure, and uncertainty information. In particular, we represent each word with a Gaussian mixture density, where the mean of a mixture component is given by the sum of n-grams. This representation allows the model to share statistical strength across sub-word structures (e.g. Latin roots), producing accurate representations of rare, misspelt, or even unseen words. Moreover, each component of the mixture can capture a different word sense. Probabilistic FastText outperforms both FASTTEXT, which has no probabilistic model, and dictionary-level probabilistic embeddings, which do not incorporate subword structures, on several word-similarity benchmarks, including English RareWord and foreign language datasets. We also achieve state-of-art performance on benchmarks that measure ability to discern different meanings. Thus, the proposed model is the first to achieve multi-sense representations while having enriched semantics on rare words.

1 Introduction

Word embeddings are foundational to natural language processing. In order to model language, we need word representations to contain as much semantic information as possible. Most research has focused on vector word embeddings, such as WORD2VEC (Mikolov et al., 2013a), where words with similar meanings are mapped to nearby points in a vector space. Following the seminal work of Mikolov et al. (2013a), there have been numerous works looking to learn efficient word embeddings.

One shortcoming with the above approaches to word embedding that are based on a predefined dictionary (termed as dictionary-based embeddings) is their inability to learn representations of rare words. To overcome this limitation, character-level word embeddings have been proposed. FASTTEXT (Bojanowski et al., 2016) is the state-of-the-art character-level approach to embeddings. In FASTTEXT, each word is modeled by a sum of vectors, with each vector representing an n-gram. The benefit of this approach is that the training process can then share *strength* across words composed of common roots. For example, with individual representations for “circum” and “navigation”, we can construct an informative representation for “circumnavigation”, which would otherwise appear too infrequently to learn a dictionary-level embedding. In addition to effectively modelling rare words, character-level embeddings can also represent slang or misspelled words, such as “dogz”, and can share strength across different languages that share roots, e.g. Romance languages share latent roots.

A different promising direction involves representing words with probability distributions, instead of point vectors. For example, Vilnis and McCallum (2014) represents words with Gaussian distributions, which can capture uncertainty information. Athiwaratkun and Wilson (2017) generalizes this approach to multimodal probability distributions, which can naturally represent words with different meanings. For example, the distribution for “rock” could have mass near the word “jazz” and “pop”, but also “stone” and “basalt”. Athiwaratkun and Wilson (2018) further developed this approach to learn hierarchical word representations: for example, the word “music” can

[*] Work done partly during internship at Amazon.

be learned to have a broad distribution, which encapsulates the distributions for “jazz” and “rock”.

In this paper, we propose *Probabilistic FastText* (PFT), which provides probabilistic character-level representations of words. The resulting word embeddings are highly expressive, yet straightforward and interpretable, with simple, efficient, and intuitive training procedures. PFT can model rare words, uncertainty information, hierarchical representations, and multiple word senses. In particular, we represent each word with a Gaussian or a Gaussian mixture density, which we name PFT-G and PFT-GM respectively. Each component of the mixture can represent different word senses, and the mean vectors of each component decompose into vectors of n-grams, to capture character-level information. We also derive an efficient energy-based max-margin training procedure for PFT.

We perform comparison with FASTTEXT as well as existing density word embeddings W2G (Gaussian) and W2GM (Gaussian mixture). Our models extract high-quality semantics based on multiple word-similarity benchmarks, including the rare word dataset. We obtain an average weighted improvement of 3.7% over FASTTEXT (Bojanowski et al., 2016) and 3.1% over the dictionary-level density-based models. We also observe meaningful nearest neighbors, particularly in the multimodal density case, where each mode captures a distinct meaning. Our models are also directly portable to foreign languages without any hyperparameter modification, where we observe strong performance, outperforming FASTTEXT on many foreign word similarity datasets. Our multimodal word representation can also disentangle meanings, and is able to separate different senses in foreign polysemies. In particular, our models attain state-of-the-art performance on SCWS, a benchmark to measure the ability to separate different word meanings, achieving 1.0% improvement over a recent density embedding model W2GM (Athiwaratkun and Wilson, 2017).

To the best of our knowledge, we are the first to develop multi-sense embeddings with high semantic quality for rare words. Our code and embeddings are publicly available. [1]

2 Related Work

Early word embeddings which capture semantic information include Bengio et al. (2003), Collobert and Weston (2008), and Mikolov et al. (2011). Later, Mikolov et al. (2013a) developed the popular WORD2VEC method, which proposes a log-linear model and negative sampling approach that efficiently extracts rich semantics from text. Another popular approach GLOVE learns word embeddings by factorizing co-occurrence matrices (Pennington et al., 2014).

Recently there has been a surge of interest in making dictionary-based word embeddings more flexible. This flexibility has valuable applications in many end-tasks such as language modeling (Kim et al., 2016), named entity recognition (Kuru et al., 2016), and machine translation (Zhao and Zhang, 2016; Lee et al., 2017), where unseen words are frequent and proper handling of these words can greatly improve the performance. These works focus on modeling subword information in neural networks for tasks such as language modeling.

Besides vector embeddings, there is recent work on multi-prototype embeddings where each word is represented by multiple vectors. The learning approach involves using a cluster centroid of context vectors (Huang et al., 2012), or adapting the skip-gram model to learn multiple latent representations (Tian et al., 2014). Neelakantan et al. (2014) furthers adapts skip-gram with a non-parametric approach to learn the embeddings with an arbitrary number of senses per word. Chen et al. (2014) incorporates an external dataset WORDNET to learn sense vectors. We compare these models with our multimodal embeddings in Section 4.

3 Probabilistic FastText

We introduce *Probabilistic FastText*, which combines a probabilistic word representation with the ability to capture subword structure. We describe the probabilistic subword representation in Section 3.1. We then describe the similarity measure and the loss function used to train the embeddings in Sections 3.2 and 3.3. We conclude by briefly presenting a simplified version of the energy function for isotropic Gaussian representations (Section 3.4), and the negative sampling scheme we use in training (Section 3.5).

3.1 Probabilistic Subword Representation

We represent each word with a Gaussian mixture with K Gaussian components. That is, a word

[1] https://github.com/benathi/multisense-prob-fasttext

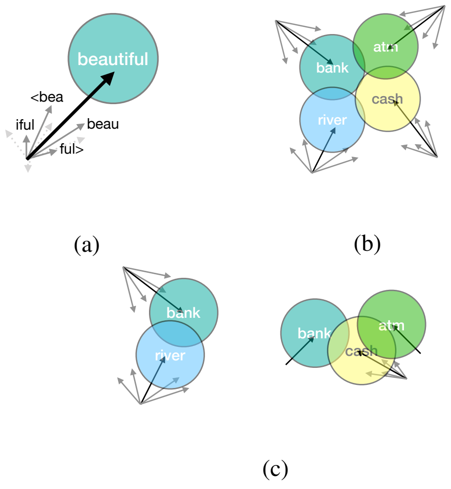

Figure 1: (1a) a Gaussian component and its subword structure. The bold arrow represents the final mean vector, estimated from averaging the grey n-gram vectors. (1b) PFT-G model: Each Gaussian component's mean vector is a subword vector. (1c) PFT-GM model: For each Gaussian mixture distribution, one component's mean vector is estimated by a subword structure whereas other components are dictionary-based vectors.

w is associated with a density function $f(x) = \sum_{i=1}^{K} p_{w,i} \mathcal{N}(x; \vec{\mu}_{w,i}, \Sigma_{w,i})$ where $\{\mu_{w,i}\}_{k=1}^{K}$ are the mean vectors and $\{\Sigma_{w,i}\}$ are the covariance matrices, and $\{p_{w,i}\}_{k=1}^{K}$ are the component probabilities which sum to 1.

The mean vectors of Gaussian components hold much of the semantic information in density embeddings. While these models are successful based on word similarity and entailment benchmarks (Vilnis and McCallum, 2014; Athiwaratkun and Wilson, 2017), the mean vectors are often dictionary-level, which can lead to poor semantic estimates for rare words, or the inability to handle words outside the training corpus. We propose using subword structures to estimate the mean vectors. We outline the formulation below.

For word w, we estimate the mean vector μ_w with the average over n-gram vectors and its dictionary-level vector. That is,

$$\mu_w = \frac{1}{|NG_w| + 1} \left(v_w + \sum_{g \in NG_w} z_g \right) \quad (1)$$

where z_g is a vector associated with an n-gram g, v_w is the dictionary representation of word w, and NG_w is a set of n-grams of word w. Examples of 3,4-grams for a word "beautiful", including the beginning-of-word character '$\langle$' and end-of-word character '$\rangle$', are:

- 3-grams: $\langle$be, bea, eau, aut, uti, tif, ful, ul$\rangle$
- 4-grams: $\langle$bea, beau .., iful ,ful$\rangle$

This structure is similar to that of FASTTEXT (Bojanowski et al., 2016); however, we note that FASTTEXT uses single-prototype deterministic embeddings as well as a training approach that maximizes the negative log-likelihood, whereas we use a multi-prototype probabilistic embedding and for training we maximize the similarity between the words' probability densities, as described in Sections 3.2 and 3.3

Figure 1a depicts the subword structure for the mean vector. Figure 1b and 1c depict our models, Gaussian probabilistic FASTTEXT (PFT-G) and Gaussian mixture probabilistic FASTTEXT (PFT-GM). In the Gaussian case, we represent each mean vector with a subword estimation. For the Gaussian mixture case, we represent one Gaussian component's mean vector with the subword structure whereas other components' mean vectors are dictionary-based. This model choice to use dictionary-based mean vectors for other components is to reduce to constraint imposed by the subword structure and promote independence for meaning discovery.

3.2 Similarity Measure between Words

Traditionally, if words are represented by vectors, a common similarity metric is a dot product. In the case where words are represented by distribution functions, we use the generalized dot product in Hilbert space $\langle \cdot, \cdot \rangle_{L_2}$, which is called the expected likelihood kernel (Jebara et al., 2004). We define the energy $E(f, g)$ between two words f and g to be $E(f, g) = \log \langle f, g \rangle_{L_2} = \log \int f(x) g(x) \, dx$. With Gaussian mixtures $f(x) = \sum_{i=1}^{K} p_i \mathcal{N}(x; \vec{\mu}_{f,i}, \Sigma_{f,i})$ and $g(x) = \sum_{i=1}^{K} q_i \mathcal{N}(x; \vec{\mu}_{g,i}, \Sigma_{g,i})$, $\sum_{i=1}^{K} p_i = 1$, and $\sum_{i=1}^{K} q_i = 1$, the energy has a closed form:

$$E(f, g) = \log \sum_{j=1}^{K} \sum_{i=1}^{K} p_i q_j e^{\xi_{i,j}} \quad (2)$$

where $\xi_{j,j}$ is the partial energy which corresponds to the similarity between component i of the first word f and component j of the second word g.[2]

$$\begin{aligned}\xi_{i,j} &\equiv \log \mathcal{N}(0; \vec{\mu}_{f,i} - \vec{\mu}_{g,j}, \Sigma_{f,i} + \Sigma_{g,j}) \\ &= -\frac{1}{2}\log\det(\Sigma_{f,i} + \Sigma_{g,j}) - \frac{D}{2}\log(2\pi) \\ -\frac{1}{2}&(\vec{\mu}_{f,i} - \vec{\mu}_{g,j})^\top(\Sigma_{f,i} + \Sigma_{g,j})^{-1}(\vec{\mu}_{f,i} - \vec{\mu}_{g,j})\end{aligned} \tag{3}$$

Figure 2 demonstrates the partial energies among the Gaussian components of two words.

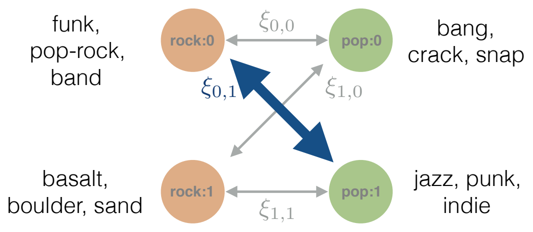

Figure 2: The interactions among Gaussian components of word `rock` and word `pop`. The partial energy is the highest for the pair `rock:0` (the zeroth component of rock) and `pop:1` (the first component of pop), reflecting the similarity in meanings.

3.3 Loss Function

The model parameters that we seek to learn are v_w for each word w and z_g for each n-gram g. We train the model by pushing the energy of a true context pair w and c to be higher than the negative context pair w and n by a margin m. We use Adagrad (Duchi et al., 2011) to minimize the following loss to achieve this outcome:

$$L(f, g) = \max\left[0, m - E(f, g) + E(f, n)\right]. \tag{4}$$

We describe how to sample words as well as its positive and negative contexts in Section 3.5.

This loss function together with the Gaussian mixture model with $K > 1$ has the ability to extract multiple senses of words. That is, for a word with multiple meanings, we can observe each mode to represent a distinct meaning. For instance, one density mode of "star" is close to the densities of "celebrity" and "hollywood" whereas another mode of "star" is near the densities of "constellation" and "galaxy".

[2]The orderings of indices of the components for each word are arbitrary.

3.4 Energy Simplification

In theory, it can be beneficial to have covariance matrices as learnable parameters. In practice, Athiwaratkun and Wilson (2017) observe that spherical covariances often perform on par with diagonal covariances with much less computational resources. Using spherical covariances for each component, we can further simplify the energy function as follows:

$$\xi_{i,j} = -\frac{\alpha}{2} \cdot ||\mu_{f,i} - \mu_{g,j}||^2, \tag{5}$$

where the hyperparameter α is the scale of the inverse covariance term in Equation 3. We note that Equation 5 is equivalent to Equation 3 up to an additive constant given that the covariance matrices are spherical and the same for all components.

3.5 Word Sampling

To generate a context word c of a given word w, we pick a nearby word within a context window of a fixed length ℓ. We also use a word sampling technique similar to Mikolov et al. (2013b). This subsampling procedure selects words for training with lower probabilities if they appear frequently. This technique has an effect of reducing the importance of words such as 'the', 'a', 'to' which can be predominant in a text corpus but are not as meaningful as other less frequent words such as 'city', 'capital', 'animal', etc. In particular, word w has probability $P(w) = 1 - \sqrt{t/f(w)}$ where $f(w)$ is the frequency of word w in the corpus and t is the frequency threshold.

A negative context word is selected using a distribution $P_n(w) \propto U(w)^{3/4}$ where $U(w)$ is a unigram probability of word w. The exponent $3/4$ also diminishes the importance of frequent words and shifts the training focus to other less frequent words.

4 Experiments

We have proposed a probabilistic FASTTEXT model which combines the flexibility of subword structure with the density embedding approach. In this section, we show that our probabilistic representation with subword mean vectors with the simplified energy function outperforms many word similarity baselines and provides disentangled meanings for polysemies.

First, we describe the training details in Section 4.1. We provide qualitative evaluation in Section

4.2, showing meaningful nearest neighbors for the Gaussian embeddings, as well as the ability to capture multiple meanings by Gaussian mixtures. Our quantitative evaluation in Section 4.3 demonstrates strong performance against the baseline models FASTTEXT (Bojanowski et al., 2016) and the dictionary-level Gaussian (W2G) (Vilnis and McCallum, 2014) and Gaussian mixture embeddings (Athiwaratkun and Wilson, 2017) (W2GM). We train our models on foreign language corpuses and show competitive results on foreign word similarity benchmarks in Section 4.4. Finally, we explain the importance of the n-gram structures for semantic sharing in Section 4.5.

4.1 Training Details

We train our models on both English and foreign language datasets. For English, we use the concatenation of UKWAC and WACKYPEDIA (Baroni et al., 2009) which consists of 3.376 billion words. We filter out word types that occur fewer than 5 times which results in a vocabulary size of 2,677,466.

For foreign languages, we demonstrate the training of our model on French, German, and Italian text corpuses. We note that our model should be applicable for other languages as well. We use FRWAC (French), DEWAC (German), ITWAC (Italian) datasets (Baroni et al., 2009) for text corpuses, consisting of 1.634, 1.716 and 1.955 billion words respectively. We use the same threshold, filtering out words that occur less than 5 times in each corpus. We have dictionary sizes of 1.3, 2.7, and 1.4 million words for FRWAC, DEWAC, and ITWAC.

We adjust the hyperparameters on the English corpus and use them for foreign languages. Note that the adjustable parameters for our models are the loss margin m in Equation 4 and the scale α in Equation 5. We search for the optimal hyperparameters in a grid $m \in \{0.01, 0.1, 1, 10, 100\}$ and $\alpha \in \{\frac{1}{5\times10^{-3}}, \frac{1}{10^{-3}}, \frac{1}{2\times10^{-4}}, \frac{1}{1\times10^{-4}}\}$ on our English corpus. The hyperpameter α affects the scale of the loss function; therefore, we adjust the learning rate appropriately for each α. In particular, the learning rates used are $\gamma = \{10^{-4}, 10^{-5}, 10^{-6}\}$ for the respective α values.

Other fixed hyperparameters include the number of Gaussian components $K = 2$, the context window length $\ell = 10$ and the subsampling threshold $t = 10^{-5}$. Similar to the setup in FASTTEXT, we use n-grams where $n = 3, 4, 5, 6$ to estimate the mean vectors.

4.2 Qualitative Evaluation - Nearest neighbors

We show that our embeddings learn the word semantics well by demonstrating meaningful nearest neighbors. Table 1 shows examples of polysemous words such as `rock`, `star`, and `cell`.

Table 1 shows the nearest neighbors of polysemous words. We note that subword embeddings prefer words with overlapping characters as nearest neighbors. For instance, "rock-y", "rockn", and "rock" are both close to the word "rock". For the purpose of demonstration, we only show words with meaningful variations and omit words with small character-based variations previously mentioned. However, all words shown are in the top-100 nearest words.

We observe the separation in meanings for the multi-component case; for instance, one component of the word "bank" corresponds to a financial bank whereas the other component corresponds to a river bank. The single-component case also has interesting behavior. We observe that the subword embeddings of polysemous words can represent both meanings. For instance, both "lava-rock" and "rock-pop" are among the closest words to "rock".

4.3 Word Similarity Evaluation

We evaluate our embeddings on several standard word similarity datasets, namely, SL-999 (Hill et al., 2014), WS-353 (Finkelstein et al., 2002), MEN-3k (Bruni et al., 2014), MC-30 (Miller and Charles, 1991), RG-65 (Rubenstein and Goodenough, 1965), YP-130 (Yang and Powers, 2006), MTurk(-287,-771) (Radinsky et al., 2011; Halawi et al., 2012), and RW-2k (Luong et al., 2013). Each dataset contains a list of word pairs with a human score of how related or similar the two words are. We use the notation DATASET-NUM to denote the number of word pairs NUM in each evaluation set. We note that the dataset RW focuses more on infrequent words and SimLex-999 focuses on the similarity of words rather than relatedness. We also compare PFT-GM with other multi-prototype embeddings in the literature using SCWS (Huang et al., 2012), a word similarity dataset that is aimed to measure the ability of embeddings to discern multiple meanings.

We calculate the Spearman correlation (Spearman, 1904) between the labels and our scores gen-

Table 2: Spearman's Correlation $\rho \times 100$ on Word Similarity Datasets.

erated by the embeddings. The Spearman correlation is a rank-based correlation measure that assesses how well the scores describe the true labels. The scores we use are cosine-similarity scores between the mean vectors. In the case of Gaussian mixtures, we use the pairwise maximum score:

$$s(f,g) = \max_{i\in 1,\dots,K} \max_{j\in 1,\dots,K} \frac{\mu_{f,i}\cdot\mu_{g,j}}{||\mu_{f,i}||\cdot||\mu_{g,j}||}. \quad (6)$$

The pair (i,j) that achieves the maximum cosine similarity corresponds to the Gaussian component pair that is the closest in meanings. Therefore, this similarity score yields the most related senses of a given word pair. This score reduces to a cosine similarity in the Gaussian case $(K = 1)$.

4.3.1 Comparison Against Dictionary-Level Density Embeddings and FASTTEXT

We compare our models against the dictionary-level Gaussian and Gaussian mixture embeddings in Table 2, with 50-dimensional and 300-dimensional mean vectors. The 50-dimensional results for W2G and W2GM are obtained directly from Athiwaratkun and Wilson (2017). For comparison, we use the public code[3] to train the 300-dimensional W2G and W2GM models and the publicly available FASTTEXT model[4].

We calculate Spearman's correlations for each of the word similarity datasets. These datasets vary greatly in the number of word pairs; therefore, we mark each dataset with its size for visibil-

[3] https://github.com/benathi/word2gm

[4] https://s3-us-west-1.amazonaws.com/fasttext-vectors/wiki.en.zip

ity. For a fair and objective comparison, we calculate a weighted average of the correlation scores for each model.

Our PFT-GM achieves the highest average score among all competing models, outperforming both FASTTEXT and the dictionary-level embeddings W2G and W2GM. Our unimodal model PFT-G also outperforms the dictionary-level counterpart W2G and FASTTEXT. We note that the model W2GM appears quite strong according to Table 2, beating PFT-GM on many word similarity datasets. However, the datasets that W2GM performs better than PFT-GM often have small sizes such as MC-30 or RG-65, where the Spearman's correlations are more subject to noise. Overall, PFT-GM outperforms W2GM by 3.1% and 8.7% in 300 and 50 dimensional models. In addition, PFT-G and PFT-GM also outperform FASTTEXT by 1.2% and 3.7% respectively.

4.3.2 Comparison Against Multi-Prototype Models

In Table 3, we compare 50 and 300 dimensional PFT-GM models against the multi-prototype embeddings described in Section 2 and the existing multimodal density embeddings W2GM. We use the word similarity dataset SCWS (Huang et al., 2012) which contains words with potentially many meanings, and is a benchmark for distinguishing senses. We use the maximum similarity score (Equation 6), denoted as MAXSIM. AVESIM denotes the average of the similarity scores, rather than the maximum.

We outperform the dictionary-based density embeddings W2GM in both 50 and 300 dimensions, demonstrating the benefits of subword information. Our model achieves state-of-the-art results, similar to that of Neelakantan et al. (2014).

Model	Dim	$\rho \times 100$
HUANG AVGSIM	50	62.8
TIAN MAXSIM	50	63.6
W2GM MAXSIM	50	62.7

W2GM MAXSIM	300	66.5
PFT-GM MAXSIM	300	**67.2**

Table 3: Spearman's Correlation $\rho \times 100$ on word similarity dataset SCWS.

4.4 Evaluation on Foreign Language Embeddings

We evaluate the foreign-language embeddings on word similarity datasets in respective languages. We use Italian WORDSIM353 and Italian SIMLEX-999 (Leviant and Reichart, 2015) for Italian models, GUR350 and GUR65 (Gurevych, 2005) for German models, and French WORDSIM353 (Finkelstein et al., 2002) for French models. For datasets GUR350 and GUR65, we use the results reported in the FASTTEXT publication (Bojanowski et al., 2016). For other datasets, we train FASTTEXT models for comparison using the public code[5] on our text corpuses. We also train dictionary-level models W2G, and W2GM for comparison.

Table 4 shows the Spearman's correlation results of our models. We outperform FASTTEXT on many word similarity benchmarks. Our results are also significantly better than the dictionary-based models, W2G and W2GM. We hypothesize that W2G and W2GM can perform better than the current reported results given proper pre-processing of words due to special characters such as accents.

We investigate the nearest neighbors of polysemies in foreign languages and also observe clear sense separation. For example, *piano* in Italian can mean "floor" or "slow". These two meanings are reflected in the nearest neighbors where one component is close to *piano-piano*, *pianod* which mean "slowly" whereas the other component is close to *piani* (floors), *istrutturazione* (renovation) or *infrastruttre* (infrastructure). Table 5 shows additional results, demonstrating that the disentangled semantics can be observed in multiple languages.

4.5 Qualitative Evaluation - Subword Decomposition

One of the motivations for using subword information is the ability to handle out-of-vocabulary words. Another benefit is the ability to help improve the semantics of rare words via subword sharing. Due to an observation that text corpuses follow Zipf's power law (Zipf, 1949), words at the tail of the occurrence distribution appears much

less frequently. Training these words to have a good semantic representation is challenging if done at the word level alone. However, an n-gram such as 'abnorm' is trained during both occurrences of "abnormal" and "abnormality" in the corpus, hence further augments both words's semantics.

Figure 3 shows the contribution of n-grams to the final representation. We filter out to show only the n-grams with the top-5 and bottom-5 similarity scores. We observe that the final representations of both words align with n-grams "abno", "bnor", "abnorm", "anbnor", "<abn". In fact, both "abnormal" and "abnormality" share the same top-5 n-grams. Due to the fact that many rare words such as "autobiographer", "circumnavigations", or "hypersensitivity" are composed from many common sub-words, the n-gram structure can help improve the representation quality.

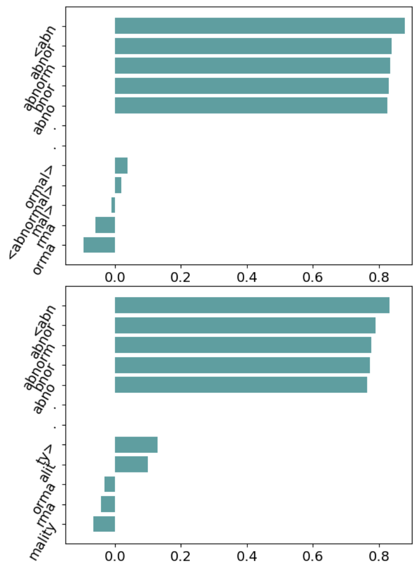

Figure 3: Contribution of each n-gram vector to the final representation for word "abnormal" (top) and "abnormality" (bottom). The x-axis is the cosine similarity between each n-gram vector $z_g^{(w)}$ and the final vector μ_w.

5 Numbers of Components

It is possible to train our approach with $K > 2$ mixture components; however, Athiwaratkun and Wilson (2017) observe that dictionary-level Gaussian mixtures with $K = 3$ do not overall improve word similarity results, even though these mixtures can discover 3 distinct senses for certain words. Indeed, while $K > 2$ in principle allows for greater flexibility than $K = 2$, most words can be very flexibly modelled with a mixture of two Gaussians, leading to $K = 2$ representing a good balance between flexibility and Occam's razor.

Even for words with single meanings, our PFT model with $K = 2$ often learns richer representations than a $K = 1$ model. For example, the two mixture components can learn to cluster together to form a more heavy tailed unimodal distribution which captures a word with one dominant meaning but with close relationships to a wide range of other words.

In addition, we observe that our model with K components can capture more than K meanings. For instance, in $K = 1$ model, the word pairs ("cell", "jail") and ("cell", "biology") and ("cell", "phone") will all have positive similarity scores based on $K = 1$ model. In general, if a word has multiple meanings, these meanings are usually compressed into the linear substructure of the embeddings (Arora et al., 2016). However, the pairs of non-dominant words often have lower similarity scores, which might not accurately reflect their true similarities.

6 Conclusion and Future Work

We have proposed models for probabilistic word representations equipped with flexible sub-word structures, suitable for rare and out-of-vocabulary words. The proposed probabilistic formulation incorporates uncertainty information and naturally allows one to uncover multiple meanings with multimodal density representations. Our models offer better semantic quality, outperforming competing models on word similarity benchmarks. Moreover, our multimodal density models can provide interpretable and disentangled representations, and are the first multi-prototype embeddings that can handle rare words.

Future work includes an investigation into the trade-off between learning full covariance matrices for each word distribution, computational complexity, and performance. This direction can potentially have a great impact on tasks where the variance information is crucial, such as for hierarchical modeling with probability distributions (Athiwaratkun and Wilson, 2018).

Other future work involves co-training PFT on many languages. Currently, existing work on multi-lingual embeddings align the word semantics on pre-trained vectors (Smith et al., 2017), which can be suboptimal due to polysemies. We envision that the multi-prototype nature can help disambiguate words with multiple meanings and facilitate semantic alignment.

Abstract

Motivations like domain adaptation, transfer learning, and feature learning have fueled interest in inducing embeddings for rare or unseen words, n-grams, synsets, and other textual features. This paper introduces *à la carte* embedding, a simple and general alternative to the usual word2vec-based approaches for building such representations that is based upon recent theoretical results for GloVe-like embeddings. Our method relies mainly on a linear transformation that is efficiently learnable using pretrained word vectors and linear regression. This transform is applicable "on the fly" in the future when a new text feature or rare word is encountered, even if only a single usage example is available. We introduce a new dataset showing how the *à la carte* method requires fewer examples of words in context to learn high-quality embeddings and we obtain state-of-the-art results on a nonce task and some unsupervised document classification tasks.

1 Introduction

Distributional word embeddings, which represent the "meaning" of a word via a low-dimensional vector, have been widely applied by many natural language processing (NLP) pipelines and algorithms (Goldberg, 2016). Following the success of recent neural (Mikolov et al., 2013) and matrix-factorization (Pennington et al., 2014) methods, researchers have sought to extend the approach to other text features, from subword elements to n-grams to sentences (Bojanowski et al., 2016; Poliak et al., 2017; Kiros et al., 2015). However, the performance of both word embeddings and their extensions is known to degrade in small corpus settings (Adams et al., 2017) or when embedding sparse, low-frequency features (Lazaridou et al., 2017). Attempts to address these issues often involve task-specific approaches (Rothe and Schütze, 2015; Iacobacci et al., 2015; Pagliardini et al., 2018) or extensively tuning existing architectures such as skip-gram (Poliak et al., 2017; Herbelot and Baroni, 2017).

For computational efficiency it is desirable that methods be able to induce embeddings for only those features (e.g. bigrams or synsets) needed by the downstream task, rather than having to pay a computational *prix fixe* to learn embeddings for all features occurring frequently-enough in a corpus. We propose an alternative, novel solution via *à la carte* embedding, a method which bootstraps existing high-quality word vectors to learn a feature representation in the same semantic space via a linear transformation of the average word embeddings in the feature's available contexts. This can be seen as a shallow extension of the distributional hypothesis (Harris, 1954), "a feature is characterized by the words in its context," rather than the computationally more-expensive "a feature is characterized by the features in its context" that has been used implicitly by past work (Rothe and Schütze, 2015; Logeswaran and Lee, 2018).

Despite its elementary formulation, we demonstrate that the *à la carte* method can learn faithful word embeddings from single examples and feature vectors improving performance on important downstream tasks. Furthermore, the approach is resource-efficient, needing only pretrained embeddings of common words and the text corpus used to train them, and easy to implement and compute via vector addition and linear regression. After motivating and specifying the method, we illustrate these benefits through several applications:

- **Embeddings of rare words:** we introduce a dataset[1] for few-shot learning of word vectors and achieve state-of-the-art results on the task of representing unseen words using only the definition (Herbelot and Baroni, 2017).
- **Synset embeddings:** we show how the method can be applied to learn more fine-grained lexico-semantic representations and give evidence of its usefulness for standard word-sense disambiguation tasks (Navigli et al., 2013; Moro and Navigli, 2015).
- **n-gram embeddings:** we build seven million n-gram embeddings from large text corpora and use them to construct document embeddings that are competitive with unsupervised deep learning approaches when evaluated on linear text classification.

Our experimental results[2] clearly demonstrate the advantages of *à la carte* embedding. For word embeddings, the approach is an easy way to get a good vector for a new word from its definition or a few examples in context. For feature embeddings, the method can embed anything that does not need labeling (such as a bigram) or occurs in an annotated corpus (such as a word-sense). Our document embeddings, constructed directly using *à la carte* n-gram vectors, compete well with recent deep neural representations; this provides further evidence that simple methods can outperform modern deep learning on many NLP benchmarks (Arora et al., 2017; Mu and Viswanath, 2018; Arora et al., 2018a,b; Pagliardini et al., 2018).

2 Related Work

Many methods have been proposed for extending word embeddings to semantic feature vectors, with the aim of using them as interpretable and structure-aware building blocks of NLP pipelines (Kiros et al., 2015; Yamada et al., 2016). Many exploit the structure and resources available for specific feature types, such as methods for sense, synsets, and lexemes (Rothe and Schütze, 2015; Iacobacci et al., 2015) that make heavy use of the graph structure of the Princeton WordNet (PWN) and similar resources (Fellbaum, 1998). By contrast, our work is more general, with incorporation of structure left as an open problem. Embeddings of n-grams are of special interest because they do not need annotation or expert knowledge and can often be effective on downstream tasks. Their computation has been studied both explicitly (Yin and Schutze, 2014; Poliak et al., 2017) and as an implicit part of models for document embeddings (Hill et al., 2016; Pagliardini et al., 2018), which we use for comparison. Supervised and multi-task learning of text embeddings has also been attempted (Wang et al., 2017; Wu et al., 2017).

A main motivation of our work is to learn good embeddings, of both words and features, from only one or a few examples. Efforts in this area can in many cases be split into contextual approaches (Lazaridou et al., 2017; Herbelot and Baroni, 2017) and morphological methods (Luong et al., 2013; Bojanowski et al., 2016; Pado et al., 2016). The current paper provides a more effective formulation for context-based embeddings, which are often simpler to implement, can improve with more context information, and do not require morphological annotation. Subword approaches, on the other hand, are often more compositional and flexible, and we leave the extension of our method to handle subword information to future work. Our work is also related to some methods in domain adaptation and multi-lingual correlation, such as that of Bollegala et al. (2014).

Mathematically, this work builds upon the linear algebraic understanding of modern word embeddings developed by Arora et al. (2018b) via an extension to the latent-variable embedding model of Arora et al. (2016). Although there have been several other applications of this model for natural language representation (Arora et al., 2017; Mu and Viswanath, 2018), ours is the first to provide a general approach for learning semantic features using corpus context.

3 Method Specification

We begin by assuming a large text corpus $\mathcal{C}_\mathcal{V}$ consisting of contexts c of words w in a vocabulary $\mathcal{V}$, with the contexts themselves being sequences of words in $\mathcal{V}$ (e.g. a fixed-size window around the word or feature). We further assume that we have trained word embeddings $\mathbf{v}_w \in \mathbb{R}^d$ on this collo-

[1]Dataset: `nlp.cs.princeton.edu/CRW`
[2]Code: `www.github.com/NLPrinceton/ALaCarte`

cation information using a standard algorithm (e.g. word2vec / GloVe). Our goal is to construct a good embedding $\mathbf{v}_f \in \mathbb{R}^d$ of a text feature f given a set $\mathcal{C}_f$ of contexts it occurs in. Both f and its contexts are assumed to arise via the same process that generates the large corpus $\mathcal{C}_\mathcal{V}$. In many settings below, the number $|\mathcal{C}_f|$ of contexts available for a feature f of interest is much smaller than the number $|\mathcal{C}_w|$ of contexts that the typical word $w \in \mathcal{V}$ occurs in. This could be because the feature is rare (e.g. unseen words, n-grams) or due to limited human annotation (e.g. word senses, named entities).

3.1 A Linear Approach

A naive first approach to construct feature embeddings using context is *additive*, i.e. taking the average over all contexts of a feature f of the average word vector in each context:

$$\mathbf{v}_f^{\text{additive}} = \frac{1}{|\mathcal{C}_f|} \sum_{c \in \mathcal{C}_f} \frac{1}{|c|} \sum_{w \in c} \mathbf{v}_w \tag{1}$$

This formulation reflects the training of commonly used embeddings, which employs additive composition to represent the context (Mikolov et al., 2013; Pennington et al., 2014). It has proved successful in the bag-of-embeddings approach to sentence representation (Wieting et al., 2016; Arora et al., 2017), which can compete with LSTM representations, and has also been given theoretical justification as the *maximum a posteriori* (MAP) context vector under a generative model related to popular embedding objectives (Arora et al., 2016). Lazaridou et al. (2017) use this approach to learn embeddings of unknown word amalgamations, or *chimeras*, given a few context examples.

The additive approach has some limitations because the set of all word vectors is seen to share a few common directions. Simple addition amplifies the component in these directions, at the expense of less common directions that presumably carry more "signal." Stop-word removal can help to ameliorate this (Lazaridou et al., 2017; Herbelot and Baroni, 2017), but does not deal with the fact that content-words also have significant components in the same direction as these deleted words. Another mathematical framework to address this lacuna is to remove the top one or top few principal components, either from the word embeddings themselves (Mu and Viswanath, 2018) or from their summations (Arora et al., 2017). However, this approach is liable to either not remove enough noise or cause too much information loss without careful tuning (c.f. Figure 1).

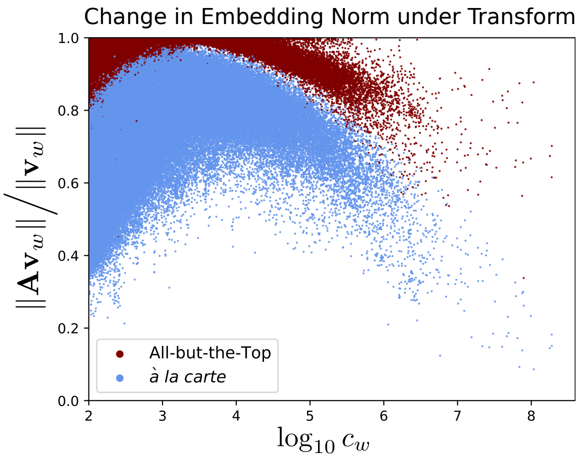

Figure 1: Plot of the ratio of embedding norms after transformation as a function of word count. While All-but-the-Top tends to affect only very frequent words, *à la carte* learns to remove components even from less common words.

We now note that removing the component along the top few principal directions is tantamount to multiplying the additive composition by a fixed (but data-dependent) matrix. Thus a natural extension is to use an arbitrary linear transformation which will be *learned* from the data, and hence guaranteed to do at least as well as any of the above ideas. Specifically, we find the transform that can best recover *existing* word vectors $\mathbf{v}_w$ —which are presumed to be of high quality— from their additive context embeddings $\mathbf{v}_w^{\text{additive}}$. This can be posed as the following linear regression problem

$$\mathbf{v}_w \approx \mathbf{A}\mathbf{v}_w^{\text{additive}} = \mathbf{A}\left(\frac{1}{|\mathcal{C}_w|} \sum_{c \in \mathcal{C}_w} \sum_{w' \in c} \mathbf{v}_{w'}\right) \tag{2}$$

where $\mathbf{A} \in \mathbb{R}^{d \times d}$ is learned and we assume for simplicity that $\frac{1}{|c|}$ is constant (e.g. if c has a fixed window size) and is thus subsumed by the transform. After learning the matrix, we can embed any text feature in the same semantic space as the word embeddings via the following expression:

$$\mathbf{v}_f = \mathbf{A}\mathbf{v}_f^{\text{additive}} = \mathbf{A}\left(\frac{1}{|\mathcal{C}_f|} \sum_{c \in \mathcal{C}_f} \sum_{w \in c} \mathbf{v}_w\right) \tag{3}$$

Note that $\mathbf{A}$ is fixed for a given corpus and set of pretrained word embeddings and so does not need to be re-computed to embed different features or feature types.

Algorithm 1: The basic *à la carte* feature embedding induction method. All contexts c consist of sequences of words drawn from the vocabulary $\mathcal{V}$.

```
Data: vocabulary $\mathcal{V}$, corpus $\mathcal{C}_\mathcal{V}$, vectors $\mathbf{v}_w \in \mathbb{R}^d \ \forall\, w \in \mathcal{V}$, feature $f$, corpus $\mathcal{C}_f$ of contexts of $f$
Result: feature embedding $\mathbf{v}_f \in \mathbb{R}^d$
1 for $w \in \mathcal{V}$ do
2     let $\mathcal{C}_w \subset \mathcal{C}_\mathcal{V}$ be the subcorpus of contexts of $w$
3     $\mathbf{u}_w \leftarrow \frac{1}{|\mathcal{C}_w|} \sum_{c \in \mathcal{C}_w} \sum_{w' \in c} \mathbf{v}_{w'}$    // compute each word's context embedding $\mathbf{u}_w$
4 $\mathbf{A} \leftarrow \arg\min_{\mathbf{A} \in \mathbb{R}^{d \times d}} \sum_{w \in \mathcal{V}} \|\mathbf{v}_w - \mathbf{A}\mathbf{u}_w\|_2^2$  // compute context-to-feature transform $\mathbf{A}$
5 $\mathbf{u}_f \leftarrow \frac{1}{|\mathcal{C}_f|} \sum_{c \in \mathcal{C}_f} \sum_{w \in c} \mathbf{v}_w$    // compute feature's context embedding $\mathbf{u}_f$
6 $\mathbf{v}_f \leftarrow \mathbf{A}\mathbf{u}_f$    // transform feature's context embedding
```

Theoretical Justification: As shown by Arora et al. (2018b, Theorem 1), the approximation (2) holds exactly in expectation for some matrix $\mathbf{A}$ when contexts $c \in \mathcal{C}$ are generated by sampling a context vector $\mathbf{v}_c \in \mathbb{R}^d$ from a zero-mean Gaussian with fixed covariance and drawing $|c|$ words using $\mathbb{P}(w|\mathbf{v}_c) \propto \exp\langle \mathbf{v}_c, \mathbf{v}_w \rangle$. The correctness (again in expectation) of (3) under this model is a direct extension. Arora et al. (2018b) use large text corpora to verify their model assumptions, providing theoretical justification for our approach. We observe that the best linear transform $\mathbf{A}$ can recover vectors with mean cosine similarity as high as 0.9 or more with the embeddings used to learn it, thus also justifying the method empirically.

3.2 Practical Details

The basic *à la carte* method, as motivated in Section 3.1 and specified in Algorithm 1, is straightforward and parameter-free (the dimension d is assumed to have been chosen beforehand, along with the other parameters of the original word embeddings). In practice we may wish to modify the regression step in an attempt to learn a better transformation matrix $\mathbf{A}$. However, the standard first approach of using ℓ_2-regularized (Ridge) regression instead of simple linear regression gives little benefit, even when we have more parameters than word embeddings (i.e. when $d^2 > |\mathcal{V}|$).

A more useful modification is to weight each point by some non-decreasing function α of each word's corpus count c_w, i.e. to solve

$$\mathbf{A} = \arg\min_{\mathbf{A} \in \mathbb{R}^{d \times d}} \sum_{w \in \mathcal{V}} \alpha(c_w) \|\mathbf{v}_w - \mathbf{A}\mathbf{u}_w\|_2^2 \qquad (4)$$

where $\mathbf{u}_w$ is the additive context embedding. This reflects the fact that more frequent words likely have better pretrained embeddings. In settings where $|\mathcal{V}|$ is large we find that a hard threshold ($\alpha(c) = \mathbf{1}_{c \geq \tau}$ for some $\tau \geq 1$) is often useful. When we do not have many embeddings we can still give more importance to words with better embeddings via a function such as $\alpha(c) = \log c$, which we use in Section 5.1.

4 One-Shot and Few-Shot Learning of Word Embeddings

While we can use our method to embed any type of text feature, its simplicity and effectiveness is rooted in word-level semantics: the approach assumes pre-existing high quality word embeddings and only considers collocations of features with words rather than with other features. Thus to verify that our approach is reasonable we first check how it performs on word representation tasks, specifically those where word embeddings need to be learned from very few examples. In this section we first investigate how representation quality varies with number of occurrences, as measured by performance on a similarity task that we introduce. We then apply the *à la carte* method to two tasks measuring the ability to learn new or synthetic words from context, achieving strong results on the nonce task of Herbelot and Baroni (2017).

4.1 Similarity Correlation vs. Sample Size

Performance on pairwise word similarity tasks is a standard way to evaluate word embeddings, with success measured via the Spearman correlation between a human score and the cosine similarity between word vectors. An overview of widely used datasets is given by Faruqui and Dyer (2014). However, none of these datasets can be used directly to measure the effect of word frequency on embedding quality, which would help us understand the data requirements of our approach. We address this issue by introducing the *Contextual Rare Words* (CRW) dataset, a subset of 562 pairs from the Rare Word (RW) dataset (Luong et al., 2013) supplemented by 255 sentences (contexts) for each rare word sampled from the Westbury Wikipedia Corpus (WWC) (Shaoul and Westbury, 2010). In addition we provide a subset of the WWC from which all sentences containing these rare words have been removed. The task is to use embeddings trained on this subcorpus to induce rare word embeddings from the sampled contexts.

More specifically, the CRW dataset is constructed using all pairs from the RW dataset where the rarer word occurs between 512 and 10000 times in WWC; this yields a set of 455 distinct rare words. The lower bound ensures that we have a sufficient number of rare word contexts, while the upper bound ensures that a significant fraction of the sentences from the original WWC remain in the subcorpus we provide. In CRW, the first word in every pair is the more frequent word and occurs in the subcorpus, while the second word occurs in the 255 sampled contexts but not in the subcorpus. We provide word2vec embeddings trained on all words occurring at least 100 times in the WWC subcorpus; these vectors include those assigned to the first (non-rare) words in the evaluation pairs.

Evaluation: For every rare word the method under consideration is given eight disjoint subsets containing $1, 2, 4, \dots, 128$ example contexts. The method induces an embedding of the rare word for each subset, letting us track how the quality of rare word vectors changes with more examples. We report the Spearman ρ (as described above) at each sample size, averaged over 100 trials obtained by shuffling each rare word's 255 contexts.

The results in Figure 2 show that our *à la carte* method significantly outperforms the additive baseline (1) and its variants, including stopword removal, SIF-weighting (Arora et al., 2017), and top principal component removal (Mu and Viswanath, 2018). We find that combining SIF-weighting and top component removal also beats these baselines, but still does worse than our method. These experiments consolidate our intuitions from Section 3 that removing common components and frequent words is important and that learning a data-dependent transformation is an effective way to do this. However, if we train

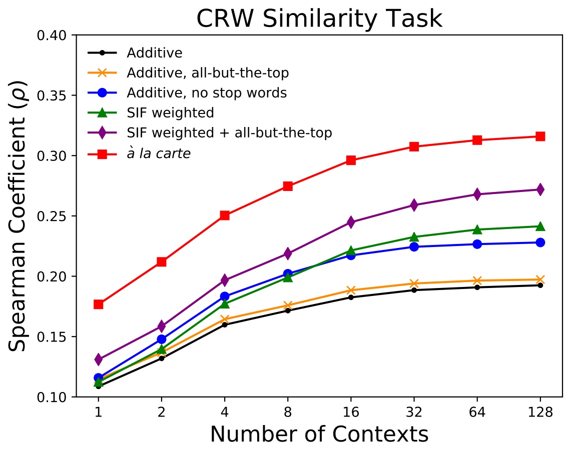

Figure 2: Spearman correlation between cosine similarity and human scores for pairs of words in the CRW dataset given an increasing number of contexts per rare word. Our *à la carte* method outperforms all previous approaches, even when restricted to only eight example contexts.

word2vec embeddings from scratch on the subcorpus together with the sampled contexts we achieve a Spearman correlation of 0.45; this gap between word2vec and our method shows that there remains room for even better approaches for few-shot learning of word embeddings.

4.2 Learning Embeddings of New Concepts: Nonces and Chimeras

We now evaluate our work directly on the tasks posed by Herbelot and Baroni (2017), who developed simple datasets and methods to "simulate the process by which a competent speaker encounters a new word in known contexts." The general goal will be to construct embeddings of new concepts in the same semantic space as a known embedding vocabulary using contextual information consisting of definitions or example sentences.

Nonces: We first discuss the definitional nonce dataset made by the authors themselves, which has a test-set consisting of 300 single-word concepts and their definitions. The task of learning each concept's embedding is simulated by removing or randomly re-initializing its vector and requiring the system to use the remaining embeddings and the definition to make a new vector that is close to the original. Because the embeddings were constructed using data that includes these concepts, an implicit assumption is made that including or excluding one word does not greatly affect the se-

Table 1: Comparison with baselines and nonce2vec (Herbelot and Baroni, 2017) on few-shot embedding tasks. Performance on the chimeras task is measured using the Spearman correlation with human ratings. Note that the additive baseline requires removing stop-words in order to improve with more data.

mantic space; this assumption is necessary in order to have a good target vector for the system to be evaluated against.

Using 259,376 word2vec embeddings trained on Wikipedia as the base vectors, Herbelot and Baroni (2017) heavily modify the skip-gram algorithm to successfully learn on one definition, creating the *nonce2vec* system. The original skip-gram algorithm and $\mathbf{v}_w^{\text{additive}}$ are used as baselines, with performance measured as the mean reciprocal rank and median rank of the concept's original vector among the nearest neighbors of the output.

To compare directly to their approach, we use their word2vec embeddings along with contexts from the Wikipedia corpus to construct context vectors $\mathbf{u}_w$ for all words w apart from the 300 nonces. We then learn the *à la carte* transform $\mathbf{A}$, weighting the data points in the regression (4) using a hard threshold of at least 1000 occurrences in Wikipedia. An embedding for each nonce can then be constructed by multiplying $\mathbf{A}$ by the sum over all word embeddings in the nonce's definition. As can be seen in Table 1, this approach significantly improves over both baselines and nonce2vec; the median rank of 165.5 of the original embedding among the nearest neighbors of the nonce vector is very low considering the vocabulary size is more than 250,000, and is also significantly lower than that of all previous methods.

Chimeras: The second dataset Herbelot and Baroni (2017) consider is that of Lazaridou et al. (2017), who construct unseen concepts by combining two related words into a fake nonce word (the "chimera") and provide two, four, or six example sentences for this nonce drawn from sentences containing one of the two component words. The desired nonce embeddings is then evaluated via the correlation of its cosine similarity with the embeddings of several other words, with ratings provided by human judges.

We use the same approach as in the nonce task, except that the chimera embedding is the result of summing over multiple sentences. From Table 1 we see that, while our method is consistently better than both the additive baseline and nonce2vec, removing stop-words from the additive baseline leads to stronger performance for more sentences. Since the *à la carte* algorithm explicitly trains the transform to match the true word embedding rather than human similarity measures, it is perhaps not surprising that our approach is much more dominant on the definitional nonce task.

5 Building Feature Embeddings using Large Corpora

Having witnessed its success at representing unseen words, we now apply the *à la carte* method to two types of feature embeddings: synset embeddings and n-gram embeddings. Using these two examples we demonstrate the flexibility and adaptability of our approach when handling different corpora, base word embeddings, and downstream applications.

5.1 Supervised Synset Embeddings for Word-Sense Disambiguation

Embeddings of synsets, or sets of cognitive synonyms, and related entities such as senses and lexemes have been widely studied, often due to the desire to account for polysemy (Rothe and Schütze, 2015; Iacobacci et al., 2015). Such representations can be evaluated in several ways, including via their use for word-sense disambiguation (WSD), the task of determining a word's sense from context. While current state-of-the-art methods often use powerful recurrent models (Raganato et al., 2017), we will instead use a sim-

	SemEval-2013 Task 12	SemEval-2015 Task 13				
Method	nouns	adj.	nouns	adv.	verbs	comb.
à la carte (SemCor)	60.0	72.2	67.7	85.2	60.6	68.1
à la carte (glosses)	51.8	75.3	62.5	79.0	55.8	64.2
à la carte (combined)	**60.5**	74.1	**70.3**	86.4	59.4	**69.6**
MFS (SemCor)	58.8	**79.5**	60.0	**87.6**	**66.7**	66.8
Raganato et al. (2017)	**66.9**					**72.4**

Table 2: Application of *à la carte* synset embeddings to two standard WSD tasks. As all systems always return exactly one answer, performance is measured in terms of accuracy. Results due to Raganato et al. (2017), who use a bi-LSTM for this task, are given as the recent state-of-the-art result.

ple similarity-based approach that heavily depends on the synset embedding itself and thus serves as a more useful indicator of representation quality. A major target for our simple systems is to beat the most-frequent sense (MFS) method, which returns for each word the sense that occurs most frequently in a corpus such as SemCor. This baseline is "notoriously hard-to-beat," routinely besting many systems in SemEval WSD competitions (Navigli et al., 2013).

Synset Embeddings: We use SemCor (Langone et al., 2004), a subset of the Brown Corpus (BC) (Francis and Kucera, 1979) annotated using PWN synsets. However, because the corpus is quite small we use GloVe trained on Wikipedia instead of on BC itself. The transform $\mathbf{A}$ is learned using context embeddings $\mathbf{u}_w$ computed with windows of size ten around occurrences of w in BC and weighting each word by the log of its count during the regression stage (4). Then we set the context embedding $\mathbf{u}_s$ of each synset s to be the average sum of word embeddings representation over all sentences in SemCor containing s. Finally, we apply the *à la carte* transform to get the synset embedding $\mathbf{v}_s = \mathbf{A}\mathbf{u}_s$.

Sense Disambiguation: To determine the sense of a word w given its context c, we convert c into a vector using the *à la carte* transform $\mathbf{A}$ on the sum of its word embeddings and return the synset s of w whose embedding $\mathbf{v}_s$ is most similar to this vector. We try two different synset embeddings: those induced from SemCor as above and those obtained by embedding a synset using its *gloss*, or PWN-provided definition, in the same way as a nonce in Section 4.2. We also consider a *combined* approach in which we fall back on the gloss vector if the synset does not appear in SemCor and thus has no induced embedding.

As shown in Table 2, synset embeddings induced from SemCor alone beat MFS overall, largely due to good noun results. The method improves further when combined with the gloss approach. While we do not match the state-of-the-art, our success in besting a difficult baseline using very little fine-tuning and exploiting none of the underlying graph structure suggests that the *à la carte* method can learn useful synset embeddings, even from relatively small data.

5.2 N-Gram Embeddings for Classification

As some of the simplest and most useful linguistic features, n-grams have long been a focus of embedding studies. Compositional approaches, such as sums and products of unigram vectors, are often used and work well on some evaluations, but are often order-insensitive or very high-dimensional (Mitchell and Lapata, 2010). Recent work by Poliak et al. (2017) works around this while staying compositional; however, as we will see their approach does not seem to capture a bigram's meaning much better than the sum of its word vectors. n-grams embeddings have also gained interest for low-dimensional document representation schemes (Hill et al., 2016; Pagliardini et al., 2018; Arora et al., 2018a), largely due to the success of their sparse high-dimensional Bag-of-n-Grams (BonG) counterparts (Wang and Manning, 2012). This setting of document embeddings derived from n-gram features will be used for quantitative evaluation in this section.

We build n-gram embeddings using two corpora: 300-dimensional Wikipedia embeddings, which we evaluate qualitatively, and 1600-dimensional embeddings on the Amazon Product Corpus (McAuley et al., 2015), which we use for document classification. For both we use as source embeddings GloVe vectors trained on the respec-

Table 3: Closest word embeddings (measured via cosine similarity) to the embeddings of four idiomatic or entity-associated bigrams. From these examples we see that purely compositional methods may struggle to construct context-aware bigram embeddings, even when the features are present in the corpus. On the other hand, adding up corpus contexts (1) is dominated by stop-word information. Sent2Vec is successful on half the examples, reflecting its focus on good sentence, not bigram, embeddings.

tive corpora over words occurring at least a hundred times. Context embeddings are constructed using a window of size ten and a hard threshold at 1000 occurrences is used as the word-weighting function in the regression (4). Unlike Poliak et al. (2017), who can construct arbitrary embeddings but need to train at least two sets of vectors of dimension at least $2d$ to do so, and Yin and Schutze (2014), who determine which n-grams to represent via corpus counts, our *à la carte* approach allows us to train exactly those embeddings that we need for downstream tasks. This, combined with our method's efficiency, allows us to construct more than two million bigram embeddings and more than five million trigram embeddings, constrained only by their presence in the large source corpus.

Qualitative Evaluation: We first compare bigram embedding methods by picking some idiomatic and entity-related bigrams and examining the closest word vectors to their representations. These word-pairs are picked because we expect sophisticated feature embedding methods to encode a better vector than the sum of the two embeddings, which we use as a baseline. From Table 3 we see that embeddings based on corpora rather than composition are better able to embed these bigrams to be close to concepts that are semantically similar. On the other hand, as discussed in Section 3 and evident from these results, the additive context approach is liable to emphasize stop-word directions due to their high frequency.

Document Embedding: Our main application and quantitative evaluation of n-gram vectors is to use them to construct document embeddings. Given a length L document $D=\{w_1,\dots,w_L\}$, we define its embedding $\mathbf{v}_D$ as a weighted concatenation over sums of our induced n-gram embeddings, i.e.

$$\mathbf{v}_D^T = \left(\sum_{t=1}^{L} \mathbf{v}_{w_t}^T \quad \cdots \quad \frac{1}{n} \sum_{t=1}^{L-n+1} \mathbf{v}_{(w_t,\dots,w_{t+n-1})}^T \right)$$

where $\mathbf{v}_{(w_t,\dots,w_{t+n-1})}$ is the embedding of the n-gram $(w_t,\dots,w_{t+n-1})$. Following Arora et al. (2018a), we weight each n-gram component by $\frac{1}{n}$ to reflect the fact that higher-order n-grams have lower quality embeddings because they occur less often in the source corpus. While we concatenate across unigram, bigram, and trigram embeddings to construct our text representations, separate experiments show that simply adding up the vectors of all features also yields a smaller but still substantial improvement over the unigram performance. The higher embedding dimension due to concatenation is in line with previous methods and can also be theoretically supported as yielding a less lossy compression of the n-gram information (Arora et al., 2018a).

In Table 4 we display the result of running cross-validated, ℓ_2-regularized logistic regression on documents from MR movie reviews (Pang and Lee, 2005), CR customer reviews (Hu and Liu, 2004), SUBJ subjectivity dataset (Pang and Lee, 2004), MPQA opinion polarity subtask (Wiebe et al., 2005), TREC question classification (Li and Roth, 2002), SST sentiment classification (binary and fine-grained) (Socher et al., 2013), and IMDB movie reviews (Maas et al., 2011). The first four are evaluated using tenfold cross-validation, while the others have train-test splits.

Despite the simplicity of our embeddings (a concatenation over sums of *à la carte* n-gram vectors), we find that our results are very competitive with many recent unsupervised methods, achieving the best word-level results on two of the tested

Table 4: Performance of document embeddings built using *à la carte* n-gram vectors and recent unsupervised word-level approaches on classification tasks, with the character LSTM of (Radford et al., 2017) shown for comparison. Top three results are **bolded** and the best word-level performance is underlined.

datasets. The fact that we do especially well on the sentiment tasks indicates strong exploitation of the Amazon review corpus, which was also used by DisC, CNN-LSTM, and byte mLSTM. At the same time, the fact that our results are comparable to neural approaches indicates that local word-order may contain much of the information needed to do well on these tasks. On the other hand, separate experiments do not show a substantial improvement from our approach over unigram methods such as SIF (Arora et al., 2017) on sentence similarity tasks such as STS (Cer et al., 2017). This could reflect either noise in the n-gram embeddings themselves or the comparative lower importance of local word-order for textual similarity compared to classification.

6 Conclusion

We have introduced *à la carte* embedding, a simple method for representing semantic features using unsupervised context information. A natural and principled integration of recent ideas for composing word vectors, the approach achieves strong performance on several tasks and promises to be useful in many linguistic settings and to yield many further research directions. Of particular interest is the replacement of simple window contexts by other structures, such as dependency parses, that could yield results in domains such as question answering or semantic role labeling. Extensions of the mathematical formulation, such as the use of word weighting when building context vectors as in Arora et al. (2018b) or of spectral information along the lines of Mu and Viswanath (2018), are also worthy of further study.

More practically, the Contextual Rare Words (CRW) dataset we provide will support research on few-shot learning of word embeddings. Both in this area and for n-grams there is great scope for combining our approach with compositional approaches (Bojanowski et al., 2016; Poliak et al., 2017) that can handle settings such as zero-shot learning. More work is needed to understand the usefulness of our method for representing (potentially cross-lingual) entities such as synsets, whose embeddings have found use in enhancing WordNet and related knowledge bases (Camacho-Collados et al., 2016; Khodak et al., 2017). Finally, there remain many language features, such as named entities and morphological forms, whose representation by our method remains unexplored.

Abstract

Word embedding models such as GloVe rely on co-occurrence statistics to learn vector representations of word meaning. While we may similarly expect that co-occurrence statistics can be used to capture rich information about the relationships between different words, existing approaches for modeling such relationships are based on manipulating pre-trained word vectors. In this paper, we introduce a novel method which directly learns relation vectors from co-occurrence statistics. To this end, we first introduce a variant of GloVe, in which there is an explicit connection between word vectors and PMI weighted co-occurrence vectors. We then show how relation vectors can be naturally embedded into the resulting vector space.

1 Introduction

Word embeddings are vector space representations of word meaning (Mikolov et al., 2013b; Pennington et al., 2014). A remarkable property of these models is that they capture various lexical relationships, beyond mere similarity. For example, (Mikolov et al., 2013b) found that analogy questions of the form "a is to b what c is to ?" can often be answered by finding the word d that maximizes $\cos(w_b - w_a + w_c, w_d)$, where we write w_x for the vector representation of a word x.

Intuitively, the word vector w_a represents a in terms of its most salient features. For example, w_{paris} implicitly encodes that Paris is located in France and that it is a capital city, which is intuitively why the 'capital of' relation can be modeled in terms of a vector difference. Other relationships, however, such as the fact that Macron succeeded Hollande as president of France, are unlikely to be captured by word embeddings. Relation extraction methods can discover such information by analyzing sentences that contain both of the words or entities involved (Mintz et al., 2009; Riedel et al., 2010; dos Santos et al., 2015), but they typically need a large number of training examples to be effective.

A third alternative, which we consider in this paper, is to characterize the relatedness between two words s and t by learning a relation vector r_{st} in an unsupervised way from corpus statistics. Among others, such vectors can be used to find word pairs that are similar to a given word pair (i.e. finding analogies), or to find the most prototypical examples among a given set of relation instances. They can also be used as an alternative to the aforementioned relation extraction methods, by subsequently training a classifier that uses the relation vectors as input, which might be particularly effective in cases where only limited amounts of training data are available (with the case of analogy finding from a single instance being an extreme example).

The most common unsupervised approach for learning relation vectors consists of averaging the embeddings of the words that occur in between s and t, in sentences that contain both (Weston et al., 2013; Fan et al., 2015; Hashimoto et al., 2015). While this strategy is often surprisingly effective (Hill et al., 2016), it is sub-optimal for two reasons. First, many of the words co-occurring with s and t will be semantically related to s or to t, but will not actually be descriptive for the relationship between s and t; e.g. the vector describing the relation between *Paris* and *France* should not be affected by words such as *eiffel* (which only relates to Paris). Second, it gives too much weight to stop-words, which cannot be addressed in a straightforward way as some stop-words are actually crucial for modeling relationships (e.g. prepositions such as 'in' or 'of' or Hearst patterns (Indurkhya and Damerau, 2010)).

In this paper, we propose a method for learning relation vectors directly from co-occurrence statistics. We first introduce a variant of GloVe, in which word vectors can be directly interpreted as smoothed PMI-weighted bag-of-words representations. We then represent relationships between words as weighted bag-of-words representations, using generalizations of PMI to three arguments, and learn vectors that correspond to smoothed versions of these representations.

As far as the possible applications of our methodology is concerned, we imagine that relation vectors can be used in various ways to enrich the input to neural network models. As a simple example, in a question answering system, we could "annotate" mentions of entities with relation vectors encoding their relationship to the different words from the question. As another example, we could consider a recommendation system which takes advantage of vectors expressing the relationship between items that have been bought (or viewed) by a customer and other items from the catalogue. Finally, relation vectors should also be useful for knowledge completion, especially in cases where few training examples per relation type are given (meaning that neural network models could not be used) and where relations cannot be predicted from the already available knowledge (meaning that knowledge graph embedding methods could not be used, or are at least not sufficient).

2 Related Work

The problem of characterizing the relationship between two words has been studied in various settings. From a learning point of view, the most straightforward setting is where we are given labeled training sentences, with each label explicitly indicating what relationship is expressed in the sentence. This fully supervised setting has been the focus of several evaluation campaigns, including as part of ACE (Doddington et al., 2004) and at SemEval 2010 (Hendrickx et al., 2010). A key problem with this setting, however, is that labeled training data is hard to obtain. A popular alternative is to use known instances of the relations of interest as a form of distant supervision (Mintz et al., 2009; Riedel et al., 2010). Some authors have also considered unsupervised relation extraction methods (Shinyama and Sekine, 2006; Banko et al., 2007), in which case the aim is essentially to find clusters of patterns that express similar relationships, although these relationships may not correspond to the ones that are needed for the considered application. Finally, several systems have also used bootstrapping strategies (Brin, 1998; Agichtein and Gravano, 2000; Carlson et al., 2010), where a small set of instances are used to find extraction patterns, which are used to find more instances, which can in turn be used to find better extraction patterns, etc.

Traditionally, relation extraction systems have relied on a variety of linguistic features, such as lexical patterns, part-of-speech tags and dependency parsers. More recently, several neural network architectures have been proposed for the relation extraction problem. These architectures rely on word embeddings to represent the words in the input sentence, and manipulate these word vectors to construct a relation vector. Some approaches simply represent the sentence (or the phrase connecting the entities whose relationship we want to determine) as a sequence of words, and use e.g. convolutional networks to aggregate the vectors of the words in this sequence (Zeng et al., 2014; dos Santos et al., 2015). Another possibility, explored in (Socher et al., 2012), is to use parse trees to capture the structure of the sentence, and to use recursive neural networks (RNNs) to aggregate the word vectors in a way which respects this structure. A similar approach is taken in (Xu et al., 2015), where LSTMs are applied to the shortest path between the two target words in a dependency parser. A straightforward baseline method is to simply take the average of the word vectors (Mitchell and Lapata, 2010). While conceptually much simpler, variants of this approach have obtained state-of-the-art performance for relation classification (Hashimoto et al., 2015) and a variety of tasks that require sentences to be represented as a vector (Hill et al., 2016).

Given the effectiveness of word vector averaging, in (Kenter et al., 2016) a model was proposed that explicitly tries to learn word vectors that generalize well when being averaged. Similarly, the model proposed in (Hashimoto et al., 2015) aims to produce word vectors that perform well for the specific task of relation classification. The ParagraphVector method from (Le and Mikolov, 2014) is related to the aformentioned approaches, but it explicitly learns a vector representation for each paragraph along with the word embeddings. However, this method is computationally expensive, and often fails to outperform simpler approaches (Hill et al., 2016).

To the best of our knowledge, existing methods for learning relation vectors are all based on manipulating pre-trained word vectors. In contrast, we will directly learn relation vectors from corpus statistics, which will have the important advantage that we can focus on words that describe the interaction between the two words s and t, i.e. words that commonly occur in sentences that contain both s and t, but are comparatively rare in sentences that only contain s or only contain t.

Finally, note that our work is fundamentally different from Knowledge Graph Embedding (KGE) (Wang et al., 2014b), (Wang et al., 2014a), (Bordes et al., 2011) in at least two ways: (i) KGE models start from a structured knowledge graph whereas we only take a text corpus as input, and (ii) KGE models represent relations as geometric objects in the "entity embedding" itself (e.g. as translations, linear maps, combinations of projections and translations, etc), whereas we represent words and relations in different vector spaces.

3 Word Vectors as PMI Encodings

Our approach to relation embedding is based on a variant of the GloVe word embedding model (Pennington et al., 2014). In this section, we first briefly recall the GloVe model itself, after which we discuss our proposed variant. A key advantage of this variant is that it allows us to directly interpret word vectors in terms of the Pointwise Mutual Information (PMI), which will be central to the way in which we learn relation vectors.

3.1 Background

The GloVe model (Pennington et al., 2014) learns a vector w_i for each word i in the vocabulary, based on a matrix of co-occurrence counts, encoding how often two words appear within a given window. Let us write x_{ij} for the number of times word j appears in the context of word i in some text corpus. More precisely, assume that there are m sentences in the corpus, and let $\mathcal{P}_i^l \subseteq \{1, ..., n_l\}$ be the set of positions from the l^{th} sentence where the word i can be found (with n_l the length of the sentence). Then x_{ij} is defined as follows:

$$\sum_{l=1}^{m} \sum_{p \in \mathcal{P}_i^l} \sum_{q \in \mathcal{P}_j^l} \mathit{weight}(p, q)$$

where $\mathit{weight}(p,q) = \frac{1}{|p-q|}$ if $0 < |p-q| \leq W$, and $\mathit{weight}(p,q) = 0$ otherwise, where the window size W is usually set to 5 or 10.

The GloVe model learns for each word i two vectors w_i and $\tilde{w}_i$ by optimizing the following objective:

$$\sum_i \sum_{j: x_{ij} \neq 0} f(x_{ij})(w_i \cdot \tilde{w}_j + b_i + \tilde{b_j} - \log x_{ij})^2$$

where f is a weighting function, aimed at reducing the impact of rare terms, and b_i and $\tilde{b_j}$ are bias terms. The GloVe model is closely related to the notion of pointwise mutual information (PMI), which is defined for two words i and j as $\mathit{PMI}(i,j) = \log\left(\frac{P(i,j)}{P(i)P(j)}\right)$, where $P(i,j)$ is the probability of seeing the words i and j if we randomly pick a word position from the corpus and a second word position within distance W from the first position. The PMI between i and j is usually estimated as follows:

$$\mathit{PMI}_X(i,j) = \log\left(\frac{x_{ij} x_{**}}{x_{i*} x_{*j}}\right)$$

where $x_{i*} = \sum_j x_{ij}$, $x_{*j} = \sum_i x_{ij}$ and $x_{**} = \sum_i \sum_j x_{ij}$. In particular, it is straightforward to see that after the reparameterization given by $b_i \mapsto b_i + \log x_{i*} - \log x_{**}$ and $b_j \mapsto b_j + \log x_{*j}$, the GloVe model is equivalent to

$$\sum_i \sum_{\substack{j \\ x_{ij} \neq 0}} f(x_{ij})(w_i \cdot \tilde{w}_j + b_i + \tilde{b_j} - \mathit{PMI}_X(i,j))^2 \tag{1}$$

3.2 A Variant of GloVe

In this paper, we will use the following variant of the formulation in (1):

$$\sum_i \sum_{j \in J_i} \frac{1}{\sigma_j^2}(w_i \cdot \tilde{w}_j + \tilde{b_j} - \mathit{PMI}_S(i,j))^2 \tag{2}$$

Despite its similarity, this formulation differs from the GloVe model in a number of important ways. First, we use smoothed frequency counts instead of the observed frequency counts x_{ij}. In particular, the PMI between words i and j is given as:

$$\mathit{PMI}_S(i,j) = \log\left(\frac{P(i,j)}{P(i)P(j)}\right)$$

where the probabilities are estimated as follows:

$$P(i) = \frac{x_{i*} + \alpha}{x_{**} + n\alpha} \qquad P(j) = \frac{x_{*j} + \alpha}{x_{**} + n\alpha}$$
$$P(i,j) = \frac{x_{ij} + \alpha}{x_{**} + n^2\alpha}$$

where $\alpha \geq 0$ is a parameter controlling the amount of smoothing and n is the size of the vocabulary. This ensures that the estimation of $\mathit{PMI}(i,j)$ is well-defined even in cases where $x_{ij} = 0$, meaning that we no longer have to restrict the inner summation to those j for which $x_{ij} > 0$. For efficiency reasons, in practice, we only consider a small subset of all context words j for which $x_{ij} = 0$, which is similar in spirit to the use of negative sampling in Skip-gram (Mikolov et al., 2013b). In particular, the set J_i contains each j such that $x_{ij} > 0$ as well as M uniformly[1] sampled context words j for which $x_{ij} = 0$, where we choose $M = 2 \cdot |\{j : x_{ij} > 0\}|$.

Second, following (Jameel and Schockaert, 2016), the weighting function $f(x_{ij})$ has been replaced by $\frac{1}{\sigma_j^2}$, where σ_j^2 is the residual variance of the regression problem for context word j, estimated follows:

$$\sigma_j^2 = \frac{1}{|J_j^{-1}|} \sum_{i \in J_j^{-1}} (w_i \cdot \tilde{w_j} + \tilde{b_j} - \mathit{PMI}_S(i,j))^2$$

with $J_j^{-1} = \{i : j \in J_i\}$. Since we need the word vectors to estimate this residual variance, we re-estimate σ_j^2 after every five iterations of the SGD optimization. For the first 5 iterations, where no estimation for σ_j^2 is available, we use the GloVe weighting function.

The use of smoothed frequency counts and residual variance based weighting make the word embedding model more robust for rare words. For instance, if w only co-occurs with a handful of other terms, it is important to prioritize the most informative context words, which is exactly what the use of the residual variance achieves, i.e. σ_j^2 is small for informative terms and large for stop words; see (Jameel and Schockaert, 2016). This will be important for modeling relations, as the relation vectors will often have to be estimated from very sparse co-occurrence counts.

[1]While the negative sampling method used in Skip-gram favors more frequent words, initial experiments suggested that deviating from a uniform distribution almost had no impact in our setting.

Finally, the bias term b_i has been omitted from the model in (2). We have empirically found that omitting this bias term does not affect the performance of the model, while it allows us to have a more direct connection between the vector w_i and the corresponding PMI scores.

3.3 Word Vectors and PMI

Let us define PMI_W as follows:

$$\mathit{PMI}_W(i,j) = w_i{\cdot}\tilde{w_j} + \tilde{b_j}$$

Clearly, when the word vectors are trained according to (2), it holds that $\mathit{PMI}_W(i,j) \approx \mathit{PMI}_S(i,j)$. In other words, we can think of the word vector w_i as a low-dimensional encoding of the vector $(\mathit{PMI}_S(i,1), ..., \mathit{PMI}_S(i,n))$, with n the number of words in the vocabulary. This view allows us to assign a natural interpretation to some word vector operations. In particular, the vector difference $w_i - w_k$ is commonly used as a model for the relationship between words i and k. For a given context word j, we have

$$(w_i - w_k) \cdot \tilde{w_j} = \mathit{PMI}_W(i,j) - \mathit{PMI}_W(k,j)$$

The latter is an estimation of $\log\left(\frac{P(i,j)}{P(i)P(j)}\right) - \log\left(\frac{P(k,j)}{P(k)P(j)}\right) = \log\left(\frac{P(j|i)}{P(j|k)}\right)$. In other words, the vector translation $w_i - w_k$ encodes for each context word j the (log) ratio of the probability of seeing j in the context of i and in the context of k, which is in line with the original motivation underlying the GloVe model (Pennington et al., 2014). In the following section, we will propose a number of alternative vector representations for the relationship between two words, based on generalizations of PMI to three arguments.

4 Learning Global Relation Vectors

We now turn to the problem of learning a vector r_{ik} that encodes how the source word i and target word k are related. The main underlying idea is that r_{ik} will capture which context words j are most closely associated with the word pair (i,k). Whereas the GloVe model is based on statistics about (*main word*, *context word*) pairs, here we will need statistics on (*source word*, *context word*, *target word*) triples. First, we discuss how co-occurrence statistics among three words can be expressed using generalizations of PMI to three arguments. Then we explain how this can be used to learn relation vectors in natural way.

4.1 Co-occurrence Statistics for Triples

Let $\mathcal{P}_i^l \subseteq \{1, ..., n_l\}$ again be the set of positions from the l^{th} sentence corresponding to word i. We define:

$$y_{ijk} = \sum_{l=1}^{m} \sum_{p \in \mathcal{P}_i^l} \sum_{q \in \mathcal{P}_j^l} \sum_{r \in \mathcal{P}_k^l} \mathit{weight}(p, q, r)$$

where $\mathit{weight}(p, q, r) = \max(\frac{1}{q-p}, \frac{1}{r-q})$ if $p < q < r$ and $r - p \leq W$, and $\mathit{weight}(p, q, r) = 0$ otherwise. In other words, y_{ijk} reflects the (weighted) number of times word j appears between words i and k in a sentence in which i and k occur sufficiently close to each other, in that order. Note that by taking word order into account in this way, we will be able to model asymmetric relationships.

To model how strongly a context word j is associated with the word pair (i, k), we will consider the following two well-known generalizations of PMI to three arguments (Van de Cruys, 2011):

$$\mathit{SI}^1(i, j, k) = \log\left(\frac{P(i, j)P(i, k)P(j, k)}{P(i)P(j)P(k)P(i, j, k)}\right)$$
$$\mathit{SI}^2(i, j, k) = \log\left(\frac{P(i, j, k)}{P(i)P(j)P(k)}\right)$$

where $P(i, j, k)$ is the probability of seeing the word triple (i, j, k) when randomly choosing a sentence and three (ordered) word positions in that sentence within a window size of W. In addition we will also consider two ways in which PMI can be used more directly:

$$\mathit{SI}^3(i, j, k) = \log\left(\frac{P(i, j, k)}{P(i, k)P(j)}\right)$$
$$\mathit{SI}^4(i, j, k) = \log\left(\frac{P(i, k|j)}{P(i|j)P(k|j)}\right)$$

Note that $\mathit{SI}^3(i, j, k)$ corresponds to the PMI between (i, k) and j, whereas $\mathit{SI}^4(i, j, k)$ is the PMI between i and k conditioned on the fact that j occurs. The measures SI^3 and SI^4 are closely related to SI^1 and SI^2 respectively[2]. In particular, the following identities are easy to show:

$$\mathit{PMI}(i, j) + \mathit{PMI}(j, k) - \mathit{SI}^1(i, j, k) = \mathit{SI}^3(i, j, k)$$
$$\mathit{SI}^2(i, j, k) - \mathit{PMI}(i, j) - \mathit{PMI}(j, k) = \mathit{SI}^4(i, j, k)$$

[2]Note that probabilities of the form $P(i, j)$ or $P(i)$ here refer to marginal probabilities over ordered triples. In contrast, the PMI scores from the word embedding model are based on probabilities over unordered word pairs, as is common for word embeddings.

Using smoothed versions of the counts y_{ijk}, we can use the following probability estimates for $\mathit{SI}^1(i, j, k)$–$\mathit{SI}^4(i, j, k)$:

$$P(i, j, k) = \frac{y_{ijk} + \alpha}{y_{***} + n^3\alpha} \qquad P(i, j) = \frac{y_{ij*} + \alpha}{y_{***} + n^2\alpha}$$
$$P(i, k) = \frac{y_{i*k} + \alpha}{y_{***} + n^2\alpha} \qquad P(j, k) = \frac{y_{*jk} + \alpha}{y_{***} + n^2\alpha}$$
$$P(i) = \frac{y_{i**} + \alpha}{y_{***} + n\alpha} \qquad P(j) = \frac{y_{*j*} + \alpha}{y_{***} + n\alpha}$$
$$P(k) = \frac{y_{**k} + \alpha}{y_{***} + n\alpha}$$

where $y_{ij*} = \sum_k y_{ijk}$, and similar for the other counts. For efficiency reasons, the counts of the form y_{ij*}, y_{i*k} and y_{*jk} are pre-computed for all word pairs, which can be done efficiently due to the sparsity of co-occurrence counts (i.e. these counts will be 0 for most pairs of words), similarly to how to the counts x_{ij} are computed in GloVe. From these counts, we can also efficiently pre-compute the counts y_{i**}, y_{*j*}, y_{**k} and y_{***}. On the other hand, the counts y_{ijk} cannot be pre-computed, since the total number of triples for which $y_{ijk} \neq 0$ is prohibitively high in a typical corpus. However, using an inverted index, we can efficiently retrieve the sentences that contain the words i and k, and since this number of sentences is typically small, we can efficiently obtain the counts y_{ijk} corresponding to a given pair (i, k) whenever they are needed.

4.2 Relation Vectors

Our aim is to learn a vector r_{ik} that models the relationship between i and k. Computing such a vector for each pair of words (which co-occur at least once) is not feasible, given the number of triples (i, j, k) that would need to be considered. Instead, we first learn a word embedding, by optimizing (2). Then, fixing the context vectors $\tilde{w}_j$ and bias terms b_j, we learn a vector representation for a given pair (i, k) of interest by solving the following objective:

$$\sum_{j \in J_{i,k}} (r_{ik} \cdot \tilde{w}_j + \tilde{b_j} - \mathit{SI}(i, j, k))^2 \qquad (3)$$

where SI refers to one of $\mathit{SI}_S^1, \mathit{SI}_S^2, \mathit{SI}_S^3, \mathit{SI}_S^4$. Note that (3) is essentially the counterpart of (1), where we have replaced the role of the PMI measure by SI. In this way, we can exploit the representations of the context words from the word embedding model for learning relation vectors. Note that the factor $\frac{1}{\sigma_j^2}$ has been omitted. This is because words j that are normally relatively uninformative (e.g. stop words), for which σ_j^2 would be high, can actually be very important for characterizing the relationship between i and k. For instance, the phrase "X such as Y" clearly suggests a hyponomy relationship between X and Y, but both 'such' and 'as' would be associated with a high residual variance σ_j^2. The set $J_{i,k}$ contains every j for which $y_{ijk} > 0$ as well as a random sample of m words for which $y_{ijk} = 0$, where $m = 2 \cdot |\{j : y_{ijk} > 0|$. Note that because $\tilde{w_j}$ is now fixed, (3) is a linear least squares regression problem, which can be solved exactly and efficiently.

The vector r_{ik} is based on words that appear between i and k. In the same way, we can learn a vector s_{ik} based on the words that appear before i and a vector t_{ik} based on the words that appear after k, in sentences where i occurs before k. Furthermore, we also learn vectors r_{ki}, s_{ki} and t_{ki} from the sentences where k occurs before i. As the final representation R_{ik} of the relationship between i and k, we concatenate the vectors $r_{ik}, r_{ki}, s_{ik}, s_{ki}, t_{ik}, t_{ki}$ as well as the word vectors w_i and w_k. We write R^l_{ik} to denote the vector that results from using measure *SI*^{l} ($l \in \{1, 2, 3, 4\}$).

5 Experimental Results

In our experiments, we have used the Wikipedia dump from November 2nd, 2015, which consists of 1,335,766,618 tokens. We have removed punctuations and HTML/XML tags, and we have lowercased all tokens. Words with fewer than 10 occurrences have been removed from the corpus. To detect sentence boundaries, we have used the Apache sentence segmentation tool. In all our experiments, we have set the number of dimensions to 300, which was found to be a good choice in previous work, e.g. (Pennington et al., 2014). We use a context window size W of 10 words. The number of iterations for SGD was set to 50. For our model, we have tuned the smoothing parameter α based on held-out tuning data, considering values from $\{0.1, 0.01, 0.001, 0.0001, 0.00001, 0.000001\}$. We have noticed that in most of the cases the value of α was automatically selected as 0.00001. To efficiently compute the triples, we have used the Zettair[3] retrieval engine.

As our main baselines, we use three popular unsupervised methods for constructing relation vectors. First, *Diff* uses the vector difference $w_k - w_i$, following the common strategy of modeling relations as vector differences, as e.g. in (Vylomova et al., 2016). Second, *Conc* uses the concatenation of w_i and w_k. This model is more general than *Diff* but it uses twice as many dimensions, which may make it harder to learn a good classifier from few examples. The use of concatenations is popular e.g. in the context of hypernym detection (Baroni et al., 2012). Finally, *Avg* averages the vector representations of the words occurring in sentences that *Diff*, contain i and k. In particular, let r^{avg}_{ik} be obtained by averaging the word vectors of the context words appearing between i and k for each sentence containing i and k (in that order), and then averaging the vectors obtained from each of these sentences. Let s^{avg}_{ik} and t^{avg}_{ik} be similarly obtained from the words occurring before i and the words occurring after k respectively. The considered relation vector is then defined as the concatenation of r^{avg}_{ik}, r^{avg}_{ki}, s^{avg}_{ik}, s^{avg}_{ki}, t^{avg}_{ik}, t^{avg}_{ki}, w_i and w_k. The *Avg* will allow us to directly compare how much we can improve relation vectors by deviating from the common strategy of averaging word vectors.

5.1 Relation Induction

In the relation induction task, we are given word pairs $(s_1, t_1), ..., (s_k, t_k)$ that are related in some way, and the task is to decide for a number of test examples (s, t) whether they also have this relationship. Among others, this task was considered in (Vylomova et al., 2016), and a ranking version of this task was studied in (Drozd et al., 2016). As test sets we use the Google Analogy Test Set (Mikolov et al., 2013a), which contains instances of 14 different types of relations, and the DiffVec dataset, which was introduced in (Vylomova et al., 2016). This dataset contains instances of 36 dif-

ferent types of relations[4]. Note that both datasets contain a mix of semantic and syntactic relations.

In our evaluation, we have used 10-fold cross-validation (or leave-one-out for relations with fewer than 10 instances). In the experiments, we consider for each relation in the test set a separate binary classification task, which was found to be considerably more challenging than a multi-class classification setting in (Vylomova et al., 2016). To generate negative examples in the training data (resp. test data), we have used three strategies, following (Vylomova et al., 2016). First, for a given positive example (s,t) of the considered relation, we add (t,s) as a negative example. Second, for each positive example (s,t), we generate two negative examples (s,t_1) and (s,t_2) by randomly selecting two tail words t_1,t_2 from the other training (resp. test) examples of the same relation. Finally, for each positive example, we also generate a negative example by randomly selecting two words from the vocabulary. For each relation, we then train a linear SVM classifier. To set the parameters of the SVM, we initially use 25% of the training data for tuning, and then retrain the SVM with the optimal parameters on the full training data.

The results are summarized in Table 1 in terms of accuracy and (macro-averaged) precision, recall and F1 score. As can be observed, our model outperforms the baselines on both datasets, with the R^2_{ik} variant outperforming the others.

To analyze the benefit of our proposed word embedding variant, Table 2 shows the results that were obtained when we use standard word embedding models. In particular, we show results for the standard GloVe model, SkipGram and the Continuous Bag of Words (CBOW) model. As can be observed, our variant leads to better results than the original GloVe model, even for the baselines.

[4]Note that in contrast to (Vylomova et al., 2016) we use all 36 relations from this dataset, including those with very few instances.

R^1_{ik}	90.0	82.5	29.9	22.3
R^2_{ik}	92.3	85.8	31.2	24.2
R^3_{ik}	90.5	83.2	30.2	23.0
R^4_{ik}	90.3	83.1	29.8	22.3

The difference is particularly noticeable for DiffVec. The difference is also larger for our relation vectors than for the baselines, which is expected as our method is based on the assumption that context word vectors can be interpreted in terms of PMI scores, which is only true for our variant.

Similar as in the GloVe model, the context words in our model are weighted based on their distance to the nearest target word. Table 3 shows the results of our model without this weighting, for the relation induction task. Comparing these results with those in Table 1 shows that the weighting scheme indeed leads to a small improvement (except for the accuracy of R^1_{ik} for DiffVec). Similarly, in Table 3, we show what happens if the relation vectors s_{ik}, s_{ki}, t_{ik} and t_{ki} are omitted. In other words, for the results in Table 3, we only use context words that appear between the two target words. Again, the results are worse than those in Table 1 (with the accuracy of R^1_{ik} for DiffVec again being an exception), although the differences are very small in this case. While including the vectors s_{ik}, s_{ki}, t_{ik}, t_{ki} should be helpful, it also significantly increases the dimensionality of the vectors R^l_{ik}. Given that the number of instances per relation is typically quite small for this

Table 4: Results for measuring degrees of prototypicality (Spearman $\rho \times 100$).

Diff	Conc	Avg	R^1_{ik}	R^2_{ik}	R^3_{ik}	R^4_{ik}
17.3	16.7	21.1	22.7	**23.9**	21.8	22.2

task, this can also make it harder to learn a suitable classifier.

5.2 Measuring Degrees of Prototypicality

Instances of relations can often have different degrees of prototypicality. For example, for the relation "X characteristically makes the sound Y", the pair (*dog*,*bark*) should be considered more prototypical than the pair (*floor*,*squeak*), even though both pairs might be considered to be instances of the relation (Jurgens et al., 2012). A suitable relation vector should allow us to rank word pairs according to how prototypical they are as instances of that relation. We evaluate this ability using a dataset that was produced in the aftermath of SemEval 2012 Task 2. In particular, we have used the "Phase2AnswerScaled" data from the platinum rankings dataset, which is available from the SemEval 2012 Task 2 website[5]. In this dataset, 79 ranked list of word pairs are provided, each of which corresponds to a particular relation. For each relation, we first split the associated ranking into 60% training, 20% tuning, and 20% testing (i.e. we randomly select 60% of the word pairs and use their ranking as training data, and similar for tuning and test data). We then train a linear SVM regression model on the ranked word pairs. Note that this task slightly differs from the task that was considered at SemEval 2012, to allow us to use an SVM based model for consistency with the rest of the paper.

We report results using Spearman's ρ in Table 4. Our model again outperforms the baselines, with R^2_{ik} again being the best variant. Interestingly, in this case, the Avg baseline is considerably stronger than Diff and Conc. Intuitively, we might indeed expect that this ranking problem requires a more fine-grained representation than the relation induction setting. Note that the Diff representations were found to achieve near state-of-the-art performance on a closely related task in (Zhila et al., 2013). The only model that was found to perform (slightly) better was a hybrid model, combining Diff representations with linguistic patterns (inspired by (Rink and Harabagiu, 2012)) and lexical databases, among others.

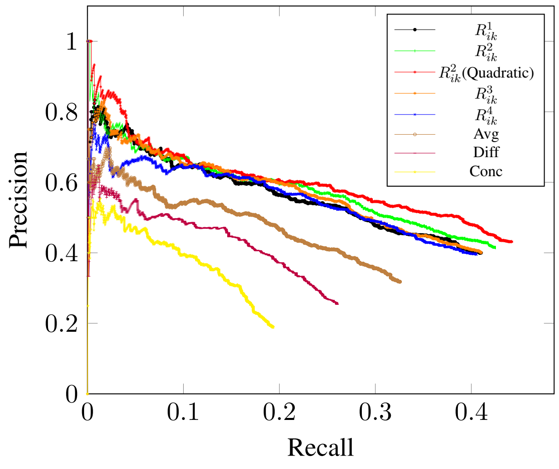

Figure 1: Results for the relation extraction from the NYT corpus: comparison with the main baselines.

5.3 Relation Extraction

Finally, we consider the problem of relation extraction from a text corpus. Specifically, we consider the task proposed in (Riedel et al., 2010), which is to extract (subject,predicate,object) triples from the New York Times (NYT) corpus. Rather than having labelled sentences as training data, the task requires using the existing triples from Freebase as a form of distant supervision, i.e. for some pairs of entities we know some of the relations that hold between them, but not which sentences assert these relationships (if any). To be consistent with published results for this task, we have used a word embedding that was trained from the NYT corpus[6], rather than Wikipedia (using the same preprocessing and set-up). We have used the training and test data that was shared publicly for this task[7], which consist of sentences from articles published in 2005-2006 and in 2007, respectively. Each of these sentences contains two entities, which are already linked to Freebase. We learn relation vectors from the sentences in the training and test sets, and learn a linear SVM classifier based on the Freebase triples that are available in the training set. Initially, we split the training data into 75% training and 25% tuning to find the optimal parameters of the linear SVM model. We tuned the parameters for each test fold sepa-

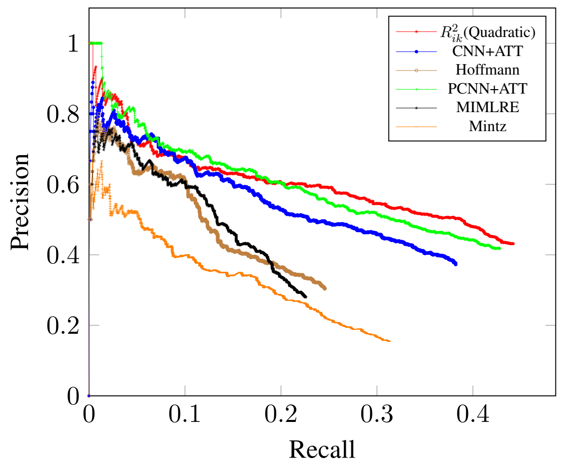

Figure 2: Results for the relation extraction from the NYT corpus: comparison with state-of-the-art neural network models.

rately. For each test fold, we used 25% of the 9 training folds as tuning data. After the optimal parameters have been determined, we retrain the model on the full training data, and apply it on the test fold. We used this approach (rather than e.g. fixing a train/tune/test split) because the total number of examples for some of the relations is very small. After tuning, we re-train the SVM models on the full training data. As the number of training examples is larger for this task, we also consider SVMs with a quadratic kernel.

Following earlier work on this task, we report our results on the test set as a precision-recall graph in Figure 1. This shows that the best performance is again achieved by R^2_{ik}, especially for larger recall values. Furthermore, using a quadratic kernel (only shown for R^2_{ik}) outperforms the linear SVM models. Note that the differences between the baselines are more pronounced in this task, with Avg being clearly better than Diff, which is in turn better than Conc. For this relation extraction task, a large number of methods have already been proposed in the literature, with variants of convolutional neural network models with attention mechanisms achieving state-of-the-art performance[8]. A comparison with these models[9] is shown in Figure 2. The performance of R^2_{ik} is comparable with the state-of-the-art PCNN+ATT model (Lin et al., 2016), outperforming it for larger recall values. This is remarkable, as our model is conceptually much simpler, and has not been specifically tuned for this task. For instance, it could easily be improved by incorporating the attention mechanism from the PCNN+ATT model to focus the relation vectors on the considered task. Similarly, we could consider a supervised variant of (3), in which a learned relation-specific weight is added to each term.

[8]Note that such models would not be suitable for the evaluation tasks in Sections 5.1 and 5.2, due to the very limited number of training examples.

[9]Results for the neural network models have been obtained from `https://github.com/thunlp/TensorFlow-NRE/tree/master/data`.

6 Conclusions

We have proposed an unsupervised method which uses co-occurrences statistics to represent the relationship between a given pair of words as a vector. In contrast to neural network models for relation extraction, our model learns relation vectors in an unsupervised way, which means that it can be used for measuring relational similarities and related tasks. Moreover, even in (distantly) supervised tasks (where we need to learn a classifier on top of the unsupervised relation vectors), our model has proven competitive with state-of-the-art neural network models. Compared to approaches that rely on averaging word vectors, our method is able to learn more faithful representations by focusing on the words that are most strongly related to the considered relationship.

Abstract

Semantic specialization of distributional word vectors, referred to as *retrofitting*, is a process of fine-tuning word vectors using external lexical knowledge in order to better embed some semantic relation. Existing retrofitting models integrate linguistic constraints directly into learning objectives and, consequently, specialize only the vectors of words from the constraints. In this work, in contrast, we transform external lexico-semantic relations into training examples which we use to learn an *explicit retrofitting model (ER)*. The ER model allows us to learn a global specialization function and specialize the vectors of words unobserved in the training data as well. We report large gains over original distributional vector spaces in (1) intrinsic word similarity evaluation and on (2) two downstream tasks – *lexical simplification* and *dialog state tracking*. Finally, we also successfully specialize vector spaces of new languages (i.e., unseen in the training data) by coupling ER with shared multilingual distributional vector spaces.

1 Introduction

Algebraic modeling of word vector spaces is one of the core research areas in modern Natural Language Processing (NLP) and its usefulness has been shown across a wide variety of NLP tasks (Collobert et al., 2011; Chen and Manning, 2014; Melamud et al., 2016). Commonly employed *distributional* models for word vector induction are based on the distributional hypothesis (Harris, 1954), i.e., they rely on word co-occurrences obtained from large text corpora (Mikolov et al., 2013b; Pennington et al., 2014; Levy and Goldberg, 2014a; Levy et al., 2015; Bojanowski et al., 2017).

The dependence on purely distributional knowledge results in a well-known tendency of fusing semantic similarity with other types of semantic relatedness (Hill et al., 2015; Schwartz et al., 2015) in the induced vector spaces. Consequently, the similarity between distributional vectors indicates just an abstract semantic association and not a precise semantic relation (Yih et al., 2012; Mohammad et al., 2013). For example, it is difficult to discern synonyms from antonyms in distributional spaces. This property has a particularly negative effect on NLP applications like text simplification and statistical dialog modeling, in which discerning semantic similarity from other types of semantic relatedness is pivotal to the system performance (Glavaš and Štajner, 2015; Faruqui et al., 2015; Mrkšić et al., 2016; Kim et al., 2016b).

A standard solution is to move beyond purely unsupervised learning of word representations, in a process referred to as *word vector space specialization* or *retrofitting*. Specialization models leverage external lexical knowledge from lexical resources, such as WordNet (Fellbaum, 1998), the Paraphrase Database (Ganitkevitch et al., 2013), or BabelNet (Navigli and Ponzetto, 2012), to *specialize* distributional spaces for a particular lexical relation, e.g., synonymy (Faruqui et al., 2015; Mrkšić et al., 2017) or hypernymy (Glavaš and Ponzetto, 2017). External constraints are commonly pairs of words between which a particular relation holds.

Existing specialization methods exploit the external linguistic constraints in two prominent ways: (1) *joint specialization* models modify the learning objective of the original distributional model by integrating the constraints into it (Yu and Dredze, 2014; Kiela et al., 2015; Nguyen et al., 2016, *inter alia*); (2) *post-processing* models fine-tune distributional vectors retroactively after training to satisfy the external constraints (Faruqui et al., 2015;

Mrkšić et al., 2017, *inter alia*). The latter, in general, outperform the former (Mrkšić et al., 2016). Retrofitting models can be applied to arbitrary distributional spaces but they suffer from a major limitation – they *locally* update only vectors of words present in the external constraints, whereas vectors of all other (unseen) words remain intact. In contrast, joint specialization models propagate the external signal to all words via the joint objective.

In this paper, we propose a new approach for specializing word vectors that unifies the strengths of both prior strategies, while mitigating their limitations. Same as retrofitting models, our novel framework, termed *explicit retrofitting (ER)*, is applicable to *arbitrary* distributional spaces. At the same time, the method learns an *explicit global specialization* function that can specialize vectors for *all* vocabulary words, similar as in joint models. Yet, unlike the joint models, ER does not require expensive re-training on large text corpora, but is directly applied on top of any pre-trained vector space. The key idea of ER is to directly learn a specialization function in a *supervised* setting, using lexical constraints as *training instances*. In other words, our model, implemented as a deep feed-forward neural architecture, learns a (non-linear) function which "translates" word vectors from the distributional space into the specialized space.

We show that the proposed ER approach yields considerable gains over distributional spaces in word similarity evaluation on standard benchmarks (Hill et al., 2015; Gerz et al., 2016), as well as in two downstream tasks – lexical simplification and dialog state tracking. Furthermore, we show that, by coupling the ER model with shared multilingual embedding spaces (Mikolov et al., 2013a; Smith et al., 2017), we can also specialize distributional spaces for languages unseen in the training data in a zero-shot language transfer setup. In other words, we show that an explicit retrofitting model trained with external constraints from one language can be successfully used to specialize the distributional space of another language.

2 Related Work

The importance of vector space specialization for downstream tasks has been observed, *inter alia*, for dialog state tracking (Mrkšić et al., 2017; Vulić et al., 2017b), spoken language understanding (Kim et al., 2016b,a), judging lexical entailment (Nguyen et al., 2017; Glavaš and Ponzetto, 2017; Vulić and Mrkšić, 2017), lexical contrast modeling (Nguyen et al., 2016), and cross-lingual transfer of lexical resources (Vulić et al., 2017a). A common goal pertaining to all retrofitting models is to pull the vectors of similar words (e.g., synonyms) closer together, while some models also push the vectors of dissimilar words (e.g., antonyms) further apart. The specialization methods fall into two categories: (1) joint specialization methods, and (2) post-processing (i.e., retrofitting) methods. Methods from both categories make use of similar lexical resources – they typically leverage WordNet (Fellbaum, 1998), FrameNet (Baker et al., 1998), the Paraphrase Database (PPDB) (Ganitkevitch et al., 2013; Pavlick et al., 2015), morphological lexicons (Cotterell et al., 2016), or simple hand-crafted linguistic rules (Vulić et al., 2017b). In what follows, we discuss the two model categories.

Joint Specialization Models. These models integrate external constraints into the distributional training procedure of general word embedding algorithms such as CBOW, Skip-Gram (Mikolov et al., 2013b), or Canonical Correlation Analysis (Dhillon et al., 2015). They modify the prior or the regularization of the original objective (Yu and Dredze, 2014; Xu et al., 2014; Bian et al., 2014; Kiela et al., 2015) or integrate the constraints directly into the, e.g., an SGNS- or CBOW-style objective (Liu et al., 2015; Ono et al., 2015; Bollegala et al., 2016; Osborne et al., 2016; Nguyen et al., 2016, 2017). Besides generally displaying lower performance compared to retrofitting methods (Mrkšić et al., 2016), these models are also tied to the distributional objective and any change of the underlying distributional model induces a change of the entire joint model. This makes them less versatile than the retrofitting methods.

Post-Processing Models. Models from the popularly termed *retrofitting* family inject lexical knowledge from external resources into arbitrary pre-trained word vectors (Faruqui et al., 2015; Jauhar et al., 2015; Rothe and Schütze, 2015; Wieting et al., 2015; Nguyen et al., 2016; Mrkšić et al., 2016). These models fine-tune the vectors of words present in the linguistic constraints to reflect the ground-truth lexical knowledge. While the large majority of specialization models from both classes operate only with similarity constraints, a line of recent work (Mrkšić et al., 2016; Mrkšić et al., 2017; Vulić et al., 2017b) demonstrates that knowledge about both similar and dissimilar words leads to improved performance in downstream tasks. The main shortcoming of the existing retrofitting models is their inability to specialize vectors of words unseen in external lexical resources.

Our explicit retrofitting framework brings together desirable properties of both model classes: (1) unlike joint models, it does not require adaptation to the underlying distributional model and expensive re-training, i.e., it is applicable to any pre-trained distributional space; (2) it allows for easy integration of both similarity and dissimilarity constraints into the specialization process; and (3) unlike post-processors, it specializes the full vocabulary of the original distributional space and not only vectors of words from external constraints.

3 Explicit Retrofitting

Our explicit retrofitting (ER) approach, illustrated by Figure 1a, consists of two major components: (1) an algorithm for preparing training instances from external lexical constraints, and (2) a supervised specialization model, based on a deep feed-forward neural network. This network, shown in Figure 1b learns a non-linear global specialization function from the training instances.

3.1 From Constraints to Training Instances

Let $\mathbf{X} = \{\mathbf{x}_i\}_{i=1}^{N}$, $\mathbf{x}_i \in \mathbb{R}^d$ be the d-dimensional distributional vector space that we want to specialize (with $V = \{w_i\}_{i=1}^{N}$ referring to the associated vocabulary) and let $\mathbf{X}' = \{\mathbf{x}'_i\}_{i=1}^{N}$ be the corresponding specialized vector space that we seek to obtain through explicit retrofitting. Let $\mathbf{C} = \{(w_i, w_j, r)_l\}_{l=1}^{L}$ be the set of L linguistic constraints from an external lexical resource, each consisting of a pair of vocabulary words w_i and w_j and a semantic relation r that holds between them. The most recent state-of-the-art retrofitting work (Mrkšić et al., 2017; Vulić et al., 2017b) suggests that using both similarity and dissimilarity constraints leads to better performance compared to using only similarity constraints. Therefore, we use synonymy and antonymy relations from external resources, i.e., $r_l \in \{ant, syn\}$. Let g be the function measuring the distance between words w_i and w_j based on their vector representations. The algorithm for preparing training instances from constraints is guided by the following assumptions:

1. All synonymy pairs (w_i, w_j, syn) should have a minimal possible distance score in the specialized space, i.e., $g(\mathbf{x}'_i, \mathbf{x}'_j) = g_{min}$;[1]
2. All antonymy pairs (w_i, w_j, ant) should have a maximal distance in the specialized space, i.e., $g(\mathbf{x}'_i, \mathbf{x}'_j) = g_{max}$;[2]
3. The distances $g(\mathbf{x}'_i, \mathbf{x}'_k)$ in the specialized space between some word w_i and all other words w_k that are not synonyms or antonyms of w_i should be in the interval (g_{min}, g_{max}).

Our goal is to discern semantic similarity from semantic relatedness by comparing, in the specialized space, the distances between word pairs $(w_i, w_j, r) \in \mathbf{C}$ with distances that words w_i and w_j from those pairs have with other vocabulary words w_m. It is intuitive to enforce that the synonyms are as close as possible and antonyms as far as possible. However, we do not know what the distances between non-synonymous and non-antonymous words $g(\mathbf{x}'_i, \mathbf{x}_m)$ in the specialized space should look like. This is why, for all other words, similar to (Faruqui et al., 2016; Mrkšić et al., 2017), we assume that the distances in the specialized space for all word pairs not found in C should stay the same as in the distributional space: $g(\mathbf{x}'_i, \mathbf{x}'_m) = g(\mathbf{x}_i, \mathbf{x}_m)$. This way we preserve the useful semantic content available in the original distributional space.

In downstream tasks most errors stem from vectors of semantically related words (e.g., *car – driver*) being as similar as vectors of semantically similar words (e.g., *car – automobile*). To anticipate this, we compare the distances of pairs $(w_i, w_j, r) \in \mathbf{C}$ with the distances for pairs (w_i, w_m) and (w_j, w_n), where w_m and w_n are *negative examples*: the vocabulary words that are *most similar* to w_i and w_j, respectively, in the original distributional space $\mathbf{X}$. Concretely, for each constraint $(w_i, w_j, r) \in \mathbf{C}$ we retrieve (1) K vocabulary words $\{w_m^k\}_{k=1}^{K}$ that are closest in the input distributional space (according to the distance function g) to the word w_i and (2) K vocabulary words $\{w_n^k\}_{k=1}^{K}$ that are closest to the word w_j. We then create, for each constraint $(w_i, w_j, r) \in \mathbf{C}$, a corresponding set M (termed *micro-batch*) of $2K+1$ embedding pairs coupled with a corresponding distance in the input distributional space:

[1]The minimal distance value is $g_{min} = 0$ for, e.g., cosine distance or Euclidean distance.

[2]While some distance functions do have a theoretical maximum (e.g., $g_{max} = 2$ for cosine distance), others (e.g., Euclidean distance) may be theoretically unbounded. For unbounded distance measures, we propose using the maximal distance between any two words from the vocabulary as g_{max}.

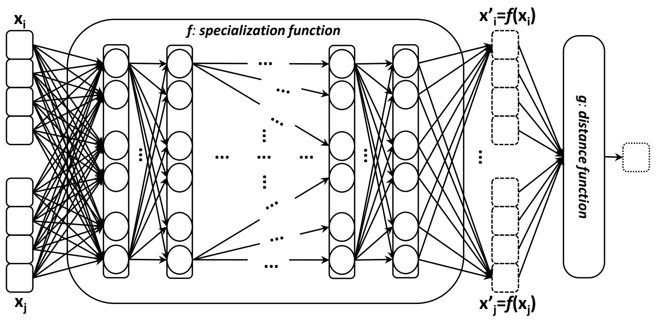
(a) Illustration of the explicit retrofitting approach



(b) Supervised specialization model

Figure 1: **(a)** High-level illustration of the explicit retrofitting approach: lexical constraints, i.e., pairs of synonyms and antonyms, are transformed into respective micro-batches, which are then used to train the supervised specialization model. **(b)** The low-level implementation of the specialization model, combining the non-linear embedding specialization function f, defined as the deep fully-connected feed-forward network, with the distance metric g, measuring the distance between word vectors after their specialization.

$$
\begin{aligned}
M(w_i, w_j, r) = \{(\mathbf{x}_i, \mathbf{x}_j, g_r)\} \; \cup \\
\{(\mathbf{x}_i, \mathbf{x}_m^k, g(\mathbf{x}_i, \mathbf{x}_m^k))\}_{k=1}^{K} \; \cup \\
\{(\mathbf{x}_j, \mathbf{x}_n^k, g(\mathbf{x}_j, \mathbf{x}_n^k))\}_{k=1}^{K}
\end{aligned} \quad (1)
$$

with $g_r = g_{min}$ if $r = syn$; $g_r = g_{max}$ if $r = ant$.

3.2 Non-Linear Specialization Function

Our retrofitting framework learns a global *explicit specialization function* which, when applied on a distributional vector space, transforms it into a space that better captures semantic similarity, i.e., discerns similarity from all other types of semantic relatedness. We seek the optimal parameters θ of the parametrized function $f(\mathbf{x}; \theta) : \mathbb{R}^d \rightarrow \mathbb{R}^d$ (where d is the dimensionality of the input space). The specialized embedding $\mathbf{x'}_i$ of the word w_i is then obtained as $\mathbf{x'}_i = f(\mathbf{x}_i; \theta)$. The specialized space $\mathbf{X'}$ is obtained by transforming distributional vectors of *all* vocabulary words, $\mathbf{X'} = f(\mathbf{X}; \theta)$.

We define the specialization function f to be a multi-layer fully-connected feed-forward network with H hidden layers and non-linear activations ϕ. The illustration of this network is given in Figure 1b. The i-th hidden layer is defined with a weight matrix $\mathbf{W}^i$ and a bias vector $\mathbf{b}^i$:

$$
h^i(\mathbf{x}; \theta_i) = \phi\left(h^{i-1}(\mathbf{x}; \theta_{i-1})\mathbf{W}^i + \mathbf{b}^i\right) \quad (2)
$$

where θ_i is the subset of network's parameters up to the i-th layer. Note that in this notation, $\mathbf{x} = h^0(\mathbf{x}; \emptyset)$ and $\mathbf{x'} = f(\mathbf{x}, \theta) = h^H(\mathbf{x}; \theta)$. Let d_h be the size of the hidden layers. The network's parameters are then as follows: $\mathbf{W}^1 \in \mathbb{R}^{d \times d_h}$; $\mathbf{W}^i \in \mathbb{R}^{d_h \times d_h}$, $i \in \{2, \dots, H-1\}$; $\mathbf{W}^H \in \mathbb{R}^{d_h \times d}$; $\mathbf{b}^i \in \mathbb{R}^{d_h}$, $i \in \{1, \dots, H-1\}$; $\mathbf{b}^H \in \mathbb{R}^d$.

3.3 Optimization Objectives

We feed the micro-batches consisting of $2K+1$ training instances to the specialization model (see Section 3.1). Each training instance consists of a pair of distributional (i.e., unspecialized) embedding vectors $\mathbf{x}_i$ and $\mathbf{x}_j$ and a score g denoting the desired distance between the specialized vectors $\mathbf{x'}_i$ and $\mathbf{x'}_j$ of corresponding words w_i and w_j.

Mean Square Distance Objective (ER-MSD). Let our training batch consist of N training instances, $\{(\mathbf{x}_1^i, \mathbf{x}_2^i, g^i)\}_{i=1}^N$. The simplest objective function is then the difference between the desired and obtained distances of specialized vectors:

$$
J_{MSD} = \sum_{i=1}^{N} \left(g(f(\mathbf{x}_1^i), f(\mathbf{x}_2^i)) - g^i\right)^2 \quad (3)
$$

By minimizing the MSD objective we simply force the specialization model to produce a specialized embedding space $\mathbf{X'}$ in which distances between all synonyms amount to g_{min}, distances between all antonyms amount to g_{max} and distances between all other word pairs remain the same as in the original space. The MSD objective does not leverage negative examples: it only indirectly enforces that synonym (or antonym) pairs (w_i, w_j) have smaller (or larger) distances than corresponding non-constraint word pairs (w_i, w_k) and (w_j, w_k).

Contrastive Objective (ER-CNT). An alternative to MSD is to *directly* contrast the distances of constraint pairs (i.e., antonyms and synonyms) with the distances of their corresponding negative examples, i.e., the pairs from their respective micro-batch (cf. Eq. (1) in Section 3.1). Such an objective should directly enforce that the similarity scores for synonyms (antonyms) (w_i, w_j) are larger (or smaller, for antonyms) than for pairs (w_i, w_k) and (w_j, w_k) involving the same words w_i and w_j, respectively. Let S and A be the sets of micro-batches created from synonymy and antonymy constraints. Let $M_s = \{(\mathbf{x}_1^i, \mathbf{x}_2^i, g^i)\}_{i=1}^{2K+1}$ be one micro-batch created from one synonymy constraint and let M_a be the analogous micro-batch created from one antonymy constraint. Let us then assume that the first triple (i.e., for $i = 1$) in every micro-batch corresponds to the constraint pair and the remaining $2K$ triples (i.e., for $i \in \{2, \dots, 2K+1\}$) to respective non-constraint word pairs. We then define the contrastive objective as follows:

$$J_{CNT} = \sum_{M_s \in S} \sum_{i=2}^{2K+1} \left((g^i - g_{min}) - ({g'}^i - {g'}^1) \right)^2 + \sum_{M_a \in A} \sum_{i=2}^{2K+1} \left((g_{max} - g^i) - ({g'}^1 - {g'}^i) \right)^2$$

where g' is a short-hand notation for the distance between vectors in the specialized space, i.e., $g'(\mathbf{x}_1, \mathbf{x}_2) = g(\mathbf{x}'_1, \mathbf{x}'_2) = g(f(\mathbf{x}_1), f(\mathbf{x}_2))$.

Topological Regularization. Because the distributional space $\mathbf{X}$ already contains useful semantic information, we want our specialized space $\mathbf{X}'$ to move similar words closer together and dissimilar words further apart, but without disrupting the overall topology of $\mathbf{X}$. To this end, we define an additional regularization objective that measures the distance between the original vectors $\mathbf{x}_1$ and $\mathbf{x}_2$ and their specialized counterparts $\mathbf{x}'_1 = f(\mathbf{x}_1)$ and $\mathbf{x}'_2 = f(\mathbf{x}_2)$, for all examples in the training set:

$$J_{REG} = \sum_{i=1}^{N} g(\mathbf{x}_1^i, f(\mathbf{x}_1^i)) + g(\mathbf{x}_2^i, f(\mathbf{x}_2^i)) \tag{4}$$

We minimize the final objective function $J' = J + \lambda J_{REG}$. J is either J_{MSD} or J_{CNT} and λ is the regularization factor which determines how strictly we retain the topology of the original space.

4 Experimental Setup

Distributional Vectors. In order to estimate the robustness of the proposed explicit retrofitting procedure, we experiment with three different publicly available and widely used collections of pre-trained distributional vectors for English: (1) SGNS-W2 – vectors trained on the Wikipedia dump from the Polyglot project (Al-Rfou et al., 2013) using the Skip-Gram algorithm with Negative Sampling (SGNS) (Mikolov et al., 2013b) by Levy and Goldberg (2014b), using the context windows of size 2; (2) GLOVE-CC – vectors trained with the GloVe (Pennington et al., 2014) model on the Common Crawl; and (3) FASTTEXT – vectors trained on Wikipedia with a variant of SGNS that builds word vectors by summing the vectors of their constituent character n-grams (Bojanowski et al., 2017).

Linguistic Constraints. We experiment with the sets of linguistic constraints used in prior work (Zhang et al., 2014; Ono et al., 2015). These constraints, extracted from WordNet (Fellbaum, 1998) and Roget's Thesaurus (Kipfer, 2009), comprise a total of 1,023,082 synonymy word pairs and 380,873 antonymy word pairs.

Although this seems like a large number of linguistic constraints, there is only 57,320 unique words in all synonymy and antonymy constraints combined, and not all of these words are found in the dictionary of the pre-trained distributional vector space. For example, only 15.3% of the words from constraints are found in the whole vocabulary of SGNS-W2 embeddings. Similarly, we find only 13.3% and 14.6% constraint words among the 200K most frequent words from the GLOVE-CC and FASTTEXT vocabularies, respectively. This low coverage emphasizes the core limitation of current retrofitting methods, being able to specialize only the vectors of words seen in the external constraints, and the need for our global ER method which can specialize all word vectors from the distributional space.

ER Model Configuration. In all experiments, we set the distance function g to cosine distance: $g(\mathbf{x}_1, \mathbf{x}_2) = 1 - (\mathbf{x}_1 \cdot \mathbf{x}_2 / (\|\mathbf{x}_1\| \|\mathbf{x}_2\|))$ and use the hyperbolic tangent as activation, $\phi = \tanh$. For each constraint (w_i, w_j), we create $K = 4$ corresponding negative examples for both w_i and w_j, resulting in micro-batches with $2K + 1 = 9$ training instances.[3] We separate 10% of the created micro-batches as the validation set. We then tune the hyper-parameter values, the number of hidden layers $H = 5$ and their size $d_h = 1000$, and the

[3]For $K < 4$ we observed significant performance drop. Setting $K > 4$ resulted in negligible performance gains but significantly increased the model training time.

topological regularization factor $\lambda = 0.3$ by minimizing the model's objective J' on the validation set. We train the model in mini-batches, each containing $N_b = 100$ constraints (i.e., 900 training instances, see above), using the Adam optimizer (Kingma and Ba, 2015) with initial learning rate set to 10^{-4}. We use the loss on the validation set as the early stopping criteria.

5 Results and Discussion

5.1 Word Similarity

Evaluation Setup. We first evaluate the quality of the explicitly retrofitted embedding spaces intrinsically, on two word similarity benchmarks: SimLex-999 dataset (Hill et al., 2015) and SimVerb-3500 (Gerz et al., 2016), a recent dataset containing human similarity ratings for 3,500 verb pairs.[4] We use Spearman's ρ rank correlation between gold and predicted word pair scores as the evaluation metric. We evaluate the specialized embedding spaces in two settings. In the first setting, termed *lexically disjoint*, we remove from our training set all linguistic constraints that contain any of the words found in SimLex or SimVerb. This way, we effectively evaluate the model's ability to generalize the specialization function to *unseen* words. In the second setting (*lexical overlap*) we retain the constraints containing SimLex or SimVerb words in the training set. For comparison, we also report performance of the state-of-the-art local retrofitting model ATTRACT-REPEL (Mrkšić et al., 2017), which is able to specialize only the words from the linguistic constraints.

Results. The results with our ER model applied to three distributional spaces are shown in Table 1. The scores suggest that the proposed ER model is universally useful and robust. The ER-specialized spaces outperform original distributional spaces across the board, for both objective functions. The results in the *lexically disjoint* setting are especially indicative of the improvements achieved by the ER. For example, we achieve a correlation gain of 18% for the GLOVE-CC vectors on SimLex using a specialization function learned *without* seeing a single constraint with any SimLex word.

[4]Other word similarity datasets such as MEN (Bruni et al., 2014) or WordSim-353 (Finkelstein et al., 2002) conflate the concepts of true semantic similarity and semantic relatedness in a broader sense. In contrast, SimLex and SimVerb explicitly discern between the two, with pairs of semantically related but not similar words (e.g. *car* and *wheel*) having low ratings.

In the *lexical overlap* setting, we observe substantial gains only for GLOVE-CC. The modest gains in this setting with FASTTEXT and SGNS-W2 in fact strengthen the impression that the ER model learns a *general* specialization function, i.e., it does not "overfit" to words from linguistic constraints. The ER model with the contrastive objective (ER-CNT) yields better performance on average than the one using the simpler square distance objective (ER-MSD). This is expected, given that the contrastive objective enforces the model to distinguish pairs of semantically (dis)similar words from pairs of semantically related words.

Finally, the post-processing ATTRACT-REPEL model based on local vector updates seems to substantially outperform the ER method in this task. The gap is especially visible for FASTTEXT and SGNS-W2 vectors. However, since ATTRACT-REPEL specializes only words seen in linguistic constraints,[5] its performance crucially depends on the coverage of test set words in the constraints. ATTRACT-REPEL excels on the intrinsic evaluation as the constraints cover 99.2% of SimLex words and 99.9% of SimVerb words. However, its usefulness is less pronounced in real-life downstream scenarios in which such high coverage cannot be guaranteed, as demonstrated in Section 5.3.

Analysis. We examine in more detail the performance of the ER model with respect to (1) the type of constraints used for training the model: synonyms and antonyms, only synonyms, or only antonyms and (2) the extent to which we retain the topology of the original distributional space (i.e., with respect to the value of the topological regularization factor λ). All reported results were obtained by specializing the GLOVE-CC distributional space in the *lexically disjoint* setting (i.e., employed constraints did not contain any of the SimLex or SimVerb words).

In Table 2 we show the specialization performance of the ER-CNT models ($H = 5$, $\lambda = 0.3$), using different types of constraints on SimLex-999 (SL) and SimVerb-3500 (SV). We compare the standard model, which exploits both synonym and antonym pairs for creating training instances, with the models employing only synonym and only antonym constraints, respectively. Clearly, we obtain the best specialization when combining synonyms and antonyms. Note, however, that using

[5]This is why ATTRACT-REPEL cannot be applied in the *lexically disjoint* setting: the scores simply stay the same.

only synonyms or only antonyms also improves over the original distributional space.

Next, in Figure 2 we depict the specialization performance (on SimLex and SimVerb) of the ER models with different values of the topology regularization factor λ (H fixed to 5). The best performance for is obtained for $\lambda = 0.3$. Smaller lambda values overly distort the original distributional space, whereas larger lambda values dampen the specialization effects of linguistic constraints.

5.2 Language Transfer

Readily available large collections of synonymy and antonymy word pairs do not exist for many languages. This is why we also investigate *zero-shot specialization*: we test if it is possible, with the help of cross-lingual word embeddings, to transfer the specialization knowledge learned from English constraints to languages without any training data.

Evaluation Setup. We use the mapping model of Smith et al. (2017) to induce a multilingual vec-

Model	German	Italian	Croatian

tor space[6] containing word vectors of three other languages – German, Italian, and Croatian – along with the English vectors.[7] Concretely, we map the Italian CBOW vectors (Dinu et al., 2015), German FastText vectors trained on German Wikipedia (Bojanowski et al., 2017), and Croatian Skip-Gram vectors trained on HrWaC corpus (Ljubešić and Erjavec, 2011) to the GLOVE-CC English space. We create the translation pairs needed to learn the projections by automatically translating 4,000 most frequent English words to all three other languages with Google Translate. We then employ the ER model trained to specialize the GLOVE-CC space using the full set of English constraints, to specialize the distributional spaces of other languages. We evaluate the quality of the specialized spaces on the respective SimLex-999 dataset for each language (Leviant and Reichart, 2015; Mrkšić et al., 2017).

Results. The results are provided in Table 3. They indicate that the ER models can substantially improve (e.g., by 13% for German vector space) over distributional spaces also in the language transfer setup without seeing a single constraint in the target language. These transfer results hold promise to support vector space specialization

[6]This model was chosen for its ease of use, readily available implementation, and strong comparative results (see (Ruder et al., 2017)). For more details we refer the reader to the original paper and the survey.

[7]The choice of languages was determined by the availability of the language-specific SimLex-999 variants.

even for resource-lean languages. The more sophisticated contrastive ER-CNT model variant again outperforms the simpler ER-MSD variant, and it does so for all three languages, which is consistent with the findings from the monolingual English experiments (see Table 1).

5.3 Downstream Tasks

We now evaluate the impact of our global ER method on two downstream tasks in which differentiating semantic similarity from semantic relatedness is particularly important: lexical text simplification (LS) and dialog state tracking (DST).

5.3.1 Lexical Text Simplification

Lexical simplification aims to replace complex words – used less frequently and known to fewer speakers – with their simpler synonyms that fit into the context, that is, without changing the meaning of the original text. Because retaining the meaning of the original text is a strict requirement, complex words need to be replaced with semantically similar words, whereas replacements with semantically related words (e.g., replacing *"pilot"* with *"airplane"* in *"Ferrari's pilot won the race"*) produce incorrect text which is more difficult to comprehend.

Simplification Using Distributional Vectors. We use the LIGHT-LS lexical simplification algorithm of Glavaš and Štajner (2015) which makes the word replacement decisions primarily based on semantic similarities between words in a distributional vector space.[8] For each word in the input text LIGHT-LS retrieves most similar replacement candidates from the vector space. The candidates are then ranked according to several measures of simplicity and fitness for the context. Finally, the replacement is made if the top-ranked candidate is estimated to be simpler than the original word. By plugging-in vector spaces specialized by the ER model into LIGHT-LS, we hope to generate true synonymous candidates more frequently than with the unspecialized distributional space.

Evaluation Setup. We evaluate LIGHT-LS on the LS dataset crowdsourced by Horn et al. (2014). For each indicated complex word Horn et al. (2014) collected 50 manual simplifications. We use two evaluation metrics from prior work (Horn et al., 2014; Glavaš and Štajner, 2015) to quantify the quality and frequency of word replacements: (1)

[8]The Light-LS implementation is available at: https://bitbucket.org/gg42554/embesimp

	GLOVE-CC		FASTTEXT		SGNS-W2	
Emb. space	A	C	A	C	A	C
Distributional	66.0	**94.0**	57.8	84.0	56.0	79.1
Specialized						
ATTRACT-REPEL	67.6	87.0	69.8	89.4	64.4	86.7
ER-CNT	**73.8**	93.0	**71.2**	**93.2**	**68.4**	**92.3**

Table 4: Lexical simplification performance with explicit retrofitting applied on three input spaces.

accurracy (A) is the number of correct simplifications made (i.e., when the replacement made by the system is found in the list of manual replacements) divided by the total number of indicated complex words; and (2) *change* (C) is the percentage of indicated complex words that were replaced by the system (regardless of whether the replacement was correct). We plug into LIGHT-LS both unspecialized and specialized variants of three previously used English embedding spaces: GLOVE-CC, FASTTEXT, and SGNS-W2. Additionally, we again evaluate specializations of the same spaces produced by the state-of-the-art local retrofitting model ATTRACT-REPEL (Mrkšić et al., 2017).

Results and Analysis. The results with LIGHT-LS are summarized in Table 4. ER-CNT model yields considerable gains over unspecialized spaces for both metrics. This suggests that the ER-specialized embedding spaces allow LIGHT-LS to generate true synonymous candidate replacements more often than with unspecialized spaces, and also verifies the importance of specialization for the LS task. Our ER-CNT model now also yields better results than ATTRACT-REPEL in a real-world downstream task. Only 59.6 % of all indicated complex words and manual replacement candidates from the LS dataset are now covered by the linguistic constraints. This accentuates the need to specialize the full distributional space in downstream applications as done by the ER model, while ATTRACT-REPEL is limited to local vector updates only of words seen in the constraints. By learning a global specialization function the proposed ER models seem more resilient to the observed drop in coverage of test words by linguistic constraints. Table 5 shows example substitutions of LIGHT-LS when using different embedding spaces: original GLOVE-CC space and its specializations obtained with ER-CNT and ATTRACT-REPEL.

5.3.2 Dialog State Tracking

Finally, we also evaluate the importance of explicit retrofitting in a downstream language understand-

Table 6: DST performance of GloVe-CC embeddings specialized using explicit retrofitting.

ing task, namely dialog state tracking (DST) (Henderson et al., 2014; Williams et al., 2016). A DST model is typically the first component of a dialog system pipeline (Young, 2010), tasked with capturing user's goals and updating the dialog state at each dialog turn. Similarly as in lexical simplification, discerning similarity from relatedness is crucial in DST (e.g., a dialog system should not recommend an *"expensive pub in the south"* when asked for a *"cheap bar in the east"*).

Evaluation Setup. To evaluate the impact of specialized word vectors on DST, we employ the Neural Belief Tracker (NBT), a DST model that makes inferences purely based on pre-trained word vectors (Mrkšić et al., 2017).[9] NBT composes word embeddings into intermediate utterance and context representations. For full model details, we refer the reader to the original paper. Following prior work, our DST evaluation is based on the Wizard-of-Oz (WOZ) v2.0 dataset (Wen et al., 2017; Mrkšić et al., 2017) which contains 1,200 dialogs (600 training, 200 validation, and 400 test dialogs). We evaluate performance of the distributional and specialized GloVe-CC embeddings and report it in terms of *joint goal accuracy* (JGA), a standard DST evaluation metric. All reported results are averages over 5 runs of the NBT model.

Results. We show DST performance in Table 6. The DST results tell a similar story like word similarity and lexical simplification results – the ER model substantially improves over the distributional space. With linguistic specialization constraints covering 57% of words from the WOZ dataset, ER model's performance is on a par with the Attract-Repel specialization. This further confirms our hypothesis that the importance of learning a global specialization for the full vocabulary in downstream tasks grows with the drop of the test word coverage by specialization constraints.

[9]https://github.com/nmrksic/neural-belief-tracker

6 Conclusion

We presented a novel method for specializing word embeddings to better discern similarity from other types of semantic relatedness. Unlike existing retrofitting models, which directly update vectors of words from external constraints, we use the constraints as training examples to learn an explicit specialization function, implemented as a deep feed-forward neural network. Our global specialization approach resolves the well-known inability of retrofitting models to specialize vectors of words unseen in the constraints. We demonstrated the effectiveness of the proposed model on word similarity benchmarks, and in two downstream tasks: lexical simplification and dialog state tracking. We also showed that it is possible to transfer the specialization to languages without linguistic constraints.

In future work, we will investigate explicit retrofitting methods for asymmetric relations like hypernymy and meronymy. We also intend to apply the method to other downstream tasks and to investigate the zero-shot language transfer of the specialization function for more language pairs.

ER code is publicly available at: `https://github.com/codogogo/explirefit`.

Abstract

Unsupervised neural machine translation (NMT) is a recently proposed approach for machine translation which aims to train the model without using any labeled data. The models proposed for unsupervised NMT often use only one shared encoder to map the pairs of sentences from different languages to a shared-latent space, which is weak in keeping the unique and internal characteristics of each language, such as the style, terminology, and sentence structure. To address this issue, we introduce an extension by utilizing two independent encoders but sharing some partial weights which are responsible for extracting high-level representations of the input sentences. Besides, two different generative adversarial networks (GANs), namely the local GAN and global GAN, are proposed to enhance the cross-language translation. With this new approach, we achieve significant improvements on English-German, English-French and Chinese-to-English translation tasks.

1 Introduction

Neural machine translation (Kalchbrenner and Blunsom, 2013; Sutskever et al., 2014; Cho et al., 2014; Bahdanau et al., 2014), directly applying a single neural network to transform the source sentence into the target sentence, has now reached impressive performance (Shen et al., 2015; Wu et al., 2016; Johnson et al., 2016; Gehring et al., 2017; Vaswani et al., 2017). The NMT typically consists of two sub neural networks. The encoder network reads and encodes the source sentence into a context vector, and the decoder network generates the target sentence iteratively based on the context vector. NMT can be studied in supervised and unsupervised learning settings. In the supervised setting, bilingual corpora is available for training the NMT model. In the unsupervised setting, we only have two independent monolingual corpora with one for each language and there is no bilingual training example to provide alignment information for the two languages. Due to lack of alignment information, the unsupervised NMT is considered more challenging. However, this task is very promising, since the monolingual corpora is usually easy to be collected.

Motivated by recent success in unsupervised cross-lingual embeddings (Artetxe et al., 2016; Zhang et al., 2017b; Conneau et al., 2017), the models proposed for unsupervised NMT often assume that a pair of sentences from two different languages can be mapped to a same latent representation in a shared-latent space (Lample et al., 2017; Artetxe et al., 2017b). Following this assumption, Lample et al. (2017) use a single encoder and a single decoder for both the source and target languages. The encoder and decoder, acting as a standard auto-encoder (AE), are trained to reconstruct the inputs. And Artetxe et al. (2017b) utilize a shared encoder but two independent decoders. With some good performance, they share a glaring defect, i.e., only one encoder is shared by the source and target languages. Although the shared encoder is vital for mapping sentences from different languages into the shared-latent space, it is weak in keeping the uniqueness and internal characteristics of each language, such as the style, terminology and sentence structure. Since each language has its own characteristics, the source and target languages should be encoded and learned independently. Therefore, we conjecture that the shared encoder may be a factor limit-

[1]Feng Wang is the corresponding author of this paper

ing the potential translation performance.

In order to address this issue, we extend the encoder-shared model, i.e., the model with one shared encoder, by leveraging two independent encoders with each for one language. Similarly, two independent decoders are utilized. For each language, the encoder and its corresponding decoder perform an AE, where the encoder generates the latent representations from the perturbed input sentences and the decoder reconstructs the sentences from the latent representations. To map the latent representations from different languages to a shared-latent space, we propose the weight-sharing constraint to the two AEs. Specifically, we share the weights of the last few layers of two encoders that are responsible for extracting high-level representations of input sentences. Similarly, we share the weights of the first few layers of two decoders. To enforce the shared-latent space, the word embeddings are used as a reinforced encoding component in our encoders. For cross-language translation, we utilize the back-translation following (Lample et al., 2017). Additionally, two different generative adversarial networks (GAN) (Yang et al., 2017), namely the local and global GAN, are proposed to further improve the cross-language translation. We utilize the local GAN to constrain the source and target latent representations to have the same distribution, whereby the encoder tries to fool a local discriminator which is simultaneously trained to distinguish the language of a given latent representation. We apply the global GAN to finetune the corresponding generator, i.e., the composition of the encoder and decoder of the other language, where a global discriminator is leveraged to guide the training of the generator by assessing how far the generated sentence is from the true data distribution [1]. In summary, we mainly make the following contributions:

- We propose the weight-sharing constraint to unsupervised NMT, enabling the model to utilize an independent encoder for each language. To enforce the shared-latent space, we also propose the embedding-reinforced encoders and two different GANs for our model.
- We conduct extensive experiments on English-German, English-French and Chinese-to-English translation tasks. Experimental results show that the proposed approach consistently achieves great success.
- Last but not least, we introduce the directional self-attention to model temporal order information for the proposed model. Experimental results reveal that it deserves more efforts for researchers to investigate the temporal order information within self-attention layers of NMT.

2 Related Work

Several approaches have been proposed to train NMT models without direct parallel corpora. The scenario that has been widely investigated is one where two languages have little parallel data between them but are well connected by one pivot language. The most typical approach in this scenario is to independently translate from the source language to the pivot language and from the pivot language to the target language (Saha et al., 2016; Cheng et al., 2017). To improve the translation performance, Johnson et al. (2016) propose a multilingual extension of a standard NMT model and they achieve substantial improvement for language pairs without direct parallel training data.

Recently, motivated by the success of cross-lingual embeddings, researchers begin to show interests in exploring the more ambitious scenario where an NMT model is trained from monolingual corpora only. Lample et al. (2017) and Artetxe et al. (2017b) simultaneously propose an approach for this scenario, which is based on pre-trained cross lingual embeddings. Lample et al. (2017) utilizes a single encoder and a single decoder for both languages. The entire system is trained to reconstruct its perturbed input. For cross-lingual translation, they incorporate back-translation into the training procedure. Different from (Lample et al., 2017), Artetxe et al. (2017b) use two independent decoders with each for one language. The two works mentioned above both use a single shared encoder to guarantee the shared latent space. However, a concomitant defect is that the shared encoder is weak in keeping the uniqueness of each language. Our work also belongs to this more ambitious scenario, and to the best of our knowledge, we are one among the first endeavors to investigate how to train an NMT model with monolingual corpora only.

Figure 1: The architecture of the proposed model. We implement the shared-latent space assumption using a weight sharing constraint where the connection of the last few layers in Enc_s and Enc_t are tied (illustrated with dashed lines) and the connection of the first few layers in Dec_s and Dec_t are tied. $\tilde{x}_s^{Enc_s-Dec_s}$ and $\tilde{x}_t^{Enc_t-Dec_t}$ are self-reconstructed sentences in each language. $\tilde{x}_s^{Enc_s-Dec_t}$ is the translated sentence from source to target and $\tilde{x}_t^{Enc_t-Dec_s}$ is the translation in reversed direction. D_l is utilized to assess whether the hidden representation of the encoder is from the source or target language. D_{g1} and D_{g2} are used to evaluate whether the translated sentences are realistic for each language respectively. Z represents the shared-latent space.

3 The Approach

3.1 Model Architecture

The model architecture, as illustrated in figure 1, is based on the AE and GAN. It consists of seven sub networks: including two encoders Enc_s and Enc_t, two decoders Dec_s and Dec_t, the local discriminator D_l, and the global discriminators D_{g1} and D_{g2}. For the encoder and decoder, we follow the newly emerged Transformer (Vaswani et al., 2017). Specifically, the encoder is composed of a stack of four identical layers [2]. Each layer consists of a multi-head self-attention and a simple position-wise fully connected feed-forward network. The decoder is also composed of four identical layers. In addition to the two sub-layers in each encoder layer, the decoder inserts a third sublayer, which performs multi-head attention over the output of the encoder stack. For more details about the multi-head self-attention layer, we refer the reader to (Vaswani et al., 2017). We implement the local discriminator as a multi-layer perceptron and implement the global discriminator based on the convolutional neural network (CNN). Several ways exist to interpret the roles of the sub networks are summarised in table 1. The proposed system has several striking components , which are critical either for the system to be trained in an unsupervised manner or for improving the translation performance.

[2]The layer number is selected according to our preliminary experiment, which is presented in appendix **??**.

Networks	Roles
$\{Enc_s, Dec_s\}$	AE for source language
$\{Enc_t, Dec_t\}$	AE for target language
$\{Enc_s, Dec_t\}$	translation $source \rightarrow target$
$\{Enc_t, Dec_s\}$	translation $target \rightarrow source$
$\{Enc_s, D_l\}$	1st local GAN (GAN_{l1})
$\{Enc_t, D_l\}$	2nd local GAN (GAN_{l2})
$\{Enc_t, Dec_s, D_{g1}\}$	1st global GAN (GAN_{g1})
$\{Enc_s, Dec_t, D_{g2}\}$	2nd global GAN (GAN_{g2})

Table 1: Interpretation of the roles for the subnetworks in the proposed system.

Directional self-attention Compared to recurrent neural network, a disadvantage of the simple self-attention mechanism is that the temporal order information is lost. Although the Transformer applies the positional encoding to the sequence before processed by the self-attention, how to model temporal order information within an attention is still an open question. Following (Shen et al., 2017), we build the encoders in our model on the directional self-attention which utilizes the positional masks to encode temporal order information into attention output. More concretely, two positional masks, namely the forward mask M^f and backward mask M^b, are calculated as:

$$M_{ij}^f = \begin{cases} 0 & i < j \\ -\infty & otherwise \end{cases} \quad (1)$$

$$M_{ij}^b = \begin{cases} 0 & i > j \\ -\infty & otherwise \end{cases} \quad (2)$$

With the forward mask M^f, the later token only makes attention connections to the early tokens in the sequence, and vice versa with the backward mask. Similar to (Zhou et al., 2016; Wang et al., 2017), we utilize a self-attention network to process the input sequence in forward direction. The output of this layer is taken by an upper self-attention network as input, processed in the reverse direction.

Weight sharing Based on the shared-latent space assumption, we apply the weight sharing constraint to relate the two AEs. Specifically, we share the weights of the last few layers of the Enc_s and Enc_t, which are responsible for extracting high-level representations of the input sentences. Similarly, we also share the first few layers of the Dec_s and Dec_t, which are expected to decode high-level representations that are vital for reconstructing the input sentences. Compared to (Cheng et al., 2016; Saha et al., 2016) which use the fully shared encoder, we only share partial weights for the encoders and decoders. In the proposed model, the independent weights of the two encoders are expected to learn and encode the hidden features about the internal characteristics of each language, such as the terminology, style, and sentence structure. The shared weights are utilized to map the hidden features extracted by the independent weights to the shared-latent space.

Embedding reinforced encoder We use pretrained cross-lingual embeddings in the encoders that are kept fixed during training. And the fixed embeddings are used as a reinforced encoding component in our encoder. Formally, given the input sequence embedding vectors $E = \{e_1, \ldots, e_t\}$ and the initial output sequence of the encoder stack $H = \{h_1, \ldots, h_t\}$, we compute H_r as:

$$H_r = g \odot H + (1 - g) \odot E \quad (3)$$

where H_r is the final output sequence of the encoder which will be attended by the decoder (In Transformer, H is the final output of the encoder), g is a gate unit and computed as:

$$g = \sigma(W_1 E + W_2 H + b) \quad (4)$$

where W_1, W_2 and b are trainable parameters and they are shared by the two encoders. The motivation behind is twofold. Firstly, taking the fixed cross-lingual embedding as the other encoding component is helpful to reinforce the shared-latent space. Additionally, from the point of multi-channel encoders (Xiong et al., 2017), providing encoding components with different levels of composition enables the decoder to take pieces of source sentence at varying composition levels suiting its own linguistic structure.

3.2 Unsupervised Training

Based on the architecture proposed above, we train the NMT model with the monolingual corpora only using the following four strategies:

Denoising auto-encoding Firstly, we train the two AEs to reconstruct their inputs respectively. In this form, each encoder should learn to compose the embeddings of its corresponding language and each decoder is expected to learn to decompose this representation into its corresponding language. Nevertheless, without any constraint, the AE quickly learns to merely copy every word one by one, without capturing any internal structure of the language involved. To address this problem, we utilize the same strategy of denoising AE (Vincent et al., 2008) and add some noise to the input sentences (Hill et al., 2016; Artetxe et al., 2017b). To this end, we shuffle the input sentences randomly. Specifically, we apply a random permutation ε to the input sentence, verifying the condition:

$$|\varepsilon(i) - i| \leq \min(k([\frac{steps}{s}] + 1), n), \forall i \in \{1, n\} \quad (5)$$

where n is the length of the input sentence, $steps$ is the global steps the model has been updated, k and s are the tunable parameters which can be set by users beforehand. This way, the system needs to learn some useful structure of the involved languages to be able to recover the correct word order. In practice, we set $k = 2$ and $s = 100000$.

Back-translation In spite of denoising auto-encoding, the training procedure still involves a single language at each time, without considering our final goal of mapping an input sentence from the source/target language to the target/source language. For the cross language training, we utilize the back-translation approach for our unsupervised training procedure. Back-translation has shown its great effectiveness on improving NMT model with monolingual data and has been widely investigated by (Sennrich et al., 2015a; Zhang and Zong, 2016). In our approach, given an input sentence in a given language, we apply the corresponding encoder and the decoder of the other language to translate it to the other language [3]. By combining the translation with its original sentence, we get a pseudo-parallel corpus which is utilized to train the model to reconstruct the original sentence from its translation.

Local GAN Although the weight sharing constraint is vital for the shared-latent space assumption, it alone does not guarantee that the corresponding sentences in two languages will have the same or similar latent code. To further enforce the shared-latent space, we train a discriminative neural network, referred to as the local discriminator, to classify between the encoding of source sentences and the encoding of target sentences. The local discriminator, implemented as a multi-layer perceptron with two hidden layers of size 256, takes the output of the encoder, i.e., H_r calculated as equation 3, as input, and produces a binary prediction about the language of the input sentence. The local discriminator is trained to predict the language by minimizing the following cross-entropy loss:

$$\begin{aligned} L_{D_l}(\theta_{D_l}) = \\ - \mathbb{E}_{x \in x_s}[\log p(f = s|Enc_s(x))] \\ - \mathbb{E}_{x \in x_t}[\log p(f = t|Enc_t(x))] \end{aligned} \tag{6}$$

where θ_{D_l} represents the parameters of the local discriminator and $f \in \{s, t\}$. The encoders are trained to fool the local discriminator:

$$\begin{aligned} L_{Enc_s}(\theta_{Enc_s}) = \\ - \mathbb{E}_{x \in x_s}[\log p(f = t|Enc_s(x))] \end{aligned} \tag{7}$$

$$\begin{aligned} L_{Enc_t}(\theta_{Enc_t}) = \\ - \mathbb{E}_{x \in x_t}[\log p(f = s|Enc_t(x))] \end{aligned} \tag{8}$$

where θ_{Enc_s} and θ_{Enc_t} are the parameters of the two encoders.

Global GAN We apply the global GANs to fine tune the whole model so that the model is able to generate sentences undistinguishable from the true data, i.e., sentences in the training corpus. Different from the local GANs which updates the parameters of the encoders locally, the global GANs are utilized to update the whole parameters of the proposed model, including the parameters of encoders and decoders. The proposed model has two global GANs: GAN_{g1} and GAN_{g2}. In GAN_{g1}, the Enc_t and Dec_s act as the generator, which generates the sentence $\tilde{x}_t$ [4] from x_t. The D_{g1}, implemented based on CNN, assesses whether the generated sentence $\tilde{x}_t$ is the true target-language sentence or the generated sentence. The global discriminator aims to distinguish among the true sentences and generated sentences, and it is trained to minimize its classification error rate. During training, the D_{g1} feeds back its assessment to fine-tune the encoder Enc_t and decoder Dec_s. Since the machine translation is a sequence generation problem, following (Yang et al., 2017), we leverage policy gradient reinforcement training to back-propagate the assessment. We apply a similar processing to GAN_{g2} (The details about the architecture of the global discriminator and the training procedure of the global GANs can be seen in appendix **??** and **??**).

There are two stages in the proposed unsupervised training. In the first stage, we train the proposed model with denoising auto-encoding, back-translation and the local GANs, until no improvement is achieved on the development set. Specifically, we perform one batch of denoising auto-encoding for the source and target languages, one batch of back-translation for the two languages, and another batch of local GAN for the two languages. In the second stage, we fine tune the proposed model with the global GANs.

4 Experiments and Results

We evaluate the proposed approach on English-German, English-French and Chinese-to-English translation tasks [5]. We firstly describe the datasets, pre-processing and model hyper-parameters we used, then we introduce the baseline systems, and finally we present our experimental results.

4.1 Data Sets and Preprocessing

In English-German and English-French translation, we make our experiments comparable with previous work by using the datasets from the

[3]Since the quality of the translation shows little effect on the performance of the model (Sennrich et al., 2015a), we simply use greedy decoding for speed.

[4]The $\tilde{x}_t$ is $\tilde{x}_t^{Enc_t - Dec_s}$ in figure 1. We omit the superscript for simplicity.

[5]The reason that we do not conduct experiments on English-to-Chinese translation is that we do not get public test sets for English-to-Chinese.

WMT 2014 and WMT 2016 shared tasks respectively. For Chinese-to-English translation, we use the datasets from LDC, which has been widely utilized by previous works (Tu et al., 2017; Zhang et al., 2017a).

WMT14 English-French Similar to (Lample et al., 2017), we use the full training set of 36M sentence pairs and we lower-case them and remove sentences longer than 50 words, resulting in a parallel corpus of about 30M pairs of sentences. To guarantee no exact correspondence between the source and target monolingual sets, we build monolingual corpora by selecting English sentences from 15M random pairs, and selecting the French sentences from the complementary set. Sentences are encoded with byte-pair encoding (Sennrich et al., 2015b), which has an English vocabulary of about 32000 tokens, and French vocabulary of about 33000 tokens. We report results on $newstest2014$.

WMT16 English-German We follow the same procedure mentioned above to create monolingual training corpora for English-German translation, and we get two monolingual training data of 1.8M sentences each. The two languages share a vocabulary of about 32000 tokens. We report results on $newstest2016$.

LDC Chinese-English For Chinese-to-English translation, our training data consists of 1.6M sentence pairs randomly extracted from LDC corpora [6]. Since the data set is not big enough, we just build the monolingual data set by randomly shuffling the Chinese and English sentences respectively. In spite of the fact that some correspondence between examples in these two monolingual sets may exist, we never utilize this alignment information in our training procedure (see Section 3.2). Both the Chinese and English sentences are encoded with byte-pair encoding. We get an English vocabulary of about 34000 tokens, and Chinese vocabulary of about 38000 tokens. The results are reported on $NIST02$.

Since the proposed system relies on the pre-trained cross-lingual embeddings, we utilize the monolingual corpora described above to train the embeddings for each language independently by using word2vec (Mikolov et al., 2013). We then apply the public implementation [7] of the method proposed by (Artetxe et al., 2017a) to map these embeddings to a shared-latent space [8].

4.2 Model Hyper-parameters and Evaluation

Following the base model in (Vaswani et al., 2017), we set the dimension of word embedding as 512, dropout rate as 0.1 and the head number as 8. We use beam search with a beam size of 4 and length penalty $\alpha = 0.6$. The model is implemented in TensorFlow (Abadi et al., 2015) and trained on up to four K80 GPUs synchronously in a multi-GPU setup on a single machine.

For model selection, we stop training when the model achieves no improvement for the tenth evaluation on the development set, which is comprised of 3000 source and target sentences extracted randomly from the monolingual training corpora. Following (Lample et al., 2017), we translate the source sentences to the target language, and then translate the resulting sentences back to the source language. The quality of the model is then evaluated by computing the BLEU score over the original inputs and their reconstructions via this two-step translation process. The performance is finally averaged over two directions, i.e., from source to target and from target to source. BLEU (Papineni et al., 2002) is utilized as the evaluation metric. For Chinese-to-English, we apply the script *mteval-v11b.pl* to evaluate the translation performance. For English-German and English-French, we evaluate the translation performance with the script *multi-belu.pl* [9].

4.3 Baseline Systems

Word-by-word translation (WBW) The first baseline we consider is a system that performs word-by-word translations using the inferred bilingual dictionary. Specifically, it translates a sentence word-by-word, replacing each word with its nearest neighbor in the other language.

Lample et al. (2017) The second baseline is a previous work that uses the same training and testing sets with this paper. Their model belongs to the standard attention-based encoder-decoder framework, which implements the encoder using a bidirectional long short term memory network (LSTM) and implements the decoder using a simple forward LSTM. They apply one single encoder and

[8]The configuration we used to run these open-source toolkits can be found in appendix **??**

decoder for the source and target languages.

Supervised training We finally consider exactly the same model as ours, but trained using the standard cross-entropy loss on the original parallel sentences. This model can be viewed as an upper bound for the proposed unsupervised model.

4.4 Results and Analysis

4.4.1 Number of weight-sharing layers

We firstly investigate how the number of weight-sharing layers affects the translation performance. In this experiment, we vary the number of weight-sharing layers in the AEs from 0 to 4. Sharing one layer in AEs means sharing one layer for the encoders and in the meanwhile, sharing one layer for the decoders. The BLEU scores of English-to-German, English-to-French and Chinese-to-English translation tasks are reported in figure 2. Each curve corresponds to a different translation task and the x-axis denotes the number of weight-sharing layers for the AEs. We find that the number of weight-sharing layers shows much effect on the translation performance. And the best translation performance is achieved when only one layer is shared in our system. When all of the four layers are shared, i.e., only one shared encoder is utilized, we get poor translation performance in all of the three translation tasks. This verifies our conjecture that the shared encoder is detrimental to the performance of unsupervised NMT especially for the translation tasks on distant language pairs. More concretely, for the related language pair translation, i.e., English-to-French, the encoder-shared model achieves -0.53 BLEU points decline than the best model where only one layer is shared. For the more distant language pair English-to-German, the encoder-shared model achieves more significant decline, i.e., -0.85 BLEU points decline. And for the most distant language pair Chinese-to-English, the decline is as large as -1.66 BLEU points. We explain this as that the more distant the language pair is, the more different characteristics they have. And the shared encoder is weak in keeping the unique characteristic of each language. Additionally, we also notice that using two completely independent encoders, i.e., setting the number of weight-sharing layers as 0, results in poor translation performance too. This confirms our intuition that the shared layers are vital to map the source and target latent representations to a shared-latent space. In the rest of our experiments, we set the number of weight-sharing layer as 1.

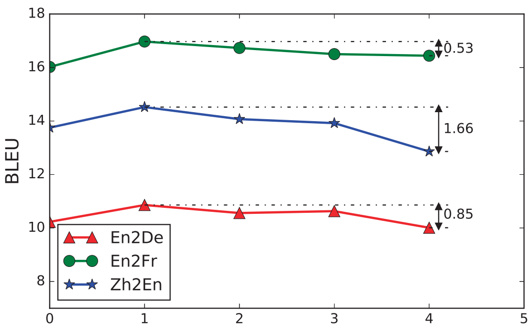

Figure 2: The effects of the weight-sharing layer number on English-to-German, English-to-French and Chinese-to-English translation tasks.

4.4.2 Translation results

Table 2 shows the BLEU scores on English-German, English-French and English-to-Chinese test sets. As it can be seen, the proposed approach obtains significant improvements than the word-by-word baseline system, with at least +5.01 BLEU points in English-to-German translation and up to +13.37 BLEU points in English-to-French translation. This shows that the proposed model only trained with monolingual data effec-

tively learns to use the context information and the internal structure of each language. Compared to the work of (Lample et al., 2017), our model also achieves up to +1.92 BLEU points improvement on English-to-French translation task. We believe that the unsupervised NMT is very promising. However, there is still a large room for improvement compared to the supervised upper bound. The gap between the supervised and unsupervised model is as large as 12.3-25.5 BLEU points depending on the language pair and translation direction.

4.4.3 Ablation study

To understand the importance of different components of the proposed system, we perform an ablation study by training multiple versions of our model with some missing components: the local GANs, the global GANs, the directional self-attention, the weight-sharing, the embedding-reinforced encoders, etc. Results are reported in table 3. We do not test the the importance of the auto-encoding, back-translation and the pre-trained embeddings because they have been widely tested in (Lample et al., 2017; Artetxe et al., 2017b). Table 3 shows that the best performance is obtained with the simultaneous use of all the tested elements. The most critical component is the weight-sharing constraint, which is vital to map sentences of different languages to the shared-latent space. The embedding-reinforced encoder also brings some improvement on all of the translation tasks. When we remove the directional self-attention, we get up to -0.3 BLEU points decline. This indicates that it deserves more efforts to investigate the temporal order information in self-attention mechanism. The GANs also significantly improve the translation performance of our system. Specifically, the global GANs achieve improvement up to +0.78 BLEU points on English-to-French translation and the local GANs also obtain improvement up to +0.57 BLEU points on English-to-French translation. This reveals that the proposed model benefits a lot from the cross-domain loss defined by GANs.

5 Conclusion and Future work

The models proposed recently for unsupervised NMT use a single encoder to map sentences from different languages to a shared-latent space. We conjecture that the shared encoder is problematic for keeping the unique and inherent characteristic of each language. In this paper, we propose the weight-sharing constraint in unsupervised NMT to address this issue. To enhance the cross-language translation performance, we also propose the embedding-reinforced encoders, local GAN and global GAN into the proposed system. Additionally, the directional self-attention is introduced to model the temporal order information for our system.

We test the proposed model on English-German, English-French and Chinese-to-English translation tasks. The experimental results reveal that our approach achieves significant improvement and verify our conjecture that the shared encoder is really a bottleneck for improving the unsupervised NMT. The ablation study shows that each component of our system achieves some improvement for the final translation performance.

Unsupervised NMT opens exciting opportunities for the future research. However, there is still a large room for improvement compared to the supervised NMT. In the future, we would like to investigate how to utilize the monolingual data more effectively, such as incorporating the language model and syntactic information into unsupervised NMT. Besides, we decide to make more efforts to explore how to reinforce the temporal order information for the proposed model.

Abstract

Neural Machine Translation (NMT) performs poor on the low-resource language pair (X, Z), especially when Z is a rare language. By introducing another rich language Y, we propose a novel triangular training architecture (TA-NMT) to leverage bilingual data (Y, Z) (may be small) and (X, Y) (can be rich) to improve the translation performance of low-resource pairs. In this triangular architecture, Z is taken as the intermediate latent variable, and translation models of Z are jointly optimized with a unified bidirectional EM algorithm under the goal of maximizing the translation likelihood of (X, Y). Empirical results demonstrate that our method significantly improves the translation quality of rare languages on MultiUN and IWSLT2012 datasets, and achieves even better performance combining back-translation methods.

1 Introduction

In recent years, Neural Machine Translation (NMT) (Kalchbrenner and Blunsom, 2013; Sutskever et al., 2014; Bahdanau et al., 2014) has achieved remarkable performance on many translation tasks (Jean et al., 2015; Sennrich et al., 2016; Wu et al., 2016; Sennrich et al., 2017). Being an end-to-end architecture, an NMT system first encodes the input sentence into a sequence of real vectors, based on which the decoder generates the target sequence word by word with the attention mechanism (Bahdanau et al., 2014; Luong et al., 2015). During training, NMT systems are optimized to maximize the translation probability of a given language pair with the Maximum Likelihood Estimation (MLE) method, which requires large bilingual data to fit the large parameter space. Without adequate data, which is common especially when it comes to a rare language, NMT usually falls short on low-resource language pairs (Zoph et al., 2016).

In order to deal with the data sparsity problem for NMT, exploiting monolingual data (Sennrich et al., 2015; Zhang and Zong, 2016; Cheng et al., 2016; Zhang et al., 2018; He et al., 2016) is the most common method. With monolingual data, the back-translation method (Sennrich et al., 2015) generates pseudo bilingual sentences with a target-to-source translation model to train the source-to-target one. By extending back-translation, source-to-target and target-to-source translation models can be jointly trained and boost each other (Cheng et al., 2016; Zhang et al., 2018). Similar to joint training (Cheng et al., 2016; Zhang et al., 2018), dual learning (He et al., 2016) designs a reinforcement learning framework to better capitalize on monolingual data and jointly train two models.

Instead of leveraging monolingual data (X or Z) to enrich the low-resource bilingual pair (X, Z), in this paper, we are motivated to introduce another rich language Y, by which additionally acquired bilingual data (Y, Z) and (X, Y) can be exploited to improve the translation performance of (X, Z). This requirement is easy to satisfy, especially when Z is a rare language but X is not. Under this scenario, (X, Y) can be a rich-resource pair and provide much bilingual data, while (Y, Z) would also be a low-resource pair mostly because Z is rare. For example, in the dataset IWSLT2012, there are only 112.6K bilingual sentence pairs of English-Hebrew, since Hebrew is a rare language. If French is introduced as the third language, we can have another low-resource bilingual data of French-Hebrew (116.3K sentence pairs), and easily-acquired bilingual data

[*]Contribution during internship at MSRA.

of the rich-resource pair English-French.

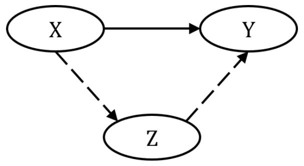

Figure 1: Triangular architecture for rare language translation. The solid lines mean rich-resource and the dash lines mean low-resource. X, Y and Z are three different languages.

With the introduced rich language Y, in this paper, we propose a novel triangular architecture (TA-NMT) to exploit the additional bilingual data of (Y, Z) and (X, Y), in order to get better translation performance on the low-resource pair (X, Z), as shown in Figure 1. In this architecture, (Y, Z) is used for training another translation model to score the translation model of (X, Z), while (X, Y) is used to provide large bilingual data with favorable alignment information.

Under the motivation to exploit the rich-resource pair (X, Y), instead of modeling $X \Rightarrow Z$ directly, our method starts from modeling the translation task $X \Rightarrow Y$ while taking Z as a latent variable. Then, we decompose $X \Rightarrow Y$ into two phases for training two translation models of low-resource pairs ((X, Z) and (Y, Z)) respectively. The first translation model generates a sequence in the hidden space of Z from X, based on which the second one generates the translation in Y. These two models can be optimized jointly with an Expectation Maximization (EM) framework with the goal of maximizing the translation probability $p(y|x)$. In this framework, the two models can boost each other by generating pseudo bilingual data for model training with the weights scored from the other. By reversing the translation direction of $X \Rightarrow Y$, our method can be used to train another two translation models $p(z|y)$ and $p(x|z)$. Therefore, the four translation models ($p(z|x)$, $p(x|z)$, $p(z|y)$ and $p(y|z)$) of the rare language Z can be optimized jointly with our proposed unified bidirectional EM algorithm.

Experimental results on the MultiUN and IWSLT2012 datasets demonstrate that our method can achieve significant improvements for rare languages translation. By incorporating back-translation (a method leveraging more monolingual data) into our method, TA-NMT can achieve even further improvements.

Our contributions are listed as follows:

- We propose a novel triangular training architecture (TA-NMT) to effectively tackle the data sparsity problem for rare languages in NMT with an EM framework.
- Our method can exploit two additional bilingual datasets at both the model and data levels by introducing another rich language.
- Our method is a unified bidirectional EM algorithm, in which four translation models on two low-resource pairs are trained jointly and boost each other.

2 Method

As shown in Figure 1, our method tries to leverage (X, Y) (a rich-resource pair) and (Y, Z) to improve the translation performance of low-resource pair (X, Z), during which translation models of (X, Z) and (Y, Z) can be improved jointly.

Instead of directly modeling the translation probabilities of low-resource pairs, we model the rich-resource pair translation $X \Rightarrow Y$, with the language Z acting as a bridge to connect X and Y. We decompose $X \Rightarrow Y$ into two phases for training two translation models. The first model $p(z|x)$ generates the latent translation in Z from the input sentence in X, based on which the second one $p(y|z)$ generate the final translation in language Y. Following the standard EM procedure (Borman, 2004) and Jensen's inequality, we derive the lower bound of $p(y|x)$ over the whole training data D as follows:

$$\begin{aligned}
&L(\Theta; D) \\
&= \sum_{(x,y)\in D} \log p(y|x) \\
&= \sum_{(x,y)\in D} \log \sum_z p(z|x)p(y|z) \\
&= \sum_{(x,y)\in D} \log \sum_z Q(z)\frac{p(z|x)p(y|z)}{Q(z)} \\
&\geq \sum_{(x,y)\in D} \sum_z Q(z) \log \frac{p(z|x)p(y|z)}{Q(z)} \\
&\doteq \mathcal{L}(Q)
\end{aligned} \tag{1}$$

where Θ is the model parameters set of $p(z|x)$ and $p(y|z)$, and $Q(z)$ is an arbitrary posterior distribution of z. We denote the lower-bound in the last but one line as $\mathcal{L}(Q)$. Note that we use an approximation that $p(y|x,z) \approx p(y|z)$ due to the semantic equivalence of parallel sentences x and y.

In the following subsections, we will first propose our EM method in subsection 2.1 based on the lower-bound derived above. Next, we will extend our method to two directions and give our unified bidirectional EM training in subsection 2.2. Then, in subsection 2.3, we will discuss more training details of our method and present our algorithm in the form of pseudo codes.

2.1 EM Training

To maximize $L(\Theta; D)$, the EM algorithm can be leveraged to maximize its lower bound $\mathcal{L}(Q)$. In the E-step, we calculate the expectation of the variable z using current estimate for the model, namely find the posterior distribution $Q(z)$. In the M-step, with the expectation $Q(z)$, we maximize the lower bound $\mathcal{L}(Q)$. Note that conditioned on the observed data and current model, the calculation of $Q(z)$ is intractable, so we choose $Q(z) = p(z|x)$ approximately.

M-step: In the M-step, we maximize the lower bound $\mathcal{L}(Q)$ w.r.t model parameters given $Q(z)$. By substituting $Q(z) = p(z|x)$ into $\mathcal{L}(Q)$, we can get the M-step as follows:

$$\begin{aligned}\Theta_{y|z} &= \arg\max_{\Theta_{y|z}} \mathcal{L}(Q) \\ &= \arg\max_{\Theta_{y|z}} \sum_{(x,y)\in D} \sum_{z} p(z|x) \log p(y|z) \\ &= \arg\max_{\Theta_{y|z}} \sum_{(x,y)\in D} E_{z\sim p(z|x)} \log p(y|z)\end{aligned} \tag{2}$$

E-step: The approximate choice of $Q(z)$ brings in a gap between $\mathcal{L}(Q)$ and $L(\Theta; D)$, which can be minimized in the E-step with Generalized EM method (McLachlan and Krishnan, 2007). According to Bishop (2006), we can write this gap explicitly as follows:

$$\begin{aligned}L(\Theta; D) - \mathcal{L}(Q) &= \sum_{z} Q(z) \log \frac{Q(z)}{p(z|y)} \\ &= KL(Q(z)||p(z|y)) \\ &= KL(p(z|x)||p(z|y))\end{aligned} \tag{3}$$

where $KL(\cdot)$ is the KullbackLeibler divergence, and the approximation that $p(z|x,y) \approx p(z|y)$ is also used above.

In the E-step, we minimize the gap between $\mathcal{L}(Q)$ and $L(\Theta; D)$ as follows:

$$\Theta_{z|x} = \arg\min_{\Theta_{z|x}} KL(p(z|x)||p(z|y)) \tag{4}$$

To sum it up, the E-step optimizes the model $p(z|x)$ by minimizing the gap between $\mathcal{L}(Q)$ and $L(\Theta; D)$ to get a better lower bound $\mathcal{L}(Q)$. This lower bound is then maximized in the M-step to optimize the model $p(y|z)$. Given the new model $p(y|z)$, the E-step tries to optimize $p(z|x)$ again to find a new lower bound, with which the M-step is re-performed. This iteration process continues until the models converge, which is guaranteed by the convergence of the EM algorithm.

2.2 Unified Bidirectional Training

The model $p(z|y)$ is used as an approximation of $p(z|x,y)$ in the E-step optimization (Equation 3). Due to the low resource property of the language pair (Y, Z), $p(z|y)$ cannot be well trained. To solve this problem, we can jointly optimize $p(x|z)$ and $p(z|y)$ similarly by maximizing the reverse translation probability $p(x|y)$.

We now give our unified bidirectional generalized EM procedures as follows:

- Direction of $X \Rightarrow Y$

  E: Optimize $\Theta_{z|x}$.

  $$\arg\min_{\Theta_{z|x}} KL(p(z|x)||p(z|y)) \tag{5}$$

  M: Optimize $\Theta_{y|z}$.

  $$\arg\max_{\Theta_{y|z}} \sum_{(x,y)\in D} E_{z\sim p(z|x)} \log p(y|z) \tag{6}$$

- Direction of $Y \Rightarrow X$

  E: Optimize $\Theta_{z|y}$.

  $$\arg\min_{\Theta_{z|y}} KL(p(z|y)||p(z|x)) \tag{7}$$

  M: Optimize $\Theta_{x|z}$.

  $$\arg\max_{\Theta_{x|z}} \sum_{(x,y)\in D} E_{z\sim p(z|y)} \log p(x|z) \tag{8}$$

Based on the above derivation, the whole architecture of our method can be illustrated in Figure 2, where the dash arrows denote the direction of $p(y|x)$, in which $p(z|x)$ and $p(y|z)$ are trained jointly with the help of $p(z|y)$, while the solid ones denote the direction of $p(x|y)$, in which $p(z|y)$ and $p(x|z)$ are trained jointly with the help of $p(z|x)$.

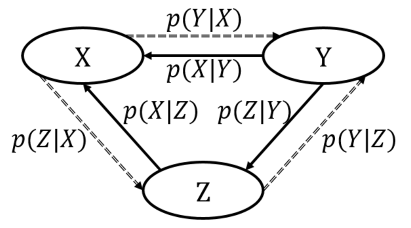

Figure 2: Triangular Learning Architecture for Low-Resource NMT

2.3 Training Details

A major difficulty in our unified bidirectional training is the exponential search space of the translation candidates, which could be addressed by either sampling (Shen et al., 2015; Cheng et al., 2016) or mode approximation (Kim and Rush, 2016). In our experiments, we leverage the sampling method and simply generate the top target sentence for approximation.

In order to perform gradient descend training, the parameter gradients for Equations 5 and 7 are formulated as follows:

$$\begin{aligned}
&\nabla_{\Theta_{z|x}} KL(p(z|x)||p(z|y)) \\
&= E_{z\sim p(z|x)} \log \frac{p(z|x)}{p(z|y)} \nabla_{\Theta_{z|x}} \log p(z|x) \\
&\nabla_{\Theta_{z|y}} KL(p(z|y)||p(z|x)) \\
&= E_{z\sim p(z|y)} \log \frac{p(z|y)}{p(z|x)} \nabla_{\Theta_{z|y}} \log p(z|y)
\end{aligned} \tag{9}$$

Similar to reinforcement learning, models $p(z|x)$ and $p(z|y)$ are trained using samples generated by the models themselves. According to our observation, some samples are noisy and detrimental to the training process. One way to tackle this is to filter out the bad ones using some additional metrics (BLEU, etc.). Nevertheless, in our settings, BLEU scores cannot be calculated during training due to the absence of the golden targets (z is generated based on x or y from the rich-resource pair (x, y)). Therefore we choose IBM model1 scores to weight the generated translation candidates, with the word translation probabilities calculated based on the given bilingual data (the low-resource pair (x, z) or (y, z)). Additionally, to stabilize the training process, the pseudo samples generated by model $p(z|x)$ or $p(z|y)$ are mixed with true bilingual samples in the same mini-batch with the ratio of 1-1. The whole training procedure is described in the following Algorithm 1, where the 5th and 9th steps are generating pseudo data.

Algorithm 1 Training low-resource translation models with the triangular architecture

```
Input: Rich-resource bilingual data $(x, y)$; low-resource bilingual data $(x, z)$ and $(y, z)$
Output: Parameters $\Theta_{z|x}$, $\Theta_{y|z}$, $\Theta_{z|y}$ and $\Theta_{x|z}$
 1: Pre-train $p(z|x), p(z|y), p(x|z), p(y|z)$
 2: while not convergence do
 3:     Sample $(x, y), (x^*, z^*), (y^*, z^*) \in D$
 4:             $\triangleright X \Rightarrow Y$: Optimize $\Theta_{z|x}$ and $\Theta_{y|z}$
 5:     Generate $z'$ from $p(z'|x)$ and build the training batches $B_1 = (x, z') \cup (x^*, z^*)$, $B_2 = (y, z') \cup (y^*, z^*)$
 6:     E-step: update $\Theta_{z|x}$ with $B_1$ (Equation 5)
 7:     M-step: update $\Theta_{y|z}$ with $B_2$ (Equation 6)
 8:             $\triangleright Y \Rightarrow X$: Optimize $\Theta_{z|y}$ and $\Theta_{x|z}$
 9:     Generate $z'$ from $p(z'|y)$ and build the training batches $B_3 = (y, z') \cup (y^*, z^*)$, $B_4 = (x, z') \cup (x^*, z^*)$
10:     E-step: update $\Theta_{z|y}$ with $B_3$ (Equation 7)
11:     M-step: update $\Theta_{x|z}$ with $B_4$ (Equation 8)
12: end while
13: return $\Theta_{z|x}$, $\Theta_{y|z}$, $\Theta_{z|y}$ and $\Theta_{x|z}$
```

3 Experiments

3.1 Datasets

In order to verify our method, we conduct experiments on two multilingual datasets. The one is MultiUN (Eisele and Chen, 2010), which is a collection of translated documents from the United Nations, and the other is IWSLT2012 (Cettolo et al., 2012), which is a set of multilingual transcriptions of TED talks. As is mentioned in section 1, our method is compatible with methods exploiting monolingual data. So we also find some extra monolingual data of rare languages in both datasets and conduct experiments incorporating back-translation into our method.

MultiUN: English-French (EN-FR) bilingual data are used as the rich-resource pair (X, Y). Arabic (AR) and Spanish (ES) are used as two simulated rare languages Z. We randomly choose subsets of bilingual data of (X, Z) and (Y, Z) in the original dataset to simulate low-resource situations, and make sure there is no overlap in Z between chosen data of (X, Z) and (Y, Z).

IWSLT2012[1]**:** English-French is used as the rich-resource pair (X, Y), and two rare languages Z are Hebrew (HE) and Romanian (RO) in our

[1]https://wit3.fbk.eu/mt.php?release=2012-02-plain

Pair	MultiUN		IWSLT2012	
	Lang	Size	Lang	Size
(X, Y)	EN-FR	9.9 M	EN-FR [3]	7.9 M
(X, Z)	EN-AR	116 K	EN-HE	112.6 K
(Y, Z)	FR-AR	116 K	FR-HE	116.3 K
mono Z	AR	3 M	HE	512.5 K
(X, Z)	EN-ES	116 K	EN-RO [4]	467.3 K

mono Z	ES	3 M	RO	885.0 K

Table 1: training data size of each language pair.

choice. Note that in this dataset, low-resource pairs (X, Z) and (Y, Z) are severely overlapped in Z. In addition, English-French bilingual data from WMT2014 dataset are also used to enrich the rich-resource pair. We also use additional English-Romanian bilingual data from Europarlv7 dataset (Koehn, 2005). The monolingual data of Z (HE and RO) are taken from the web[2].

In both datasets, all sentences are filtered within the length of 5 to 50 after tokenization. Both the validation and the test sets are 2,000 parallel sentences sampled from the bilingual data, with the left as training data. The size of training data of all language pairs are shown in Table 1.

3.2 Baselines

We compare our method with four baseline systems. The first baseline is the **RNNSearch** model (Bahdanau et al., 2014), which is a sequence-to-sequence model with attention mechanism trained with given small-scale bilingual data. The trained translation models are also used as pre-trained models for our subsequent training processes.

The second baseline is **PBSMT** (Koehn et al., 2003), which is a phrase-based statistical machine translation system. PBSMT is known to perform well on low-resource language pairs, so we want to compare it with our proposed method. And we use the public available implementation of Moses[5] for training and test in our experiments.

The third baseline is a teacher-student alike method (Chen et al., 2017). For the sake of brevity, we will denote it as **T-S**. The process is illustrated in Figure 3. We treat this method as a second baseline because it can also be regarded as a method exploiting (Y, Z) and (X, Y) to improve the translation of (X, Z) if we regard (X, Z) as the zero-resource pair and $p(x|y)$ as the teacher model when training $p(z|x)$ and $p(x|z)$.

The fourth baseline is back-translation (Sennrich et al., 2015). We will denote it as **Back-Trans**. More concretely, to train the model $p(z|x)$, we use extra monolingual Z described in Table 1 to do back-translation; to train the model $p(x|z)$, we use monolingual X taken from (X, Y). Procedures for training $p(z|y)$ and $p(y|z)$ are similar. This method use extra monolingual data of Z compared with our TA-NMT method. But we can incorporate it into our method.

Method	Resources
PBSMT	(X, Z), (Y, Z)
RNNSearch	(X, Z), (Y, Z)
T-S	(X, Z), (Y, Z), (X, Y)
BackTrans	(X, Z), (Y, Z), (X, Y), mono Z
TA-NMT	(X, Z), (Y, Z), (X, Y)
TA-NMT(GI)	(X, Z), (Y, Z), (X, Y), mono Z

Table 2: Resources that different methods use

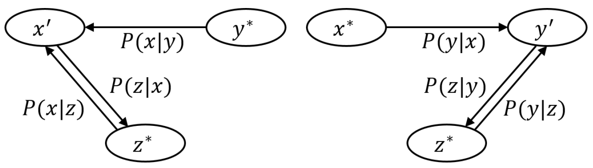

Figure 3: A teacher-student alike method for low-resource translation. For training $p(z|x)$ and $p(x|z)$, we mix the true pair $(y^*, z^*) \in D$ with the pseudo pair (x', z^*) generated by teacher model $p(x'|y^*)$ in the same mini-batch. The training procedure of $p(z|y)$ and $p(y|z)$ is similar.

3.3 Overall Results

Experimental results on both datasets are shown in Table 3 and 4 respectively, in which **RNNSearch**, **PBSMT**, **T-S** and **BackTrans** are four baselines. **TA-NMT** is our proposed method, and **TA-NMT(GI)** is our method incorporating back-translation as good initialization. For the purpose of clarity and a fair comparison, we list the resources that different methods exploit in Table 2.

From Table 3 on MultiUN, the performance of RNNSearch is relatively poor. As is expected, PBSMT performs better than RNNSearch on low-resource pairs by the average of 1.78 BLEU. The T-S method which can doubling the training data

Table 4: Test BLEU on IWSLT Dataset.

for both (X, Z) and (Y, Z) by generating pseudo data from each other, leads up to 1.1 BLEU points improvement on average over RNNSearch. Compared with T-S, our method gains a further improvement of about 0.9 BLEU on average, because our method can better leverage the rich-resource pair (X, Y). With extra large monolingual Z introduced, BackTrans can improve the performance of $p(z|x)$ and $p(z|y)$ significantly compared with all the methods without monolingual Z. However TA-NMT is comparable with or even better than BackTrans for $p(x|z)$ and $p(y|z)$ because both of the methods leverage resources from rich-resource pair (X, Y), but BackTrans does not use the alignment information it provides. Moreover, with back-translation as good initialization, further improvement is achieved by TA-NMT(GI) of about 0.7 BLEU on average over BackTrans.

In Table 4, we can draw the similar conclusion. However, different from MultiUN, in the EN-FR-HE group of IWSLT, (X, Z) and (Y, Z) are severely overlapped in Z. Therefore, T-S cannot improve the performance obviously (only about 0.2 BLEU) on RNNSearch because it fails to essentially double training data via the teacher model. As for EN-FR-RO, with the additionally introduced EN-RO data from Europarlv7, which has no overlap in RO with FR-RO, T-S can improve the average performance more than the EN-FR-HE group. TA-NMT outperforms T-S by 0.93 BLEU on average. Note that even though BackTrans uses extra monolingual Z, the improvements are not so obvious as the former dataset, the reason for which we will delve into in the next subsection. Again, with back-translation as good initialization, TA-NMT(GI) can get the best result.

Note that BLEU scores of TA-NMT are lower than BackTrans in the directions of X⇒Z and Y⇒Z. The reason is that the resources used by these two methods are different, as shown in Table 2. To do back translation in two directions (e.g., X⇒Z and Z⇒X), we need monolingual data from both sides (e.g., X and Z), however, in TA-NMT, the monolingual data of Z is not necessary. Therefore, in the translation of X⇒Z or Y⇒Z, BackTrans uses additional monolingual data of Z while TA-NMT does not, that is why BackTrans outperforms TA-NMT in these directions. Our method can leverage back translation as a good initialization, aka TA-NMT(GI) , and outperforms BackTrans on all translation directions.

The average test BLEU scores of different methods in each data group (EN-FR-AR, EN-FR-ES, EN-FR-HE, and EN-FR-RO) are listed in the column **Ave** of the tables for clear comparison.

3.4 The Effect of Extra Monolingual Data

Comparing the results of BackTrans and TA-NMT(GI) on both datasets, we notice the improvements of both methods on IWSLT are not as significant as MultiUN. We speculate the reason is the relatively less amount of monolingual Z we use in the experiments on IWSLT as shown in Table 1. So we conduct the following experiment to verify the conjecture by changing the scale of monolingual Arabic data in the MultiUN dataset, of which the data utilization rates are set to 0%, 10%, 30%, 60% and 100% respectively. Then we compare the performance of BackTrans and TA-NMT(GI) in the EN-FR-AR group. As Figure 4 shows, the amount of monolingual Z actually has a big effect on the results, which can also verify our conjecture above upon the less significant improvement of BackTrans and TA-NMT(GI) on IWSLT. In addition, even with poor "good-initialization", TA-NMT(GI) still get the best results.

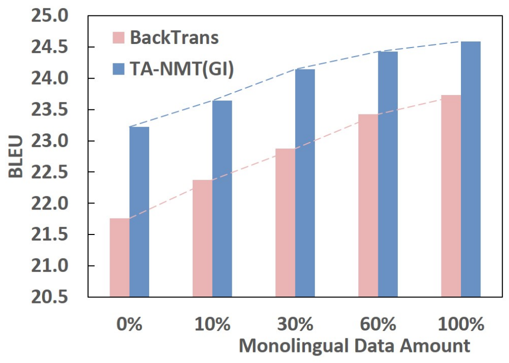

Figure 4: Test BLEU of the EN-FR-AR group performed by BackTrans and TA-NMT(GI) with different amount of monolingual Arabic data.

3.5 EM Training Curves

To better illustrate the behavior of our method, we print the training curves in both the M-steps and E-steps of TA-NMT and TA-NMT(GI) in Figure 5 above. The chosen models printed in this figure are EN2AR and AR2FR on MultiUN, and EN2RO and RO2FR on IWLST.

From Figure 5, we can see that the two low-resource translation models are improved nearly simultaneously along with the training process, which verifies our point that two weak models could boost each other in our EM framework. Notice that at the early stage, the performance of all models stagnates for several iterations, especially of TA-NMT. The reason could be that the pseudo bilingual data and the true training data are heterogeneous, and it may take some time for the models to adapt to a new distribution which both models agree. Compared with TA-NMT, TA-NMT(GI) are more stable, because the models may have adapted to a mixed distribution of heterogeneous data in the preceding back-translation phase.

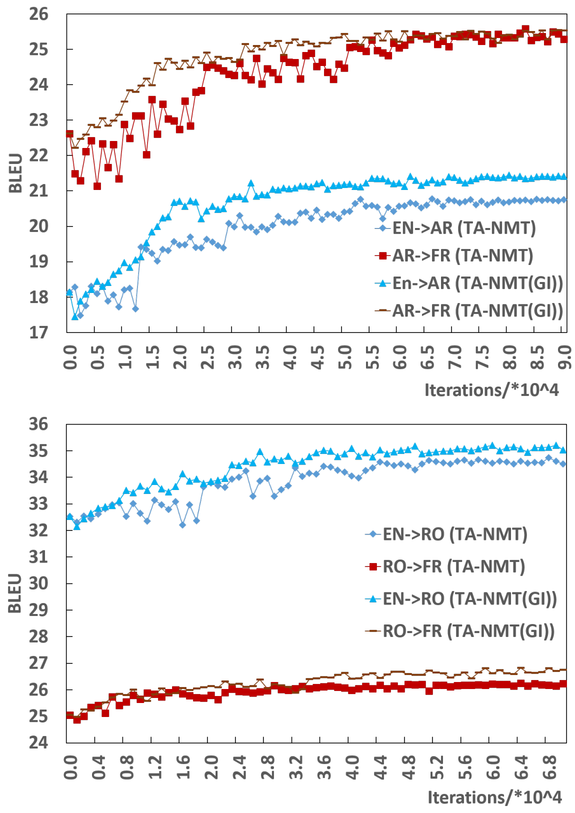

Figure 5: BLEU curves on validation sets during the training processes of TA-NMT and TA-NMT(GI). (Top: EN2AR (the E-step) and AR2FR (the M-step); Bottom: EN2RO (the E-step) and RO2FR (the M-step))

3.6 Reinforcement Learning Mechanism in Our Method

As shown in Equation 9, the E-step actually works as a reinforcement learning (RL) mechanism. Models $p(z|x)$ and $p(z|y)$ generate samples by themselves and receive rewards to update their parameters. Note that the reward here is described by the log terms in Equation 9, which is derived from our EM algorithm rather than defined artificially. In Table 5, we do a case study of the EN2ES translation sampled by $p(z|x)$ as well as its time-step rewards during the E-step.

In the first case, the best translation of "political" is "políticos". When the model $p(z|x)$ generates an inaccurate one "políticas", it receives a negative reward (-0.01), with which the model parameters will be updated accordingly. In the sec-

ond case, the output misses important words and is not fluent. Rewards received by the model $p(z|x)$ are zero for nearly all tokens in the output, leading to an invalid updating. In the last case, the output sentence is identical to the human reference. The rewards received are nearly all positive and meaningful, thus the RL rule will update the parameters to encourage this translation candidate.

4 Related Work

NMT systems, relying heavily on the availability of large bilingual data, result in poor translation quality for low-resource pairs (Zoph et al., 2016). This low-resource phenomenon has been observed in much preceding work. A very common approach is exploiting monolingual data of both source and target languages (Sennrich et al., 2015; Zhang and Zong, 2016; Cheng et al., 2016; Zhang et al., 2018; He et al., 2016).

As a kind of data augmentation technique, exploiting monolingual data can enrich the training data for low-resource pairs. Sennrich et al. (2015) propose back-translation, exploits the monolingual data of the target side, which is then used to generate pseudo bilingual data via an additional target-to-source translation model. Different from back-translation, Zhang and Zong (2016) propose two approaches to use source-side monolingual data, of which the first is employing a self-learning algorithm to generate pseudo data, while the second is using two NMT models to predict the translation and to reorder the source-side monolingual sentences. As an extension to these two methods, Cheng et al. (2016) and Zhang et al. (2018) combine two translation directions and propose a training framework to jointly optimize the source-to-target and target-to-source translation models. Similar to joint training, He et al. (2016) propose a dual learning framework with a reinforcement learning mechanism to better leverage monolingual data and make two translation models promote each other. All of these methods are concentrated on exploiting either the monolingual data of the source and target language or both of them.

Our method takes a different angle but is compatible with existing approaches, we propose a novel triangular architecture to leverage two additional language pairs by introducing a third rich language. By combining our method with existing approaches such as back-translation, we can make a further improvement.

Another approach for tackling the low-resource translation problem is multilingual neural machine translation (Firat et al., 2016), where different encoders and decoders for all languages with a shared attention mechanism are trained. This method tends to exploit the network architecture to relate low-resource pairs. Our method is different from it, which is more like a training method rather than network modification.

5 Conclusion

In this paper, we propose a triangular architecture (TA-NMT) to effectively tackle the problem of low-resource pairs translation with a unified bidirectional EM framework. By introducing another rich language, our method can better exploit the additional language pairs to enrich the original low-resource pair. Compared with the RNNSearch (Bahdanau et al., 2014), a teacher-student alike method (Chen et al., 2017) and the back-translation (Sennrich et al., 2015) on the same data level, our method achieves significant improvement on the MutiUN and IWSLT2012 datasets. Note that our method can be combined with methods exploiting monolingual data for NMT low-resource problem such as back-translation and make further improvements.

In the future, we may extend our architecture to other scenarios, such as totally unsupervised training with no bilingual data for the rare language.

Subword Regularization: Improving Neural Network Translation Models with Multiple Subword Candidates

Taku Kudo
Google, Inc.
`taku@google.com`

Abstract

Subword units are an effective way to alleviate the open vocabulary problems in neural machine translation (NMT). While sentences are usually converted into unique subword sequences, subword segmentation is potentially ambiguous and multiple segmentations are possible even with the same vocabulary. The question addressed in this paper is whether it is possible to harness the segmentation ambiguity as a noise to improve the robustness of NMT. We present a simple regularization method, subword regularization, which trains the model with multiple subword segmentations probabilistically sampled during training. In addition, for better subword sampling, we propose a new subword segmentation algorithm based on a unigram language model. We experiment with multiple corpora and report consistent improvements especially on low resource and out-of-domain settings.

1 Introduction

Neural Machine Translation (NMT) models (Bahdanau et al., 2014; Luong et al., 2015; Wu et al., 2016; Vaswani et al., 2017) often operate with fixed word vocabularies, as their training and inference depend heavily on the vocabulary size. However, limiting vocabulary size increases the amount of unknown words, which makes the translation inaccurate especially in an open vocabulary setting.

A common approach for dealing with the open vocabulary issue is to break up rare words into subword units (Schuster and Nakajima, 2012; Chitnis and DeNero, 2015; Sennrich et al., 2016; Wu et al., 2016). Byte-Pair-Encoding (BPE) (Sennrich et al., 2016) is a de facto standard subword segmentation algorithm applied to many NMT systems and achieving top translation quality in several shared tasks (Denkowski and Neubig, 2017; Nakazawa et al., 2017). BPE segmentation gives a good balance between the vocabulary size and the decoding efficiency, and also sidesteps the need for a special treatment of unknown words.

Subwords (_ means spaces)	Vocabulary id sequence
_Hell/o/_world	13586 137 255
_H/ello/_world	320 7363 255
_He/llo/_world	579 10115 255
_/He/l/l/o/_world	7 18085 356 356 137 255
_H/el/l/o/_/world	320 585 356 137 7 12295

Table 1: Multiple subword sequences encoding the same sentence "Hello World"

BPE encodes a sentence into a unique subword sequence. However, a sentence can be represented in multiple subword sequences even with the same vocabulary. Table 1 illustrates an example. While these sequences encode the same input "Hello World", NMT handles them as completely different inputs. This observation becomes more apparent when converting subword sequences into id sequences (right column in Table 1). These variants can be viewed as a spurious ambiguity, which might not always be resolved in decoding process. At training time of NMT, multiple segmentation candidates will make the model robust to noise and segmentation errors, as they can indirectly help the model to learn the compositionality of words, e.g., "books" can be decomposed into "book" + "s".

In this study, we propose a new regularization method for open-vocabulary NMT, called **subword regularization**, which employs multiple subword segmentations to make the NMT model accurate and robust. Subword regularization consists of the following two sub-contributions:

- We propose a simple NMT training algorithm to integrate multiple segmentation candidates. Our approach is implemented as an on-the-fly data sampling, which is not specific to NMT architecture. Subword regularization can be applied to any NMT system without changing the model structure.

- We also propose a new subword segmentation algorithm based on a language model, which provides multiple segmentations with probabilities. The language model allows to emulate the noise generated during the segmentation of actual data.

Empirical experiments using multiple corpora with different sizes and languages show that subword regularization achieves significant improvements over the method using a single subword sequence. In addition, through experiments with out-of-domain corpora, we show that subword regularization improves the robustness of the NMT model.

2 Neural Machine Translation with multiple subword segmentations

2.1 NMT training with on-the-fly subword sampling

Given a source sentence X and a target sentence Y, let $\mathbf{x} = (x_1, \ldots, x_M)$ and $\mathbf{y} = (y_1, \ldots, y_N)$ be the corresponding subword sequences segmented with an underlying subword segmenter, e.g., BPE. NMT models the translation probability $P(Y|X) = P(\mathbf{y}|\mathbf{x})$ as a target language sequence model that generates target subword y_n conditioning on the target history $y_{<n}$ and source input sequence $\mathbf{x}$:

$$P(\mathbf{y}|\mathbf{x};\theta) = \prod_{n=1}^{N} P(y_n|\mathbf{x}, y_{<n};\theta), \qquad (1)$$

where θ is a set of model parameters. A common choice to predict the subword y_n is to use a recurrent neural network (RNN) architecture. However, note that subword regularization is not specific to this architecture and can be applicable to other NMT architectures without RNN, e.g., (Vaswani et al., 2017; Gehring et al., 2017).

NMT is trained using the standard maximum likelihood estimation, i.e., maximizing the log-likelihood $\mathcal{L}(\theta)$ of a given parallel corpus $D =$

$$\begin{aligned} \{\langle X^{(s)}, Y^{(s)}\rangle\}_{s=1}^{|D|} &= \{\langle \mathbf{x}^{(s)}, \mathbf{y}^{(s)}\rangle\}_{s=1}^{|D|}, \\ \theta_{MLE} &= \arg\max_{\theta} \mathcal{L}(\theta) \\ where,\ \mathcal{L}(\theta) &= \sum_{s=1}^{|D|} \log P(\mathbf{y}^{(s)}|\mathbf{x}^{(s)};\theta). \quad (2) \end{aligned}$$

We here assume that the source and target sentences X and Y can be segmented into multiple subword sequences with the segmentation probabilities $P(\mathbf{x}|X)$ and $P(\mathbf{y}|Y)$ respectively. In subword regularization, we optimize the parameter set θ with the marginalized likelihood as (3).

$$\mathcal{L}_{marginal}(\theta) = \sum_{s=1}^{|D|} \mathbb{E}_{\substack{\mathbf{x}\sim P(\mathbf{x}|X^{(s)}) \\ \mathbf{y}\sim P(\mathbf{y}|Y^{(s)})}} [\log P(\mathbf{y}|\mathbf{x};\theta)] \quad (3)$$

Exact optimization of (3) is not feasible as the number of possible segmentations increases exponentially with respect to the sentence length. We approximate (3) with finite k sequences sampled from $P(\mathbf{x}|X)$ and $P(\mathbf{y}|Y)$ respectively.

$$\begin{gathered} \mathcal{L}_{marginal}(\theta) \cong \frac{1}{k^2} \sum_{s=1}^{|D|} \sum_{i=1}^{k} \sum_{j=1}^{k} \log P(\mathbf{y}_j|\mathbf{x}_i;\theta) \\ \mathbf{x}_i \sim P(\mathbf{x}|X^{(s)}), \quad \mathbf{y}_j \sim P(\mathbf{y}|Y^{(s)}). \end{gathered} \quad (4)$$

For the sake of simplicity, we use $k = 1$. Training of NMT usually uses an online training for efficiency, in which the parameter θ is iteratively optimized with respect to the smaller subset of D (mini-batch). When we have a sufficient number of iterations, subword sampling is executed via the data sampling of online training, which yields a good approximation of (3) even if $k = 1$. It should be noted, however, that the subword sequence is sampled on-the-fly for each parameter update.

2.2 Decoding

In the decoding of NMT, we only have a raw source sentence X. A straightforward approach for decoding is to translate from the best segmentation $\mathbf{x}^*$ that maximizes the probability $P(\mathbf{x}|X)$, i.e., $\mathbf{x}^* = argmax_{\mathbf{x}} P(\mathbf{x}|X)$. Additionally, we can use the n-best segmentations of $P(\mathbf{x}|X)$ to incorporate multiple segmentation candidates. More specifically, given n-best segmentations $(\mathbf{x}_1, \ldots, \mathbf{x}_n)$, we choose the best translation $\mathbf{y}^*$ that maximizes the following score.

$$score(\mathbf{x}, \mathbf{y}) = \log P(\mathbf{y}|\mathbf{x})/|\mathbf{y}|^{\lambda}, \qquad (5)$$

where $|\mathbf{y}|$ is the number of subwords in $\mathbf{y}$ and $\lambda \in \mathbb{R}^+$ is the parameter to penalize shorter sentences. λ is optimized with the development data.

In this paper, we call these two algorithms **one-best decoding** and **n-best decoding** respectively.

3 Subword segmentations with language model

3.1 Byte-Pair-Encoding (BPE)

Byte-Pair-Encoding (BPE) (Sennrich et al., 2016; Schuster and Nakajima, 2012) is a subword segmentation algorithm widely used in many NMT systems[1]. BPE first splits the whole sentence into individual characters. The most frequent[2] adjacent pairs of characters are then consecutively merged until reaching a desired vocabulary size. Subword segmentation is performed by applying the same merge operations to the test sentence.

An advantage of BPE segmentation is that it can effectively balance the vocabulary size and the step size (the number of tokens required to encode the sentence). BPE trains the merged operations only with a frequency of characters. Frequent substrings will be joined early, resulting in common words remaining as one unique symbol. Words consisting of rare character combinations will be split into smaller units, e.g., substrings or characters. Therefore, only with a small fixed size of vocabulary (usually 16k to 32k), the number of required symbols to encode a sentence will not significantly increase, which is an important feature for an efficient decoding.

One downside is, however, that BPE is based on a greedy and deterministic symbol replacement, which can not provide multiple segmentations with probabilities. It is not trivial to apply BPE to the subword regularization that depends on segmentation probabilities $P(\mathbf{x}|X)$.

3.2 Unigram language model

In this paper, we propose a new subword segmentation algorithm based on a unigram language model, which is capable of outputing multiple subword segmentations with probabilities. The unigram language model makes an assumption that each subword occurs independently, and consequently, the probability of a subword sequence $\mathbf{x} = (x_1, \ldots, x_M)$ is formulated as the product of the subword occurrence probabilities $p(x_i)$[3]:

$$P(\mathbf{x}) = \prod_{i=1}^{M} p(x_i), \tag{6}$$

$$\forall i \; x_i \in \mathcal{V}, \; \sum_{x \in \mathcal{V}} p(x) = 1,$$

where $\mathcal{V}$ is a pre-determined vocabulary. The most probable segmentation $\mathbf{x}^*$ for the input sentence X is then given by

$$\mathbf{x}^* = \operatorname*{arg\,max}_{\mathbf{x} \in \mathcal{S}(X)} P(\mathbf{x}), \tag{7}$$

where $\mathcal{S}(X)$ is a set of segmentation candidates built from the input sentence X. $\mathbf{x}^*$ is obtained with the Viterbi algorithm (Viterbi, 1967).

If the vocabulary $\mathcal{V}$ is given, subword occurrence probabilities $p(x_i)$ are estimated via the EM algorithm that maximizes the following marginal likelihood $\mathcal{L}$ assuming that $p(x_i)$ are hidden variables.

$$\mathcal{L} = \sum_{s=1}^{|D|} \log(P(X^{(s)})) = \sum_{s=1}^{|D|} \log\Big(\sum_{\mathbf{x} \in \mathcal{S}(X^{(s)})} P(\mathbf{x}) \Big)$$

In the real setting, however, the vocabulary set $\mathcal{V}$ is also unknown. Because the joint optimization of vocabulary set and their occurrence probabilities is intractable, we here seek to find them with the following iterative algorithm.

1. Heuristically make a reasonably big seed vocabulary from the training corpus.
2. Repeat the following steps until $|\mathcal{V}|$ reaches a desired vocabulary size.
   (a) Fixing the set of vocabulary, optimize $p(x)$ with the EM algorithm.
   (b) Compute the $loss_i$ for each subword x_i, where $loss_i$ represents how likely the likelihood $\mathcal{L}$ is reduced when the subword x_i is removed from the current vocabulary.
   (c) Sort the symbols by $loss_i$ and keep top η % of subwords (η is 80, for example). Note that we always keep the subwords consisting of a single character to avoid out-of-vocabulary.

[1]Strictly speaking, wordpiece model (Schuster and Nakajima, 2012) is different from BPE. We consider wordpiece as a variant of BPE, as it also uses an incremental vocabulary generation with a different loss function.

[2]Wordpiece model uses a likelihood instead of frequency.

[3]Target sequence $\mathbf{y} = (y_1, \ldots, y_N)$ can also be modeled similarly.

There are several ways to prepare the seed vocabulary. The natural choice is to use the union of all characters and the most frequent substrings in the corpus[4]. Frequent substrings can be enumerated in $O(T)$ time and $O(20T)$ space with the Enhanced Suffix Array algorithm (Nong et al., 2009), where T is the size of the corpus. Similar to (Sennrich et al., 2016), we do not consider subwords that cross word boundaries.

As the final vocabulary $\mathcal{V}$ contains all individual characters in the corpus, character-based segmentation is also included in the set of segmentation candidates $\mathcal{S}(X)$. In other words, subword segmentation with the unigram language model can be seen as a probabilsitic mixture of characters, subwords and word segmentations.

3.3 Subword sampling

Subword regularization samples one subword segmentation from the distribution $P(\mathbf{x}|X)$ for each parameter update. A straightforward approach for an approximate sampling is to use the l-best segmentations. More specifically, we first obtain l-best segmentations according to the probability $P(\mathbf{x}|X)$. l-best search is performed in linear time with the Forward-DP Backward-A* algorithm (Nagata, 1994). One segmentation $\mathbf{x}_i$ is then sampled from the multinomial distribution $P(\mathbf{x}_i|X) \cong P(\mathbf{x}_i)^{\alpha} / \sum_{i=1}^{l} P(\mathbf{x}_i)^{\alpha}$, where $\alpha \in \mathbb{R}^{+}$ is the hyperparameter to control the smoothness of the distribution. A smaller α leads to sample $\mathbf{x}_i$ from a more uniform distribution. A larger α tends to select the Viterbi segmentation.

Setting $l \rightarrow \infty$, in theory, allows to take all possible segmentations into account. However, it is not feasible to increase l explicitly as the number of candidates increases exponentially with respect to the sentence length. In order to exactly sample from all possible segmentations, we use the Forward-Filtering and Backward-Sampling algorithm (FFBS) (Scott, 2002), a variant of the dynamic programming originally introduced by Bayesian hidden Markov model training. In FFBS, all segmentation candidates are represented in a compact lattice structure, where each node denotes a subword. In the first pass, FFBS computes a set of forward probabilities for all subwords in the lattice, which provide the probability of ending up in any particular subword w. In the second pass, traversing the nodes in the lattice from the end of the sentence to the beginning of the sentence, subwords are recursively sampled for each branch according to the forward probabilities.

[4]It is also possible to run BPE with a sufficient number of merge operations.

3.4 BPE vs. Unigram language model

BPE was originally introduced in the data compression literature (Gage, 1994). BPE is a variant of dictionary (substitution) encoder that incrementally finds a set of symbols such that the total number of symbols for encoding the text is minimized. On the other hand, the unigram language model is reformulated as an entropy encoder that minimizes the total code length for the text. According to Shannon's coding theorem, the optimal code length for a symbol s is $-\log p_s$, where p_s is the occurrence probability of s. This is essentially the same as the segmentation strategy of the unigram language model described as (7).

BPE and the unigram language model share the same idea that they encode a text using fewer bits with a certain data compression principle (dictionary vs. entropy). Therefore, we expect to see the same benefit as BPE with the unigram language model. However, the unigram language model is more flexible as it is based on a probabilistic language model and can output multiple segmentations with their probabilities, which is an essential requirement for subword regularization.

4 Related Work

Regularization by noise is a well studied technique in deep neural networks. A well-known example is dropout (Srivastava et al., 2014), which randomly turns off a subset of hidden units during training. Dropout is analyzed as an ensemble training, where many different models are trained on different subsets of the data. Subword regularization trains the model on different data inputs randomly sampled from the original input sentences, and thus is regarded as a variant of ensemble training.

The idea of noise injection has previously been used in the context of Denoising Auto-Encoders (DAEs) (Vincent et al., 2008), where noise is added to the inputs and the model is trained to reconstruct the original inputs. There are a couple of studies that employ DAEs in natural language processing.

(Lample et al., 2017; Artetxe et al., 2017) independently propose DAEs in the context of sequence-to-sequence learning, where they randomly alter the word order of the input sentence and the model is trained to reconstruct the original sentence. Their technique is applied to an unsupervised machine translation to make the encoder truly learn the compositionality of input sentences.

Word dropout (Iyyer et al., 2015) is a simple approach for a bag-of-words representation, in which the embedding of a certain word sequence is simply calculated by averaging the word embeddings. Word dropout randomly drops words from the bag before averaging word embeddings, and consequently can see $2^{|X|}$ different token sequences for each input X.

(Belinkov and Bisk, 2017) explore the training of character-based NMT with a synthetic noise that randomly changes the order of characters in a word. (Xie et al., 2017) also proposes a robust RNN language model that interpolates random unigram language model.

The basic idea and motivation behind subword regularization are similar to those of previous work. In order to increase the robustness, they inject noise to input sentences by randomly changing the internal representation of sentences. However, these previous approaches often depend on heuristics to generate synthetic noises, which do not always reflect the real noises on training and inference. In addition, these approaches can only be applied to source sentences (encoder), as they irreversibly rewrite the surface of sentences. Subword regularization, on the other hand, generates synthetic subword sequences with an underlying language model to better emulate the noises and segmentation errors. As subword regularization is based on an invertible conversion, we can safely apply it both to source and target sentences.

Subword regularization can also be viewed as a data augmentation. In subword regularization, an input sentence is converted into multiple invariant sequences, which is similar to the data augmentation for image classification tasks, for example, random flipping, distorting, or cropping.

There are several studies focusing on segmentation ambiguities in language modeling. Latent Sequence Decompositions (LSDs) (Chan et al., 2016) learns the mapping from the input and the output by marginalizing over all possible segmentations. LSDs and subword regularization do not assume a predetermined segmentation for a sentence, and take multiple segmentations by a similar marginalization technique. The difference is that subword regularization injects the multiple segmentations with a separate language model through an on-the-fly subword sampling. This approach makes the model simple and independent from NMT architectures.

Lattice-to-sequence models (Su et al., 2017; Sperber et al., 2017) are natural extension of sequence-to-sequence models, which represent inputs uncertainty through lattices. Lattice is encoded with a variant of TreeLSTM (Tai et al., 2015), which requires changing the model architecture. In addition, while subword regularization is applied both to source and target sentences, lattice-to-sequence models do not handle target side ambiguities.

A mixed word/character model (Wu et al., 2016) addresses the out-of-vocabulary problem with a fixed vocabulary. In this model, out-of-vocabulary words are not collapsed into a single UNK symbol, but converted into the sequence of characters with special prefixes representing the positions in the word. Similar to BPE, this model also encodes a sentence into a unique fixed sequence, thus multiple segmentations are not taken into account.

5 Experiments

5.1 Setting

We conducted experiments using multiple corpora with different sizes and languages. Table 2 summarizes the evaluation data we used [5] [6] [7] [8] [9] [10]. IWSLT15/17 and KFTT are relatively small corpora, which include a wider spectrum of languages with different linguistic properties. They can evaluate the language-agnostic property of subword regularization. ASPEC and WMT14 (en↔de) are medium-sized corpora. WMT14 (en↔cs) is a rather big corpus consisting of more than 10M parallel sentences.

We used GNMT (Wu et al., 2016) as the implementation of the NMT system for all experiments. We generally followed the settings and training procedure described in (Wu et al., 2016), however, we changed the settings according to the

[5]IWSLT15: http://workshop2015.iwslt.org/

[6]IWSLT17: http://workshop2017.iwslt.org/

[7]KFTT: http://www.phontron.com/kftt/

[8]ASPEC: http://lotus.kuee.kyoto-u.ac.jp/ASPEC/

[9]WMT14: http://statmt.org/wmt14/

[10]WMT14(en↔de) uses the same setting as (Wu et al., 2016).

corpus size. Table 2 shows the hyperparameters we used in each experiment. As common settings, we set the dropout probability to be 0.2. For parameter estimation, we used a combination of Adam (Kingma and Adam, 2014) and SGD algorithms. Both length normalization and converge penalty parameters are set to 0.2 (see section 7 in (Wu et al., 2016)). We set the decoding beam size to 4.

The data was preprocessed with Moses tokenizer before training subword models. It should be noted, however, that Chinese and Japanese have no explicit word boundaries and Moses tokenizer does not segment sentences into words, and hence subword segmentations are trained almost from unsegmented raw sentences in these languages.

We used the case sensitive BLEU score (Papineni et al., 2002) as an evaluation metric. As the output sentences are not segmented in Chinese and Japanese, we segment them with characters and KyTea[11] for Chinese and Japanese respectively before calculating BLEU scores.

BPE segmentation is used as a baseline system. We evaluate three test systems with different sampling strategies: (1) Unigram language model-based subword segmentation without subword regularization ($l = 1$), (2) with subword regularization ($l = 64,\ \alpha = 0.1$) and (3) ($l = \infty,\ \alpha = 0.2/0.5$) 0.2: IWSLT, 0.5: others. These sampling parameters were determined with preliminary experiments. $l = 1$ is aimed at a pure comparison between BPE and the unigram language model. In addition, we compare one-best decoding and n-best decoding (See section 2.2). Because BPE is not able to provide multiple segmentations, we only evaluate one-best decoding for BPE. Consequently, we compare 7 systems ($1 + 3 \times 2$) for each language pair.

5.2 Main Results

Table 3 shows the translation experiment results.

First, as can be seen in the table, BPE and unigram language model without subword regularization ($l = 1$) show almost comparable BLEU scores. This is not surprising, given that both BPE and the unigram language model are based on data compression algorithms.

We can see that subword regularization ($l > 1$) boosted BLEU scores quite impressively (+1 to 2 points) in all language pairs except for WMT14 (en→cs) dataset. The gains are larger especially in lower resource settings (IWSLT and KFTT). It can be considered that the positive effects of data augmentation with subword regularization worked better in lower resource settings, which is a common property of other regularization techniques.

As for the sampling algorithm, ($l = \infty\ \alpha = 0.2/0.5$) slightly outperforms ($l = 64,\ \alpha = 0.1$) on IWSLT corpus, but they show almost comparable results on larger data set. Detailed analysis is described in Section 5.5.

On top of the gains with subword regularization, n-best decoding yields further improvements in many language pairs. However, we should note that the subword regularization is mandatory for n-best decoding and the BLEU score is degraded in some language pairs without subword regularization ($l = 1$). This result indicates that the decoder is more confused for multiple segmentations when they are not explored at training time.

5.3 Results with out-of-domain corpus

To see the effect of subword regularization on a more open-domain setting, we evaluate the systems with out-of-domain in-house data consisting of multiple genres: Web, patents and query logs. Note that we did not conduct the comparison with KFTT and ASPEC corpora, as we found that the domains of these corpora are too specific[12], and preliminary evaluations showed extremely poor BLEU scores (less than 5) on out-of-domain corpora.

Table 4 shows the results. Compared to the gains obtained with the standard in-domain evaluations in Table 3, subword regularization achieves significantly larger improvements (+2 points) in every domain of corpus. An interesting observation is that we have the same level of improvements even on large training data sets (WMT14), which showed marginal or small gains with the in-domain data. This result strongly supports our claim that subword regularization is more useful for open-domain settings.

5.4 Comparison with other segmentation algorithms

Table 5 shows the comparison on different segmentation algorithms: word, character, mixed word/character (Wu et al., 2016), BPE

[11] http://www.phontron.com/kytea

[12] KFTT focuses on Wikipedia articles related to Kyoto, and ASPEC is a corpus of scientific paper domain. Therefore, it is hard to translate out-of-domain texts.

	cs → en	28.78	28.84	29.64*	29.41*	25.77	29.23*	29.15*

Table 3: Main Results (BLEU(%)) (l: sampling size in SR, α: smoothing parameter). * indicates statistically significant difference ($p < 0.05$) from baselines with bootstrap resampling (Koehn, 2004). The same mark is used in Table 4 and 6.

(Sennrich et al., 2016) and our unigram model with or without subword regularization. The BLEU scores of word, character and mixed word/character models are cited from (Wu et al., 2016). As German is a morphologically rich language and needs a huge vocabulary for word models, subword-based algorithms perform a gain of more than 1 BLEU point than word model. Among subword-based algorithms, the unigram language model with subword regularization achieved the best BLEU score (25.04), which demonstrates the effectiveness of multiple subword segmentations.

5.5 Impact of sampling hyperparameters

Subword regularization has two hyperparameters: l: size of sampling candidates, α: smoothing constant. Figure 1 shows the BLEU scores of various hyperparameters on IWSLT15 (en → vi) dataset.

First, we can find that the peaks of BLEU scores against smoothing parameter α are different depending on the sampling size l. This is expected, because $l = \infty$ has larger search space than $l = 64$, and needs to set α larger to sample sequences close to the Viterbi sequence $\mathbf{x}^*$.

Another interesting observation is that $\alpha = 0.0$ leads to performance drops especially on $l = \infty$. When $\alpha = 0.0$, the segmentation probability $P(\mathbf{x}|X)$ is virtually ignored and one segmentation is uniformly sampled. This result suggests that biased sampling with a language model is helpful to emulate the real noise in the actual translation.

In general, larger l allows a more aggressive regularization and is more effective for low resource settings such as IWSLT. However, the estimation of α is more sensitive and performance becomes even worse than baseline when α is extremely small. To weaken the effect of regularization and avoid selecting invalid parameters, it might be more reasonable to use $l = 64$ for high resource languages.

Domain (size)	Corpus	Language pair	Baseline (BPE)	Proposed (SR)
Web (5k)	IWSLT15	en → vi	13.86	17.36*
		vi → en	7.83	11.69*
		en → zh	9.71	13.85*
		zh → en	5.93	8.13*
	IWSLT17	en → fr	16.09	20.04*
		fr → en	14.77	19.99*
	WMT14	en → de	22.71	26.02*

Query (2k)	IWSLT15	en → zh	9.30	12.47*
		zh → en	14.94	19.99*
	IWSLT17	en → fr	10.79	10.99
		fr → en	19.01	23.96*
	WMT14	en → de	25.93	29.82*
		de → en	26.24	30.90*

Table 4: Results with out-of-domain corpus
($l = \infty$, $\alpha = 0.2$: IWSLT15/17, $l = 64$, $\alpha = 0.1$: others, one-best decding)

Model	BLEU
Word	23.12
Character (512 nodes)	22.62
Mixed Word/Character	24.17
BPE	24.53
Unigram w/o SR ($l = 1$)	24.50
Unigram w/ SR ($l = 64$, $\alpha = 0.1$)	25.04

Table 5: Comparison of different segmentation algorithms (WMT14 en→de)

Although we can see in general that the optimal hyperparameters are roughly predicted with the held-out estimation, it is still an open question how to choose the optimal size l in subword sampling.

5.6 Results with single side regularization

Table 6 summarizes the BLEU scores with subword regularization either on source or target sentence to figure out which components (encoder or decoder) are more affected. As expected, we can see that the BLEU scores with single side regularization are worse than full regularization. However, it should be noted that single side regularization still has positive effects. This result implies that subword regularization is not only helpful for encoder-decoder architectures, but applicable to other NLP tasks that only use an either encoder or decoder, including text classification (Iyyer et al., 2015) and image caption generation (Vinyals et al., 2015).

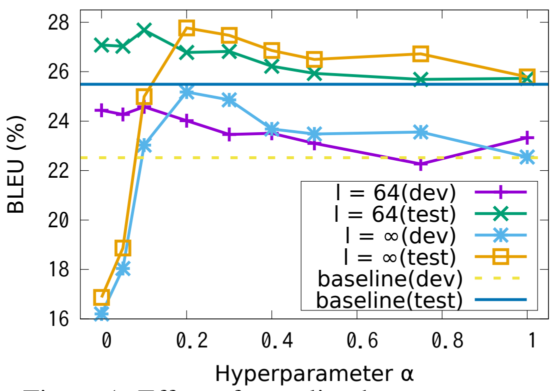

Figure 1: Effect of sampling hyperparameters

Table 6: Comparison on different regularization strategies (IWSLT15/17, $l = 64$, $\alpha = 0.1$)

6 Conclusions

In this paper, we presented a simple regularization method, **subword regularization**[13], for NMT, with no change to the network architecture. The central idea is to virtually augment training data with on-the-fly subword sampling, which helps to improve the accuracy as well as robustness of NMT models. In addition, for better subword sampling, we propose a new subword segmentation algorithm based on the unigram language model. Experiments on multiple corpora with different sizes and languages show that subword regularization leads to significant improvements especially on low resource and open-domain settings.

Promising avenues for future work are to apply subword regularization to other NLP tasks based on encoder-decoder architectures, e.g., dialog generation (Vinyals and Le, 2015) and automatic summarization (Rush et al., 2015). Compared to machine translation, these tasks do not have enough training data, and thus there could be a large room for improvement with subword regularization. Additionally, we would like to explore the application of subword regularization for machine learning, including Denoising Auto Encoder (Vincent et al., 2008) and Adversarial Training (Goodfellow et al., 2015).

Abstract

The past year has witnessed rapid advances in sequence-to-sequence (seq2seq) modeling for Machine Translation (MT). The classic RNN-based approaches to MT were first out-performed by the convolutional seq2seq model, which was then out-performed by the more recent Transformer model. Each of these new approaches consists of a fundamental architecture accompanied by a set of modeling and training techniques that are in principle applicable to other seq2seq architectures. In this paper, we tease apart the new architectures and their accompanying techniques in two ways. First, we identify several key modeling and training techniques, and apply them to the RNN architecture, yielding a new RNMT+ model that outperforms all of the three fundamental architectures on the benchmark WMT'14 English→French and English→German tasks. Second, we analyze the properties of each fundamental seq2seq architecture and devise new hybrid architectures intended to combine their strengths. Our hybrid models obtain further improvements, outperforming the RNMT+ model on both benchmark datasets.

1 Introduction

In recent years, the emergence of seq2seq models (Kalchbrenner and Blunsom, 2013; Sutskever et al., 2014; Cho et al., 2014) has revolutionized the field of MT by replacing traditional phrase-based approaches with neural machine translation (NMT) systems based on the encoder-decoder paradigm. In the first architectures that surpassed the quality of phrase-based MT, both the encoder and decoder were implemented as Recurrent Neural Networks (RNNs), interacting via a soft-attention mechanism (Bahdanau et al., 2015). The RNN-based NMT approach, or RNMT, was quickly established as the de-facto standard for NMT, and gained rapid adoption into large-scale systems in industry, e.g. Baidu (Zhou et al., 2016), Google (Wu et al., 2016), and Systran (Crego et al., 2016).

Following RNMT, convolutional neural network based approaches (LeCun and Bengio, 1998) to NMT have recently drawn research attention due to their ability to fully parallelize training to take advantage of modern fast computing devices. such as GPUs and Tensor Processing Units (TPUs) (Jouppi et al., 2017). Well known examples are ByteNet (Kalchbrenner et al., 2016) and ConvS2S (Gehring et al., 2017). The ConvS2S model was shown to outperform the original RNMT architecture in terms of quality, while also providing greater training speed.

Most recently, the Transformer model (Vaswani et al., 2017), which is based solely on a self-attention mechanism (Parikh et al., 2016) and feed-forward connections, has further advanced the field of NMT, both in terms of translation quality and speed of convergence.

In many instances, new architectures are accompanied by a novel set of techniques for performing training and inference that have been carefully optimized to work in concert. This 'bag of tricks' can be crucial to the performance of a proposed architecture, yet it is typically under-documented and left for the enterprising researcher to discover in publicly released code (if any) or through anecdotal evidence. This is not simply a problem for reproducibility; it obscures the central scientific question of how much of the observed gains come from the new architecture

* Equal contribution.

and how much can be attributed to the associated training and inference techniques. In some cases, these new techniques may be broadly applicable to other architectures and thus constitute a major, though implicit, contribution of an architecture paper. Clearly, they need to be considered in order to ensure a fair comparison across different model architectures.

In this paper, we therefore take a step back and look at which techniques and methods contribute significantly to the success of recent architectures, namely ConvS2S and Transformer, and explore applying these methods to other architectures, including RNMT models. In doing so, we come up with an enhanced version of RNMT, referred to as RNMT+, that significantly outperforms all individual architectures in our setup. We further introduce new architectures built with different components borrowed from RNMT+, ConvS2S and Transformer. In order to ensure a fair setting for comparison, all architectures were implemented in the same framework, use the same pre-processed data and apply no further post-processing as this may confound bare model performance.

Our contributions are three-fold:

1. In ablation studies, we quantify the effect of several modeling improvements (including multi-head attention and layer normalization) as well as optimization techniques (such as synchronous replica training and label-smoothing), which are used in recent architectures. We demonstrate that these techniques are applicable across different model architectures.

2. Combining these improvements with the RNMT model, we propose the new RNMT+ model, which significantly outperforms all fundamental architectures on the widely-used WMT'14 En$\rightarrow$Fr and En$\rightarrow$De benchmark datasets. We provide a detailed model analysis and comparison of RNMT+, ConvS2S and Transformer in terms of model quality, model size, and training and inference speed.

3. Inspired by our understanding of the relative strengths and weaknesses of individual model architectures, we propose new model architectures that combine components from the RNMT+ and the Transformer model, and achieve better results than both individual architectures.

We quickly note two prior works that provided empirical solutions to the difficulty of training NMT architectures (specifically RNMT). In (Britz et al., 2017) the authors systematically explore which elements of NMT architectures have a significant impact on translation quality. In (Denkowski and Neubig, 2017) the authors recommend three specific techniques for strengthening NMT systems and empirically demonstrated how incorporating those techniques improves the reliability of the experimental results.

2 Background

In this section, we briefly discuss the commmonly used NMT architectures.

2.1 RNN-based NMT Models - RNMT

RNMT models are composed of an encoder RNN and a decoder RNN, coupled with an attention network. The encoder summarizes the input sequence into a set of vectors while the decoder conditions on the encoded input sequence through an attention mechanism, and generates the output sequence one token at a time.

The most successful RNMT models consist of stacked RNN encoders with one or more bidirectional RNNs (Schuster and Paliwal, 1997; Graves and Schmidhuber, 2005), and stacked decoders with unidirectional RNNs. Both encoder and decoder RNNs consist of either LSTM (Hochreiter and Schmidhuber, 1997; Gers et al., 2000) or GRU units (Cho et al., 2014), and make extensive use of residual (He et al., 2015) or highway (Srivastava et al., 2015) connections.

In Google-NMT (GNMT) (Wu et al., 2016), the best performing RNMT model on the datasets we consider, the encoder network consists of one bi-directional LSTM layer, followed by 7 uni-directional LSTM layers. The decoder is equipped with a single attention network and 8 uni-directional LSTM layers. Both the encoder and the decoder use residual skip connections between consecutive layers.

In this paper, we adopt GNMT as the starting point for our proposed RNMT+ architecture.

2.2 Convolutional NMT Models - ConvS2S

In the most successful convolutional sequence-to-sequence model (Gehring et al., 2017), both the encoder and decoder are constructed by stacking multiple convolutional layers, where each layer contains 1-dimensional convolutions followed by a gated linear units (GLU) (Dauphin et al., 2016). Each decoder layer computes a separate dot-product attention by using the current decoder layer output and the final encoder layer outputs. Positional embeddings are used to provide explicit positional information to the model. Following the practice in (Gehring et al., 2017), we scale the gradients of the encoder layers to stabilize training. We also use residual connections across each convolutional layer and apply weight normalization (Salimans and Kingma, 2016) to speed up convergence. We follow the public ConvS2S codebase[1] in our experiments.

2.3 Conditional Transformation-based NMT Models - Transformer

The Transformer model (Vaswani et al., 2017) is motivated by two major design choices that aim to address deficiencies in the former two model families: (1) Unlike RNMT, but similar to the ConvS2S, the Transformer model avoids any sequential dependencies in both the encoder and decoder networks to maximally parallelize training. (2) To address the limited context problem (limited receptive field) present in ConvS2S, the Transformer model makes pervasive use of self-attention networks (Parikh et al., 2016) so that each position in the current layer has access to information from all other positions in the previous layer.

The Transformer model still follows the encoder-decoder paradigm. Encoder transformer layers are built with two sub-modules: (1) a self-attention network and (2) a feed-forward network. Decoder transformer layers have an additional cross-attention layer sandwiched between the self-attention and feed-forward layers to attend to the encoder outputs.

There are two details which we found very important to the model's performance: (1) Each sub-layer in the transformer (i.e. self-attention, cross-attention, and the feed-forward sub-layer) follows a strict computation sequence: *normalize* $\rightarrow$ *transform* $\rightarrow$ *dropout* $\rightarrow$ *residual-add*. (2) In addition to per-layer normalization, the final encoder output is again normalized to prevent a blow up after consecutive residual additions.

In this paper, we follow the latest version of the Transformer model in the Tensor2Tensor[2] codebase.

2.4 A Theory-Based Characterization of NMT Architectures

From a theoretical point of view, RNNs belong to the most expressive members of the neural network family (Siegelmann and Sontag, 1995)[3]. Possessing an infinite Markovian structure (and thus an infinite receptive fields) equips them to model sequential data (Elman, 1990), especially natural language (Grefenstette et al., 2015) effectively. In practice, RNNs are notoriously hard to train (Hochreiter, 1991; Bengio et al., 1994; Hochreiter et al., 2001), confirming the well known dilemma of trainability versus expressivity.

Convolutional layers are adept at capturing local context and local correlations by design. A fixed and narrow receptive field for each convolutional layer limits their capacity when the architecture is shallow. In practice, this weakness is mitigated by stacking more convolutional layers (e.g. 15 layers as in the ConvS2S model), which makes the model harder to train and demands meticulous initialization schemes and carefully designed regularization techniques.

The transformer network is capable of approximating arbitrary squashing functions (Hornik et al., 1989), and can be considered a strong feature extractor with extended receptive fields capable of linking salient features from the entire sequence. On the other hand, lacking a memory component (as present in the RNN models) prevents the network from modeling a state space, reducing its theoretical strength as a sequence model, thus it requires additional positional information (e.g. sinusoidal positional encodings).

Above theoretical characterizations will drive our explorations in the following sections.

3 Experiment Setup

We train our models on the standard WMT'14 En$\rightarrow$Fr and En$\rightarrow$De datasets that comprise 36.3M and 4.5M sentence pairs, respectively. Each sentence was encoded into a sequence of sub-word units obtained by first tokenizing the sentence with the Moses tokenizer, then splitting tokens into sub-word units (also known as "wordpieces") using the approach described in (Schuster and Nakajima, 2012).

[1]https://github.com/facebookresearch/fairseq-py

[2]https://github.com/tensorflow/tensor2tensor

[3]Assuming that data complexity is satisfied.

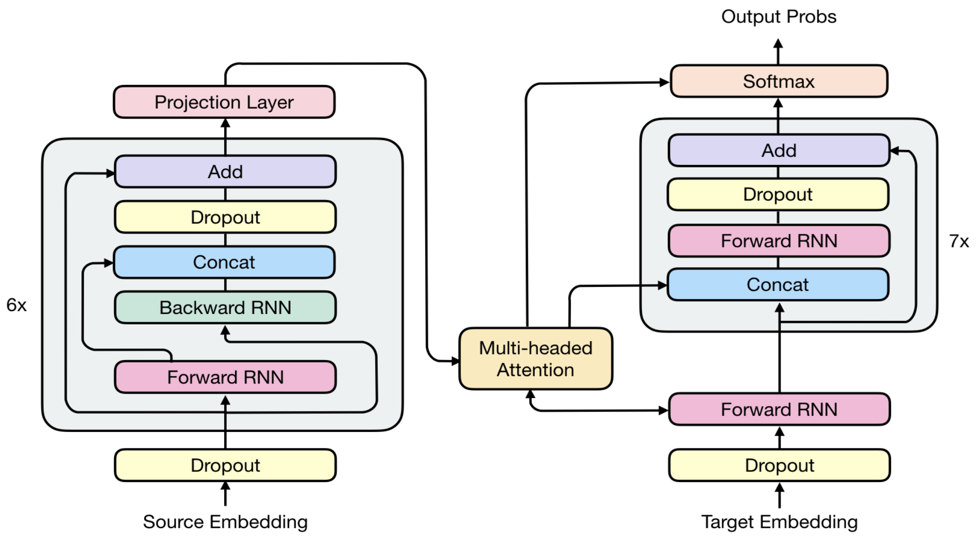

Figure 1: Model architecture of RNMT+. On the left side, the encoder network has 6 bidirectional LSTM layers. At the end of each bidirectional layer, the outputs of the forward layer and the backward layer are concatenated. On the right side, the decoder network has 8 unidirectional LSTM layers, with the first layer used for obtaining the attention context vector through multi-head additive attention. The attention context vector is then fed directly into the rest of the decoder layers as well as the softmax layer.

We use a shared vocabulary of 32K sub-word units for each source-target language pair. No further manual or rule-based post processing of the output was performed beyond combining the sub-word units to generate the targets. We report all our results on newstest 2014, which serves as the test set. A combination of newstest 2012 and newstest 2013 is used for validation.

To evaluate the models, we compute the BLEU metric on tokenized, true-case output.[4] For each training run, we evaluate the model every 30 minutes on the dev set. Once the model converges, we determine the best window based on the average dev-set BLEU score over 21 consecutive evaluations. We report the mean test score and standard deviation over the selected window. This allows us to compare model architectures based on their mean performance after convergence rather than individual checkpoint evaluations, as the latter can be quite noisy for some models.

To enable a fair comparison of architectures, we use the same pre-processing and evaluation methodology for all our experiments. We refrain from using checkpoint averaging (exponential moving averages of parameters) (Junczys-Dowmunt et al., 2016) or checkpoint ensembles (Jean et al., 2015; Chen et al., 2017) to focus on evaluating the performance of individual models.

4 RNMT+

4.1 Model Architecture of RNMT+

The newly proposed RNMT+ model architecture is shown in Figure 1. Here we highlight the key architectural choices that are different between the RNMT+ model and the GNMT model. There are 6 bidirectional LSTM layers in the encoder instead of 1 bidirectional LSTM layer followed by 7 unidirectional layers as in GNMT. For each bidirectional layer, the outputs of the forward layer and the backward layer are concatenated before being fed into the next layer. The decoder network consists of 8 unidirectional LSTM layers similar to the GNMT model. Residual connections are added to the third layer and above for both the encoder and decoder. Inspired by the Transformer model, per-gate layer normalization (Ba et al., 2016) is applied within each LSTM cell. Our empirical results show that layer normalization greatly stabilizes training. No non-linearity is applied to the LSTM output. A projection layer is added to the encoder final output.[5] Multi-head additive attention is used instead of the single-head attention in the GNMT model. Similar to GNMT, we use the

[4]This procedure is used in the literature to which we compare (Gehring et al., 2017; Wu et al., 2016).

[5]Additional projection aims to reduce the dimensionality of the encoder output representations to match the decoder stack dimension.

bottom decoder layer and the final encoder layer output after projection for obtaining the recurrent attention context. In addition to feeding the attention context to all decoder LSTM layers, we also feed it to the softmax by concatenating it with the layer input. This is important for both the quality of the models with multi-head attention and the stability of the training process.

Since the encoder network in RNMT+ consists solely of bi-directional LSTM layers, model parallelism is not used during training. We compensate for the resulting longer per-step time with increased data parallelism (more model replicas), so that the overall time to reach convergence of the RNMT+ model is still comparable to that of GNMT.

We apply the following regularization techniques during training.

- **Dropout:** We apply dropout to both embedding layers and each LSTM layer output before it is added to the next layer's input. Attention dropout is also applied.

- **Label Smoothing:** We use uniform label smoothing with an uncertainty=0.1 (Szegedy et al., 2015). Label smoothing was shown to have a positive impact on both Transformer and RNMT+ models, especially in the case of RNMT+ with multi-head attention. Similar to the observations in (Chorowski and Jaitly, 2016), we found it beneficial to use a larger beam size (e.g. 16, 20, etc.) during decoding when models are trained with label smoothing.

- **Weight Decay:** For the WMT'14 En→De task, we apply L2 regularization to the weights with $\lambda = 10^{-5}$. Weight decay is only applied to the En→De task as the corpus is smaller and thus more regularization is required.

We use the Adam optimizer (Kingma and Ba, 2014) with $\beta_1 = 0.9, \beta_2 = 0.999, \epsilon = 10^{-6}$ and vary the learning rate according to this schedule:

$$lr = 10^{-4} \cdot \min\left(1 + \frac{t \cdot (n-1)}{np}, n, n \cdot (2n)^{\frac{s-nt}{e-s}}\right) \quad (1)$$

Here, t is the current step, n is the number of concurrent model replicas used in training, p is the number of warmup steps, s is the start step of the exponential decay, and e is the end step of the decay. Specifically, we first increase the learning rate linearly during the number of warmup steps, keep it a constant until the decay start step s, then exponentially decay until the decay end step e, and keep it at $5 \cdot 10^{-5}$ after the decay ends. This learning rate schedule is motivated by a similar schedule that was successfully applied in training the Resnet-50 model with a very large batch size (Goyal et al., 2017).

In contrast to the asynchronous training used for GNMT (Dean et al., 2012), we train RNMT+ models with synchronous training (Chen et al., 2016). Our empirical results suggest that when hyper-parameters are tuned properly, synchronous training often leads to improved convergence speed and superior model quality.

To further stabilize training, we also use adaptive gradient clipping. We discard a training step completely if an anomaly in the gradient norm value is detected, which is usually an indication of an imminent gradient explosion. More specifically, we keep track of a moving average and a moving standard deviation of the $\log$ of the gradient norm values, and we abort a step if the norm of the gradient exceeds four standard deviations of the moving average.

4.2 Model Analysis and Comparison

In this section, we compare the results of RNMT+ with ConvS2S and Transformer.

All models were trained with synchronous training. RNMT+ and ConvS2S were trained with 32 NVIDIA P100 GPUs while the Transformer Base and Big models were trained using 16 GPUs.

For RNMT+, we use sentence-level cross-entropy loss. Each training batch contained 4096 sentence pairs (4096 source sequences and 4096 target sequences). For ConvS2S and Transformer models, we use token-level cross-entropy loss. Each training batch contained 65536 source tokens and 65536 target tokens. For the GNMT baselines on both tasks, we cite the largest BLEU score reported in (Wu et al., 2016) without reinforcement learning.

Table 1 shows our results on the WMT'14 En→Fr task. Both the Transformer Big model and RNMT+ outperform GNMT and ConvS2S by about 2 BLEU points. RNMT+ is slightly better than the Transformer Big model in terms of its mean BLEU score. RNMT+ also yields a much lower standard deviation, and hence we observed much less fluctuation in the training curve. It takes approximately 3 days for the Transformer

Base model to converge, while both RNMT+ and the Transformer Big model require about 5 days to converge. Although the batching schemes are quite different between the Transformer Big and the RNMT+ model, they have processed about the same amount of training samples upon convergence.

Model	Test BLEU	Epochs	Training Time
GNMT	38.95	-	-
ConvS2S [7]	39.49 ± 0.11	62.2	438h
Trans. Base	39.43 ± 0.17	20.7	90h
Trans. Big [8]	40.73 ± 0.19	8.3	120h
RNMT+	41.00 ± 0.05	8.5	120h

Table 1: Results on WMT14 En→Fr. The numbers before and after '±' are the mean and standard deviation of test BLEU score over an evaluation window. Note that Transformer models are trained using 16 GPUs, while ConvS2S and RNMT+ are trained using 32 GPUs.

Table 2 shows our results on the WMT'14 En→De task. The Transformer Base model improves over GNMT and ConvS2S by more than 2 BLEU points while the Big model improves by over 3 BLEU points. RNMT+ further outperforms the Transformer Big model and establishes a new state of the art with an averaged value of 28.49. In this case, RNMT+ converged slightly faster than the Transformer Big model and maintained much more stable performance after convergence with a very small standard deviation, which is similar to what we observed on the En-Fr task.

Table 3 summarizes training performance and model statistics. The Transformer Base model is the fastest model in terms of training speed. RNMT+ is slower to train than the Transformer Big model on a per-GPU basis. However, since the RNMT+ model is quite stable, we were able to offset the lower per-GPU throughput with higher concurrency by increasing the number of model replicas, and hence the overall time to convergence was not slowed down much. We also computed the number of floating point operations (FLOPs) in the model's forward path as well as the number of total parameters for all architectures (cf. Table 3). RNMT+ requires fewer FLOPs than the Transformer Big model, even though both models have a comparable number of parameters.

[6]Since the ConvS2S model convergence is very slow we did not explore further tuning on En→Fr, and validated our implementation on En→De.

[7]The BLEU scores for Transformer model are slightly lower than those reported in (Vaswani et al., 2017) due to four differences:

1) We report the mean test BLEU score using the strategy described in section 3.

2) We did not perform checkpoint averaging since it would be inconsistent with our evaluation for other models.

3) We avoided any manual post-processing, like unicode normalization using Moses replace-unicode-punctuation.perl or output tokenization using Moses tokenizer.perl, to rule out its effect on the evaluation. We observed a significant BLEU increase (about 0.6) on applying these post processing techniques.

4) In (Vaswani et al., 2017), reported BLEU scores are calculated using mteval-v13a.pl from Moses, which re-tokenizes its input.

Model	Test BLEU	Epochs	Training Time
GNMT	24.67	-	-
ConvS2S	25.01 ±0.17	38	20h
Trans. Base	27.26 ± 0.15	38	17h
Trans. Big	27.94 ± 0.18	26.9	48h
RNMT+	28.49 ± 0.05	24.6	40h

Table 2: Results on WMT14 En→De. Note that Transformer models are trained using 16 GPUs, while ConvS2S and RNMT+ are trained using 32 GPUs.

Model	Examples/s	FLOPs	Params
ConvS2S	80	15.7B	263.4M
Trans. Base	160	6.2B	93.3M
Trans. Big	50	31.2B	375.4M
RNMT+	30	28.1B	378.9M

Table 3: Performance comparison. Examples/s are normalized by the number of GPUs used in the training job. FLOPs are computed assuming that source and target sequence length are both 50.

5 Ablation Experiments

In this section, we evaluate the importance of four main techniques for both the RNMT+ and the Transformer Big models. We believe that these techniques are universally applicable across different model architectures, and should always be employed by NMT practitioners for best performance.

We take our best RNMT+ and Transformer Big models and remove each one of these techniques independently. By doing this we hope to learn two things about each technique: (1) How much does it affect the model performance? (2) How useful is it for stable training of other techniques and hence the final model?

Model	RNMT+	Trans. Big
Baseline	41.00	40.73
- Label Smoothing	40.33	40.49
- Multi-head Attention	40.44	39.83
- Layer Norm.	*	*
- Sync. Training	39.68	*

Table 4: Ablation results of RNMT+ and the Transformer Big model on WMT'14 En $\rightarrow$ Fr. We report average BLEU scores on the test set. An asterisk '*' indicates an unstable training run (training halts due to non-finite elements).

From Table 4 we draw the following conclusions about the four techniques:

- **Label Smoothing** We observed that label smoothing improves both models, leading to an average increase of 0.7 BLEU for RNMT+ and 0.2 BLEU for Transformer Big models.

- **Multi-head Attention** Multi-head attention contributes significantly to the quality of both models, resulting in an average increase of 0.6 BLEU for RNMT+ and 0.9 BLEU for Transformer Big models.

- **Layer Normalization** Layer normalization is most critical to stabilize the training process of either model, especially when multi-head attention is used. Removing layer normalization results in unstable training runs for both models. Since by design, we remove one technique at a time in our ablation experiments, we were unable to quantify how much layer normalization helped in either case. To be able to successfully train a model without layer normalization, we would have to adjust other parts of the model and retune its hyper-parameters.

- **Synchronous training** Removing synchronous training has different effects on RNMT+ and Transformer. For RNMT+, it results in a significant quality drop, while for the Transformer Big model, it causes the model to become unstable. We also notice that synchronous training is only successful when coupled with a tailored learning rate schedule that has a warmup stage at the beginning (cf. Eq. 1 for RNMT+ and Eq. 2 for Transformer). For RNMT+, removing this warmup stage during synchronous training causes the model to become unstable.

6 Hybrid NMT Models

In this section, we explore hybrid architectures that shed some light on the salient behavior of each model family. These hybrid models outperform the individual architectures on both benchmark datasets and provide a better understanding of the capabilities and limitations of each model family.

6.1 Assessing Individual Encoders and Decoders

In an encoder-decoder architecture, a natural assumption is that the role of an encoder is to build feature representations that can best encode the meaning of the source sequence, while a decoder should be able to process and interpret the representations from the encoder and, at the same time, track the current target history. Decoding is inherently auto-regressive, and keeping track of the state information should therefore be intuitively beneficial for conditional generation.

We set out to study which family of encoders is more suitable to extract rich representations from a given input sequence, and which family of decoders can make the best of such rich representations. We start by combining the encoder and decoder from different model families. Since it takes a significant amount of time for a ConvS2S model to converge, and because the final translation quality was not on par with the other models, we focus on two types of hybrids only: Transformer encoder with RNMT+ decoder and RNMT+ encoder with Transformer decoder.

Encoder	Decoder	En$\rightarrow$Fr Test BLEU
Trans. Big	Trans. Big	40.73 ± 0.19
RNMT+	RNMT+	41.00 ± 0.05
Trans. Big	RNMT+	$\mathbf{41.12 \pm 0.16}$
RNMT+	Trans. Big	39.92 ± 0.21

Table 5: Results for encoder-decoder hybrids.

From Table 5, it is clear that the Transformer encoder is better at encoding or feature extraction than the RNMT+ encoder, whereas RNMT+ is better at decoding or conditional language modeling, confirming our intuition that a stateful decoder is beneficial for conditional language generation.

6.2 Assessing Encoder Combinations

Next, we explore how the features extracted by an encoder can be further enhanced by incorporating additional information. Specifically, we investigate the combination of transformer layers with RNMT+ layers in the same encoder block to build even richer feature representations. We exclusively use RNMT+ decoders in the following architectures since stateful decoders show better performance according to Table 5.

We study two mixing schemes in the encoder (see Fig. 2):

(1) *Cascaded Encoder*: The cascaded encoder aims at combining the representational power of RNNs and self-attention. The idea is to enrich a set of stateful representations by cascading a feature extractor with a focus on vertical mapping, similar to (Pascanu et al., 2013; Devlin, 2017). Our best performing cascaded encoder involves fine tuning transformer layers stacked on top of a pre-trained frozen RNMT+ encoder. Using a pre-trained encoder avoids optimization difficulties while significantly enhancing encoder capacity. As shown in Table 6, the cascaded encoder improves over the Transformer encoder by more than 0.5 BLEU points on the WMT'14 En→Fr task. This suggests that the Transformer encoder is able to extract richer representations if the input is augmented with sequential context.

(2) *Multi-Column Encoder*: As illustrated in Fig. 2b, a multi-column encoder merges the outputs of several independent encoders into a single combined representation. Unlike a cascaded encoder, the multi-column encoder enables us to investigate whether an RNMT+ decoder can distinguish information received from two different channels and benefit from its combination. A crucial operation in a multi-column encoder is therefore how different sources of information are merged into a unified representation. Our best multi-column encoder performs a simple concatenation of individual column outputs.

The model details and hyperparameters of the above two encoders are described in Appendix A.5 and A.6. As shown in Table 6, the multi-column encoder followed by an RNMT+ decoder achieves better results than the Transformer and the RNMT model on both WMT'14 benchmark tasks.

Model	En→Fr BLEU	En→De BLEU
Trans. Big	40.73 ± 0.19	27.94 ± 0.18
RNMT+	41.00 ± 0.05	28.49 ± 0.05
Cascaded	**41.67** ± **0.11**	28.62 ± 0.06
MultiCol	41.66 ± 0.11	**28.84** ± **0.06**

Table 6: Results for hybrids with cascaded encoder and multi-column encoder.

7 Conclusion

In this work we explored the efficacy of several architectural and training techniques proposed in recent studies on seq2seq models for NMT. We demonstrated that many of these techniques are broadly applicable to multiple model architectures. Applying these new techniques to RNMT models yields RNMT+, an enhanced RNMT model that significantly outperforms the three fundamental architectures on WMT'14 En→Fr and En→De tasks. We further presented several hybrid models developed by combining encoders and decoders from the Transformer and RNMT+ models, and empirically demonstrated the superiority of the Transformer encoder and the RNMT+ decoder in comparison with their counterparts. We then enhanced the encoder architecture by horizontally and vertically mixing components borrowed from these architectures, leading to hybrid architectures that obtain further improvements over RNMT+.

We hope that our work will motivate NMT researchers to further investigate generally applicable training and optimization techniques, and that our exploration of hybrid architectures will open paths for new architecture search efforts for NMT.

Our focus on a standard single-language-pair translation task leaves important open questions to be answered: How do our new architectures compare in multilingual settings, i.e., modeling an *interlingua*? Which architecture is more efficient and powerful in processing finer grained inputs and outputs, e.g., characters or bytes? How transferable are the representations learned by the different architectures to other tasks? And what are the characteristic errors that each architecture makes, e.g., linguistic plausibility?

Acknowledgments

We would like to thank the entire Google Brain Team and Google Translate Team for their foundational contributions to this project. We would also like to thank the entire Tensor2Tensor development team for their useful inputs and discussions.

Ultra-Fine Entity Typing

Abstract

We introduce a new entity typing task: given a sentence with an entity mention, the goal is to predict a set of free-form phrases (e.g. skyscraper, songwriter, or criminal) that describe appropriate types for the target entity. This formulation allows us to use a new type of distant supervision at large scale: head words, which indicate the type of the noun phrases they appear in. We show that these ultra-fine types can be crowd-sourced, and introduce new evaluation sets that are much more diverse and fine-grained than existing benchmarks. We present a model that can predict open types, and is trained using a multitask objective that pools our new head-word supervision with prior supervision from entity linking. Experimental results demonstrate that our model is effective in predicting entity types at varying granularity; it achieves state of the art performance on an existing fine-grained entity typing benchmark, and sets baselines for our newly-introduced datasets.[1]

1 Introduction

Entities can often be described by very fine grained types. Consider the sentences "Bill robbed John. He was arrested." The noun phrases "John," "Bill," and "he" have very specific types that can be inferred from the text. This includes the facts that "Bill" and "he" are both likely "criminal" due to the "robbing" and "arresting," while "John" is more likely a "victim" because he was "robbed." Such fine-grained types (victim, criminal) are important for context-sensitive tasks such as coreference resolution and question answering (e.g. "Who was the victim?"). Inferring such types for each mention (John, he) is not possible given current typing models that only predict relatively coarse types and only consider named entities.

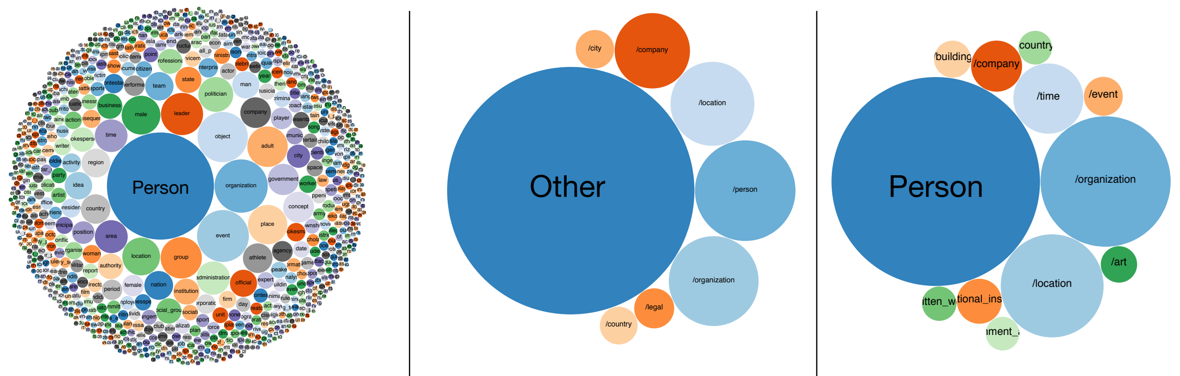
[1]Our data and model can be downloaded from: http://nlp.cs.washington.edu/entity_type

Sentence with Target Entity	Entity Types
During the Inca Empire, {**the Inti Raymi**} was the most important of four ceremonies celebrated in Cusco.	event, festival, **ritual, custom, ceremony, party, celebration**
{**They**} have been asked to appear in court to face the charge.	person, **accused, suspect, defendant**
Ban praised Rwanda's commitment to the UN and its role in {**peacemaking operations**}.	event, **plan, mission, action**

Table 1: Examples of entity mentions and their annotated types, as annotated in our dataset. The entity mentions are bold faced and in the curly brackets. The bold blue types do not appear in existing fine-grained type ontologies.

To address this challenge, we present a new task: given a sentence with a target entity mention, predict free-form noun phrases that describe appropriate types for the role the target entity plays in the sentence. Table 1 shows three examples that exhibit a rich variety of types at different granularities. Our task effectively subsumes existing fine-grained named entity typing formulations due to the use of a very large type vocabulary and the fact that we predict types for all noun phrases, including named entities, nominals, and pronouns.

Incorporating fine-grained entity types has improved entity-focused downstream tasks, such as relation extraction (Yaghoobzadeh et al., 2017a), question answering (Yavuz et al., 2016), query analysis (Balog and Neumayer, 2012), and coreference resolution (Durrett and Klein, 2014). These systems used a relatively coarse type ontology. However, manually designing the ontology is a challenging task, and it is difficult to cover all pos-



a) Our Dataset b) OntoNotes c) FIGER

Figure 1: A visualization of all the labels that cover 90% of the data, where a bubble's size is proportional to the label's frequency. Our dataset is much more diverse and fine grained when compared to existing datasets (OntoNotes and FIGER), in which the top 5 types cover 70-80% of the data.

sible concepts even within a limited domain. This can be seen empirically in existing datasets, where the label distribution of fine-grained entity typing datasets is heavily skewed toward coarse-grained types. For instance, annotators of the OntoNotes dataset (Gillick et al., 2014) marked about half of the mentions as "other," because they could not find a suitable type in their ontology (see Figure 1 for a visualization and Section 2.2 for details).

Our more open, ultra-fine vocabulary, where types are free-form noun phrases, alleviates the need for hand-crafted ontologies, thereby greatly increasing overall type coverage. To better understand entity types in an unrestricted setting, we crowdsource a new dataset of 6,000 examples. Compared to previous fine-grained entity typing datasets, the label distribution in our data is substantially more *diverse* and *fine-grained*. Annotators easily generate a wide range of types and can determine with 85% agreement if a type generated by another annotator is appropriate. Our evaluation data has over 2,500 unique types, posing a challenging learning problem.

While our types are harder to predict, they also allow for a new form of contextual distant supervision. We observe that text often contains cues that explicitly match a mention to its type, in the form of the mention's head word. For example, "the incumbent chairman of the African Union" is a type of "chairman." This signal complements the supervision derived from linking entities to knowledge bases, which is context-oblivious. For example, "Clint Eastwood" can be described with dozens of types, but context-sensitive typing would prefer "director" instead of "mayor" for the sentence "Clint Eastwood won 'Best Director' for Million Dollar Baby."

We combine head-word supervision, which provides ultra-fine type labels, with traditional signals from entity linking. Although the problem is more challenging at finer granularity, we find that mixing fine and coarse-grained supervision helps significantly, and that our proposed model with a multitask objective exceeds the performance of existing entity typing models. Lastly, we show that head-word supervision can be used for previous formulations of entity typing, setting the new state-of-the-art performance on an existing fine-grained NER benchmark.

2 Task and Data

Given a sentence and an entity mention e within it, the task is to predict a set of natural-language phrases T that describe the type of e. The selection of T is context sensitive; for example, in "Bill Gates has donated billions to eradicate malaria," Bill Gates should be typed as "philanthropist" and not "inventor." This distinction is important for context-sensitive tasks such as coreference resolution and question answering (e.g. "Which philanthropist is trying to prevent malaria?").

We annotate a dataset of about 6,000 mentions via crowdsourcing (Section 2.1), and demonstrate that using an large type vocabulary substantially increases annotation coverage and diversity over existing approaches (Section 2.2).

2.1 Crowdsourcing Entity Types

To capture multiple domains, we sample sentences from Gigaword (Parker et al., 2011), OntoNotes (Hovy et al., 2006), and web articles (Singh et al., 2012). We select entity mentions by taking maximal noun phrases from a constituency parser (Manning et al., 2014) and mentions from a coreference resolution system (Lee et al., 2017).

We provide the sentence and the target entity mention to five crowd workers on Mechanical Turk, and ask them to annotate the entity's type. To encourage annotators to generate fine-grained types, we require at least one general type (e.g. person, organization, location) and two specific types (e.g. doctor, fish, religious institute), from a type vocabulary of about 10K frequent noun phrases. We use WordNet (Miller, 1995) to expand these types automatically by generating all their synonyms and hypernyms based on the most common sense, and ask five different annotators to validate the generated types. Each pair of annotators agreed on 85% of the binary validation decisions (i.e. whether a type is suitable or not) and 0.47 in Fleiss's κ. To further improve consistency, the final type set contained only types selected by at least 3/5 annotators. Further crowdsourcing details are available in the supplementary material.

Our collection process focuses on precision. Thus, the final set is diverse but not comprehensive, making evaluation non-trivial (see Section 5).

2.2 Data Analysis

We collected about 6,000 examples. For analysis, we classified each type into three disjoint bins:

- 9 **general** types: person, location, object, organization, place, entity, object, time, event
- 121 **fine-grained** types, mapped to fine-grained entity labels from prior work (Ling and Weld, 2012; Gillick et al., 2014) (e.g. film, athlete)
- 10,201 **ultra-fine** types, encompassing every other label in the type space (e.g. detective, lawsuit, temple, weapon, composer)

On average, each example has 5 labels: 0.9 general, 0.6 fine-grained, and 3.9 ultra-fine types. Among the 10,000 ultra-fine types, 2,300 unique types were actually found in the 6,000 crowdsourced examples. Nevertheless, our distant supervision data (Section 3) provides positive training examples for every type in the entire vocabulary, and our model (Section 4) can and does predict from a 10K type vocabulary. For example, the model correctly predicts "television network" and "archipelago" for some mentions, even though that type never appears in the 6,000 crowdsourced examples.

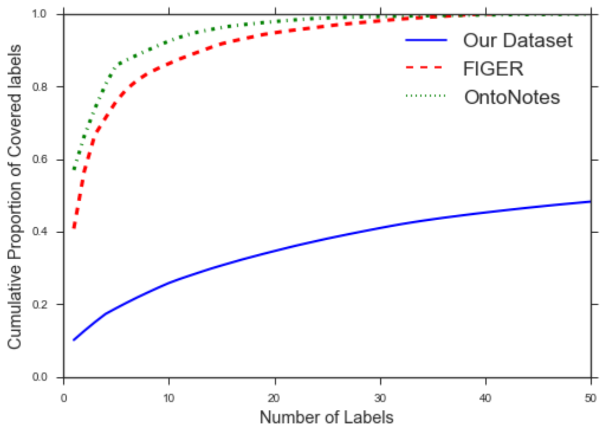


Figure 2: The label distribution across different evaluation datasets. In existing datasets, the top 4 or 7 labels cover over 80% of the labels. In ours, the top 50 labels cover less than 50% of the data.

Improving Type Coverage We observe that prior fine-grained entity typing datasets are heavily focused on coarse-grained types. To quantify our observation, we calculate the distribution of types in FIGER (Ling and Weld, 2012), OntoNotes (Gillick et al., 2014), and our data. For examples with multiple types ($|T| > 1$), we counted each type $1/|T|$ times.

Figure 2 shows the percentage of labels covered by the top N labels in each dataset. In previous enitity typing datasets, the distribution of labels is highly skewed towards the top few labels. To cover 80% of the examples, FIGER requires only the top 7 types, while OntoNotes needs only 4; our dataset requires 429 different types.

Figure 1 takes a deeper look by visualizing the types that cover 90% of the data, demonstrating the diversity of our dataset. It is also striking that more than half of the examples in OntoNotes are classified as "other," perhaps because of the limitation of its predefined ontology.

Improving Mention Coverage Existing datasets focus mostly on named entity mentions, with the exception of OntoNotes, which contained nominal expressions. This has implications on the transferability of FIGER/OntoNotes-based models to tasks such as coreference resolution, which need to analyze all types of entity mentions (pronouns, nominal expressions, and named entity

Source	Example Sentence	Labels	Size	Prec.
Head Words	**Western powers that brokered the proposed deal in Vienna** are likely to balk, said Valerie Lincy, a researcher with the Wisconsin Project.	power	20M	80.4%
	Alexis Kaniaris, CEO of the organizing company Europartners, explained, speaking in a radio program in **national radio station NET**.	radio, station, radio_station

Entity Linking + KB	Iced Earth's musical style is influenced by many traditional heavy metal groups such as **Black Sabbath**.	person, artist, actor, author, musician	2.5M	77.6%

Table 2: Distant supervision examples and statistics. We extracted the headword and Wikipedia definition supervision from Gigaword and Wikilink corpora. KB-based supervision is mapped from prior work, which used Wikipedia and news corpora.

mentions). Our new dataset provides a well-rounded benchmark with roughly 40% pronouns, 38% nominal expressions, and 22% named entity mentions. The case of pronouns is particularly interesting, since the mention itself provides little information.

3 Distant Supervision

Training data for fine-grained NER systems is typically obtained by linking entity mentions and drawing their types from knowledge bases (KBs). This approach has two limitations: recall can suffer due to KB incompleteness (West et al., 2014), and precision can suffer when the selected types do not fit the context (Ritter et al., 2011). We alleviate the recall problem by mining entity mentions that were linked to Wikipedia in HTML, and extract relevant types from their encyclopedic definitions (Section 3.1). To address the precision issue (context-insensitive labeling), we propose a new source of distant supervision: automatically extracted nominal head words from raw text (Section 3.2). Using head words as a form of distant supervision provides fine-grained information about named entities and nominal mentions. While a KB may link "the 44th president of the United States" to many types such as author, lawyer, and professor, head words provide only the type "president", which is relevant in the context.

We experiment with the new distant supervision sources as well as the traditional KB supervision. Table 2 shows examples and statistics for each source of supervision. We annotate 100 examples from each source to estimate the noise and usefulness in each signal (precision in Table 2).

3.1 Entity Linking

For KB supervision, we leveraged training data from prior work (Ling and Weld, 2012; Gillick et al., 2014) by manually mapping their ontology to our 10,000 noun type vocabulary, which covers 130 of our labels (general and fine-grained).[2] Section 6 defines this mapping in more detail.

To improve both entity and type coverage of KB supervision, we use definitions from Wikipedia. We follow Shnarch et al. () who observed that the first sentence of a Wikipedia article often states the entity's type via an "is a" relation; for example, "Roger Federer is a Swiss professional tennis player." Since we are using a large type vocabulary, we can now mine this typing information.[3] We extracted descriptions for 3.1M entities which contain 4,600 unique type labels such as "competition," "movement," and "village."

We bypass the challenge of automatically linking entities to Wikipedia by exploiting existing hyperlinks in web pages (Singh et al., 2012), following prior work (Ling and Weld, 2012; Yosef et al., 2012). Since our heuristic extraction of types from the definition sentence is somewhat noisy, we use a more conservative entity linking policy[4] that yields a signal with similar overall accuracy to KB-linked data.

[2] Data from: https://github.com/shimaokasonse/NFGEC

[3] We extract types by applying a dependency parser (Manning et al., 2014) to the definition sentence, and taking nouns that are dependents of a copular edge or connected to nouns linked to copulars via appositive or conjunctive edges.

[4] Only link if the mention contains the Wikipedia entity's name *and* the entity's name contains the mention's head.

3.2 Contextualized Supervision

Many nominal entity mentions include detailed type information within the mention itself. For example, when describing Titan V as "the newly-released graphics card", the head words and phrases of this mention ("graphics card" and "card") provide a somewhat noisy, but very easy to gather, context-sensitive type signal.

We extract nominal head words with a dependency parser (Manning et al., 2014) from the Gigaword corpus as well as the Wikilink dataset. To support multiword expressions, we included nouns that appear next to the head if they form a phrase in our type vocabulary. Finally, we lowercase all words and convert plural to singular.

Our analysis reveals that this signal has a comparable accuracy to the types extracted from entity linking (around 80%). Many errors are from the parser, and some errors stem from idioms and transparent heads (e.g. "parts of capital" labeled as "part"). While the headword is given as an input to the model, with heavy regularization and multitasking with other supervision sources, this supervision helps encode the context.

4 Model

We design a model for predicting sets of types given a mention in context. The architecture resembles the recent neural AttentiveNER model (Shimaoka et al., 2017), while improving the sentence and mention representations, and introducing a new multitask objective to handle multiple sources of supervision. The hyperparameter settings are listed in the supplementary material.

Context Representation Given a sentence $x_1, \ldots, x_n$, we represent each token x_i using a pre-trained word embedding w_i. We concatenate an additional location embedding l_i which indicates whether x_i is before, inside, or after the mention. We then use $[x_i; l_i]$ as an input to a bidirectional LSTM, producing a contextualized representation h_i for each token; this is different from the architecture of Shimaoka et al. 2017, who used two separate bidirectional LSTMs on each side of the mention. Finally, we represent the context c as a weighted sum of the contextualized token representations using MLP-based attention:

$$a_i = \text{SoftMax}_i(v_a \cdot \text{relu}(W_a h_i))$$

Where W_a and v_a are the parameters of the attention mechanism's MLP, which allows interaction between the forward and backward directions of the LSTM before computing the weight factors.

Mention Representation We represent the mention m as the concatenation of two items: (a) a character-based representation produced by a CNN on the entire mention span, and (b) a weighted sum of the pre-trained word embeddings in the mention span computed by attention, similar to the mention representation in a recent coreference resolution model (Lee et al., 2017). The final representation is the concatenation of the context and mention representations: $r = [c; m]$.

Label Prediction We learn a type label embedding matrix $W_t \in \mathbb{R}^{n \times d}$ where n is the number of labels in the prediction space and d is the dimension of r. This matrix can be seen as a combination of three sub matrices, $W_{general}, W_{fine}, W_{ultra}$, each of which contains the representations of the general, fine, and ultra-fine types respectively. We predict each type's probability via the sigmoid of its inner product with r: $y = \sigma(W_t r)$. We predict every type t for which $y_t > 0.5$, or $\arg\max y_t$ if there is no such type.

Multitask Objective The distant supervision sources provide partial supervision for ultra-fine types; KBs often provide more general types, while head words usually provide only ultra-fine types, without their generalizations. In other words, the absence of a type at a different level of abstraction does not imply a negative signal; e.g. when the head word is "inventor", the model should not be discouraged to predict "person".

Prior work used a customized hinge loss (Abhishek et al., 2017) or max margin loss (Ren et al., 2016a) to improve robustness to noisy or incomplete supervision. We propose a multitask objective that reflects the characteristic of our training dataset. Instead of updating all labels for each example, we divide labels into three bins (general, fine, and ultra-fine), and update labels only in bin containing at least one positive label. Specifically, the training objective is to minimize J where t is the target vector at each granularity:

$$\begin{aligned} J_{\text{all}} = {} & J_{\text{general}} \cdot \mathbb{1}_{\text{general}}(t) \\ & + J_{\text{fine}} \cdot \mathbb{1}_{\text{fine}}(t) \\ & + J_{\text{ultra}} \cdot \mathbb{1}_{\text{ultra}}(t) \end{aligned}$$

Where $\mathbb{1}_{\text{category}}(t)$ is an indicator function that checks if t contains a type in the category, and

Model	Dev				Test			
	MRR	P	R	F1	MRR	P	R	F1
AttentiveNER	0.221	**53.7**	15.0	23.5	0.223	**54.2**	15.2	23.7
Our Model	**0.229**	48.1	**23.2**	**31.3**	**0.234**	47.1	**24.2**	**32.0**

Table 3: Performance of our model and AttentiveNER (Shimaoka et al., 2017) on the new entity typing benchmark, using same training data. We show results for both development and test sets.

Train Data	Total				General (1918)			Fine (1289)			Ultra-Fine (7594)		
	MRR	P	R	F1	P	R	F1	P	R	F1	P	R	F1
All	**0.229**	48.1	**23.2**	**31.3**	60.3	61.6	61.0	40.4	**38.4**	**39.4**	42.8	8.8	14.6
– Crowd	0.173	40.1	14.8	21.6	53.7	45.6	49.3	20.8	18.5	19.6	54.4	4.6	8.4

– EL	0.225	48.4	22.3	30.6	**62.2**	60.1	**61.2**	40.3	26.1	31.7	41.4	**9.9**	**16.0**

Table 4: Results on the development set for different type granularity and for different supervision data with our model. In each row, we remove a single source of supervision. Entity linking (EL) includes supervision from both KB and Wikipedia definitions. The numbers in the first row are example counts for each type granularity.

J_{category} is the category-specific logistic regression objective:

$$J = -\sum_i t_i \cdot \log(y_i) + (1 - t_i) \cdot \log(1 - y_i)$$

5 Evaluation

Experiment Setup The crowdsourced dataset (Section 2.1) was randomly split into train, development, and test sets, each with about 2,000 examples. We use this relatively small manually-annotated training set (*Crowd* in Table 4) alongside the two distant supervision sources: entity linking (KB and Wikipedia definitions) and head words. To combine supervision sources of different magnitudes (2K crowdsourced data, 4.7M entity linking data, and 20M head words), we sample a batch of equal size from each source at each iteration. We reimplement the recent AttentiveNER model (Shimaoka et al., 2017) for reference.[5]

We report macro-averaged precision, recall, and F1, and the average mean reciprocal rank (MRR).

Results Table 3 shows the performance of our model and our reimplementation of AttentiveNER. Our model, which uses a multitask objective to learn finer types without punishing more general types, shows recall gains at the cost of drop in precision. The MRR score shows that our model is slightly better than the baseline at ranking correct types above incorrect ones.

Table 4 shows the performance breakdown for different type granularity and different supervision. Overall, as seen in previous work on fine-grained NER literature (Gillick et al., 2014; Ren et al., 2016a), finer labels were more challenging to predict than coarse grained labels, and this issue is exacerbated when dealing with ultra-fine types. All sources of supervision appear to be useful, with crowdsourced examples making the biggest impact. Head word supervision is particularly helpful for predicting ultra-fine labels, while entity linking improves fine label prediction. The low general type performance is partially because of nominal/pronoun mentions (e.g. "it"), and because of the large type inventory (sometimes "location" and "place" are annotated interchangeably).

Analysis We manually analyzed 50 examples from the development set, four of which we present in Table 5. Overall, the model was able to generate accurate general types and a diverse set of type labels. Despite our efforts to annotate a comprehensive type set, the gold labels still miss many potentially correct labels (example (a): "man" is reasonable but counted as incorrect). This makes the precision estimates lower than the actual performance level, with about half the precision errors belonging to this category. Real precision errors include predicting co-hyponyms (example (b): "accident" instead of "attack"), and types that

[5] We use the AttentiveNER model with no engineered features or hierarchical label encoding (as a hierarchy is not clear in our label setting) and let it predict from the same label space, training with the same supervision data.

(a)	Example Annotation	Bruguera said {he} had problems with his left leg and had grown tired early during the match . **person, athlete, player, adult, male, contestant**
	Prediction	**person, athlete, player, adult, male, contestant**, defendant, man
(b)	Example Annotation	{The explosions} occurred on the night of October 7 , against the Hilton Taba and campsites used by Israelis in Ras al-Shitan. **event** *calamity, attack, disaster*
	Prediction	**event,** accident
(c)	Example Annotation	Similarly , Enterprise was considered for refit to replace Challenger after {the latter} was destroyed , but Endeavour was built from structural spares instead . *object, spacecraft, rocket, thing, vehicle, shuttle*
	Prediction	event
(d)	Context Annotation	" There is a wealth of good news in this report , and I 'm particularly encouraged by the progress {we} are making against AIDS , " HHS Secretary Donna Shalala said in a statement. **government, group,** *organization,hospital,administration,socialist*
	Prediction	**government, group**, person

Table 5: Example and predictions from our best model on the development set. Entity mentions are marked with curly brackets, the correct predictions are boldfaced, and the missing labels are italicized and written in red.

may be true, but are not supported by the context.

We found that the model often abstained from predicting any fine-grained types. Especially in challenging cases as in example (c), the model predicts only general types, explaining the low recall numbers (28% of examples belong to this category). Even when the model generated correct fine-grained types as in example (d), the recall was often fairly low since it did not generate a complete set of related fine-grained labels.

Estimating the performance of a model in an incomplete label setting and expanding label coverage are interesting areas for future work. Our task also poses a potential modeling challenge; sometimes, the model predicts two incongruous types (e.g. "location" and "person"), which points towards modeling the task as a joint set prediction task, rather than predicting labels individually. We provide sample outputs on the project website.

6 Improving Existing Fine-Grained NER with Better Distant Supervision

We show that our model and distant supervision can improve performance on an existing fine-grained NER task. We chose the widely-used OntoNotes (Gillick et al., 2014) dataset which includes nominal and named entity mentions.[6]

[6]While we were inspired by FIGER (Ling and Weld, 2012), the dataset presents technical difficulties. The test set has only 600 examples, and the development set was labeled with distant supervision, not manual annotation. We therefore focus our evaluation on OntoNotes.

Augmenting the Training Data The original OntoNotes training set (ONTO in Tables 6 and 7) is extracted by linking entities to a KB. We supplement this dataset with our two new sources of distant supervision: Wikipedia definition sentences (WIKI) and head word supervision (HEAD) (see Section 3). To convert the label space, we manually map a single noun from our natural-language vocabulary to each formal-language type in the OntoNotes ontology. 77% of OntoNote's types directly correspond to suitable noun labels (e.g. "doctor" to "/person/doctor"), whereas the other cases were mapped with minimal manual effort (e.g. "musician" to "person/artist/music", "politician" to "/person/political_figure"). We then expand these labels according to the ontology to include their hypernyms ("/person/political_figure" will also generate "/person"). Lastly, we create negative examples by assigning the "/other" label to examples that are not mapped to the ontology. The augmented dataset contains 2.5M/0.6M new positive/negative examples, of which 0.9M/0.1M are from Wikipedia definition sentences and 1.6M/0.5M from head words.

Experiment Setup We compare performance to other published results and to our reimplementation of AttentiveNER (Shimaoka et al., 2017). We also compare models trained with different sources of supervision. For this dataset, we did not use our multitask objective (Section 4), since expanding types to include their ontological hypernyms largely eliminates the partial supervision as-

	Acc.	Ma-F1	Mi-F1
AttentiveNER++	51.7	70.9	64.9
AFET (Ren et al., 2016a)	55.1	71.1	64.7
LNR (Ren et al., 2016b)	57.2	71.5	66.1
Ours (ONTO+WIKI+HEAD)	**59.5**	**76.8**	**71.8**

Table 6: Results on the OntoNotes fine-grained entity typing test set. The first two models (AttentiveNER++ and AFET) use only KB-based supervision. LNR uses a filtered version of the KB-based training set. Our model uses all our distant supervision sources.

Model	Training Data			Performance		
	ONTO	WIKI	HEAD	Acc.	MaF1	MiF1
Attn. NER	✓			46.5	63.3	58.3
	✓	✓	✓	53.7	72.8	68.0
Ours	✓			41.7	64.2	59.5
	✓	✓		48.5	67.6	63.6
	✓		✓	57.9	73.0	66.9
		✓	✓	60.1	75.0	68.7
	✓	✓	✓	**61.6**	**77.3**	**71.8**

Table 7: Ablation study on the OntoNotes fine-grained entity typing development. The second row isolates dataset improvements, while the third row isolates the model.

sumption. Following prior work, we report macro- and micro-averaged F1 score, as well as accuracy (exact set match).

Results Table 6 shows the overall performance on the test set. Our combination of model and training data shows a clear improvement from prior work, setting a new state-of-the art result.[7]

In Table 7, we show an ablation study. Our new supervision sources improve the performance of both the AttentiveNER model and our own. We observe that every supervision source improves performance in its own right. Particularly, the naturally-occurring head-word supervision seems to be the prime source of improvement, increasing performance by about 10% across all metrics.

Predicting Miscellaneous Types While analyzing the data, we observed that over half of the mentions in OntoNotes' development set were annotated only with the miscellaneous type ("/other"). For both models in our evaluation, detecting the miscellaneous category is substantially easier than producing real types (94% F1 vs. 58% F1 with our best model). We provide further details of this analysis in the supplementary material.

7 Related Work

Fine-grained NER has received growing attention, and is used in many applications (Gupta et al., 2017; Ren et al., 2017; Yaghoobzadeh et al., 2017b; Raiman and Raiman, 2018). Researchers studied typing in varied contexts, including mentions in specific sentences (as we consider) (Ling and Weld, 2012; Gillick et al., 2014; Yogatama et al., 2015; Dong et al., 2015; Schutze et al., 2017), corpus-level prediction (Yaghoobzadeh and Schütze, 2016), and lexicon level (given only a noun phrase with no context) (Yao et al., 2013).

Recent work introduced fine-grained type ontologies (Rabinovich and Klein, 2017; Murty et al., 2017; Corro et al., 2015), defined using Wikipedia categories (100), Freebase types (1K) and WordNet senses (16K). However, they focus on named entities, and data has been challenging to gather, often approximating gold annotations with distant supervision. In contrast, (1) our ontology contains any frequent noun phrases that depicts a type, (2) our task goes beyond named entities, covering every noun phrase (even pronouns), and (3) we provide crowdsourced annotations which provide context-sensitive, fine grained type labels.

Contextualized fine-grained entity typing is related to selectional preference (Resnik, 1996; Pantel et al., 2007; Zapirain et al., 2013; de Cruys, 2014), where the goal is to induce semantic generalizations on the type of arguments a predicate prefers. Rather than focusing on predicates, we condition on the entire sentence to deduce the arguments' types, which allows us to capture more nuanced types. For example, not every type that fits "**He** played the violin in his room" is also suitable for "**He** played the violin in the Carnegie Hall". Entity typing here can be connected to argument finding in semantic role labeling.

To deal with noisy distant supervision for KB population and entity typing, researchers used multi-instance multi-label learning (Surdeanu et al., 2012; Yaghoobzadeh et al., 2017b) or custom losses (Abhishek et al., 2017; Ren et al., 2016a). Our multitask objective handles noisy supervision by pooling different distant supervision sources across different levels of granularity.

[7] We did not compare to a system from (Yogatama et al., 2015), which reports slightly higher test number (72.98 micro F1) as they used a different, unreleased test set.

8 Conclusion

Using virtually unrestricted types allows us to expand the standard KB-based training methodology with typing information from Wikipedia definitions and naturally-occurring head-word supervision. These new forms of distant supervision boost performance on our new dataset as well as on an existing fine-grained entity typing benchmark. These results set the first performance levels for our evaluation dataset, and suggest that the data will support significant future work.

Acknowledgement

The research was supported in part the ARO (W911NF-16-1-0121) the NSF (IIS-1252835, IIS-1562364), and an Allen Distinguished Investigator Award. We would like to thank the reviewers for constructive feedback. Also thanks to Yotam Eshel and Noam Cohen for providing the Wikilink dataset. Special thanks to the members of UW NLP for helpful discussions and feedback.

Abstract

Extraction from raw text to a knowledge base of entities and fine-grained types is often cast as prediction into a flat set of entity and type labels, neglecting the rich hierarchies over types and entities contained in curated ontologies. Previous attempts to incorporate hierarchical structure have yielded little benefit and are restricted to shallow ontologies. This paper presents new methods using real and complex bilinear mappings for integrating hierarchical information, yielding substantial improvement over flat predictions in entity linking and fine-grained entity typing, and achieving new state-of-the-art results for end-to-end models on the benchmark FIGER dataset. We also present two new human-annotated datasets containing wide and deep hierarchies which we will release to the community to encourage further research in this direction: *MedMentions*, a collection of PubMed abstracts in which 246k mentions have been mapped to the massive UMLS ontology; and *TypeNet*, which aligns Freebase types with the WordNet hierarchy to obtain nearly 2k entity types. In experiments on all three datasets we show substantial gains from hierarchy-aware training.

1 Introduction

Identifying and understanding entities is a central component in knowledge base construction (Roth et al., 2015) and essential for enhancing downstream tasks such as relation extraction (Yaghoobzadeh et al., 2017b), question answering (Das et al., 2017; Welbl et al., 2017) and search (Dalton et al., 2014). This has led to considerable research in automatically identifying entities in text, predicting their types, and linking them to existing structured knowledge sources.

Current state-of-the-art models encode a textual mention with a neural network and classify the mention as being an instance of a fine grained type or entity in a knowledge base. Although in many cases the types and their entities are arranged in a hierarchical ontology, most approaches ignore this structure, and previous attempts to incorporate hierarchical information yielded little improvement in performance (Shimaoka et al., 2017). Additionally, existing benchmark entity typing datasets only consider small label sets arranged in very shallow hierarchies. For example, FIGER (Ling and Weld, 2012), the *de facto* standard fine grained entity type dataset, contains only 113 types in a hierarchy only two levels deep.

In this paper we investigate models that explicitly integrate hierarchical information into the embedding space of entities and types, using a hierarchy-aware loss on top of a deep neural network classifier over textual mentions. By using this additional information, we learn a richer, more robust representation, gaining statistical efficiency when predicting similar concepts and aiding the classification of rarer types. We first validate our methods on the narrow, shallow type system of FIGER, out-performing state-of-the-art methods not incorporating hand-crafted features and matching those that do.

To evaluate on richer datasets and stimulate further research into hierarchical entity/typing prediction with larger and deeper ontologies, we introduce two new human annotated datasets. The first is *MedMentions*, a collection of PubMed ab-

*equal contribution
Data and code for experiments: https://github.com/MurtyShikhar/Hierarchical-Typing

stracts in which 246k concept mentions have been annotated with links to the Unified Medical Language System (UMLS) ontology (Bodenreider, 2004), an order of magnitude more annotations than comparable datasets. UMLS contains over 3.5 million concepts in a hierarchy having average depth 14.4. Interestingly, UMLS does not distinguish between types and entities (an approach we heartily endorse), and the technical details of linking to such a massive ontology lead us to refer to our MedMentions experiments as entity linking. Second, we present *TypeNet*, a curated mapping from the Freebase type system into the WordNet hierarchy. TypeNet contains over 1900 types with an average depth of 7.8.

In experimental results, we show improvements with a hierarchically-aware training loss on each of the three datasets. In entity-linking MedMentions to UMLS, we observe a 6% relative increase in accuracy over the base model. In experiments on entity-typing from Wikipedia into TypeNet, we show that incorporating the hierarchy of types and including a hierarchical loss provides a dramatic 29% relative increase in MAP. Our models even provide benefits for shallow hierarchies allowing us to match the state-of-art results of Shimaoka et al. (2017) on the FIGER (GOLD) dataset without requiring hand-crafted features.

We will publicly release the TypeNet and MedMentions datasets to the community to encourage further research in truly fine-grained, hierarchical entity-typing and linking.

2 New Corpora and Ontologies

2.1 MedMentions

Over the years researchers have constructed many large knowledge bases in the biomedical domain (Apweiler et al., 2004; Davis et al., 2008; Chatraryamontri et al., 2017). Many of these knowledge bases are specific to a particular sub-domain encompassing a few particular types such as genes and diseases (Piñero et al., 2017).

UMLS (Bodenreider, 2004) is particularly comprehensive, containing over 3.5 million concepts (UMLS does not distinguish between entities and types) defining their relationships and a curated hierarchical ontology. For example *LETM1 Protein* IS-A *Calcium Binding Protein* IS-A *Binding Protein* IS-A *Protein* IS-A *Genome Encoded Entity*. This fact makes UMLS particularly well suited for methods explicitly exploiting hierarchical structure.

Accurately linking textual biological entity mentions to an existing knowledge base is extremely important but few richly annotated resources are available. Even when resources do exist, they often contain no more than a few thousand annotated entity mentions which is insufficient for training state-of-the-art neural network entity linkers. State-of-the-art methods must instead rely on string matching between entity mentions and canonical entity names (Leaman et al., 2013; Wei et al., 2015; Leaman and Lu, 2016). To address this, we constructed MedMentions, a new, large dataset identifying and linking entity mentions in PubMed abstracts to specific UMLS concepts. Professional annotators exhaustively annotated UMLS entity mentions from 3704 PubMed abstracts, resulting in 246,000 linked mention spans. The average depth in the hierarchy of a concept from our annotated set is 14.4 and the maximum depth is 43.

MedMentions contains an order of magnitude more annotations than similar biological entity linking PubMed datasets (Doğan et al., 2014; Wei et al., 2015; Li et al., 2016). Additionally, these datasets contain annotations for only one or two entity types (genes or chemicals and disease etc.). MedMentions instead contains annotations for a wide diversity of entities linking to UMLS. Statistics for several other datasets are in Table 1 and further statistics are in 2.

Dataset	mentions	unique entities
MedMentions	246,144	25,507
BCV-CDR	28,797	2,356
NCBI Disease	6,892	753
BCII-GN Train	6,252	1,411
NLM Citation GIA	1,205	310

Table 1: Statistics from various biological entity linking data sets from scientific articles. NCBI Disease (Doğan et al., 2014) focuses exclusively on disease entities. BCV-CDR (Li et al., 2016) contains both chemicals and diseases. BCII-GN and NLM (Wei et al., 2015) both contain genes.

Statistic	Train	Dev	Test
#Abstracts	2,964	370	370
#Sentences	28,457	3,497	3,268
#Mentions	199,977	24,026	22,141
#Entities	22,416	5,934	5,521

Table 2: MedMentions statistics.

2.2 TypeNet

TypeNet is a new dataset of hierarchical entity types for extremely fine-grained entity typing. TypeNet was created by manually aligning Freebase types (Bollacker et al., 2008) to noun synsets from the WordNet hierarchy (Fellbaum, 1998), naturally producing a hierarchical type set.

To construct TypeNet, we first consider all Freebase types that were linked to more than 20 entities. This is done to eliminate types that are either very specific or very rare. We also remove all Freebase API types, e.g. the [/freebase, /dataworld, /schema, /atom, /scheme, and /topics] domains.

For each remaining Freebase type, we generate a list of candidate WordNet synsets through a substring match. An expert annotator then attempted to map the Freebase type to one or more synsets in the candidate list with a *parent-of*, *child-of* or *equivalence* link by comparing the definitions of each synset with example entities of the Freebase type. If no match was found, the annotator manually formulated queries for the online WordNet API until an appropriate synset was found. See Table 9 for an example annotation.

Two expert annotators independently aligned each Freebase type before meeting to resolve any conflicts. The annotators were conservative with assigning equivalence links resulting in a greater number of *child-of* links. The final dataset contained 13 *parent-of*, 727 *child-of*, and 380 *equivalence* links. Note that some Freebase types have multiple *child-of* links to WordNet, making TypeNet, like WordNet, a directed acyclic graph. We then took the union of each of our annotated Freebase types, the synset that they linked to, and any ancestors of that synset.

Typeset	Count	Depth	Gold KB links
CoNLL-YAGO	4	1	Yes
OntoNotes 5.0	19	1	No
Gillick et al. (2014)	88	3	Yes
Figer	112	2	Yes
Hyena	505	9	No
Freebase	2k	2	Yes
WordNet	16k	14	No
TypeNet*	1,941	14	Yes

Table 3: Statistics from various type sets. TypeNet is the largest type hierarchy with a gold mapping to KB entities. *The entire WordNet could be added to TypeNet increasing the total size to 17k types.

We also added an additional set of 614 *FB* $\rightarrow$ *FB* links 4. This was done by computing conditional probabilities of Freebase types given other Freebase types from a collection of 5 million randomly chosen Freebase entities. The conditional probability P($t_2 \mid t_1$) of a Freebase type t_2 given another Freebase type t_1 was calculated as $\frac{\#(t_1,t_2)}{\#t_1}$. Links with a conditional probability less than or equal to 0.7 were discarded. The remaining links were manually verified by an expert annotator and valid links were added to the final dataset, preserving acyclicity.

Freebase Types	1081
WordNet Synsets	860
child-of links	727
equivalence links	380
parent-of links	13
Freebase-Freebase links	614

Table 4: Stats for the final TypeNet dataset. child-of, parent-of, and equivalence links are from Freebase types $\rightarrow$ WordNet synsets.

3 Model

3.1 Background: Entity Typing and Linking

We define a textual mention m as a sentence with an identified entity. The goal is then to classify m with one or more labels. For example, we could take the sentence m = "*Barack Obama is the President of the United States.*" with the identified entity string **Barack Obama**. In the task of *entity linking*, we want to map m to a specific entity in a knowledge base such as "m/02mjmr" in Freebase. In *mention-level typing*, we label m with one or more types from our type system T such as t^m = {president, leader, politician} (Ling and Weld, 2012; Gillick et al., 2014; Shimaoka et al., 2017). In *entity-level typing*, we instead consider a bag of mentions B_e which are all linked to the same entity. We label B_e with t^e, the set of all types expressed in all $m \in B_e$ (Yao et al., 2013; Neelakantan and Chang, 2015; Verga et al., 2017; Yaghoobzadeh et al., 2017a).

3.2 Mention Encoder

Our model converts each mention m to a d dimensional vector. This vector is used to classify the type or entity of the mention. The basic model depicted in Figure 1 concatenates the averaged word embeddings of the mention string with the output of a convolutional neural network (CNN). The

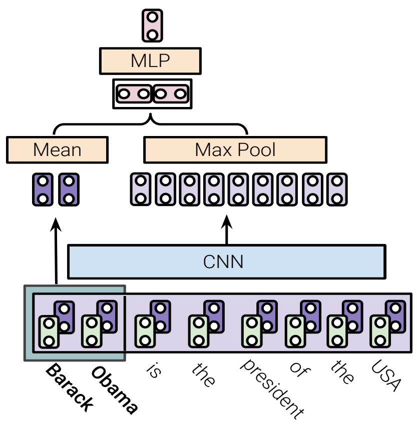

Figure 1: Sentence encoder for all our models. The input to the CNN consists of the concatenation of position embeddings with word embeddings. The output of the CNN is concatenated with the mean of mention surface form embeddings, and then passed through a 2 layer MLP.

word embeddings of the mention string capture global, context independent semantics while the CNN encodes a context dependent representation.

3.2.1 Token Representation

Each sentence is made up of s tokens which are mapped to d_w dimensional word embeddings. Because sentences may contain mentions of more than one entity, we explicitly encode a distinguished mention in the text using position embeddings which have been shown to be useful in state of the art relation extraction models (dos Santos et al., 2015; Lin et al., 2016) and machine translation (Vaswani et al., 2017). Each word embedding is concatenated with a d_p dimensional learned position embedding encoding the token's relative distance to the target entity. Each token within the distinguished mention span has position 0, tokens to the left have a negative distance from $[-s, 0)$, and tokens to the right of the mention span have a positive distance from $(0, s]$. We denote the final sequence of token representations as M.

3.2.2 Sentence Representation

The embedded sequence M is then fed into our context encoder. Our context encoder is a single layer CNN followed by a $\tanh$ non-linearity to produce C. The outputs are max pooled across time to get a final context embedding, m_{CNN}.

$$c_i = \tanh(b + \sum_{j=0}^{w} W[j]M[i - \lfloor \frac{w}{2} \rfloor + j])$$

$$m_{\text{CNN}} = \max_{0 \le i \le n-w+1} c_i$$

Each $W[j] \in \mathbb{R}^{d \times d}$ is a CNN filter, the bias $b \in \mathbb{R}^d$, $M[i] \in \mathbb{R}^d$ is a token representation, and the max is taken pointwise. In all of our experiments we set $w = 5$.

In addition to the contextually encoded mention, we create a global mention encoding, m_{G}, by averaging the word embeddings of the tokens within the mention span.

The final mention representation m_{F} is constructed by concatenating m_{CNN} and m_{G} and applying a two layer feed-forward network with $\tanh$ non-linearity (see Figure 1):

$$m_{\text{F}} = W_2 \tanh(W_1 \begin{bmatrix} m_{\text{SFM}} \\ m_{\text{CNN}} \end{bmatrix} + b_1) + b_2$$

4 Training

4.1 Mention-Level Typing

Mention level entity typing is treated as multi-label prediction. Given the sentence vector m_{F}, we compute a score for each type in typeset T as:

$$y_j = \mathbf{t_j}^{\top} m_{\text{F}}$$

where $\mathbf{t_j}$ is the embedding for the j^{th} type in T and y_j is its corresponding score. The mention is labeled with t^m, a binary vector of all types where $t^m_j = 1$ if the j^{th} type is in the set of gold types for m and 0 otherwise. We optimize a multi-label binary cross entropy objective:

$$\mathcal{L}_{\text{type}}(m) = -\sum_j t^m_j \log y_j + (1 - t^m_j) \log(1 - y_j)$$

4.2 Entity-Level Typing

In the absence of mention-level annotations, we instead must rely on distant supervision (Mintz et al., 2009) to noisily label all mentions of entity e with all types belonging to e. This procedure inevitably leads to noise as not all mentions of an entity express each of its known types. To alleviate this noise, we use multi-instance multi-label learning (MIML) (Surdeanu et al., 2012) which operates over *bags* rather than mentions. A bag of mentions $B_e = \{m^1, m^2, \ldots, m^n\}$ is the set of all mentions belonging to entity e. The bag is labeled with t^e, a binary vector of all types where $t^e_j = 1$ if the j^th type is in the set of gold types for e and 0 otherwise.

For every entity, we subsample k mentions from its bag of mentions. Each mention is then encoded independently using the model described in Section 3.2 resulting in a bag of vectors. Each of the k sentence vectors m^i_{F} is used to compute a score for each type in t^e:

$$y^i_j = \mathbf{t_j}^\top m^i_{\mathrm{F}}$$

where $\mathbf{t_j}$ is the embedding for the j^th type in t^e and y^i is a vector of logits corresponding to the i^th mention. The final bag predictions are obtained using element-wise LogSumExp pooling across the k logit vectors in the bag to produce entity level logits y:

$$y = \log \sum_i \exp(y^i)$$

We use these final bag level predictions to optimize a multi-label binary cross entropy objective:

$$\mathcal{L}_{\text{type}}(B_e) = -\sum_j t^e_j \log y_j + (1 - t^e_j)\log(1 - y_j)$$

4.3 Entity Linking

Entity linking is similar to mention-level entity typing with a single correct class per mention. Because the set of possible entities is in the millions, linking models typically integrate an alias table mapping entity mentions to a set of possible candidate entities. Given a large corpus of entity linked data, one can compute conditional probabilities from mention strings to entities (Spitkovsky and Chang, 2012). In many scenarios this data is unavailable. However, knowledge bases such as UMLS contain a canonical string name for each of its curated entities. State-of-the-art biological entity linking systems tend to operate on various string edit metrics between the entity mention string and the set of canonical entity strings in the existing structured knowledge base (Leaman et al., 2013; Wei et al., 2015).

For each mention in our dataset, we generate 100 candidate entities $e_c = (e_1, e_2, \ldots, e_{100})$ each with an associated string similarity score csim. See Appendix A.5.1 for more details on candidate generation. We generate the sentence representation m_{F} using our encoder and compute a similarity score between m_{F} and the learned embedding e of each of the candidate entities. This score and string cosine similarity csim are combined via a learned linear combination to generate our final score. The final prediction at test time $\hat{e}$ is the maximally similar entity to the mention.

$$\phi(m, e) = \alpha\, e^\top m_{\mathrm{F}} + \beta\, \mathrm{csim}(m, e)$$
$$\hat{e} = \operatorname*{argmax}_{e \in e_c} \phi(m, e)$$

We optimize this model by multinomial cross entropy over the set of candidate entities and correct entity e.

$$\mathcal{L}_{\text{link}}(m, e_c) = -\,\phi(m, e) + \log \sum_{e' \in e_c} \exp \phi(m, e')$$

5 Encoding Hierarchies

Both entity typing and entity linking treat the label space as prediction into a flat set. To explicitly incorporate the structure between types/entities into our training, we add an additional loss. We consider two methods for modeling the hierarchy of the embedding space: real and complex bilinear maps, which are two of the state-of-the-art knowledge graph embedding models.

5.1 Hierarchical Structure Models

Bilinear: Our standard bilinear model scores a hypernym link between (c_1, c_2) as:

$$s(c_1, c_2) = c_1{}^\top A c_2$$

where A $\in \mathbb{R}^{d\times d}$ is a learned real-valued non-diagonal matrix and c_1 is the child of c_2 in the hierarchy. This model is equivalent to RESCAL (Nickel et al., 2011) with a single IS-A relation type. The type embeddings are the same whether used on the left or right side of the relation. We merge this with the base model by using the parameter A as an additional map before type/entity scoring.

Complex Bilinear: We also experiment with a complex bilinear map based on the ComplEx model (Trouillon et al., 2016), which was shown to have strong performance predicting the hypernym relation in WordNet, suggesting suitability for asymmetric, transitive relations such as those in our type hierarchy. ComplEx uses complex valued vectors for types, and diagonal complex matrices for relations, using Hermitian inner products (taking the complex conjugate of the second argument, equivalent to treating the right-hand-side type embedding to be the complex conjugate of the left hand side), and finally taking the real part of the score[1]. The score of a hypernym link between (c_1, c_2) in the ComplEx model is defined as:

$$\begin{aligned}
s(c_1, c_2) &= \text{Re}(< c_1, r_{\text{IS-A}}, c_2 >) \\
&= \text{Re}(\sum_k c_{1k} r_k \bar{c}_{2k}) \\
&= \langle \text{Re}(c_1), \text{Re}(r_{\text{IS-A}}), \text{Re}(c_2) \rangle \\
&+ \langle \text{Re}(c_1), \text{Im}(r_{\text{IS-A}}), \text{Im}(c_2) \rangle \\
&+ \langle \text{Im}(c_1), \text{Re}(r_{\text{IS-A}}), \text{Im}(c_2) \rangle \\
&- \langle \text{Im}(c_1), \text{Im}(r_{\text{IS-A}}), \text{Re}(c_2) \rangle
\end{aligned}$$

where c_1, c_2 and $r_{\text{IS-A}}$ are complex valued vectors representing c_1, c_2 and the IS-A relation respectively. $\text{Re}(z)$ represents the real component of z and $\text{Im}(z)$ is the imaginary component. As noted in Trouillon et al. (2016), the above function is antisymmetric when $r_{\text{IS-A}}$ is purely imaginary.

Since entity/type embeddings are complex vectors, in order to combine it with our base model, we also need to represent mentions with complex vectors for scoring. To do this, we pass the output of the mention encoder through two different affine transformations to generate a real and imaginary component:

$$\begin{aligned}
\text{Re}(m_{\text{F}}) &= W_{\text{real}} m_{\text{F}} + b_{\text{real}} \\
\text{Im}(m_{\text{F}}) &= W_{\text{img}} m_{\text{F}} + b_{\text{img}}
\end{aligned}$$

where m_{F} is the output of the mention encoder, and W_{real}, $W_{\text{img}} \in \mathbb{R}^{d \times d}$ and b_{real}, $b_{\text{img}} \in \mathbb{R}^d$.

5.2 Training with Hierarchies

Learning a hierarchy is analogous to learning embeddings for nodes of a knowledge graph with a single hypernym/IS-A relation. To train these embeddings, we sample (c_1, c_2) pairs, where each pair is a positive link in our hierarchy. For each positive link, we sample a set N of n negative links. We encourage the model to output high scores for positive links, and low scores for negative links via a binary cross entropy (BCE) loss:

$$\begin{aligned}
\mathcal{L}_{\text{struct}} &= -\log \sigma(s(c_{1i}, c_{2i})) \\
&\quad + \sum_N \log(1 - \sigma(s(c_{1i}, c'_{2i}))) \\
\mathcal{L} &= \mathcal{L}_{\text{type/link}} + \gamma \mathcal{L}_{\text{struct}}
\end{aligned}$$

[1]This step makes the scoring function technically not bilinear, as it commutes with addition but not complex multiplication, but we term it *bilinear* for ease of exposition.

where $s(c_1, c_2)$ is the score of a link (c_1, c_2), and $\sigma(\cdot)$ is the logistic sigmoid. The weighting parameter γ is $\in \{0.1, 0.5, 0.8, 1, 2.0, 4.0\}$. The final loss function that we optimize is $\mathcal{L}$.

6 Experiments

We perform three sets of experiments: mention-level entity typing on the benchmark dataset FIGER, entity-level typing using Wikipedia and TypeNet, and entity linking using MedMentions.

6.1 Models

CNN: Each mention is encoded using the model described in Section 3.2. The resulting embedding is used for classification into a flat set labels. Specific implementation details can be found in Appendix A.2.
CNN+Complex: The CNN+Complex model is equivalent to the CNN model but uses complex embeddings and Hermitian dot products.
Transitive: This model does not add an additional hierarchical loss to the training objective (unless otherwise stated). We add additional labels to each entity corresponding to the transitive closure, or the union of all ancestors of its known types. This provides a rich additional learning signal that greatly improves classification of specific types.
Hierarchy: These models add an explicit hierarchical loss to the training objective, as described in Section 5, using either complex or real-valued bilinear mappings, and the associated parameter sharing.

6.2 Mention-Level Typing in FIGER

To evaluate the efficacy of our methods we first compare against the current state-of-art models of Shimaoka et al. (2017). The most widely used type system for fine-grained entity typing is FIGER which consists of 113 types organized in a 2 level hierarchy. For training, we use the publicly available W2M data (Ren et al., 2016) and optimize the mention typing loss function defined in Section-4.1 with the additional hierarchical loss where specified. For evaluation, we use the manually annotated FIGER (GOLD) data by Ling and Weld (2012). See Appendix A.2 and A.3 for specific implementation details.

6.2.1 Results

In Table 5 we see that our base CNN models (CNN and CNN+Complex) match LSTM models of Shimaoka et al. (2017) and Gupta et al. (2017), the

Model	Acc	Macro F1	Micro F1

CNN+Complex	67.23	82.17
+ hierarchy	**68.34**	**83.52**

Table 7: Accuracy on entity linking in MedMentions. Maximum recall is 81.82% because we use an imperfect alias table to generate candidates. Normalized scores consider only mentions which contain the gold entity in the candidate set. Mention tfidf is $csim$ from Section 4.3.

previous state-of-the-art for models without hand-crafted features. When incorporating structure into our models, we gain 2.5 points of accuracy in our CNN+Complex model, matching the overall state of the art attentive LSTM that relied on hand-crafted features from syntactic parses, topic models, and character n-grams. The structure can help our model predict lower frequency types which is a similar role played by hand-crafted features.

6.3 Entity-Level Typing in TypeNet

Next we evaluate our models on entity-level typing in TypeNet using Wikipedia. For each entity, we follow the procedure outlined in Section 4.2. We predict labels for each instance in the entity's bag and aggregate them into entity-level predictions using $\mathrm{LogSumExp}$ pooling. Each type is assigned a predicted score by the model. We then rank these scores and calculate average precision for each of the types in the test set, and use these scores to calculate mean average precision (MAP). We evaluate using MAP instead of accuracy which is standard in large knowledge base link prediction tasks (Verga et al., 2017; Trouillon et al., 2016). These scores are calculated only over Freebase types, which tend to be lower in the hierarchy. This is to avoid artificial score inflation caused by trivial predictions such as 'entity.' See Appendix A.4 for more implementation details.

6.3.1 Results

Table 6 shows the results for entity level typing on our Wikipedia TypeNet dataset. We see that both the basic CNN and the CNN+Complex models perform similarly with the CNN+Complex model doing slightly better on the full data regime. We also see that both models get an improvement when adding an explicit hierarchy loss, even before adding in the transitive closure. The transitive closure itself gives an additional increase in performance to both models. In both of these cases, the basic CNN model improves by a greater amount than CNN+Complex. This could be a result of the complex embeddings being more difficult to optimize and therefore more susceptible to variations in hyperparameters. When adding in both the transitive closure and the explicit hierarchy loss, the performance improves further. We observe similar trends when training our models in a lower data regime with ~150,000 examples, or about 5% of the total data.

In all cases, we note that the baseline models that do not incorporate any hierarchical information (neither the transitive closure nor the hierarchy loss) perform ~9 MAP worse, demonstrating the benefits of incorporating structure information.

6.4 MedMentions Entity Linking with UMLS

In addition to entity typing, we evaluate our model's performance on an entity linking task using MedMentions, our new PubMed / UMLS dataset described in Section 2.1.

6.4.1 Results

Table 7 shows results for baselines and our proposed variant with additional hierarchical loss. None of these models incorporate transitive clo-

Tips and Pitfalls in **Direct Ligation** of Large Spontaneous Splenorenal Shunt during Liver Transplantation Patients with large spontaneous splenorenal shunt . . .
baseline: Direct [Direct → General Modifier → Qualifier → Property or Attribute]
+hierarchy: Ligature (correct) [Ligature → Surgical Procedures → medical treatment approach]
A novel approach for selective chemical functionalization and localized assembly of one-dimensional **nanostructures**.
baseline: Structure [Structure → order or structure → general epistemology]
+hierarchy: Nanomaterials (correct) [Nanomaterials → Nanoparticle Complex → Drug or Chemical by Structure]
Gcn5 is recruited onto the **il-2** promoter by interacting with the NFAT in T cells upon TCR stimulation .
baseline: Interleukin-27 [Interleukin-27 → IL2 → Interleukin Gene]
+hierarchy: IL2 Gene (correct) [IL2 Gene → Interleukin Gene]

Table 8: Example predictions from MedMentions. Each example shows the sentence with entity mention span in bold. **Baseline**, shows the predicted entity and its ancestors of a model not incorporating structure. Finally, **+hierarchy** shows the prediction and ancestors for a model which explicitly incorporates the hierarchical structure information.

sure information, due to difficulty incorporating it in our candidate generation, which we leave to future work. The *Normalized* metric considers performance only on mentions with an alias table hit; all models have 0 accuracy for mentions otherwise. We also report the overall score for comparison in future work with improved candidate generation. We see that incorporating structure information results in a 1.1% reduction in absolute error, corresponding to a ~6% reduction in relative error on this large-scale dataset.

Table 8 shows qualitative predictions for models with and without hierarchy information incorporated. Each example contains the sentence (with target entity in bold), predictions for the baseline and hierarchy aware models, and the ancestors of the predicted entity. In the first and second example, the baseline model becomes extremely dependent on TFIDF string similarities when the gold candidate is rare ($\leq$ 10 occurrences). This shows that modeling the structure of the entity hierarchy helps the model disambiguate rare entities. In the third example, structure helps the model understand the hierarchical nature of the labels and prevents it from predicting an entity that is overly specific (e.g predicting Interleukin-27 rather than the correct and more general entity IL2 Gene).

Note that, in contrast with the previous tasks, the complex hierarchical loss provides a significant boost, while the real-valued bilinear model does not. A possible explanation is that UMLS is a far larger/deeper ontology than even TypeNet, and the additional ability of complex embeddings to model intricate graph structure is key to realizing gains from hierarchical modeling.

7 Related Work

By directly linking a large set of mentions and typing a large set of entities with respect to a new ontology and corpus, and our incorporation of structural learning between the many entities and types in our ontologies of interest, our work draws on many different but complementary threads of research in information extraction, knowledge base population, and completion.

Our structural, hierarchy-aware loss between types and entities draws on research in Knowledge Base Inference such as Jain et al. (2018), Trouillon et al. (2016) and Nickel et al. (2011). Combining KB completion with hierarchical structure in knowledge bases has been explored in (Dalvi et al., 2015; Xie et al., 2016). Recently, Wu et al. (2017) proposed a hierarchical loss for text classification.

Linking mentions to a flat set of entities, often in Freebase or Wikipedia, is a long-standing task in NLP (Bunescu and Pasca, 2006; Cucerzan, 2007; Durrett and Klein, 2014; Francis-Landau et al., 2016). Typing of mentions at varying levels of granularity, from CoNLL-style named entity recognition (Tjong Kim Sang and De Meulder, 2003), to the more fine-grained recent approaches (Ling and Weld, 2012; Gillick et al., 2014; Shimaoka et al., 2017), is also related to our task. A few prior attempts to incorporate a very shallow hierarchy into fine-grained entity typing have not lead to significant or consistent improvements (Gillick et al., 2014; Shimaoka et al., 2017).

The knowledge base Yago (Suchanek et al., 2007) includes integration with WordNet and type hierarchies have been derived from its type system (Yosef et al., 2012). Del Corro et al. (2015) use manually crafted rules and patterns (Hearst patterns (Hearst, 1992), appositives, etc) to automatically match entity types to Wordnet synsets.

Recent work has moved towards unifying these two highly related tasks by improving entity linking by simultaneously learning a fine grained entity type predictor (Gupta et al., 2017). Learning hierarchical structures or transitive relations between concepts has been the subject of much recent work (Vilnis and McCallum, 2015; Vendrov et al., 2016; Nickel and Kiela, 2017)

We draw inspiration from all of this prior work, and contribute datasets and models to address previous challenges in jointly modeling the structure of large-scale hierarchical ontologies and mapping textual mentions into an extremely fine-grained space of entities and types.

8 Conclusion

We demonstrate that explicitly incorporating and modeling hierarchical information leads to increased performance in experiments on entity typing and linking across three challenging datasets. Additionally, we introduce two new human-annotated datasets: MedMentions, a corpus of 246k mentions from PubMed abstracts linked to the UMLS knowledge base, and TypeNet, a new hierarchical fine-grained entity typeset an order of magnitude larger and deeper than previous datasets.

While this work already demonstrates considerable improvement over non-hierarchical modeling, future work will explore techniques such as Box embeddings (Vilnis et al., 2018) and Poincaré embeddings (Nickel and Kiela, 2017) to represent the hierarchical embedding space, as well as methods to improve recall in the candidate generation process for entity linking. Most of all, we are excited to see new techniques from the NLP community using the resources we have presented.

A Supplementary Materials

A.1 TypeNet Construction

Freebase type: musical_chord
Example entities: psalms_chord, power_chord harmonic_seventh_chord
chord.n.01: a straight line connecting two points on a curve
chord.n.02: a combination of three or more notes that blend harmoniously when sounded together
musical.n.01: a play or film whose action and dialogue is interspersed with singing and dancing

Table 9: Example given to TypeNet annotators. Here, the Freebase type to be linked is musical_chord. This type is annotated in Freebase belonging to the entities psalms_chord, harmonic_seventh_chord, and power_chord. Below the list of example entities are candidate WordNet synsets obtained by substring matching between the Freebase type and all WordNet synsets. The correctly aligned synset is chord.n.02 shown in bold.

A.2 Model Implementation Details

For all of our experiments, we use pretrained 300 dimensional word vectors from Pennington et al. (2014). These embeddings are fixed during training. The type vectors and entity vectors are all 300 dimensional vectors initialized using Glorot initialization (Glorot and Bengio, 2010). The number of negative links for hierarchical training $n \in \{16, 32, 64, 128, 256\}$.

For regularization, we use dropout (Srivastava et al., 2014) with p $\in \{0.5, 0.75, 0.8\}$ on the sentence encoder output and L2 regularize all learned parameters with $\lambda \in \{$1e-5, 5e-5, 1e-4$\}$. All our parameters are optimized using Adam (Kingma and Ba, 2014) with a learning rate of 0.001. We tune our hyper-parameters via grid search and early stopping on the development set.

A.3 FIGER Implementation Details

To train our models, we use the mention typing loss function defined in Section-5. For models with structure training, we additionally add in the hierarchical loss, along with a weight that is obtained by tuning on the dev set. We follow the same inference time procedure as Shimaoka et al. (2017) For each mention, we first assign the type with the largest probability according to the logits, and then assign additional types based on the condition that their corresponding probability be greater than 0.5.

A.4 Wikipedia Data and Implementation Details

At train time, each training example randomly samples an entity bag of 10 mentions. At test time we classify bags of 20 mentions of an entity. The dataset contains a total of 344,246 entities mapped to the 1081 Freebase types from TypeNet. We consider all sentences in Wikipedia between 10 and 50 tokens long. Tokenization and sentence splitting was performed using NLTK (Loper and Bird, 2002). From these sentences, we considered all entities annotated with a cross-link in Wikipedia that we could link to Freebase and assign types in TypeNet. We then split the data by entities into a 90-5-5 train, dev, test split.

A.5 UMLS Implementation details

We pre-process each string by lowercasing and removing stop words. We consider ngrams from size 1 to 5 and keep the top 100,000 features and the final vectors are L2 normalized. For each mention, In our experiments we consider the top 100 most similar entities as the candidate set.

A.5.1 Candidate Generation Details

Each mention and each canonical entity string in UMLS are mapped to TFIDF character ngram vectors. We pre-process each string by lowercasing and removing stop words. We consider ngrams from size 1 to 5 and keep the top 100,000 features and the final vectors are L2 normalized. For each mention, we calculate the cosine similarity, csim, between the mention string and each canonical entity string. In our experiments we consider the top 100 most similar entities as the candidate set.

Improving Knowledge Graph Embedding Using Simple Constraints

Abstract

Embedding knowledge graphs (KGs) into continuous vector spaces is a focus of current research. Early works performed this task via simple models developed over KG triples. Recent attempts focused on either designing more complicated triple scoring models, or incorporating extra information beyond triples. This paper, by contrast, investigates the potential of using very simple constraints to improve KG embedding. We examine *non-negativity constraints* on entity representations and *approximate entailment constraints* on relation representations. The former help to learn compact and interpretable representations for entities. The latter further encode regularities of logical entailment between relations into their distributed representations. These constraints impose prior beliefs upon the structure of the embedding space, without negative impacts on efficiency or scalability. Evaluation on WordNet, Freebase, and DBpedia shows that our approach is simple yet surprisingly effective, significantly and consistently outperforming competitive baselines. The constraints imposed indeed improve model interpretability, leading to a substantially increased structuring of the embedding space. Code and data are available at `https://github.com/iieir-km/ComplEx-NNE_AER`.

1 Introduction

The past decade has witnessed great achievements in building web-scale knowledge graphs (KGs), *e.g.*, Freebase (Bollacker et al., 2008), DBpedia (Lehmann et al., 2015), and Google's Knowledge Vault (Dong et al., 2014). A typical KG is a multi-relational graph composed of entities as nodes and relations as different types of edges, where each edge is represented as a triple of the form (*head entity*, *relation*, *tail entity*). Such KGs contain rich structured knowledge, and have proven useful for many NLP tasks (Wasserman-Pritsker et al., 2015; Hoffmann et al., 2011; Yang and Mitchell, 2017).

Recently, the concept of *knowledge graph embedding* has been presented and quickly become a hot research topic. The key idea there is to embed components of a KG (*i.e.*, entities and relations) into a continuous vector space, so as to simplify manipulation while preserving the inherent structure of the KG. Early works on this topic learned such vectorial representations (*i.e.*, embeddings) via just simple models developed over KG triples (Bordes et al., 2011, 2013; Jenatton et al., 2012; Nickel et al., 2011). Recent attempts focused on either designing more complicated triple scoring models (Socher et al., 2013; Bordes et al., 2014; Wang et al., 2014; Lin et al., 2015b; Xiao et al., 2016; Nickel et al., 2016b; Trouillon et al., 2016; Liu et al., 2017), or incorporating extra information beyond KG triples (Chang et al., 2014; Zhong et al., 2015; Lin et al., 2015a; Neelakantan et al., 2015; Guo et al., 2015; Luo et al., 2015b; Xie et al., 2016a,b; Xiao et al., 2017). See (Wang et al., 2017) for a thorough review.

This paper, by contrast, investigates the potential of using very simple constraints to improve the KG embedding task. Specifically, we examine two types of constraints: (i) *non-negativity constraints* on entity representations and (ii) *approximate entailment constraints* over relation representations. By using the former, we learn compact representations for entities, which would naturally induce sparsity and interpretability (Murphy et al., 2012). By using the latter, we further encode regularities of logical entailment between relations into their

[*]Corresponding author: Quan Wang.

distributed representations, which might be advantageous to downstream tasks like link prediction and relation extraction (Rocktäschel et al., 2015; Guo et al., 2016). These constraints impose prior beliefs upon the structure of the embedding space, and will help us to learn more predictive embeddings, without significantly increasing the space or time complexity.

Our work has some similarities to those which integrate logical background knowledge into KG embedding (Rocktäschel et al., 2015; Wang et al., 2015; Guo et al., 2016, 2018). Most of such works, however, need grounding of first-order logic rules. The grounding process could be time and space inefficient especially for complicated rules. To avoid grounding, Demeester et al. (2016) tried to model rules using only relation representations. But their work creates vector representations for entity pairs rather than individual entities, and hence fails to handle unpaired entities. Moreover, it can only incorporate strict, hard rules which usually require extensive manual effort to create. Minervini et al. (2017b) proposed adversarial training which can integrate first-order logic rules without grounding. But their work, again, focuses on strict, hard rules. Minervini et al. (2017a) tried to handle uncertainty of rules. But their work assigns to different rules a same confidence level, and considers only equivalence and inversion of relations, which might not always be available in a given KG.

Our approach differs from the aforementioned works in that: (i) it imposes constraints directly on entity and relation representations without grounding, and can easily scale up to large KGs; (ii) the constraints, *i.e.*, non-negativity and approximate entailment derived automatically from statistical properties, are quite universal, requiring no manual effort and applicable to almost all KGs; (iii) it learns an individual representation for each entity, and can successfully make predictions between unpaired entities.

We evaluate our approach on publicly available KGs of WordNet, Freebase, and DBpedia as well. Experimental results indicate that our approach is simple yet surprisingly effective, achieving significant and consistent improvements over competitive baselines, but without negative impacts on efficiency or scalability. The non-negativity and approximate entailment constraints indeed improve model interpretability, resulting in a substantially increased structuring of the embedding space.

The remainder of this paper is organized as follows. We first review related work in Section 2, and then detail our approach in Section 3. Experiments and results are reported in Section 4, followed by concluding remarks in Section 5.

2 Related Work

Recent years have seen growing interest in learning distributed representations for entities and relations in KGs, a.k.a. KG embedding. Early works on this topic devised very simple models to learn such distributed representations, solely on the basis of triples observed in a given KG, *e.g.*, TransE which takes relations as translating operations between head and tail entities (Bordes et al., 2013), and RESCAL which models triples through bilinear operations over entity and relation representations (Nickel et al., 2011). Later attempts roughly fell into two groups: (i) those which tried to design more complicated triple scoring models, *e.g.*, the TransE extensions (Wang et al., 2014; Lin et al., 2015b; Ji et al., 2015), the RESCAL extensions (Yang et al., 2015; Nickel et al., 2016b; Trouillon et al., 2016; Liu et al., 2017), and the (deep) neural network models (Socher et al., 2013; Bordes et al., 2014; Shi and Weninger, 2017; Schlichtkrull et al., 2017; Dettmers et al., 2018); (ii) those which tried to integrate extra information beyond triples, *e.g.*, entity types (Guo et al., 2015; Xie et al., 2016b), relation paths (Neelakantan et al., 2015; Lin et al., 2015a), and textual descriptions (Xie et al., 2016a; Xiao et al., 2017). Please refer to (Nickel et al., 2016a; Wang et al., 2017) for a thorough review of these techniques. In this paper, we show the potential of using very simple constraints (*i.e.*, non-negativity constraints and approximate entailment constraints) to improve KG embedding, without significantly increasing the model complexity.

A line of research related to ours is KG embedding with logical background knowledge incorporated (Rocktäschel et al., 2015; Wang et al., 2015; Guo et al., 2016, 2018). But most of such works require grounding of first-order logic rules, which is time and space inefficient especially for complicated rules. To avoid grounding, Demeester et al. (2016) proposed lifted rule injection, and Minervini et al. (2017b) investigated adversarial training. Both works, however, can only handle strict, hard rules which usually require extensive effort to create. Minervini et al. (2017a) tried to handle uncertainty of background knowledge. But their work considers only equivalence and inversion between relations, which might not always be available in a given KG. Our approach, in contrast, imposes constraints directly on entity and relation representations without grounding. And the constraints used are quite universal, requiring no manual effort and applicable to almost all KGs.

Non-negativity has long been a subject studied in various research fields. Previous studies reveal that non-negativity could naturally induce sparsity and, in most cases, better interpretability (Lee and Seung, 1999). In many NLP-related tasks, non-negativity constraints are introduced to learn more interpretable word representations, which capture the notion of semantic composition (Murphy et al., 2012; Luo et al., 2015a; Fyshe et al., 2015). In this paper, we investigate the ability of non-negativity constraints to learn more accurate KG embeddings with good interpretability.

3 Our Approach

This section presents our approach. We first introduce a basic embedding technique to model triples in a given KG (§ 3.1). Then we discuss the non-negativity constraints over entity representations (§ 3.2) and the approximate entailment constraints over relation representations (§ 3.3). And finally we present the overall model (§ 3.4).

3.1 A Basic Embedding Model

We choose ComplEx (Trouillon et al., 2016) as our basic embedding model, since it is simple and efficient, achieving state-of-the-art predictive performance. Specifically, suppose we are given a KG containing a set of triples $\mathcal{O} = \{(e_i, r_k, e_j)\}$, with each triple composed of two entities $e_i, e_j \in \mathcal{E}$ and their relation $r_k \in \mathcal{R}$. Here $\mathcal{E}$ is the set of entities and $\mathcal{R}$ the set of relations. ComplEx then represents each entity $e \in \mathcal{E}$ as a complex-valued vector $\mathbf{e} \in \mathbb{C}^d$, and each relation $r \in \mathcal{R}$ a complex-valued vector $\mathbf{r} \in \mathbb{C}^d$, where d is the dimensionality of the embedding space. Each $\mathbf{x} \in \mathbb{C}^d$ consists of a real vector component $\text{Re}(\mathbf{x})$ and an imaginary vector component $\text{Im}(\mathbf{x})$, *i.e.*, $\mathbf{x} = \text{Re}(\mathbf{x}) + i\text{Im}(\mathbf{x})$. For any given triple $(e_i, r_k, e_j) \in \mathcal{E} \times \mathcal{R} \times \mathcal{E}$, a multi-linear dot product is used to score that triple, *i.e.*,

$$\begin{aligned}\phi(e_i, r_k, e_j) &\triangleq \text{Re}(\langle \mathbf{e}_i, \mathbf{r}_k, \bar{\mathbf{e}}_j \rangle) \\ &\triangleq \text{Re}(\textstyle\sum_\ell [\mathbf{e}_i]_\ell [\mathbf{r}_k]_\ell [\bar{\mathbf{e}}_j]_\ell), \end{aligned} \quad (1)$$

where $\mathbf{e}_i, \mathbf{r}_k, \mathbf{e}_j \in \mathbb{C}^d$ are the vectorial representations associated with e_i, r_k, e_j, respectively; $\bar{\mathbf{e}}_j$ is the conjugate of $\mathbf{e}_j$; $[\cdot]_\ell$ is the ℓ-th entry of a vector; and $\text{Re}(\cdot)$ means taking the real part of a complex value. Triples with higher $\phi(\cdot, \cdot, \cdot)$ scores are more likely to be true. Owing to the asymmetry of this scoring function, *i.e.*, $\phi(e_i, r_k, e_j) \neq \phi(e_j, r_k, e_i)$, ComplEx can effectively handle asymmetric relations (Trouillon et al., 2016).

3.2 Non-negativity of Entity Representations

On top of the basic ComplEx model, we further require entities to have non-negative (and bounded) vectorial representations. In fact, these distributed representations can be taken as feature vectors for entities, with latent semantics encoded in different dimensions. In ComplEx, as well as most (if not all) previous approaches, there is no limitation on the range of such feature values, which means that both positive and negative properties of an entity can be encoded in its representation. However, as pointed out by Murphy et al. (2012), it would be uneconomical to store all negative properties of an entity or a concept. For instance, to describe cats (a concept), people usually use positive properties such as cats are mammals, cats eat fishes, and cats have four legs, but hardly ever negative properties like cats are not vehicles, cats do not have wheels, or cats are not used for communication.

Based on such intuition, this paper proposes to impose non-negativity constraints on entity representations, by using which only positive properties will be stored in these representations. To better compare different entities on the same scale, we further require entity representations to stay within the hypercube of $[0, 1]^d$, as approximately Boolean embeddings (Kruszewski et al., 2015), *i.e.*,

$$\mathbf{0} \leq \text{Re}(\mathbf{e}), \text{Im}(\mathbf{e}) \leq \mathbf{1}, \quad \forall e \in \mathcal{E}, \quad (2)$$

where $\mathbf{e} \in \mathbb{C}^d$ is the representation for entity $e \in \mathcal{E}$, with its real and imaginary components denoted by $\text{Re}(\mathbf{e}), \text{Im}(\mathbf{e}) \in \mathbb{R}^d$; $\mathbf{0}$ and $\mathbf{1}$ are d-dimensional vectors with all their entries being 0 or 1; and $\geq, \leq, =$ denote the entry-wise comparisons throughout the paper whenever applicable. As shown by Lee and Seung (1999), non-negativity, in most cases, will further induce sparsity and interpretability.

3.3 Approximate Entailment for Relations

Besides the non-negativity constraints over entity representations, we also study approximate entailment constraints over relation representations. By approximate entailment, we mean an ordered pair of relations that the former approximately entails the latter, *e.g.*, `BornInCountry` and `Nationality`, stating that a person born in a country is very likely, but not necessarily, to have a nationality of that country. Each such relation pair is associated with a weight to indicate the confidence level of entailment. A larger weight stands for a higher level of confidence. We denote by $r_p \xrightarrow{\lambda} r_q$ the approximate entailment between relations r_p and r_q, with confidence level λ. This kind of entailment can be derived automatically from a KG by modern rule mining systems (Galárraga et al., 2015). Let $\mathcal{T}$ denote the set of all such approximate entailments derived beforehand.

Before diving into approximate entailment, we first explore the modeling of strict entailment, *i.e.*, entailment with infinite confidence level $\lambda = +\infty$. The strict entailment $r_p \rightarrow r_q$ states that if relation r_p holds then relation r_q must also hold. This entailment can be roughly modelled by requiring

$$\phi(e_i, r_p, e_j) \leq \phi(e_i, r_q, e_j), \quad \forall e_i, e_j \in \mathcal{E}, \tag{3}$$

where $\phi(\cdot,\cdot,\cdot)$ is the score for a triple predicted by the embedding model, defined by Eq. (1). Eq. (3) can be interpreted as follows: for any two entities e_i and e_j, if (e_i, r_p, e_j) is a true fact with a high score $\phi(e_i, r_p, e_j)$, then the triple (e_i, r_q, e_j) with an even higher score should also be predicted as a true fact by the embedding model. Note that given the non-negativity constraints defined by Eq. (2), a sufficient condition for Eq. (3) to hold, is to further impose

$$\mathrm{Re}(\mathbf{r}_p) \leq \mathrm{Re}(\mathbf{r}_q), \ \ \mathrm{Im}(\mathbf{r}_p) = \mathrm{Im}(\mathbf{r}_q), \tag{4}$$

where $\mathbf{r}_p$ and $\mathbf{r}_q$ are the complex-valued representations for r_p and r_q respectively, with the real and imaginary components denoted by $\mathrm{Re}(\cdot), \mathrm{Im}(\cdot) \in \mathbb{R}^d$. That means, when the constraints of Eq. (4) (along with those of Eq. (2)) are satisfied, the requirement of Eq. (3) (or in other words $r_p \rightarrow r_q$) will always hold. We provide a proof of sufficiency as supplementary material.

Next we examine the modeling of approximate entailment. To this end, we further introduce the confidence level λ and allow slackness in Eq. (4), which yields

$$\lambda\big(\mathrm{Re}(\mathbf{r}_p) - \mathrm{Re}(\mathbf{r}_q)\big) \leq \boldsymbol{\alpha}, \tag{5}$$

$$\lambda\big(\mathrm{Im}(\mathbf{r}_p) - \mathrm{Im}(\mathbf{r}_q)\big)^2 \leq \boldsymbol{\beta}. \tag{6}$$

Here $\boldsymbol{\alpha}, \boldsymbol{\beta} \geq \mathbf{0}$ are slack variables, and $(\cdot)^2$ means an entry-wise operation. Entailments with higher confidence levels show less tolerance for violating the constraints. When $\lambda = +\infty$, Eqs. (5) – (6) degenerate to Eq. (4). The above analysis indicates that our approach can model entailment simply by imposing constraints over relation representations, without traversing all possible (e_i, e_j) entity pairs (*i.e.*, grounding). In addition, different confidence levels are encoded in the constraints, making our approach moderately tolerant of uncertainty.

3.4 The Overall Model

Finally, we combine together the basic embedding model of ComplEx, the non-negativity constraints on entity representations, and the approximate entailment constraints over relation representations. The overall model is presented as follows:

$$\begin{aligned} \min_{\Theta,\{\boldsymbol{\alpha},\boldsymbol{\beta}\}} \ & \sum_{\mathcal{D}^+\cup\mathcal{D}^-} \log\big(1 + \exp(-y_{ijk}\phi(e_i, r_k, e_j))\big) \\ & + \mu \sum\nolimits_{\mathcal{T}} \mathbf{1}^\top(\boldsymbol{\alpha}+\boldsymbol{\beta}) + \eta\|\Theta\|_2^2, \\ \text{s.t.} \ \ & \lambda\big(\mathrm{Re}(\mathbf{r}_p) - \mathrm{Re}(\mathbf{r}_q)\big) \leq \boldsymbol{\alpha}, \\ & \lambda\big(\mathrm{Im}(\mathbf{r}_p) - \mathrm{Im}(\mathbf{r}_q)\big)^2 \leq \boldsymbol{\beta}, \\ & \boldsymbol{\alpha}, \boldsymbol{\beta} \geq \mathbf{0}, \quad \forall r_p \xrightarrow{\lambda} r_q \in \mathcal{T}, \\ & \mathbf{0} \leq \mathrm{Re}(\mathbf{e}), \mathrm{Im}(\mathbf{e}) \leq \mathbf{1}, \quad \forall e \in \mathcal{E}. \end{aligned} \tag{7}$$

Here, $\Theta \triangleq \{\mathbf{e} : e \in \mathcal{E}\} \cup \{\mathbf{r} : r \in \mathcal{R}\}$ is the set of all entity and relation representations; $\mathcal{D}^+$ and $\mathcal{D}^-$ are the sets of positive and negative training triples respectively; a positive triple is directly observed in the KG, *i.e.*, $(e_i, r_k, e_j) \in \mathcal{O}$; a negative triple can be generated by randomly corrupting the head or the tail entity of a positive triple, *i.e.*, (e_i', r_k, e_j) or (e_i, r_k, e_j'); $y_{ijk} = \pm 1$ is the label (positive or negative) of triple (e_i, r_k, e_j). In this optimization, the first term of the objective function is a typical logistic loss, which enforces triples to have scores close to their labels. The second term is the sum of slack variables in the approximate entailment constraints, with a penalty coefficient $\mu \geq 0$. The motivation is, although we allow slackness in those constraints we hope the total slackness to be small, so that the constraints can be better satisfied. The last term is L_2 regularization to avoid over-fitting, and $\eta \geq 0$ is the regularization coefficient.

To solve this optimization problem, the approximate entailment constraints (as well as the corresponding slack variables) are converted into penalty terms and added to the objective function, while the non-negativity constraints remain as they are. As such, the optimization problem of Eq. (7) can be rewritten as:

$$
\begin{aligned}
\min_{\Theta} \quad & \sum_{\mathcal{D}^+ \cup \mathcal{D}^-} \log\big(1+\exp(-y_{ijk}\phi(e_i, r_k, e_j))\big) \\
& + \mu \sum\nolimits_{\mathcal{T}} \lambda \mathbf{1}^\top \big[\mathrm{Re}(\mathbf{r}_p) - \mathrm{Re}(\mathbf{r}_q)\big]_+ \\
& + \mu \sum\nolimits_{\mathcal{T}} \lambda \mathbf{1}^\top \big(\mathrm{Im}(\mathbf{r}_p) - \mathrm{Im}(\mathbf{r}_q)\big)^2 + \eta \|\Theta\|_2^2, \\
\text{s.t.} \quad & \mathbf{0} \leq \mathrm{Re}(\mathbf{e}), \mathrm{Im}(\mathbf{e}) \leq \mathbf{1}, \quad \forall e \in \mathcal{E}, \qquad (8)
\end{aligned}
$$

where $[\mathbf{x}]_+ = \max(\mathbf{0}, \mathbf{x})$ with $\max(\cdot, \cdot)$ being an entry-wise operation. The equivalence between Eq. (7) and Eq. (8) is shown in the supplementary material. We use SGD in mini-batch mode as our optimizer, with AdaGrad (Duchi et al., 2011) to tune the learning rate. After each gradient descent step, we project (by truncation) real and imaginary components of entity representations into the hypercube of $[0, 1]^d$, to satisfy the non-negativity constraints.

While favouring a better structuring of the embedding space, imposing the additional constraints will not substantially increase model complexity. Our approach has a space complexity of $O(nd + md)$, which is the same as that of ComplEx. Here, n is the number of entities, m the number of relations, and $O(nd + md)$ to store a d-dimensional complex-valued vector for each entity and each relation. The time complexity (per iteration) of our approach is $O(sd+td+\bar{n}d)$, where s is the average number of triples in a mini-batch, $\bar{n}$ the average number of entities in a mini-batch, and t the total number of approximate entailments in $\mathcal{T}$. $O(sd)$ is to handle triples in a mini-batch, $O(td)$ penalty terms introduced by the approximate entailments, and $O(\bar{n}d)$ further the non-negativity constraints on entity representations. Usually there are much fewer entailments than triples, *i.e.*, $t \ll s$, and also $\bar{n} \leq 2s$.[1] So the time complexity of our approach is on a par with $O(sd)$, *i.e.*, the time complexity of ComplEx.

4 Experiments and Results

This section presents our experiments and results. We first introduce the datasets used in our experiments (§ 4.1). Then we empirically evaluate our approach in the link prediction task (§ 4.2). After that, we conduct extensive analysis on both entity representations (§ 4.3) and relation representations (§ 4.4) to show the interpretability of our model. Code and data used in the experiments are available at `https://github.com/iieir-km/ComplEx-NNE_AER`.

4.1 Datasets

The first two datasets we used are WN18 and FB15K, released by Bordes et al. (2013).[2] WN18 is a subset of WordNet containing 18 relations and 40,943 entities, and FB15K a subset of Freebase containing 1,345 relations and 14,951 entities. We create our third dataset from the mapping-based objects of core DBpedia.[3] We eliminate relations not included within the DBpedia ontology such as `HomePage` and `Logo`, and discard entities appearing less than 20 times. The final dataset, referred to as DB100K, is composed of 470 relations and 99,604 entities. Triples on each datasets are further divided into training, validation, and test sets, used for model training, hyperparameter tuning, and evaluation respectively. We follow the original split for WN18 and FB15K, and draw a split of 597,572/50,000/50,000 triples for DB100K.

We further use AMIE+ (Galárraga et al., 2015)[4] to extract approximate entailments automatically from the *training* set of each dataset. As suggested by Guo et al. (2018), we consider entailments with PCA confidence higher than 0.8.[5] As such, we extract 17 approximate entailments from WN18, 535 from FB15K, and 56 from DB100K. Table 1 gives some examples of these approximate entailments, along with their confidence levels. Table 2 further summarizes the statistics of the datasets.

4.2 Link Prediction

We first evaluate our approach in the link prediction task, which aims to predict a triple (e_i, r_k, e_j) with e_i or e_j missing, *i.e.*, predict e_i given (r_k, e_j) or predict e_j given (e_i, r_k).

Evaluation Protocol: We follow the protocol introduced by Bordes et al. (2013). For each test triple (e_i, r_k, e_j), we replace its head entity e_i with every entity $e_i' \in \mathcal{E}$, and calculate a score for the corrupted triple (e_i', r_k, e_j), *e.g.*, $\phi(e_i', r_k, e_j)$ defined by Eq. (1). Then we sort these scores in de-

[1]There will be at most $2s$ entities contained in s triples.

Dataset	# Ent	# Rel	# Train/Valid/Test			# Cons
WN18	40,943	18	141,442	5,000	5,000	17
FB15K	14,951	1,345	483,142	50,000	59,071	535
DB100K	99,604	470	597,572	50,000	50,000	56

Table 2: Statistics of datasets, where the columns respectively indicate the number of entities, relations, training/validation/test triples, and approximate entailments.

scending order, and get the rank of the correct entity e_i. During ranking, we remove corrupted triples that already exist in either the training, validation, or test set, *i.e.*, the *filtered* setting as described in (Bordes et al., 2013). This whole procedure is repeated while replacing the tail entity e_j. We report on the *test* set the mean reciprocal rank (MRR) and the proportion of correct entities ranked in the top n (HITS@N), with $n = 1, 3, 10$.

Comparison Settings: We compare the performance of our approach against a variety of KG embedding models developed in recent years. These models can be categorized into three groups:

- Simple embedding models that utilize triples alone without integrating extra information, including TransE (Bordes et al., 2013), DistMult (Yang et al., 2015), HolE (Nickel et al., 2016b), ComplEx (Trouillon et al., 2016), and ANALOGY (Liu et al., 2017). Our approach is developed on the basis of ComplEx.

- Other extensions of ComplEx that integrate logical background knowledge in addition to triples, including RUGE (Guo et al., 2018) and ComplEx$^{\mathrm{R}}$ (Minervini et al., 2017a). The former requires grounding of first-order logic rules. The latter is restricted to relation equivalence and inversion, and assigns an identical confidence level to all different rules.

- Latest developments or implementations that achieve current state-of-the-art performance reported on the benchmarks of WN18 and FB15K, including R-GCN (Schlichtkrull et al., 2017), ConvE (Dettmers et al., 2018), and Single DistMult (Kadlec et al., 2017).[6] The first two are built based on neural network architectures, which are, by nature, more complicated than the simple models. The last one is a re-implementation of DistMult, generating 1000 to 2000 negative training examples per positive one, which leads to better performance but requires significantly longer training time.

We further evaluate our approach in two different settings: (i) ComplEx-NNE that imposes only the Non-Negativity constraints on Entity representations, *i.e.*, optimization Eq. (8) with $\mu = 0$; and (ii) ComplEx-NNE+AER that further imposes the Approximate Entailment constraints over Relation representations besides those non-negativity ones, *i.e.*, optimization Eq. (8) with $\mu > 0$.

Implementation Details: We compare our approach against all the three groups of baselines on the benchmarks of WN18 and FB15K. We directly report their original results on these two datasets to avoid re-implementation bias. On DB100K, the newly created dataset, we take the first two groups of baselines, *i.e.*, those simple embedding models and ComplEx extensions with logical background knowledge incorporated. We do not use the third group of baselines due to efficiency and complexity issues. We use the code provided by Trouillon et al. (2016)[7] for TransE, DistMult, and ComplEx, and the code released by their authors for ANALOGY[8] and RUGE[9]. We re-implement HolE and ComplEx$^{\mathrm{R}}$ so that all the baselines (as well as our approach) share the same optimization mode, *i.e.*, SGD with AdaGrad and gradient normalization, to facilitate a fair comparison.[10] We follow Trouillon et al. (2016) to adopt a ranking loss for TransE and a logistic loss for all the other methods.

[6] We do not consider Ensemble DistMult (Dettmers et al., 2018) which combines several different models together, to facilitate a fair comparison.

ComplEx-NNE+AER	**0.306***	**0.244***	**0.334***	0.418

Table 4: Link prediction results on the test set of DB100K, with best scores highlighted in bold, statistically significant improvements marked by "$*$".

Among those baselines, RUGE and ComplEx$^{\mathrm{R}}$ require additional logical background knowledge. RUGE makes use of soft rules, which are extracted by AMIE+ from the *training* sets. As suggested by Guo et al. (2018), length-1 and length-2 rules with PCA confidence higher than 0.8 are utilized. Note that our approach also makes use of AMIE+ rules with PCA confidence higher than 0.8. But it only considers entailments between a pair of relations, *i.e.*, length-1 rules. ComplEx$^{\mathrm{R}}$ takes into account equivalence and inversion between relations. We derive such axioms directly from our approximate entailments. If $r_p \xrightarrow{\lambda_1} r_q$ and $r_q \xrightarrow{\lambda_2} r_p$ with $\lambda_1, \lambda_2 > 0.8$, we think relations r_p and r_q are equivalent. And similarly, if $r_p^{-1} \xrightarrow{\lambda_1} r_q$ and $r_q^{-1} \xrightarrow{\lambda_2} r_p$ with $\lambda_1, \lambda_2 > 0.8$, we consider r_p as an inverse of r_q.

For all the methods, we create 100 mini-batches on each dataset, and conduct a grid search to find hyperparameters that maximize MRR on the validation set, with at most 1000 iterations over the training set. Specifically, we tune the embedding size $d \in \{100, 150, 200\}$, the L_2 regularization coefficient $\eta \in \{0.001, 0.003, 0.01, 0.03, 0.1\}$, the ratio of negative over positive training examples $\alpha \in \{2, 10\}$, and the initial learning rate $\gamma \in \{0.01, 0.05, 0.1, 0.5, 1.0\}$. For TransE, we tune the margin of the ranking loss $\delta \in \{0.1, 0.2, 0.5, 1, 2, 5, 10\}$. Other hyperparameters of ANALOGY and RUGE are set or tuned according to the default settings suggested by their authors (Liu et al., 2017; Guo et al., 2018). After getting the best ComplEx model, we tune the relation constraint penalty of our approach ComplEx-NNE+AER (μ in Eq. (8)) in the range of $\{10^{-5}, 10^{-4}, \cdots, 10^4, 10^5\}$, with all its other hyperparameters fixed to their optimal configurations. We then directly set $\mu = 0$ to get the optimal ComplEx-NNE model. The weight of soft constraints in ComplEx$^{\mathrm{R}}$ is tuned in the same range as μ. The optimal configurations for our approach are: $d = 200$, $\eta = 0.03$, $\alpha = 10$, $\gamma = 1.0$, $\mu = 10$ on WN18; $d = 200$, $\eta{=}0.01$, $\alpha{=}10$, $\gamma = 0.5$, $\mu = 10^{-3}$ on FB15K; and $d = 150$, $\eta = 0.03$, $\alpha = 10$, $\gamma = 0.1$, $\mu = 10^{-5}$ on DB100K.

Experimental Results: Table 3 presents the results on the test sets of WN18 and FB15K, where the results for the baselines are taken directly from previous literature. Table 4 further provides the results on the test set of DB100K, with all the methods tuned and tested in (almost) the same setting. On all the datasets, we test statistical significance of the improvements achieved by ComplEx-NNE/ ComplEx-NNE+AER over ComplEx, by using a paired t-test. The reciprocal rank or HITS@N value with $n = 1, 3, 10$ for each test triple is used as paired data. The symbol "$*$" indicates a significance level of $p < 0.05$.

The results demonstrate that imposing the non-negativity and approximate entailment constraints indeed improves KG embedding. ComplEx-NNE and ComplEx-NNE+AER perform better than (or at least equally well as) ComplEx in almost all the metrics on all the three datasets, and most of the improvements are statistically significant (except those on WN18). More interestingly, just by introducing these simple constraints, ComplEx-NNE+ AER can beat very strong baselines, including the best performing basic models like ANALOGY, those previous extensions of ComplEx like RUGE or ComplEx$^{\mathrm{R}}$, and even the complicated developments or implementations like ConvE or Single DistMult. This demonstrates the superiority of our approach.

4.3 Analysis on Entity Representations

This section inspects how the structure of the entity embedding space changes when the constraints are imposed. We first provide the visualization of entity representations on DB100K. On this dataset each entity is associated with a single type label.[11] We pick 4 types `reptile`, `wine_region`, `species`, and `programming_language`, and randomly select 30 entities from each type. Figure 1 visualizes the representations of these entities learned by ComplEx and ComplEx-NNE+AER (real components only), with the optimal configurations determined by link prediction (see § 4.2 for details, applicable to all analysis hereafter). During the visualization, we normalize the real component of each entity by $[\tilde{\mathbf{x}}]_\ell = \frac{[\mathbf{x}]_\ell - \min(\mathbf{x})}{\max(\mathbf{x}) - \min(\mathbf{x})}$, where $\min(\mathbf{x})$ or $\max(\mathbf{x})$ is the minimum or maximum entry of $\mathbf{x}$ respectively. We observe that after imposing the non-negativity constraints, ComplEx-NNE+AER indeed obtains compact and interpretable representations for entities. Each entity is represented by only a relatively small number of "active" dimensions. And entities

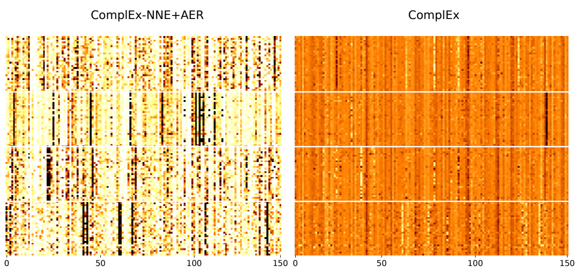

Figure 1: Visualization of real components of entity representations (rows) learned by ComplEx-NNE+AER (left) and ComplEx (right). From top to bottom, entities belong to type `reptile`, `wine_region`, `species`, and `programming_language` in turn. Values range from 0 (white) via 0.5 (orange) to 1 (black). Best viewed in color.

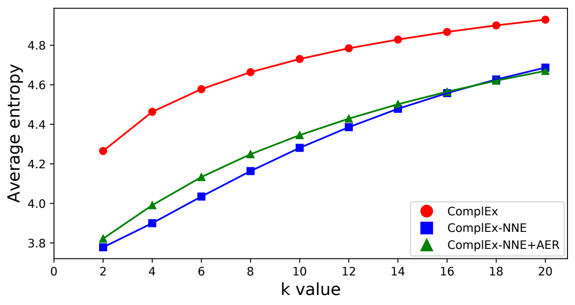

Figure 2: Average entropy over all dimensions of real components of entity representations learned by ComplEx (circles), ComplEx-NNE (squares), and ComplEx-NNE+AER (triangles) as K varies.

with the same type tend to activate the same set of dimensions, while entities with different types often get clearly different dimensions activated.

Then we investigate the semantic purity of these dimensions. Specifically, we collect the representations of all the entities on DB100K (real components only). For each dimension of these representations, top K percent of entities with the highest activation values on this dimension are picked. We can calculate the entropy of the type distribution of the entities selected. This entropy reflects diversity of entity types, or in other words, semantic purity. If all the K percent of entities have the same type, we will get the lowest entropy of zero (the highest semantic purity). On the contrary, if each of them has a distinct type, we will get the highest entropy (the lowest semantic purity). Figure 2 shows the average entropy over all dimensions of entity representations (real components only) learned by ComplEx, ComplEx-NNE, and ComplEx-NNE+

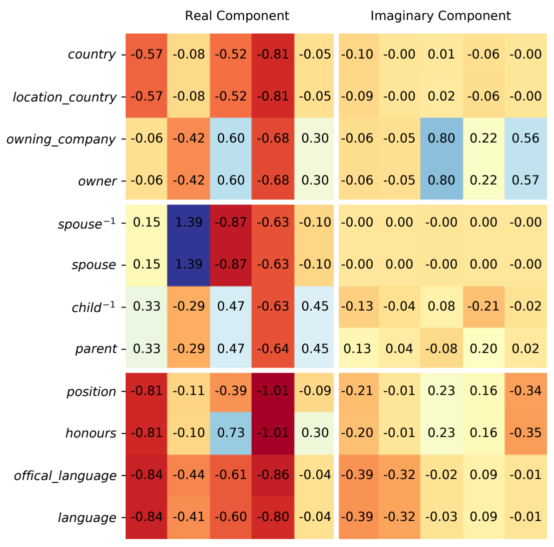

Figure 3: Visualization of relation representations learned by ComplEx-NNE+AER, with the top 4 relations from the equivalence class, the middle 4 the inversion class, and the bottom 4 others.

AER, as K varies. We can see that after imposing the non-negativity constraints, ComplEx-NNE and ComplEx-NNE+AER can learn entity representations with latent dimensions of consistently higher semantic purity. We have conducted the same analyses on imaginary components of entity representations, and observed similar phenomena. The results are given as supplementary material.

4.4 Analysis on Relation Representations

This section further provides a visual inspection of the relation embedding space when the constraints are imposed. To this end, we group relation pairs involved in the DB100K entailment constraints into 3 classes: equivalence, inversion, and others.[12] We choose 2 pairs of relations from each class, and visualize these relation representations learned by ComplEx-NNE+AER in Figure 3, where for each relation we randomly pick 5 dimensions from both its real and imaginary components. By imposing the approximate entailment constraints, these relation representations can encode logical regularities quite well. Pairs of relations from the first class (equivalence) tend to have identical representations $\mathbf{r}_p \approx \mathbf{r}_q$, those from the second class (inversion) complex conjugate representations $\mathbf{r}_p \approx \bar{\mathbf{r}}_q$; and the others representations that $\mathrm{Re}(\mathbf{r}_p) \leq \mathrm{Re}(\mathbf{r}_q)$ and $\mathrm{Im}(\mathbf{r}_p) \approx \mathrm{Im}(\mathbf{r}_q)$.

[12]Equivalence and inversion are detected using heuristics introduced in § 4.2 (implementation details). See the supplementary material for detailed properties of these three classes.

5 Conclusion

This paper investigates the potential of using very simple constraints to improve KG embedding. Two types of constraints have been studied: (i) the non-negativity constraints to learn compact, interpretable entity representations, and (ii) the approximate entailment constraints to further encode logical regularities into relation representations. Such constraints impose prior beliefs upon the structure of the embedding space, and will not significantly increase the space or time complexity. Experimental results on benchmark KGs demonstrate that our method is simple yet surprisingly effective, showing significant and consistent improvements over strong baselines. The constraints indeed improve model interpretability, yielding a substantially increased structuring of the embedding space.

Abstract

Knowledge Graph (KG) embedding has emerged as a very active area of research over the last few years, resulting in the development of several embedding methods. These KG embedding methods represent KG entities and relations as vectors in a high-dimensional space. Despite this popularity and effectiveness of KG embeddings in various tasks (e.g., link prediction), geometric understanding of such embeddings (i.e., arrangement of entity and relation vectors in vector space) is unexplored – we fill this gap in the paper. We initiate a study to analyze the geometry of KG embeddings and correlate it with task performance and other hyperparameters. To the best of our knowledge, this is the first study of its kind. Through extensive experiments on real-world datasets, we discover several insights. For example, we find that there are sharp differences between the geometry of embeddings learnt by different classes of KG embeddings methods. We hope that this initial study will inspire other follow-up research on this important but unexplored problem.

1 Introduction

Knowledge Graphs (KGs) are multi-relational graphs where nodes represent entities and typed-edges represent relationships among entities. Recent research in this area has resulted in the development of several large KGs, such as NELL (Mitchell et al., 2015), YAGO (Suchanek et al., 2007), and Freebase (Bollacker et al., 2008), among others. These KGs contain thousands of predicates (e.g., *person*, *city*, *mayorOf(person, city)*, etc.), and millions of triples involving such predicates, e.g., *(Bill de Blasio, mayorOf, New York City)*.

The problem of learning embeddings for Knowledge Graphs has received significant attention in recent years, with several methods being proposed (Bordes et al., 2013; Lin et al., 2015; Nguyen et al., 2016; Nickel et al., 2016; Trouillon et al., 2016). These methods represent entities and relations in a KG as vectors in high dimensional space. These vectors can then be used for various tasks, such as, link prediction, entity classification etc. Starting with TransE (Bordes et al., 2013), there have been many KG embedding methods such as TransH (Wang et al., 2014), TransR (Lin et al., 2015) and STransE (Nguyen et al., 2016) which represent relations as translation vectors from head entities to tail entities. These are *additive models*, as the vectors interact via addition and subtraction. Other KG embedding models, such as, DistMult (Yang et al., 2014), HolE (Nickel et al., 2016), and ComplEx (Trouillon et al., 2016) are *multiplicative* where entity-relation-entity triple likelihood is quantified by a multiplicative score function. All these methods employ a score function for distinguishing correct triples from incorrect ones.

In spite of the existence of many KG embedding methods, our understanding of the geometry and structure of such embeddings is very shallow. A recent work (Mimno and Thompson, 2017) analyzed the geometry of word embeddings. However, the problem of analyzing geometry of KG embeddings is still unexplored – we fill this important gap. In this paper, we analyze the geometry of such vectors in terms of their lengths and conicity, which, as defined in Section 4, describes their positions and orientations in the vector space. We later study the effects of model type and training hyperparameters on the geometry of KG embeddings and correlate geometry with performance.

We make the following contributions:

- We initiate a study to analyze the geometry of various Knowledge Graph (KG) embeddings. To the best of our knowledge, this is the first study of its kind. We also formalize various metrics which can be used to study geometry of a set of vectors.
- Through extensive analysis, we discover several interesting insights about the geometry of KG embeddings. For example, we find systematic differences between the geometries of embeddings learned by additive and multiplicative KG embedding methods.
- We also study the relationship between geometric attributes and predictive performance of the embeddings, resulting in several new insights. For example, in case of multiplicative models, we observe that for entity vectors generated with a fixed number of negative samples, lower conicity (as defined in Section 4) or higher average vector length lead to higher performance.

Source code of all the analysis tools developed as part of this paper is available at `https://github.com/malllabiisc/kg-geometry`. We are hoping that these resources will enable one to quickly analyze the geometry of any KG embedding, and potentially other embeddings as well.

2 Related Work

In spite of the extensive and growing literature on both KG and non-KG embedding methods, very little attention has been paid towards understanding the geometry of the learned embeddings. A recent work (Mimno and Thompson, 2017) is an exception to this which addresses this problem in the context of word vectors. This work revealed a surprising correlation between word vector geometry and the number of negative samples used during training. Instead of word vectors, in this paper we focus on understanding the geometry of KG embeddings. In spite of this difference, the insights we discover in this paper generalizes some of the observations in the work of (Mimno and Thompson, 2017). Please see Section 6.2 for more details.

Since KGs contain only positive triples, negative sampling has been used for training KG embeddings. Effect of the number of negative samples in KG embedding performance was studied by (Toutanova et al., 2015). In this paper, we study the effect of the number of negative samples on KG embedding geometry as well as performance.

In addition to the additive and multiplicative KG embedding methods already mentioned in Section 1, there is another set of methods where the entity and relation vectors interact via a neural network. Examples of methods in this category include NTN (Socher et al., 2013), CONV (Toutanova et al., 2015), ConvE (Dettmers et al., 2017), R-GCN (Schlichtkrull et al., 2017), ER-MLP (Dong et al., 2014) and ER-MLP-2n (Ravishankar et al., 2017). Due to space limitations, in this paper we restrict our scope to the analysis of the geometry of additive and multiplicative KG embedding models only, and leave the analysis of the geometry of neural network-based methods as part of future work.

3 Overview of KG Embedding Methods

For our analysis, we consider six representative KG embedding methods: TransE (Bordes et al., 2013), TransR (Lin et al., 2015), STransE (Nguyen et al., 2016), DistMult (Yang et al., 2014), HolE (Nickel et al., 2016) and ComplEx (Trouillon et al., 2016). We refer to TransE, TransR and STransE as *additive* methods because they learn embeddings by modeling relations as translation vectors from one entity to another, which results in vectors interacting via the addition operation during training. On the other hand, we refer to DistMult, HolE and ComplEx as *multiplicative* methods as they quantify the likelihood of a triple belonging to the KG through a multiplicative score function. The score functions optimized by these methods are summarized in Table 1.

Notation: Let $\mathcal{G} = (\mathcal{E}, \mathcal{R}, \mathcal{T})$ be a Knowledge Graph (KG) where $\mathcal{E}$ is the set of entities, $\mathcal{R}$ is the set of relations and $\mathcal{T} \subset \mathcal{E} \times \mathcal{R} \times \mathcal{E}$ is the set of triples stored in the graph. Most of the KG embedding methods learn vectors $\mathbf{e} \in \mathbb{R}^{d_e}$ for $e \in \mathcal{E}$, and $\mathbf{r} \in \mathbb{R}^{d_r}$ for $r \in \mathcal{R}$. Some methods also learn projection matrices $M_r \in \mathbb{R}^{d_r \times d_e}$ for relations. The correctness of a triple is evaluated using a model specific score function $\sigma : \mathcal{E} \times \mathcal{R} \times \mathcal{E} \to \mathbb{R}$. For learning the embeddings, a loss function $\mathcal{L}(\mathcal{T}, \mathcal{T}'; \theta)$, defined over a set of positive triples $\mathcal{T}$, set of (sampled) negative triples $\mathcal{T}'$, and the parameters θ is optimized.

We use small italics characters (e.g., h, r) to represent entities and relations, and correspond-

Type	Model	Score Function $\sigma(h,r,t)$
Additive	TransE (Bordes et al., 2013)	$-\left\|\mathbf{h}+\mathbf{r}-\mathbf{t}\right\|_1$
	TransR (Lin et al., 2015)	$-\left\|M_r\mathbf{h}+\mathbf{r}-M_r\mathbf{t}\right\|_1$
	STransE (Nguyen et al., 2016)	$-\left\|M_r^1\mathbf{h}+\mathbf{r}-M_r^2\mathbf{t}\right\|_1$
Multiplicative	DistMult (Yang et al., 2014)	$\mathbf{r}^\top(\mathbf{h}\odot\mathbf{t})$
	HolE (Nickel et al., 2016)	$\mathbf{r}^\top(\mathbf{h}\star\mathbf{t})$
	ComplEx (Trouillon et al., 2016)	$\mathbf{Re}(\mathbf{r}^\top(\mathbf{h}\odot\bar{\mathbf{t}}))$

ing bold characters to represent their vector embeddings (e.g., $\mathbf{h}$, $\mathbf{r}$). We use bold capitalization (e.g., $\mathbf{V}$) to represent a set of vectors. Matrices are represented by capital italics characters (e.g., M).

3.1 Additive KG Embedding Methods

This is the set of methods where entity and relation vectors interact via additive operations. The score function for these models can be expressed as below

$$\sigma(h,r,t) = -\left\|M_r^1\mathbf{h}+\mathbf{r}-M_r^2\mathbf{t}\right\|_1 \qquad (1)$$

where $\mathbf{h},\mathbf{t} \in \mathbb{R}^{d_e}$ and $\mathbf{r} \in \mathbb{R}^{d_r}$ are vectors for head entity, tail entity and relation respectively. $M_r^1, M_r^2 \in \mathbb{R}^{d_r \times d_e}$ are projection matrices from entity space $\mathbb{R}^{d_e}$ to relation space $\mathbb{R}^{d_r}$.

TransE (Bordes et al., 2013) is the simplest additive model where the entity and relation vectors lie in same $d-$dimensional space, i.e., $d_e = d_r = d$. The projection matrices $M_r^1 = M_r^2 = \mathcal{I}_d$ are identity matrices. The relation vectors are modeled as translation vectors from head entity vectors to tail entity vectors. Pairwise ranking loss is then used to learn these vectors. Since the model is simple, it has limited capability in capturing many-to-one, one-to-many and many-to-many relations.

TransR (Lin et al., 2015) is another translation-based model which uses separate spaces for entity and relation vectors allowing it to address the shortcomings of TransE. Entity vectors are projected into a relation specific space using the corresponding projection matrix $M_r^1 = M_r^2 = M_r$. The training is similar to TransE.

STransE (Nguyen et al., 2016) is a generalization of TransR and uses different projection matrices for head and tail entity vectors. The training is similar to TransE. STransE achieves better performance than the previous methods but at the cost of more number of parameters.

Equation 1 is the score function used in STransE. TransE and TransR are special cases of STransE with $M_r^1 = M_r^2 = \mathcal{I}_d$ and $M_r^1 = M_r^2 = M_r$, respectively.

3.2 Multiplicative KG Embedding Methods

This is the set of methods where the vectors interact via multiplicative operations (usually dot product). The score function for these models can be expressed as

$$\sigma(h,r,t) = \mathbf{r}^\top f(\mathbf{h},\mathbf{t}) \qquad (2)$$

where $\mathbf{h},\mathbf{t},\mathbf{r} \in \mathbb{F}^d$ are vectors for head entity, tail entity and relation respectively. $f(\mathbf{h},\mathbf{t}) \in \mathbb{F}^d$ measures compatibility of head and tail entities and is specific to the model. $\mathbb{F}$ is either real space $\mathbb{R}$ or complex space $\mathbb{C}$. Detailed descriptions of the models we consider are as follows.

DistMult (Yang et al., 2014) models entities and relations as vectors in $\mathbb{R}^d$. It uses an entry-wise product ($\odot$) to measure compatibility between head and tail entities, while using logistic loss for training the model.

$$\sigma_{DistMult}(h,r,t) = \mathbf{r}^\top(\mathbf{h}\odot\mathbf{t}) \qquad (3)$$

Since the entry-wise product in (3) is symmetric, DistMult is not suitable for asymmetric and anti-symmetric relations.

HolE (Nickel et al., 2016) also models entities and relations as vectors in $\mathbb{R}^d$. It uses circular correlation operator ($\star$) as compatibility function defined as

$$[\mathbf{h}\star\mathbf{t}]_k = \sum_{i=0}^{d-1} \mathbf{h}_i\mathbf{t}_{(k+i) \bmod d}$$

The score function is given as

$$\sigma_{HolE}(h,r,t) = \mathbf{r}^\top(\mathbf{h}\star\mathbf{t}) \qquad (4)$$

The circular correlation operator being asymmetric, can capture asymmetric and anti-symmetric relations, but at the cost of higher time complexity

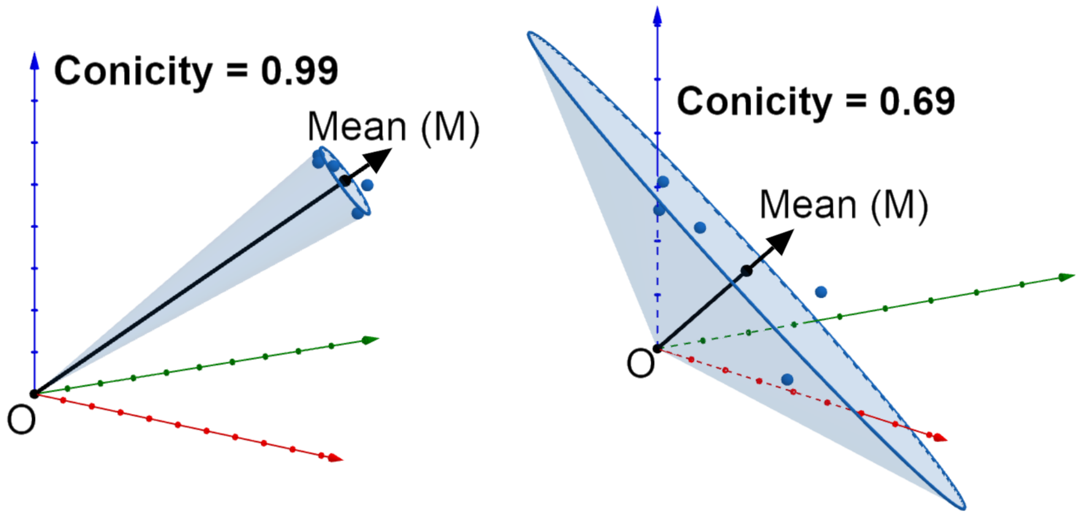

Figure 1: Comparison of high vs low Conicity. Randomly generated vectors are shown in blue with their sample mean vector M in black. Figure on the left shows the case when vectors lie in narrow cone resulting in high Conicity value. Figure on the right shows the case when vectors are spread out having relatively lower Conicity value. We skipped very low values of Conicity as it was difficult to visualize. The points are sampled from 3d Spherical Gaussian with mean (1,1,1) and standard deviation 0.1 (left) and 1.3 (right). Please refer to Section 4 for more details.

($\mathcal{O}(d \log d)$). For training, we use pairwise ranking loss.

ComplEx (Trouillon et al., 2016) represents entities and relations as vectors in $\mathbb{C}^d$. The compatibility of entity pairs is measured using entry-wise product between head and complex conjugate of tail entity vectors.

$$\sigma_{ComplEx}(h, r, t) = \mathbf{Re}(\mathbf{r}^\top(\mathbf{h} \odot \bar{\mathbf{t}})) \qquad (5)$$

In contrast to (3), using complex vectors in (5) allows ComplEx to handle symmetric, asymmetric and anti-symmetric relations using the same score function. Similar to DistMult, logistic loss is used for training the model.

4 Metrics

For our geometrical analysis, we first define a term **'alignment to mean'** (**ATM**) of a vector $\mathbf{v}$ belonging to a set of vectors $\mathbf{V}$, as the cosine similarity[1] between $\mathbf{v}$ and the mean of all vectors in $\mathbf{V}$.

$$\text{ATM}(\mathbf{v}, \mathbf{V}) = \text{cosine}\left(\mathbf{v}, \frac{1}{|\mathbf{V}|}\sum_{\mathbf{x}\in\mathbf{V}} \mathbf{x}\right)$$

We also define '**conicity**' of a set $\mathbf{V}$ as the mean ATM of all vectors in $\mathbf{V}$.

$$\text{Conicity}(\mathbf{V}) = \frac{1}{|\mathbf{V}|}\sum_{\mathbf{v}\in\mathbf{V}} \text{ATM}(\mathbf{v}, \mathbf{V})$$

[1]cosine$(u, v) = \frac{u^\top v}{\|u\|\|v\|}$

Dataset		FB15k	WN18
#Relations		1,345	18
#Entities		14,541	40,943
#Triples	Train	483,142	141,440
	Validation	50,000	5,000
	Test	59,071	5,000

Table 2: Summary of datasets used in the paper.

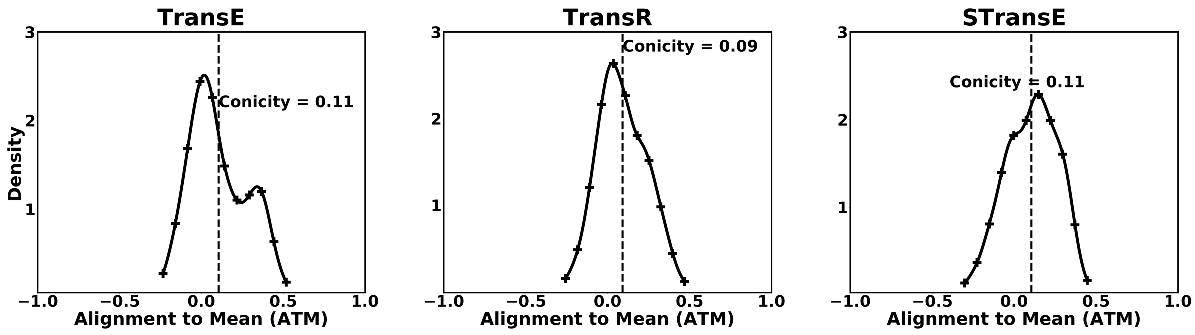
By this definition, a high value of Conicity($\mathbf{V}$) would imply that the vectors in $\mathbf{V}$ lie in a narrow cone centered at origin. In other words, the vectors in the set $\mathbf{V}$ are highly aligned with each other. In addition to that, we define the variance of ATM across all vectors in $\mathbf{V}$, as the '**vector spread**'(VS) of set $\mathbf{V}$,

$$\text{VS}(\mathbf{V}) = \frac{1}{|\mathbf{V}|}\sum_{\mathbf{v}\in\mathbf{V}} \Big(\text{ATM}(\mathbf{v}, \mathbf{V}) - \text{Conicity}(\mathbf{V})\Big)^2$$

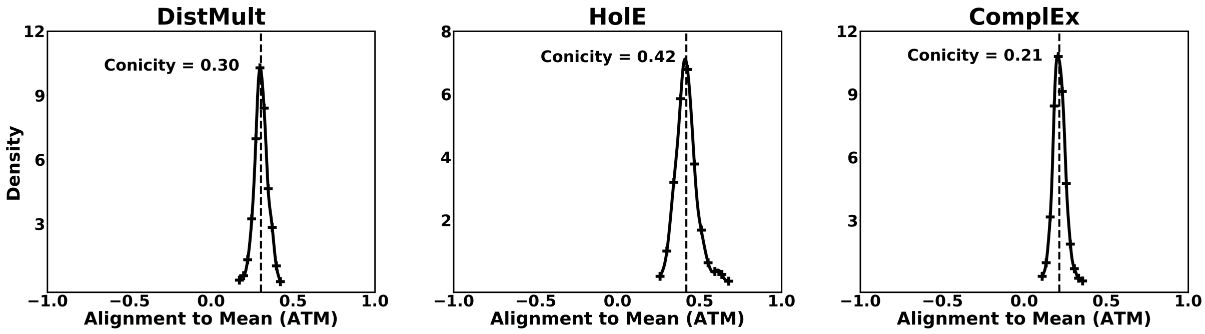
Figure 1 visually demonstrates these metrics for randomly generated 3-dimensional points. The left figure shows high Conicity and low vector spread while the right figure shows low Conicity and high vector spread.

We define the length of a vector $\mathbf{v}$ as L_2-norm of the vector $\|\mathbf{v}\|_2$ and **'average vector length'** (**AVL**) for the set of vectors $\mathbf{V}$ as

$$\text{AVL}(\mathbf{V}) = \frac{1}{|\mathbf{V}|}\sum_{\mathbf{v}\in\mathbf{V}} \|\mathbf{v}\|_2$$



(a) Additive Models



(b) Multiplicative Models

Figure 2: Alignment to Mean (ATM) vs Density plots for entity embeddings learned by various additive (top row) and multiplicative (bottom row) KG embedding methods. For each method, a plot averaged across entity frequency bins is shown. From these plots, we conclude that entity embeddings from additive models tend to have low (positive as well as negative) ATM and thereby low Conicity and high vector spread. Interestingly, this is reversed in case of multiplicative methods. Please see Section 6.1 for more details.

5 Experimental Setup

Datasets: We run our experiments on subsets of two widely used datasets, viz., Freebase (Bollacker et al., 2008) and WordNet (Miller, 1995), called FB15k and WN18 (Bordes et al., 2013), respectively. We detail the characteristics of these datasets in Table 2.

Please note that while the results presented in Section 6 are on the FB15K dataset, we reach the same conclusions on WN18. The plots for our experiments on WN18 can be found in the Supplementary Section.

Hyperparameters: We experiment with multiple values of hyperparameters to understand their effect on the geometry of KG embeddings. Specifically, we vary the dimension of the generated vectors between $\{50, 100, 200\}$ and the number of negative samples used during training between $\{1, 50, 100\}$. For more details on algorithm specific hyperparameters, we refer the reader to the Supplementary Section.[2]

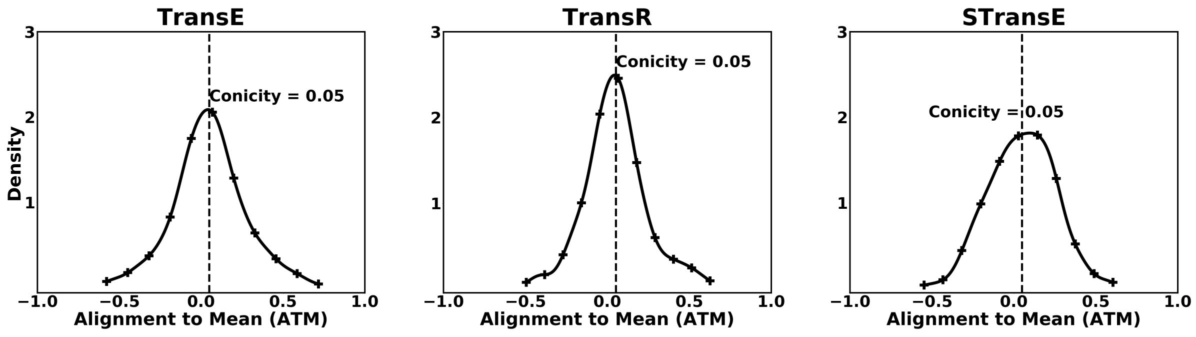
Frequency Bins: We follow (Mimno and Thompson, 2017) for entity and relation samples used in the analysis. Multiple bins of entities and relations are created based on their frequencies and 100 randomly sampled vectors are taken from each bin. These set of sampled vectors are then used for our analysis. For more information about sampling vectors, please refer to (Mimno and Thompson, 2017).

6 Results and Analysis

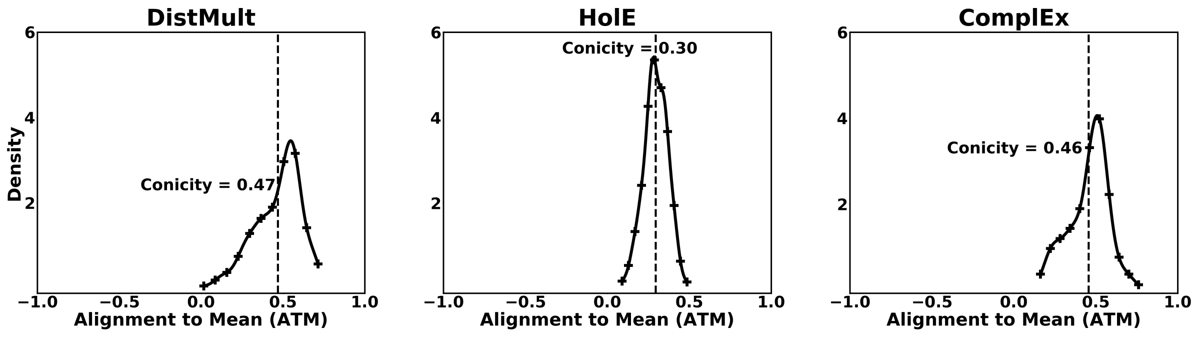
In this section, we evaluate the following questions.

- Does model type (e.g., additive vs multiplicative) have any effect on the geometry of embeddings? (Section 6.1)

[2]For training, we used codes from `https://github.com/Mrlyk423/Relation_Extraction` (TransE, TransR), `https://github.com/datquocnguyen/STransE` (STransE), `https://github.com/mnick/holographic-embeddings` (HolE) and `https://github.com/ttrouill/complex` (ComplEx and DistMult).



(a) Additive Models



(b) Multiplicative Models

Figure 3: Alignment to Mean (ATM) vs Density plots for relation embeddings learned by various additive (top row) and multiplicative (bottom row) KG embedding methods. For each method, a plot averaged across entity frequency bins is shown. Trends in these plots are similar to those in Figure 2. Main findings from these plots are summarized in Section 6.1.

- Does negative sampling have any effect on the embedding geometry? (Section 6.2)
- Does the dimension of embedding have any effect on its geometry? (Section 6.3)
- How is task performance related to embedding geometry? (Section 6.4)

In each subsection, we summarize the main findings at the beginning, followed by evidence supporting those findings.

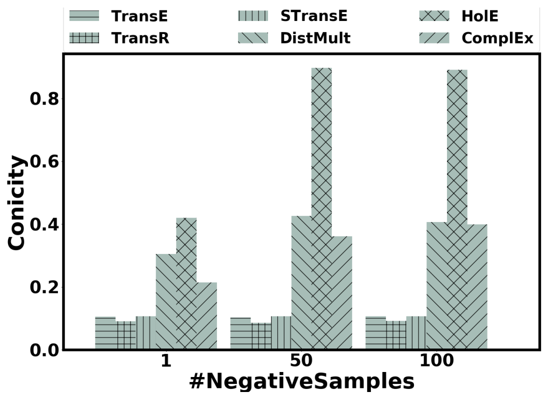
6.1 Effect of Model Type on Geometry

Summary of Findings:
Additive: Low conicity and high vector spread.
Multiplicative: High conicity and low vector spread.

In this section, we explore whether the type of the score function optimized during the training has any effect on the geometry of the resulting embedding. For this experiment, we set the number of negative samples to 1 and the vector dimension to 100 (we got similar results for 50-dimensional vectors). Figure 2 and Figure 3 show the distribution of ATMs of these sampled entity and relation vectors, respectively.[3]

Entity Embeddings: As seen in Figure 2, there is a stark difference between the geometries of entity vectors produced by additive and multiplicative models. The ATMs of all entity vectors produced by multiplicative models are positive with very low vector spread. Their high conicity suggests that they are not uniformly dispersed in the vector space, but lie in a narrow cone along the mean vector. This is in contrast to the entity vectors obtained from additive models which are both positive and negative with higher vector spread. From the lower values of conicity, we conclude that entity vectors from additive models are evenly dispersed in the vector space. This observation is also reinforced by looking at the high vector spread of additive models in comparison to that of multiplicative models. We also observed that additive models are sensitive to the frequency of entities, with high frequency bins having higher conicity than low frequency bins. However, no such pattern was observed for multiplicative models and

[3]We also tried using the *global* mean instead of mean of the sampled set for calculating cosine similarity in ATM, and got very similar results.



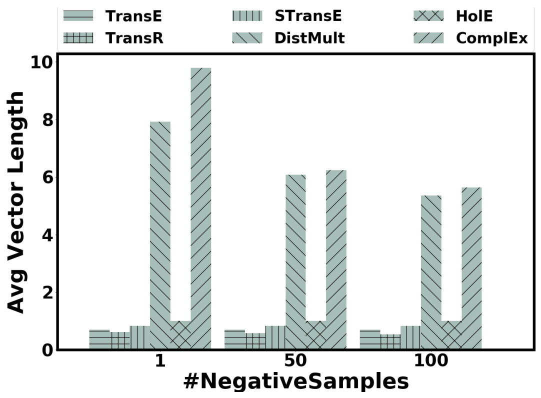


Figure 4: Conicity (left) and Average Vector Length (right) vs Number of negative samples for entity vectors learned using various KG embedding methods. In each bar group, first three models are additive, while the last three are multiplicative. Main findings from these plots are summarized in Section 6.2

conicity was consistently similar across frequency bins. For clarity, we have not shown different plots for individual frequency bins.

Relation Embeddings: As in entity embeddings, we observe a similar trend when we look at the distribution of ATMs for relation vectors in Figure 3. The conicity of relation vectors generated using additive models is almost zero across frequency bands. This coupled with the high vector spread observed, suggests that these vectors are scattered throughout the vector space. Relation vectors from multiplicative models exhibit high conicity and low vector spread, suggesting that they lie in a narrow cone centered at origin, like their entity counterparts.

6.2 Effect of Number of Negative Samples on Geometry

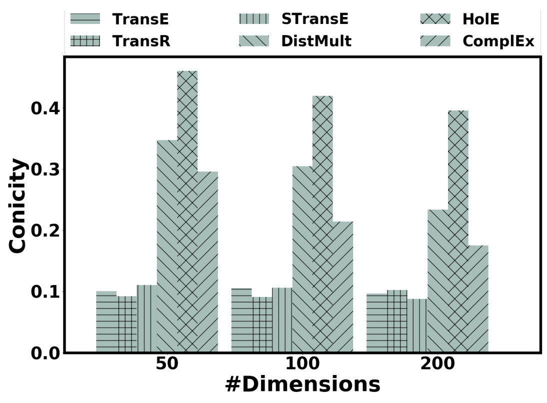
Summary of Findings:
Additive: Conicity and average length are invariant to changes in #NegativeSamples for both entities and relations.
Multiplicative: Conicity increases while average vector length decrease with increasing #NegativeSamples for entities. Conicity decreases, while average vector length remains constant (except HolE) for relations.

For experiments in this section, we keep the vector dimension constant at 100.

Entity Embeddings: As seen in Figure 4 (left), the conicity of entity vectors increases as the number of negative samples is increased for multiplicative models. In contrast, conicity of the entity vectors generated by additive models is unaffected by change in number of negative samples and they continue to be dispersed throughout the vector space. From Figure 4 (right), we observe that the average length of entity vectors produced by additive models is also invariant of any changes in number of negative samples. On the other hand, increase in negative sampling decreases the average entity vector length for all multiplicative models except HolE. The average entity vector length for HolE is nearly 1 for any number of negative samples, which is understandable considering it constrains the entity vectors to lie inside a unit ball (Nickel et al., 2016). This constraint is also enforced by the additive models: TransE, TransR, and STransE.

Relation Embeddings: Similar to entity embeddings, in case of relation vectors trained using additive models, the average length and conicity do not change while varying the number of negative samples. However, the conicity of relation vectors from multiplicative models decreases with increase in negative sampling. The average relation vector length is invariant for all multiplicative methods, except for HolE. We see a surprisingly big jump in average relation vector length for HolE going from 1 to 50 negative samples, but it does not change after that. Due to space constraints in the paper, we refer the reader to the Supplementary Section for plots discussing the effect of number of negative samples on geometry of relation vectors.

We note that the multiplicative score between two vectors may be increased by either increasing the alignment between the two vectors (i.e., increasing Conicity and reducing vector spread between them), or by increasing their lengths. It is interesting to note that we see exactly these effects in the geometry of multiplicative methods



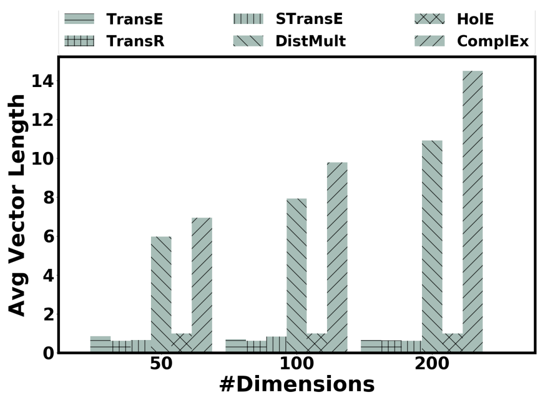


Figure 5: Conicity (left) and Average Vector Length (right) vs Number of Dimensions for entity vectors learned using various KG embedding methods. In each bar group, first three models are additive, while the last three are multiplicative. Main findings from these plots are summarized in Section 6.3.

analyzed above.

6.2.1 Correlation with Geometry of Word Embeddings

Our conclusions from the geometrical analysis of entity vectors produced by multiplicative models are similar to the results in (Mimno and Thompson, 2017), where increase in negative sampling leads to increased conicity of word vectors trained using the skip-gram with negative sampling (SGNS) method. On the other hand, additive models remain unaffected by these changes.

SGNS tries to maximize a score function of the form $\mathbf{w}^T \cdot \mathbf{c}$ for positive word context pairs, where $\mathbf{w}$ is the word vector and $\mathbf{c}$ is the context vector (Mikolov et al., 2013). This is very similar to the score function of multiplicative models as seen in Table 1. Hence, SGNS can be considered as a multiplicative model in the word domain.

Hence, we argue that our result on the increase in negative samples increasing the conicity of vectors trained using a multiplicative score function can be considered as a generalization of the one in (Mimno and Thompson, 2017).

6.3 Effect of Vector Dimension on Geometry

Summary of Findings:
Additive: Conicity and average length are invariant to changes in dimension for both entities and relations.
Multiplicative: Conicity decreases for both entities and relations with increasing dimension. Average vector length increases for both entities and relations, except for HolE entities.

Entity Embeddings: To study the effect of vector dimension on conicity and length, we set the number of negative samples to 1, while varying the vector dimension. From Figure 5 (left), we observe that the conicity for entity vectors generated by any additive model is almost invariant of increase in dimension, though STransE exhibits a slight decrease. In contrast, entity vector from multiplicative models show a clear decreasing pattern with increasing dimension.

As seen in Figure 5 (right), the average lengths of entity vectors from multiplicative models increase sharply with increasing vector dimension, except for HolE. In case of HolE, the average vector length remains constant at one. Deviation involving HolE is expected as it enforces entity vectors to fall within a unit ball. Similar constraints are enforced on entity vectors for additive models as well. Thus, the average entity vector lengths are not affected by increasing vector dimension for all additive models.

Relation Embeddings: We reach similar conclusion when analyzing against increasing dimension the change in geometry of relation vectors produced using these KG embedding methods. In this setting, the average length of relation vectors learned by HolE also increases as dimension is increased. This is consistent with the other methods in the multiplicative family. This is because, unlike entity vectors, the lengths of relation vectors of HolE are not constrained to be less than unit length. Due to lack of space, we are unable to show plots for relation vectors here, but the same can be found in the Supplementary Section.

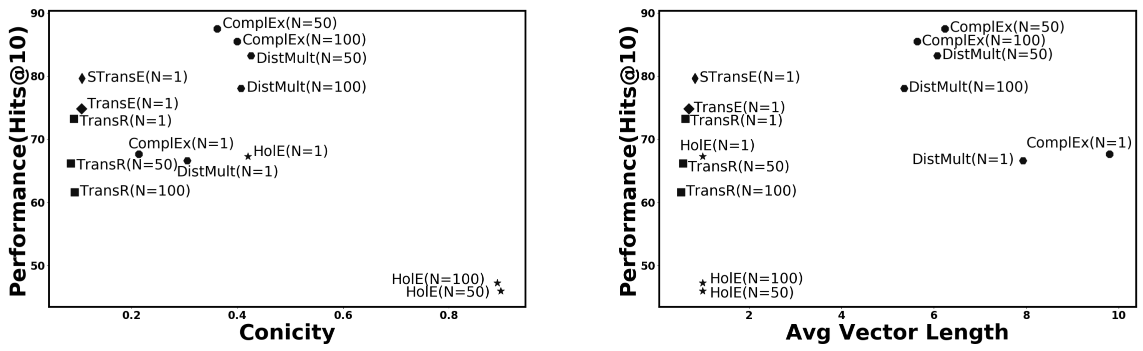

Figure 6: Relationship between Performance (HITS@10) on a link prediction task vs Conicity (left) and Avg. Vector Length (right). For each point, N represents the number of negative samples used. Main findings are summarized in Section 6.4.

6.4 Relating Geometry to Performance

Summary of Findings:
Additive: Neither entites nor relations exhibit correlation between geometry and performance.
Multiplicative: Keeping negative samples fixed, lower conicity or higher average vector length for entities leads to improved performance. No relationship for relations.

In this section, we analyze the relationship between geometry and performance on the Link prediction task, using the same setting as in (Bordes et al., 2013). Figure 6 (left) presents the effects of conicity of entity vectors on performance, while Figure 6 (right) shows the effects of average entity vector length.[4]

As we see from Figure 6 (left), for fixed number of negative samples, the multiplicative model with lower conicity of entity vectors achieves better performance. This performance gain is larger for higher numbers of negative samples (N). Additive models don't exhibit any relationship between performance and conicity, as they are all clustered around zero conicity, which is in-line with our observations in previous sections. In Figure 6 (right), for all multiplicative models except HolE, a higher average entity vector length translates to better performance, while the number of negative samples is kept fixed. Additive models and HolE don't exhibit any such patterns, as they are all clustered just below unit average entity vector length.

The above two observations for multiplicative models make intuitive sense, as lower conicity and higher average vector length would both translate to vectors being more dispersed in the space.

[4]A more focused analysis for multiplicative models is presented in Section 3 of Supplementary material.

We see another interesting observation regarding the high sensitivity of HolE to the number of negative samples used during training. Using a large number of negative examples (e.g., $N = 50$ or 100) leads to very high conicity in case of HolE. Figure 6 (right) shows that average entity vector length of HolE is always one. These two observations point towards HolE's entity vectors lying in a tiny part of the space. This translates to HolE performing poorer than all other models in case of high numbers of negative sampling.

We also did a similar study for relation vectors, but did not see any discernible patterns.

7 Conclusion

In this paper, we have initiated a systematic study into the important but unexplored problem of analyzing geometry of various Knowledge Graph (KG) embedding methods. To the best of our knowledge, this is the first study of its kind. Through extensive experiments on multiple real-world datasets, we are able to identify several insights into the geometry of KG embeddings. We have also explored the relationship between KG embedding geometry and its task performance. We have shared all our source code to foster further research in this area.

A Unified Model for Extractive and Abstractive Summarization using Inconsistency Loss

Wan-Ting Hsu[1], **Chieh-Kai Lin**[1], **Ming-Ying Lee**[1], **Kerui Min**[2], **Jing Tang**[2], **Min Sun**[1]

Abstract

We propose a unified model combining the strength of extractive and abstractive summarization. On the one hand, a simple extractive model can obtain sentence-level attention with high ROUGE scores but less readable. On the other hand, a more complicated abstractive model can obtain word-level dynamic attention to generate a more readable paragraph. In our model, sentence-level attention is used to modulate the word-level attention such that words in less attended sentences are less likely to be generated. Moreover, a novel inconsistency loss function is introduced to penalize the inconsistency between two levels of attentions. By end-to-end training our model with the inconsistency loss and original losses of extractive and abstractive models, we achieve state-of-the-art ROUGE scores while being the most informative and readable summarization on the CNN/Daily Mail dataset in a solid human evaluation.

1 Introduction

Text summarization is the task of automatically condensing a piece of text to a shorter version while maintaining the important points. The ability to condense text information can aid many applications such as creating news digests, presenting search results, and generating reports. There are mainly two types of approaches: extractive and abstractive. Extractive approaches assemble summaries directly from the source text typically selecting one whole sentence at a time. In contrast, abstractive approaches can generate novel words and phrases not copied from the source text.

Original Article: McDonald's says...... The company says it expects the new 'Artisan Grilled Chicken' to be in its more than 14,300 U.S. stores by the end of next week, in products including a new sandwich, as well as existing sandwiches, wraps and salads. It says the biggest change is the removal of sodium phosphates, which it said was used to keep the chicken moist, in favor of vegetable starch. The new recipe also does not use maltodextrin, which McDonald's said is generally used as a sugar to increase browning or as a carrier for seasoning. Jessica Foust, director of culinary innovation at McDonald's, said the changes were made because customers said they want 'simple, clean ingredients' they are familiar with...... And *Panera Bread has said* it plans to purge artificial colors, flavors and preservatives from its food by 2016......

Extractive Approach: **The company** says it expects the new 'Artisan Grilled Chicken' to be in its more than 14,300 U.S. stores by the end of next week, in products including a new sandwich, as well as existing sandwiches, wraps and salads. It says the biggest change is the removal of sodium phosphates, **which it said was used to keep the chicken moist, in favor of vegetable starch**. The new recipe also does not use maltodextrin, which McDonald's said is generally used as a sugar to increase browning or as a carrier for seasoning.

Abstractive Approach: McDonald's says it expects the new 'Artisan Grilled Chicken' to be in its more than 14,300 U.S. stores by the end of next week. The company says the changes were made because customers said they want 'simple, clean ingredients' they are familiar with. *McDonald's said* it plans to purge artificial colors, flavors and preservatives from its food by 2016.

Unified Approach: **McDonald's says it expects** the new 'Artisan Grilled Chicken' to be in its more than 14,300 U.S. stores by the end of next week, in products including a new sandwich, as well as existing sandwiches, wraps and salads. It says the biggest change is the removal of sodium phosphates. The new recipe also does not use maltodextrin, which McDonald's said is generally used as a sugar to increase browning or as a carrier for seasoning.

Figure 1: Comparison of extractive, abstractive, and our unified summaries on a news article. The extractive model picks most important but **incoherent or not concise** (see blue bold font) sentences. The abstractive summary is readable, concise but still *loses or mistakes some facts* (see red italics font). The final summary rewritten from fragments (see underline font) has the advantages from both extractive (importance) and abstractive advantage (**coherence** (see green bold font)).

Hence, abstractive summaries can be more coherent and concise than extractive summaries.

Extractive approaches are typically simpler. They output the probability of each sentence to be selected into the summary. Many earlier works on summarization (Cheng and Lapata, 2016; Nallapati et al., 2016a, 2017; Narayan et al., 2017; Yasunaga et al., 2017) focus on extractive summarization. Among them, Nallapati et al.

(2017) have achieved high ROUGE scores. On the other hand, abstractive approaches (Nallapati et al., 2016b; See et al., 2017; Paulus et al., 2017; Fan et al., 2017; Liu et al., 2017) typically involve sophisticated mechanism in order to paraphrase, generate unseen words in the source text, or even incorporate external knowledge. Neural networks (Nallapati et al., 2017; See et al., 2017) based on the attentional encoder-decoder model (Bahdanau et al., 2014) were able to generate abstractive summaries with high ROUGE scores but suffer from inaccurately reproducing factual details and an inability to deal with out-of-vocabulary (OOV) words. Recently, See et al. (2017) propose a pointer-generator model which has the abilities to copy words from source text as well as generate unseen words. Despite recent progress in abstractive summarization, extractive approaches (Nallapati et al., 2017; Yasunaga et al., 2017) and lead-3 baseline (i.e., selecting the first 3 sentences) still achieve strong performance in ROUGE scores.

We propose to explicitly take advantage of the strength of state-of-the-art extractive and abstractive summarization and introduced the following unified model. Firstly, we treat the probability output of each sentence from the extractive model (Nallapati et al., 2017) as sentence-level attention. Then, we modulate the word-level dynamic attention from the abstractive model (See et al., 2017) with sentence-level attention such that words in less attended sentences are less likely to be generated. In this way, extractive summarization mostly benefits abstractive summarization by mitigating spurious word-level attention. Secondly, we introduce a novel inconsistency loss function to encourage the consistency between two levels of attentions. The loss function can be computed without additional human annotation and has shown to ensure our unified model to be mutually beneficial to both extractive and abstractive summarization. On CNN/Daily Mail dataset, our unified model achieves state-of-the-art ROUGE scores and outperforms a strong extractive baseline (i.e., lead-3). Finally, to ensure the quality of our unified model, we conduct a solid human evaluation and confirm that our method significantly outperforms recent state-of-the-art methods in informativity and readability.

To summarize, our contributions are twofold:

- We propose a unified model combining sentence-level and word-level attentions to take advantage of both extractive and abstractive summarization approaches.
- We propose a novel inconsistency loss function to ensure our unified model to be mutually beneficial to both extractive and abstractive summarization. The unified model with inconsistency loss achieves the best ROUGE scores on CNN/Daily Mail dataset and outperforms recent state-of-the-art methods in informativity and readability on human evaluation.

2 Related Work

Text summarization has been widely studied in recent years. We first introduce the related works of neural-network-based extractive and abstractive summarization. Finally, we introduce a few related works with hierarchical attention mechanism.

Extractive summarization. Kågebäck et al. (2014) and Yin and Pei (2015) use neural networks to map sentences into vectors and select sentences based on those vectors. Cheng and Lapata (2016), Nallapati et al. (2016a) and Nallapati et al. (2017) use recurrent neural networks to read the article and get the representations of the sentences and article to select sentences. Narayan et al. (2017) utilize side information (i.e., image captions and titles) to help the sentence classifier choose sentences. Yasunaga et al. (2017) combine recurrent neural networks with graph convolutional networks to compute the salience (or importance) of each sentence. While some extractive summarization methods obtain high ROUGE scores, they all suffer from low readability.

Abstractive summarization. Rush et al. (2015) first bring up the abstractive summarization task and use attention-based encoder to read the input text and generate the summary. Based on them, Miao and Blunsom (2016) use a variational auto-encoder and Nallapati et al. (2016b) use a more powerful sequence-to-sequence model. Besides, Nallapati et al. (2016b) create a new article-level summarization dataset called CNN/Daily Mail by adapting DeepMind question-answering dataset (Hermann et al., 2015). Ranzato et al. (2015) change the traditional training method to directly optimize evaluation metrics (e.g., BLEU and ROUGE). Gu et al. (2016), See et al. (2017) and Paulus et al. (2017) combine pointer networks

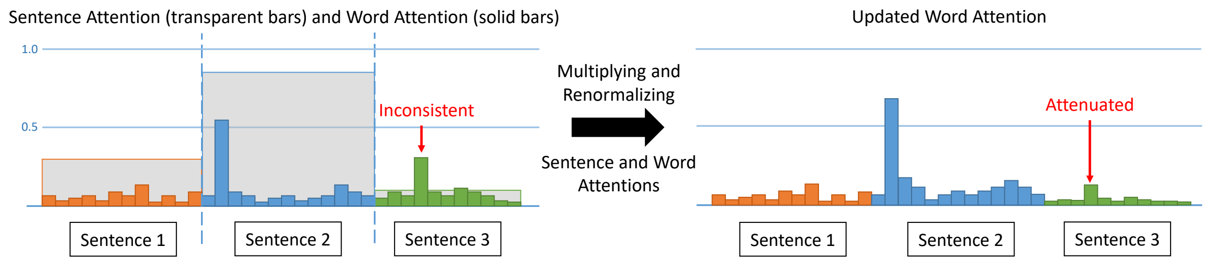

Figure 2: Our unified model combines the word-level and sentence-level attentions. Inconsistency occurs when word attention is high but sentence attention is low (see red arrow).

(Vinyals et al., 2015) into their models to deal with out-of-vocabulary (OOV) words. Chen et al. (2016) and See et al. (2017) restrain their models from attending to the same word to decrease repeated phrases in the generated summary. Paulus et al. (2017) use policy gradient on summarization and state out the fact that high ROUGE scores might still lead to low human evaluation scores. Fan et al. (2017) apply convolutional sequence-to-sequence model and design several new tasks for summarization. Liu et al. (2017) achieve high readability score on human evaluation using generative adversarial networks.

Hierarchical attention. Attention mechanism was first proposed by Bahdanau et al. (2014). Yang et al. (2016) proposed a hierarchical attention mechanism for document classification. We adopt the method of combining sentence-level and word-level attention in Nallapati et al. (2016b). However, their sentence attention is dynamic, which means it will be different for each generated word. Whereas our sentence attention is fixed for all generated words. Inspired by the high performance of extractive summarization, we propose to use fixed sentence attention.

Our model combines state-of-the-art extractive model (Nallapati et al., 2017) and abstractive model (See et al., 2017) by combining sentence-level attention from the former and word-level attention from the latter. Furthermore, we design an inconsistency loss to enhance the cooperation between the extractive and abstractive models.

3 Our Unified Model

We propose a unified model to combine the strength of both state-of-the-art extractor (Nallapati et al., 2017) and abstracter (See et al., 2017). Before going into details of our model, we first define the tasks of the extractor and abstracter.

Problem definition. The input of both extractor and abstracter is a sequence of words $\mathbf{w} = [w_1, w_2, ..., w_m, ...]$, where m is the word index. The sequence of words also forms a sequence of sentences $\mathbf{s} = [s_1, s_2, ..., s_n, ...]$, where n is the sentence index. The m^{th} word is mapped into the $n(m)^{th}$ sentence, where $n(\cdot)$ is the mapping function. The output of the extractor is the sentence-level attention $\boldsymbol{\beta} = [\beta_1, \beta_2, ..., \beta_n, ...]$, where β_n is the probability of the n^{th} sentence been extracted into the summary. On the other hand, our attention-based abstractor computes word-level attention $\boldsymbol{\alpha}^t = \left[\alpha_1^t, \alpha_2^t, ..., \alpha_m^t, ...\right]$ dynamically while generating the t^{th} word in the summary. The output of the abstracter is the summary text $\mathbf{y} = \left[y^1, y^2, ..., y^t, ...\right]$, where y^t is t^{th} word in the summary.

In the following, we introduce the mechanism to combine sentence-level and word-level attentions in Sec. 3.1. Next, we define the novel inconsistency loss that ensures extractor and abstracter to be mutually beneficial in Sec. 3.2. We also give the details of our extractor in Sec. 3.3 and our abstracter in Sec. 3.4. Finally, our training procedure is described in Sec. 3.5.

3.1 Combining Attentions

Pieces of evidence (e.g., Vaswani et al. (2017)) show that attention mechanism is very important for NLP tasks. Hence, we propose to explicitly combine the sentence-level β_n and word-level α_m^t attentions by simple scalar multiplication and renormalization. The updated word attention $\hat{\alpha}_m^t$ is

$$\hat{\alpha}_m^t = \frac{\alpha_m^t \times \beta_{n(m)}}{\sum_m \alpha_m^t \times \beta_{n(m)}}. \quad (1)$$

The multiplication ensures that only when both word-level α_m^t and sentence-level β_n attentions are high, the updated word attention $\hat{\alpha}_m^t$ can be high. Since the sentence-level attention β_n from the extractor already achieves high ROUGE

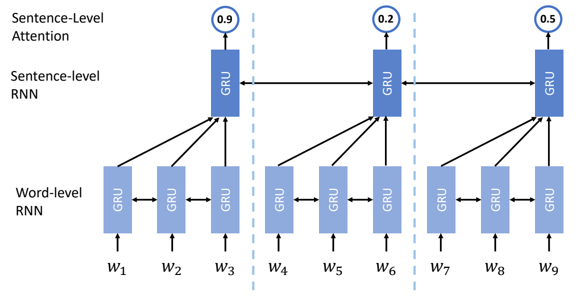

Figure 3: Architecture of the extractor. We treat the sigmoid output of each sentence as sentence-level attention $\in [0, 1]$.

scores, β_n intuitively modulates the word-level attention α^t_m to mitigate spurious word-level attention such that words in less attended sentences are less likely to be generated (see Fig. 2). As highlighted in Sec. 3.4, the word-level attention $\hat{\alpha}^t_m$ significantly affects the decoding process of the abstracter. Hence, an updated word-level attention is our key to improve abstractive summarization.

3.2 Inconsistency Loss

Instead of only leveraging the complementary nature between sentence-level and word-level attentions, we would like to encourage these two-levels of attentions to be mostly consistent to each other during training as an intrinsic learning target for free (i.e., without additional human annotation). Explicitly, we would like the sentence-level attention to be high when the word-level attention is high. Hence, we design the following inconsistency loss,

$$L_{inc} = -\frac{1}{T}\sum_{t=1}^{T}\log\left(\frac{1}{|\mathcal{K}|}\sum_{m\in\mathcal{K}}\alpha^t_m \times \beta_{n(m)}\right), \quad (2)$$

where $\mathcal{K}$ is the set of top K attended words and T is the number of words in the summary. This implicitly encourages the distribution of the word-level attentions to be sharp and sentence-level attention to be high. To avoid the degenerated solution for the distribution of word attention to be one-hot and sentence attention to be high, we include the original loss functions for training the extractor (L_{ext} in Sec. 3.3) and abstracter (L_{abs} and L_{cov} in Sec. 3.4). Note that Eq. 1 is the only part that the extractor is interacting with the abstracter. Our proposed inconsistency loss facilitates our end-to-end trained unified model to be mutually beneficial to both the extractor and abstracter.

3.3 Extractor

Our extractor is inspired by Nallapati et al. (2017). The main difference is that our extractor does not need to obtain the final summary. It mainly needs to obtain a short list of important sentences with a high recall to further facilitate the abstractor. We first introduce the network architecture and the loss function. Finally, we define our ground truth important sentences to encourage high recall.

Architecture. The model consists of a hierarchical bidirectional GRU which extracts sentence representations and a classification layer for predicting the sentence-level attention β_n for each sentence (see Fig. 3).

Extractor loss. The following sigmoid cross entropy loss is used,

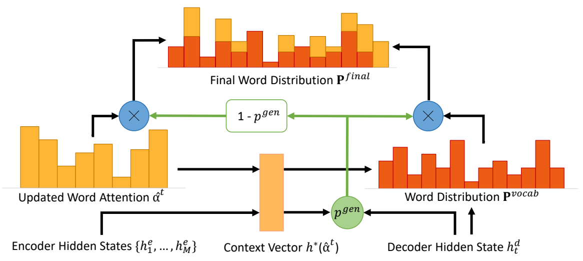
$$L_{ext} = -\frac{1}{N}\sum_{n=1}^{N}(g_n \log\beta_n + (1-g_n)\log(1-\beta_n)), \quad (3)$$

where $g_n \in \{0, 1\}$ is the ground-truth label for the n^{th} sentence and N is the number of sentences. When $g_n = 1$, it indicates that the n^{th} sentence should be attended to facilitate abstractive summarization.

Ground-truth label. The goal of our extractor is to extract sentences with high informativity, which means the extracted sentences should contain information that is needed to generate an abstractive summary as much as possible. To obtain the ground-truth labels $\mathbf{g} = \{g_n\}_n$, first, we measure the informativity of each sentence s_n in the article by computing the ROUGE-L recall score (Lin, 2004) between the sentence s_n and the reference abstractive summary $\hat{\mathbf{y}} = \{\hat{y}^t\}_t$. Second, we sort the sentences by their informativity and select the sentence in the order of high to low informativity. We add one sentence at a time if the new sentence can increase the informativity of all the selected sentences. Finally, we obtain the ground-truth labels $\mathbf{g}$ and train our extractor by minimizing Eq. 3. Note that our method is different from Nallapati et al. (2017) who aim to extract a final summary for an article so they use ROUGE F-1 score to select ground-truth sentences; while we focus on high informativity, hence, we use ROUGE recall score to obtain as much information as possible with respect to the reference summary $\hat{\mathbf{y}}$.

3.4 Abstracter

The second part of our model is an abstracter that reads the article; then, generate a summary



Final Word Distribution $\mathbf{P}^{final}$
1 - p^{gen}
Updated Word Attention $\hat{\alpha}^t$
Word Distribution $\mathbf{P}^{vocab}$
p^{gen}
Encoder Hidden States $\{h_1^e, \ldots, h_M^e\}$
Context Vector $h^*(\hat{\alpha}^t)$
Decoder Hidden State h_t^d

Figure 4: Decoding mechanism in the abstracter. In the decoder step t, our updated word attention $\hat{\boldsymbol{\alpha}}^t$ is used to generate context vector $h^*(\hat{\boldsymbol{\alpha}}^t)$. Hence, it updates the final word distribution $\mathbf{P}^{final}$.

word-by-word. We use the pointer-generator network proposed by See et al. (2017) and combine it with the extractor by combining sentence-level and word-level attentions (Sec. 3.1).

Pointer-generator network. The pointer-generator network (See et al., 2017) is a specially designed sequence-to-sequence attentional model that can generate the summary by copying words in the article or generating words from a fixed vocabulary at the same time. The model contains a bidirectional LSTM which serves as an encoder to encode the input words $\mathbf{w}$ and a unidirectional LSTM which serves as a decoder to generate the summary $\mathbf{y}$. For details of the network architecture, please refer to See et al. (2017). In the following, we describe how the updated word attention $\hat{\boldsymbol{\alpha}}^t$ affects the decoding process.

Notations. We first define some notations. h_m^e is the encoder hidden state for the m^{th} word. h_t^d is the decoder hidden state in step t. $h^*(\hat{\boldsymbol{\alpha}}^t) = \sum_m^M \hat{\alpha}_m^t \times h_m^e$ is the context vector which is a function of the updated word attention $\hat{\boldsymbol{\alpha}}^t$. $\mathbf{P}^{vocab}(h^*(\hat{\boldsymbol{\alpha}}^t))$ is the probability distribution over the fixed vocabulary before applying the copying mechanism.

$$\begin{aligned}&\mathbf{P}^{vocab}(h^*(\hat{\boldsymbol{\alpha}}^t)) \qquad (4)\\ &= \text{softmax}(W_2(W_1[h_t^d, h^*(\hat{\boldsymbol{\alpha}}^t)] + b_1) + b_2),\end{aligned}$$

where W_1, W_2, b_1 and b_2 are learnable parameters. $\mathbf{P}^{vocab} = \{P_w^{vocab}\}_w$ where $P_w^{vocab}(h^*(\hat{\boldsymbol{\alpha}}^t))$ is the probability of word w being decoded. $p^{gen}(h^*(\hat{\boldsymbol{\alpha}}^t)) \in [0, 1]$ is the generating probability (see Eq.8 in See et al. (2017)) and $1 - p^{gen}(h^*(\hat{\boldsymbol{\alpha}}^t))$ is the copying probability.

Final word distribution. $P_w^{final}(\hat{\boldsymbol{\alpha}}^t)$ is the final probability of word w being decoded (i.e., $y^t = w$). It is related to the updated word attention $\hat{\boldsymbol{\alpha}}^t$ as follows (see Fig. 4),

$$\begin{aligned}P_w^{final}(\hat{\boldsymbol{\alpha}}^t) &= p^{gen}(h^*(\hat{\boldsymbol{\alpha}}^t))P_w^{vocab}(h^*(\hat{\boldsymbol{\alpha}}^t)) \quad (5)\\ &+ (1 - p^{gen}(h^*(\hat{\boldsymbol{\alpha}}^t))) \sum_{m:w_m=w} \hat{\alpha}_m^t.\end{aligned}$$

Note that $\mathbf{P}^{final} = \{P_w^{final}\}_w$ is the probability distribution over the fixed vocabulary and out-of-vocabulary (OOV) words. Hence, OOV words can be decoded. Most importantly, it is clear from Eq. 5 that $P_w^{final}(\hat{\boldsymbol{\alpha}}^t)$ is a function of the updated word attention $\hat{\boldsymbol{\alpha}}^t$. Finally, we train the abstracter to minimize the negative log-likelihood:

$$L_{abs} = -\frac{1}{T}\sum_{t=1}^{T} \log P_{\hat{y}^t}^{final}(\hat{\boldsymbol{\alpha}}^t)\;, \qquad (6)$$

where $\hat{y}^t$ is the t^{th} token in the reference abstractive summary.

Coverage mechanism. We also apply coverage mechanism (See et al., 2017) to prevent the abstracter from repeatedly attending to the same place. In each decoder step t, we calculate the coverage vector $\mathbf{c}^t = \sum_{t'=0}^{t-1} \hat{\boldsymbol{\alpha}}^{t'}$ which indicates so far how much attention has been paid to every input word. The coverage vector $\mathbf{c}^t$ will be used to calculate word attention $\hat{\boldsymbol{\alpha}}^t$ (see Eq.11 in See et al. (2017)). Moreover, coverage loss L_{cov} is calculated to directly penalize the repetition in updated word attention $\hat{\boldsymbol{\alpha}}^t$:

$$L_{cov} = \frac{1}{T}\sum_{t=1}^{T}\sum_{m=1}^{M} \min(\hat{\alpha}_m^t, \mathbf{c}_m^t)\;. \qquad (7)$$

The objective function for training the abstracter with coverage mechanism is the weighted sum of negative log-likelihood and coverage loss.

3.5 Training Procedure

We first pre-train the extractor by minimizing L_{ext} in Eq. 3 and the abstracter by minimizing L_{abs} and L_{cov} in Eq. 6 and Eq. 7, respectively. When pre-training, the abstracter takes ground-truth extracted sentences (i.e., sentences with $g_n = 1$) as input. To combine the extractor and abstracter, we proposed two training settings : (1) two-stages training and (2) end-to-end training.

Two-stages training. In this setting, we view the sentence-level attention $\boldsymbol{\beta}$ from the pre-trained extractor as hard attention. The extractor becomes a classifier to select sentences with high attention (i.e., $\beta_n >$ threshold). We simply combine the extractor and abstracter by feeding the extracted sentences to the abstracter. Note that we finetune the abstracter since the input text becomes extractive summary which is obtained from the extractor.

End-to-end training. For end-to-end training, the sentence-level attention $\boldsymbol{\beta}$ is soft attention and will be combined with the word-level attention $\boldsymbol{\alpha}^t$ as described in Sec. 3.1. We end-to-end train the extractor and abstracter by minimizing four loss functions: L_{ext}, L_{abs}, L_{cov}, as well as L_{inc} in Eq. 2. The final loss is as below:

$$L_{e2e} = \lambda_1 L_{ext} + \lambda_2 L_{abs} + \lambda_3 L_{cov} + \lambda_4 L_{inc}, \tag{8}$$

where λ_1, λ_2, λ_3, λ_4 are hyper-parameters. In our experiment, we give L_{ext} a bigger weight (e.g., $\lambda_1 = 5$) when end-to-end training with L_{inc} since we found that L_{inc} is relatively large such that the extractor tends to ignore L_{ext}.

4 Experiments

We introduce the dataset and implementation details of our method evaluated in our experiments.

4.1 Dataset

We evaluate our models on the CNN/Daily Mail dataset (Hermann et al., 2015; Nallapati et al., 2016b; See et al., 2017) which contains news stories in CNN and Daily Mail websites. Each article in this dataset is paired with one human-written multi-sentence summary. This dataset has two versions: *anonymized* and *non-anonymized*. The former contains the news stories with all the named entities replaced by special tokens (e.g., `@entity2`); while the latter contains the raw text of each news story. We follow See et al. (2017) and obtain the *non-anonymized* version of this dataset which has 287,113 training pairs, 13,368 validation pairs and 11,490 test pairs.

4.2 Implementation Details

We train our extractor and abstracter with 128-dimension word embeddings and set the vocabulary size to 50k for both source and target text. We follow Nallapati et al. (2017) and See et al. (2017) and set the hidden dimension to 200 and 256 for the extractor and abstracter, respectively. We use Adagrad optimizer (Duchi et al., 2011) and apply early stopping based on the validation set. In the testing phase, we limit the length of the summary to 120.

Pre-training. We use learning rate 0.15 when pre-training the extractor and abstracter. For the extractor, we limit both the maximum number of sentences per article and the maximum number of tokens per sentence to 50 and train the model for 27k iterations with the batch size of 64. For the abstracter, it takes ground-truth extracted sentences (i.e., sentences with $g_n = 1$) as input. We limit the length of the source text to 400 and the length of the summary to 100 and use the batch size of 16. We train the abstracter without coverage mechanism for 88k iterations and continue training for 1k iterations with coverage mechanism ($L_{abs} : L_{cov} = 1 : 1$).

Two-stages training. The abstracter takes extracted sentences with $\beta_n > 0.5$, where $\boldsymbol{\beta}$ is obtained from the pre-trained extractor, as input during two-stages training. We finetune the abstracter for 10k iterations.

End-to-end training. During end-to-end training, we will minimize four loss functions (Eq. 8) with $\lambda_1 = 5$ and $\lambda_2 = \lambda_3 = \lambda_4 = 1$. We set K to 3 for computing L_{inc}. Due to the limitation of the memory, we reduce the batch size to 8 and thus use a smaller learning rate 0.01 for stability. The abstracter here reads the whole article. Hence, we increase the maximum length of source text to 600. We end-to-end train the model for 50k iterations.

5 Results

Our unified model not only generates an abstractive summary but also extracts the important sentences in an article. Our goal is that both of the two types of outputs can help people to read and understand an article faster. Hence, in this section, we evaluate the results of our extractor in Sec. 5.1 and unified model in Sec. 5.2. Furthermore, in Sec. 5.3, we perform human evaluation and show that our model can provide a better abstractive summary than other baselines.

5.1 Results of Extracted Sentences

To evaluate whether our extractor obtains enough information for the abstracter, we use full-length ROUGE recall scores[1] between the extracted sentences and reference abstractive summary. High ROUGE recall scores can be obtained if the extracted sentences include more words or sequences overlapping with the reference abstractive summary. For each article, we select sentences with the sentence probabilities β greater than 0.5. We show the results of the ground-truth sentence labels (Sec. 3.3) and our models on the

[1]All our ROUGE scores are reported by the official ROUGE script. We use the `pyrouge` package. `https://pypi.org/project/pyrouge/0.1.3/`

Method	ROUGE-1	ROUGE-2	ROUGE-L

lead-3 (See et al., 2017)	40.34	17.70	36.57

Table 2: ROUGE F-1 scores of the generated abstractive summaries on the CNN/Daily Mail test set. Our two-stages model outperforms pointer-generator model on ROUGE-1 and ROUGE-2. In addition, our model trained end-to-end with inconsistency loss exceeds the lead-3 baseline. All our ROUGE scores have a 95% confidence interval with at most ±0.24. '*' indicates the model is trained and evaluated on the anonymized dataset and thus is not strictly comparable with ours.

test set of the CNN/Daily Mail dataset in Table 1. Note that the ground-truth extracted sentences can't get ROUGE recall scores of 100 because reference summary is abstractive and may contain some words and sequences that are not in the article. Our extractor performs the best when end-to-end trained with inconsistency loss.

5.2 Results of Abstractive Summarization

We use full-length ROUGE-1, ROUGE-2 and ROUGE-L F-1 scores to evaluate the generated summaries. We compare our models (two-stage and end-to-end) with state-of-the-art abstractive summarization models (Nallapati et al., 2016b; Paulus et al., 2017; See et al., 2017; Liu et al., 2017) and a strong lead-3 baseline which directly uses the first three article sentences as the summary. Due to the writing style of news articles, the most important information is often written at the beginning of an article which makes lead-3 a strong baseline. The results of ROUGE F-1 scores are shown in Table 2. We prove that with help of the extractor, our unified model can outperform pointer-generator (the third row in Table 2) even with two-stages training (the fifth row in Table 2). After end-to-end training without inconsistency loss, our method already achieves better ROUGE scores by cooperating with each other. Moreover, our model end-to-end trained with inconsistency loss achieves state-of-the-art ROUGE scores and exceeds lead-3 baseline.

In order to quantify the effect of inconsistency loss, we design a metric – inconsistency rate R_{inc} – to measure the inconsistency for each generated summary. For each decoder step t, if the word with maximum attention belongs to a sentence with low attention (i.e., $\beta_{n(\text{argmax}(\boldsymbol{\alpha}^t))} < \text{mean}(\boldsymbol{\beta})$), we define this step as an inconsistent step t_{inc}. The inconsistency rate R_{inc} is then defined as the percentage of the inconsistent steps in the summary.

$$R_{inc} = \frac{\text{Count}(t_{inc})}{T}, \tag{9}$$

where T is the length of the summary. The average inconsistency rates on test set are shown in Table 4. Our inconsistency loss significantly decrease R_{inc} from about 20% to 4%. An example of inconsistency improvement is shown in Fig. 5.

Method	informativity	conciseness	readability

Figure 5: Visualizing the consistency between sentence and word attentions on the original article. We highlight word (bold font) and sentence (underline font) attentions. We compare our methods trained with and without inconsistency loss. Inconsistent fragments (see red bold font) occur when trained without the inconsistency loss.

5.3 Human Evaluation

We perform human evaluation on Amazon Mechanical Turk (MTurk)[2] to evaluate the informativity, conciseness and readability of the summaries. We compare our best model (end2end with inconsistency loss) with pointer-generator (See et al., 2017), generative adversarial network (Liu et al., 2017) and deep reinforcement model (Paulus et al., 2017). For these three models, we use the test set outputs provided by the authors[3].

We randomly pick 100 examples in the test set. All generated summaries are re-capitalized and de-tokenized. Since Paulus et al. (2017) trained their model on anonymized data, we also recover the anonymized entities and numbers of their outputs.

We show the article and 6 summaries (reference summary, 4 generated summaries and a random summary) to each human evaluator. The random summary is a reference summary randomly picked from other articles and is used as a trap. We show the instructions of three different aspects as: (1) Informativity: how well does the summary capture the important parts of the article? (2) Conciseness: is the summary clear enough to explain everything without being redundant? (3) Readability: how well-written (fluent and grammatical) the summary is? The user interface of our human evaluation is shown in the supplementary material.

We ask the human evaluator to evaluate each summary by scoring the three aspects with 1 to 5 score (higher the better). We reject all the evaluations that score the informativity of the random summary as 3, 4 and 5. By using this trap mechanism, we can ensure a much better quality of our human evaluation. For each example, we first ask 5 human evaluators to evaluate. However, for those articles that are too long, which are always skipped by the evaluators, it is hard to collect 5 reliable evaluations. Hence, we collect at least 3 evaluations for every example. For each summary, we average the scores over different human evaluators.

The results are shown in Table 3. The reference summaries get the best score on conciseness since the recent abstractive models tend to copy sentences from the input articles. However, our model learns well to select important information and form complete sentences so we even get slightly better scores on informativity and readability than the reference summaries. We show a typical example of our model comparing with other state-of-

[2]`https://www.mturk.com/`

Original article (truncated):
A chameleon balances carefully on a branch, waiting calmly for its prey... except that if you look closely, you will see that this picture is not all that it seems. For the 'creature' poised to pounce is not a colourful species of lizard but something altogether more human. Featuring two carefully painted female models, it is a clever piece of sculpture designed to create an amazing illusion. It is the work of Italian artist Johannes Stoetter. Scroll down for video. Can you see us? Italian artist **Johannes Stoetter has painted two naked women to look like a chameleon. The 37-year-old has previously transformed his models into frogs and parrots** but this may be his most intricate and impressive piece to date. **Stoetter daubed water-based body paint on the naked models to create the multicoloured effect, then intertwined them to form the shape of a chameleon.** To complete the deception, the models rested on a bench painted to match their skin and held the green branch in the air beneath them. Stoetter can take weeks to plan one of his pieces and hours to paint it. Speaking about The Chameleon, he said: 'I worked about four days to design the motif bigger and paint it with colours. The body painting took me about six hours with the help of an assistant. I covered the hair with natural clay to make the heads look bald.' Camouflage job: A few finishing touches are applied to the two naked models to complete the transformation. 'There are different difficulties on different levels as in every work, but I think that my passion and love to my work is so big, that I figure out a way to deal with difficulties. My main inspirations are nature, my personal life-philosophy, every-day-life and people themselves.' However, the finished result existed only briefly before the models were able to get up and wash the paint off with just a video and some photographs to record it. (...)

Reference summary:
Johannes Stoetter's artwork features two carefully painted female models. The 37-year-old has previously transformed models into frogs and parrots. Daubed water-based body paint on naked models to create the effect. Completing the deception, models rested on bench painted to match skin.

DeepRL:
Italian artist Johannes Stoetter has painted female models to look like a chameleon. The 37-year-old has previously transformed his models into frogs and parrots but *this may be the work of Italian artist*. He has painted nude models and it is a clever piece of sculpture designed to create an amazing illusion. *It is work of artist Johannes Stoetter.*

Pointer-generator:
Italian artist Johannes Stoetter has painted two naked women to look like a chameleon. *It is the work of Italian artist Johannes Stoetter.* Stoetter daubed water-based body paint on the naked models to create the multicoloured effect, then intertwined them to form the shape of a chameleon.

Our unified model (with inconsistency loss):
Johannes Stoetter has painted two naked women to look like a chameleon. The 37-year-old has previously transformed his models into frogs and parrots. Stoetter daubed water-based body paint on the naked models to create the multicoloured effect, then intertwined them to form the shape of a chameleon.

Figure 6: Typical Comparison. Our model attended at the most important information (blue bold font) matching well with the reference summary; while other state-of-the-art methods generate repeated or less important information (red italic font).

the-art methods in Fig. 6. More examples (5 using CNN/Daily Mail news articles and 3 using non-news articles as inputs) are provided in the supplementary material.

6 Conclusion

We propose a unified model combining the strength of extractive and abstractive summarization. Most importantly, a novel inconsistency loss function is introduced to penalize the inconsistency between two levels of attentions. The inconsistency loss enables extractive and abstractive summarization to be mutually beneficial. By end-to-end training of our model, we achieve the best ROUGE-recall and ROUGE while being the most informative and readable summarization on the CNN/Daily Mail dataset in a solid human evaluation.

Abstract

We present a new neural sequence-to-sequence model for extractive summarization called SWAP-NET (Sentences and Words from Alternating Pointer Networks). Extractive summaries comprising a salient subset of input sentences, often also contain important key words. Guided by this principle, we design SWAP-NET that models the interaction of key words and salient sentences using a new two-level pointer network based architecture. SWAP-NET identifies both salient sentences and key words in an input document, and then combines them to form the extractive summary. Experiments on large scale benchmark corpora demonstrate the efficacy of SWAP-NET that outperforms state-of-the-art extractive summarizers.

1 Introduction

Automatic summarization aims to shorten a text document while maintaining the salient information of the original text. The practical need for such systems is growing with the rapid and continuous increase in textual information sources in multiple domains.

Summarization tools can be broadly classified into two categories: extractive and abstractive. *Extractive* summarization selects parts of the input document to create its summary while *abstractive* summarization generates summaries that may have words or phrases not present in the input document. Abstractive summarization is clearly harder as methods have to address factual and grammatical errors that may be introduced and problems in utilizing external knowledge sources to obtain paraphrasing or generalization. Extractive summarizers obviate the need to solve these problems by selecting the most salient textual units (usually sentences) from the input documents. As a result, they generate summaries that are grammatically and semantically more accurate than those from abstractive methods. While they may have problems like incorrect or unclear referring expressions or lack of coherence, they are computationally simpler and more efficient to generate. Indeed, state-of-the-art extractive summarizers are comparable or often better in performance to competitive abstractive summarizers (see (Nallapati et al., 2017) for a recent empirical comparison).

Classical approaches to extractive summarization have relied on human-engineered features from the text that are used to score sentences in the input document and select the highest-scoring sentences. These include graph or constraint-optimization based approaches as well as classifier-based methods. A review of these approaches can be found in Nenkova et al. (2011). Some of these methods generate summaries from multiple documents. In this paper, we focus on single document summarization.

Modern approaches that show the best performance are based on end-to-end deep learning models that do not require human-crafted features. Neural models have tremendously improved performance in several difficult problems in NLP such as machine translation (Chen et al., 2017) and question-answering (Hao et al., 2017). Deep models with thousands of parameters require large, labeled datasets and for summarization this hurdle of labeled data was surmounted by Cheng and Lapata (2016), through the creation of a labeled dataset of news stories from CNN and Daily Mail consisting of around 280,000 documents and human-generated summaries.

Recurrent neural networks with *encoder-decoder* architecture (Sutskever et al., 2014) have been successful in a variety of NLP tasks where an encoder obtains representations of input sequences and a decoder generates target sequences. Attention mechanisms (Bahdanau et al., 2015) are used to model the effects of different loci in the input sequence during decoding. Pointer networks (Vinyals et al., 2015) use this mechanism to obtain target sequences wherein each decoding step is used to *point* to elements of the input sequence. This pointing ability has been effectively utilized by state-of-the-art extractive and abstractive summarizers (Cheng and Lapata, 2016; Nallapati et al., 2016; See et al., 2017).

In this work, we design SWAP-NET a new deep learning model for extractive summarization. Similar to previous models, we use an encoder-decoder architecture with attention mechanism to select important sentences. Our key contribution is to design an architecture that utilizes key words in the selection process. Salient sentences of a document, that are useful in summaries, often contain key words and, to our knowledge, none of the previous models have explicitly modeled this interaction. We model this interaction through a two-level encoder and decoder, one for words and the other for sentences. An attention-based mechanism, similar to that of Pointer Networks, is used to learn important words and sentences from labeled data. A switch mechanism is used to select between words and sentences during decoding and the final summary is generated using a combination of selected sentences and words. We demonstrate the efficacy of our model on the CNN/Daily Mail corpus where it outperforms state-of-the-art extractive summarizers. Our experiments also suggest that the semantic redundancy in SWAP-NET generated summaries is comparable to that of human-generated summaries.

2 Problem Formulation

Let D denote an input document, comprising of a sequence of N sentences: $s_1, \ldots, s_N$. Ignoring sentence boundaries, let $w_1, \ldots, w_n$ be the sequence of n words in document D. An extractive summary aims to obtain a subset of the input sentences that forms a salient summary.

We use the interaction between words and sentences in a document to predict important words and sentences. Let the target sequence of indices of important words and sentences be $V = v_1, \ldots, v_m$, where each index v_j can point to either a sentence or a word in an input document. We design a supervised sequence-to-sequence recurrent neural network model, SWAP-NET, that uses these target sequences (of sentences and words) to learn salient sentences and key words. Our objective is to find SWAP-NET model parameters M that maximize the probability $p(V|M, D) = \prod_j p(v_j|v_1, \ldots, v_{j-1}, M, D) = \prod_j p(v_j|v_{<j}, M, D)$. We omit M in the following to simplify notation. SWAP-NET predicts both key words and salient sentences, that are subsequently used for extractive summary generation.

3 Background

We briefly describe Pointer Networks (Vinyals et al., 2015). Our approach, detailed in the following sections, uses a similar attention mechanism.

Given a sequence of n vectors $X = x_1, \ldots. x_n$ and a sequence of indices $R = r_1, \ldots. r_m$, each between 1 and n, the Pointer Network is an encoder-decoder architecture trained to maximize $p(R|X;\theta) = \prod_{j=1}^{m} p_\theta(r_j|r_1, \ldots. r_{j-1}, X;\theta)$, where θ denotes the model parameters. Let the encoder and decoder hidden states be $(e_1, \ldots., e_n)$ and $(d_1, \ldots., d_m)$ respectively. The attention vector at each output step j is computed as follows:

$$u_i^j = v^T \tanh(W_e e_i + W_d d_j),\ i \in (1, \ldots, n)$$

$$\alpha_i^j = \text{softmax}(u_i^j),\ i \in (1, \ldots, n)$$

The softmax normalizes vector u^j to be an *attention* mask over inputs. In a pointer network, the same attention mechanism is used to select one of the n input vectors with the highest probability, at each decoding step, thus effectively *pointing* to an input:

$$p(r_j|r_1, \ldots. r_{j-1}, X) = \text{softmax}(u^j)$$

Here, v, W_d, and W_e are learnable parameters of the model.

4 SWAP-NET

We use an encoder-decoder architecture with an attention mechanism similar to that of Pointer Networks. To model the interaction between words and sentences in a document we use two encoders and decoders, one at the word level and the other at the sentence level. The sentence-level decoder learns to *point* to important sentences while the

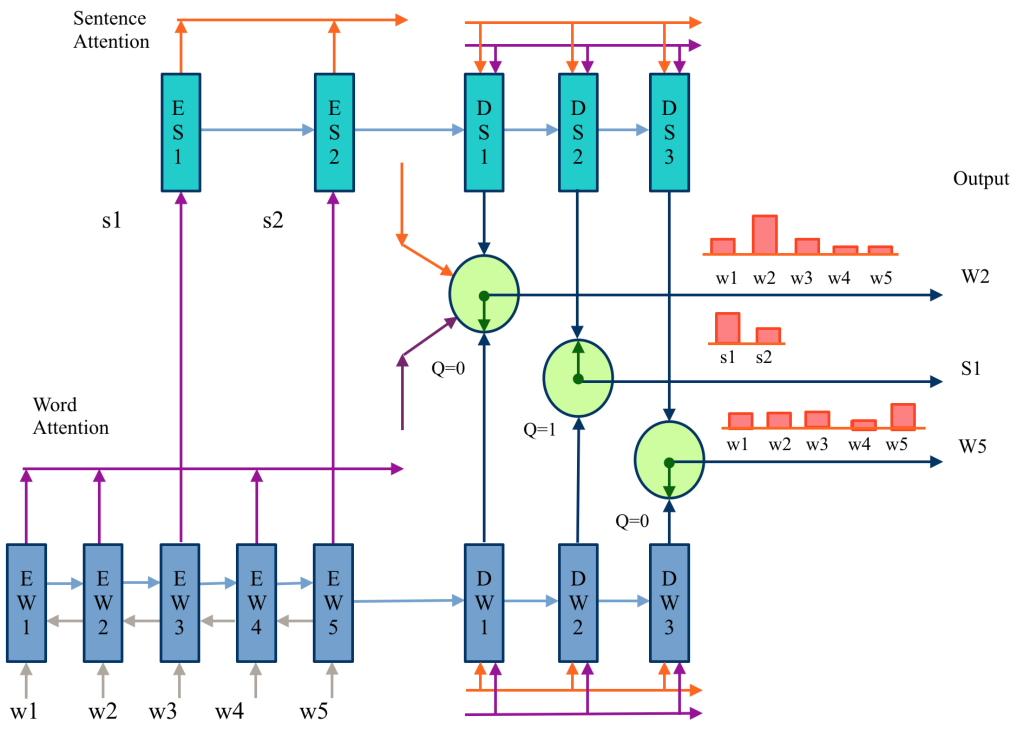

Figure 1: SWAP-NET architecture. EW: word encoder, ES: sentence encoder, DW: word decoder, DS: sentence decoder, Q: switch. Input document has words $[w1, \ldots, w5]$ and sentences $[s1, s2]$. Target sequence shown: $v_1 = w2, v_2 = s1, v_3 = w5$. Best viewed in color.

word-level decoder learns to *point* to important words. A switch mechanism is trained to select either a word or a sentence at each decoding step. The final summary is created using the output words and sentences. We now describe the details of the architecture.

4.1 Encoder

We use two encoders: a bi-directional LSTM at the word level and a LSTM at the sentence level. Each word w_i is represented by a K-dimensional embedding (e.g., via word2vec), denoted by x_i. The word embedding x_i is encoded as e_i using bi-directional LSTM for $i = 1, \ldots, n$. The vector output of BiLSTM at the end of a sentence is used to represent that entire sentence, which is further encoded by the sentence-level LSTM as $E_k = \text{LSTM}(e_{k^l}, E_{k-1})$, where k^l is the index of the last word in the k^{th} sentence in D and E_k is the hidden state at the k^{th} step of LSTM, for $k = 1, \ldots, N$. See figure 1.

4.2 Decoder

We use two decoders – a sentence-level and a word-level decoder, that are both LSTMs, with each decoder *pointing* to sentences and words respectively (similar to a pointer network). Thus, we can consider the output of each decoder step to be an index in the input sequence to the encoder. Let m be the number of steps in each decoder. Let $T_1, \ldots, T_m$ be the sequence of indices generated by the sentence-level decoder, where each index $T_j \in \{1, \ldots, N\}$; and let $t_1, \ldots, t_m$ be the sequence of indices generated by the word-level decoder, where each index $t_j \in \{1, \ldots, n\}$.

4.3 Network Details

At the j^{th} decoding step, we have to select a sentence or a word which is done through a binary switch Q_j that has two states $Q_j = 0$ and $Q_j = 1$ to denote word and sentence selection respectively. So, we first determine the switch probability $p(Q_j | v_{<j}, D)$. Let α^s_{kj} denote the probability of selecting the k^{th} input sentence at the j^{th} decoding step of sentence decoder:

$$\alpha^s_{kj} = p(T_j = k | v_{<j}, Q_j = 1, D),$$

and let α^w_{ij} denote the probability of selecting the i^{th} input word at the j^{th} decoding step of word decoder:

$$\alpha^w_{ij} = p(t_j = i | v_{<j}, Q_j = 0, D),$$

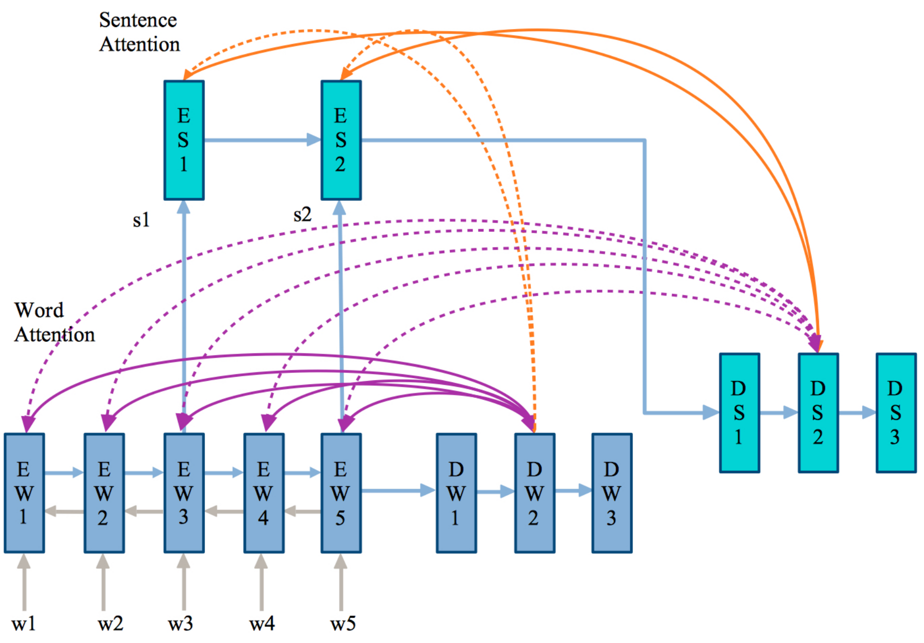

Figure 2: Illustration of word and sentence level attention in the second decoder step (Eq. 1 and Eq. 2). Purple: attention on words, Orange: attention on sentences, Unidirectional dotted arrows: attention from previous step, Bidirectional arrows: attention from previous and to present step. Best viewed in color.

both conditional on the corresponding switch selection. We set v_j based on the probability values:

$$v_j = \begin{cases} k = \arg\max_k p^s_{kj} & \text{if } \max_k p^s_{kj} > \max_i p^w_{ij} \\ i = \arg\max_i p^w_{ij} & \text{if } \max_i p^w_{ij} > \max_k p^s_{kj} \end{cases}$$

$$p^s_{kj} = \alpha^s_{kj} p(Q_j = 1 | v_{<j}, D),$$

$$p^w_{ij} = \alpha^w_{ij} p(Q_j = 0 | v_{<j}, D).$$

These probabilities are obtained through the attention weight vectors at the word and sentence levels and the switch probabilities:

$$\alpha^w_{ij} = \text{softmax}(v_t^T \phi(w_h h_j + w_t e_i)),$$

$$\alpha^s_{kj} = \text{softmax}(V_T^T \phi(W_H H_j + W_T E_k)).$$

Parameters v_t, w_h, w_t, V_T, W_H and W_T are trainable parameters. Parameters h_j and H_j are the hidden vectors at the j^{th} step of the word-level and sentence-level decoder respectively defined as:

$$h_j = LSTM(h_{j-1}, a_{j-1}, \phi(A_{j-1})) \qquad (1)$$

$$H_j = LSTM(H_{j-1}, A_{j-1}, \phi(a_{j-1})) \qquad (2)$$

where $a_j = \sum_{i=0}^{n} \alpha^w_{ij} e_i$, $A_j = \sum_{k=0}^{N} \alpha^s_{kj} E_k$. The non-linear transformation, ϕ (we choose tanh), is used to connect the word-level encodings to the sentence decoder and the sentence-level encodings to the word decoder. Specifically, the word-level decoder updates its state by considering a sum of sentence encodings, weighted by the attentions from the previous state and *mutatis mutandis* for the sentence-level decoder.

The switch probability $p(Q_j | v_{<j}, D)$ at the j^{th} decoding step is given by:

$$p(Q_j = 1 | v_{<j}, D) = \sigma(w_Q^T(H_{j-1}, A_{j-1}, \phi(h_{j-1}, a_{j-1})))$$

$$p(Q_j = 0 | v_{<j}, D) = 1 - p(Q_j = 1 | v_{<j}, D)$$

where w_Q is a trainable parameter and σ denotes the sigmoid function and ϕ is the chosen non-linear transformation (tanh).

During training the loss function l_j at j^{th} step is set to $l_j = -\log(p^s_{kj} q^s_j + p^w_{ij} q^w_j) - \log p(Q_j | v_{<j}, D)$. Note that at each decoding step, switch is either $q^w_j = 1, q^s_j = 0$ if the j^{th} output is a word or $q^w_j = 0, q^s_j = 1$ if the j^{th} output is a sentence. The switch probability is also considered in the loss function.

4.4 Summary Generation

Given a document whose summary is to be generated, its sentences and words are given as input to the trained encoder. At the j^{th} decoding step, either a sentence or a word is chosen based on the probability values α_{kj}^{s} and α_{ij}^{w} and the switch probability $p(Q_j|v_{<j}, D)$. We assign importance scores to the selected sentences based on their probability values during decoding as well as the probabilities of the selected words that are present in the selected sentences. Thus sentences with words selected by the decoder are given higher importance. Let the k^{th} input sentence s_k be selected at the j^{th} decoding step and i^{th} input word w_i be selected at the l^{th} decoding step. Then the importance of s_k is defined as

$$I(s_k) = \alpha_{kj}^{s} + \lambda \sum_{w_i \in s_k} \alpha_{il}^{w} \qquad (3)$$

In our experiments we choose $\lambda = 1$. The final summary consists of three sentences with the highest importance scores.

5 Related Work

Traditional approaches to extractive summarization rely on human-engineered features based on, for example, part of speech (Erkan and Radev, 2004) and term frequency (Nenkova et al., 2006). Sentences in the input document are scored using these features, ranked and then selected for the final summary. Methods used for extractive summarization include graph-based approaches (Mihalcea, 2005) and Integer Linear Programming (Gillick and Favre, 2009). There are many classifier-based approaches that select sentences for the extractive summary using methods such as Conditional Random Fields (Shen et al., 2007) and Hidden Markov models (Conroy and O'leary, 2001). A review of these classical approaches can be found in Nenkova et al. (2011).

End-to-end deep learning based neural models that can effectively learn from text data, without human-crafted features, have witnessed rapid development, resulting in improved performance in multiple areas such as machine translation (Chen et al., 2017) and question-answering (Hao et al., 2017), to name a few. Large labelled corpora based on news stories from CNN and Daily Mail, with human generated summaries have become available (Cheng and Lapata, 2016), that have spurred the use of deep learning models in summarization. Recurrent neural network based architectures have been designed for both extractive (Cheng and Lapata, 2016; Nallapati et al., 2017) and abstractive (See et al., 2017; Tan et al., 2017) summarization problems. Among these, the work of Cheng and Lapata (2016) and Nallapati et al. (2017) are closest to our work on extractive single-document summarization.

An encoder-decoder architecture with an attention mechanism similar to that of a pointer network is used by Cheng and Lapata (2016). Their hierarchical encoder uses a CNN at the word level leading to sentence representations that are used in an RNN to obtain document representations. They use a hierarchical attention model where the first level decoder predicts salient sentences used for an extractive summary and based on this output, the second step predicts keywords which are used for abstractive summarization. Thus they do not use key words for extractive summarization and for abstractive summarization they generate key words based on sentences predicted independently of key words. SWAP-NET, in contrast, is simpler using only two-level RNNs for word and sentence level representations in both the encoder and decoder. In our model we predict both words and sentences in such a way that their attentions interact with each other and generate extractive summaries considering both the attentions. By modeling the interaction between these key words and important sentences in our decoder architecture, we are able to extract sentences that are closer to the gold summaries.

SummaRuNNer, the method developed by Nallapati et al. (2017) is not similar to our method in its architecture but only in the aim of extractive summary generation. It does not use an encoder-decoder architecture; instead it is an RNN based binary classifier that decides whether or not to include a sentence in the summary. The RNN is multi-layered representing inputs, words, sentences and the final sentence labels. The decision of selecting a sentence at each step of the RNN is based on the content of the sentence, salience in the document, novelty with respect to previously selected sentences and other positional features. Their approach is considerably simpler than that of Cheng and Lapata (2016) but obtains summaries closer to the gold summaries, and additionally, facilitates interpretable visualization and training from abstractive summaries. Their experiments show improved performance over both abstractive and extractive summarizers from several previous models (Nallapati et al., 2017).

We note that several elements of our architecture have been introduced and used in earlier work. Pointer networks (Vinyals et al., 2015) used the attention mechanism of (Bahdanau et al., 2015) to solve combinatorial optimization problems. They have also been used to *point* to sentences in extractive (Cheng and Lapata, 2016) and abstractive (Nallapati et al., 2016; See et al., 2017) summarizers. The switch mechanism was introduced to incorporate rare or out-of-vocabulary words (Gulcehre et al., 2016) and are used in several summarizers (e.g. (Nallapati et al., 2016)). However, we use it to select between word and sentence level decoders in our model.

The importance of all the three interactions: (i) sentence-sentence, (ii) word-word and (iii) sentence-word, for summarization, have been studied by Wan et al. (2007) using graph-based approaches. In particular, they show that methods that account for saliency using both the following considerations perform better than methods that consider either one of them alone, and SWAP-NET is based on the same principles.

- A sentence should be salient if it is heavily linked with other salient sentences, and a word should be salient if it is heavily linked with other salient words.
- A sentence should be salient if it contains many salient words, and a word should be salient if it appears in many salient sentences.

6 Data and Experiments

6.1 Experimental Settings

In our experiments the maximum number of words per document is limited to 800, and the maximum number of sentences per document to 50 (padding is used to maintain the length of word sequences). We also use the symbols <GO> and <EOS> to indicate start and end of prediction by decoders. The total vocabulary size is 150,000 words.

We use word embeddings of dimension 100 pretrained using word2vec (Mikolov et al., 2013) on the training dataset. We fix the LSTM hidden state size at 200. We use a batch size of 16 and the ADAM optimizer (Kingma and Ba, 2015) with parameters: learning rate = 0.001, $\beta_1 = 0.9, \beta_2 = 0.999$ to train SWAP-NET. We employ gradient clipping to regularize our model and an early stopping criterion based on the validation loss.

During training we find that SWAP-NET learns to predict important sentences faster than to predict words. To speed up learning of word probabilities, we add the term $-\log \alpha^w_{ij}$ to our loss function l_j in the final iterations of training. It is possible to get the same sentence or word in multiple (usually consecutive) decoding steps. In that case, in Eq. 3 we consider the maximum value of alpha obtained across these steps and calculate maximum scores of distinct sentences and words.

We select 3 top scoring sentences for the summary, as there are 3.11 sentences on average in the gold summary of the training set (similar to settings used by others, e.g., (Narayan et al., 2017)).

6.2 Baselines

Two state-of-the-art methods for extractive summarization are **SummaRuNNer** (Nallapati et al., 2017) and **NN**, the neural summarizer of Cheng and Lapata (2016). SummaRuNNer can also provide extractive summaries while being trained abstractively (Nallapati et al., 2017); we denote this method by **SummaRuNNer-abs**. In addition, we compare our method with the **Lead-3** summary which consists of the first three sentences from each document. We also compare our method with an abstractive summarizer that uses a similar attention-based encoder-decoder architecture (Nallapati et al., 2016), denoted by **ABS**.

6.3 Benchmark Datasets

For our experiments, we use the CNN/DailyMail corpus (Hermann et al., 2015). We use the anonymized version of this dataset, from Cheng and Lapata (2016), which has labels for important sentences, that are used for training. To obtain labels for words, we extract keywords from each gold summary using RAKE, an unsupervised keyword extraction method (Rose et al., 2010). These keywords are used to label words in the corresponding input document during training. We replace numerical values in the documents by zeros to limit the vocabulary size.

We have 193,986 training documents, 12,147 validation documents and 10,346 test documents from the DailyMail corpus and 83,568 training documents, 1,220 validation documents and 1,093 test documents from CNN subset with labels for sentences and words.

6.4 Evaluation Metrics

We use the ROUGE toolkit (Lin and Hovy, 2003) for evaluation of the generated summaries in comparison to the gold summaries. We use three variants of this metric: ROUGE-1 (R1), ROUGE-2 (R2) and ROUGE-L (RL) that are computed by matching unigrams, bigrams and longest common subsequences respectively between the two summaries. To compare with (Cheng and Lapata, 2016) and (Nallapati et al., 2017) we use limited length ROUGE recall at 75 and 275 bytes for the Daily-Mail test set, and full length ROUGE-F1 score, as reported by them.

6.5 Results on Benchmark Datasets

Performance on Daily Mail Data

Models	R1	R2	RL
Lead-3	21.9	7.2	11.6
NN	22.7	8.5	12.5
SummaRuNNer-abs	23.8	9.6	13.3
SummaRuNNer	26.2	**10.8**	**14.4**
SWAP-NET	**26.4**	10.7	**14.4**

Table 1: Performance on Daily-Mail test set using the limited length recall of Rouge at 75 bytes.

Models	R1	R2	RL
Lead-3	40.5	14.9	32.6
NN	42.2	17.3	34.8
SummaRuNNer-abs	40.4	15.5	32.0
SummaRuNNer	42.0	16.9	34.1
SWAP-NET	**43.6**	**17.7**	**35.5**

Table 2: Performance on Daily-Mail test set using the limited length recall of Rouge at 275 bytes.

Table 1 shows the performance of SWAP-NET, state-of-the-art baselines NN and SummaRuNNer and other baselines, using ROUGE recall with summary length of 75 bytes, on the entire Daily Mail test set. The performance of SWAP-NET is comparable to that of SummaRuNNer and better than NN and other baselines. Table 2 compares the same algorithms using ROUGE recall with summary length of 275 bytes. SWAP-NET outperforms both state-of-the-art summarizers SummaRuNNer as well as NN.

Performance on CNN/DailyMail Data

SWAP-NET has the best performance on the combined CNN and Daily Mail corpus, outperforming the previous best reported F-score by SummaRuNNer, as seen in table 3, with a consistent improvement of over 2 ROUGE points in all three metrics.

Models	R1	R2	RL
Lead-3	39.2	15.7	35.5
ABS	35.4	13.3	32.6
SummaRuNNer-abs	37.5	14.5	33.4
SummaRuNNer	39.6	16.2	35.3
SWAP-NET	**41.6**	**18.3**	**37.7**

Table 3: Performance on CNN and Daily-Mail test set using the full length Rouge F score.

6.6 Discussion

SWAP-NET outperforms state-of-the-art extractive summarizers SummaRuNNer (Nallapati et al., 2017) and NN (Cheng and Lapata, 2016) on benchmark datasets. Our model is similar, although simpler, than that of NN and the main difference between SWAP-NET and these baselines is its explicit modeling of the interaction between key words and salient sentences.

Automatic keyword extraction has been studied extensively (Hasan and Ng, 2014). We use a popular and well tested method, RAKE (Rose et al., 2010) to obtain key words in the training documents. A disadvantage with such methods is that they do not guarantee representation, via extracted keywords, of all the topics in the text (Hasan and Ng, 2014). So, if RAKE key words are directly applied to the input test document (without using word decoder trained on RAKE words, obtained from gold summary as done in SWAP-NET), then there is a possibility of missing sentences from the missed topics. So, we train SWAP-NET to predict key words and also model their interactions with sentences.

Statistics	Lead-3	SWAP-NET
KW coverage	61.6%	73.8%
Sentences with KW	92.2%	98%

Table 4: Key word (KW) statistics per summary (average percentage) from 500 documents in Daily Mail test set. See text for definitions.

We investigate the importance of modeling this interaction and the role of key words in the final summary. Table 4 shows statistics that reflect the importance of key words in extractive summaries. *Key word coverage* measures the proportion of key

Title: @entity19 vet surprised reason license plate denial
Gold Summary: @entity9 of @entity10 , @entity1 , wanted to get ' @entity11 - 0 ' put on a license plate . that would have commemorated both @entity9 getting the @entity8 in 0 and his @entity16 . the @entity1 @entity21 denied his request , citing state regulations prohibiting the use of the number 0 because of its indecent connotations .
SWAP-NET Summary: **@entity9 of @entity10 wanted to get ' @entity11 ' put on a license plate** , the @entity14 newspaper of @entity10 reported . **that would have commemorated both @entity9 getting the @entity8 in 0 and his @entity16** , according to the newspaper . **the @entity1 @entity21 denied his request , citing state regulations prohibiting the use of the number 0 because of its indecent connotations** @entity9 had been an armored personnel carrier 's gunner during his time in the @entity29 .
SWAP-NET Key words: @entity1, @entity9, @entity8, citing, number, year, indecent, personalized, war, surprised, plate, @entity14, @entity11, @entity10, regulations, reported, wanted, connotations, license, request, according,@entity21, armored, @entity16
Lead 3 Summary: a @entity19 war veteran in @entity1 has said he 's surprised over the reason for the denial of his request for a personalized license plate commemorating the year he was wounded and awarded a @entity8 . **@entity9 of @entity10 wanted to get ' @entity11 ' put on a license plate** , the @entity14 newspaper of @entity10 reported . **that would have commemorated both @entity9 getting the @entity8 in 0 and his @entity16** , according to the newspaper .

Table 5: Sample gold summary and summaries generated by SWAP-NET and Lead-3. Key words are highlighted, bold font indicates overlap with gold summary.

words from those in the gold summary present in the generated summary. SWAP-NET obtains nearly 74% of the key words. In comparison Lead-3 has only about 62% of the key words from the gold summary.

Sentences with key words measures the proportion of sentences containing at least one key word. It is not surprising that in SWAP-NET summaries 98% of the sentences, on average, contain at least one key word: this is by design of SWAP-NET. However, note that Lead-3 which has poorer performance in all the benchmark datasets has much fewer sentences with key words. This highlights the importance of key words in finding salient sentences for extractive summaries.

Gold summary	Lead-3	SWAP-NET
0.81	0.553	0.8

Table 6: Average pairwise cosine distance between paragraph vector representations of sentences in summaries.

We also find the SWAP-NET obtains summaries that have less semantic redundancy. Table 6 shows the average distance between pairs of sentences from the gold summary, and summaries generated from SWAP-NET and Lead-3. Distances are measured using cosine distance of paragraph vectors of each sentence (Le and Mikolov, 2014) from randomly selected 500 documents of the Daily Mail test set. Paragraph vectors have been found to be effective semantic representations of sentences (Le and Mikolov, 2014) and experiments in (Dai et al., 2015) also show that paragraph vectors can be effectively used to measure semantic similarity using cosine distance. For training we use GENSIM (Řehůřek and Sojka, 2010) with embedding size 200 and initial learning rate 0.025. The model is trained on 500 documents from DailyMail dataset for 10 epochs and learning rate is decreased by 0.002 at each epoch.

The average pair-wise distance of SWAP-NET is very close to that of the gold summary, both nearly 0.8. In contrast, the average pairwise distance in Lead-3 summaries is 0.553 indicating higher redundancy. This highly desirable feature of SWAP-NET is likely due to use of of key words, that is affecting the choice of sentences in the final summary.

Table 5 shows a sample gold summary from the Daily Mail dataset and the generated summary from SWAP-NET and, for comparison, from Lead-3. We observe the presence of key words in all the overlapping segments of text with the gold summary indicating the importance of key words in finding salient sentences. Modeling this interaction, we believe, is the reason for the superior performance of SWAP-NET in our experiments.

An implementation of SWAP-NET and all the generated summaries from the test sets are available online in a github repository[1].

7 Conclusion

We present SWAP-NET, a neural sequence-to-sequence model for extractive summarization that outperforms state-of-the-art extractive summarizers SummaRuNNer (Nallapati et al., 2017) and NN (Cheng and Lapata, 2016) on large scale benchmark datasets. The architecture of SWAP-NET is simpler than that of NN but due to its effective modeling of interaction between salient sentences and key words in a document, SWAP-NET achieves superior performance. SWAP-NET models this interaction using a new two-level pointer network based architecture with a switching mechanism. Our experiments also suggest that modeling sentence-keyword interaction has the desirable property of less semantic redundancy in summaries generated by SWAP-NET.

Abstract

Most previous seq2seq summarization systems purely depend on the source text to generate summaries, which tends to work unstably. Inspired by the traditional template-based summarization approaches, this paper proposes to use existing summaries as soft templates to guide the seq2seq model. To this end, we use a popular IR platform to Retrieve proper summaries as candidate templates. Then, we extend the seq2seq framework to jointly conduct template Reranking and template-aware summary generation (Rewriting). Experiments show that, in terms of informativeness, our model significantly outperforms the state-of-the-art methods, and even soft templates themselves demonstrate high competitiveness. In addition, the import of high-quality external summaries improves the stability and readability of generated summaries.

1 Introduction

The exponentially growing online information has necessitated the development of effective automatic summarization systems. In this paper, we focus on an increasingly intriguing task, i.e., abstractive sentence summarization (Rush et al., 2015a), which generates a shorter version of a given sentence while attempting to preserve its original meaning. It can be used to design or refine appealing headlines. Recently, the application of the attentional sequence-to-sequence (seq2seq) framework has attracted growing attention and achieved state-of-the-art performance on this task (Rush et al., 2015a; Chopra et al., 2016; Nallapati et al., 2016).

Most previous seq2seq models purely depend on the source text to generate summaries. However, as reported in many studies (Koehn and Knowles, 2017), the performance of a seq2seq model deteriorates quickly with the increase of the length of generation. Our experiments also show that seq2seq models tend to "lose control" sometimes. For example, 3% of summaries contain less than 3 words, while there are 4 summaries repeating a word for even 99 times. These results largely reduce the informativeness and readability of the generated summaries. In addition, we find seq2seq models usually focus on copying source words in order, without any actual "summarization". Therefore, we argue that, the free generation based on the source sentence is not enough for a seq2seq model.

Template based summarization (e.g., Zhou and Hovy (2004)) is a traditional approach to abstractive summarization. In general, a template is an incomplete sentence which can be filled with the input text using the manually defined rules. For instance, a concise template to conclude the stock market quotation is: *[REGION] shares [open/close] [NUMBER] percent [lower/higher]*, e.g., "hong kong shares close #.# percent lower". Since the templates are written by humans, the produced summaries are usually fluent and informative. However, the construction of templates is extremely time-consuming and requires a plenty of domain knowledge. Moreover, it is impossible to develop all templates for summaries in various domains.

Inspired by retrieve-based conversation systems (Ji et al., 2014), we assume the golden summaries of the similar sentences can provide a reference point to guide the input sentence summarization process. We call these existing summaries **soft templates** since no actual rules are needed to build new summaries from them. Due to the strong rewriting ability of the seq2seq framework (Cao et al., 2017a), in this paper, we propose to combine the seq2seq and template based summarization approaches. We call our summarization system Re^{3}Sum, which consists of three modules: **Re**trieve, **Re**rank and **Re**write. We utilize a widely-used Information Retrieval (IR) platform to find out candidate soft templates from the training corpus. Then, we extend the seq2seq model to jointly learn template saliency measurement (Rerank) and final summary generation (Rewrite). Specifically, a Recurrent Neural Network (RNN) encoder is applied to convert the input sentence and each candidate template into hidden states. In Rerank, we measure the informativeness of a candidate template according to its hidden state relevance to the input sentence. The candidate template with the highest predicted informativeness is regarded as the actual soft template. In Rewrite, the summary is generated according to the hidden states of both the sentence and template.

We conduct extensive experiments on the popular Gigaword dataset (Rush et al., 2015b). Experiments show that, in terms of informativeness, Re^{3}Sum significantly outperforms the state-of-the-art seq2seq models, and even soft templates themselves demonstrate high competitiveness. In addition, the import of high-quality external summaries improves the stability and readability of generated summaries.

The contributions of this work are summarized as follows:

- We propose to introduce soft templates as additional input to improve the readability and stability of seq2seq summarization systems. Code and results can be found at `http://www4.comp.polyu.edu.hk/~cszqcao/`
- We extend the seq2seq framework to conduct template reranking and template-aware summary generation simultaneously.
- We fuse the popular IR-based and seq2seq-based summarization systems, which fully utilize the supervisions from both sides.

2 Method

As shown in Fig. 1, our summarization system consists of three modules, i.e., Retrieve, Rerank and Rewrite. Given the input sentence $\mathbf{x}$, the Retrieve module filters candidate soft templates $\mathbf{C} = \{\mathbf{r}_i\}$ from the training corpus. For validation and test, we regard the candidate template with the highest predicted saliency (a.k.a informativeness) score as the actual soft template $\mathbf{r}$. For training, we choose the one with the maximal actual saliency score in $\mathbf{C}$, which speeds up convergence and shows no obvious side effect in the experiments.

Then, we jointly conduct reranking and rewriting through a shared encoder. Specifically, both the sentence $\mathbf{x}$ and the soft template $\mathbf{r}$ are converted into hidden states with a RNN encoder. In the Rerank module, we measure the saliency of $\mathbf{r}$ according to its hidden state relevance to $\mathbf{x}$. In the Rewrite module, a RNN decoder combines the hidden states of $\mathbf{x}$ and $\mathbf{r}$ to generate a summary $\mathbf{y}$. More details will be described in the rest of this section

2.1 Retrieve

The purpose of this module is to find out candidate templates from the training corpus. We assume that similar sentences should hold similar summary patterns. Therefore, given a sentence $\mathbf{x}$, we find out its analogies in the corpus and pick their summaries as the candidate templates. Since the size of our dataset is quite large (over 3M), we leverage the widely-used Information Retrieve (IR) system Lucene[1] to index and search efficiently. We keep the default settings of Lucene[2] to build the IR system. For each input sentence, we select top 30 searching results as candidate templates.

2.2 Jointly Rerank and Rewrite

To conduct template-aware seq2seq generation (rewriting), it is a necessary step to encode both the source sentence $\mathbf{x}$ and soft template $\mathbf{r}$ into hidden states. Considering that the matching networks based on hidden states have demonstrated the strong ability to measure the relevance of two pieces of texts (e.g., Chen et al. (2016)), we propose to jointly conduct reranking and rewriting through a shared encoding step. Specifically, we employ a bidirectional Recurrent Neural Network (BiRNN) encoder (Cho et al., 2014) to read $\mathbf{x}$ and $\mathbf{r}$. Take the sentence $\mathbf{x}$ as an example. Its hidden state of the forward RNN at timestamp i can be

[1]`https://lucene.apache.org/`
[2]TextField with EnglishAnalyzer

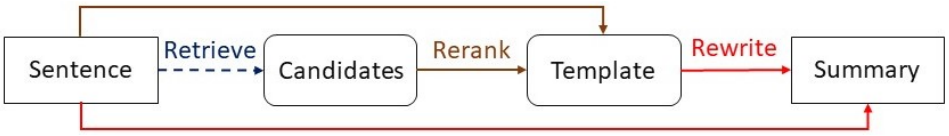

Figure 1: Flow chat of the proposed method. We use the dashed line for Retrieve since there is an IR system embedded.

represented by:

$$\overrightarrow{\mathbf{h}}_i^x = \text{RNN}(x_i, \overrightarrow{\mathbf{h}}_{i-1}^x) \quad (1)$$

The BiRNN consists of a forward RNN and a backward RNN. Suppose the corresponding outputs are $[\overrightarrow{\mathbf{h}}_1^x; \cdots; \overrightarrow{\mathbf{h}}_{-1}^x]$ and $[\overleftarrow{\mathbf{h}}_1^x; \cdots; \overleftarrow{\mathbf{h}}_{-1}^x]$, respectively, where the index "-1" stands for the last element. Then, the composite hidden state of a word is the concatenation of the two RNN representations, i.e., $\mathbf{h}_i^x = [\overrightarrow{\mathbf{h}}_i^x; \overleftarrow{\mathbf{h}}_i^x]$. The entire representation for the source sentence is $[\mathbf{h}_1^x; \cdots; \mathbf{h}_{-1}^x]$. Since a soft template $\mathbf{r}$ can also be regarded as a readable concise sentence, we use the same BiRNN encoder to convert it into hidden states $[\mathbf{h}_1^r; \cdots; \mathbf{h}_{-1}^r]$.

2.2.1 Rerank

In Retrieve, the template candidates are ranked according to the text similarity between the corresponding indexed sentences and the input sentence. However, for the summarization task, we expect the soft template $\mathbf{r}$ resembles the actual summary $\mathbf{y}^*$ as much as possible. Here we use the widely-used summarization evaluation metrics ROUGE (Lin, 2004) to measure the actual saliency $s^*(\mathbf{r}, \mathbf{y}^*)$ (see Section 3.2). We utilize the hidden states of $\mathbf{x}$ and $\mathbf{r}$ to predict the saliency s of the template. Specifically, we regard the output of the BiRNN as the representation of the sentence or template:

$$\mathbf{h}_x = [\overleftarrow{\mathbf{h}}_1^x; \overrightarrow{\mathbf{h}}_{-1}^x] \quad (2)$$

$$\mathbf{h}_r = [\overleftarrow{\mathbf{h}}_1^r; \overrightarrow{\mathbf{h}}_{-1}^r] \quad (3)$$

Next, we use Bilinear network to predict the saliency of the template for the input sentence.

$$s(\mathbf{r}, \mathbf{x}) = \text{sigmoid}(\mathbf{h}_r \mathbf{W}_s \mathbf{h}_x^{\mathbf{T}} + b_s), \quad (4)$$

where $\mathbf{W}_s$ and b_s are parameters of the Bilinear network, and we add the sigmoid activation function to make the range of s consistent with the actual saliency s^*. According to Chen et al. (2016), Bilinear outperforms multi-layer forward neural networks in relevance measurement. As shown later, the difference of s and s^* will provide additional supervisions for the seq2seq framework.

2.2.2 Rewrite

The soft template $\mathbf{r}$ selected by the Rerank module has already competed with the state-of-the-art method in terms of ROUGE evaluation (see Table 4). However, $\mathbf{r}$ usually contains a lot of named entities that does not appear in the source (see Table 5). Consequently, it is hard to ensure that the soft templates are faithful to the input sentences. Therefore, we leverage the strong rewriting ability of the seq2seq model to generate more faithful and informative summaries. Specifically, since the input of our system consists of both the sentence and soft template, we use the concatenation function[3] to combine the hidden states of the sentence and template:

$$\mathbf{H}_c = [\mathbf{h}_1^x; \cdots; \mathbf{h}_{-1}^x; \mathbf{h}_1^r; \cdots; \mathbf{h}_{-1}^r] \quad (5)$$

The combined hidden states are fed into the prevailing attentional RNN decoder (Bahdanau et al., 2014) to generate the decoding hidden state at the position t:

$$\mathbf{s}_t = \text{Att-RNN}(\mathbf{s}_{t-1}, y_{t-1}, \mathbf{H}_c), \quad (6)$$

where y_{t-1} is the previous output summary word. Finally, a $softmax$ layer is introduced to predict the current summary word:

$$\mathbf{o_t} = softmax(\mathbf{s}_t \mathbf{W}_o), \quad (7)$$

where $\mathbf{W}_o$ is a parameter matrix.

2.3 Learning

There are two types of costs in our system. For Rerank, we expect the predicted saliency $s(\mathbf{r}, \mathbf{x})$ close to the actual saliency $s^*(\mathbf{r}, \mathbf{y}^*)$. Therefore,

[3]We also attempted complex combination approaches such as the gate network Cao et al. (2017b) but failed to achieve obvious improvement. We assume the Rerank module has partially played the role of the gate network.

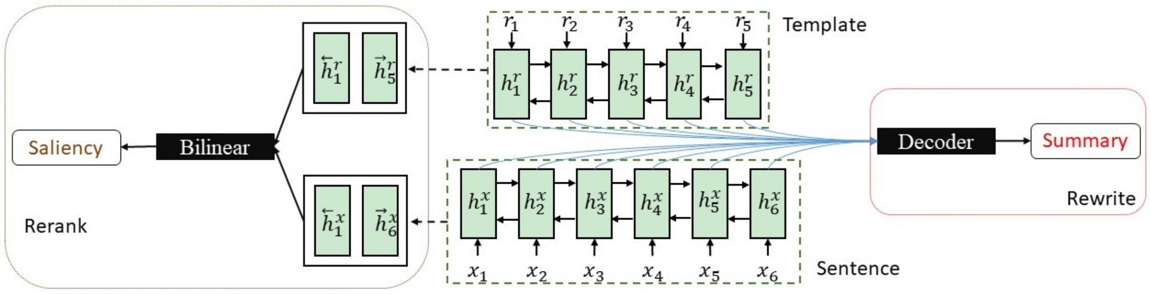

Figure 2: Jointly Rerank and Rewrite

we use the cross entropy (CE) between s and s^* as the loss function:

$$\begin{aligned} J_R(\theta) &= \text{CE}(s(\mathbf{r},\mathbf{x}), s^*(\mathbf{r},\mathbf{y}^*)) \\ &= -s^* \log s - (1-s^*)\log(1-s), \end{aligned} \tag{8}$$

where θ stands for the model parameters. For Rewrite, the learning goal is to maximize the estimated probability of the actual summary $\mathbf{y}^*$. We adopt the common negative log-likelihood (NLL) as the loss function:

$$\begin{aligned} J_G(\theta) &= -\log(p(\mathbf{y}^*|\mathbf{x},\mathbf{r})) \\ &= -\sum\nolimits_t \log(\mathbf{o}_t[y_t^*]) \end{aligned} \tag{9}$$

To make full use of supervisions from both sides, we combine the above two costs as the final loss function:

$$J(\theta) = J_R(\theta) + J_G(\theta) \tag{10}$$

We use mini-batch Stochastic Gradient Descent (SGD) to tune model parameters. The batch size is 64. To enhance generalization, we introduce dropout (Srivastava et al., 2014) with probability $p = 0.3$ for the RNN layers. The initial learning rate is 1, and it will decay by 50% if the generation loss does not decrease on the validation set.

3 Experiments

3.1 Datasets

We conduct experiments on the Annotated English Gigaword corpus, as with (Rush et al., 2015b). This parallel corpus is produced by pairing the first sentence in the news article and its headline as the summary with heuristic rules. All the training, development and test datasets can be downloaded at `https://github.com/harvardnlp/sent-summary`. The statistics of the Gigaword corpus is presented in Table 1.

Dataset	Train	Dev.	Test
Count	3.8M	189k	1951
AvgSourceLen	31.4	31.7	29.7
AvgTargetLen	8.3	8.3	8.8
COPY(%)	45	46	36

Table 1: Data statistics for English Gigaword. AvgSourceLen is the average input sentence length and AvgTargetLen is the average summary length. COPY means the copy ratio in the summaries (without stopwords).

3.2 Evaluation Metrics

We adopt ROUGE (Lin, 2004) for automatic evaluation. ROUGE has been the standard evaluation metric for DUC shared tasks since 2004. It measures the quality of summary by computing the overlapping lexical units between the candidate summary and actual summaries, such as uni-gram, bi-gram and longest common subsequence (LCS). Following the common practice, we report ROUGE-1 (uni-gram), ROUGE-2 (bi-gram) and ROUGE-L (LCS) F1 scores[4] in the following experiments. We also measure the actual saliency of a candidate template $\mathbf{r}$ with its combined ROUGE scores given the actual summary $\mathbf{y}^*$:

$$s^*(\mathbf{r},\mathbf{y}^*) = \text{RG}(\mathbf{r},\mathbf{y}^*) + \text{RG}(\mathbf{r},\mathbf{y}^*), \tag{11}$$

where "RG" stands for ROUGE for short.

ROUGE mainly evaluates informativeness. We also introduce a series of metrics to measure the summary quality from the following aspects:

LEN_DIF The absolute value of the length difference between the generated summaries and the actual summaries. We use mean value $\pm$ standard deviation to illustrate this item. The average value partially reflects the readability and informativeness, while the standard deviation links to stability.

[4]We use the ROUGE evaluation option: -m -n 2 -w 1.2

LESS_3 The number of the generated summaries, which contains less than three tokens. These extremely short summaries are usually unreadable.

COPY The proportion of the summary words (without stopwords) copied from the source sentence. A seriously large copy ratio indicates that the summarization system pays more attention to compression rather than required abstraction.

NEW_NE The number of the named entities that do not appear in the source sentence or actual summary. Intuitively, the appearance of new named entities in the summary is likely to bring unfaithfulness. We use Stanford CoreNLP (Manning et al., 2014) to recognize named entities.

3.3 Implementation Details

We use the popular seq2seq framework OpenNMT[5] as the starting point. To make our model more general, we retain the default settings of OpenNMT to build the network architecture. Specifically, the dimensions of word embeddings and RNN are both 500, and the encoder and decoder structures are two-layer bidirectional Long Short Term Memory Networks (LSTMs). The only difference is that we add the argument "-share_embeddings" to share the word embeddings between the encoder and decoder. This practice largely reduces model parameters for the monolingual task. On our computer (GPU: GTX 1080, Memory: 16G, CPU: i7-7700K), the training spends about 2 days.

During test, we use beam search of size 5 to generate summaries. We add the argument "-replace_unk" to replace the generated unknown words with the source word that holds the highest attention weight. Since the generated summaries are often shorter than the actual ones, we introduce an additional length penalty argument "-alpha 1" to encourage longer generation, like Wu et al. (2016).

3.4 Baselines

We compare our proposed model with the following state-of-the-art neural summarization systems:

ABS Rush et al. (2015a) used an attentive CNN encoder and a NNLM decoder to summarize the sentence.

ABS+ Rush et al. (2015a) further tuned the ABS model with additional hand-crafted features to balance between abstraction and extraction.

RAS-Elman As the extension of the ABS model, it used a convolutional attention-based encoder and a RNN decoder (Chopra et al., 2016).

Featseq2seq Nallapati et al. (2016) used a complete seq2seq RNN model and added the hand-crafted features such as POS tag and NER, to enhance the encoder representation.

Luong-NMT Chopra et al. (2016) implemented the neural machine translation model of Luong et al. (2015) for summarization. This model contained two-layer LSTMs with 500 hidden units in each layer.

OpenNMT We also implement the standard attentional seq2seq model with OpenNMT. All the settings are the same as our system. It is noted that OpenNMT officially examined the Gigaword dataset. We distinguish the official result[6] and our experimental result with suffixes "O" and "I" respectively.

FTSum Cao et al. (2017b) encoded the facts extracted from the source sentence to improve both the faithfulness and informativeness of generated summaries.

In addition, to evaluate the effectiveness of our joint learning framework, we develop a baseline named "PIPELINE". Its architecture is identical to Re^{3}Sum. However, it trains the Rerank module and Rewrite module in pipeline.

3.5 Informativeness Evaluation

Model	Perplexity
ABS†	27.1
RAS-Elman†	18.9
FTSum†	16.4
OpenNMT$_I$	13.2
PIPELINE	**12.5**
Re^{3}Sum	12.9

Table 2: Final perplexity on the development set. † indicates the value is cited from the corresponding paper. ABS+, Featseq2seq and Luong-NMT do not provide this value.

Let's first look at the final cost values (Eq. 9) on the development set. From Table 2, we can

[5] https://github.com/OpenNMT/OpenNMT-py

[6] http://opennmt.net/Models/

Model	RG-1	RG-2	RG-L
ABS†	29.55*	11.32*	26.42*
ABS+†	29.78*	11.89*	26.97*
Featseq2seq†	32.67*	15.59*	30.64*
RAS-Elman†	33.78*	15.97*	31.15*
Luong-NMT†	33.10*	14.45*	30.71*
FTSum†	**37.27**	17.65*	34.24
$\text{OpenNMT}_O^{\dagger}$	33.13*	16.09*	31.00*
OpenNMT_I	35.01*	16.55*	32.42*
PIPELINE	36.49	17.48*	33.90
Re^3Sum	37.04	**19.03**	**34.46**

Table 3: ROUGE F1 (%) performance. "RG" represents "ROUGE" for short. "*" indicates statistical significance of the corresponding model with respect to the baseline model on the 95% confidence interval in the official ROUGE script.

Type	RG-1	RG-2	RG-L
Random	2.81	0.00	2.72
First	24.44	9.63	22.05
Max	38.90	19.22	35.54
Optimal	52.91	31.92	48.63
Rerank	28.77	12.49	26.40

Table 4: ROUGE F1 (%) performance of different types of soft templates.

see that our model achieves much lower perplexity compared against the state-of-the-art systems. It is also noted that PIPELINE slightly outperforms Re^3Sum. One possible reason is that Re^3Sum additionally considers the cost derived from the Rerank module.

The ROUGE F1 scores of different methods are then reported in Table 3. As can be seen, our model significantly outperforms most other approaches. Note that, ABS+ and Featseq2seq have utilized a series of hand-crafted features, but our model is completely data-driven. Even though, our model surpasses Featseq2seq by 22% and ABS+ by 60% on ROUGE-2. When soft templates are ignored, our model is equivalent to the standard attentional seq2seq model OpenNMT_I. Therefore, it is safe to conclude that soft templates have great contribute to guide the generation of summaries.

Item	Template	OpenNMT	Re^3Sum
LEN_DIF	2.6±2.6	3.0±4.4	2.7±2.6
LESS_3	0	53	1
COPY(%)	31	80	74
NEW_NE	0.51	0.34	0.30

Table 5: Statistics of different types of summaries.

Type	RG-1	RG-2	RG-L
+Random	32.60	14.31	30.19
+First	36.01	17.06	33.21
+Max	41.50	21.97	38.80
+Optimal	46.21	26.71	43.19
+Rerank(Re^3Sum)	37.04	19.03	34.46

Table 6: ROUGE F1 (%) performance of Re^3Sum generated with different soft templates.

We also examine the performance of directly regarding soft templates as output summaries. We introduce five types of different soft templates:

Random An existing summary randomly selected from the training corpus.

First The top-ranked candidate template given by the Retrieve module.

Max The template with the maximal actual ROUGE scores among the 30 candidate templates.

Optimal An existing summary in the training corpus which holds the maximal ROUGE scores.

Rerank The template with the maximal predicted ROUGE scores among the 30 candidate templates. It is the actual soft template we adopt.

As shown in Table 4, the performance of Random is terrible, indicating it is impossible to use one summary template to fit various actual summaries. Rerank largely outperforms First, which verifies the effectiveness of the Rerank module. However, according to Max and Rerank, we find the Rerank performance of Re^3Sum is far from perfect. Likewise, comparing Max and First, we observe that the improving capacity of the Retrieve module is high. Notice that Optimal greatly exceeds all the state-of-the-art approaches. This finding strongly supports our practice of using existing summaries to guide the seq2seq models.

3.6 Linguistic Quality Evaluation

We also measure the linguistic quality of generated summaries from various aspects, and the results are present in Table 5. As can be seen from the rows "LEN_DIF" and "LESS_3", the performance of Re^3Sum is almost the same as that of soft templates. The soft templates indeed well guide the summary generation. Compared with

Source	grid positions after the final qualifying session in the indonesian motorcycle grand prix at the sentul circuit , west java , saturday : UNK
Target	indonesian motorcycle grand prix grid positions
Template	grid positions for **british** grand prix
OpenNMT	circuit
Re^{3}Sum	grid positions for indonesian grand prix
Source	india 's children are getting increasingly overweight and unhealthy and the government is asking schools to ban junk food , officials said thursday .
Target	indian government asks schools to ban junk food
Template	**skorean** schools to ban **soda** junk food
OpenNMT	india 's children getting fatter
Re^{3}Sum	indian schools to ban junk food

Table 7: Examples of generated summaries. We use Bold font to indicate the crucial rewriting behavior from the templates to generated summaries.

Re^{3}Sum, the standard deviation of LEN_DF is 0.7 times larger in OpenNMT, indicating that OpenNMT works quite unstably. Moreover, OpenNMT generates 53 extreme short summaries, which seriously reduces readability. Meanwhile, the copy ratio of actual summaries is 36%. Therefore, the copy mechanism is severely overweighted in OpenNMT. Our model is encouraged to generate according to human-written soft templates, which relatively diminishes copying from the source sentences. Look at the last row "NEW_NE". A number of new named entities appear in the soft templates, which makes them quite unfaithful to source sentences. By contrast, this index in Re^{3}Sum is close to the OpenNMT's. It highlights the rewriting ability of our seq2seq framework.

3.7 Effect of Templates

In this section, we investigate how soft templates affect our model. At the beginning, we feed different types of soft templates (refer to Table 4) into the Rewriting module of Re^{3}Sum. As illustrated in Table 6, the more high-quality templates are provided, the higher ROUGE scores are achieved. It is interesting to see that,while the ROUGE-2 score of Random templates is zero, our model can still generate acceptable summaries with Random templates. It seems that Re^{3}Sum can automatically judge whether the soft templates are trustworthy and ignore the seriously irrelevant ones. We believe that the joint learning with the Rerank model plays a vital role here.

Next, we manually inspect the summaries generated by different methods. We find the outputs of Re^{3}Sum are usually longer and more fluent than the outputs of OpenNMT. Some illustrative examples are shown in Table 7. In Example 1, there is no predicate in the source sentence. Since OpenNMT prefers selecting source words around the predicate to form the summary, it fails on this sentence. By contract, Re^{3}Sum rewrites the template and produces an informative summary. In Example 2, OpenNMT deems the starting part of the sentences are more important, while our model, guided by the template, focuses on the second part to generate the summary.

In the end, we test the ability of our model to generate diverse summaries. In practice, a system that can provide various candidate summaries is probably more welcome. Specifically, two candidate templates with large text dissimilarity are manually fed into the Rewriting module. The corresponding generated summaries are shown in Table 8. For the sake of comparison, we also present the 2-best results of OpenNMT with beam search. As can be seen, with different templates given, our model is likely to generate dissimilar summaries. In contrast, the 2-best results of OpenNMT is almost the same, and often a shorter summary is only a piece of the other one. To sum up, our model demonstrates promising prospect in generation diversity.

4 Related Work

Abstractive sentence summarization aims to produce a shorter version of a given sentence while preserving its meaning (Chopra et al., 2016). This task is similar to text simplification (Saggion, 2017) and facilitates headline design and refine. Early studies on sentence summariza-

Source	anny ainge said thursday he had two one-hour meetings with the new owners of the boston celtics but no deal has been completed for him to return to the franchise .

	european stocks rise ahead of us rate hike

Table 8: Examples of generation with diversity. We use Bold font to indicate the difference between two summaries

tion include template-based methods (Zhou and Hovy, 2004), syntactic tree pruning (Knight and Marcu, 2002; Clarke and Lapata, 2008) and statistical machine translation techniques (Banko et al., 2000). Recently, the application of the attentional seq2seq framework has attracted growing attention and achieved state-of-the-art performance on this task (Rush et al., 2015a; Chopra et al., 2016; Nallapati et al., 2016).

In addition to the direct application of the general seq2seq framework, researchers attempted to integrate various properties of summarization. For example, Nallapati et al. (2016) enriched the encoder with hand-crafted features such as named entities and POS tags. These features have played important roles in traditional feature based summarization systems. Gu et al. (2016) found that a large proportion of the words in the summary were copied from the source text. Therefore, they proposed CopyNet which considered the copying mechanism during generation. Recently, See et al. (2017) used the coverage mechanism to discourage repetition. Cao et al. (2017b) encoded facts extracted from the source sentence to enhance the summary faithfulness. There were also studies to modify the loss function to fit the evaluation metrics. For instance, Ayana et al. (2016) applied the Minimum Risk Training strategy to maximize the ROUGE scores of generated summaries. Paulus et al. (2017) used the reinforcement learning algorithm to optimize a mixed objective function of likelihood and ROUGE scores.

Guu et al. (2017) also proposed to encode human-written sentences to improvement the performance of neural text generation. However, they handled the task of Language Modeling and randomly picked an existing sentence in the training corpus. In comparison, we develop an IR system to find proper existing summaries as soft templates. Moreover, Guu et al. (2017) used a general seq2seq framework while we extend the seq2seq framework to conduct template reranking and template-aware summary generation simultaneously.

5 Conclusion and Future Work

This paper proposes to introduce soft templates as additional input to guide the seq2seq summarization. We use the popular IR platform Lucene to retrieve proper existing summaries as candidate soft templates. Then we extend the seq2seq framework to jointly conduct template reranking and template-aware summary generation. Experiments show that our model can generate informative, readable and stable summaries. In addition, our model demonstrates promising prospect in generation diversity.

We believe our work can be extended in various aspects. On the one hand, since the candidate templates are far inferior to the optimal ones, we intend to improve the Retrieve module, e.g., by indexing both the sentence and summary fields. On the other hand, we plan to test our system on the other tasks such as document-level summarization and short text conversation.

Simple and Effective Text Simplification Using Semantic and Neural Methods

Elior Sulem, Omri Abend, Ari Rappoport
Department of Computer Science, The Hebrew University of Jerusalem
{eliors|oabend|arir}@cs.huji.ac.il

Abstract

Sentence splitting is a major simplification operator. Here we present a simple and efficient splitting algorithm based on an automatic semantic parser. After splitting, the text is amenable for further fine-tuned simplification operations. In particular, we show that neural Machine Translation can be effectively used in this situation. Previous application of Machine Translation for simplification suffers from a considerable disadvantage in that they are over-conservative, often failing to modify the source in any way. Splitting based on semantic parsing, as proposed here, alleviates this issue. Extensive automatic and human evaluation shows that the proposed method compares favorably to the state-of-the-art in combined lexical and structural simplification.

1 Introduction

Text Simplification (TS) is generally defined as the conversion of a sentence into one or more simpler sentences. It has been shown useful both as a preprocessing step for tasks such as Machine Translation (MT; Mishra et al., 2014; Štajner and Popović, 2016) and relation extraction (Niklaus et al., 2016), as well as for developing reading aids, e.g. for people with dyslexia (Rello et al., 2013) or non-native speakers (Siddharthan, 2002).

TS includes both structural and lexical operations. The main structural simplification operation is sentence splitting, namely rewriting a single sentence into multiple sentences while preserving its meaning. While recent improvement in TS has been achieved by the use of neural MT (NMT) approaches (Nisioi et al., 2017; Zhang et al., 2017; Zhang and Lapata, 2017), where TS is considered a case of monolingual translation, the sentence splitting operation has not been addressed by these systems, potentially due to the rareness of this operation in the training corpora (Narayan and Gardent, 2014; Xu et al., 2015).

We show that the explicit integration of sentence splitting in the simplification system could also reduce conservatism, which is a grave limitation of NMT-based TS systems (Alva-Manchego et al., 2017). Indeed, experimenting with a state-of-the-art neural system (Nisioi et al., 2017), we find that 66% of the input sentences remain unchanged, while none of the corresponding references is identical to the source. Human and automatic evaluation of the references (against other references), confirm that the references are indeed simpler than the source, indicating that the observed conservatism is excessive. Our methods for performing sentence splitting as pre-processing allows the TS system to perform other structural (e.g. deletions) and lexical (e.g. word substitutions) operations, thus increasing both structural and lexical simplicity.

For combining linguistically informed sentence splitting with data-driven TS, two main methods have been proposed. The first involves hand-crafted syntactic rules, whose compilation and validation are laborious (Shardlow, 2014). For example, Siddharthan and Angrosh (2014) used 111 rules for relative clauses, appositions, subordination and coordination. Moreover, syntactic splitting rules, which form a substantial part of the rules, are usually language specific, requiring the development of new rules when ported to other languages (Aluísio and Gasperin, 2010; Seretan, 2012; Hung et al., 2012; Barlacchi and Tonelli, 2013, for Portuguese, French, Vietnamese, and Italian respectively). The second method uses linguistic information for detecting potential splitting points, while splitting probabilities are learned using a parallel corpus. For example, in the system of Narayan and Gardent (2014) (henceforth, HYBRID), the state-of-the-art for joint structural and lexical TS, potential splitting points are determined by event boundaries.

In this work, which is the first to combine structural semantics and neural methods for TS, we propose an intermediate way for performing sentence splitting, presenting Direct Semantic Splitting (DSS), a simple and efficient algorithm based on a semantic parser which supports the direct decomposition of the sentence into its main semantic constituents. After splitting, NMT-based simplification is performed, using the NTS system. We show that the resulting system outperforms HYBRID in both automatic and human evaluation.

We use the UCCA scheme for semantic representation (Abend and Rappoport, 2013), where the semantic units are anchored in the text, which simplifies the splitting operation. We further leverage the explicit distinction in UCCA between types of Scenes (events), applying a specific rule for each of the cases. Nevertheless, the DSS approach can be adapted to other semantic schemes, like AMR (Banarescu et al., 2013).

We collect human judgments for multiple variants of our system, its sub-components, HYBRID and similar systems that use phrase-based MT. This results in a sizable human evaluation benchmark, which includes 28 systems, totaling at 1960 complex-simple sentence pairs, each annotated by three annotators using four criteria.[1] This benchmark will support the future analysis of TS systems, and evaluation practices.

Previous work is discussed in §2, the semantic and NMT components we use in §3 and §4 respectively. The experimental setup is detailed in §5. Our main results are presented in §6, while §7 presents a more detailed analysis of the system's sub-components and related settings.

2 Related Work

MT-based sentence simplification. Phrase-based Machine Translation (PBMT; Koehn et al., 2003) was first used for TS by Specia (2010), who showed good performance on lexical simplification and simple rewriting, but under-prediction of other operations. Štajner et al. (2015) took a similar approach, finding that it is beneficial to use training data where the source side is highly similar to the target. Other PBMT for TS systems include the work of Coster and Kauchak (2011b), which uses Moses (Koehn et al., 2007), the work of Coster and Kauchak (2011a), where the model is extended to include deletion, and PBMT-R (Wubben et al., 2012), where Levenshtein distance to the source is used for re-ranking to overcome conservatism.

The NTS NMT-based system (Nisioi et al., 2017) (henceforth, N17) reported superior performance over PBMT in terms of BLEU and human evaluation scores, and serves as a component in our system (see Section 4). Zhang et al. (2017) took a similar approach, adding lexical constraints to an NMT model. Zhang and Lapata (2017) combined NMT with reinforcement learning, using SARI (Xu et al., 2016), BLEU, and cosine similarity to the source as the reward. None of these models explicitly addresses sentence splitting.

Alva-Manchego et al. (2017) proposed to reduce conservatism, observed in PBMT and NMT systems, by first identifying simplification operations in a parallel corpus and then using sequence-labeling to perform the simplification. However, they did not address common structural operations, such as sentence splitting, and claimed that their method is not applicable to them.

Xu et al. (2016) used Syntax-based Machine Translation (SBMT) for sentence simplification, using a large scale paraphrase dataset (Ganitketitch et al., 2013) for training. While it does not target structural simplification, we include it in our evaluation for completeness.

Structural sentence simplification. Syntactic hand-crafted sentence splitting rules were proposed by Chandrasekar et al. (1996), Siddharthan (2002), Siddhathan (2011) in the context of rule-based TS. The rules separate relative clauses and coordinated clauses and un-embed appositives. In our method, the use of semantic distinctions instead of syntactic ones reduces the number of rules. For example, relative clauses and appositives can correspond to the same semantic category. In syntax-based splitting, a generation module is sometimes added after the split (Siddharthan, 2004), addressing issues such as reordering and determiner selection. In our model, no explicit regeneration is applied to the split sentences, which are fed directly to an NMT system.

Glavaš and Štajner (2013) used a rule-based system conditioned on event extraction and syntax

[1]The benchmark can be found in `https://github.com/eliorsulem/simplification-acl2018`.

for defining two simplification models. The event-wise simplification one, which separates events to separate output sentences, is similar to our semantic component. Differences are in that we use a single semantic representation for defining the rules (rather than a combination of semantic and syntactic criteria), and avoid the need for complex rules for retaining grammaticality by using a subsequent neural component.

Combined structural and lexical TS. Earlier TS models used syntactic information for splitting. Zhu et al. (2010) used syntactic information on the source side, based on the SBMT model of Yamada and Knight (2001). Syntactic structures were used on both sides in the model of Woodsend and Lapata (2011), based on a quasi-synchronous grammar (Smith and Eisner, 2006), which resulted in 438 learned splitting rules.

The model of Siddharthan and Angrosh (2014) is similar to ours in that it combines linguistic rules for structural simplification and statistical methods for lexical simplification. However, we use 2 semantic splitting rules instead of their 26 syntactic rules for relative clauses and appositions, and 85 syntactic rules for subordination and coordination.

Narayan and Gardent (2014) argued that syntactic structures do not always capture the semantic arguments of a frame, which may result in wrong splitting boundaries. Consequently, they proposed a supervised system (HYBRID) that uses semantic structures (Discourse Semantic Representations, (Kamp, 1981)) for sentence splitting and deletion. Splitting candidates are pairs of event variables associated with at least one core thematic role (e.g., agent or patient). Semantic annotation is used on the source side in both training and test. Lexical simplification is performed using the Moses system. HYBRID is the most similar system to ours architecturally, in that it uses a combination of a semantic structural component and an MT component. Narayan and Gardent (2016) proposed instead an unsupervised pipeline, where sentences are split based on a probabilistic model trained on the semantic structures of Simple Wikipedia as well as a language model trained on the same corpus. Lexical simplification is there performed using the unsupervised model of Biran et al. (2011). As their BLEU and adequacy scores are lower than HYBRID's, we use the latter for comparison.

Štajner and Glavaš (2017) combined rule-based simplification conditioned on event extraction, together with an unsupervised lexical simplifier. They tackle a different setting, and aim to simplify texts (rather than sentences), by allowing the deletion of entire input sentences.

Split and Rephrase. Narayan et al. (2017) recently proposed the Split and Rephrase task, focusing on sentence splitting. For this purpose they presented a specialized parallel corpus, derived from the WebNLG dataset (Gardent et al., 2017). The latter is obtained from the DBPedia knowledge base (Mendes et al., 2012) using content selection and crowdsourcing, and is annotated with semantic triplets of subject-relation-object, obtained semi-automatically. They experimented with five systems, including one similar to HYBRID, as well as sequence-to-sequence methods for generating sentences from the source text and its semantic forms.

The present paper tackles both structural and lexical simplification, and examines the effect of sentence splitting on the subsequent application of a neural system, in terms of its tendency to perform other simplification operations. For this purpose, we adopt a semantic corpus-independent approach for sentence splitting that can be easily integrated in any simplification system. Another difference is that the semantic forms in Split and Rephrase are derived semi-automatically (during corpus compilation), while we automatically extract the semantic form, using a UCCA parser.

3 Direct Semantic Splitting

3.1 Semantic Representation

UCCA (Universal Cognitive Conceptual Annotation; Abend and Rappoport, 2013) is a semantic annotation scheme rooted in typological and cognitive linguistic theory (Dixon, 2010b,a, 2012; Langacker, 2008). It aims to represent the main semantic phenomena in the text, abstracting away from syntactic forms. UCCA has been shown to be preserved remarkably well across translations (Sulem et al., 2015) and has also been successfully used for the evaluation of machine translation (Birch et al., 2016) and, recently, for the evaluation of TS (Sulem et al., 2018) and grammatical error correction (Choshen and Abend, 2018).

Formally, UCCA structures are directed acyclic graphs whose nodes (or *units*) correspond either to the leaves of the graph or to several elements viewed as a single entity according to some semantic or cognitive consideration.

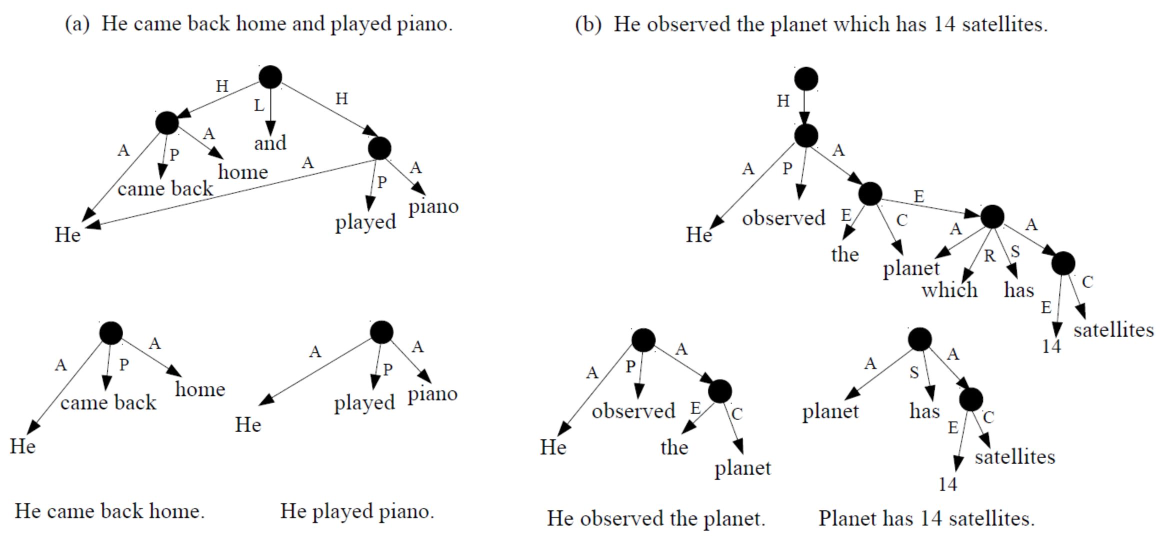

Figure 1: Example applications of rules 1 (Figure 1a) and 2 (Figure 1b). In both cases, the original sentence, the semantic parse, the extracted Scenes with the required modifications, and the output of the rules are presented top to bottom. The UCCA categories used are: Parallel Scene (H), Linker (L), Participant (A), Process/State (P/S), Center (C), Elaborator (E), Relator (R).

A *Scene* is UCCA's notion of an event or a frame, and is a unit that corresponds to a movement, an action or a state which persists in time. Every Scene contains one main relation, which can be either a Process or a State. Scenes contain one or more Participants, interpreted in a broad sense to include locations and destinations. For example, the sentence "He went to school" has a single Scene whose Process is "went". The two Participants are "He" and "to school".

Scenes can have several roles in the text. First, they can provide additional information about an established entity (Elaborator Scenes), commonly participles or relative clauses. For example, "(child) who went to school" is an Elaborator Scene in "The child who went to school is John" ("child" serves both as an argument in the Elaborator Scene and as the Center). A Scene may also be a Participant in another Scene. For example, "John went to school" in the sentence: "He said John went to school". In other cases, Scenes are annotated as Parallel Scenes (H), which are flat structures and may include a Linker (L), as in: "When$_L$ [he arrives]$_H$, [he will call them]$_H$".

With respect to units which are not Scenes, the category Center denotes the semantic head. For example, "dogs" is the Center of the expression "big brown dogs", and "box" is the center of "in the box". There could be more than one Center in a unit, for example in the case of coordination, where all conjuncts are Centers. We define the minimal center of a UCCA unit u to be the UCCA graph's leaf reached by starting from u and iteratively selecting the child tagged as Center.

For generating UCCA's structures we use TUPA, a transition-based parser (Hershcovich et al., 2017) (specifically, the TUPA$_{BiLSTM}$ model). TUPA uses an expressive set of transitions, able to support all structural properties required by the UCCA scheme. Its transition classifier is based on an MLP that receives a BiLSTM encoding of elements in the parser state (buffer, stack and intermediate graph), given word embeddings and other features.

3.2 The Semantic Rules

For performing DSS, we define two simple splitting rules, conditioned on UCCA's categories. We currently only consider Parallel Scenes and Elaborator Scenes, not separating Participant Scenes, in order to avoid splitting in cases of nominalizations or indirect speech. For example, the sentence "His arrival surprised everyone", which has, in addition to the Scene evoked by "surprised", a Participant Scene evoked by "arrival", is not split here.

Rule #1. Parallel Scenes of a given sentence are extracted, separated in different sentences, and concatenated according to the order of appearance. More formally, given a decomposition of a sentence S into parallel Scenes $Sc_1, Sc_2, \cdots Sc_n$ (indexed by the order of the first token), we obtain the following rule, where "|" is the sentence delimiter:

$$S \longrightarrow Sc_1|Sc_2|\cdots|Sc_n$$

As UCCA allows argument sharing between Scenes, the rule may duplicate the same sub-span of S across sentences. For example, the rule will convert "He came back home and played piano" into "He came back home"|"He played piano."

Rule #2. Given a sentence S, the second rule extracts Elaborator Scenes and corresponding minimal centers. Elaborator Scenes are then concatenated to the original sentence, where the Elaborator Scenes, except for the minimal center they elaborate, are removed. Pronouns such as "who", "which" and "that" are also removed.

Formally, if $\{(Sc_1, C_1)\cdots(Sc_n, C_n)\}$ are the Elaborator Scenes of S and their corresponding minimal centers, the rewrite is:

$$S \longrightarrow S - \bigcup_{i=1}^{n}(Sc_i - C_i)|Sc_1|\cdots|Sc_n$$

where $S - A$ is S without the unit A. For example, this rule converts the sentence "He observed the planet which has 14 known satellites" to "He observed the planet| Planet has 14 known satellites.". Article regeneration is not covered by the rule, as its output is directly fed into the NMT component.

After the extraction of Parallel Scenes and Elaborator Scenes, the resulting simplified Parallel Scenes are placed before the Elaborator Scenes. See Figure 1.

4 Neural Component

The split sentences are run through the NTS state-of-the-art neural TS system (Nisioi et al., 2017), built using the OpenNMT neural machine translation framework (Klein et al., 2017). The architecture includes two LSTM layers, with hidden states of 500 units in each, as well as global attention combined with input feeding (Luong et al., 2015). Training is done with a 0.3 dropout probability (Srivastava et al., 2014). This model uses alignment probabilities between the predictions and the original sentences, rather than character-based models, to retrieve the original words.

We here consider the w2v initialization for NTS (N17), where word2vec embeddings of size 300 are trained on Google News (Mikolov et al., 2013a) and local embeddings of size 200 are trained on the training simplification corpus (Řehůřek and Sojka, 2010; Mikolov et al., 2013b). Local embeddings for the encoder are trained on the source side of the training corpus, while those for the decoder are trained on the simplified side.

For sampling multiple outputs from the system, beam search is performed during decoding by generating the first 5 hypotheses at each step ordered by the log-likelihood of the target sentence given the input sentence. We here explore both the highest (h1) and fourth-ranked (h4) hypotheses, which we show to increase the SARI score and to be much less conservative.[2] We thus experiment with two variants of the neural component, denoted by NTS-h1 and NTS-h4. The pipeline application of the rules and the neural system results in two corresponding models: SENTS-h1 and SENTS-h4.

5 Experimental Setup

Corpus All systems are tested on the test corpus of Xu et al. (2016),[3] comprising 359 sentences from the PWKP corpus (Zhu et al., 2010) with 8 references collected by crowdsourcing for each of the sentences.

Semantic component. The TUPA parser[4] is trained on the UCCA-annotated *Wiki* corpus.[5]

Neural component. We use the NTS-w2v model[6] provided by N17, obtained by training on the corpus of Hwang et al. (2015) and tuning on the corpus of Xu et al. (2016). The training set is based on manual and automatic alignments between standard English Wikipedia and Simple English Wikipedia, including both good matches and partial matches whose similarity score is above the 0.45 scale threshold (Hwang et al., 2015). The total size of the training set is about 280K aligned sentences, of which 150K sentences are full matches and 130K are partial matches.[7]

Comparison systems. We compare our findings to HYBRID, which is the state of the art for joint structural and lexical simplification, imple-

[2]Similarly, N17 considered the first two hypotheses and showed that h2 has an higher SARI score and is less conservative than h1.

[3]https://github.com/cocoxu/simplification (This also includes SARI tools and the SBMT-SARI system.)

[4]https://github.com/danielhers/tupa

[5]http://www.cs.huji.ac.il/~oabend/ucca.html

[6]https://github.com/senisioi/NeuralTextSimplification

[7]We also considered the default initialization for the neural component, using the NTS model without word embeddings. Experimenting on the tuning set, the w2v approach got higher BLEU and SARI scores (for h1 and h4 respectively) than the default approach.

mented by Zhang and Lapata (2017).[8] We use the released output of HYBRID, trained on a corpus extracted from Wikipedia, which includes the aligned sentence pairs from Kauchak (2013), the aligned revision sentence pairs in Woodsend and Lapata (2011), and the PWKP corpus, totaling about 296K sentence pairs. The tuning set is the same as for the above systems.

In order to isolate the effect of NMT, we also implement SEMoses, where the neural-based component is replaced by the phrase-based MT system Moses,[9] which is also used in HYBRID. The training, tuning and test sets are the same as in the case of SENTS. MGIZA[10] is used for word alignment. The KenLM language model is trained using the target side of the training corpus.

Additional baselines. We report human and automatic evaluation scores for Identity (where the output is identical to the input), for Simple Wikipedia where the output is the corresponding aligned sentence in the PWKP corpus, and for the SBMT-SARI system, tuned against SARI (Xu et al., 2016), which maximized the SARI score on this test set in previous works (Nisioi et al., 2017; Zhang and Lapata, 2017).

Automatic evaluation. The automatic metrics used for the evaluation are: (1) BLEU (Papineni et al., 2002) (2) SARI (System output Against References and against the Input sentence; Xu et al., 2016), which compares the n-grams of the system output with those of the input and the human references, separately evaluating the quality of words that are added, deleted and kept by the systems. (3) F_{add}: the addition component of the SARI score (F-score); (4) F_{keep}: the keeping component of the SARI score (F-score); (5) P_{del}: the deletion component of the SARI score (precision).[11] Each metric is computed against the 8 available references. We also assess system conservatism, reporting the percentage of sentences copied from the input (%Same), the averaged Levenshtein distance from the source (LD_{SC}, which considers additions, deletions, and substitutions), and the number of source sentences that are split (#Split).[12]

Human evaluation. Human evaluation is carried out by 3 in-house native English annotators, who rated the different input-output pairs for the different systems according to 4 parameters: Grammaticality (G), Meaning preservation (M), Simplicity (S) and Structural Simplicity (StS). Each input-output pair is rated by all 3 annotators. Elicitation questions are given in Table 1.

As the selection process of the input-output pairs in the test corpus of Xu et al. (2016), as well as their crowdsourced references, are explicitly biased towards lexical simplification, the use of human evaluation permits us to evaluate the structural aspects of the system outputs, even where structural operations are not attested in the references. Indeed, we show that system outputs may receive considerably higher structural simplicity scores than the source, in spite of the sample selection bias.

Following previous work (e.g., Narayan and Gardent, 2014; Xu et al., 2016; Nisioi et al., 2017), Grammaticality (G) and Meaning preservation (M) are measured using a 1 to 5 scale. Note that in the first question, the input sentence is not taken into account. The grammaticality of the input is assessed by evaluating the Identity transformation (see Table 2), providing a baseline for the grammaticality scores of the other systems.

Following N17, a -2 to +2 scale is used for measuring simplicity, where a 0 score indicates that the input and the output are equally complex. This scale, compared to the standard 1 to 5 scale, permits a better differentiation between cases where simplicity is hurt (the output is more complex than the original) and between cases where the output is as simple as the original, for example in the case of the identity transformation. Structural simplicity is also evaluated with a -2 to +2 scale. The question for eliciting StS is accompanied with a negative example, showing a case of lexical simplification, where a complex word is replaced by a simple one (the other questions appear without examples). A positive example is not included so as not to bias the annotators by revealing the nature of the operations we focus on (splitting and deletion). We follow N17 in applying human evaluation on the first 70 sentences of the test corpus.[13]

The resulting corpus, totaling 1960 sentence pairs, each annotated by 3 annotators, also include

[9] http://www.statmt.org/moses/

[10] https://github.com/moses-smt/mgiza

[11] Uniform tokenization and truecasing styles for all systems are obtained using the Moses toolkit.

[12] We used the NLTK package (Loper and Bird, 2002) for these computations.

[13] We do not exclude system outputs identical to the source, as done by N17.

the additional experiments described in Section 7 as well as the outputs of the NTS and SENTS systems used with the default initialization.

The inter-annotator agreement, using Cohen's quadratic weighted κ (Cohen, 1968), is computed as the average agreement of the 3 annotator pairs. The obtained rates are 0.56, 0.75, 0.47 and 0.48 for G, M, S and StS respectively.

System scores are computed by averaging over the 3 annotators and the 70 sentences.

G	Is the output fluent and grammatical?
M	Does the output preserve the meaning of the input?
S	Is the output simpler than the input?
StS	Is the output simpler than the input, ignoring the complexity of the words?

Table 1: Questions for the human evaluation.

	G	M	S	StS
Identity	4.80	5.00	0.00	0.00
Simple Wikipedia	4.60	4.21	0.83	0.38
Only MT-Based Simplification				
SBMT-SARI	3.71	3.96	0.14	-0.15
NTS-h1	4.56	**4.48**	0.22	0.15
NTS-h4	4.29	3.90	0.31	0.19
Only Structural Simplification				
DSS	3.42	4.15	0.16	0.16
Structural+MT-based Simplification				
Hybrid	2.96	2.46	0.43	0.43
SEMoses	3.27	3.98	0.16	0.13
SENTS-h1	3.98	3.33	**0.68**	**0.63**
SENTS-h4	3.54	2.98	0.50	0.36

Table 2: Human evaluation of the different NMT-based systems. Grammaticality (G) and Meaning preservation (M) are measured using a 1 to 5 scale. A -2 to +2 scale is used for measuring simplicity (S) and structural simplicity (StS) of the output relative to the input sentence. The highest score in each column appears in bold. Structural simplification systems are those that explicitly model structural operations.

6 Results

Human evaluation. Results are presented in Table 2. First, we can see that the two SENTS systems outperform HYBRID in terms of G, M, and S. SENTS-h1 is the best scoring system, under all human measures.

In comparison to NTS, SENTS scores markedly higher on the simplicity judgments. Meaning preservation and grammaticality are lower for SENTS, which is likely due to the more conservative nature of NTS. Interestingly, the application of the splitting rules by themselves does not yield a considerably simpler sentence. This likely stems from the rules not necessarily yielding grammatical sentences (NTS often serves as a grammatical error corrector over it), and from the incorporation of deletions, which are also structural operations, and are performed by the neural system.

An example of high structural simplicity scores for SENTS resulting from deletions is presented in Table 5, together with the outputs of the other systems and the corresponding human evaluation scores. NTS here performs lexical simplification, replacing the word "incursions" by "raids" or "attacks"'. On the other hand, the high StS scores obtained by DSS and SEMoses are due to sentence splittings.

Automatic evaluation. Results are presented in Table 3. Identity obtains much higher BLEU scores than any other system, suggesting that BLEU may not be informative in this setting. SARI seems more informative, and assigns the lowest score to Identity and the second highest to the reference.

Both SENTS systems outperform HYBRID in terms of SARI and all its 3 sub-components. The h4 setting (hypothesis #4 in the beam) is generally best, both with and without the splitting rules.

Comparing SENTS to using NTS alone (without splitting), we see that SENTS obtains higher SARI scores when hypothesis #1 is used and that NTS obtains higher scores when hypothesis #4 is used. This may result from NTS being more conservative than SENTS (and HYBRID), which is rewarded by SARI (conservatism is indicated by the %Same column). Indeed for h1, %Same is reduced from around 66% for NTS, to around 7% for SENTS. Conservatism further decreases when h4 is used (for both NTS and SENTS). Examining SARI's components, we find that SENTS outperforms NTS on F_{add}, and is comparable (or even superior for $h1$ setting) to NTS on P_{del}. The superior SARI score of NTS over SENTS is thus entirely a result of a superior F_{keep}, which is easier for a conservative system to maximize.

Comparing HYBRID with SEMoses, both of which use Moses, we find that SEMoses obtains higher BLEU and SARI scores, as well as G and M human scores, and splits many more sentences. HYBRID scores higher on the human simplicity measures. We note, however, that applying NTS alone is inferior to HYBRID in terms of simplicity, and that both components are required to obtain high simplicity scores (with SENTS).

We also compare the sentence splitting component used in our systems (namely DSS) to that used in HYBRID, abstracting away from deletion-based and lexical simplification. We therefore apply DSS to the test set (554 sentences) of the

Table 4: Automatic and human evaluation for the different combinations of Moses and DSS. The automatic metrics as well as the lexical and structural properties reported (%Same: proportion of sentences copied from the input; $\mathrm{LD}_{\mathrm{SC}}$: Averaged Levenshtein distance from the source; #Split: number of split sentences) concern the 359 sentences of the test corpus. Human evaluation, with the G, M, S, and StS parameters, is applied to the first 70 sentences of the corpus. The highest score in each column appears in bold.

WEB-SPLIT corpus (Narayan et al., 2017) (See Section 2), which focuses on sentence splitting. We compare our results to those reported for a variant of HYBRID used without the deletion module, and trained on WEB-SPLIT (Narayan et al., 2017). DSS gets a higher BLEU score (46.45 vs. 39.97) and performs more splittings (number of output sentences per input sentence of 1.73 vs. 1.26).

7 Additional Experiments

Replacing the parser by manual annotation. In order to isolate the influence of the parser on the results, we implement a semi-automatic version of the semantic component, which uses manual UCCA annotation instead of the parser, focusing of the first 70 sentences of the test corpus. We employ a single expert UCCA annotator and use the UCCAApp annotation tool (Abend et al., 2017).

Results are presented in Table 6, for both SENTS and SEMoses. In the case of SEMoses, meaning preservation is improved when manual UCCA annotation is used. On the other hand, simplicity degrades, possibly due to the larger number of Scenes marked by the human annotator (TUPA tends to under-predict Scenes). This effect doesn't show with SENTS, where trends are similar to the automatic parses case, and high simplicity scores are obtained. This demonstrates that UCCA parsing technology is sufficiently mature to be used to carry out structural simplification.

We also directly evaluate the performance of the parser by computing F1, Recall and Precision DAG scores (Hershcovich et al., 2017), against the manual UCCA annotation.[14] We obtain for primary edges (i.e. edges that form a tree structure) scores of 68.9 %, 70.5%, and 67.4% for F1, Recall and Precision respectively. For remotes edges (i.e. additional edges, forming a DAG), the scores are 45.3%, 40.5%, and 51.5%. These results are comparable with the out-of-domain results reported by Hershcovich et al. (2017).

Experiments on Moses. We test other variants of SEMoses, where phrase-based MT is used instead of NMT. Specifically, we incorporate semantic information in a different manner by implementing two additional models: (1) SETrain1-Moses, where a new training corpus is obtained by applying the splitting rules to the target side of the

[14]We use the evaluation tools provided in `https://github.com/danielhers/ucca`, ignoring 9 sentences for which different tokenizations of proper nouns are used in the automatic and manual parsing.

Table 5: System outputs for one of the test sentences with the corresponding human evaluation scores (averaged over the 3 annotators). Grammaticality (G) and Meaning preservation (M) are measured using a 1 to 5 scale. A -2 to +2 scale is used for measuring simplicity (S) and structural simplicity (StS) of the output relative to the input sentence.

	G	M	S	StS
DSS^m	3.38	3.91	-0.16	-0.16
SENTS^m-h1	4.12	3.34	0.61	0.58
SENTS^m-h4	3.60	3.24	0.26	0.12
SEMoses^m	3.32	4.27	-0.25	-0.25
SEMoses$^m_{LM}$	3.43	4.28	-0.18	-0.19

Table 6: Human evaluation using manual UCCA annotation. Grammaticality (G) and Meaning preservation (M) are measured using a 1 to 5 scale. A -2 to +2 scale is used for measuring simplicity (S) and structural simplicity (StS) of the output relative to the input sentence. X^m refers to the semi-automatic version of the system X.

training corpus; (2) SETrain2-Moses, where the rules are applied to the source side. The resulting parallel corpus is concatenated to the original training corpus. We also examine whether training a language model (LM) on split sentences has a positive effect, and train the LM on the split target side. For each system X, the version with the LM trained on split sentences is denoted by X_{LM}.

We repeat the same human and automatic evaluation protocol as in §6, presenting results in Table 4. Simplicity scores are much higher in the case of SENTS (that uses NMT), than with Moses. The two best systems according to SARI are SEMoses and SEMoses$_{LM}$ which use DSS. In fact, they resemble the performance of DSS applied alone (Tables 2 and 3), which confirms the high degree of conservatism observed by Moses in simplification (Alva-Manchego et al., 2017). Indeed, all Moses-based systems that don't apply DSS as preprocessing are conservative, obtaining high scores for BLEU, grammaticality and meaning preservation, but low scores for simplicity. Training the LM on split sentences shows little improvement.

8 Conclusion

We presented the first simplification system combining semantic structures and neural machine translation, showing that it outperforms existing lexical and structural systems. The proposed approach addresses the over-conservatism of MT-based systems for TS, which often fail to modify the source in any way. The semantic component performs sentence splitting without relying on a specialized corpus, but only an off-the-shelf semantic parser. The consideration of sentence splitting as a decomposition of a sentence into its Scenes is further supported by recent work on structural TS evaluation (Sulem et al., 2018), which proposes the SAMSA metric. The two works, which apply this assumption to different ends (TS system construction, and TS evaluation), confirm its validity. Future work will leverage UCCA's cross-linguistic applicability to support multi-lingual TS and TS pre-processing for MT.

Acknowledgments

We would like to thank Shashi Narayan for sharing his data and the annotators for participating in our evaluation and UCCA annotation experiments. We also thank Daniel Hershcovich and the anonymous reviewers for their helpful advices. Obtaining Reliable Human Ratings of Valence, Arousal, and Dominance for 20,000 English Words

Saif M. Mohammad
National Research Council Canada
saif.mohammad@nrc-cnrc.gc.ca

Abstract

Words play a central role in language and thought. Factor analysis studies have shown that the primary dimensions of meaning are valence, arousal, and dominance (VAD). We present the NRC VAD Lexicon, which has human ratings of valence, arousal, and dominance for more than 20,000 English words. We use Best–Worst Scaling to obtain fine-grained scores and address issues of annotation consistency that plague traditional rating scale methods of annotation. We show that the ratings obtained are vastly more reliable than those in existing lexicons. We also show that there exist statistically significant differences in the shared understanding of valence, arousal, and dominance across demographic variables such as age, gender, and personality.

1 Introduction

Words are the smallest meaningful utterances in language. They play a central role in our understanding and descriptions of the world around us. Some believe that the structure of a language even affects how we think (principle of linguistic relativity aka the SapirWhorf hypothesis). Several influential factor analysis studies have shown that the three most important, largely independent, dimensions of word meaning are valence (positiveness–negativeness/pleasure–displeasure), arousal (active–passive), and dominance (dominant–submissive) (Osgood et al., 1957; Russell, 1980, 2003).[1] Thus, when comparing the meanings of two words, we can compare their degrees of valence, arousal, or dominance. For example, the word *banquet* indicates more positiveness than the word *funeral*; *nervous* indicates more arousal than *lazy*; and *fight* indicates more dominance than *delicate*.

Access to these degrees of valence, arousal, and dominance of words is beneficial for a number of applications, including those in natural language processing (e.g., automatic sentiment and emotion analysis of text), in cognitive science (e.g., for understanding how humans represent and use language), in psychology (e.g., for understanding how people view the world around them), in social sciences (e.g., for understanding relationships between people), and even in evolutionary linguistics (e.g., for understanding how language and behaviour inter-relate to give us an advantage).

Existing VAD lexicons (Bradley and Lang, 1999; Warriner et al., 2013) were created using rating scales and thus suffer from limitations associated with the method (Presser and Schuman, 1996; Baumgartner and Steenkamp, 2001). These include: inconsistencies in annotations by different annotators, inconsistencies in annotations by the same annotator, scale region bias (annotators often have a bias towards a portion of the scale), and problems associated with a fixed granularity.

In this paper, we describe how we obtained human ratings of valence, arousal, and dominance for more than 20,000 commonly used English words by crowdsourcing. Notably, we use a comparative annotation technique called *Best-Worst Scaling (BWS)* that addresses the limitations of traditional rating scales (Louviere, 1991; Cohen, 2003; Louviere et al., 2015). The scores are fine-grained real-valued numbers in the interval from 0 (lowest V, A, or D) to 1 (highest V, A, or D). We will refer to this new lexicon as the *NRC Valence, Arousal, and Dominance (VAD) Lexicon.*[2]

[1] We will refer to the three dimensions individually as *V, A,* and *D*, and together as *VAD*.

[2] NRC refers to National Research Council Canada.

Correlations (r) between repeated annotations, through metrics such as *split-half reliability (SHR)*, are a common way to evaluate the reliabilities of ordinal and rank annotations. We show that our annotations have SHR scores of $r = 0.95$ for valence, $r = 0.90$ for arousal, and $r = 0.91$ for dominance. These scores are well above the SHR scores obtained by Warriner et al. (2013), and indicate high reliability.

Respondents who provided valence, arousal, and dominance annotations, were given the option of additionally filling out a brief demographic questionnaire to provide details of their age, gender, and personality traits. This demographic information along with the VAD annotations allows us to determine whether attributes such as age, gender, and personality impact our understanding of the valence, arousal, and dominance of words. We show that even though overall the annotations are consistent (as seen from the high SHR scores), people aged over 35 are significantly more consistent in their annotations than people aged 35 or less. We show for the first time that men have a significantly higher shared understanding of dominance and valence of words, whereas women have a higher shared understanding of the degree of arousal of words. We find that some personality traits significantly impact a person's annotations of one or more of valence, arousal, and dominance. We hope that these and other findings described in the paper foster further research into how we use language, how we represent concepts in our minds, and how certain aspects of the world are more important to certain demographic groups leading to higher degrees of shared representations of those concepts within those groups.

All of the annotation tasks described in this paper were approved by our institution's review board, which examined the methods to ensure that they were ethical. Special attention was paid to obtaining informed consent and protecting participant anonymity. The NRC VAD Lexicon is made freely available for research and non-commercial use through our project webpage.[3]

2 Related Work

Primary Dimensions of Meaning: Osgood et al. (1957) asked human participants to rate words along dimensions of opposites such as *heavy–light, good–bad, strong–weak,* etc. Factor analysis of these judgments revealed that the three most prominent dimensions of meaning are evaluation (*good–bad*), potency (*strong–weak*), and activity (*active–passive*). Russell (1980, 2003) showed through similar analyses of emotion words that the three primary independent dimensions of emotions are valence or pleasure (positiveness–negativeness/pleasure–displeasure), arousal (active–passive), and dominance (dominant–submissive). He argues that individual emotions such as joy, anger, and fear are points in a three-dimensional space of valence, arousal, and dominance. It is worth noting that even though the names given by Osgood et al. (1957) and Russell (1980) are different, they describe similar dimensions (Bakker et al., 2014).

Existing Affect Lexicons: Bradley and Lang (1999) asked annotators to rate valence, arousal, and dominance—for more than 1,000 words—on a 9-point rating scale. The ratings from multiple annotators were averaged to obtain a score between 1 (lowest V, A, or D) to 9 (highest V, A, or D). Their lexicon, called the *Affective Norms of English Words (ANEW)*, has since been widely used across many different fields of study. More than a decade later, Warriner et al. (2013) created a similar lexicon for more than 13,000 words, using a similar annotation method. There exist a small number of VAD lexicons in non-English languages as well, such as the ones created by Moors et al. (2013) for Dutch, by Võ et al. (2009) for German, and by Redondo et al. (2007) for Spanish. The NRC VAD lexicon is the largest manually created VAD lexicon (in any language), and the only one that was created via comparative annotations (instead of rating scales).

Best-Worst Scaling: Best-Worst Scaling (BWS) was developed by (Louviere, 1991), building on work in the 1960's in mathematical psychology and psychophysics. Annotators are given n items (an n-tuple, where $n > 1$ and commonly $n = 4$).[4] They are asked which item is the *best* (highest in terms of the property of interest) and which is the *worst* (least in terms of the property of interest). When working on 4-tuples, best–worst annotations are particularly efficient because each best and worst annotation will reveal the order of five of the six item pairs (e.g., for a 4-tuple with items

[3]http://saifmohammad.com/WebPages/nrc-vad.html

[4]At its limit, when $n = 2$, BWS becomes a *paired comparison* (Thurstone, 1927; David, 1963), but then a much larger set of tuples need to be annotated (closer to N^2).

A, B, C, and D, if A is the best, and D is the worst, then A > B, A > C, A > D, B > D, and C > D). Real-valued scores of association between the items and the property of interest can be determined using simple arithmetic on the number of times an item was chosen best and number of times it was chosen worst (as described in Section 3) (Orme, 2009; Flynn and Marley, 2014).

It has been empirically shown that three annotations each for $2N$ 4-tuples is sufficient for obtaining reliable scores (where N is the number of items) (Louviere, 1991; Kiritchenko and Mohammad, 2016). Kiritchenko and Mohammad (2017) showed through empirical experiments that BWS produces more reliable and more discriminating scores than those obtained using rating scales. (See Kiritchenko and Mohammad (2016, 2017) for further details on BWS.)

Within the NLP community, BWS has been used for creating datasets for relational similarity (Jurgens et al., 2012), word-sense disambiguation (Jurgens, 2013), word–sentiment intensity (Kiritchenko and Mohammad, 2016), word–emotion intensity (Mohammad, 2018), and tweet–emotion intensity (Mohammad and Bravo-Marquez, 2017; Mohammad et al., 2018; Mohammad and Kiritchenko, 2018).

Automatically Creating Affect Lexicons: There is growing work on automatically determining word–sentiment and word–emotion associations (Yang et al., 2007; Mohammad and Kiritchenko, 2015; Yu et al., 2015; Staiano and Guerini, 2014). The VAD Lexicon can be used to evaluate how accurately the automatic methods capture valence, arousal, and dominance.

3 Obtaining Human Ratings of Valence, Arousal, and Dominance

We now describe how we selected the terms to be annotated and how we crowdsourced the annotation of the terms using best–worst scaling.

3.1 Term Selection

We chose to annotate commonly used English terms. We especially wanted to include terms that denotate or connotate emotions. We also include terms common in tweets.[5] Specifically, we include terms from the following sources:

- All terms in the NRC Emotion Lexicon (Mohammad and Turney, 2013). It has about 14,000 words with labels indicating whether they are associated with any of the eight basic emotions: anger, anticipation, disgust, fear, joy, sadness, surprise, and trust (Plutchik, 1980).
- All 4,206 terms in the positive and negative lists of the General Inquirer (Stone et al., 1966).
- All 1,061 terms listed in ANEW (Bradley and Lang, 1999).
- All 13,915 terms listed in the Warriner et al. (2013) lexicon.
- 520 words from the Roget's Thesaurus categories corresponding to the eight basic Plutchik emotions.[6]
- About 1000 high-frequency content terms, including emoticons, from the Hashtag Emotion Corpus (HEC) (Mohammad, 2012).[7]

The union of the above sets resulted in 20,007 terms that were then annotated for valence, arousal, and dominance.

3.2 Annotating VAD via Best–Worst Scaling

We describe below how we annotated words for valence. The same approach is followed for arousal and dominance. The annotators were presented with four words at a time (4-tuples) and asked to select the word with the highest valence and the word with the lowest valence. The questionnaire uses a set of paradigm words that signify the two ends of the valence dimension. The paradigm words were taken from past literature on VAD (Bradley and Lang, 1999; Osgood et al., 1957; Russell, 1980). The questions used for valence are shown below.

Q1. Which of the four words below is associated with the MOST happiness / pleasure / positiveness / satisfaction / contentedness / hopefulness OR LEAST unhappiness / annoyance / negativeness / dissatisfaction / melancholy / despair? (Four words listed as options.)

Q2. Which of the four words below is associated with the LEAST happiness / pleasure / positiveness / satisfaction / contentedness / hopefulness OR MOST unhappiness / annoyance / negativeness / dissatisfaction / melancholy / despair? (Four words listed as options.)

[5]Tweets include non-standard language such as emoticons, emojis, creatively spelled words (*happee*), hashtags (*#takingastand, #lonely*) and conjoined words (*loveumom*).

[6]http://www.gutenberg.org/ebooks/10681

[7]All tweets in the HEC include at least one of the eight basic emotion words as a hashtag word (*#anger, #sadness*, etc.).

Dataset	#words	Location of Annotators	Annotation Item	#Items	#Annotators	MAI	#Q/Item	#Best–Worst Annotations
valence	20,007	worldwide	4-tuple of words	40,014	1,020	6	2	243,295
arousal	20,007	worldwide	4-tuple of words	40,014	1,081	6	2	258,620
dominance	20,007	worldwide	4-tuple of words	40,014	965	6	2	276,170
Total								**778,085**

Table 1: A summary of the annotations for valence, arousal, and dominance. MAI = minimum number of annotations per item. Q = questions. A total of 778,085 pairs of best–worst responses were obtained.

Questions for arousal and dominance are similar.[8]

Detailed directions and example questions (with suitable responses) were provided in advance. $2 \times N$ distinct 4-tuples were randomly generated in such a manner that each word is seen in eight different 4-tuples and no two 4-tuples have more than two items in common (where N is the number of words to be annotated).[9]

Crowdsourcing: We setup three separate crowdsourcing tasks corresponding to valence, arousal, and dominance. The 4-tuples of words were uploaded for annotation on the crowdsourcing platform, *CrowdFlower*.[10] We obtained annotations from native speakers of English residing around the world. Annotators were free to provide responses to as many 4-tuples as they wished. The annotation tasks were approved by our institution's review board.

About 2% of the data was annotated beforehand by the authors. These questions are referred to as gold questions. CrowdFlower interspersed the gold questions with the other questions. If a crowd worker answered a gold question incorrectly, then they were immediately notified, the annotation was discarded, and an additional annotation was requested from a different annotator. If an annotator's accuracy on the gold questions fell below 80%, then they were refused further annotation, and all of their annotations were discarded. This served as a mechanism to avoid malicious and random annotations. The gold questions also served as examples to guide the annotators.

[8]The two ends of the arousal dimension were described with the words: arousal, activeness, stimulation, frenzy, jitteriness, alertness AND unarousal, passiveness, relaxation, calmness, sluggishness, dullness, sleepiness. The two ends of the dominance dimension were described with the words: dominant, in control of the situation, powerful, influential, important, autonomous AND submissive, controlled by outside factors, weak, influenced, cared-for, guided.

[9]We used the script provided by Kiritchenko and Mohammad (2016) to generate the 4-tuples from the list of terms: http://saifmohammad.com/WebPages/BestWorst.html

[10]CrowdFlower later changed its name to Figure Eight: https://www.figure-eight.com

Dimension	Word	Score↑	Word	Score↓
valence	*love*	1.000	*toxic*	0.008
	happy	1.000	*nightmare*	0.005
	happily	1.000	*shit*	0.000
arousal	*abduction*	0.990	*mellow*	0.069
	exorcism	0.980	*siesta*	0.046
	homicide	0.973	*napping*	0.046
dominance	*powerful*	0.991	*empty*	0.081
	leadership	0.983	*frail*	0.069
	success	0.981	*weak*	0.045

Table 2: The terms with the highest (↑) and lowest (↓) valence (V), arousal (A), and dominance (D) scores in the VAD Lexicon.

In the task settings for CrowdFlower, we specified that we needed annotations from six people for each word.[11] However, because of the way the gold questions work in CrowdFlower, they were annotated by more than six people. Both the minimum and the median number of annotations per item was six. See Table 1 for summary statistics on the annotations.[12]

Annotation Aggregation: The final VAD scores were calculated from the BWS responses using a simple counting procedure (Orme, 2009; Flynn and Marley, 2014): For each item, the score is the proportion of times the item was chosen as the best (highest V/A/D) minus the proportion of times the item was chosen as the worst (lowest V/A/D). The scores were linearly transformed to the interval: 0 (lowest V/A/D) to 1 (the highest V/A/D). We refer to the list of words along with their scores for valence, arousal, and dominance as the *NRC Valence, Arousal, and Dominance Lexicon*, or the *NRC VAD Lexicon* for short. Table 2 shows entries from the lexicon with the highest and lowest scores for V, A, and D.

[11]Note that since each word occurs in eight different 4-tuples, it is involved in $8 \times 6 = 48$ best–worst judgments.

[12]In a post-annotation survey, the respondents gave the task high scores for clarity of instruction (an average of 4.5 out of 5) and overall satisfaction (an average of 4.3 out of 5).

Attribute	Value	%	Value	%
Gender	f	37	m	63
Age	≤35	70	>35	30
Personality	Ag	69	Di	31
	Co	52	Ea	48
	Ex	52	In	48
	Ne	40	Se	60
	Op	50	Cl	50

Table 3: Summary of the demographic information provided by the annotators.

4 Demographic Survey

Respondents who annotated our VAD questionnaires were given a special code through which they could then optionally respond to a separate CrowdFlower survey asking for their demographic information: age, gender, country they live in, and personality traits. For the latter, we asked how they viewed themselves across the big five (Barrick and Mount, 1991) personality traits:

- Agreeableness (Ag) – Disagreeableness (Di): friendly and compassionate or careful in whom to trust, argumentative
- Conscientiousness (Co) – Easygoing (Ea): efficient and organized (prefer planned and self-disciplined behaviour) or easy-going and carefree (prefer flexibility and spontaneity)
- Extrovert (Ex) – Introvert (In): outgoing, energetic, seek the company of others or solitary, reserved, meeting many people causes anxiety
- Neurotic (Ne) – Secure (Se): sensitive and nervous (often feel anger, anxiety, depression, and vulnerability) or secure and confident (rarely feel anger, anxiety, depression, and vulnerability)
- Open to experiences (Op) – Closed to experiences (Cl): inventive and curious (seek out new experiences) or consistent and cautious (anxious about new experiences)

The questionnaire described the two sides of the dimension using only the texts after the colons above.[13] The questionnaire did not ask for identifying information such as name or date of birth.

In total, 991 people (55% of the VAD annotators) chose to provide their demographic information. Table 3 shows the details.

	V	A	D
Ours–Warriner	0.814	0.615	0.326

Table 4: Pearson correlations between our V, A, and D scores and the Warriner scores.

Lexicon	V–A	A–D	V–D
Ours	-0.268	0.302	0.488
Ours (Warriner subset)	-0.287	0.322	0.463
Warriner	-0.185	-0.180	0.717

Table 5: Pearson correlations between various pair-wise combinations of V, A, and D.

5 Examining of the NRC VAD Lexicon

5.1 A Comparsion of the NRC VAD Lexicon and the Warriner et al. Lexicon Scores

We calculated the Pearson correlations r between the NRC VAD Lexicon scores and the Warriner et al. Lexicon scores. Table 4 shows the results. (These numbers were calculated for the 13,915 common terms across the two lexicons.) Observe that the especially low correlations for dominance and arousal indicate that our lexicon has substantially different scores and rankings of terms by these dimensions. Even for valence, a correlation of 0.81 indicates a marked amount of differences in scores.

5.2 Independence of Dimensions

Russell (1980) found through his factor analysis work that valence, arousal, and dominance are nearly independent dimensions. However, Warriner et al. (2013) report that their scores for valence and dominance have substantial correlation ($r = 0.717$). Given that the split-half reliability score for their dominance annotations is only 0.77, the high V–D correlations raises the suspicion whether annotators sufficiently understood the difference between dominance and valence. Table 5 shows the correlations between various pair-wise combinations of valence, arousal, and dominance for both our lexicon and the Warriner lexicon. Observe that unlike the Warriner annotations where V and D are highly correlated, our annotations show that V and D are only slightly correlated. The correlations for V–A and A–D are low in both our and Warriner annotations, albeit slightly higher in magnitude in our annotations.

[13]How people view themselves may be different from what they truly are. The conclusions in this paper apply to groups that view themselves to be a certain personality type.

Annotations	#Terms	#Annotations	V	A	D
a. Ours (on all terms)	20,007	6 per tuple	0.950	0.899	0.902
b. Ours (on only those terms also in Warriner)	13,915	6 per tuple	0.952	0.905	0.906
c. Warriner et al. (2013)	13,915	20 per term	0.914	0.689	0.770

Table 6: Split-half reliabilities (as measured by Pearson correlation) for valence, arousal, and dominance scores obtained from our annotations and the Warriner et al. annotations.

5.3 Reliability of the Annotations

A useful measure of quality is reproducibility of the end result—repeated independent manual annotations from multiple respondents should result in similar scores. To assess this reproducibility, we calculate average *split-half reliability (SHR)* over 100 trials. All annotations for an item (in our case, 4-tuples) are randomly split into two halves. Two sets of scores are produced independently from the two halves. Then the correlation between the two sets of scores is calculated. If the annotations are of good quality, then the correlation between the two halves will be high. Table 6 shows the split-half reliabilities (SHR) for valence, arousal, and dominance annotations. Row *a.* shows the SHR on the full set of terms in the VAD lexicon. Row *b.* shows the SHR on just the Warriner subset of terms in the VAD lexicon. Row *c.* shows the SHR reported by Warriner et al. (2013) on their annotations. Observe that the SHR scores for our annotations are markedly higher than those reported by Warriner et al. (2013), especially for arousal and dominance. All differences in SHR scores between rows b and c are statistically significant.

Summary of Main Results: The low correlations between the scores in our lexicon and the Warriner lexicon (especially for D and A) show that the scores in the two lexicons are substantially different. The scores for correlations across all pairs of dimensions in our lexicon are low ($r < 0.5$). SHR scores of 0.95 for valence, 0.9 for arousal, and 0.9 for dominance show for the first time that highly reliable fine-grained ratings can be obtained for valence, arousal, and dominance.

6 Shared Understanding of VAD Within and Across Demographic Groups

Human cognition and behaviour is impacted by evolutionary and socio-cultural factors. These factors are known to impact different groups of people differently (men vs. women, young vs. old, etc.). Thus it is not surprising that our understanding of the world may be slightly different depending on our demographic attributes. Consider gender—a key demographic attribute.[14] Men, women, and other genders are substantially more alike than they are different. However, they have encountered different socio-cultural influences for thousands of years. Often these disparities have been a means to exert unequal status and asymmetric power relations. Thus a crucial area in gender studies is to examine both the overt and subtle impacts of these socio-cultural influences, as well as ways to mitigate the inequity. Understanding how different genders perceive and use language is an important component of that research. Language use is also relevant to the understanding and treatment of neuropsychiatric disorders, such as sleep, mood, and anxiety disorders, which have been shown to occur more frequently in women than men (Bao and Swaab, 2011; Lewinsohn et al., 1998; McLean et al., 2011; Johnson et al., 2006; Chmielewski et al., 1995).

In addition to the VAD Lexicon (created by aggregating human judgments), we also make available the demographic information of the annotators. This demographic information along with the individual judgments on the best–worst tuples forms a significant resource in the study of how demographic attributes are correlated with our understanding of language. The data can be used to shed light on research questions such as: 'are there significant differences in the shared understanding of word meanings in men and women?', 'how is the social construct of gender reflected in language, especially in socio-political interactions?', 'does age impact our view of the valence, arousal, and dominance of concepts?', 'do people that view themselves as conscientious have slightly different judgments of valence, arousal, and dominance, than people who view themselves as easy going?', and so on.

[14]Note that the term *sex* refers to a biological attribute pertaining to the anatomy of one's reproductive system and sex chromosomes, whereas *gender* refers to a psycho-socio-cultural construct based on a person's sex or a person's self identification of levels of masculinity and femininity. One may identify their gender as female, male, agender, trans, queer, etc.

	V	A	D
f–f pairs	56.55	44.15	42.55
m–m pairs	56.88	43.80	43.55
f–m pairs	56.41	43.65	43.03

Table 7: Gender: Average agreement % on best–worst responses.

	V	A	D
f–f pairs vs. m–m pairs	y	y	y
f–f pairs vs. f–m pairs	-	y	y
m–m pairs vs. f–m pairs	y	-	y

Table 8: Gender: Significance of difference in average agreement scores (p = 0.05). 'y' = yes significant. '-' = not significant.

6.1 Experiments

We now describe experiments we conducted to determine whether demographic attributes impact how we judge words for valence, arousal, and dominance. For each demographic attribute, we partitioned the annotators into two groups: male (m) and female (f), ages 18 to 35 ($\leq$35) and ages over 35 ($>$35), and so on.[15] For each of the five personality traits, annotators are partitioned into the two groups shown in the bullet list of Section 4. We then calculated the extent to which people within the same group agreed with each other, and the extent to which people across groups agreed with each other on the VAD annotations (as described in the paragraph below). We also determined if the differences in agreement were statistically significant.

For each dimension (V, A, and D), we first collected only those 4-tuples where at least two female and at least two male responses were available. We will refer to this set as the *base set*. For each of the base set 4-tuples, we calculated three agreement percentages: 1. the percentage of all female–female best–worst responses where the two agreed with each other, 2. the percentage of all male–male responses where the two agreed with each other, and 3. the percentage of all female–male responses where the two agreed with each other. We then calculated the averages of the agreement percentages across all the 4-tuples in the base set. We conducted similar experiments for age groups and personality traits.

[15]For age, we chose 35 to create the two groups because several psychology and medical studies report changes in health and well-being at this age. Nonetheless, other partitions of age are also worth exploring.

	V	A	D
$\leq$35–$\leq$35 pairs	56.10	43.84	43.81
$>$35–$>$35 pairs	57.56	44.10	42.49
$\leq$35–$>$35 pairs	56.40	43.58	43.07

Table 9: Age: Average agreement % on best–worst responses.

	V	A	D

$\leq$35–$\leq$35 pairs vs. $\leq$35–$>$35 pairs	y	y	y
$>$35–$>$35 pairs vs. $\leq$35–$>$35 pairs	y	y	y

Table 10: Age: Significance of difference in average agreement scores (p = 0.05).

6.2 Results

Table 7 shows the results for gender. Note that the average agreement numbers are not expected to be high because often a 4-tuple may include two words that are close to each other in terms of the property of interest (V/A/D).[16] However, the relative values of the agreement percentages indicate the relative levels of agreements within groups and across groups.

Table 7 numbers indicate that women have a higher shared understanding of the degree of arousal of words (higher f–f average agreement scores on A), whereas men have a higher shared understanding of dominance and valence of words (higher m–m average agreement scores on V and D). The table also shows the cross-group (f–m) average agreements are the lowest for valence and arousal, but higher than f–f pairs for dominance. (Each of these agreements was determined from 1 to 1.5 million judgment pairs.)

Table 8 shows which of the Table 7 average agreements are statistically significantly different (shown with a 'y'). Significance values were calculated using the chi-square test for independence and significance level of 0.05. Observe that all score differences are statistically significant except for between f–f and f–m scores for V and m–m and f–m scores for A.

Tables 9 through 12 are similar to Tables 7 and 8, but for age groups and personality traits. Tables 9 and 10 show that respondents over the age of 35 obtain significantly higher agreements with each other on valence and arousal and lower agreements on dominance, than respondents aged 35 and under (with each other). Tables 11 and 12 show that

[16]Such disagreements are useful as they cause the two words to obtain scores close to each other.

Table 12: Personality Trait: Significance of difference in average agreement scores (p = 0.05).

some personality traits significantly impact a person's annotations of one or more of V, A, and D. Notably, those who view themselves as conscientious have a particularly higher shared understanding of the dominance of words, as compared to those who view themselves as easy going. They also have higher in-group agreement for arousal, than those who view themselves as easy going, but the difference for valence is not statistically significant. Also notable, is that those who view themselves as extroverts have a particularly higher shared understanding of the valence, arousal, and dominance of words, as compared to those who view themselves as introverts.

Finally, as a sanity check, we divided respondents into those whose CrowdFlower worker ids are odd and those whose worker ids are even. We then determined average agreements for even–even, odd-odd, and even–odd groups just as we did for the demographic variables. We found that, as expected, there were no significant differences in average agreements.

Summary of Main Results: We showed that several demographic attributes such as age, gender, and personality traits impact how we judge words for valence, arousal, and dominance. Further, people that share certain demographic attributes show a higher shared understanding of the relative rankings of words by (one or more of) V, A, or D than others. However, this raises new questions: why do certain demographic attributes impact our judgments of V, A, and D? Are there evolutionary forces that caused some groups such as women to develop a higher shared understanding or the arousal, whereas different evolutionary forces caused some groups, such as men, to have a higher shared understanding of dominance? We hope that the data collected as part of this project will spur further inquiry into these and other questions.

7 Applications and Future Work

The large number of entries in the VAD Lexicon and the high reliability of the scores make it useful for a number of research projects and applications. We list a few below:

- To provide features for sentiment or emotion detection systems. They can also be used to obtain sentiment-aware word embeddings and sentiment-aware sentence representations.
- To study the interplay between the basic emotion model and the VAD model of affect. The VAD lexicon can be used along with lists of words associated with emotions such as joy, sadness, fear, etc. to study the correlation of V, A, and D, with those emotions.

- To study the role emotion words play in high emotion intensity sentences or tweets. The Tweet Emotion Intensity Dataset has emotion intensity and valence scores for whole tweets (Mohammad and Bravo-Marquez, 2017). We will use the VAD lexicon to determine the extent to which high intensity and high valence tweets consist of high V, A, and D words, and to identify sentences that express high emotional intensity without using high V, A, and D words.
- To identify syllables that tend to occur in words with high VAD scores, which in turn can be used to generate names for literary characters and commercial products that have the desired affectual response.
- To identify high V, A, and D words in books and literature. To facilitate research in digital humanities. To facilitate work on literary analysis.
- As a source of gold (reference) scores, the entries in the VAD lexicon can be used in the evaluation of automatic methods of determining V, A, and D.
- To analyze V, A, ad D annotations for different groups of words, such as: hashtag words and emojis common in tweets, emotion denotating words, emotion associated words, neutral terms, words belonging to particular parts of speech such as nouns, verbs, and adjectives, etc.
- To analyze interactions between demographic groups and specific groups of words, for example, whether younger annotators have a higher shared understanding of tweet terms, whether a certain gender is associated with a higher shared understanding of adjectives, etc.
- To analyze the shared understanding of V, A, and D within and across geographic and language groups. We are interested in creating VAD lexicons for other languages. We can then explore characteristics of valence, arousal, and dominance that are common across cultures. We can also test whether some of the conclusions reached in this work apply only to English, or more broadly to multiple languages.
- The dataset is of use to psychologists and evolutionary linguists interested in determining how evolution shaped our representation of the world around us, and why certain personality traits are associated with higher or lower shared understanding of V, A, and D.

8 Conclusions

We obtained reliable human ratings of valence, arousal, and dominance for more than 20,000 English words. (It has about 40% more words than the largest existing manually created VAD lexicon). We used best–worst scaling to obtain fine-grained scores (and word rankings) and addressed issues of annotation consistency that plague traditional rating scale methods of annotation. We showed that the lexicon has split-half reliability scores of 0.95 for valence, 0.90 for arousal, and 0.90 for dominance. These scores are markedly higher than that of existing lexicons.

We analyzed demographic information to show that even though the annotations overall lead to consistent scores in repeated annotations, there exist statistically significant differences in agreements across demographic groups such as males and females, those above the age of 35 and those that are 35 or under, and across personality dimensions (extroverts and introverts, neurotic and secure, etc.). These results show that certain demographic attributes impact how we view the world around us in terms of the relative valence, arousal, and dominance of the concepts in it.

The NRC Valence, Arousal, and Dominance Lexicon is made available.[17] It can be used in combination with other manually created affect lexicons such as the NRC Word–Emotion Association Lexicon (Mohammad and Turney, 2013)[18] and the NRC Affect Intensity Lexicon (Mohammad, 2018).[19]

Acknowledgments

Many thanks to Svetlana Kiritchenko, Michael Wojatzki, Norm Vinson, and Tara Small for helpful discussions.

[17]**The NRC Valence, Arousal, and Dominance Lexicon** provides human ratings of valence, arousal, and dominance for more than 20,000 English words: http://saifmohammad.com/WebPages/nrc-vad.html

[18]**The NRC Emotion Lexicon** includes about 14,000 words annotated to indicate whether they are associated with any of the eight basic emotions (anger, anticipation, disgust, fear, joy, sadness, surprise, and trust): http://saifmohammad.com/WebPages/NRC-Emotion-Lexicon.htm

[19]**The NRC Affect Intensity Lexicon** provides real-valued affect intensity scores for four basic emotions (anger, fear, sadness, joy): http://saifmohammad.com/WebPages/AffectIntensity.htm

Abstract

Semantic relations are often signaled with prepositional or possessive marking—but extreme polysemy bedevils their analysis and automatic interpretation. We introduce a new annotation scheme, corpus, and task for the disambiguation of prepositions and possessives in English. Unlike previous approaches, our annotations are comprehensive with respect to types and tokens of these markers; use broadly applicable supersense classes rather than fine-grained dictionary definitions; unite prepositions and possessives under the same class inventory; and distinguish between a marker's *lexical* contribution and the *role* it marks in the context of a predicate or scene. Strong interannotator agreement rates, as well as encouraging disambiguation results with established supervised methods, speak to the viability of the scheme and task.

1 Introduction

Grammar, as per a common metaphor, gives speakers of a language a shared toolbox to construct and deconstruct meaningful and fluent utterances. Being highly analytic, English relies heavily on word order and closed-class function words like prepositions, determiners, and conjunctions. Though function words bear little semantic content, they are nevertheless crucial to the meaning. Consider prepositions: they serve, for example, to convey place and time (*We met* ***at/in/outside*** *the restaurant* ***for/after*** *an hour*), to express configurational relationships like quantity, possession, part/whole, and membership (*the coats* ***of*** *dozens* ***of*** *children* ***in*** *the class*), and to indicate semantic roles in argument structure (*Grandma cooked dinner* ***for*** *the children* vs. *Grandma cooked the children* ***for*** *dinner*). Frequent prepositions like **for** are maddeningly polysemous, their interpretation depending especially on the object of the preposition—*I rode the bus* ***for*** *5 dollars/minutes*—and the governor of the prepositional phrase (PP): *I Ubered/asked* ***for*** *\$5*. Possessives are similarly ambiguous: *Whistler****'s*** *mother/painting/hat/death*. Semantic interpretation requires some form of sense disambiguation, but arriving at a linguistic representation that is flexible enough to generalize across usages and types, yet simple enough to support reliable annotation, has been a daunting challenge (§2).

(1) I was booked **for**/DURATION 2 nights **at**/LOCUS this hotel **in**/TIME Oct 2007 .

(2) I went **to**/GOAL ohm **after**/EXPLANATION⇝TIME reading some **of**/QUANTITY⇝WHOLE the reviews .

Figure 1: Annotated sentences from our corpus.

This work represents a new attempt to strike that balance. Building on prior work, we argue for an approach to describing English preposition and possessive semantics with broad coverage. Given the semantic overlap between prepositions and possessives (*the hood* ***of*** *the car* vs. *the car****'s*** *hood* or ***its*** *hood*), we analyze them using the same inventory of semantic labels.[1] Our contributions include:

- a new hierarchical **inventory** ("SNACS") of 50 supersense classes, extensively documented in guidelines for English (§3);
- a gold-standard **corpus** with *comprehensive* annotations: all types and tokens of prepositions and possessives are disambiguated (§4; example sentences appear in figure 1);
- an **interannotator agreement** study that

[*] nathan.schneider@georgetown.edu

[1] Some uses of certain other closed-class markers—intransitive particles, subordinators, infinitive **to**—are also included (§3.1).

shows the scheme is reliable and generalizes across genres—and for the first time demonstrating empirically that the lexical semantics of a preposition can sometimes be detached from the PP's semantic role (§5);

- **disambiguation** experiments with two supervised classification architectures to establish the difficulty of the task (§6).

2 Background: Disambiguation of Prepositions and Possessives

Studies of preposition semantics in linguistics and cognitive science have generally focused on the domains of space and time (e.g., Herskovits, 1986; Bowerman and Choi, 2001; Regier, 1996; Khetarpal et al., 2009; Xu and Kemp, 2010; Zwarts and Winter, 2000) or on motivated polysemy structures that cover additional meanings beyond core spatial senses (Brugman, 1981; Lakoff, 1987; Tyler and Evans, 2003; Lindstromberg, 2010). Possessive constructions can likewise denote a number of semantic relations, and various factors—including semantics—influence whether attributive possession in English will be expressed with **of**, or with **'s** and possessive pronouns (the 'genitive alternation'; Taylor, 1996; Nikiforidou, 1991; Rosenbach, 2002; Heine, 2006; Wolk et al., 2013; Shih et al., 2015).

Corpus-based computational work on semantic disambiguation specifically of prepositions and possessives[2] falls into two categories: the **lexicographic/word sense disambiguation** approach (Litkowski and Hargraves, 2005, 2007; Litkowski, 2014; Ye and Baldwin, 2007; Saint-Dizier, 2006; Dahlmeier et al., 2009; Tratz and Hovy, 2009; Hovy et al., 2010, 2011; Tratz and Hovy, 2013), and the **semantic class** approach (Moldovan et al., 2004; Badulescu and Moldovan, 2009; O'Hara and Wiebe, 2009; Srikumar and Roth, 2011, 2013; Schneider et al., 2015, 2016; Hwang et al., 2017, see also Müller et al., 2012 for German). The lexicographic approach can capture finer-grained meaning distinctions, at a risk of relying upon idiosyncratic and potentially incomplete dictionary definitions. The semantic class approach, which we follow here, focuses on commonalities in meaning across multiple lexical items, and aims to generalize more easily to new types and usages.

[2]Of course, meanings marked by prepositions/possessives are to some extent captured in predicate-argument or graph-based meaning representations (e.g., Palmer et al., 2005; Fillmore and Baker, 2009; Oepen et al., 2016; Banarescu et al., 2013) and domain-centric representations like TimeML and ISO-Space (Pustejovsky et al., 2003, 2012).

The most recent class-based approach to prepositions was our initial framework of 75 **preposition supersenses** arranged in a multiple inheritance taxonomy (Schneider et al., 2015, 2016). It was based largely on relation/role inventories of Srikumar and Roth (2013) and VerbNet (Bonial et al., 2011; Palmer et al., 2017). The framework was realized in version 3.0 of our comprehensively annotated corpus, STREUSLE[3] (Schneider et al., 2016). However, several limitations of our approach became clear to us over time.

First, as pointed out by Hwang et al. (2017), the one-label-per-token assumption in STREUSLE is flawed because it in some cases puts into conflict the semantic role of the PP with respect to a predicate, and the lexical semantics of the preposition itself. Hwang et al. (2017) suggested a solution, discussed in §3.3, but did not conduct an annotation study or release a corpus to establish its feasibility empirically. We address that gap here.

Second, 75 categories is an unwieldy number for both annotators and disambiguation systems. Some are quite specialized and extremely rare in STREUSLE 3.0, which causes data sparseness issues for supervised learning. In fact, the only published disambiguation system for preposition supersenses collapsed the distinctions to just 12 labels (Gonen and Goldberg, 2016). Hwang et al. (2017) remarked that solving the aforementioned problem could remove the need for many of the specialized categories and make the taxonomy more tractable for annotators and systems. We substantiate this here, defining a new hierarchy with just 50 categories (SNACS, §3) and providing disambiguation results for the full set of distinctions.

Finally, given the semantic overlap of possessive case and the preposition **of**, we saw an opportunity to broaden the application of the scheme to include possessives. Our reannotated corpus, STREUSLE 4.0, thus has supersense annotations for over 1000 possessive tokens that were not semantically annotated in version 3.0. We include these in our annotation and disambiguation experiments alongside reannotated preposition tokens.

3 Annotation Scheme

3.1 Lexical Categories of Interest

Apart from canonical prepositions and possessives, there are many lexically and semantically overlap-

[3]`https://github.com/nert-gu/streusle/`

ping closed-class items which are sometimes classified as other parts of speech, such as adverbs, particles, and subordinating conjunctions. *The Cambridge Grammar of the English Language* (Huddleston and Pullum, 2002) argues for an expansive definition of 'preposition' that would encompass these other categories. As a practical measure, we decided to encourage annotators to focus on the semantics of these functional items rather than their syntax, so we take an inclusive stance.

Another consideration is developing annotation guidelines that can be adapted for other languages. This includes languages which have *post*positions, *circum*positions, or *in*positions rather than prepositions; the general term for such items is *ad*positions.[4] English possessive marking (via **'s** or possessive pronouns like **my**) is more generally an example of *case* marking. Note that prepositions (4a–4c) differ in word order from possessives (4d), though semantically the object of the preposition and the possessive nominal pattern together:

(4) a. eat **in** a restaurant
 b. the man **in** a blue shirt
 c. the wife **of** the ambassador
 d. the ambassador**'s** wife

Cross-linguistically, adpositions and case marking are closely related, and in general both grammatical strategies can express similar kinds of semantic relations. This motivates a common semantic inventory for adpositions and case.

We also cover multiword prepositions (e.g., **out_of**, **in_front_of**), intransitive particles (*He flew* ***away***), purpose infinitive clauses (*Open the door* ***to*** *let in some air*[5]), prepositions with clausal complements (*It rained* ***before*** *the party started*), and idiomatic prepositional phrases (***at****_large*). Our annotation guidelines give further details.

3.2 The SNACS Hierarchy

The hierarchy of preposition and possessive supersenses, which we call Semantic Network of Adposition and Case Supersenses (SNACS), is shown in figure 2. It is simpler than its predecessor—Schneider et al.'s (2016) preposition supersense hierarchy—in both size and structural complexity.

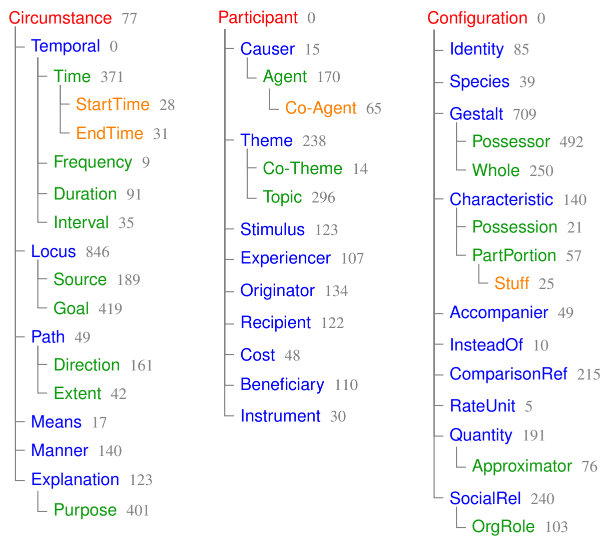

Figure 2: SNACS hierarchy of 50 supersenses and their token counts in the annotated corpus described in §4. Counts are of direct uses of labels, excluding uses of subcategories. Role and function positions are not distinguished (so if a token has different role and function labels, it will count toward two supersense frequencies).

SNACS has 50 supersenses at 4 levels of depth; the previous hierarchy had 75 supersenses at 7 levels. The top-level categories are the same:

- CIRCUMSTANCE: Circumstantial information, usually non-core properties of events (e.g., location, time, means, purpose)
- PARTICIPANT: Entity playing a role in an event
- CONFIGURATION: Thing, usually an entity or property, involved in a static relationship to some other entity

The 3 subtrees loosely parallel adverbial adjuncts, event arguments, and adnominal complements, respectively. The PARTICIPANT and CIRCUMSTANCE subtrees primarily reflect semantic relationships prototypical to verbal arguments/adjuncts and were inspired by VerbNet's thematic role hierarchy (Palmer et al., 2017; Bonial et al., 2011). Many CIRCUMSTANCE subtypes, like LOCUS (the concrete or abstract location of something), can be governed by eventive and non-eventive nominals as well as verbs: *eat* ***in*** *the restaurant*, *a party* ***in*** *the restaurant*, *a table* ***in*** *the restaurant*. CONFIGURATION mainly encompasses non-spatiotemporal relations holding between entities, such as quantity, possession, and part/whole. Unlike the previous hierarchy, SNACS does not use multiple inheritance, so there is no overlap between the 3 regions.

The supersenses can be understood as roles in fundamental types of scenes (or schemas) such as: LOCATION—THEME is located at LO-

[4]In English, **ago** is arguably a postposition because it follows rather than precedes its complement: *five minutes* ***ago***, not ****ago*** *five minutes*.

[5]**To** can be rephrased as **in_order_to** and have prepositional counterparts like in *Open the door* ***for*** *some air*.

CUS; MOTION—THEME moves from SOURCE along PATH to GOAL; TRANSITIVE ACTION—AGENT acts on THEME, perhaps using an INSTRUMENT; POSSESSION—POSSESSION belongs to POSSESSOR; TRANSFER—THEME changes possession from ORIGINATOR to RECIPIENT, perhaps with COST; PERCEPTION—EXPERIENCER is mentally affected by STIMULUS; COGNITION—EXPERIENCER contemplates TOPIC; COMMUNICATION—information (TOPIC) flows from ORIGINATOR to RECIPIENT, perhaps via an INSTRUMENT. For AGENT, CO-AGENT, EXPERIENCER, ORIGINATOR, RECIPIENT, BENEFICIARY, POSSESSOR, and SOCIALREL, the object of the preposition is prototypically animate.

Because prepositions and possessives cover a vast swath of semantic space, limiting ourselves to 50 categories means we need to address a great many nonprototypical, borderline, and special cases. We have done so in a 75-page annotation manual with over 400 example sentences (Schneider et al., 2018).

Finally, we note that the Universal Semantic Tagset (Abzianidze and Bos, 2017) defines a cross-linguistic inventory of semantic classes for content and function words. SNACS takes a similar approach to prepositions and possessives, which in Abzianidze and Bos's (2017) specification are simply tagged REL, which does not disambiguate the nature of the relational meaning. Our categories can thus be understood as refinements to REL.

3.3 Adopting the Construal Analysis

Hwang et al. (2017) have pointed out the perils of teasing apart and generalizing preposition semantics so that each use has a clear supersense label. One key challenge they identified is that the preposition itself and the situation as established by the verb may suggest different labels. For instance:

(5) a. Vernon works **at** Grunnings.
 b. Vernon works **for** Grunnings.

The semantics of the *scene* in (5a, 5b) is the same: it is an employment relationship, and the PP contains the employer. SNACS has the label ORGROLE for this purpose.[6] At the same time, **at** in (5a) strongly suggests a locational relationship, which would correspond to the label LOCUS; consistent with this hypothesis, *Where does Vernon work?* is a perfectly good way to ask a question that could be answered by the PP. In this example, then, there is overlap between locational meaning and organizational-belonging meaning. (5b) is similar except the **for** suggests a notion of BENEFICIARY: the employee is working *on behalf of* the employer. Annotators would face a conundrum if forced to pick a single label when multiple ones appear to be relevant. Schneider et al. (2016) handled overlap via multiple inheritance, but entertaining a new label for every possible case of overlap is impractical, as this would result in a proliferation of supersenses.

Instead, Hwang et al. (2017) suggest a **construal analysis** in which the lexical semantic contribution, or henceforth the **function**, of the preposition itself may be distinct from the semantic role or relation mediated by the preposition in a given sentence, called the **scene role**. The notion of scene role is a widely accepted idea that underpins the use of semantic or thematic roles: semantics licensed by the governor[7] of the prepositional phrase dictates its relationship to the prepositional phrase. The innovative claim is that, in addition to a preposition's relationship with its head, the prepositional *choice* introduces another layer of meaning or **construal** that brings additional nuance, creating the difficulty we see in the annotation of (5a, 5b). Construal is notated by ROLE⇝FUNCTION. Thus, (5a) would be annotated ORGROLE⇝LOCUS and (5b) as ORGROLE⇝BENEFICIARY to expose their common truth-semantic meaning but slightly different portrayals owing to the different prepositions.

Another useful application of the construal analysis is with the verb *put*, which can combine with any locative PP to express a destination:

(6) Put it **on/by/behind/on_top_of/**... the door.
 GOAL⇝LOCUS

I.e., the preposition signals a LOCUS, but the door serves as the GOAL with respect to the scene. This approach also allows for resolution of various se-

[6] ORGROLE is defined as "Either a party in a relation between an organization/institution and an individual who has a stable affiliation with that organization, such as membership or a business relationship."

[7] By "governor" of the preposition or prepositional phrase, we mean the head of the phrase to which the PP attaches in a constituency representation. In a dependency representation, this would be the head of the preposition itself or of the object of the preposition depending on which convention is used for PP headedness: e.g., the preposition heads the PP in CoNLL and Stanford Dependencies whereas the object is the head in Universal Dependencies. The governor is most often a verb or noun. Where the PP is a predicate complement (e.g. *Vernon is **with** Grunnings*), there is no governor to specify the nature of the scene, so annotators must rely on world knowledge and context to determine the scene.

	Train	Dev	Test	Total

Table 1: Counts for the data splits used in our experiments.

mantic phenomena including perceptual scenes (e.g., *I care* ***about*** *education*, where **about** is both the topic of cogitation and perceptual stimulus of caring: STIMULUS⇝TOPIC), and fictive motion (Talmy, 1996), where static location is described using motion verbiage (as in *The road runs* ***through*** *the forest*: LOCUS⇝PATH).

Both role and function slots are filled by supersenses from the SNACS hierarchy. Annotators have the option of using distinct supersenses for the role and function; in general it is not a requirement (though we stipulate that certain SNACS supersenses can only be used as the role). When the same label captures both role and function, we do not repeat it: *Vernon lives* ***in***/LOCUS *England*. Figure 1 shows some real examples from our corpus.

We apply the construal analysis in SNACS annotation of our corpus to test its feasibility. It has proved useful not only for prepositions, but also possessives, where the general sense of possession may overlap with other scene relations, like creator/initial-possessor (ORIGINATOR): *Da Vinci'****s***/ORIGINATOR⇝POSSESSOR *sculptures*.

4 Annotated Reviews Corpus

We applied the SNACS annotation scheme (§3) to prepositions and possessives in the STREUSLE corpus (§2), a collection of online consumer reviews taken from the English Web Treebank (Bies et al., 2012). The sentences from the English Web Treebank also comprise the primary reference treebank for English Universal Dependencies (UD; Nivre et al., 2016), and we bundle the UD version 2 syntax alongside our annotations. Table 1 shows the total number of tokens present and those that we annotated. Altogether, 5,455 tokens were annotated for scene role and function.

Rank	Role		Function	
1	LOCUS	636	LOCUS	780
2	POSSESSOR	381	GESTALT	699
⋮	⋮		⋮	
last	DIRECTION	1	POSSESSION	2

Table 2: Most and least frequent role and function labels.

The new hierarchy and annotation guidelines were developed by consensus. The original preposition supersense annotations were placed in a spreadsheet and discussed. While most tokens were unambiguously annotated, some cases required a new analysis throughout the corpus. For example, the functions of **for** were so broad that they needed to be (manually) clustered before mapping clusters onto hierarchy labels. Unusual or rare contexts also presented difficulties. Where the correct supersense remained unclear, specific instructions and examples were included in the guidelines. Possessives were not covered by the original preposition supersense annotations, and thus were annotated from scratch.[8] **Special labels** were applied to tokens deemed not to be prepositions or possessives evoking semantic relations, including uses of the infinitive marker that do not fall within the scope of SNACS (487 tokens: a majority of infinitives) and preposition-initial discourse expressions (e.g. ***after****_all*) and coordinating conjunctions (***as****_well_as*).[9] Other tokens requiring special labels are the opaque possessive slot in a multiword idiom (12 tokens), and tokens where unintelligble, incomplete, marginal, or nonnative usage made it impossible to assign a supersense (48 tokens).

Table 2 shows the most and least common labels occurring as scene role and function. Three labels never appear in the annotated corpus: TEMPORAL from the CIRCUMSTANCE hierarchy, and PARTICIPANT and CONFIGURATION which are both the highest supersense in their respective hierarchies. While all remaining supersenses are attested as scene roles, there are some that never occur as functions, such as ORIGINATOR, which is most often realized as POSSESSOR or SOURCE, and EXPERIENCER. It is interesting to note that every subtype of CIRCUMSTANCE (except TEMPORAL) appears as both scene role and function, whereas many of the subtypes of the other two hierarchies are lim-

[8] Blodgett and Schneider (2018) detail the extension of the scheme to possessives.

[9] In the corpus, lexical expression tokens appear alongside a **lexical category** indicating which inventory of supersenses, if any, applies. SNACS-annotated units are those with ADP (adposition), PP, PRON.POSS (possessive pronoun), etc., whereas DISC (discourse) and CCONJ expressions do not receive any supersense. Refer to the STREUSLE README for details.

ited to either role or function. This reflects our view that prepositions primarily capture circumstantial notions such as space and time, but have been extended to cover other semantic relations.[10]

5 Interannotator Agreement Study

Because the online reviews corpus was so central to the development of our guidelines, we sought to estimate the reliability of the annotation scheme on a new corpus in a new genre. We chose Saint-Exupéry's novella *The Little Prince*, which is readily available in many languages and has been annotated with semantic representations such as AMR (Banarescu et al., 2013). The genre is markedly different from online reviews—it is quite literary, and employs archaic or poetic figures of speech. It is also a translation from French, contributing to the markedness of the language. This text is therefore a challenge for an annotation scheme based on colloquial contemporary English. We addressed this issue by running 3 practice rounds of annotation on small passages from *The Little Prince*, both to assess whether the scheme was applicable without major guidelines changes and to prepare the annotators for this genre. For the final annotation study, we chose chapters 4 and 5, in which 242 markables of 52 types were identified heuristically (§6.2). The types *of*, *to*, *in*, *as*, *from*, and *for*, as well as possessives, occurred at least 10 times. Annotators had the option to mark units as false positives using special labels (see §4) in addition to expressing uncertainty about the unit.

For the annotation process, we adapted the open source web-based annotation tool UCCAApp (Abend et al., 2017) to our workflow, by extending it with a type-sensitive ranking module for the list of categories presented to the annotators.

Annotators. Five annotators (A, B, C, D, E), all authors of this paper, took part in this study. All are computational linguistics researchers with advanced training in linguistics. Their involvement in the development of the scheme falls on a spectrum, with annotator A being the most active figure in guidelines development, and annotator E not being involved in developing the guidelines and learning the scheme solely from reading the manual. Annotators A, B, and C are native speakers of English, while Annotators D and E are nonnative but highly fluent speakers.

	Labels	Role	Function
Exact	47	74.4%	81.3%
Depth-3	43	75.0%	81.8%
Depth-2	26	79.9%	87.4%
Depth-1	3	92.6%	93.9%

Table 3: Interannotator agreement rates (pairwise averages) on *Little Prince* sample (216 tokens) with different levels of hierarchy coarsening according to figure 2 ("Exact" means no coarsening). "Labels" refers to the number of distinct labels that annotators could have provided at that level of coarsening. Excludes tokens where at least one annotator assigned a non-semantic label.

Results. In the *Little Prince* sample, 40 out of 47 possible supersenses were applied at least once by some annotator; 36 were applied at least once by a majority of annotators; and 33 were applied at least once by all annotators. APPROXIMATOR, CO-THEME, COST, INSTEADOF, INTERVAL, RATEUNIT, and SPECIES were not used by any annotator.

To evaluate interannotator agreement, we excluded 26 tokens for which at least one annotator has assigned a non-semantic label, considering only the 216 tokens that were identified correctly as SNACS targets and were clear to all annotators. Despite varying exposure to the scheme, there is no obvious relationship between annotators' backgrounds and their agreement rates.[11]

Table 3 shows the interannotator agreement rates, averaged across all pairs of annotators. Average agreement is 74.4% on the scene role and 81.3% on the function (row 1).[12] All annotators agree on the role for 119, and on the function for 139 tokens. Agreement is higher on the function slot than on the scene role slot, which implies that the former is an easier task than the latter. This is expected considering the definition of construal: the *function* of an adposition is more lexical and less context-dependent, whereas the *role* depends on the context (the scene) and can be highly idiomatic (§3.3).

The supersense hierarchy allows us to analyze agreement at different levels of granularity (rows

[10]All told, 41 supersenses are attested as both role and function for the same token, and there are 136 unique construal combinations where the role differs from the function. Only four supersenses are never found in such a divergent construal: EXPLANATION, SPECIES, STARTTIME, RATEUNIT. Except for RATEUNIT which occurs only 5 times, their narrow use does not arise because they are rare. EXPLANATION, for example, occurs over 100 times, more than many labels which often appear in construal.

[11]See table 7 in appendix A for a more detailed description of the annotators' backgrounds and pairwise IAA results.

[12]Average of pairwise Cohen's κ is 0.733 and 0.799 on, respectively, role and function, suggesting strong agreement. However, it is worth noting that annotators selected labels from a ranked list, with the ranking determined by preposition type. The model of chance agreement underlying κ does not take the identity of the preposition into account, and thus likely underestimates the probability of chance agreement.

2–4 in table 3; see also confusion matrix in supplement). Coarser-grained analyses naturally give better agreement, with depth-1 coarsening into only 3 categories. Results show that most confusions are local with respect to the hierarchy.

6 Disambiguation Systems

We now describe systems that identify and disambiguate SNACS-annotated prepositions and possessives in two steps. Target identification heuristics (§6.2) first determine which tokens (single-word or multiword) should receive a SNACS supersense. A supervised classifier then predicts a supersense analysis for each identified target. The research objectives are (a) to study the ability of statistical models to learn roles and functions of prepositions and possessives, and (b) to compare two different modeling strategies (feature-rich and neural), and the impact of syntactic parsing.

6.1 Experimental Setup

Our experiments use the reviews corpus described in §4. We adopt the official training/development/ test splits of the Universal Dependencies (UD) project; their sizes are presented in table 1. All systems are trained on the training set only and evaluated on the test set; the development set was used for tuning hyperparameters. Gold tokenization was used throughout. Only targets with a semantic supersense analysis involving labels from figure 2 were included in training and evaluation—i.e., tokens with special labels (see §4) were excluded.

To test the impact of automatic syntactic parsing, models in the **auto syntax** condition were trained and evaluated on automatic lemmas, POS tags, and Basic Universal Dependencies (according to the v1 standard) produced by Stanford CoreNLP version 3.8.0 (Manning et al., 2014).[13] Named entity tags from the default 12-class CoreNLP model were used in all conditions.

6.2 Target Identification

§3.1 explains that the categories in our scheme apply not only to (transitive) adpositions in a very narrow definition of the term, but also to lexical items that traditionally belong to variety of syntactic classes (such as adverbs and particles), as well as possessive case markers and multiword expressions. 61.2% of the units annotated in our corpus are adpositions according to gold POS annotation, 20.2% are possessives, and 18.6% belong to other POS classes. Furthermore, 14.1% of tokens labeled as adpositions or possessives are not annotated because they are part of a multiword expression (MWE). It is therefore neither obvious nor trivial to decide which tokens and groups of tokens should be selected as targets for SNACS annotation.

To facilitate both manual annotation and automatic classification, we developed heuristics for identifying annotation targets. The algorithm first scans the sentence for known multiword expressions, using a blacklist of non-prepositional MWEs that contain preposition tokens (e.g., *take_care_of*) and a whitelist of prepositional MWEs (multiword prepositions like **out_of** and PP idioms like **in_town**). Both lists were constructed from the training data. From segments unaffected by the MWE heuristics, single-word candidates are identified by matching a high-recall set of parts of speech, then filtered through 5 different heuristics for adpositions, possessives, subordinating conjunctions, adverbs, and infinitivals. Most of these filters are based on lexical lists learned from the training portion of the STREUSLE corpus, but there are some specific rules for infinitivals that handle *for*-subjects (*I opened the door for Steve* **to** *take out the trash*—**to**, but not *for*, should receive a supersense) and comparative constructions with *too* and *enough* (*too short* **to** *ride*).

6.3 Classification

The next step of disambiguation is predicting the role and function labels. We explore two different modeling strategies.

Feature-rich Model. Our first model is based on the features for preposition relation classification developed by Srikumar and Roth (2013), which were themselves extended from the preposition sense disambiguation features of Hovy et al. (2010). We briefly describe the feature set here, and refer the reader to the original work for further details. At a high level, it consists of features extracted from selected neighboring words in the dependency tree (i.e., heuristically identified governor and object) and in the sentence (previous verb, noun and adjective, and next noun). In addition, all these features are also conjoined with the lemma of the rightmost word in the preposition token to capture

[13]The CoreNLP parser was trained on all 5 genres of the English Web Treebank—i.e., a superset of our training set. Gold syntax follows the UDv2 standard, whereas the classifiers in the auto syntax conditions are trained and tested with UDv1 parses produced by CoreNLP.

target-specific interactions with the labels. The features extracted from each neighboring word are listed in the supplementary material.

Using these features extracted from targets, we trained two multi-class SVM classifiers to predict the role and function labels using the LIBLINEAR library (Fan et al., 2008).

Neural Model. Our second classifier is a multi-layer perceptron (MLP) stacked on top of a BiLSTM. For every sentence, tokens are first embedded using a concatenation of fixed pre-trained word2vec (Mikolov et al., 2013) embeddings of the word and the lemma, and an internal embedding vector, which is updated during training.[14] Token embeddings are then fed into a 2-layer BiLSTM encoder, yielding a list of token representations.

For each identified target unit *u*, we extract its first token, and its governor and object headword. For each of these tokens, we construct a feature vector by concatenating its token representation with embeddings of its (1) language-specific POS tag, (2) UD dependency label, and (3) NER label. We additionally concatenate embeddings of *u*'s lexical category, a syntactic label indicating whether *u* is predicative/stranded/subordinating/none of these, and an indicator of whether either of the two tokens following the unit is capitalized. All these embeddings, as well as internal token embedding vectors, are considered part of the model parameters and are initialized randomly using the Xavier initialization (Glorot and Bengio, 2010). A NONE label is used when the corresponding feature is not given, both in training and at test time. The concatenated feature vector for *u* is fed into two separate 2-layered MLPs, followed by a separate softmax layer that yields the predicted probabilities for the role and function labels.

We tuned hyperparameters on the development set to maximize F-score (see supplementary material). We used the cross-entropy loss function, optimizing with simple gradient ascent for 80 epochs with minibatches of size 20. Inverted dropout was used during training. The model is implemented with the DyNet library (Neubig et al., 2017).

The model architecture is largely comparable to that of Gonen and Goldberg (2016), who experimented with a coarsened version of STREUSLE 3.0. The main difference is their use of unlabeled multilingual datasets to improve prediction by exploiting the differences in preposition ambiguities across languages.

[14] Word2vec is pre-trained on the Google News corpus. Zero vectors are used where vectors are not available.

Syntax	P	R	F
gold	88.8	89.6	89.2
auto	86.0	85.8	85.9

Table 4: Target identification results for disambiguation.

6.4 Results & Analysis

Following the two-stage disambiguation pipeline (i.e. target identification and classification), we separate the evaluation across the phases. Table 4 reports the precision, recall, and F-score (P/R/F) of the target identification heuristics. Table 5 reports the disambiguation performance of both classifiers with gold (left) and automatic target identification (right). We evaluate each classifier along three dimensions—role and function independently, and full (i.e. both role and function together). When we have the gold targets, we only report accuracy because precision and recall are equal. With automatically identified targets, we report P/R/F for each dimension. Both tables show the impact of syntactic parsing on quality. The rest of this section presents analyses of the results along various axes.

Target identification. The identification heuristics described in §6.2 achieve an F_1 score of 89.2% on the test set using gold syntax.[15] Most false positives (47/54=87%) can be ascribed to tokens that are part of a (non-adpositional or larger adpositional) multiword expression. 9 of the 50 false negatives (18%) are rare multiword expressions not occurring in the training data and there are 7 partially identified ones, which are counted as both false positives and false negatives.

Automatically generated parse trees slightly decrease quality (table 4). Target identification, being the first step in the pipeline, imposes an upper bound on disambiguation scores. We observe this degradation when we compare the Gold ID and the Auto ID blocks of table 5, where automatically identified targets decrease F-score by about 10 points in all settings.[16]

Classification. Along with the statistical classifier results in table 5, we also report performance

[15] Our evaluation script counts tokens that received special labels in the gold standard (see §4) as negative examples of SNACS targets, with the exception of the tokens labeled as unintelligible/nonnative/etc., which are not counted toward or against target ID performance.

[16] A variant of the target ID module, optimized for recall, is used as preprocessing for the agreement study discussed in §5. With this setting, the heuristic achieves an F_1 score of 90.2% (P=85.3%, R=95.6%) on the test set.

		Gold ID			Auto ID								
		Role	*Func.*	*Full*	*Role*			*Func.*			*Full*		
	Syntax	Acc.	Acc.	Acc.	P	R	F	P	R	F	P	R	F
Most frequent	N/A	40.6	53.3	37.9	37.0	37.3	37.1	49.8	50.2	50.0	34.3	34.6	34.4
Neural	gold	71.7	82.5	67.5	62.0	62.5	62.2	73.1	73.8	73.4	58.7	59.2	58.9
Feature-rich	gold	73.5	81.0	70.0	62.0	62.5	62.2	70.7	71.2	71.0	59.3	59.8	59.5
Neural	auto	67.7	78.5	64.4	56.4	56.2	56.3	66.8	66.7	66.7	53.7	53.5	53.6
Feature-rich	auto	67.9	79.4	65.2	58.2	58.1	58.2	66.8	66.7	66.7	55.7	55.6	55.7

Table 5: Overall performance of SNACS disambiguation systems on the test set. Results are reported for the role supersense (*Role*), the function supersense (*Func.*), and their conjunction (*Full*). All figures are percentages. *Left:* Accuracies with gold standard target identification (480 targets). *Right:* Precision, recall, and F_1 with automatic target identification (§6.2 and table 4).

for the most frequent baseline, which selects the most frequent role–function label pair given the (gold) lemma according to the training data. Note that all learned classifiers, across all settings, outperform the most frequent baseline for both role and function prediction. The feature-rich and the neural models perform roughly equivalently despite the significantly different modeling strategies.

Function and scene role performance. Function prediction is consistently more accurate than role prediction, with roughly a 10-point gap across all systems. This mirrors a similar effect in the interannotator agreement scores (see §5), and may be due to the reduced ambiguity of functions compared to roles (as attested by the baseline's higher accuracy for functions than roles), and by the more literal nature of function labels, as opposed to role labels that often require more context to determine.

Impact of automatic syntax. Automatic syntactic analysis decreases scores by 4 to 7 points, most likely due to parsing errors which affect the identification of the preposition's object and governor. In the auto ID/auto syntax condition, the worse target ID performance with automatic parses (noted above) contributes to lower classification scores.

6.5 Errors & Confusions

We can use the structure of the SNACS hierarchy to probe classifier performance. As with the interannotator study, we evaluate the accuracy of predicted labels when they are coarsened post hoc by moving up the hierarchy to a specific depth. Table 6 shows this for the feature-rich classifier for different depths, with depth-1 representing the coarsening of the labels into the 3 root labels. Depth-4 (Exact) represents the full results in table 5. These results show that the classifiers often mistake a label for another that is nearby in the hierarchy. Examining the most frequent confusions of both models, we observe that LOCUS is overpredicted

	Labels	Role	Function
Exact	47	67.9%	79.4%
Depth-3	43	67.9%	79.6%
Depth-2	26	76.2%	86.2%
Depth-1	3	86.0%	93.8%

Table 6: Accuracy of the feature-rich model (gold identification and syntax) on the test set (480 tokens) with different levels of hierarchy coarsening of its output. "Labels" refers to the number of labels in the training set after coarsening.

(which makes sense as it is most frequent overall), and SOCIALROLE–ORGROLE and GESTALT–POSSESSOR are often confused (they are close in the hierarchy: one inherits from the other).

7 Conclusion

This paper introduced a new approach to comprehensive analysis of the semantics of prepositions and possessives in English, backed by a thoroughly documented hierarchy and annotated corpus. We found good interannotator agreement and provided initial supervised disambiguation results. We expect that future work will develop methods to scale the annotation process beyond requiring highly trained experts; bring this scheme to bear on other languages; and investigate the relationship of our scheme to more structured semantic representations, which could lead to more robust models. Our guidelines, corpus, and software are available at `https://github.com/nert-gu/streusle/blob/master/ACL2018.md`.

Abstract

We present a corpus of 5,000 richly annotated abstracts of medical articles describing clinical randomized controlled trials. Annotations include demarcations of text spans that describe the Patient population enrolled, the Interventions studied and to what they were Compared, and the Outcomes measured (the 'PICO' elements). These spans are further annotated at a more granular level, e.g., individual interventions within them are marked and mapped onto a structured medical vocabulary. We acquired annotations from a diverse set of workers with varying levels of expertise and cost. We describe our data collection process and the corpus itself in detail. We then outline a set of challenging NLP tasks that would aid searching of the medical literature and the practice of evidence-based medicine.

1 Introduction

In 2015 alone, about 100 manuscripts describing randomized controlled trials (RCTs) for medical interventions were published *every day*. It is thus practically impossible for physicians to know which is the best medical intervention for a given patient group and condition (Borah et al., 2017; Fraser and Dunstan, 2010; Bastian et al., 2010). This inability to easily search and organize the published literature impedes the aims of *evidence based medicine* (EBM), which aspires to inform patient care using the totality of relevant evidence. Computational methods could expedite biomedical evidence synthesis (Tsafnat et al., 2013; Wallace et al., 2013) and natural language processing (NLP) in particular can play a key role in the task.

Prior work has explored the use of NLP methods to automate biomedical evidence extraction and synthesis (Boudin et al., 2010; Marshall et al., 2017; Ferracane et al., 2016; Verbeke et al., 2012).[1] But the area has attracted less attention than it might from the NLP community, due primarily to a dearth of publicly available, annotated corpora with which to train and evaluate models.

Here we address this gap by introducing *EBM-NLP*, a new corpus to power NLP models in support of EBM. The corpus, accompanying documentation, baseline model implementations for the proposed tasks, and all code are publicly available.[2] EBM-NLP comprises ∼5,000 medical abstracts describing clinical trials, multiply annotated in detail with respect to characteristics of the underlying trial Populations (e.g., *diabetics*), Interventions (*insulin*), Comparators (*placebo*) and Outcomes (*blood glucose levels*). Collectively, these key informational pieces are referred to as PICO elements; they form the basis for well-formed clinical questions (Huang et al., 2006).

We adopt a hybrid crowdsourced labeling strategy using heterogeneous annotators with varying expertise and cost, from laypersons to MDs. Annotators were first tasked with marking text spans that described the respective PICO elements. Identified spans were subsequently anno-

[*] now at Google Inc.

[1] There is even, perhaps inevitably, a systematic review of such approaches (Jonnalagadda et al., 2015).

[2] http://www.ccs.neu.edu/home/bennye/EBM-NLP

tated in greater detail: this entailed finer-grained labeling of PICO elements and mapping these onto a normalized vocabulary, and indicating redundancy in the mentions of PICO elements.

In addition, we outline several NLP tasks that would directly support the practice of EBM and that may be explored using the introduced resource. We present baseline models and associated results for these tasks.

2 Related Work

We briefly review two lines of research relevant to the current effort: work on NLP to facilitate EBM, and research in crowdsourcing for NLP.

2.1 NLP for EBM

Prior work on NLP for EBM has been limited by the availability of only small corpora, which have typically provided on the order of a couple hundred annotated abstracts or articles for very complex information extraction tasks. For example, the ExaCT system (Kiritchenko et al., 2010) applies rules to extract 21 aspects of the reported trial. It was developed and validated on a dataset of 182 marked full-text articles. The ACRES system (Summerscales et al., 2011) produces summaries of several trial characteristic, and was trained on 263 annotated abstracts. Hinting at more challenging tasks that can build upon foundational information extraction, Alamri and Stevenson (2015) developed methods for detecting contradictory claims in biomedical papers. Their corpus of annotated claims contains 259 sentences (Alamri and Stevenson, 2016).

Larger corpora for EBM tasks have been derived using (noisy) automated annotation approaches. This approach has been used to build, e.g., datasets to facilitate work on Information Retrieval (IR) models for biomedical texts (Scells et al., 2017; Chung, 2009; Boudin et al., 2010). Similar approaches have been used to 'distantly supervise' annotation of full-text articles describing clinical trials (Wallace et al., 2016). In contrast to the corpora discussed above, these automatically derived datasets tend to be relatively large, but they include only shallow annotations.

Other work attempts to bypass basic extraction tasks and address more complex biomedical QA and (multi-document) summarization problems to support EBM (Demner-Fushman and Lin, 2007; Mollá and Santiago-Martinez, 2011; Abacha and Zweigenbaum, 2015). Such systems would directly benefit from more accurate extraction of the types codified in the corpus we present here.

2.2 Crowdsourcing

Crowdsourcing, which we here define operationally as the use of distributed lay annotators, has shown encouraging results in NLP (Novotney and Callison-Burch, 2010; Sabou et al., 2012). Such annotations are typically imperfect, but methods that aggregate redundant annotations can mitigate this problem (Dalvi et al., 2013; Hovy et al., 2014; Nguyen et al., 2017).

Medical articles contain relatively technical content, which intuitively may be difficult for persons without domain expertise to annotate. However, recent promising preliminary work has found that crowdsourced approaches can yield surprisingly high-quality annotations in the domain of EBM specifically (Mortensen et al., 2017; Thomas et al., 2017; Wallace et al., 2017).

3 Data Collection

PubMed provides access to the MEDLINE database[3] which indexes titles, abstracts and metadata for articles from selected medical journals dating back to the 1970s. MEDLINE indexes over 24 million abstracts; the majority of these have been manually assigned metadata which we used to retrieved a set of 5,000 articles describing RCTs with an emphasis on cardiovascular diseases, cancer, and autism. These particular topics were selected to cover a range of common conditions.

We decomposed the annotation process into two steps, performed in sequence. First, we acquired labels demarcating spans in the text describing the clinically salient abstract elements mentioned above: the trial Population, the Interventions and Comparators studied, and the Outcomes measured. We collapse Interventions and Comparators into a single category (I). In the second annotation step, we tasked workers with providing more granular (sub-span) annotations on these spans.

For each PIO element, all abstracts were annotated with the following four types of information.

1. **Spans** exhaustive marking of text spans containing information relevant to the respective PIO categories (Stage 1 annotation).

2. **Hierarchical labels** assignment of more specific labels to subsequences comprising the marked relevant spans (Stage 2 annotation).

3. **Repetition** grouping of labeled tokens to indicate repeated occurrences of the same information (Stage 2 annotation).

4. **MeSH terms** assignment of the metadata MeSH terms associated with the abstract to labeled subsequences (Stage 2 annotation).[4]

We collected annotations for each P, I and O element individually to avoid the cognitive load imposed by switching between label sets, and to reduce the amount of instruction required to begin the task. All annotation was performed using a modified version of the Brat Rapid Annotation Tool (BRAT) (Stenetorp et al., 2012). We include all annotation instructions provided to workers for all tasks in the Appendix.

3.1 Non-Expert (Layperson) Workers

For large scale crowdsourcing via recruitment of layperson annotators, we used Amazon Mechanical Turk (AMT). All workers were required to have an overall job approval rate of at least 90%. Each job presented to the workers required the annotation of three randomly selected abstracts from our pool of documents. As we received initial results, we blocked workers who were clearly not following instructions, and we actively recruited the best workers to continue working on our task at a higher pay rate.

We began by collecting the least technical annotations, moving on to more difficult tasks only after restricting our pool of workers to those with a demonstrated aptitude for the jobs. We obtained annotations from ≥ 3 different workers for each of the 5,000 abstracts to enable robust inference of reliable labels from noisy data. After performing filtering passes to remove non-RCT documents or those missing relevant data for the second annotation task, we are left with between 4,000 and 5,000 sets of annotations for each PIO element after the second phase of annotation.

3.2 Expert Workers

To supplement our larger-scale data collection via AMT, we collected annotations for 200 abstracts for each PIO element from workers with advanced medical training. The idea is for these to serve as reference annotations, i.e., a test set with which to evaluate developed NLP systems. We plan to enlarge this test set in the near future, at which point we will update the website accordingly.

For the initial span labeling task, two medical students from the University of Pennsylvania and Drexel University provided the reference labels. In addition, for both stages of annotation and for the detailed subspan annotation in Stage 2, we hired three medical professionals via Upwork,[5] an online platform for hiring skilled freelancers. After reviewing several dozen suggested profiles, we selected three workers that had the following characteristics: Advanced medical training (the majority of hired workers were Medical Doc-

[4]MeSH is a controlled, structured medical vocabulary maintained by the National Library of Medicine.

[5]http://www.upwork.com

tors, the one exception being a fourth-year medical student); Strong technical reading and writing skills; And an interest in medical research. In addition to providing high-quality annotations, individuals hired via Upwork also provided feedback regarding the instructions to help make the task as clear as possible for the AMT workers.

4 The Corpus

We now present corpus details, paying special attention to worker performance and agreement. We discuss and present statistics for acquired annotations on spans, tokens, repetition and MeSH terms in Sections 4.1, 4.2, 4.3, and 4.4, respectively.

4.1 Spans

For each P, I and O element, workers were asked to read the abstract and highlight all spans of text including any pertinent information. Annotations for 5,000 articles were collected from a total of 579 AMT workers across the three annotation types, and expert annotations were collected for 200 articles from two medical students.

We first evaluate the quality of the annotations by calculating token-wise label agreement between the expert annotators; this is reported in Table 2. Due to the difficulty and technicality of the material, agreement between even well-trained domain experts is imperfect. The effect is magnified by the unreliability of AMT workers, motivating our strategy of collecting several noisy annotations and aggregating over them to produce a single cleaner annotation. We tested three different aggregation strategies: a simple majority vote, the Dawid-Skene model (Dawid and Skene, 1979) which estimates worker reliability, and HMM-Crowd, a recent extension to Dawid-Skene that includes a HMM component, thus explicitly leveraging the sequential structure of contiguous spans of words (Nguyen et al., 2017).

For each aggregation strategy, we compute the token-wise precision and recall of the output labels against the unioned expert labels. As shown in Table 3, the HMMCrowd model afforded modest improvement in F-1 scores over the standard Dawid-Skene model, and was thus used to generate the inputs for the second annotation phase.

The limited overlap in the document subsets annotated by any given pair of workers, and wide variation in the number of annotations per worker make interpretation of standard agreement statistics tricky. We quantify the centrality of the AMT span annotations by calculating token-wise precision and recall for each annotation against the aggregated version of the labels (Table 4).

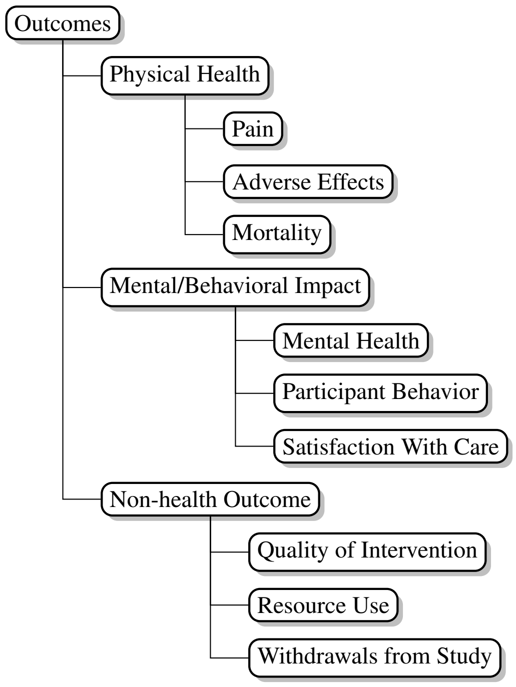

Figure 2: Outcome task label hierarchy

When comparing the average precision and recall for individual crowdworkers against the aggregated labels in Table 4, scores are poor showing very low agreement between the workers. Despite this, the aggregated labels compare favorably against the expert labels. This further supports the intuition that it is feasible to collect multiple low-quality annotations for a document and synthesize them to extract the signal from the noise.

On the dataset website, we provide a variant of the corpus that includes all individual worker span annotations (e.g., for researchers interested in crowd annotation aggregated methods), and also a version with pre-aggregated annotations for convenience.

4.2 Hierarchical Labels

For each P, I, and O category we developed a hierarchy of labels intended to capture important sub categories within these. Our labels are aligned to (and thus compatible with) the concepts codified by the Medical Subject Headings (MeSH) vocabulary of medical terms maintained by the National Library of Medicine (NLM).[6] In consulta-

tion with domain experts, we selected subsets of MeSH terms for each PIO category that captured relatively precise information without being overwhelming. For illustration, we show the outcomes label hierarchy we used in Figure 2. We reproduce the label hierarchies used for all PIO categories in the Appendix.

At this stage, workers were presented with abstracts in which relevant spans were highlighted, based on the annotations collected in the first annotation phase (and aggregated via the HMM-Crowd model). This two-step approach served dual purposes: (i) increasing the rate at which workers could complete tasks, and (ii) improving recall by directing workers to all areas in abstracts where they might find the structured information of interest. Our choice of a high recall aggregation strategy for the starting spans ensured that the large majority of relevant sections of the article were available as inputs to this task.

The three trained medical personnel hired via Upwork each annotated 200 documents and reported that spans sufficiently captured the target information. These domain experts received feedback and additional training after labeling an initial round of documents, and all annotations were reviewed for compliance. The average inter-annotator agreement is reported in Table 6.

	Agreement
Participants	0.50
Interventions	0.59
Outcomes	0.51

Table 6: Average pair-wise Cohen's κ between three medical experts for the 200 reference documents.

With respect to crowdsourcing on AMT, the task for Participants was published first, allowing us to target higher quality workers for the more technical Interventions and Outcomes annotations. We retained labels from 118 workers for Participants, the top 67 of whom were invited to continue on to the following tasks. Of these, 37 continued to contribute to the project. Several workers provided $\geq$ 1,000 annotations and continued to work on the task over a period of several months.

To produce final per-token labels, we again turned to aggregation. The subspans annotated in this second pass were by construction shorter than the starting spans, and (perhaps as a result) informal experiments revealed little benefit from HMMCrowd's sequential modeling aspect. The introduction of many label types significantly increased the complexity of the task, resulting in both lower expert inter-annotator agreement (Table 6 and decreased performance when comparing the crowdsourced labels against those of the experts (Table 7.

Participants	Precision	Recall	F-1
Majority Vote	0.46	0.58	0.51
Dawid Skene	0.66	0.60	0.63

Dawid Skene	0.73	0.80	0.76

Table 7: Precision, recall, and F-1 for AMT labels against expert labels using different aggregation strategies.

Most observed token-level disagreements (and errors, with respect to reference annotations) involve differences in the span lengths demarcated by individuals. For example, many abstracts contain an information-dense description of the patient population, focusing on their medical condition but also including information about their sex and/or age. Workers would also sometimes fail

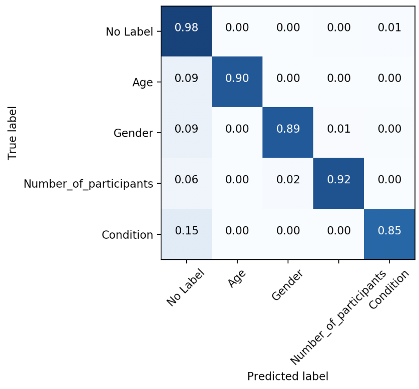

Figure 3: Confusion matrix for token-level labels provided by experts.

to capture repeated mentions of the same information, producing Type 2 errors more frequently than Type 1. This tendency can be seen in the overall token-level confusion matrix for AMT workers on the Participants task, shown in Figure 3.

In a similar though more benign category of error, workers differed in the amount of context they included surrounding each subspan. Although the instructions asked workers to highlight minimal subspans, there was variance in what workers considered relevant.

	Precision	Recall	F-1
Participants	0.39	0.71	0.50
Interventions	0.59	0.60	0.60
Outcomes	0.70	0.68	0.69

Table 8: Statistics for individual AMT annotations evaluated against the aggregated versions, macro-averaged over different labels.

For the same reasons mentioned above (little pairwise overlap in annotations, high variance with respect to annotations per worker), quantifying agreement between AMT workers is again difficult using traditional measures. We thus again take as a measure of agreement the precision, recall, and F-1 of the individual annotations against the aggregated labels and present the results in Table 8.

4.3 Repetition

Medical abstracts often mention the same information in multiple places. In particular, interventions and outcomes are typically described at the beginning of an abstract when introducing the purpose of the underlying study, and then again when discussing methods and results. It is important to

	Span frequency

Table 10: Comparison against the majority vote for span-level repetition labels.

be able to differentiate between novel and reiterated information, especially in cases such as complex interventions, distinct measured outcomes, or multi-armed trials. Merely identifying all occurrences of, for example, a pharmacological intervention leaves ambiguity as to how many distinct interventions were applied.

Workers identified repeated information as follows. After completing detailed labeling of abstract spans, they were asked to group together subspans that were instances of the same information (for example, redundant mentions of a particular drug evaluated as one of the interventions in the trial). This process produces labels for repetition between short spans of tokens. Due to the differences in the lengths of annotated subspans discussed in the preceding section, the labels are not naturally comparable between workers without directly modeling the entities contained in each subspan. The labels assigned by workers produce repetition labels between sets of tokens but a more sophisticated notion of co-reference is required to identify which tokens correctly represent the entity contained in the span, and which tokens are superfluous noise.

As a proxy for formally enumerating these entities, we observe that a large majority of starting spans only contain a single target relevant to the subspan labeling task, and so identifying repetition between the starting spans is sufficient. For example, consider the starting intervention span *”underwent conventional total knee arthroplasty”*; there is only one intervention in the span but some annotators assigned the SURGICAL label to all five tokens while others opted for only *”total knee arthroplasty.”* By analyzing repetition at the level of the starting spans, we can compute agreement without concern for the confounds of slight misalignments or differences in length of the subspans.

Overall agreement between AMT workers for span-level repetition, measured by computing precision and recall against the majority vote for each pair of spans, is reported in Table 10.

4.4 MeSH Terms

The National Library of Medicine maintains an extensive hierarchical ontology of medical concepts called Medical Subject Headings (MeSH terms); this is part of the overarching Metathesaurus of the Unified Medical Language System (UMLS). Personnel at the NLM manually assign citations (article titles, abstracts and meta-data) indexed in MEDLINE relevant MeSH terms. These terms have been used extensively to evaluate the content of articles, and are frequently used to facilitate document retrieval (Lu et al., 2009; Lowe and Barnett, 1994).

In the case of randomized controlled trials, MeSH terms provide structured information regarding key aspects of the underlying studies, ranging from participant demographics to methodologies to co-morbidities. A drawback to these annotations, however, is that they are applied at the document (rather than snippet or token) level. To capture where MeSH terms are instantiated within a given abstract text, we provided a list of all terms associated with said article and instructed workers to select the subset of these that applied to each set of token labels that they annotated.

MeSH terms are domain specific and many re-

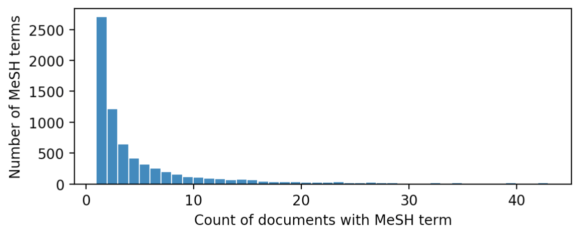

Figure 4: Histogram of the number of documents containing each MeSH term.

Inst. Freq	10%	25%	50%
Participants	65	24	7
Interventions	106	68	32
Outcomes	118	108	75

Table 11: The number of common MeSH terms (out of 135) that were assigned to a span of text in at least 10%, 25%, and 50% of the possible documents.

quire a medical background to understand, thus rendering this facet of the annotation process particularly difficult for untrained (lay) workers. Perhaps surprisingly, several AMT workers voluntarily mentioned relevant background training; our pool of workers included (self-identified) nurses and other trained medical professionals. A few workers with such training stated this background as a reason for their interest in our tasks.

The technical specificity of the more obscure MeSH terms is also exacerbated by their sparsity. Of the 6,963 unique MeSH terms occurring in our set of abstracts, 87% of them are only found in 10 documents or fewer and only 2.0% occur in at least 1% of the total documents. The full distribution of document frequency for MeSH terms is show in Figure 4.

To evaluate how often salient MeSH terms were instantiated in the text by annotators we consider only the 135 MeSH terms that occur in at least 1% of abstracts (we list these in the supplementary material). For each term, we calculate its ”instantiation frequency” as the percentage of abstracts containing the term in which at least one annotator assigned it to a span of text. The total numbers of MeSH terms with an instantiation rate above different thresholds for the respective PIO elements are shown in Table 11.

5 Tasks & Baselines

We outline a few NLP tasks that are central to the aim of processing medical literature generally and to aiding practitioners of EBM specifically. First, we consider the task of identifying spans in abstracts that describe the respective PICO elements (Section 5.1). This would, e.g., improve medical literature search and retrieval systems. Next, we outline the problem of extracting structured information from abstracts (Section 5.2). Such models would further aid search, and might eventually facilitate automated knowledge-base construction for the clinical trials literature. Furthermore, automatic extraction of structured data would enable automation of the manual evidence synthesis process (Marshall et al., 2017).

Finally, we consider the challenging task of identifying redundant mentions of the same PICO element (Section 5.3). This happens, e.g., when an intervention is mentioned by the authors repeatedly in an abstract, potentially with different terms. Achieving such disambiguation is important for systems aiming to induce structured representations of trials and their results, as this would require recognizing and normalizing the unique interventions and outcomes studied in a trial.

For each of these tasks we present baseline models and corresponding results. Note that we have pre-defined train, development and test sets across PIO elements for this corpus, comprising 4300, 500 and 200 abstracts, respectively. The latter set is annotated by domain experts (i.e., persons with medical training). These splits will, of course, be distributed along with the dataset to facilitate model comparisons.

5.1 Identifying P, I and O Spans

We consider two baseline models: a linear Conditional Random Field (CRF) (Lafferty et al., 2001) and a Long Short-Term Memory (LSTM) neural tagging model, an LSTM-CRF (Lample et al., 2016; Ma and Hovy, 2016). In both models, we treat tokens as being either Inside (I) or Outside (O) of spans.

For the CRF, features include: indicators for the current, previous and next words; part of speech tags inferred using the Stanford CoreNLP tagger (Manning et al., 2014); and character information, e.g., whether a token contains digits, uppercase letters, symbols and so on.

For the neural model, the model induces features via a bi-directional LSTM that consumes distributed vector representations of input tokens sequentially. The bi-LSTM yields a hidden vector at

CRF	Precision	Recall	F-1
Participants	0.55	0.51	0.53
Interventions	0.65	0.21	0.32
Outcomes	0.83	0.17	0.29
LSTM-CRF	Precision	Recall	F-1
Participants	0.78	0.66	0.71
Interventions	0.61	0.70	0.65
Outcomes	0.69	0.58	0.63

Table 12: Baseline models (on the test set) for the PIO span tagging task.

LogReg	Precision	Recall	F-1
Participants	0.41	0.20	0.26
Interventions	0.79	0.44	0.57
Outcomes	0.24	0.21	0.22
CRF	Precision	Recall	F-1
Participants	0.41	0.25	0.31
Interventions	0.59	0.15	0.21
Outcomes	0.60	0.51	0.55

Table 13: Baseline models for the token-level, detailed labeling task.

each token index, which is then passed to a CRF layer for prediction. We also exploit character-level information by passing a bi-LSTM over the characters comprising each word (Lample et al., 2016); these are appended to the word embedding representations before being passed through the bi-LSTM.

5.2 Extracting Structured Information

Beyond identifying the spans of text containing information pertinent to each of the PIO elements, we consider the task of predicting which of the detailed labels occur in each span, and where they are located. Specifically, we begin with the starting spans and predict a single label from the corresponding PIO hierarchy for each token, evaluating against the test set of 200 documents. Initial experiments with neural models proved unfruitful but bear further investigation.

For the CRF model we include the same features as in the previous model, supplemented with additional features encoding if the adjacent tokens include any parenthesis or mathematical operators (specifically: $\%, +, -$). For the logistic regression model, we use a one-vs-rest approach. Features include token n-grams, part of speech indicators, and the same character-level information as in the CRF model.

5.3 Detecting Repetition

To formalize repetition, we consider every pair of starting PIO spans from each abstract, and assign

	Precision	Recall	F-1
Participants	0.39	0.52	0.44
Interventions	0.41	0.50	0.45
Outcomes	0.10	0.16	0.12

Table 14: Baseline model for predicting whether pairs of spans contain redundant information.

binary labels that indicate whether they share at least one instance of the same information. Although this makes prediction easier for long and information-dense spans, a large enough majority of the spans contain only a single instance of relevant information that the task serves as a reasonable baseline. Again, the model is trained on the aggregated labels collected from AMT and evaluated against the high-quality test set.

We train a logistic regression model that operates over standard features, including bag-of-words representations and sentence-level features such as length and position in the document. All baseline model implementations are available on the corpus website.

6 Conclusions

We have presented EBM-NLP: a new, publicly available corpus comprising 5,000 richly annotated abstracts of articles describing clinical randomized controlled trials. This dataset fills a need for larger scale corpora to facilitate research on NLP methods for processing the biomedical literature, which have the potential to aid the conduct of EBM. The need for such technologies will only become more pressing as the literature continues its torrential growth.

The EBM-NLP corpus, accompanying documentation, code for working with the data, and baseline models presented in this work are all publicly available at: `http://www.ccs.neu.edu/home/bennye/EBM-NLP`.

Efficient Online Scalar Annotation with Bounded Support

Keisuke Sakaguchi and **Benjamin Van Durme**
Johns Hopkins University
{keisuke,vandurme}@cs.jhu.edu

Abstract

We describe a novel method for efficiently eliciting scalar annotations for dataset construction and system quality estimation by human judgments. We contrast direct assessment (annotators assign scores to items directly), online pairwise ranking aggregation (scores derive from annotator comparison of items), and a hybrid approach (EASL: **E**fficient **A**nnotation of **S**calar **L**abels) proposed here. Our proposal leads to increased correlation with ground truth, at far greater annotator efficiency, suggesting this strategy as an improved mechanism for dataset creation and manual system evaluation.

1 Introduction

We are concerned here with the construction of datasets and evaluation of systems within natural language processing (NLP). Specifically, humans providing responses that are used to derive graded values on natural language contexts, or in the ordering of systems corresponding to their perceived performance on some task.

Many NLP datasets involve eliciting from annotators some graded response. The most popular annotation scheme is the n-ary ordinal approach as illustrated in Figure 1(a). For example, text may be labeled for *sentiment* as *positive*, *neutral* or *negative* (Wiebe et al., 1999; Pang et al., 2002; Turney, 2002, inter alia); or under *political spectrum analysis* as *liberal*, *neutral*, or *conservative* (O'Connor et al., 2010; Bamman and Smith, 2015). A response may correspond to a likelihood judgment, e.g., how likely a predicate is factive (Lee et al., 2015), or that some natural language inference may hold (Zhang et al., 2017). Responses may correspond to a notion of semantic similarity, e.g., whether one word can be substituted for another in context (Pavlick et al., 2015), or whether an entire sentence is more or less similar than another (Marelli et al., 2014), and so on.

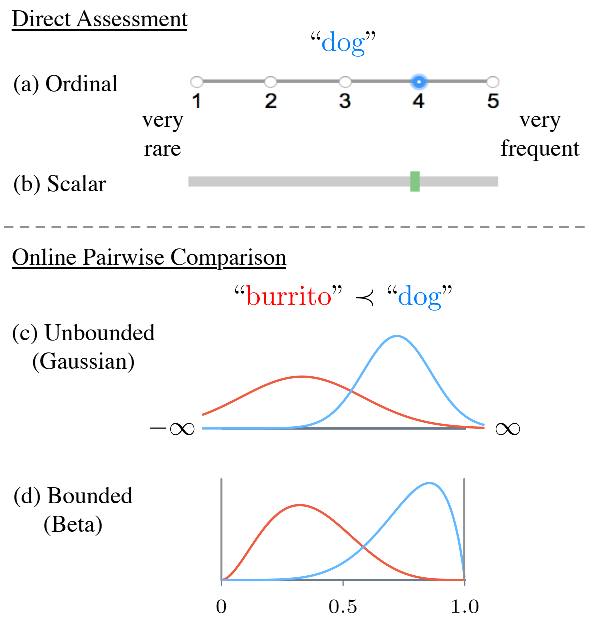

Figure 1: Elicitation strategies for graded response include direct assessment via ordinal or scalar judgments, and pairwise comparisons aggregated via an assumption of latent distributions such as Gaussians, or novel here: Beta distributions, providing bounded support. The example concerns subjective assessments of the lexical frequency of *dog*. In pairwise comparison, we assess it by comparison such as "burrito" is less frequent (≺) than "dog".

Less common in NLP are system comparisons based on direct human ratings, but an exception includes the annual shared task evaluations of the Conference on Machine Translation (WMT). There, MT practitioners submit system outputs based on a shared set of source sentences, which are then judged relative to other system outputs. Various aggregation strategies have been employed over the years to take these relative comparisons and derive competitive rankings between shared task entrants (Callison-Burch et al., 2012;

Bojar et al., 2013, 2014, 2015, 2016, 2017).

Inspired by prior work in MT system evaluation, we propose a procedure for eliciting graded responses that we demonstrate to be more efficient than prior work. While remaining applicable to system evaluation, our experimental results suggest our approach as a more general framework for a variety of future data creation tasks, allowing for higher quality data in less time and cost.

We consider three different approaches for scalar annotation: direct assessment (DA), online pairwise ranking aggregation (RA), and a hybrid method which we call EASL (**E**fficient **A**nnotation of **S**calar **L**abels).[1] DA scalar annotation, shown in Figure 1(b), directly annotates absolute judgments on some scale (e.g., 0 to 100), independently per item (§2). As an RA approach (§3), we start with conventional unbounded models, where each instance is parameterized as a Gaussian distribution, as shown in Figure 1(c). Since boundedness is essential for the scalar annotation we aim to model, we propose a bounded variant which parameterizes each instance by a beta distribution as illustrated in Figure 1(d). Finally, we propose EASL (§4) that combines benefits of DA and RA.

We illustrate the improvements enabled by our proposal on three example tasks (§5): lexical frequency inference, political spectrum inference and machine translation system ranking.[2] For example, we find that in the commonly employed condition of 3-way redundant annotation, our approach on multiple tasks gives similar quality with just 2-way redundancy: this translates to a potential 50% increase in dataset size for the same cost.

2 Direct Assessment

Direct assessment or direct annotation (DA) is a straightforward method for collecting graded response from annotators. The most popular scheme is n-ary ordinal labeling, as illustrated in Figure 1(a), where annotators are shown one instance (i.e., sample point) and asked to label one of the n-ary ordered classes.

According to the level of measurement in psychometrics (Stevens, 1946, inter alia), which classifies the numerals based on certain properties (e.g., identity, order, quantity), ordinal data do not allow for degree of difference. Namely, there is no guarantee that the distance between each label is equal, and instances in the same class are not discriminated. For example, in a typical five-level Likert scale (Likert, 1932) of likelihood – very unlikely, unlikely, unsure, likely, very likely – we cannot conclude that *very likely* instances are exactly twice as likely those marked *likely*, nor can we assume two instances with the same label have exactly the same likelihood.

The issue of distance between ordinals is perhaps obviated by using *scalar* annotations (i.e., *ratio scale* in Stevens's terminology), which directly correspond to continuous quantities (Figure 1(b)). In scalar DA,[3] each instance in the collection ($S_i \in S_1^N$) is annotated with values (e.g., on the range 0 to 100) often by several annotators. The notion of quantitative difference is enabled by the property of *absolute* zero: the scale is *bounded*. For example, distance, length, mass, size etc. are represented by this scale. In the annual shared task evaluation of the WMT, DA has been used for scoring adequacy and fluency of machine learning system outputs with human evaluation (Graham et al., 2013, 2014; Bojar et al., 2016, 2017), and has separately been used in creating datasets such as for factuality (Lee et al., 2015).

Why *perhaps* obviated? Because of two concerns: (1) annotators may not have a pre-existing, well-calibrated scale for performing DA on a particular collection according to a particular task;[4] and (2) it is known that people may be biased in their scalar estimates (Tversky and Kahneman, 1974). Regarding (1), this motivates us to consider RA on the intuition that annotators may give more calibrated responses when performed in the context of other elements. Regarding (2), our goal is not to correct for human bias, but simply to more efficiently converge to the same consensus judgments already being pursued by the community in their annotation protocols, biased or otherwise.[5]

3 Online Pairwise Ranking Aggregation

3.1 Unbounded Model

Pairwise ranking aggregation (Thurstone, 1927) is a method to obtain a total ranking on instances,

[1] Pronounced as "easel".

[2] We release the code at `http://decomp.net/`.

[3] In the rest of the paper, we take DA to mean *scalar* annotation rather than ordinals.

[4] E.g., try to imagine your level of calibration to a hypothetical task described as "On a scale of 1 to 100, label this tweet according to a conservative / liberal political spectrum."

[5] There has been a line of work on relative weighting of *annotators*, based on their agreement with others (Whitehill et al., 2009; Welinder et al., 2010; Hovy et al., 2013). In this paper, however, we do not perform such annotator weighting.

assuming that scalar value for each sample point follows a Gaussian distribution, $\mathcal{N}(\mu_i, \sigma^2)$. The parameters $\{\mu_i\}$ are interpreted as mean scalar annotation.[6]

Given the parameters, the probability that S_i is preferred ($\succ$) over S_j is defined as

$$p(S_i \succ S_j) = \Phi\left(\frac{\mu_i - \mu_j}{\sqrt{2}\sigma}\right), \tag{1}$$

where $\Phi(\cdot)$ is the cumulative distribution function of the standard normal distribution. The objective of pairwise ranking aggregation (including all the following models) is formulated as a maximum log-likelihood estimation:

$$\max_{\{S_1^N\}} \sum_{S_i, S_j \in \{S_1^N\}} \log p(S_i \succ S_j). \tag{2}$$

TrueSkill$^{\text{TM}}$ (Herbrich et al., 2006) extends the Thurstone model by applying a Bayesian online and active learning framework, allowing for ties. TrueSkill has been used in the Xbox Live online gaming community,[7] and has been applied for various NLP tasks, such as question difficulty estimation (Liu et al., 2013), ranking speech quality (Baumann, 2017), and ranking machine translation and grammatical error correction systems with human evaluation (Bojar et al., 2014, 2015; Sakaguchi et al., 2014, 2016)

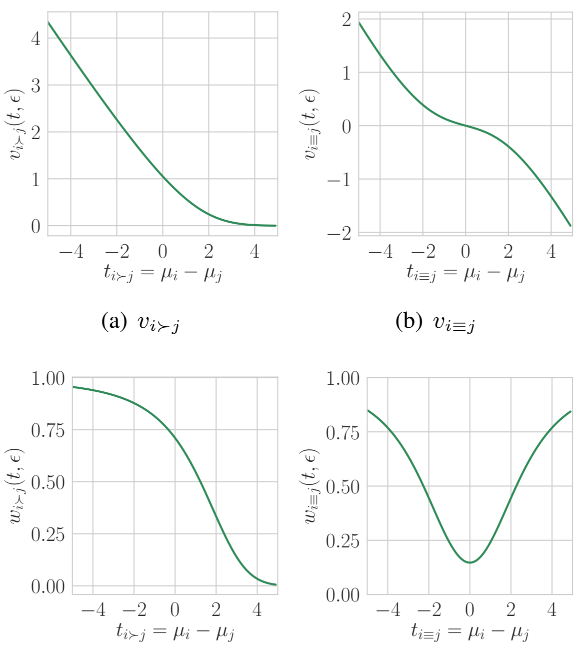
In the same way as the Thurstone model, TrueSkill assumes that scalar values for each instance S_i (i.e., skill level for each player in the context of TrueSkill) follow a Gaussian distribution $\mathcal{N}(\mu_i, \sigma_i^2)$, where σ_i is also parameterized as the *uncertainty* of the scalar value for each instance. Importantly, TrueSkill uses a Bayesian online learning scheme, and the parameters are *iteratively* updated after each observation of pairwise comparison (i.e., game result: win ($\succ$), tie ($\equiv$), or loss ($\prec$)) in proportion to how surprising the outcome is. Let $t_{i\succ j} = \mu_i - \mu_j$, the difference in scalar responses (skill levels) when we observe i wins j, and $\epsilon \geqslant 0$ be a parameter to specify the tie rate. The update functions are formulated as follows:

$$\mu_i = \mu_i + \frac{\sigma_i^2}{c} \cdot v\left(\frac{t}{c}, \frac{\epsilon}{c}\right) \tag{3}$$

$$\mu_j = \mu_j - \frac{\sigma_j^2}{c} \cdot v\left(\frac{t}{c}, \frac{\epsilon}{c}\right), \tag{4}$$

[6]Thurstone and another popular ranking method by Elo (1978) use a fixed σ for all instances.

[7]www.xbox.com/live/



(a) $v_{i\succ j}$ (b) $v_{i\equiv j}$

(c) $w_{i\succ j}$ (d) $w_{i\equiv j}$

Figure 2: Surprisal of the outcome for μ and σ^2 ($\epsilon = 0.5$).

where $c^2 = 2\gamma^2 + \sigma_i^2 + \sigma_j^2$, and v are multiplicative factors that affect the amount of change (surprisal of the outcome) in μ. In the accumulation of the variances (c^2), another free parameter called "skill chain", γ, indicates the width (or difference) of skill levels that two given players have 0.8 (80%) probability of win/lose. The multiplicative factor depends on the observation (wins or ties):

$$v_{i\succ j}(t, \epsilon) = \frac{\varphi(-\epsilon + t)}{\Phi(-\epsilon + t)}, \tag{5}$$

$$v_{i\equiv j}(t, \epsilon) = \frac{\varphi(-\epsilon - t) - \varphi(\epsilon - t)}{\Phi(\epsilon - t) - \Phi(-\epsilon - t)}, \tag{6}$$

where $\varphi(\cdot)$ is the probability density function of the standard normal distribution. As shown in Figure 2 (a) and (b), $v_{i\succ j}$ increases exponentially as t becomes smaller (i.e., the observation is unexpected), whereas $v_{i\equiv j}$ becomes close to zero when $|t|$ is close to zero. In short, v becomes larger as the outcome is more surprising.

In order to update variance (σ^2), another set of update functions is used:

$$\sigma_i^2 = \sigma_i^2 \cdot \left[1 - \frac{\sigma_i^2}{c^2} \cdot w\left(\frac{t}{c}, \frac{\epsilon}{c}\right)\right] \tag{7}$$

$$\sigma_j^2 = \sigma_j^2 \cdot \left[1 - \frac{\sigma_j^2}{c^2} \cdot w\left(\frac{t}{c}, \frac{\epsilon}{c}\right)\right], \tag{8}$$

where w serve as multiplicative factors that affect the amount of change in σ^2.

$$w_{i \succ j}(t, \epsilon) = v_{i \succ j} \cdot (v_{i \succ j} + t - \epsilon) \tag{9}$$

$$w_{i \equiv j}(t, \epsilon) = v_{i \equiv j}^2 + \frac{(\epsilon - t) \cdot \varphi(\epsilon - t) + (\epsilon + t) \cdot \varphi(\epsilon + t)}{\Phi(\epsilon - t) - \Phi(-\epsilon - t)}. \tag{10}$$

As shown in Figure 2 (c) and (d), the value of w is between 0 and 1. The underlying idea for the variance updates is that these updates always decrease the size of the variances σ^2, which means uncertainty of the instances (S_i, S_j) always decreases as we observe more pairwise comparisons. In other words, TrueSkill becomes more confident in the current estimate of μ_i and μ_j. Further details are provided by Herbrich et al. (2006).[8]

Another important property of TrueSkill is "match quality (chance to draw)". The match quality helps selecting competitive players to make games more interesting. More broadly, the match quality enables us to choose similar instances to be compared to maximize the information gain from pairwise comparisons, as in the active learning literature (Settles et al., 2008). The match quality between two instances (players) is computed as follows:

$$q(\gamma, S_i, S_j) := \sqrt{\frac{2\gamma^2}{c^2}} \exp\left(-\frac{(\mu_i - \mu_j)^2}{2c^2}\right) \tag{11}$$

Intuitively, the match quality is based on the difference $\mu_i - \mu_j$. As the difference becomes smaller, the match quality goes higher, and vice versa.

As mentioned, TrueSkill has been used for NLP tasks to infer continuous values for instances. However, it is important to note that the support of a Gaussian distribution is unbounded, namely $\mathbb{R} = (-\infty, \infty)$. This does not satisfy the property of absolute zero of scalar annotation in the level of measurement (§2). It becomes problematic when it comes to annotating a scalar (continuous) value for extremes such as extremely positive or negative sentiments. We address this issue by proposing a novel variant of TrueSkill in the next section.

3.2 Bounded Variant

TrueSkill can induce a continuous spectrum of instances (such as skill level of game players) by assuming that each instance is represented as a Gaussian distribution. However, the Gaussian distribution has unbounded support, namely $\mathbb{R} = (-\infty, \infty)$, which does not satisfy the property of *absolute* bounds for appropriate scalar annotation (i.e., ratio scale in the level of measurement).

Thus, we propose a variant of TrueSkill by changing the latent distribution from a Gaussian to a beta, using a heuristic algorithm based on TrueSkill for inference. The Beta distribution has natural $[0, 1]$ upper and lower bounds and a simple parameterization: $S_i \sim \mathcal{B}_i(\alpha_i, \beta_i)$. We choose the scalar response as the mode $\mathbb{M}[S_i]$ of the distribution and the variance as uncertainty:[9]

$$\mathbb{M}_i = \frac{\alpha_i - 1}{\alpha_i + \beta_i - 2} \tag{12}$$

$$\text{Var}_i = \sigma_i^2 = \frac{\alpha_i \beta_i}{(\alpha_i + \beta_i)^2 (\alpha_i + \beta_i + 1)} \tag{13}$$

As in TrueSkill, we iteratively update parameters of instances $\mathcal{B}(\alpha, \beta)$ according to each observation and how it is surprising. Similarly to Eqns. (3) and (4), we choose the update functions as follows;[10] first, in case that an annotator judged that S_i is preferred to S_j $(S_i \succ S_j)$,

$$\alpha_i = \alpha_i + \frac{\sigma_i^2}{c} \cdot (1 - p_{i \succ j}) \tag{14}$$

$$\beta_j = \beta_j + \frac{\sigma_j^2}{c} \cdot (1 - p_{j \prec i}) \tag{15}$$

in case of ties with $|D| > \epsilon$ and $\mathbb{M}_i > \mathbb{M}_j$,

$$\alpha_j = \alpha_j + \frac{\sigma_j^2}{c} \cdot (1 - p_{i \equiv j}) \tag{16}$$

$$\beta_i = \beta_i + \frac{\sigma_i^2}{c} \cdot (1 - p_{i \equiv j}) \tag{17}$$

and in case of ties with $|D| \leqslant \epsilon$, for both S_i, S_j,

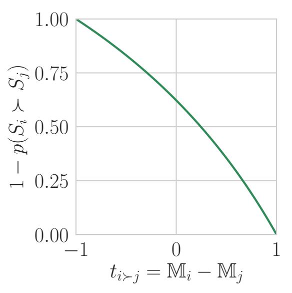
$$\alpha_{i,j} = \alpha_{i,j} + \frac{\sigma_{i,j}^2}{c} \cdot (1 - p_{i \equiv j}) \tag{18}$$

$$\beta_{i,j} = \beta_{i,j} + \frac{\sigma_{i,j}^2}{c} \cdot (1 - p_{i \equiv j}). \tag{19}$$

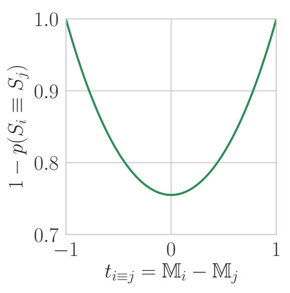
[8]The following material is also useful to understand the math behind TrueSkill (http://www.moserware.com/assets/computing-your-skill/The%20Math%20Behind%20TrueSkill.pdf).

[9]We may have instead used the mean ($\mathbb{E}[S_i] = \frac{\alpha_i}{\alpha_i + \beta_i}$) of the distribution, where in a beta ($\alpha, \beta > 1$) the mean is always closer to 0.5 than the mode, whereas mean and mode are always the same in a Gaussian distribution. The mode was selected owing to better performance in development.

[10]There may be other potential update (and surprisal) functions such as $-\log p$, instead of $1 - p$. As in our use of the mode rather than mean as scalar response, we empirically developed our update functions with respect to annotation efficiency observed through experimentation (§ 5).



(a) $1 - p_{i \succ j}$



(b) $1 - p_{i \equiv j}$

Figure 3: Surprisal of the outcome for the bounded variant ($\epsilon = 0.5$).

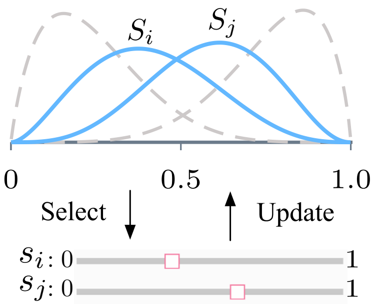


Figure 4: Illustrative example of the EASL protocol. Each instance is represented as a beta distribution. Instances are chosen to annotate according to the variance and match quality, and the parameters are updated iteratively.

Regarding the probability of pairwise comparison between instances, we follow Bradley and Terry (1952) and Rao and Kupper (1967) to describe the chance of win, tie, or loss, as follows:

$$p(S_i \succ S_j) = p(D > \epsilon) = \frac{\pi_i}{\pi_i + \theta\pi_j} \tag{20}$$

$$p(S_i \prec S_j) = p(D < -\epsilon) = \frac{\pi_j}{\theta\pi_i + \pi_j} \tag{21}$$

$$p(S_i \equiv S_j) = p(|D| \leqslant \epsilon) = \frac{(\theta^2 - 1)\pi_i\pi_j}{(\pi_i + \theta\pi_j)(\theta\pi_i + \pi_j)} \tag{22}$$

where $D = \mathbb{M}_i - \mathbb{M}_j$, $\epsilon \geqslant 0$ is a parameter to specify the tie rate, $\theta = \exp(\epsilon)$, and π is an exponential score function of S; $\pi_i = \exp(\mathbb{M}_i)$.

It is important to note that α and β never decrease (because $1 - p \geq 0$ as shown Figure 3), which satisfies the property that variance (uncertainty) always decreases as we observe more judgments, as seen in TrueSkill (§3.1). In addition, we do not need individual update functions for μ and σ^2, since the mode and variance in beta distribution depend on two shared parameters α, β (Eqns. 12 and 13).

Regarding match quality, we use the same formulation as the TrueSkill (Eqn. 11), except that the bounded model uses $\mathbb{M}$ instead of μ:

$$q(\gamma, S_i, S_j) = \sqrt{\frac{2\gamma^2}{c^2}} \exp\left(-\frac{(\mathbb{M}_i - \mathbb{M}_j)^2}{2c^2}\right) \tag{23}$$

4 Efficient Annotation of Scalar Labels

In the previous section, we propose a *bounded* online ranking aggregation model for scalar annotation. However, the amount of update by a pairwise judgment depends only on the distance between instances, not on the distance from the bounds (i.e., 0 and 1). To integrate this property into the online ranking aggregation model, we propose EASL (**E**fficient **A**nnotation of **S**calar **L**abels) that combines benefits from both direct assessment (DA) and bounded online ranking aggregation model (RA).[11]

Similarly to RA, EASL parameterizes each instance by a beta distribution (Eqns. 12 and 13), and the parameters are inferred using a computationally efficient and easy-to-implement heuristic. The difference from RA is the type of annotation. While we ask for discrete pairwise judgment ($\succ, \prec, \equiv$) between S_i and S_j in RA, here we directly ask for scalar values for them (denoted as s_i and s_j) as in DA. Thus, given an annotated score s_i which is normalized between [0,1], we change the update functions as follows:

$$\alpha_i = \alpha_i + s_i \tag{24}$$

$$\beta_i = \beta_i + (1 - s_i) \tag{25}$$

This procedure may look similar to DA, where s_i is simply accumulated and averaged at the end. However, there are two differences. First, as illustrated in Figure 4, EASL parameterizes each instance as a probability distribution while DA does not. Second, DA elicits annotations independently per element, whereas EASL elicits annotations on elements in the context of other elements selected jointly according to match quality.

Further, DA generally uses a batch style annotation scheme, where the number of annotations per instance is independent from the latent scalar values. On the other hand, EASL uses online learning, which impacts the calculation of match quality. This allows us to choose instances to annotate

[11] Novikova et al. (2018) recently proposed a similar approach named RankME, which is a variant of DA with comparing multiple instances at a time. It can also be regarded as a batch-learning variant of EASL without probabilistic parameterization.

Figure 5: Example of partial ranking with scalars (HITS)

by order of uncertainty for each instance, and as in RA, the match quality (Eqn. 23) enables us to consider similar instances in the same context.

5 Experiments

To compare different annotation methods, we conduct three experiments: (1) lexical frequency inference, (2) political spectrum inference, and (3) human evaluation for machine translation systems.

In all experiments, data collection is conducted through Amazon Mechanical Turk (AMT). We ask annotators who meet the following minimum requirements:[12] living in the US, overall approval rate $> 98\%$, and number of tasks approved > 500.

The experimental setting for DA is straightforward. We ask annotators to annotate a scalar value for each instance, one item at a time. We collect ten annotations for each instance to see the relation between the number of annotations and accuracy (i.e., correlation).

To set up the online update in RA and EASL, we use a *partial ranking* framework with scalars, where annotators are asked to rank and score n instances at one time as illustrated in Figure 5. In all three experiments, we fix $n = 5$. The partial ranking yields $\binom{n}{2}$ pairwise comparisons for RA and n scalar values for EASL.[13] It is important to note that we can simultaneously retrieve pairwise

Algorithm 1: Online pairwise ranking aggregation with bounded support.

```

12     $S'$ = top-k instances of $S$
13     HITS = []
14     foreach $S_i \in S'$ do
15         m = []
16         foreach $S_j \in S_{/S'}$ do
17             m.append([matchQuality($S_i, S_j$), $j$])
18         $p$ = normalize(m)
19         $\tilde{S}$ = sampling n-1 items by $p$
20         HITS.append([$S_i, \tilde{S}$])
21     return HITS
```

judgments ($\succ, \prec, \equiv$) as well as scalar values from this format.

In each iteration, n instances are selected by variance and match quality. We first select top k ($= N/n$) instances according to the variance, and for each selected instance we choose the other $n - 1$ instances to be compared based on match quality. This approach has been used in the NLP community in tasks such as for assessing machine translation quality (Bojar et al., 2014; Sakaguchi et al., 2014; Bojar et al., 2015, 2016) to collect pairwise judgments efficiently. The detailed procedure of iterative parameter updates in the RA and EASL is described in Algorithm 1. As mentioned in Section 4, the main difference between RA and EASL is the update functions (line 7).

Model hyper-parameters in RA and EASL are set as follows; each instance is initialized as $\alpha_i^{\text{init}} = 1.0$, $\beta_i^{\text{init}} = 1.0$. The skill chain parameter γ and tie-rate parameter ϵ are set to be 0.1.[14]

5.1 Lexical Frequency Inference

In the first experiment, we compare the three scalar annotation approaches on lexical frequency inference, in which we ask annotators to judge frequency (from very rare to very frequent) of verbs

[12]In all experiments, we set the reward of single instance to be \$0.01 (i.e., \$0.05 in RA and EASL). This is \$8/hour, assuming that annotating one instance takes five seconds. Prior to annotation, we run a pilot to make sure that the participants understand the task correctly and the instructions are clear.

[13]The partial ranking can be regarded as mini-batching.

[14]We explored the hyper-parameters γ, ϵ in a pilot task.

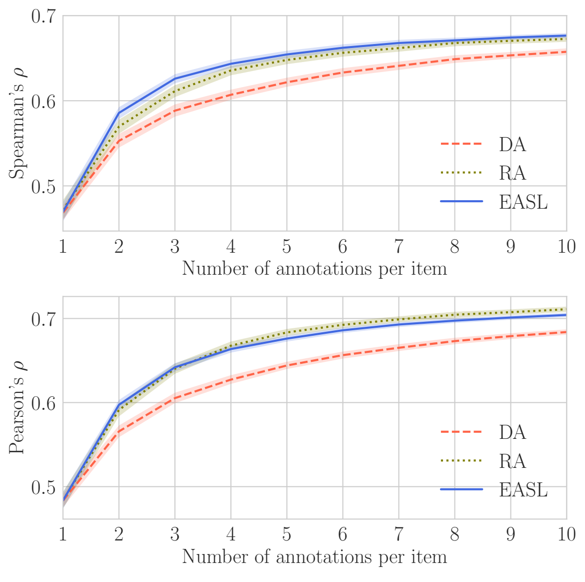

Figure 6: Spearman's (top) and Pearson's (bottom) correlations with three difference methods on lexical frequency inference annotation: direct assessment (DA), online ranking aggregation (RA), and EASL. The shade for each line indicates 95% confidence intervals by bootstrap resampling (running 100 times).

that are randomly selected from the corpus of Contemporary American English (COCA)[15]. We include this task for evaluation owing to its non-subjective ground truth (relative corpus frequency) which can be used as an oracle response we would like to maximally correlate with.[16]

We randomly select 150 verbs from COCA; the log frequency ($\log_{10}$) is regarded as the oracle. In DA, each instance is annotated by 10 different annotators.[17] In the RA and EASL, annotators are asked to rank/score five verbs for each HIT ($n = 5$). Each iteration contains 20 HITS and we run 10 iterations, which means that total number of annotations is the same in DA, RA, and EASL.[18]

Figure 6 presents Spearman's and Pearson's correlations, indicating how accurately each annotation method obtains scalar values for each instance. Overall, in all three methods, the correlations are increased as more annotations are made. The result also shows that RA and EASL approaches achieve high correlation more efficiently than DA. The gain of efficiency from DA to EASL is about 50%; two iterations in EASL achieves a close Spearman's ρ to three annotators in DA.

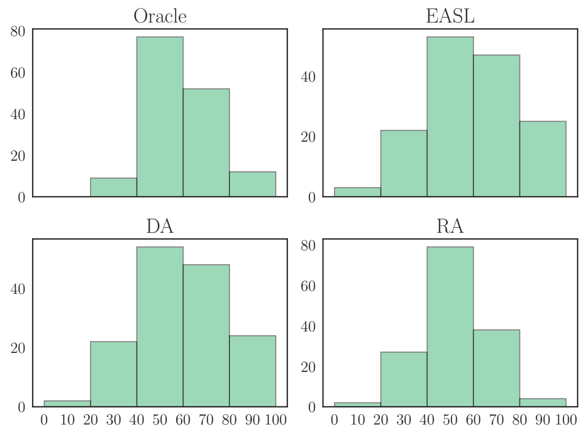

Figure 7: Histograms of scalar values on lexical frequency obtained by each annotation scheme (direct assessment (DA), online ranking aggregation (RA), and EASL), and the oracle. The scalar annotations are put into five bins to see the overall distribution. The scalar in the oracle is normalized as log_{10}(frequency(S_i)) / max log_{10}(frequency(S)).

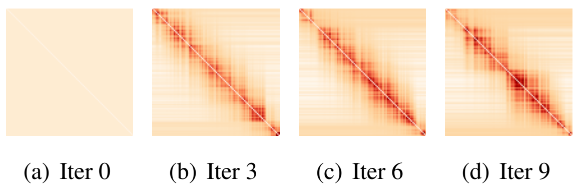

Figure 8: Heatmaps of match quality distribution across the cross-product of instances ordered by the oracle (i.e., log_{10}(frequency)).

Figure 7 presents the results of the final scalar values that each method annotated. The distribution of the histograms shows that overall three methods successfully capture the latent distribution of scalar values in the data.

Figure 8 shows a dynamic change of match quality. In the beginning (iteration 0), all the instances are equally competitive because we have no information about them and initialize them with the same parameters. As iterations go on, the instances along the diagonal have higher match quality, indicating that competitive matches are more likely to be selected for a next iteration. In other words, match-quality helps to choose informative pairs to compare at each iteration, which reduces the number of less informative annotations (e.g., a pairwise comparison between the highest and lowest instances).

[15]https://www.wordfrequency.info/

[16]Lexical frequency inference is an established experiment in (computational) psycholinguistics. E.g., human behavioral measures have been compared with predictability and bias in various corpora (Balota et al., 1999; Fine et al., 2014).

[17]The agreement rate in DA (10 annotators) is 0.37 in Spearman's ρ. Considering the difficulty of ranking 150 verbs, this rate is fair.

[18]Technically, the number of annotations per instance vary in RA and EASL, because they choose instances by match quality at each iteration.

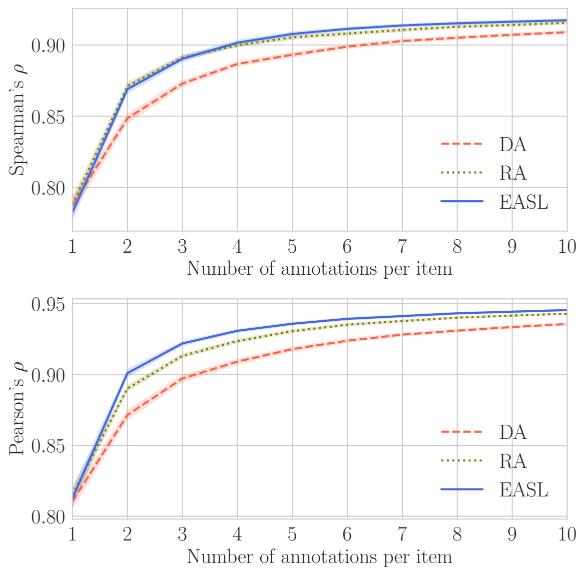

Figure 9: Spearman's (top) and Pearson's (bottom) correlations with three difference methods on political spectrum annotation: direct assessment (DA), online ranking aggregation (RA), and EASL

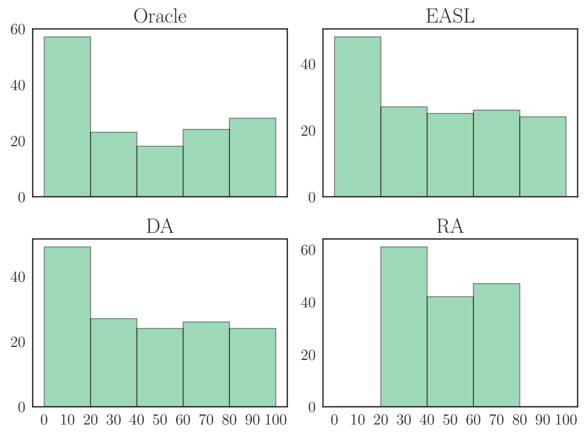

Figure 10: Histograms of scalar values on political spectrum obtained by each annotation scheme (DA, RA, EASL) and the oracle. Scalars are put into five bins to see the overall distribution.

Propositions	Gold	DA	RA	EASL
the republicans are useless	100	91.7	75.8	91.9
obama is right	92.9	90.1	74.6	90.0
hillary will win	78.6	86.3	72.9	86.4
aca is a success	75.0	78.2	68.3	77.3
harry reid is a democrat	53.6	55.5	55.8	55.9
ebola is a virus	50.0	53.0	53.8	53.5
cruz is eligible	32.2	31.0	44.0	31.4
global warming is a religion	28.6	22.4	37.3	23.0
bush kept us safe	10.7	9.6	31.5	9.6
democrats are corrupt	0.0	7.1	29.9	7.4

Table 1: Example propositions and the scalar political spectrum ranged between 0 (*very conservative*) and 100 (*very liberal*) by each approach: direct assessment, online ranking aggregation, and EASL. The dashed lines indicate a split by 5-ary ordinal scale.

5.2 Political Spectrum Inference

In the second experiment, we compare the three scalar annotation methods for political spectrum inference. We use the Fine-Grained Political Statements dataset (Bamman and Smith, 2015), which consists of 766 propositions collected from political blog comments, paired with judgments about the political belief of the statement (or the person who would say it) based on the five ordinals: *very conservative* (-2), *slightly conservative* (-1), *neutral* (0), *slightly liberal* (1), and *very liberal* (2). We normalize the ordinal scores between 0 and 1. The dataset contains the mean scores by aggregating 7 annotations for each proposition.[19]

We randomly choose 150 political propositions from the dataset (see the histogram in Figure 10 oracle).[20] The experimental setting (i.e., the number of annotations per instance, the number of iterations, and the number of HITS in each iteration) is the same as the lexical frequency inference experiment (§5.1).

Figure 9 shows Spearman's and Pearson's correlations to the oracle by each method. Overall, all the three methods achieve strong correlation above 0.9. We also find that RA and EASL reach high correlation more efficiently than DA as in the lexical frequency inference experiment (§5.1). The gain of efficiency from DA to EASL is about 50%; 4-way redundant annotation in EASL achieves a close Spearman's ρ to 6-way redundancy in DA.

Figure 10 presents the results of the annotated scalar values by each method. The distribution of the histograms shows that DA and EASL successfully fit to the distribution in the oracle, whereas RA converges to a rather narrow range. This is because of the "lack of distance from bounds" in RA that is explained in §4. We note that renormalizing the distribution in RA will not address the issue. For instance, when the dataset has only liberal propositions, RA still fails to capture the latent distribution because it looks only at relative distances between instances but not the distance from bounds. Table 1 shows the examples of scalar annotations by each method. Again, we

[19]We stress that the oracle here derives from subjective annotations: it does not necessarily reflect the true latent scalar values for each instance. However, in this experiment, we use them as a tentative oracle to compare three scalar annotation methods objectively.

[20]The agreement rate in DA (among 10 annotators) is 0.67 in Spearman's ρ. This is significantly high, considering the difficulty of ranking 150 instances in order.

see that RA approach has a narrower range than the oracle, DA, and EASL.

5.3 Ranking Machine Translation Systems

In the third experiment, we apply the scalar annotation methods for evaluating machine translation systems. This is different from two previous experiments, because the main purpose is to rank the MT systems (S_1^N) rather than the adequacy (q) of each MT output for a given source sentence (m). Namely, we want to rank S_i by observing $q_{i,m}$.

We use WMT16 German-English translation dataset (Bojar et al., 2016), which consists of 2,999 test set sentences and the translations from 10 different systems with DA annotation. Each sentence has its adequacy score annotation between 0 and 100, and the average adequacy scores are computed for each system for ranking. In this setting, annotators are asked to judge adequacy of system output(s) with the reference being given. The official scores (made by DA) and ranking in WMT16 are used as the oracle in this experiment.

In this experiment, we replicate DA and run EASL to compare the efficiency. We omit RA in this experiment, because it does not necessarily capture the distance from bounds as shown in the previous experiment (§5.2). In DA, 33,760 translation outputs (3,376 sentences per system in average) are randomly sampled without replacement to make sure that it reaches up to the same result as oracle when the entire data are used.

In EASL, we assume that adequacy (q) of an MT output by system (S_i) for a given source sentence (m) is drawn from beta distribution: $q_{i,m} \sim \mathcal{B}(\alpha_i, \beta_i)$.[21] Annotators are asked to judge adequacy of system outputs by scoring 0 and 100. Similarly to the previous experiments (§ 5.1 and § 5.2), we use the partial ranking strategy, where we show $n = 5$ system outputs (for the same source sentence l) to annotate at a time. The procedure of parameter updates is the same as previous experiments (Algorithm 1).

We compare the correlations (Spearman's ρ) of system ranking with respect to the number of annotations per system, and the result is shown in Figure 11. As seen in the previous two experiments, EASL achieves higher Spearmans correlation on ranking MT systems with smaller number of annotations than the baseline method (DA),

[21]This is the same setting as WMT14, WMT15, and WMT16 (Bojar et al., 2014, 2015), although they used TrueSkill (Gaussian) instead of EASL to rank systems.

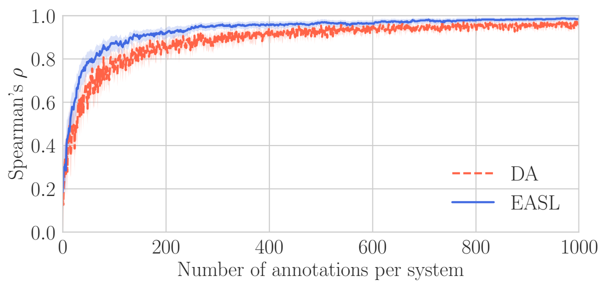

Figure 11: Spearman's correlation on ranking machine translation systems on WMT16 German-English data: direct assessment (DA), and EASL. The shade for each line indicates 95% confidence intervals by bootstrap resampling (running 100 times).

which means EASL is able to collect annotation more efficiently. The result shows that EASL can be applied for efficient system evaluation in addition to data curation.

6 Conclusions

We have presented an efficient, online model to elicit scalar annotations for computational linguistic datasets and system evaluations. The model combines two approaches for scalar annotation: direct assessment and online pairwise ranking aggregation. We conducted three illustrative experiments on lexical frequency inference, political spectrum inference, and ranking machine translation systems. We have shown that our approach, EASL (**E**fficient **A**nnotation of **S**calar **L**abels), outperforms direct assessment in terms of annotation efficiency and outperforms online ranking aggregation in terms of accurately capturing the latent distributions of scalar values. The significant gains demonstrated suggests EASL as a promising approach for future dataset curation and system evaluation in the community.

Abstract

High quality arguments are essential elements for human reasoning and decision-making processes. However, effective argument construction is a challenging task for both human and machines. In this work, we study a novel task on *automatically generating arguments of a different stance for a given statement*. We propose an encoder-decoder style neural network-based argument generation model enriched with externally retrieved evidence from Wikipedia. Our model first generates a set of talking point phrases as intermediate representation, followed by a separate decoder producing the final argument based on both input and the keyphrases. Experiments on a large-scale dataset collected from Reddit show that our model constructs arguments with more topic-relevant content than a popular sequence-to-sequence generation model according to both automatic evaluation and human assessments.

1 Introduction

Generating high quality arguments plays a crucial role in decision-making and reasoning processes (Bonet and Geffner, 1996; Byrnes, 2013). A multitude of arguments and counter-arguments are constructed on a daily basis, both online and offline, to persuade and inform us on a wide range of issues. For instance, debates are often conducted in legislative bodies to secure enough votes for bills to pass. In another example, online deliberation has become a popular way of soliciting public opinions on new policies' pros and cons (Albrecht, 2006; Park et al., 2012). Nonetheless, constructing persuasive arguments is a daunting task, for both human and computers. We believe that developing effective argument generation models will enable a broad range of compelling applications, including debate coaching, improving students' essay writing skills, and pro-

I believe the government should be allowed to view my e-mails...or national security concerns. CMV. I have nothing to hide... I'm all for them reading whatever they can get their hands on..

A second argument is, the ***government*** isn't an omnipotent infallible entity, it's a group of people. Those people can (and do) ***abuse their power and authority***...

Seriously... against the protections offered in the Fourth Amendment:

The right of the people ... the persons or things to be seized.

Figure 1: Sample user arguments from Reddit Change My View subcommunity that argue against original post's thesis on "government should be allowed to view private emails". Both arguments leverage supporting information from Wikipedia articles.

viding context of controversial issues from different perspectives. As a consequence, there exists a pressing need for automating the argument construction process.

To date, progress made in argument generation has been limited to retrieval-based methods—arguments are ranked based on relevance to a given topic, then the top ones are selected for inclusion in the output (Rinott et al., 2015; Wachsmuth et al., 2017; Hua and Wang, 2017). Although sentence ordering algorithms are developed for information structuring (Sato et al., 2015; Reisert et al., 2015), existing methods lack the ability of synthesizing information from different resources, leading to redundancy and incoherence in the output.

In general, the task of argument generation presents numerous challenges, ranging from aggregating supporting evidence to generating text with coherent logical structure. One particular hurdle comes from the underlying natural language generation (NLG) stack, whose success has been limited to a small set of domains. Especially, most previous NLG systems rely on templates that are either constructed by rules (Hovy, 1993; Belz, 2008; Bouayad-Agha et al., 2011), or acquired from a domain-specific corpus (Angeli et al., 2010) to enhance grammaticality and coherence. This makes them unwieldy to be adapted for new domains.

In this work, we study the following novel problem: *given a statement on a controversial issue, generate an argument of an alternative stance*. To address the above challenges, we present *a neural network-based argument generation framework augmented with externally retrieved evidence*. Our model is inspired by the observation that when humans construct arguments, they often collect references from external sources, e.g., Wikipedia or research papers, and then write their own arguments by synthesizing talking points from the references. Figure 1 displays sample arguments by users from Reddit subcommunity `/r/ChangeMyView` [1] who argue against the motion that "government should be allowed to view private emails". Both replies leverage information drawn from Wikipedia, such as "political corruption" and "Fourth Amendment on protections of personal privacy".

Concretely, our neural argument generation model adopts the popular encoder-decoder-based sequence-to-sequence (seq2seq) framework (Sutskever et al., 2014), which has achieved significant success in various text generation tasks (Bahdanau et al., 2015; Wen et al., 2015; Wang and Ling, 2016; Mei et al., 2016; Wiseman et al., 2017). Our encoder takes as input a statement on a disputed issue, and a set of relevant evidence automatically retrieved from English Wikipedia[2]. Our decoder consists of two separate parts, one of which first generates keyphrases as intermediate representation of "talking points", and the other then generates an argument based on both input and keyphrases.

Automatic evaluation based on BLEU (Papineni et al., 2002) shows that our framework generates better arguments than directly using retrieved sentences or popular seq2seq-based generation models (Bahdanau et al., 2015) that are also trained with retrieved evidence. We further design a novel evaluation procedure to measure whether the arguments are on-topic by predicting their relevance to the given statement based on a separately trained relevance estimation model. Results suggest that our model generated arguments are more likely to be predicted as on-topic, compared to other seq2seq-based generations models.

The rest of this paper is organized as follows. Section 2 highlights the roadmap of our system. The dataset used for our study is introduced in Section 3. The model formulation and retrieval methods are detailed in Sections 4 and 5. We then describe the experimental setup and results in Sections 6 and 7, followed by further analysis and future directions in Section 8. Related work is discussed in Section 9. Finally, we conclude in Section 10.

2 Framework

Our argument generation pipeline, consisting of *evidence retrieval* and *argument construction*, is depicted in Figure 2. Given a statement, a set of queries are constructed based on its topic signature words (e.g., "government" and "national security") to retrieve a list of relevant articles from Wikipedia. A reranking component further extracts sentences that may contain supporting evidence, which are used as additional input information for the neural argument generation model.

The generation model then encodes the statement and the evidence with a shared encoder in sequence. Two decoders are designed: the *keyphrase decoder* first generates an intermediate representation of talking points in the form of keyphrases (e.g., "right to privacy", "political corruption"), followed by a separate *argument decoder* which produces the final argument.

3 Data Collection and Processing

We draw data from Reddit subcommunity `/r/ChangeMyView` (henceforth CMV), which focuses on facilitating open discussions on a wide range of disputed issues. Specifically, CMV is structured as discussion threads, where the original post (OP) starts with a viewpoint on a controversial topic, followed with detailed reasons, then other users reply with counter-arguments. Importantly, when a user believes his view has been changed by an argument, a *delta* is often awarded to the reply.

In total, 26,761 threads from CMV are downloaded, dating from January 2013 to June 2017[3].

Figure 2: Overview of our system pipeline (best viewed in color). Given a statement, relevant articles are retrieved from Wikipedia with topic signatures from statement as queries (marked in red and boldface). A reranking module then outputs top sentences as evidence. The statement and the evidence (encoder states in gray panel) are concatenated and encoded as input for our argument generation model. During decoding, the keyphrase decoder first generates talking points as phrases, followed by the argument decoder which constructs the argument by attending both input and keyphrases.

Only root replies (i.e., replies directly addressing OP) that meet all of the following requirements are included: (1) longer than 5 words, (2) without offensive language[4], (3) awarded with *delta* or with more upvotes than downvotes, and (4) not generated by system moderators.

After filtering, the resultant dataset contains 26,525 OPs along with 305,475 relatively high quality root replies. We treat each OP as the input statement, and the corresponding root replies as target arguments, on which our model is trained and evaluated.

A Focused Domain Dataset. The current dataset contains diverse domains with unbalanced numbers of arguments. We therefore choose samples from the politics domain due to its large volume of discussions and good coverage of popular arguments in the domain.

However, topic labels are not available for the discussions. We thus construct a domain classifier for politics vs. non-politics posts based on a logistic regression model with unigram features, trained from our heuristically labeled Wikipedia abstracts[5]. Concretely, we manually collect two lists of keywords that are indicative of politics and non-politics. Each abstract is labeled as politics or non-politics if its title only matches keywords from one category.[6] In total, 264,670 politics abstracts and 827,437 of non-politics are labeled. Starting from this dataset, our domain classifier is trained in a bootstrapping manner by gradually adding OPs predicted as politics or non-politics.[7] Finally, 12,549 OPs are labeled as politics, each of which is paired with 9.4 high-quality target arguments on average. The average length for OPs is 16.1 sentences of 356.4 words, and 7.7 sentences of 161.1 words for arguments.

4 Model

In this section, we present our argument generation model, which jointly learns to generate talking points in the form of keyphrases and produce arguments based on the input and keyphrases. Extended from the successful seq2seq attentional model (Bahdanau et al., 2015), our proposed model is novel in the following ways. First, two separate decoders are designed, one for generating keyphrases, the other for argument construction. By sharing the encoder with keyphrase generation, our argument decoder is better aware of salient talking points in the input. Second, a novel

[4] We use offensive words collected by Google's What Do You Love project: `https://gist.github.com/jamiew/1112488`, last accessed on February 22nd, 2018.

[5] About 1.3 million English Wikipedia abstracts are downloaded from `http://dbpedia.org/page/`.

[6] Sample keywords for politics: "congress", "election", "constitution"; for non-politics: "art", "fashion","music". Full lists are provided in the supplementary material.

[7] More details about our domain classifier are provided in the supplementary material.

attention mechanism is designed for argument decoding by attending both input and the previously generated keyphrases. Finally, a reranking-based beam search decoder is introduced to promote topic-relevant generations.

4.1 Model Formulation

Our model takes as input a sequence of tokens $\boldsymbol{x} = \{\boldsymbol{x}^O; \boldsymbol{x}^E\}$, where $\boldsymbol{x}^O$ is the statement sequence and $\boldsymbol{x}^E$ contains relevant evidence that is extracted from Wikipedia based on a separate retrieval module. A special token `<evd>` is inserted between $\boldsymbol{x}^O$ and $\boldsymbol{x}^E$. Our model then first generates a set of keyphrases as a sequence $\boldsymbol{y}^p = \{y_l^p\}$, followed by an argument $\boldsymbol{y}^a = \{y_t^a\}$, by maximizing $\log P(\boldsymbol{y}|\boldsymbol{x})$, where $\boldsymbol{y} = \{\boldsymbol{y}^p; \boldsymbol{y}^a\}$.

The objective is further decomposed into $\sum_t \log P(y_t|y_{1:t-1}, \boldsymbol{x})$, with each term estimated by a softmax function over a non-linear transformation of decoder hidden states $\boldsymbol{s}_t^a$ and $\boldsymbol{s}_t^p$, for argument decoder and keyphrase decoder, respectively. The hidden states are computed as done in Bahdanau et al. (2015) with attention:

$$\boldsymbol{s}_t = g(\boldsymbol{s}_{t-1}, \boldsymbol{c}_t, y_t) \tag{1}$$

$$\boldsymbol{c}_t = \sum_{j=1}^{T} \alpha_{tj} \boldsymbol{h}_j \tag{2}$$

$$\alpha_{tj} = \frac{\exp(e_{tj})}{\sum_{k=1}^{T} \exp(e_{tk})} \tag{3}$$

$$e_{tj} = \boldsymbol{v}^T \tanh(\boldsymbol{W_h} \boldsymbol{h}_j + \boldsymbol{W_s} \boldsymbol{s}_t + \boldsymbol{b}_{attn}) \tag{4}$$

Notice that two sets of parameters and different state update functions $g(\cdot)$ are learned for separate decoders: $\{\boldsymbol{W}_h^a, \boldsymbol{W}_s^a, \boldsymbol{b}_{attn}^a, g^a(\cdot)\}$ for the argument decoder; $\{\boldsymbol{W}_h^p, \boldsymbol{W}_s^p, \boldsymbol{b}_{attn}^p, g^p(\cdot)\}$ for the keyphrase decoder.

Encoder. A two-layer bidirectional LSTM (biLSTM) is used to obtain the encoder hidden states $\boldsymbol{h}_i$ for each time step i. For biLSTM, the hidden state is the concatenation of forward and backward hidden states: $\boldsymbol{h}_i = [\overrightarrow{\boldsymbol{h}_i}; \overleftarrow{\boldsymbol{h}_i}]$. Word representations are initialized with 200-dimensional pre-trained GloVe embeddings (Pennington et al., 2014), and updated during training. The last hidden state of encoder is used to initialize both decoders. In our model the encoder is shared by argument and keyphrase decoders.

Decoders. Our model is equipped with two decoders: *keyphrase decoder* and *argument decoder*, each is implemented with a separate two-layer unidirectional LSTM, in a similar spirit with one-to-many multi-task sequence-to-sequence learning (Luong et al., 2015). The distinction is that our training objective is the sum of two loss functions:

$$\mathcal{L}(\theta) = -\frac{\alpha}{T_p} \sum_{(\boldsymbol{x}, \boldsymbol{y}^p) \in D} \log P(\boldsymbol{y}^p | \boldsymbol{x}; \theta) - \frac{(1-\alpha)}{T_a} \sum_{(\boldsymbol{x}, \boldsymbol{y}^a) \in D} \log P(\boldsymbol{y}^a | \boldsymbol{x}; \theta) \tag{5}$$

where T_p and T_a denote the lengths of reference keyphrase sequence and argument sequence. α is a weighting parameter, and it is set as 0.5 in our experiments.

Attention over Both Input and Keyphrases. Intuitively, the argument decoder should consider the generated keyphrases as talking points during the generation process. We therefore propose an attention mechanism that can attend both encoder hidden states and the keyphrase decoder hidden states. Additional context vector $\boldsymbol{c}'_t$ is then computed over keyphrase decoder hidden states $\boldsymbol{s}_j^p$, which is used for computing the new argument decoder state:

$$\boldsymbol{s}_t^a = g'(\boldsymbol{s}_{t-1}^a, [\boldsymbol{c}_t; \boldsymbol{c}'_t], y_t^a) \tag{6}$$

$$\boldsymbol{c}'_t = \sum_{j=1}^{T_p} \alpha'_{tj} \boldsymbol{s}_j^p \tag{7}$$

$$\alpha'_{tj} = \frac{\exp(e'_{tj})}{\sum_{k=1}^{T_p} \exp(e'_{tk})} \tag{8}$$

$$e'_{tj} = \boldsymbol{v}'^T \tanh(\boldsymbol{W'_p} \boldsymbol{s}_j^p + \boldsymbol{W'_a} \boldsymbol{s}_t^a + \boldsymbol{b}'_{attn}) \tag{9}$$

where $\boldsymbol{s}_j^p$ is the hidden state of keyphrase decoder at position j, $\boldsymbol{s}_t^a$ is the hidden state of argument decoder at timestep t, and $\boldsymbol{c}_t$ is computed in Eq. 2.

Decoder Sharing. We also experiment with a shared decoder between keyphrase generation and argument generation: the last hidden state of the keyphrase decoder is used as the initial hidden state for the argument decoder. A special token `<arg>` is inserted between the two sequences, indicating the start of argument generation.

4.2 Hybrid Beam Search Decoding

Here we describe our decoding strategy on the argument decoder. We design a hybrid beam expansion method combined with segment-based reranking to promote diversity of beams and informativeness of the generated arguments.

Hybrid Beam Expansion. In the standard beam search, the top k words of highest probability are selected deterministically based on the softmax output to expand each hypothesis. However, this may lead to suboptimal output for text generation (Wiseman and Rush, 2016), e.g., one beam often dominates and thus inhibits hypothesis diversity. Here we only pick the top n words ($n < k$), and randomly draw another $k - n$ words based on the multinomial distribution after removing the n expanded words from the candidates. This leads to a more diverse set of hypotheses.

Segment-based Reranking. We also propose to rerank the beams every p steps based on beam's coverage of content words from input. Based on our observation that likelihood-based reranking often leads to overly generic arguments (e.g., "I don't agree with you"), this operation has the potential of encouraging more informative generation. $k = 10$, $n = 3$, and $p = 10$ are used for experiments. The effect of parameter selection is studied in Section 7.

5 Relevant Evidence Retrieval

5.1 Retrieval Methodology

We take a two-step approach for retrieving *evidence sentences*: given a statement, (1) constructing one query per sentence and retrieving relevant articles from Wikipedia, and (2) reranking paragraphs and then sentences to create the final set of evidence sentences. Wikipedia is used as our evidence source mainly due to its objective perspective and broad coverage of topics. A dump of December 21, 2016 was downloaded. For training, evidence sentences are retrieved with queries constructed from target user arguments. For test, queries are constructed from OP.

Article Retrieval. We first create an inverted index lookup table for Wikipedia as done in Chen et al. (2017). For a given statement, we construct one query per sentence to broaden the diversity of retrieved articles. Therefore, multiple passes of retrieval will be conducted if more than one query is created. Specifically, we first collect topic signature words of the post. Topic signatures (Lin and Hovy, 2000) are terms strongly correlated with a given post, measured by log-likelihood ratio against a background corpus. We treat posts from other discussions in our dataset as background. For each sentence, one query is constructed based on the noun phrases and verbs containing at least one topic signature word. For instance, a query "`the government, my e-mails, national security`" is constructed for the first sentence of OP in the motivating example (Figure 2). Top five retrieved articles with highest TF-IDF similarity scores are kept per query.

	Queries Constructed from	
	OP	**Argument**
Avg # Topic Sig.	17.2	9.8
Avg # Query	6.7	1.9
Avg # Article Retrieved	26.1	8.0
Avg # Sent. Retrieved	67.3	8.5

Table 1: Statistics for evidence sentence retrieval from Wikipedia. Considering query construction from either OP or target user arguments, we show the average numbers of topic signatures collected, queries constructed, and retrieved articles and sentences.

Sentence Reranking. The retrieved articles are first segmented into paragraphs, which are reranked by TF-IDF similarity to the given statement. Up to 100 top ranked paragraphs with positive scores are retained. These paragraphs are further segmented into sentences, and reranked according to TF-IDF similarity again. We only keep up to 10 top sentences with positive scores for inclusion in the evidence set.

5.2 Gold-Standard Keyphrase Construction

To create training data for the keyphrase decoder, we use the following rules to identify keyphrases from evidence sentences that are reused by human writers for argument construction:

- Extract noun phrases and verb phrases from evidence sentences using Stanford CoreNLP (Manning et al., 2014).
- Keep phrases of length between 2 and 10 that overlap with content words in the argument.
- If there is span overlap between phrases, the longer one is kept if it has more content word coverage of the argument; otherwise the shorter one is retained.

The resultant phrases are then concatenated with a special delimiter `<phrase>` and used as gold-standard generation for training.

6 Experimental Setup

6.1 Final Dataset Statistics

Encoding the full set of evidence by our current decoder takes a huge amount of time. We there propose a sampling strategy to allow the encoder to finish encoding within reasonable time by considering only a subset of the evidence: For each sentence in the statement, up to three evidence sentences are randomly sampled from the retrieved set; then the sampled sentences are concatenated. This procedure is repeated three times per statement, where a statement is an user argument for training data and an OP for test set. In our experiments, we remove duplicates samples and the ones without any retrieved evidence sentence. Finally, we break down the augmented data into a training set of 224,553 examples (9,737 unique OPs), 13,911 for validation (640 OPs), and 30,417 retained for test (1,892 OPs).

6.2 Training Setup

For all models, we use a two-layer biLSTM as encoder and a two-layer unidirectional LSTM as decoder, with 200-dimensional hidden states in each layer. We apply dropout (Gal and Ghahramani, 2016) on RNN cells with a keep probability of 0.8. We use Adam (Kingma and Ba, 2015) with an initial learning rate of 0.001 to optimize the cross-entropy loss. Gradient clipping is also applied with the maximum norm of 2. The input and output vocabulary sizes are both 50k.

Curriculum Training. We train the models in three stages where the truncated input and output lengths are gradually increased. Details are listed in Table 2. Importantly, this strategy allows model training to make rapid progress during early stages. Training each of our full models takes about 4 days on a Quadro P5000 GPU card with a batch size of 32. The model converges after about 10 epochs in total with pre-training initialization, which is described below.

Component	Stage 1	Stage 2	Stage 3
Encoder			
OP	50	150	400
Evidence	0	80	120
Decoder			
Keyphrases	0	80	120
Target Argument	30	80	120

Table 2: Truncation size (i.e., number of tokens including delimiters) for different stages during training. Note that in the first stage we do not include evidence and keyphrases.

Adding Pre-training. We pre-train a two-layer seq2seq model with OP as input and target argument as output from our training set. After 20 epochs (before converging), parameters for the first layer are used to initialize the first layer of all comparison models and our models (except for the keyphrase decoder). Experimental results show that pre-training boosts all methods by roughly 2 METEOR (Denkowski and Lavie, 2014) points. We describe more detailed results in the supplementary material.

6.3 Baseline and Comparisons

We first consider a RETRIEVAL-based baseline, which concatenates retrieved evidence sentences to form the argument. We further compare with three seq2seq-based generation models with different training data: (1) SEQ2SEQ: training with OP as input and the argument as output; (2) SEQ2SEQ + *encode evd*: augmenting input with evidence sentences as in our model; (3) SEQ2SEQ + *encode KP*: augmenting input with gold-standard keyphrases, which assumes some of the talking points are known. All seq2seq models use a regular beam search decoder with the same beam size as ours.

Variants of Our Models. We experiment with variants of our models based on the proposed separate decoder model (DEC-SEPARATE) or using a shared decoder (DEC-SHARED). For each, we further test whether adding keyphrase attention for argument decoding is helpful (+ *attend KP*).

System vs. Oracle Retrieval. For test time, evidence sentences are retrieved with queries constructed from OP (*System Retrieval*). We also experiment with an *Oracle Retrieval* setup, where the evidence is retrieved based on user arguments, to indicate how much gain can be expected with better retrieval results.

7 Results

7.1 Automatic Evaluation

For automatic evaluation, we use BLEU (Papineni et al., 2002), an n-gram precision-based metric (up to bigrams are considered), and METEOR (Denkowski and Lavie, 2014), measuring unigram recall and precision by considering paraphrases, synonyms, and stemming. Human arguments are used as the gold-standard. Because each OP may be paired with more than one high-quality arguments, we compute BLEU and METEOR scores for the system argument compared against all arguments, and report the best. We do not use multiple reference evaluation because

Table 3: Results on argument generation by BLEU and METEOR (MTR), with system retrieved evidence and oracle retrieval. The best performing model is highlighted in **bold** per metric. Our separate decoder models, with and without keyphrase attention, statistically significantly outperform all seq2seq-based models based on approximation randomization testing (Noreen, 1989), $p < 0.0001$.

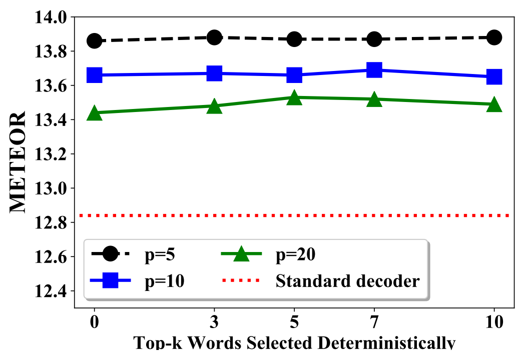

Figure 3: Effect of our reranking-based decoder. Beams are reranked at every 5, 10, and 20 steps (p). For each step size, we also show the effect of varying k, where top-k words are selected deterministically for beam expansion, with $10 - k$ randomly sampled over multinomial distribution after removing the k words. Reranking with smaller step size yields better results.

the arguments are often constructed from different angles and cover distinct aspects of the issue. For models that generate more than one arguments based on different sets of sampled evidence, the one with the highest score is considered.

As can be seen from Table 3, our models produce better BLEU scores than almost all the comparisons. Especially, our models with separate decoder yield significantly higher BLEU and METEOR scores than all seq2seq-based models (approximation randomization testing, $p < 0.0001$) do. Better METEOR scores are achieved by the RETRIEVAL baseline, mainly due to its significantly longer arguments.

Moreover, utilizing attention over both input and the generated keyphrases further boosts our models' performance. Interestingly, utilizing system retrieved evidence yields better BLEU scores than using oracle retrieval for testing. The reason could be that arguments generated based on system retrieval contain less topic-specific words and more generic argumentative phrases. Since the later is often observed in human written arguments, it may lead to higher precision and thus better BLEU scores.

Decoder Strategy Comparison. We also study the effect of our reranking-based decoder by varying the reranking step size (p) and the number of top words expanded to beam hypotheses deterministically (k). From the results in Figure 3, we find that reranking with a smaller step size, e.g., $p = 5$, can generally lead to better METEOR scores. Although varying the number of top words for beam expansion does not yield significant difference, we do observe more diverse beams from the system output if more candidate words are selected stochastically (i.e. with a smaller k).

7.2 Topic-Relevance Evaluation

During our pilot study, we observe that generic arguments, such as "I don't agree with you" or "this is not true", are prevalent among generations by seq2seq models. We believe that good arguments should include content that addresses the given topic. Therefore, we design a novel evaluation method to measure whether the generated arguments contain topic-relevant information.

To achieve the goal, we first train a topic-relevance estimation model inspired by the latent semantic model in Huang et al. (2013). A pair of OP and argument, each represented as the average of word embeddings, are separately fed into a two-layer transformation model. A dot-product is computed over the two projected low-dimensional vectors, and then a sigmoid function outputs the relevance score. For model learning, we further divide our current training data into training, developing, and test sets. For each OP and argument pair, we first randomly sample 100 arguments from other threads, and then pick the top 5 dissimilar ones, measured by Jaccard distance, as negative training samples. This model achieves a Mean Reciprocal Rank (MRR) score of 0.95 on the test set. Descriptions about model formulation and related training

	Standard Decoder		Our Decoder	
	MRR	P@1	MRR	P@1
Baseline				
RETRIEVAL	81.08	65.45	-	-
Comparisons				
SEQ2SEQ	75.29	58.85	74.46	57.06
+ *encode evd*	83.73	71.59	88.24	78.76
Our Models				
DEC-SHARED	79.80	65.57	**95.18**	**90.91**
+ *attend KP*	**94.33**	**89.76**	93.48	87.91
DEC-SEPARATE	86.85	76.74	91.70	84.72
+ *attend KP*	88.53	79.05	92.77	86.46

Table 4: Evaluation on topic relevance—models that generate arguments highly related with OP should be ranked high by a separately trained relevance estimation model, i.e., higher Mean Reciprocal Rank (MRR) and Precision at 1 (P@1) scores. All models trained with evidence significantly outperform seq2seq trained without evidence (approximation randomization testing, $p < 0.0001$).

details are included in the supplementary material.

We then take this trained model to evaluate the relevance between OP and the corresponding system arguments. Each system argument is treated as positive sample; we then select five negative samples from arguments generated for other OPs whose evidence sentences most similar to that of the positive sample. Intuitively, if an argument contains more topic relevant information, then the relevance estimation model will output a higher score for it; otherwise, the argument will receive a lower similarity score, and thus cannot be easily distinguished from negative samples. Ranking metrics of MRR and Precision at 1 (P@1) are utilized, with results reported in Table 4. The ranker yields significantly better scores over arguments generated from models trained with evidence, compared to arguments generated by SEQ2SEQ model.

Moreover, we manually pick 29 commonly used generic responses (e.g., "I don't think so") and count their frequency in system outputs. For the seq2seq model, more than 75% of its outputs contain at least one generic argument, compared to 16.2% by our separate decoder model with attention over keyphrases. This further implies that our model generates more topic-relevant content.

7.3 Human Evaluation

We also hire three trained human judges who are fluent English speakers to rate system arguments for the following three aspects on a scale of 1 to 5 (with 5 as best): *Grammaticality*—whether an argument is fluent, *informativeness*—whether the argument contains useful information and is not generic, and *relevance*—whether the argument contains information of a different stance or off-topic. 30 CMV threads are randomly selected, each of which is presented with randomly-shuffled OP statement and four system arguments.

System	Gram	Info	Rel
RETRIEVAL	**4.5** $\pm$ 0.6	**3.7** $\pm$ 0.9	**3.3** $\pm$ 1.1
SEQ2SEQ	3.3 $\pm$ 1.1	1.2 $\pm$ 0.5	1.4 $\pm$ 0.7
OUR MODEL	2.5 $\pm$ 0.8	1.6 $\pm$ 0.8	1.8 $\pm$ 0.8

Table 5: Human evaluation results on grammaticality (**Gram**), informativeness (**Info**), and relevance (**Rel**) of arguments. Our model with separate decoder and attention over keyphrases receives significantly better ratings in informativeness and relevance than seq2seq (one-way ANOVA, $p < 0.005$).

Table 5 shows that our model with separate decoder and attention over keyphrases produce significantly more informative and relevant arguments than seq2seq trained without evidence.[8] However, we also observe that human judges prefer the retrieved arguments over generation-based models, illustrating the gap between system arguments and human edited text. Sample arguments are displayed in Figure 4.

8 Further Discussion

Keyphrase Generation Analysis. Here we provide further analysis over the generated keyphrases by our separate decoder model. First, about 10% of the keyphrases output by our model also appear in the gold-standard (i.e., used by human arguments). Furthermore, 36% of generated keyphrases are reused by our system arguments. With human inspection, we find that although some keyphrases are not directly reused by the argument decoder, they represent high level talking points in the argument. For instance, in the first sample argument by our model in Figure 4, keyphrases "the motive" and "russian" are generated. Although not used, they suggest the topics that the argument should stay on.

Sample Arguments and Future Directions. As can be seen from the sample outputs in Figure 4, our model generally captures more relevant concepts, e.g., "military army" and "wars

[8]Inter-rater agreement scores for these three aspects are 0.50, 0.60, and 0.48 by Krippendorff's α.

Input: Putin is trying to re-form a “Soviet Union” with his past actions in Georgia and current actions in Ukraine
Human: So far Putin has only really targeted areas where the local population is majority russian (or historically majority russian) and sympathetic to russia. That’s not to say that he wouldn’t go further, but I don’t think there is yet any compelling reason to believe he would.
Retrieval: In 1968, the Soviet Union and Warsaw pact allies invaded Czechoslovakia to halt the Prague spring reforms. It was this significant lack of flexibility that was exploited by the US to undermine the strength of the Soviet Union and thus foster its reform. In the summer of 1991, the new union treaty, which would have turned the Soviet Union into a much looser union, was agreed upon by eight republics.
Our Model: There are two reasons you are so far beyond. There is no reason to see the military army. You can infer what they assume it, so they tend to protect up. There. If we assume it were bad, they can not be controlled. So we’re talking going to ignore the wars of the world. The fact of the matter is not bad. I would also assume it. However, the government can not be reminded of the world.
Seq2seq + evd: 1. The reason is that the government isn’t the power of the war of Russia, at the time of the war of Russia. In Russia, there is no way to continue to control the military.
Seq2seq + KP: I don’t think it’s a bit. I don’t think you’re forgetting. I don’t want to see the Syrian American dream in the US. I don’t see the Syrian American dream of American citizens. I don’t see the Syrian American dream of American citizens. I don’t see the Syrian American military in the world. I don’t think it wouldn’t be true.

Input: Voting for either Hillary or Trump is morally reprehensible.
Human: I don’t think a vote for either of them means ”I’m totally fine with...” as you say. Why is it not acceptable to pick the option whose platform most closely aligns to your values/beliefs/desires, while acknowledging neither candidate is ideal?
Retrieval: Vote trading under a democratic, majority-rule institution is sometimes considered morally reprehensible behavior.
Our Model: He’s going to happen. You’re overestimating the more premise. He’s already overestimating to this hypothetical party. He’s already killed over the supreme court positions. Looking for Bernie. This is the same reasons: Clinton is not the supreme court presidency. You’ve already sent Trump’s right to vote. The fact is that he’s going to happen. He’s already going to notice. However, it’s a long way.
Seq2seq + evd: 1. If they don’t vote the vote, they would not be able to vote for any candidate. They don’t have the same effect on their political power. They are not voting for them.
Seq2seq + KP: I agree with your view. I don’t agree with you. I don’t think it’s easy to appeal to the Clintons. If you don’t want to do this?

Figure 4: Sample arguments generated by human, our system, and seq2seq trained with evidence. Only the main thesis is shown for the input OP. System generations are manually detokenized and capitalized.

of the world”, as discussed in the first example. Meanwhile, our model also acquires argumentative style language, though there is still a noticeable gap between system arguments and human constructed arguments. As discovered by our prior work (Wang et al., 2017), both topical content and language style are essential elements for high quality arguments. For future work, generation models with a better control on linguistic style need to be designed. As for improving coherence, we believe that discourse-aware generation models (Ji et al., 2016) should also be explored in the future work to enhance text planning.

9 Related Work

There is a growing interest in argumentation mining from the natural language processing research community (Park and Cardie, 2014; Ghosh et al., 2014; Palau and Moens, 2009; Niculae et al., 2017; Eger et al., 2017). While argument understanding has received increasingly more attention, the area of automatic argument generation is much less studied. Early work on argument construction investigates the design of argumentation strategies (Reed et al., 1996; Carenini and Moore, 2000; Zukerman et al., 2000). For instance, Reed (1999) describes the first full natural language argument generation system, called Rhetorica. It however only outputs a text plan, mainly relying on heuristic rules. Due to the difficulty of text generation, none of the previous work represents a fully automated argument generation system. This work aims to close the gap by proposing an end-to-end trained argument construction framework.

Additionally, argument retrieval and extraction are investigated (Rinott et al., 2015; Hua and Wang, 2017) to deliver relevant arguments for user-specified queries. Wachsmuth et al. (2017) build a search engine from arguments collected from various online debate portals. After the retrieval step, sentence ordering algorithms are often applied to improve coherence (Sato et al., 2015; Reisert et al., 2015). Nevertheless, simply merging arguments from different resources inevitably introduces redundancy. To the best of our knowledge, this is the first automatic argument generation system that can synthesize retrieved content from different articles into fluent arguments.

10 Conclusion

We studied the novel problem of generating arguments of a different stance for a given statement. We presented a neural argument generation framework enhanced with evidence retrieved from Wikipedia. Separate decoders were designed to first produce a set of keyphrases as talking points, and then generate the final argument. Both automatic evaluation against human arguments and human assessment showed that our model produced more informative arguments than popular sequence-to-sequence-based generation models.

A Stylometric Inquiry into Hyperpartisan and Fake News

Abstract

We report on a comparative style analysis of hyperpartisan (extremely one-sided) news and fake news. A corpus of 1,627 articles from 9 political publishers, three each from the mainstream, the hyperpartisan left, and the hyperpartisan right, have been fact-checked by professional journalists at BuzzFeed: 97% of the 299 fake news articles identified are also hyperpartisan. We show how a style analysis can distinguish hyperpartisan news from the mainstream ($F_1 = 0.78$), and satire from both ($F_1 = 0.81$). But stylometry is no silver bullet as style-based fake news detection does not work ($F_1 = 0.46$). We further reveal that left-wing and right-wing news share significantly more stylistic similarities than either does with the mainstream. This result is robust: it has been confirmed by three different modeling approaches, one of which employs Unmasking in a novel way. Applications of our results include partisanship detection and pre-screening for semi-automatic fake news detection.

1 Introduction

The media and the public are currently discussing the recent phenomenon of “fake news” and its potential role in swaying elections, how it may affect society, and what can and should be done about it. Prone to misunderstanding and misue, the term “fake news” arose from the observation that, in social media, a certain kind of ‘news’ spreads much more successfully than others, and this kind of ‘news’ is typically extremely one-sided (hyperpartisan), inflammatory, emotional, and often riddled with untruths. Although traditional yellow press has been spreading ‘news’ of varying degrees of truthfulness long before the digital revolution, its amplification over *real* news within social media gives many people pause. The fake news hype caused a widespread disillusionment about social media, and many politicians, news publishers, IT companies, activists, and scientists concur that this is where to draw the line. For all their good intentions, however, it must be drawn very carefully (if at all), since nothing less than free speech is at stake—a fundamental right of every free society.

Many favor a two-step approach where fake news items are detected and then countermeasures are implemented to foreclose rumors and to discourage repetition. While some countermeasures are already tried in practice, such as displaying warnings and withholding ad revenue, fake news detection is still in its infancy. At any rate, a near-real time reaction is crucial: once a fake news item begins to spread virally, the damage is done and undoing it becomes arduous. Since knowledge-based and context-based approaches to fake news detection can only be applied after publication, i.e., as news events unfold and as social interactions occur, they may not be fast enough.

We have identified style-based approaches as a viable alternative, allowing for instantaneous reactions, albeit not to fake news, but to hyperpartisanship. In this regard we contribute (1) a large news corpus annotated by experts with respect to veracity and hyperpartisanship, (2) extensive experiments on discriminating fake news, hyperpartisan news, and satire based solely on writing style, and (3) validation experiments to verify our finding that the writing style of the left and the right have more in common than any of the two have with the mainstream, applying Unmasking in a novel way.

After a review of related work, Section 3 details the corpus and its construction, Section 4 introduces our methodology, and Section 5 reports the results of the aforementioned experiments.

2 Related Work

Approaches to fake news detection divide into three categories (Figure 1): they can be knowledge-based (by relating to known facts), context-based (by analyzing news spread in social media), and style-based (by analyzing writing style).

Knowledge-based fake news detection. Methods from information retrieval have been proposed early on to determine the veracity of web documents. For example, Etzioni et al. (2008) propose to identify inconsistencies by matching claims extracted from the web with those of a document in question. Similarly, Magdy and Wanas (2010) measure the frequency of documents that support a claim. Both approaches face the challenges of web data credibility, namely expertise, trustworthiness, quality, and reliability (Ginsca et al., 2015).

Other approaches rely on knowledge bases, including the semantic web and linked open data. Wu et al. (2014) "perturb" a claim in question to query knowledge bases, using the result variations as indicator of the support a knowledge base offers for the claim. Ciampaglia et al. (2015) use the shortest path between concepts in a knowledge graph, whereas Shi and Weninger (2016) use a link prediction algorithm. However, these approaches are unsuited for new claims without corresponding entries in a knowledge base, whereas knowledge bases can be manipulated (Heindorf et al., 2016).

Context-based fake news detection. Here, fake news items are identified via meta information and spread patterns. For example, Long et al. (2017) show that author information can be a useful feature for fake news detection, and Derczynski et al. (2017) attempt to determine the veracity of a claim based on the conversation it sparks on Twitter as one of the RumourEval tasks. The Facebook analysis of Mocanu et al. (2015) shows that unsubstantiated claims spread as widely as well-established ones, and that user groups predisposed to conspiracy theories are more open to sharing the former. Similarly, Acemoglu et al. (2010), Kwon et al. (2013), Ma et al. (2017), and Volkova et al. (2017) model the spread of (mis-)information, while Budak et al. (2011) and Nguyen et al. (2012) propose algorithms to limit its spread. The efficacy of countermeasures like debunking sites is studied by Tambuscio et al. (2015). While achieving good results, context-based approaches suffer from working only a posteriori, requiring large amounts of data, and disregarding the actual news content.

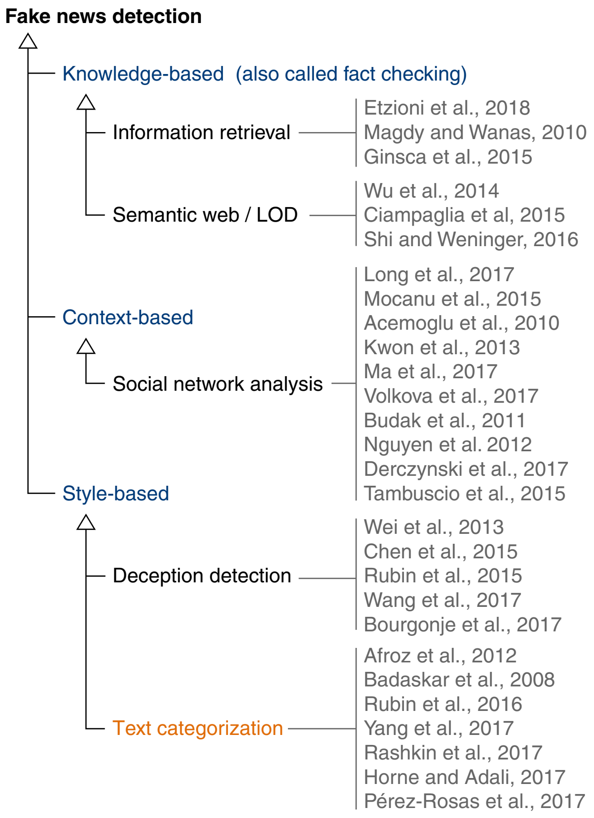

Figure 1: Taxonomy of paradigms for fake news detection alongside a selection of related work.

Style-based fake news detection. Deception detection originates from forensic linguistics and builds on the Undeutsch hypothesis—a result from forensic psychology which asserts that memories of real-life, self-experienced events differ in content and quality from imagined events (Undeutsch, 1967). The hypothesis led to the development of forensic tools to assess testimonies at the statement level. Some approaches operationalize deception detection at scale to detect uncertainty in social media posts, for example Wei et al. (2013) and Chen et al. (2015). In this regard, Rubin et al. (2015) use rhetorical structure theory as a measure of story coherence and as an indicator for fake news. Recently, Wang (2017) collected a large dataset consisting of sentence-length statements along their veracity from the fact-checking site PolitiFact.com, and then used style features to detect false statements. A related task is stance detection, where the goal is to detect the relation between a claim about an article, and the article itself (Bourgonje et al., 2017). Most prominently, stance detection was the task of the Fake News Challenge[1] which ran in 2017 and received 50 submissions, albeit hardly any participants published their approach.

[1]http://www.fakenewschallenge.org/

Where deception detection focuses on single statements, style-based text categorization as proposed by Argamon-Engelson et al. (1998) assesses entire texts. Common applications are author profiling (age, gender, etc.) and genre classification. Though susceptible to authors who can modify their writing style, such obfuscations may be detectable (e.g., Afroz et al. (2012)). As an early precursor to fake news detection, Badaskar et al. (2008) train models to identify news items that were automatically generated. Currently, text categorization methods for fake news detection focus mostly on satire detection (e.g., Rubin et al. (2016), Yang et al. (2017)). Rashkin et al. (2017) perform a statistical analysis of the stylistic differences between real, satire, hoax, and propaganda news. We make use of their results by incorporating the best-performing style features identified.

Finally, two preprint papers have been recently shared. Horne and Adali (2017) use style features for fake news detection. However, the relatively high accuracies reported must be taken with a grain of salt: their two datasets comprise only 70 news articles each, whose ground-truth is based on where an article came from, instead of resulting from a per-article expert review as in our case; their final classifier uses only 4 features (number of nouns, type-token ratio, word count, number of quotes), which can be easily manipulated; and based on their experimental setup, it cannot be ruled out that the classifier simply differentiates news portals rather than fake and real articles. We avoid this problem by testing our classifiers on articles from portals which were not represented in the training data. Similarly, Pérez-Rosas et al. (2017) also report on constructing two datasets comprising around 240 and 200 news article *excerpts* (i.e., the 5-sentence lead) with a balanced distribution of fake vs. real. The former was collected via crowdsourcing, asking workers to write a fake news item based on a real news item, the latter was collected from the web. For style analysis, the former dataset may not be suitable, since the authors note themselves that "workers succeeded in mimicking the reporting style from the original news". The latter dataset encompasses only celebrity news (i.e., yellow press), which introduces a bias. Their feature selection follows that of Rubin et al. (2016), which is covered by our experiments, but also incorporates topic features, rendering the resulting classifier not generalizable.

3 The BuzzFeed-Webis Fake News Corpus

This section introduces the BuzzFeed-Webis Fake News Corpus 2016, detailing its construction and annotation by professional journalists employed at BuzzFeed, as well as key figures and statistics.[2]

3.1 Corpus Construction

The corpus encompasses the output of 9 publishers on 7 workdays close to the US presidential elections 2016, namely September 19 to 23, 26, and 27. Table 1 gives an overview. Among the selected publishers are six prolific hyperpartisan ones (three left-wing and three right-wing), and three mainstream ones. All publishers earned Facebook's blue checkmark ✓, indicating authenticity and an elevated status within the network. Every post and linked news article has been fact-checked by 4 BuzzFeed journalists, including about 19% of posts forwarded from third parties. Having checked a total of 2,282 posts, 1,145 mainstream, 471 left-wing, and 666 right-wing, Silverman et al. (2016) reported key insights as a data journalism article. The annotations were published alongside the article.[3] However, this data only comprises URLs to the original Facebook posts. To construct our corpus, we archived the posts, the linked articles, and attached media as well as relevant meta data to ensure long-term availability. Due to the rapid pace at which the publishers change their websites, we were able to recover only 1,627 articles, 826 mainstream, 256 left-wing, and 545 right-wing.

Manual fact-checking. A binary distinction between fake and real news turned out to be infeasible, since hardly any piece of fake news is entirely false, and pieces of real news may not be flawless. Therefore, posts were rated "mostly true," "mixture of true and false," "mostly false," or, if the post was opinion-driven or otherwise lacked a factual claim, "no factual content." Four BuzzFeed journalists worked on the manual fact-checks of the news articles: to minimize costs, each article was reviewed only once and articles were assigned round robin. The ratings "mixture of true and false" and "mostly false" had to be justified, and, when in doubt about a rating, a second opinion was collected, whereas disagreements were resolved by a third one. Finally, all news rated "mostly false" underwent a final check to ensure the rating was justified, lest the respective publishers would contest it.

[2]Corpus download: https://doi.org/10.5281/zenodo.1239675
[3]http://github.com/BuzzFeedNews/2016-10-facebook-fact-check

The journalists were given the following guidance:

Mostly true: The post and any related link or image are based on factual information and portray it accurately. The authors may interpret the event/info in their own way, so long as they do not misrepresent events, numbers, quotes, reactions, etc., or make information up. This rating does not allow for unsupported speculation or claims.

Mixture of true and false (mix, for short): Some elements of the information are factually accurate, but some elements or claims are not. This rating should be used when speculation or unfounded claims are mixed with real events, numbers, quotes, etc., or when the headline of the link being shared makes a false claim but the text of the story is largely accurate. It should also only be used when the unsupported or false information is roughly equal to the accurate information in the post or link. Finally, use this rating for news articles that are based on unconfirmed information.

Mostly false: Most or all of the information in the post or in the link being shared is inaccurate. This should also be used when the central claim being made is false.

No factual content (n/a, for short): This rating is used for posts that are pure opinion, comics, satire, or any other posts that do not make a factual claim. This is also the category to use for posts that are of the "Like this if you think..." variety.

3.2 Limitations

Given the significant workload (i.e., costs) required to carry out the aforementioned annotations, the corpus is restricted to the given temporal period and biased toward the US culture and political landscape, comprising only English news articles from a limited number of publishers. Annotations were recorded at the article level, not at statement level. For text categorization, this is sufficient. At the time of writing, our corpus is the largest of its kind that has been annotated by professional journalists.

3.3 Corpus Statistics

Table 1 shows the fact-checking results and some key statistics per article. Unsurprisingly, none of the mainstream articles are mostly false, whereas 8 across all three publishers are a mixture of true and false. Disregarding non-factual articles, a little more than a quarter of all hyperpartisan left-wing articles were found faulty: 15 articles mostly false, and 51 a mixture of true and false. Publisher "The Other 98%" sticks out by achieving an almost perfect score. By contrast, almost 45% of the right-wing articles are a mixture of true and false (153) or mostly false (72). Here, publisher "Right Wing News" sticks out by supplying more than half of mixtures of true and false alone, whereas mostly false articles are equally distributed.

Orientation	**Fact-checking results**					**Key statistics per article**				
Publisher	true	mix	false	n/a	Σ	Paras.	Links		Words	
							extern	all	quoted	all
Mainstream	806	8	0	12	826	20.1	2.2	3.7	18.1	692.0
ABC News	90	2	0	3	95	21.1	1.0	4.8	21.0	551.9
CNN	295	4	0	8	307	19.3	2.4	2.5	15.3	588.3
Politico	421	2	0	1	424	20.5	2.3	4.3	19.9	798.5
Left-wing	182	51	15	8	256	14.6	4.5	4.9	28.6	423.2
Addicting Info	95	25	8	7	135	15.9	4.4	4.5	30.5	430.5
Occupy Democrats	55	23	6	0	91	10.9	4.1	4.7	29.0	421.7
The Other 98%	32	3	1	1	30	20.2	6.4	7.2	21.2	394.5
Right-wing	276	153	72	44	545	14.1	2.5	3.1	24.6	397.4
Eagle Rising	107	47	25	36	214	12.9	2.6	2.8	17.3	388.3
Freedom Daily	48	24	22	4	99	14.6	2.2	2.3	23.5	419.3
Right Wing News	121	82	25	4	232	15.0	2.5	3.6	33.6	396.6
Σ	1264	212	87	64	1627	17.2	2.7	3.7	20.6	551.0

Table 1: The BuzzFeed-Webis Fake News Corpus 2016 at a glance ("Paras." short for "paragraphs").

Regarding key statistics per article, it is interesting that the articles from all mainstream publishers are on average about 20 paragraphs long with word counts ranging from 550 words on average at ABC News to 800 at Politico. Except for one publisher, left-wing articles and right-wing articles are shorter on average in terms of paragraphs as well as word count, averaging at about 420 words and 400 words, respectively. Left-wing articles quote on average about 10 words more than the mainstream, and right-wing articles 6 words more. When articles comprise links, they are usually external ones, whereas ABC News rather uses internal links, and only half of the links found at Politico articles are external. Left-wing news articles stick out by containing almost double the amount of links across publishers than mainstream and right-wing ones.

3.4 Operationalizing Fake News

In our experiments, we operationalize the category of fake news by joining the articles that were rated mostly false with those rated a mixture of true and false. Arguably, the latter may not be exactly what is deemed "fake news" (as in: a complete fabrication), however, practice shows fake news are hardly ever devoid of truth. More often, true facts are misconstrued or framed badly. In our experiments, we hence call mostly true articles real news, mostly false plus mixtures of true and false—except for satire—fake news, and disregard all articles rated non-factual.

4 Methodology

This section covers our methodology, including our feature set to capture writing style, and a brief recap of Unmasking by Koppel et al. (2007), which we employ for the first time to distinguish genre styles as opposed to author styles. For sake of reproducibility, all our code has been published.[4]

4.1 Style Features and Feature Selection

Our writing style model incorporates common features as well as ones specific to the news domain. The former are n-grams, n in $[1, 3]$, of characters, stop words, and parts-of-speech. Further, we employ 10 readability scores[5] and dictionary features, each indicating the frequency of words from a tailor-made dictionary in a document, using the General Inquirer Dictionaries as a basis (Stone et al., 1966). The domain-specific features include ratios of quoted words and external links, the number of paragraphs, and their average length.

In each of our experiments, we carefully select from the aforementioned features the ones worthwhile using: all features are discarded that are hardly represented in our corpus, namely word tokens that occur in less than 2.5% of the documents, and n-gram features that occur in less than 10% of the documents. Discarding these features prevents overfitting and improves the chances that our model will generalize.

If not stated otherwise, our experiments share a common setup. In order to avoid biases from the respective training sets, we balance them using oversampling. Furthermore, we perform 3-fold cross-validation where each fold comprises one publisher from each orientation, so that the classifier does not learn a publisher's style. For non-Unmasking experiments we use WEKA's random forest implementation with default settings.

4.2 Unmasking Genre Styles

Unmasking, as proposed by Koppel et al. (2007), is a meta learning approach for authorship verification. We study for the first time whether it can be used to assess the similarity of more broadly defined style categories, such as left-wing vs. right-wing vs. mainstream news. This way, we uncover relations between the writing styles that people may involuntarily adopt as per their political orientation.

[4]Code download: http://www.github.com/webis-de/ACL-18

[5]Automated Readability Index, Coleman Liau Index, Flesh Kincaid Grade Level and Reading Ease, Gunning Fog Index, LIX, McAlpine EFLAW Score, RIX, SMOG Grade, Strain Index

Originally, Unmasking takes two documents as input and outputs its confidence whether they have been written by the same author. Three steps are taken to accomplish this: first, each document is chunked into a set of at least 500-word long chunks; second, classification errors are measured while iteratively removing the most discriminative features of a style model consisting of the 250 most frequent words, separating the two chunk sets with a linear classifier; and third, the resulting classification accuracy curves are analyzed with regard to their slope. A steep decrease is more likely than a shallow decrease if the two documents have been written by the same author, since there are presumably less discriminating features between documents written by the same author than between documents written by different authors. Training a classifier on many examples of error curves obtained from same-author document pairs and different-author document pairs yields an effective authorship verifier—at least for long documents that can be split up into a sufficient number of chunks.

It turns out that what applies to the style of authors also applies to genre styles. We adapt Unmasking by skipping its first step and using two sets of documents (e.g., left-wing articles and right-wing articles) as input. When plotting classification error curves for visual inspection, steeper decreases in these plots, too, indicate higher style similarity of the two input document sets, just as with chunk sets of two documents written by the same author.

4.3 Baselines

We employ four baseline models: a topic-based bag of words model, often used in the literature, but less practical since news topics change frequently and drastically; a model using only the domain-specific news style features to check whether the differences between categories measured as corpus statistics play a significant role; and naive baselines that classify all items into one of the categories in question, relating our results to the class distributions.

4.4 Performance Measures

Classification performance is measured as accuracy, and class-wise precision, recall, and F_1. We favor these measures over, e.g., areas under the ROC curve or the precision recall curve for simplicity sake. Also, the tasks we are tackling are new, so that little is known to date about user preferences. This is also why we chose the evenly-balanced F_1.

5 Experiments

We report on the results of two series of experiments that investigate style differences and similarities between hyperpartisan and mainstream news, and between fake, real, and satire news, shedding light on the following questions:

1. Can (left/right) hyperpartisanship be distinguished from the mainstream?
2. Is style-based fake news detection feasible?
3. Can fake news be distinguished from satire?

Our first experiment addressing the first question uncovered an odd behavior of our classifier: it would often misjudge left-wing for right-wing news, while being much better at distinguishing both combined from the mainstream. To explain this behavior, we hypothesized that *maybe* the writing style of the hyperpartisan left and right are more similar to one another than to the mainstream. To investigate this hypothesis, we devised two additional validation experiments, yielding three sources of evidence instead of just one.

Features	**Accuracy**	**Precision**			**Recall**			**F_1**

Table 4: Ratio of left articles misclassified right when omitting left articles from training, and vice versa.

5.1 Hyperpartisanship vs. Mainstream

A. Predicting orientation. Table 2 shows the classification performance of a ternary classifier trained to discriminate left, right, and mainstream—an obvious first experiment for our dataset. Separating the left and right orientation from the mainstream does not work too well: the topic baseline outperforms the style-based models with regard to accuracy, whereas the results for class-wise precision and recall are a mixed bag. The left-wing articles are apparently significantly more difficult to be identified compared to articles from the other two orientations. When we inspected the confusion matrix (not shown), it turned out that 66% of misclassifications of left-wing articles are falsely classified as right-wing articles, whereas 60% of all misclassified right-wing articles are classified as mainstream articles. Misclassified mainstream articles spread almost evenly across the other classes.

The poor performance of the domain-specific news style features by themselves demonstrate that orientation cannot be discriminated based on the basic corpus characteristics observed with respect to paragraphs, quotations, and hyperlinks. This holds for all subsequent experiments.

B. Predicting hyperpartisanship. Given the apparent difficulty of telling apart individual orientations, we did not frantically add features or switch classifiers to make it work. Rather, we trained a binary classifier to discriminate hyperpartisanship in general from the mainstream. Table 3 shows the performance values. This time, the best classification accuracy of 0.75 at a remarkable 0.89 recall for the hyperpartisan class is achieved by the style-based classifier, outperforming the topic baseline.

Comparing Table 2 and Table 3, we were left with a riddle: all other things being equal, how could it be that hyperpartisanship in general can be much better discriminated from the mainstream than individual orientation? Attempts to answer this question gave rise to our aforementioned hypothesis that, perhaps, the writing style of hyperpartisan left and right are not altogether different, despite their opposing agendas. Or put another way, if style and topic are orthogonal concepts, then being an extremist should not exert a different style dependent on political orientation. Excited, we sought ways to *independently* disprove the hypothesis, and found two: Experiments C and D.

C. Validation using leave-out classification. If left-wing and right-wing articles have a more similar style than either of them compared to mainstream articles, then what class would a binary classifier assign to a left-wing article, if it were trained to distinguish only the right-wing from the mainstream, and vice versa? Table 4 shows the results of this experiment. As indicated by proportions well above 0.50, full style-based classifiers have a tendency of clas-

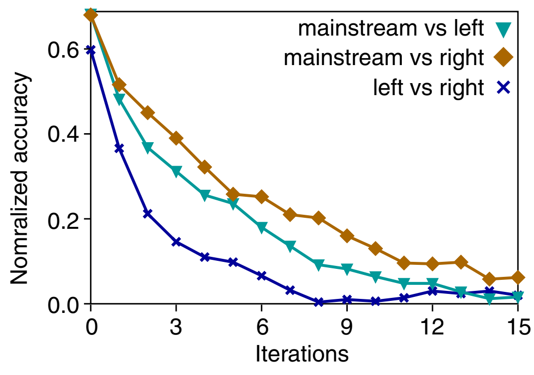

Figure 2: Unmasking applied to pairs of political orientations. The steeper a curve, the more similar the respective styles.

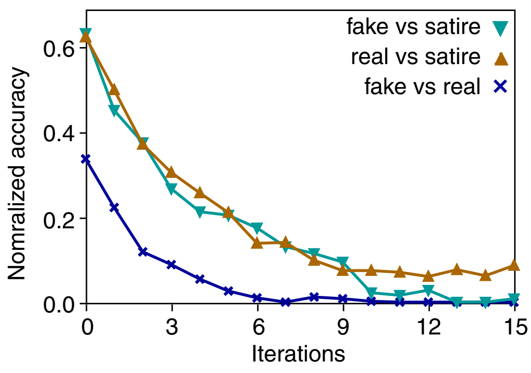

Figure 3: Unmasking applied to pairs of sets of news that are fake, real, and satire.

sifying left as right and right as left. The topic baseline, though, gets confused especially when omitting right articles from the training set with performance close to random. The fact that the topic baseline works better when omitting left from the training set may be explainable: leading up to the elections, the hyperpartisan left was often merely reacting to topics prompted by the hyperpartisan right, instead of bringing up their own.

D. Validation using Unmasking. Based on Koppel et al.'s original approach in the context of authorship verification, for the first time, we generalize Unmasking to assess genre styles: just like author style similarity, genre style similarity will be characterized by the slope of a given Unmasking curve, where a steeper decrease indicates higher similarity. We apply Unmasking as described in Section 4.2 onto pairs of sets of left, right, and mainstream articles. Figure 2 shows the resulting Unmasking curves (Unmasking is symmetrical, hence three curves). The curves are averaged over 5 runs, where each run comprised sets of 100 articles from each orientation. In case of the left-wing orientation, where less than 500 articles are available in our corpus, once all of them had been used, they were shuffled again to select articles for the remainder of the runs. As can be seen, the curve comparing left vs. right has a distinctly steeper slope than either of the others. This result hence matches the findings of the previous experiments.

With caution, we conclude that the evidence gained from our three independent experimental setups supports our hypothesis that the hyperpartisan left and the hyperpartisan right have more in common in terms of writing style than any of the two have with the mainstream. Another more tangible (e.g., practical) outcome of Experiment B is the finding that hyperpartisan news can apparently be discriminated well from the mainstream: in particular the high recall of 0.89 at a reasonable precision of 0.69 gives us confidence that, with some further effort, a practical classifier can be built that detects hyperpartisan news at scale and in real time, since an article's style can be assessed immediately without referring to external information.

5.2 Fake vs. Real (vs. Satire)

This series of experiments targets research questions (2) and (3). Again, we conduct three experiments, where the first is about predicting veracity, and the last two about discriminating satire.

A. Predicting veracity. When taking into account that the mainstream news publishers in our corpus did not publish any news items that are mostly false, and only very few instances that are mixtures of true and false, we may safely disregard them for the task of fake news detection. A reliable classifier for hyperpartisan news can act as a prefilter for a subsequent, more in-depth fake news detection approach, which may in turn be tailored to a much more narrowly defined classification task. We hence use only the left-wing articles and the right-wing articles of our corpus for our attempt at a style-based fake news classifier.

Table 5 shows the performance values for a generic classifier that predicts fake news across orientations, and orientation-specific classifiers that have been individually trained on articles from either orientation. Although all classifiers outperform the naive baselines of classifying everything into one of the classes in terms of precision, the slight increase comes at the cost of a large decrease in recall. While the orientation-specific classifiers are slightly better for most metrics, none of them outperform the naive baselines regarding the F-Measure. We conclude that style-based fake news classification simply does not work in general.

Features	Accuracy	Precision		Recall		F$_1$	
	all	fake	real	fake	real	fake	real
Generic classifier							
Style	0.55	0.42	0.62	0.41	0.64	0.41	0.63
Topic	0.52	0.41	0.62	0.48	0.55	0.44	0.58

Rubin et al.	n/a	0.90	n/a	0.84	n/a	0.87	n/a

Table 6: Performance of predicting satire (sat.).

B. Predicting satire. Yet, not all fake news are the same. One should distinguish satire from the rest, which takes the form of news but lies more or less obviously to amuse its readers. Regardless the problems that spreading fake news may cause, satire should never be filtered, but be discriminated from other fakes. Table 6 shows the performance values of our classifier in the satire-detection setting used by Rubin et al. (2016) (the S-n-L News DB corpus), distinguishing satire from real news. This setting uses a balanced 3:1 training-to-test set split over 360 articles (180 per class). As can be seen, our style-based model significantly outperforms all baselines across the board, achieving an accuracy of 0.82, and an F score of 0.81. It clearly improves over topic classification, but does not outperform Rubin et al.'s classifier, which includes features based on topic, absurdity, grammar, and punctuation. We argue that incorporating topic into satire detection is not appropriate, since the topics of satire change along the topics of news. A classifier with topic features therefore does not generalize. Apparently, a style-based model is competitive, and we believe that satire can be detected at scale this way, so as to prevent other fake news detection technology from falsely filtering it.

C. Unmasking satire. Given the above results on stylistic similarities between left and right news, the question remains how satire fits into the picture. We assess the style similarity of satire from Rubin et al.'s corpus compared to fake news and real news from ours, again applying Unmasking to compare pairs of the three categories of news as described above. Figure 3 shows the resulting Unmasking curves. The curve for the pair of fake vs. real news drops faster compared to the other two pairs. Apparently, the style of fake news has more in common with that of real news than either of the two have with satire. These results are encouraging: satire is distinct enough from fake and real news, so that, just like with hyperpartisan news compared to mainstream news, it can be discriminated with reasonable accuracy.

6 Conclusion

Fact-checking for fake news detection poses an interdisciplinary challenge: technology is required to extract factual statements from text, to match facts with a knowledge base, to dynamically retrieve and maintain knowledge bases from the web, to reliably assess the overall veracity of an entire article rather than individual statements, to do so in real time as news events unfold, to monitor the spread of fake news within and across social media, to measure the reputation of information sources, and to raise awareness in readers. These are only the most salient things that need be done to tackle the problem, and as our cross-section of related work shows, a large body of work must be covered. Notwithstanding the many attacks on fake news by developing one way or another of fact-checking, we believe it worthwhile to mount our attack from another angle: writing style.

We show that news articles conveying a hyperpartisan world view can be distinguished from more balanced news by writing style alone. Moreover, for the first time, we found quantifiable evidence that the writing styles of news of the two opposing orientations are in fact very similar: there appears to be a common writing style of left and right extremism. We further show that satire can be distinguished well from other news, ensuring that humor will not be outcast by fake news detection technology. All of these results offer new, tangible, short-term avenues of development, lest large-scale fact-checking is still far out of reach. Employed as pre-filtering technologies to separate hyperpartisan news from mainstream news, our approach allows for directing the attention of human fact checkers to the most likely sources of fake news.

Abstract

Given any argument on any controversial topic, how to counter it? This question implies the challenging retrieval task of finding the best counterargument. Since prior knowledge of a topic cannot be expected in general, we hypothesize the best counterargument to invoke the same aspects as the argument while having the opposite stance. To operationalize our hypothesis, we simultaneously model the similarity and dissimilarity of pairs of arguments, based on the words and embeddings of the arguments' premises and conclusions. A salient property of our model is its independence from the topic at hand, i.e., it applies to arbitrary arguments. We evaluate different model variations on millions of argument pairs derived from the web portal *idebate.org*. Systematic ranking experiments suggest that our hypothesis is true for many arguments: For 7.6 candidates with opposing stance on average, we rank the best counterargument highest with 60% accuracy. Even among all 2801 test set pairs as candidates, we still find the best one about every third time.

1 Introduction

Many controversial topics in real life divide us into opposing camps, such as whether to ban guns, who should become president, or what phone to buy. When being confronted with arguments against our stance, but also when forming own arguments, we need to think about how they could best be countered. Argumentation theory tells us that — aside from ad-hominem attacks — a counterargument denies either an argument's premises, its conclusion, or the reasoning between them (Walton, 2009). Take the following argument in favor of the right to bear arms from the web portal idebate.org:

Argument *"Gun ownership is an integral aspect of the right to self defence.* (conclusion)
Law-abiding citizens deserve the right to protect their families in their own homes, especially if the police are judged incapable of dealing with the threat of attack. [...]" (premise)

While the conclusion seems well-reasoned, the web portal directly provides a counter to the argument:

Counterargument *"Burglary should not be punished by vigilante killings of the offender. No amount of property is worth a human life. Perversely, the danger of attack by homeowners may make it more likely that criminals will carry their own weapons. If a right to self-defence is granted in this way, many accidental deaths are bound to result. [...]"*

As in this example, we observe that a counterargument often takes on the aspects of the topic invoked by the argument, while adding a new perspective to its conclusion and/or premises, conveying the opposite stance. Research has tackled the stance of argument units (Bar-Haim et al., 2017) as well as the attack relations between arguments (Cabrio and Villata, 2012). However, existing approaches learn the interplay of aspects and topics on training data or infer it from external knowledge bases (details in Section 2). This does not work for topics unseen before. Moreover, to our knowledge, no work so far aims at actual *counter*arguments.

This paper studies the task of automatically finding the best counterargument to any argument. In the general case, we cannot expect prior knowledge of an argument's topic. Following the observation above, we thus just hypothesize the best counterargument to invoke the same aspects as the argument while having the opposite stance. Figure 1 sketches how we operationalize the hypothesis. In particular, we simultaneously model the topic similarity and stance *dis*similarity of a candidate counterargument

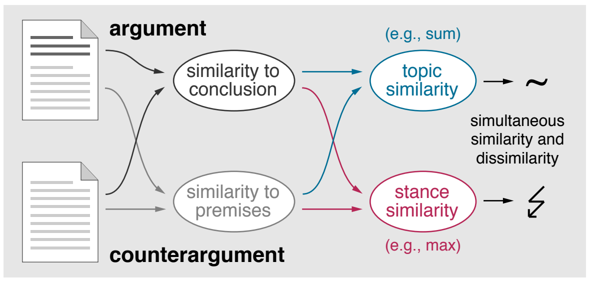

Figure 1: Modeling the simultaneous similarity and dissimilarity of a counterargument to an argument.

to the argument. Both are inferred — in different ways — from the similarities to the argument's conclusion and premises, since it is unclear in advance, whether either of these units or the reasoning between them is countered. Thereby, we find the most dissimilar among the most similar arguments.

To study counteraguments, we provide a new corpus with 6753 argument-counterargument pairs, taken from 1069 debates on idebate.org, as well as millions of false pairs derived from them. Given the corpus, we define eight retrieval tasks that differ in the types of candidate counterarguments. Based on the words and embeddings of the arguments, we develop similarity functions that realize the outlined model as a ranking approach. In systematic experiments, we evaluate the different building blocks of our model on all defined tasks.

The results suggest that our hypothesis is true for many arguments. The best model configuration improves common word and embedding similarity measures by eight to ten points accuracy in all tasks. Inter alia, we rank 60.3% of the best counterarguments highest when given all arguments with opposite stance (7.6 on average). Even with all 2801 test arguments as candidates, we still achieve 32.4% (and a mean rank of 15), fitting the intuition that off-topic arguments are easier to discard. Our analysis reveals notable gaps across topical themes though.

Contributions We believe that our findings will be important for applications such as automatic debating technologies (Rinott et al., 2015) and argument search (Wachsmuth et al., 2017b). To summarize, our main contributions are:

- A large corpus for studying multiple counterargument retrieval tasks (Sections 3 and 4).
- A topic-independent approach to find the best counterargument to any argument (Section 5).
- Evidence that many counterarguments can be found without topic knowledge (Section 6).

The corpus as well as the Java source code for reproducing the experiments are available at `http://www.arguana.com`.

2 Related Work

Counterarguments rebut arguments. In the theoretical model of Toulmin (1958), a rebuttal in fact does not attack the argument, but it merely shows exceptions to the argument's reasoning. Govier (2010) suggests to rather speak of counterconsiderations in such cases. Unlike Damer (2009), who investigates *how to attack* several kinds of fallacies, we are interested in *how to identify attacks*. We focus on those that target arguments, excluding personal (ad-hominem) attacks (Habernal et al., 2018).

Following Walton (2006), an argument can be attacked in two ways: one is to question its validity — not meaning that its conclusion must be wrong. The other is to rebut it with a *counterargument* that entails the opposite conclusion, often by revisiting aspects or introducing new ones. This is the type of attack we study. As Walton (2009) details, rebuttals may target an argument's premises or conclusion, or they may undercut the reasoning between them.

Recently, the computational analysis of natural language argumentation is receiving much attention. Most research focuses on argument mining, ranging from segmenting a text into argument units (Ajjour et al., 2017), over identifying unit types (Rinott et al., 2015) and roles (Niculae et al., 2017), to classifying argument schemes (Feng and Hirst, 2011) and relations (Lawrence and Reed, 2017). Some works detect counterconsiderations in a text (Peldszus and Stede, 2015) or their absence (Stab and Gurevych, 2016). Such considerations make arguments more balanced (see above). In contrast, we seek for arguments that defeat others.

Many approaches mine attack relations between arguments. Some use deep learning to find attacks in discussions (Cocarascu and Toni, 2017). Closer to this paper, others determine them in a given set of arguments, using textual entailment (Cabrio and Villata, 2012) or a combination of markov logic and stance classification (Hou and Jochim, 2017). In principle, any attacking argument denotes a counterargument. Unlike previous work, however, we aim for the *best* counterargument to an argument.

Classifying the stance of a text towards a topic (pro or con) generally defines an alternative way of addressing counterarguments. Sobhani et al. (2015) specifically classify health-related arguments using supervised learning, while we do not expect to have prior topic knowledge. Bar-Haim et al. (2017) approach the stance of claims towards open-domain topics. Their approach combines aspect-based sentiment with external relations between aspects and topics from Wikipedia. As such, it is in fact limited to the topics covered there. Our model applies to arbitrary arguments and counterarguments.

We need to identify only whether arguments oppose each other, not their actual stance. Similarly, Menini et al. (2017) classify only the *disagreement* of political texts. Part of their approach is to detect topical key aspects in an unsupervised manner, which seems useful for our purposes. Analogously, Beigman Klebanov et al. (2010) study differences in vocabulary choice for the related task of perspective classification, and Tan et al. (2016) find that the best way to persuade opinion holders in the *Change my view* forum on reddit.com is to use dissimilar words. As we report later, however, our experiments did not show such results for the argument-counterargument pairs we deal with.

The goal of persuasion reveals the association of counterarguments to argumentation quality. Many quality criteria have been assessed for arguments, surveyed in (Wachsmuth et al., 2017a). In the study of Habernal and Gurevych (2016), one reason annotators gave for why an argument was more convincing than another was that it tackled flaws in the opposing view. Zhang et al. (2016) even found that debate winners tend to counter opposing arguments rather than focusing on their own arguments.

Argument quality assessment is particularly important in retrieval scenarios. Existing approaches aim to retrieve documents that contain many claims (Roitman et al., 2016) or that provide most support for their claims (Braunstain et al., 2016). In Wachsmuth et al. (2017c), we adapt PageRank to argumentative relations, in order to assess argument relevance objectively. While our search engine *args* for arguments on the web still uses content-based relevance measures in its first version (Wachsmuth et al., 2017b), its long-term idea is to rank the best arguments highest.[1] The model present in this work finds the best *counter*arguments, but it is meant to be integrated into *args* at some point.

Like here, *args* uses idebate.org arguments. Others take data from that portal for studying support (Boltužić and Šnajder, 2014) or for the distant supervision of argument mining (Al-Khatib et al., 2016). Our corpus is not only larger, though, but it is the first to utilize a unique feature of idebate.org: the explicit specification of counterarguments.

[1]Argument search engine *args*: `http://args.me`

3 The ArguAna Counterargs Corpus

This section introduces our *ArguAna Counterargs corpus* with argument-counterargument pairs, created automatically from the structure of idebate.org. The corpus is freely available at `http://www.arguana.com/data`. We also provide the code to replicate the construction process.

3.1 The Web Portal idebate.org

On the *portal* idebate.org, diverse controversial topics of usually rather general interest are discussed in *debates*, subsumed under 15 *themes*, such as “economy” and “health”. Each debate has a title capturing a thesis on a topic, such as “This House would limit the right to bear arms”, followed by an introductory text, a set of mostly elaborated and well-written *points* that have a pro or a con stance towards the thesis, and a bibliography.

A specific feature of idebate.org is that virtually every point comes along with a *counter* that immediately attacks the point and its stance. Both points and counters can be seen as *arguments*. While a point consists of a one-sentence claim (the argument’s *conclusion*) and a few sentences justifying the claim (the *premise(s)*), the counter’s (opposite) conclusion remains implicit.

All arguments on the portal are established by a community with the goal of showing both sides of a topic in a balanced manner. We therefore assume each counter to be the best counterargument available for the respective point, and we use all resulting *true argument pairs* as the basis of our corpus. Figure 2 illustrates the italicized concepts, showing the structure of idebate.org. An example argument pair has been discussed in Section 1.

3.2 Corpus Construction

We crawled all debates from idebate.org that follow the portal’s theme-guided folder structure (last access: January 30, 2018). From each debate, we extracted the thesis, the introductory text, all points and counters, the bibliography, and some metadata. Each was stored separately in one plain text file, and we also created a file with the entire debate in its original order. Only points and counters are used in our experiments in Section 6. The underlying experiment settings are described in Section 4.

Table 1: Distribution of debates, points, and counters over the themes in the *counterargs-18* corpus. The bottom rows show the size of the datasets.

3.3 Corpus Statistics

Table 1 lists the number of debates crawled for each theme, along with the numbers of points and counters in the debates. The 26 found points without a counter are included in the corpus, but we do not use them in our experiments.

In total, the ArguAna Counterargs corpus consists of 1069 debates with 6753 points that have a counter. The mean length of points is 196.3 words, whereas counters span only 129.6 words, largely due to the missing explicit conclusion. To avoid exploiting this corpus bias, no approach in our experiments captures length differences.

3.4 Datasets

We split the corpus into a training set, consisting of the first 60% of all debates of each theme (ordered by alphabet), as well as a validation set and a test set, each covering 20%. The dataset sizes are found at the bottom of Table 1. By putting all arguments from a debate into a single dataset, no specific topic knowledge can be gained from the training or validation set. We include all themes in all datasets, because we expect the set of themes to be stable.

We checked for duplicates. Among the 13 532 point and counters, 3407 appear twice, 723 three times, 36 four times, and 1 five times. We ensure that no true pair is used as a false pair in our tasks.

4 Counterargument Retrieval Tasks

Based on the new corpus, we define the following eight counterargument retrieval tasks of different complexity. All tasks consider all true argument-counterargument pairs, while differing in terms of what arguments (points and/or counters) from which context (same debate, same theme, or entire portal) are candidates for a given argument.

Same Debate: Opposing Counters All counters in the same debate with stance opposite to the given argument are candidates (Figure 2: a, b). The task is to find the best counterargument among all counters to the argument's stance.

Same Debate: Counters All counters in the same debate irrespective of their stance are candidates (Figure 2: a–c). The task is to find the best counterargument among all on-topic arguments phrased as counters.

		Training Set			Validation Set			Test Set		
Context	**Candidate Counterarg's**	**True**	**False**	**Ratio**	**True**	**False**	**Ratio**	**True**	**False**	**Ratio**
Same debate	Opposing counters	4 065	11 672	1:2.9	1 287	3 590	1:2.8	1 401	4 052	1:2.9
	Counters	4 065	27 024	1:6.6	1 287	8 348	1:6.5	1 401	9 312	1:6.6
	Opposing arguments	4 065	27 026	1:6.6	1 287	8 350	1:6.5	1 401	9 312	1:6.6
	Arguments	4 065	54 070	1:13.3	1 287	16 700	1:13.0	1 401	18 630	1:13.3
Same theme	Counters	4 065	1 616 000	1:398	1 287	176 266	1:137	1 401	189 870	1:136
	Arguments	4 065	3 232 038	1:795	1 287	352 536	1:274	1 401	379 746	1:271
Entire portal	Counters	4 065	16 517 994	1:4063	1 287	1 654 878	1:1286	1 401	1 961 182	1:1400
	Arguments	4 065	33 038 154	1:8127	1 287	3 309 760	1:2572	1 401	3 922 582	1:2800

Table 2: Number of true and false argument-counterargument pairs as well as their ratio for each evaluated context and type of candidate counterarguments in the three datasets. Each line defines one retrieval task.

Same Debate: Opposing Arguments All arguments in the same debate with opposite stance are candidates (Figure 2: a, b, d). The task is to find the best among all on-topic counterarguments.

Same Debate: Arguments All arguments in the same debate irrespective of their stance are candidates (Figure 2: a–e). The task is to find the best counterargument among all on-topic arguments.

Same Theme: Counters All counters from the same theme are candidates (Figure 2: a–c, f). The task is to find the best counterargument among all on-theme arguments phrased as counters.

Same Theme: Arguments All arguments from the same theme are candidates (Figure 2: a–g). The task is to find the best counterargument among all on-theme arguments.

Entire Portal: Counters All counters are candidates (Figure 2: a–c, f, h). The task is to find the best counterargument among all arguments phrased as counters.

Entire Portal: Arguments All arguments are candidates (Figure 2: a–i). The task is to find the best counterargument among all arguments.

Table 2 lists the numbers of true and false pairs for each task. Experiment files containing the file paths of all candidate pairs are provided in our corpus.

5 Retrieval of the Best Counterargument without Prior Topic Knowledge

The eight defined tasks indicate the subproblems of retrieving the best counterargument to a given argument: Finding all arguments that address the *same topic*, filtering those arguments with an *opposite stance* towards the topic, and identifying the *best counter* among these arguments. This section presents our approach to solving these problems computationally without prior knowledge of the argument's topic, based on the simultaneous similarity and dissimilarity of arguments.[2]

5.1 Topic as Word and Embedding Similarity

We do not reinvent the wheel to assess topical relevance, but rather follow common practice. Concretely, we hypothesize a candidate counterargument to be on-topic if it is similar to the argument in terms of its words and its embedding. We capture these two types of similarity as follows.

Word Argument Similarity To best represent the words in arguments, we did initial counterargument retrieval tests with token, stem, and lemma n-grams, $n \in \{1, 2, 3\}$. While the differences were not large, stems worked best and stem 1-grams sufficed. Both might be a consequence of the limited data size. In our experiments in Section 6, we determine the *stem 1-grams* to be considered on the training set of each task.

For word similarity computation, we tested four inverse vector-based distance measures: Cosine, Euclidean, Manhattan, and, Jaccard similarity (Cha, 2007). On the validation sets, the Manhattan similarity performed best, closely followed by the Jaccard similarity. Both clearly outperformed Euclidean and especially Cosine similarity. This suggests that the presence and absence of words are equally important and that outliers should not be punished more. For brevity, we report only results for the *Manhattan similarity* below.

[2]As indicated above, counters on idebate.org (including all true counterarguments) may also differ linguistically from points (all of which are false). However, we assume this to be a specific corpus bias and hence do not explicitly account for it. Section 6 will show whether having both points and counters as candidates makes counterargument retrieval harder.

Embedding Argument Similarity We evaluated five pretrained word embedding models for representing arguments in first tests: GoogleNews-vectors (Mikolov et al., 2013), ConceptNet Numberbatch (Speer et al., 2017), wiki-news-300d-1M, wiki-news-300d-1M-subword, and crawl-300d-2M (Mikolov et al., 2017). The former two were competitive, the others performed notably worse. Since *ConceptNet Numberbatch* is smaller and supposed to have less bias, we used it in all experiments.

To capture argument-level embedding similarity, we compared the four inverse vector-based distance measures above on average word embeddings against the inverse Word Mover's distance, which quantifies the optimum alignment of two word embedding sequences (Kusner et al., 2015). This *Word Mover's similarity* consistently beat the others, so we decided to restrict our view to it.

5.2 Stance as Topic Dissimilarity

Stance classification without prior topic knowledge is challenging: While we can compare the topics of any two arguments, it is impossible in general to infer the stance of the specific aspects invoked by one argument to those of the other. As sketched in Section 2, related work employs external knowledge to infer stance relations of aspects and topics (Bar-Haim et al., 2017) or trains classifying attack relations (Cabrio and Villata, 2012). Unfortunately, both does not apply to topics unseen before.

For argument pairs invoking similar aspects, a way to go is in principle to assess sentiment polarity; intuitively, two arguments with the same topic but opposite sentiment have opposing stance. However, we tested topic-agnostic sentiment lexicons (Baccianella et al., 2010) and state-of-the-art sentiment classifiers, trained on large-scale multiple-domain review data (Prettenhofer and Stein, 2010; Joulin et al., 2017). The correlation between sentiment and stance differences of training arguments was close to zero. A possible explanation is the limited explicitness of sentiment on idebate.org, making the lexicons and classifiers fail there.

Other related work suggests that the vocabulary of opposing sides differs (Beigman Klebanov et al., 2010). We thus checked on the training set whether counterarguments are similar in their embeddings but dissimilar in their words. The measures above did not support this hypothesis, i.e., both embedding and word similarity increased the likelihood of a candidate counterargument being the best. Still, there must be a difference between an argument and its counterargument by concept. As a solution, we capture dissimilarity with the same similarity functions as above, but we change the granularity level on which we measure similarity.

5.3 Simultaneous Similarity and Dissimilarity

The arising question is how to assess similarity and dissimilarity at the same time. We hypothesize the best counterargument to be very similar in overall terms, but very dissimilar in certain respects. To capture this intuition, we rely on expert knowledge from argumentation theory (see Section 2).

Word and Embedding Unit Similarities In particular, we follow the notion that a counterargument attacks either the conclusion of an argument, the argument's premises, or both. As a consequence, we compute two word and two embedding similarities as specified above for each candidate counterargument; once to the argument's conclusion (called w_c and e_c for words and embeddings respectively) and once to the argument's premises (w_p and e_p).

Now, to capture similarity and dissimilarity simultaneously, we need multiple ways to aggregate conclusion and premise similarities. As we do not generally know which argument unit is attacked, we resort to four standard aggregation functions that generalize over the unit similarities. For words, these are the following *word unit similarities*:

$$\begin{array}{llll} w_{\downarrow} := & \min\{w_c, w_p\} \qquad & w_{\times} := & w_c \cdot w_p \\ w_{\uparrow} := & \max\{w_c, w_p\} \qquad & w_{+} := & w_c + w_p \end{array}$$

Accordingly, we define four respective *embedding unit similarities*, $e_{\downarrow}$, $e_{\uparrow}$, $e_{\times}$, and e_{+}.

As mentioned above, both word similarity and embedding similarity positively affect the likelihood that a candidate is the best counterargument. Therefore, we combine each pair of similarities as $w_{\downarrow} + e_{\downarrow}$, $w_{\uparrow} + e_{\uparrow}$, $w_{\times} + e_{\times}$, and $w_{+} + e_{+}$, but we also evaluate their impact in isolation below.[3]

Counterargument Scoring Model Based on the unit similarities, we finally define a scoring model for a given pair of argument and candidate counterargument. The model includes two unit similarity values, sim and $dissim$, but $dissim$ is subtracted from sim, such that it actually favors dissimilarity. Thereby, we realize the topic and

[3]In principle, other unit similarities could be used for words than for embeddings. However, we decided to couple them to maintain interpretability of our experiment results.

stance similarity sketched in Figure 1. We weight the two values with a damping factor α:

$$\alpha \cdot sim \;-\; (1-\alpha) \cdot dissim$$

where $sim, dissim \in \{w_{\downarrow}+e_{\downarrow}, w_{\uparrow}+e_{\uparrow}, w_{\times}+e_{\times}, w_{+}+e_{+}\}$ and $sim \neq dissim$.

The general idea of the scoring model is that sim rewards one type of similarity, whereas subtracting $dissim$ punishes another type. We seek to thereby find the most dissimilar candidate among the similar candidates. The model is meant to give a higher score to a pair the more likely the candidate is the best counterargument to the argument, so the scores can be used for ranking.

What combination of sim and $dissim$ turns out best, is hard to foresee and may depend on the retrieval task at hand. We hence evaluate different combinations empirically below. The same holds for the damping factor $\alpha \in [0, 1]$. If our hypothesis on similarity and dissimilarity is true, then the best α should be close to but lower than 1. Conversely, if $\alpha = 1.0$ achieves the best performance, then only similarity would be captured by our model.

6 Evaluation

We now report on systematic ranking experiments with our counterargument scoring model. The goal is to evaluate on all eight retrieval tasks from Section 4 to what extent our hypothesis holds that the best counterargument to an argument invokes the same aspects while having opposing stance. The Java source code of the experiments is available at: http://www.arguana.com/software

6.1 Experimental Set-up

We evaluated the following set-up of tasks, data, measures, baselines, and approaches.

Tasks We tackled each of the eight retrieval tasks as a ranking problem, i.e., we aimed to rank the best counterargument to each argument highest, given all candidates. Accordingly, only one candidate counterargument per argument is correct.[4]

Data Table 2 has shown the true and false argument pairs in all datasets. We undersampled each training set, resulting in 4065 true and 4065 false training pairs in all tasks.[5] Our model does not do any learning-to-rank on these pairs, but we derived lexicons for the word similarities from them (all stems included in at least 1% of all pairs). As detailed below, we then determined the best model configurations on the validation sets and evaluated these configurations on the test sets.

Measures As only one candidate is true per argument, we report the *accuracy@1* of each approach, i.e., the percentage of arguments for which the true counterargument was ranked highest. Besides, we compute the rounded *mean rank* of the best counterargument in all rankings, reflecting the average performance of an approach. Exemplarily, we also mention the *mean reciprocal rank (MRR)*, which is more sensitive to outliers.

Baselines A trivial way to address the given tasks is to pick any candidate by chance for each argument. This *random baseline* allows quantifying the impact of other approaches. As counterargument retrieval has not been tackled yet, we do not use any existing baseline.[6] Instead, we evaluate the effects of the different building blocks of our scoring model. On one hand, we check the need for distinguishing conclusions and premises by comparing to the word argument similarity (w) and the embedding argument similarity (e). On the other hand, we consider all eight word and embedding unit similarities ($w_{\downarrow}$, $w_{\uparrow}$, ..., e_{+}) as baselines, in order to see whether and how to best aggregate them.

Approaches After initial tests, we reduced the set of tested values of the damping factor α in our scoring model to $\{0.8, 0.9, 1.0\}$. On the validation sets of the first six tasks,[7] we then analyzed all possible combinations of $w_{\downarrow}+e_{\downarrow}$, $w_{\uparrow}+e_{\uparrow}$, $w_{\times}+e_{\times}$, $w_{+}+e_{+}$, as well as $w+e$ for sim and $dissim$. Three configurations of the model turned out best:

$$\begin{aligned} we &:= 1.0 \cdot (w_{\times} + e_{\times}) \\ we_{\downarrow} &:= 0.9 \cdot (w_{\times} + e_{\times}) - 0.1 \cdot (w_{\downarrow} + e_{\downarrow}) \\ we_{\uparrow} &:= 0.9 \cdot (w_{+} + e_{+}) - 0.1 \cdot (w_{\uparrow} + e_{\uparrow}) \end{aligned}$$

[4]One alternative would be to see each argument pair as one instance of a classification problem. However, our preliminary tests confirmed the intuition that identifying the best counterargument is hard without knowing the other candidates, i.e., there is no general (dis)similarity threshold that makes an argument the best counterargument. Rather, how similar or dissimilar a counterargument needs to be depends on the topic and on the other candidates. Another alternative would be to treat all candidates for an argument as one instance, but this makes the experimental set-up very intricated.

[5]Undersampling was done stratified, such that the same number of false counterarguments was taken from each type, b–i, in Figure 2 that is relevant in the respective task.

[6]Notice, though, that we tested a number of approaches to identify opposing stance, as discussed in Section 5.

[7]We did not expect "game-changing" validation set results for the last two tasks and, so, left them out for time reasons.

Table 3: Test set accuracy of ranking the best counterargument highest (**@1**) and mean rank (**R**) for 14 baselines and approaches (w, e, $w_\downarrow$, ..., r) in all eight tasks (given by **Context** and *Candidates*). Each best accuracy value (bold) significantly outperforms the best baseline with 99% (†) or 99.9% (‡) confidence.

we was best on the validation set of *Same Debate: Opposing Arguments* (accuracy@1: 62.1) and $we_\downarrow$ on the one of *Same Debate: Arguments* (49.0). All other tasks were dominated by $we_\uparrow$. Especially, $we_\uparrow$ was better than $1.0 \cdot (w_+ + e_+)$ in all of them with clear leads of up to 2.2 points. This underlines the importance of modeling dissimilarity for counterargument retrieval. We took we, $we_\downarrow$, and $we_\uparrow$ as our approaches for the test set.[8]

6.2 Results

Table 3 shows the accuracy@1 and the mean rank of all baselines and approaches on each of the eight given retrieval tasks.

Overall, the counter-only tasks seem slightly harder within the *same debate* (comparing *Counters* to *Opposing*), i.e., stance is harder to assess than topical relevance. Conversely, the other *Counters* tasks seem easier, suggesting that topically close but false candidate counterarguments with the same stance as the argument (which are not included in any *Counters* task) are classified wrongly most often. Besides, these results support that potential differences in the phrasing of counters are not exploited, as desired.

The accuracy of the standard similarity measures, w and e, goes from 65.9 and 62.9 respectively in the smallest task down to 21.8 and 23.9 in the largest. w is stronger when only counters are candidates, e otherwise. This implies that words capture differences between the best and other counters, whereas embeddings rather help discard false candidates with the same stance as the argument.

From the eight unit similarity baselines, w_+ performs best on five tasks ($e_\times$ twice, $w_\times$ once). w_+ finds 71.5% true counterarguments among all opposing counters in a debate, and 28.6% among all test arguments from the entire portal. In that task, however, the mean ranks of w_+ (33) and particularly of $w_\times$ (354) are much worse than for $e_\times$ (21), meaning that words are insufficient to robustly find counterarguments.

we, $we_\downarrow$, and $we_\uparrow$ outperform all baselines in all tasks, improving the accuracy by 8.1 (*Same Theme: Arguments*) to 10.3 points (*Entire Portal: Counters*) over w and e, and at least 3.0 over the best baseline in each task. Among all opposing arguments from the same debate (true-to-false ratio 1:6.6), we finds 60.3% of the best counterarguments, 44.9% when all arguments are given (1:13.3).

The winner in our evaluation is $we_\uparrow$, though, being best in five of the eight tasks. It found the true among all opposing counters in 74.5% of all cases, and about every third time (32.4) among all 2801 test set arguments; a setting where the random baseline has virtually no chance. Given all arguments from the same theme, $we_\uparrow$ puts the best counterargument at a mean rank of 5 (MRR 0.58), and for the entire portal still at 15 (MRR 0.5).

[8] All validation set results are found in the supplementary material, which we provide at `http://www.arguana.com/publications`

Entire Portal: Arguments		Accuracy@1		Mean Rank	
Theme	Arguments	w_+	$we_\uparrow$	w_+	$we_\uparrow$
Culture	69	31.9	36.2	12	9
Digital freedoms	61	37.7	44.3	58	20
Economy	125	27.2	25.6	21	10
Education	81	38.3	39.5	36	17
Environment	46	17.4	21.7	22	7
Free speech debate	58	10.3	12.1	130	55
Health	77	28.6	36.4	26	14
International	271	25.8	31.4	31	19
Law	134	38.8	38.1	16	8
Philosophy	85	34.1	38.8	29	14
Politics	202	28.7	33.2	28	11
Religion	45	24.4	33.3	58	8
Science	57	19.3	28.1	6	5
Society	60	16.7	20.0	45	22
Sport	30	43.3	46.7	35	9
All themes	**1401**	**28.6**	**32.4**	**33**	**15**

Table 4: Accuracy@1 and mean rank of the best baseline (w_+) and approach ($we_\uparrow$) on each theme when all 2801 test set arguments are candidates.

Although our scoring model thus does not *solve* the retrieval tasks, we conclude that it serves as a robust approach to rank the best counterargument high.

To test significance, we separately computed the accuracy@1 for the arguments from each theme. The differences between the 15 values of the best approach on each task and those of the best baseline (w_+, $w_\times$, or $e_\times$) were normally distributed. Since the baselines and approaches are dependent, we used a one-tailed dependent t-test with paired samples. As Table 3 specifies, our approaches are consistently better, partly with at least 99% confidence, partly even with 99.9% confidence.

In Table 4, we exemplarily detail the comparison of the best approach ($we_\uparrow$) to the best baseline (w_+) on *Entire Portal: Arguments*. The mean ranks across themes underline the robustness of $we_\uparrow$, being in the top 10 for 7 and in the top 20 even for 13 themes. Still, the accuracy@1 of both w_+ and $we_\uparrow$ varies notably, in case of $we_\uparrow$ from 12.1 for *free speech debate* to 46.7 for *sport*. For free speech debates (e.g., "This House would criminalise blasphemy"), we observed that their arguments tend to be overproportionally long, which might lead to deviating similarities. In case of sports, the topical specificity (e.g., "This House would ban boxing") reduces the probability of mistakenly choosing candidates from other themes.

Free speech debate turned out the hardest theme in seven tasks, *health* in the remaining one. Besides sports, in some tasks the best results were obtained for *religion* and *science*, both of which share the characteristic of dealing with very specific topics.[9]

7 Conclusion

This paper has asked how to find the best counterargument to any argument without prior knowledge of the argument's topic. We did *not* aim to engineer the best approach to this retrieval task, but to study whether we can model the simultaneous similarity and dissimilarity of a counterargument to an argument computationally. For the restricted domain of debate portal arguments, our main result is quite intriguing: The best model ($we_\uparrow$) rewards a high overall similarity to the argument's conclusion and premises while punishing a too high similarity to either of them. Despite its simplicity, $we_\uparrow$ found the best counterargument among 2801 candidates in almost a third of all cases, and ranked it into the top 15 on average. This speaks for our hypothesis that the best counterargument often just addresses the same topical aspects with opposite stance.

Of course, our hypothesis is simplifying, i.e., there are counterarguments that will not be found based on aspect and stance similarity only. Apart from some hyperparameters, however, our model is unsupervised and it does not make any assumption about an argument's topic. Hence, it applies to any argument, given a pool of candidate counterarguments. While the model can be considered *open-topic*, a next step will be to study counterargument retrieval *open-source*.

We are confident that the modeled intuition generalizes beyond idebate.org. To obtain further insights into the nature of counterarguments, deeper linguistic analysis along with supervised learning may be needed, though. We provide a corpus to train respective approaches, but leave the according research to future work.

The intended practical application of our model is to retrieve counterarguments in automatic debating technologies (Rinott et al., 2015) and argument search (Wachsmuth et al., 2017b). While debate portal arguments are often suitable in this regard, in general not always a real counterargument exists to an argument. Still, returning one that addresses similar aspects with opposite stance makes sense then. An alternative would be to *generate* counterarguments, but we believe that humans are better than machines in writing them — currently.

[9]The individual results of the best approach and baseline on each theme are also found in the supplementary material.

Abstract

Knowledge graphs have emerged as an important model for studying complex multi-relational data. This has given rise to the construction of numerous large scale but incomplete knowledge graphs encoding information extracted from various resources. An effective and scalable approach to jointly learn over multiple graphs and eventually construct a unified graph is a crucial next step for the success of knowledge-based inference for many downstream applications. To this end, we propose **LinkNBed**, a deep relational learning framework that learns entity and relationship representations across multiple graphs. We identify **entity linkage** across graphs as a vital component to achieve our goal. We design a novel objective that leverage entity linkage and build an efficient multi-task training procedure. Experiments on link prediction and entity linkage demonstrate substantial improvements over the state-of-the-art relational learning approaches.

1 Introduction

Reasoning over multi-relational data is a key concept in Artificial Intelligence and knowledge graphs have appeared at the forefront as an effective tool to model such multi-relational data. Knowledge graphs have found increasing importance due to its wider range of important applications such as information retrieval (Dalton et al., 2014), natural language processing (Gabrilovich and Markovitch, 2009), recommender systems (Catherine and Cohen, 2016), question-answering (Cui et al., 2017) and many more. This has led to the increased efforts in constructing numerous large-scale Knowledge Bases (e.g. Freebase (Bollacker et al., 2008), DBpedia (Auer et al., 2007), Google's Knowledge graph (Dong et al., 2014), Yago (Suchanek et al., 2007) and NELL (Carlson et al., 2010)), that can cater to these applications, by representing information available on the web in relational format.

All knowledge graphs share common drawback of *incompleteness* and *sparsity* and hence most existing relational learning techniques focus on using observed triplets in an incomplete graph to infer unobserved triplets for that graph (Nickel et al., 2016a). Neural embedding techniques that learn vector space representations of entities and relationships have achieved remarkable success in this task. However, these techniques only focus on learning from a single graph. In addition to incompleteness property, these knowledge graphs also share a set of overlapping entities and relationships with varying information about them. This makes a compelling case to design a technique that can learn over multiple graphs and eventually aid in constructing a unified giant graph out of them. While research on learning representations over single graph has progressed rapidly in recent years (Nickel et al., 2011; Dong et al., 2014; Trouillon et al., 2016; Bordes et al., 2013; Xiao et al., 2016; Yang et al., 2015), there is a conspicuous lack of principled approach to tackle the unique challenges involved in learning across multiple graphs.

One approach to multi-graph representation learning could be to first solve graph alignment problem to merge the graphs and then use existing relational learning methods on merged graph. Unfortunately, graph alignment is an important but still unsolved problem and there exist several techniques addressing its challenges (Liu and Yang, 2016; Pershina et al., 2015; Koutra et al., 2013; Buneman and Staworko, 2016) in limited settings.

[*] Correspondence: `rstrivedi@gatech.edu` and `bunyamis@amazon.com`. Work done when Rakshit Trivedi interned at Amazon.

The key challenges for the graph alignment problem emanate from the fact that the real world data are noisy and intricate in nature. The noisy or sparse data make it difficult to learn robust alignment features, and data abundance leads to computational challenges due to the combinatorial permutations needed for alignment. These challenges are compounded in multi-relational settings due to heterogeneous nodes and edges in such graphs.

Recently, deep learning has shown significant impact in learning useful information over noisy, large-scale and heterogeneous graph data (Rossi et al., 2017). We, therefore, posit that combining graph alignment task with deep representation learning across multi-relational graphs has potential to induce a synergistic effect on both tasks. Specifically, we identify that a key component of graph alignment process—entity linkage—also plays a vital role in learning across graphs. For instance, the embeddings learned over two knowledge graphs for an actor should be closer to one another compared to the embeddings of all the other entities. Similarly, the entities that are already aligned together across the two graphs should produce better embeddings due to the shared context and data. To model this phenomenon, we propose **LinkNBed**, a novel deep learning framework that jointly performs representation learning and graph linkage task. To achieve this, we identify key challenges involved in the learning process and make the following contributions to address them:

- We propose novel and principled approach towards jointly learning entity representations and entity linkage. The novelty of our framework stems from its ability to support linkage task across heterogeneous types of entities.

- We devise a graph-independent inductive framework that learns functions to capture contextual information for entities and relations. It combines the structural and semantic information in individual graphs for joint inference in a principled manner.

- Labeled instances (specifically positive instances for linkage task) are typically very sparse and hence we design a novel multi-task loss function where entity linkage task is tackled in robust manner across various learning scenarios such as learning only with unlabeled instances or only with negative instances.

- We design an efficient training procedure to perform joint training in linear time in the number of triples. We demonstrate superior performance of our method on two datasets curated from Freebase and IMDB against state-of-the-art neural embedding methods.

2 Preliminaries

2.1 Knowledge Graph Representation

A knowledge graph $\mathcal{G}$ comprises of set of facts represented as triplets (e^s, r, e^o) denoting the relationship r between subject entity e^s and object entity e^o. Associated to this knowledge graph, we have a set of attributes that describe observed characteristics of an entity. Attributes are represented as set of key-value pairs for each entity and an attribute can have null (missing) value for an entity. We follow *Open World Assumption - triplets not observed in knowledge graph are considered to be missing but not false.* We assume that there are no duplicate triplets or self-loops.

2.2 Multi-Graph Relational Learning

Definition. Given a collection of knowledge graphs $\mathcal{G}$, Multi-Graph Relational Learning refers to the the task of learning information rich representations of entities and relationships across graphs. The learned embeddings can further be used to infer new knowledge in the form of link prediction or learn new labels in the form of entity linkage. We motivate our work with the setting of two knowledge graphs where given two graphs $G_1, G_2 \in \mathcal{G}$, the task is to match an entity $e_{G_1} \in G_1$ to an entity $e_{G_2} \in G_2$ if they represent the same real-world entity. We discuss a straightforward extension of this setting to more than two graphs in Section 7.

Notations. Let X and Y represent realization of two such knowledge graphs extracted from two different sources. Let n_e^X and n_e^Y represent number of entities in X and Y respectively. Similarly, n_r^X and n_r^Y represent number of relations in X and Y. We combine triplets from both X and Y to obtain set of all observed triplets $\mathcal{D} = \{(e^s, r, e^o)_p\}_{p=1}^{P}$ where P is total number of available records across from both graphs. Let $\mathcal{E}$ and $\mathcal{R}$ be the set of all entities and all relations in $\mathcal{D}$ respectively. Let $|\mathcal{E}| = n$ and $|\mathcal{R}| = m$. In addition to $\mathcal{D}$, we also have set of linkage labels $\mathcal{L}$ for entities between X and Y. Each record in $\mathcal{L}$ is represented as triplet ($e^X \in X$, $e^Y \in Y$, $l \in \{0, 1\}$) where $l = 1$ when the entities are matched and $l = 0$ otherwise.

3 Proposed Method: LinkNBed

We present a novel *inductive multi-graph* relational learning framework that learns a set of aggregator functions capable of ingesting various contextual information for both entities and relationships in multi-relational graph. These functions encode the ingested structural and semantic information into low-dimensional entity and relation embeddings. Further, we use these representations to learn a relational score function that computes how two entities are likely to be connected in a particular relationship. The key idea behind this formulation is that when a triplet is observed, the relationship between the two entities can be explained using various contextual information such as local *neighborhood* features of both entities, *attribute* features of both entities and *type* information of the entities which participate in that relationship.

We outline two key insights for establishing the relationships between embeddings of the entities over multiple graphs in our framework:

Insight 1 (Embedding Similarity): If the two entities $e^X \in X$ and $e^Y \in Y$ represent the same real-world entity then their embeddings $\mathbf{e^X}$ and $\mathbf{e^Y}$ will be close to each other.

Insight 2 (Semantic Replacement): For a given triplet $t = (e^s, r, e^o) \in X$, denote $g(t)$ as the function that computes a relational score for t using entity and relation embeddings. If there exists a matching entity $e^{s'} \in Y$ for $e^s \in X$, denote $t' = (e^{s'}, r, e^o)$ obtained after replacing e^s with $e^{s'}$. In this case, $g(t) \sim g(t')$ i.e. score of triplets t and t' will be similar.

For a triplet $(e^s, r, e^o) \in \mathcal{D}$, we describe encoding mechanism of LinkNBed as three-layered architecture that computes the final output representations of $\mathbf{z}^r, \mathbf{z}^{e^s}, \mathbf{z}^{e^o}$ for the given triplet. Figure 1 provides an overview of LinkNBed architecture and we describe the three steps below:

3.1 Atomic Layer

Entities, Relations, Types and Attributes are first encoded in its basic vector representations. We use these basic representations to derive more complex contextual embeddings further.

Entities, Relations and Types. The embedding vectors corresponding to these three components are learned as follows:

$$\mathbf{v^{e^s}} = f(\mathbf{W^E e^s}) \qquad \mathbf{v^{e^o}} = f(\mathbf{W^E e^o}) \qquad (1)$$

$$\mathbf{v^r} = f(\mathbf{W^R r}) \qquad \mathbf{v^t} = f(\mathbf{W^T t}) \qquad (2)$$

where $\mathbf{v^{e^s}}, \mathbf{v^{e^o}} \in \mathbb{R}^d$. $\mathbf{e^s}$, $\mathbf{e^o} \in \mathbb{R}^n$ are “one-hot” representations of e^s and e^o respectively. $\mathbf{v^r} \in \mathbb{R}^k$ and $\mathbf{r} \in \mathbb{R}^m$ is “one-hot” representation of r. $\mathbf{v^t} \in \mathbb{R}^q$ and $\mathbf{t} \in \mathbb{R}^z$ is ”one-hot” representation of t . $\mathbf{W^E} \in \mathbb{R}^{d\times n}$, $\mathbf{W^R} \in \mathbb{R}^{k\times m}$ and $\mathbf{W^T} \in \mathbb{R}^{q\times z}$ are the entity, relation and type embedding matrices respectively. f is a nonlinear activation function (Relu in our case). $\mathbf{W^E}$, $\mathbf{W^R}$ and $\mathbf{W^T}$ can be initialized randomly or using pre-trained word embeddings or vector compositions based on name phrases of components (Socher et al., 2013).

Attributes. For a given attribute a represented as key-value pair, we use paragraph2vec (Le and Mikolov, 2014) type of embedding network to learn attribute embedding. Specifically, we represent attribute embedding vector as:

$$\mathbf{a} = f(\mathbf{W^{key} a_{key}} + \mathbf{W^{val} a_{val}}) \qquad (3)$$

where $\mathbf{a} \in \mathbb{R}^y$, $\mathbf{a_{key}} \in \mathbb{R}^u$ and $\mathbf{a_{val}} \in \mathbb{R}^v$. $\mathbf{W^{key}} \in \mathbb{R}^{y\times u}$ and $\mathbf{W^{val}} \in \mathbb{R}^{y\times v}$. $\mathbf{a_{key}}$ will be “one-hot” vector and $\mathbf{a_{val}}$ will be feature vector. Note that the dimensions of the embedding vectors do not necessarily need to be the same.

3.2 Contextual Layer

While the entity and relationship embeddings described above help to capture very generic latent features, embeddings can be further enriched to capture structural information, attribute information and type information to better explain the existence of a fact. Such information can be modeled as context of nodes and edges in the graph. To this end, we design the following canonical aggregator function that learns various contextual information by aggregating over relevant embedding vectors:

$$\mathbf{c}(z) = \text{AGG}(\{\mathbf{z}', \forall z' \in C(z)\}) \qquad (4)$$

where $\mathbf{c}(z)$ is the vector representation of the aggregated contextual information for component z. Here, component z can be either an entity or a relation. $C(z)$ is the set of components in the context of z and $\mathbf{z}'$ correspond to the vector embeddings of those components. AGG is the aggregator function which can take many forms such Mean, Max, Pooling or more complex LSTM based aggregators. It is plausible that different components in a context may have varied impact on the component for which the embedding is being learned. To account for this, we employ a soft attention mechanism where we learn attention coefficients

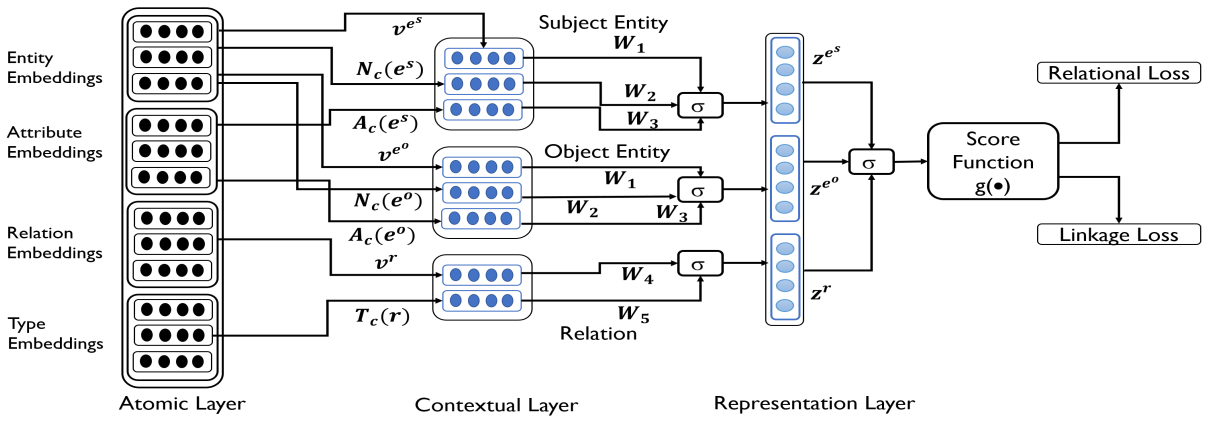

Figure 1: LinkNBed Architecture Overview - one step score computation for a given triplet (e^s, r, e^o). The Attribute embeddings are not simple lookups but they are learned as shown in Eq 3

to weight components based on their impact before aggregating them. We modify Eq. 4 as:

$$\mathbf{c}(z) = \text{AGG}(\mathbf{q}(z) * \{\mathbf{z}', \forall z' \in C(z)\}) \qquad (5)$$

where

$$\mathbf{q}(z) = \frac{\exp(\theta_z)}{\sum\limits_{z' \in C(z)} \exp(\theta_{z'})} \qquad (6)$$

and θ_z's are the parameters of attention model. Following contextual information is modeled in our framework:

Entity Neighborhood Context $\mathbf{N_c}(e) \in \mathbb{R}^d$. Given a triplet (e^s, r, e^o), the neighborhood context for an entity e^s will be the nodes located near e^s other than the node e^o. This will capture the effect of local neighborhood in the graph surrounding e^s that drives e^s to participate in fact (e^s, r, e^o). We use Mean as aggregator function. As there can be large number of neighbors, we collect the neighborhood set for each entity as a pre-processing step using a random walk method. Specifically, given a node e, we run k rounds of random-walks of length l following (Hamilton et al., 2017) and create set $\mathcal{N}(e)$ by adding all unique nodes visited across these walks. This context can be similarly computed for object entity.

Entity Attribute Context $\mathbf{A_c}(e) \in \mathbb{R}^y$. For an entity e, we collect all attribute embeddings for e obtained from Atomic Layer and learn aggregated information over them using Max operator given in Eq. 4.

Relation Type Context $\mathbf{T_c}(r) \in \mathbb{R}^q$. We use type context for relation embedding i.e. for a given relationship r, this context aims at capturing the effect of type of entities that have participated in this relationship. For a given triplet (e^s, r, e^o), type context for relationship r is computed by aggregation with mean over type embeddings corresponding to the context of r. Appendix C provides specific forms of contextual information.

3.3 Representation Layer

Having computed the atomic and contextual embeddings for a triplet (e^s, r, e^o), we obtain the final embedded representations of entities and relation in the triplet using the following formulation:

$$\mathbf{z^{e^s}} = \sigma(\underbrace{\mathbf{W_1 v^{e^s}}}_{\text{Subject Entity Embedding}} + \underbrace{\mathbf{W_2 N_c}(e^s)}_{\text{Neighborhood Context}} + \underbrace{\mathbf{W_3 A_c}(e^s))}_{\text{Subject Entity Attributes}} \qquad (7)$$

$$\mathbf{z^{e^o}} = \sigma(\underbrace{\mathbf{W_1 v^{e^o}}}_{\text{Object Entity Embedding}} + \underbrace{\mathbf{W_2 N_c}(e^o)}_{\text{Neighborhood Context}} + \underbrace{\mathbf{W_3 A_c}(e^o))}_{\text{Object Entity Attributes}} \qquad (8)$$

$$\mathbf{z^r} = \sigma(\underbrace{\mathbf{W_4 v^r}}_{\text{Relation Embedding}} + \underbrace{\mathbf{W_5 T_c}(r))}_{\text{Entity Type Context}} \qquad (9)$$

where $\mathbf{W_1}, \mathbf{W_2} \in \mathbb{R}^{d \times d}$, $\mathbf{W_3} \in \mathbb{R}^{d \times y}$, $\mathbf{W_4} \in \mathbb{R}^{d \times k}$ and $\mathbf{W_5} \in \mathbb{R}^{d \times q}$. σ is nonlinear activation function – generally Tanh or Relu.

Following is the rationale for our formulation: An entity's representation can be enriched by encoding information about the local neighborhood features and attribute information associated with the entity in addition to its own latent features. Parameters $\mathbf{W_1}, \mathbf{W_2}, \mathbf{W_3}$ learn to capture these different aspects and map them into the entity embedding space. Similarly, a relation's representation can be enriched by encoding information about entity types that participate in that relationship in addition to its own latent features. Parameters $\mathbf{W_4}, \mathbf{W_5}$ learn to capture these aspects and map them into the relation embedding space. Further, as the ultimate goal is to jointly learn over multiple graphs, shared parameterization in our model facilitate the propagation of information across graphs thereby making it a graph-independent inductive model. The flexibility of the model stems from the ability to shrink it (to a very simple model considering atomic entity and relation embeddings only) or expand it (to a complex model by adding different contextual information) without affecting any other step in the learning procedure.

3.4 Relational Score Function

Having observed a triplet (e^s, r, e^o), we first use Eq. 7, 8 and 9 to compute entity and relation representations. We then use these embeddings to capture relational interaction between two entities using the following score function $g(\cdot)$:

$$g(e^s, r, e^o) = \sigma(\mathbf{z}^{r^T} \cdot (\mathbf{z}^{e^s} \odot \mathbf{z}^{e^o})) \tag{10}$$

where $\mathbf{z}^r, \mathbf{z}^{e^s}, \mathbf{z}^{e^o} \in \mathbb{R}^d$ are d-dimensional representations of entity and relationships as described below. σ is the nonlinear activation function and $\odot$ represent element-wise product.

4 Efficient Learning Procedure

4.1 Objective Function

The complete parameter space of the model can be given by: $\mathbf{\Omega} = \{\{\mathbf{W_i}\}_{\mathbf{i=1}}^{\mathbf{5}}, \mathbf{W^E}, \mathbf{W^R}, \mathbf{W^{key}}, \mathbf{W^{val}}, \mathbf{W^t}, \mathbf{\Theta}\}$. To learn these parameters, we design a novel multi-task objective function that jointly trains over two graphs. As identified earlier, the goal of our model is to leverage the available linkage information across graphs for optimizing the entity and relation embeddings such that they can explain the observed triplets across the graphs. Further, we want to leverage these optimized embeddings to match entities across graphs and expand the available linkage information. To achieve this goal, we define following two different loss functions catering to each learning task and jointly optimize over them as a multi-task objective to learn model parameters:

Relational Learning Loss. This is conventional loss function used to learn knowledge graph embeddings. Specifically, given a p-th triplet $(e^s, r, e^o)_p$ from training set $\mathcal{D}$, we sample C negative samples by replacing either head or tail entity and define a contrastive max margin function as shown in (Socher et al., 2013):

$$\begin{aligned} L_{rel} = \sum_{c=1}^{C} \max(0, \gamma - g(e_p^s, r_p, e_p^o) \\ + g'(e_c^s, r_p, e_p^o)) \end{aligned} \tag{11}$$

where, γ is margin, e_c^s represent corrupted entity and $g'(e_c^s, r_p, e_p^o)$ represent corrupted triplet score.

Linkage Learning Loss: We design a novel loss function to leverage pairwise label set $\mathcal{L}$. Given a triplet (e_X^s, r_X, e_X^o) from knowledge graph X, we first find the entity e_Y^+ from graph Y that represent the same real-world entity as e_X^s. We then replace e_X^s with e_Y^+ and compute score $g(e_Y^+, r_X, e_X^o)$. Next, we find set of all entities E_Y^- from graph Y that has a negative label with entity e_X^s. We consider them analogous to the negative samples we generated for Eq. 11. We then propose the label learning loss function as:

$$\begin{aligned} L_{lab} = \sum_{z=1}^{Z} \max(0, \gamma - g(e_Y^+, r_X, e_X^o) \\ + (g'(e_Y^-, r_X, e_X^o)_z)) \end{aligned} \tag{12}$$

where, Z is the total number of negative labels for e_X. γ is margin which is usually set to 1 and $e_Y^- \in E_Y^-$ represent entity from graph Y with which entity e_X^s had a negative label. Please note that this applies symmetrically for the triplets that originate from graph Y in the overall dataset. Note that if both entities of a triplet have labels, we will include both cases when computing the loss. Eq. 12 is inspired by *Insight 1* and *Insight 2* defined earlier in Section 2. Given a set $\mathcal{D}$ of N observed triplets across two graphs, we define complete multi-task objective as:

$$\mathbf{L}(\mathbf{\Omega}) = \sum_{i=1}^{N} [b \cdot L_{rel} + (1-b) \cdot L_{lab}] + \lambda \left\| \mathbf{\Omega} \right\|_2^2 \tag{13}$$

Algorithm 1 LinkNBed mini-batch Training

```
Input: Mini-batch $\mathcal{M}$, Negative Sample Size $C$, Negative Label Size $Z$, Attribute data $att\_data$, Neighborhood data $nhbr\_data$, Type data $type\_data$, Positive Label Dict $pos\_dict$, Negative Label Dict $neg\_dict$
Output: Mini-batch Loss $\mathcal{L}_{\mathcal{M}}$.
$\mathcal{L}_{\mathcal{M}} = 0$
score_pos = []; score_neg = []; score_pos_lab = []; score_neg_lab = []
for $i = 0$ to size($\mathcal{M}$) do
  input_tuple = $\mathcal{M}[i]$ = $(e^s, r, e^o)$
  sc = compute_triplet_score($e^s, r, e^o$) (Eq. 10)
  score_pos.append(sc)
  for $j = 0$ to $C$ do
    Select $e^s_c$ from entity list such that $e^s_c \neq e^s$ and $e^s_c \neq e^o$ and $(e^s_c, r, e^o) \notin \mathcal{D}$
    sc_neg = compute_triplet_score($e^s_c, r, e^o$)
    score_neg.append(sc_neg)
  end for
  if $e^s$ in $pos\_dict$ then
    $e^{s+}$ = positive label for $e^s$
    sc_pos_l = compute_triplet_score($e^{s+}, r, e^o$)
    score_pos_lab.append(sc_pos_l)
  end if
  for $k = 0$ to $Z$ do
    Select $e^{s-}$ from $neg\_dict$
    sc_neg_l = compute_triplet_score($e^{s-}, r, e^o$)
    score_neg_lab.append(sc_neg_l)
  end for
end for
$\mathcal{L}_{\mathcal{M}}$ += compute_minibatch_loss(score_pos, score_neg, score_pos_lab, score_neg_lab) (Eq. 13)
Back-propagate errors and update parameters $\mathbf{\Omega}$
return $\mathcal{L}_{\mathcal{M}}$
```

where $\mathbf{\Omega}$ is set of all model parameters and λ is regularization hyper-parameter. b is weight hyper-parameter used to attribute importance to each task. We train with mini-batch SGD procedure (Algorithm 1) using Adam Optimizer.

Missing Positive Labels. It is expensive to obtain positive labels across multiple graphs and hence it is highly likely that many entities will not have positive labels available. For those entities, we will modify Eq. 12 to use the original triplet (e^s_X, r_X, e^o_X) in place of perturbed triplet $g(e^+_Y, r_X, e^o_X)$ for the positive label. The rationale here again arises from *Insight 2* wherein embeddings of two duplicate entities should be able to replace each other without affecting the score.

Training Time Complexity. Most contextual information is pre-computed and available to all training steps which leads to constant time embedding lookup for those context. But for attribute network, embedding needs to be computed for each attribute separately and hence the complexity to compute score for one triplet is $\mathcal{O}(2a)$ where a is number of attributes. Also for training, we generate C negative samples for relational loss function and use Z negative labels for label loss function. Let $k = C + Z$. Hence, the training time complexity for a set of n triplets will be $\mathcal{O}(2ak * n)$ which is linear in number of triplets with a constant factor as $ak << n$ for real world knowledge graphs. This is desirable as the number of triplets tend to be very large per graph in multi-relational settings.

Memory Complexity. We borrow notations from (Nickel et al., 2016a) and describe the parameter complexity of our model in terms of the number of each component and corresponding embedding dimension requirements. Let $H_a = 2 * N_e H_e + N_r H_r + N_t H_t + N_k H_k + N_v H_v$. The parameter complexity of our model is: $H_a * (H_b + 1)$. Here, N_e, N_r, N_t, N_k, N_v signify number of entities, relations, types, attribute keys and vocab size of attribute values across both datasets. Here H_b is the output dimension of the hidden layer.

5 Experiments

5.1 Datasets

We evaluate LinkNBed and baselines on two real world knowledge graphs: D-IMDB (derived from large scale IMDB data snapshot) and D-FB (derived from large scale Freebase data snapshot). Table 5.1 provides statistics for our final dataset used in the experiments. Appendix B.1 provides complete details about dataset processing.

Dataset Name	# Entities	# Relations	# Attributes	# Entity Types	# Available Triples
D-IMDB	378207	38	23	41	143928582
D-FB	39667	146	69	324	22140475

Table 1: Statistics for Datasets: D-IMDB and D-FB

5.2 Baselines

We compare the performance of our method against state-of-the-art representation learning baselines that use neural embedding techniques to learn entity and relation representation. Specifically, we consider compositional methods of

RESCAL (Nickel et al., 2011) as basic matrix factorization method, DISTMULT (Yang et al., 2015) as simple multiplicative model good for capturing symmetric relationships, and Complex (Trouillon et al., 2016), an upgrade over DISTMULT that can capture asymmetric relationships using complex valued embeddings. We also compare against translational model of STransE that combined original structured embedding with TransE and has shown state-of-art performance in benchmark testing (Kadlec et al., 2017). Finally, we compare with GAKE (Feng et al., 2016), a model that captures context in entity and relationship representations.

In addition to the above state-of-art models, we analyze the effectiveness of different components of our model by comparing with various versions that use partial information. Specifically, we report results on following variants:
LinkNBed - Embed Only. Only use entity embeddings, **LinkNBed - Attr Only.** Only use Attribute Context, **LinkNBed - Nhbr Only.** Only use Neighborhood Context, **LinkNBed - Embed + Attr.** Use both Entity embeddings and Attribute Context, **LinkNBed - Embed + Nhbr.** Use both Entity embeddings and Neighbor Context and **LinkNBed - Embed All.** Use all three Contexts.

5.3 Evaluation Scheme

We evaluate our model using two inference tasks:
Link Prediction. Given a test triplet (e^s, r, e^o), we first score this triplet using Eq. 10. We then replace e^o with all other entities in the dataset and filter the resulting set of triplets as shown in (Bordes et al., 2013). We score the remaining set of perturbed triplets using Eq. 10. All the scored triplets are sorted based on the scores and then the rank of the ground truth triplet is used for the evaluation. We use this ranking mechanism to compute HITS@10 (predicted rank $\leq$ 10) and reciprocal rank ($\frac{1}{rank}$) of each test triplet. We report the mean over all test samples.

Entity Linkage. In alignment with *Insight 2*, we pose a novel evaluation scheme to perform entity linkage. Let there be two ground truth test sample triplets: $(e_X, e_Y^+, 1)$ representing a positive duplicate label and $(e_X, e_Y^-, 0)$ representing a negative duplicate label. Algorithm 2 outlines the procedure to compute linkage probability or score q ($\in [0, 1]$) for the pair (e_X, e_Y). We use $L1$ distance between the two vectors analogous to Mean Absolute Error (MAE). In lieu of hard-labeling test pairs, we use score q to compute Area Under the Precision-Recall Curve (AUPRC).

For the baselines and the unsupervised version (with no labels for entity linkage) of our model, we use second stage multilayer Neural Network as classifier for evaluating entity linkage. Appendix B.2 provides training configuration details.

Algorithm 2 Entity Linkage Score Computation

```
Input: Test pair – $(e_X \in X, e_Y \in Y)$.
Output: Linkage Score – $q$.

1. Collect all triplets involving $e_X$ from graph $X$ and all triplets involving $e_Y$ from graph $Y$ into a combined set $\mathcal{O}$. Let $|\mathcal{O}| = k$.
2. Construct $S_{orig} \in \mathbb{R}^k$.
For each triplet $o \in \mathcal{O}$, compute score $g(o)$ using Eq. 10 and store the score in $S_{orig}$.
3. Create triplet set $\mathcal{O}'$ as following:
if $o \in \mathcal{O}$ contain $e^X \in X$ then
    Replace $e^X$ with $e^Y$ to create perturbed triplet $o'$ and store it in $\mathcal{O}'$
end if
if $o \in \mathcal{O}$ contain $e^Y \in Y$ then
    Replace $e^Y$ with $e^X$ to create perturbed triplet $o'$ and store it in $\mathcal{O}'$
end if
4. Construct $S_{repl} \in \mathbb{R}^k$.
For each triplet $o' \in \mathcal{O}'$, compute score $g(o')$ using Eq. 10 and store the score in $S_{repl}$.
5. Compute $q$.
Elements in $S_{orig}$ and $S_{repl}$ have one-one correspondence so take the mean absolute difference:
$q$ = $|S_{orig}$ - $S_{repl}|_1$
return $q$
```

5.4 Predictive Analysis

Link Prediction Results. We train LinkNBed model jointly across two knowledge graphs and then perform inference over individual graphs to report link prediction reports. For baselines, we train each baseline on individual graphs and use parameters specific to the graph to perform link prediction inference over each individual graph. Table 5.4 shows link prediction performance for all methods. Our model variant with attention mechanism outperforms all the baselines with 4.15% improvement over single graph state-of-the-art Complex model on D-IMDB and 8.23% improvement on D-FB dataset. D-FB is more challenging dataset to

Table 3: Entity Linkage Results - Unsupervised case uses classifier at second step

learn as it has a large set of sparse relationships, types and attributes and it has an order of magnitude lesser relational evidence (number of triplets) compared to D-IMDB. Hence, LinkNBed's pronounced improvement on D-FB demonstrates the effectiveness of the model. The simplest version of LinkNBed with only entity embeddings resembles DISTMULT model with different objective function. Hence closer performance of those two models aligns with expected outcome. We observed that the Neighborhood context alone provides only marginal improvements while the model benefits more from the use of attributes. Despite being marginal, attention mechanism also improves accuracy for both datasets. Compared to the baselines which are obtained by trained and evaluated on individual graphs, our superior performance demonstrates the effectiveness of multi-graph learning.

Entity Linkage Results. We report entity linkage results for our method in two settings: a.) Supervised case where we train using both the objective functions. b.) Unsupervised case where we learn with only the relational loss function. The latter case resembles the baseline training where each model is trained separately on two graphs in an unsupervised manner. For performing the entity linkage in unsupervised case for all models, we first train a second stage of simple neural network classifier and then perform inference. In the supervised case, we use Algorithm 2 for performing the inference. Table 5.4 demonstrates the performance of all methods on this task. Our method significantly outperforms all the baselines with 33.86% over second best baseline in supervised case and 17.35% better performance in unsupervised case. The difference in the performance of our method in two cases demonstrate that the two training objectives are helping one another by learning across the graphs. GAKE's superior performance on this task compared to the other state-of-the-art relational baselines shows the importance of using contextual information for entity linkage. Performance of other variants of our model again demonstrate that attribute information is more helpful than neighborhood context and attention provides marginal improvements. We provide further insights with examples and detailed discussion on entity linkage task in Appendix A.

6 Related Work

6.1 Neural Embedding Methods for Relational Learning

Compositional Models learn representations by various composition operators on entity and relational embeddings. These models are multiplicative in nature and highly expressive but often suffer from scalability issues. Initial models include RESCAL (Nickel et al., 2011) that uses a relation specific weight matrix to explain triplets via pairwise interactions of latent features, Neural Tensor Network (Socher et al., 2013), more expressive model that combines a standard NN layer with a bilinear tensor layer and (Dong et al., 2014) that employs a concatenation-projection method to project entities and relations to lower dimensional space. Later, many sophisticated models (Neural Association Model (Liu et al., 2016), HoLE (Nickel et al., 2016b)) have been proposed. Path based composition models (Toutanova et al., 2016) and contextual models GAKE (Feng et al., 2016) have been recently studied to capture more information from graphs. Recently, model like Complex (Trouillon et al., 2016) and Analogy (Liu et al., 2017) have demonstrated state-of-the art performance on relational learning tasks. **Translational Models** ((Bordes et al., 2014), (Bordes et al., 2011), (Bordes et al., 2013), (Wang et al., 2014), (Lin et al., 2015), (Xiao et al., 2016)) learn representation by employing translational operators on the embeddings and optimizing based on their score. They offer an additive and efficient alternative to expensive multiplicative models. Due to their simplicity, they often loose expressive power. For a comprehensive survey of relational learning methods and empirical comparisons, we refer the readers to (Nickel et al., 2016a), (Kadlec et al., 2017), (Toutanova and Chen, 2015) and (Yang et al., 2015). None of these methods address multi-graph relational learning and cannot be adapted to tasks like entity linkage in straightforward manner.

6.2 Entity Resolution in Relational Data

Entity Resolution refers to resolving entities available in knowledge graphs with entity mentions in text. (Dredze et al., 2010) proposed entity disambiguation method for KB population, (He et al., 2013) learns entity embeddings for resolution, (Huang et al., 2015) propose a sophisticated DNN architecture for resolution, (Campbell et al., 2016) proposes entity resolution across multiple social domains, (Fang et al., 2016) jointly embeds text and knowledge graph to perform resolution while (Globerson et al., 2016) proposes Attention Mechanism for Collective Entity Resolution.

6.3 Learning across multiple graphs

Recently, learning over multiple graphs have gained traction. (Liu and Yang, 2016) divides a multi-relational graph into multiple homogeneous graphs and learns associations across them by employing product operator. Unlike our work, they do not learn across multiple multi-relational graphs. (Pujara and Getoor, 2016) provides logic based insights for cross learning, (Pershina et al., 2015) does pairwise entity matching across multi-relational graphs and is very expensive, (Chen et al., 2017) learns embeddings to support multi-lingual learning and Big-Align (Koutra et al., 2013) tackles graph alignment problem efficiently for bipartite graphs. None of these methods learn latent representations or jointly train graph alignment and learning which is the goal of our work.

7 Concluding Remarks and Future Work

We present a novel relational learning framework that learns entity and relationship embeddings across multiple graphs. The proposed representation learning framework leverage an efficient learning and inference procedure which takes into account the duplicate entities representing the same real-world entity in a multi-graph setting. We demonstrate superior accuracies on link prediction and entity linkage tasks compared to the existing approaches that are trained only on individual graphs. We believe that this work opens a new research direction in joint representation learning over multiple knowledge graphs.

Many data driven organizations such as Google and Microsoft take the approach of constructing a unified super-graph by integrating data from multiple sources. Such unification has shown to significantly help in various applications, such as search, question answering, and personal assistance. To this end, there exists a rich body of work on linking entities and relations, and conflict resolution (e.g., knowledge fusion (Dong et al., 2014). Still, the problem remains challenging for large scale knowledge graphs and this paper proposes a deep learning solution that can play a vital role in this construction process. In real-world setting, we envision our method to be integrated in a large scale system that would include various other components for tasks like conflict resolution, active learning and human-in-loop learning to ensure quality of constructed super-graph. However, we point out that our method is not restricted to such use cases—one can readily apply our method to directly make inference over multiple graphs to support applications like question answering and conversations.

For future work, we would like to extend the current evaluation of our work from a two-graph setting to multiple graphs. A straightforward approach is to create a unified dataset out of more than two graphs by combining set of triplets as described in Section 2, and apply learning and inference on the unified graph without any major change in the methodology. Our inductive framework learns functions to encode contextual information and hence is graph independent. Alternatively, one can develop sophisticated approaches with iterative merging and learning over pairs of graphs until exhausting all graphs in an input collection.

Acknowledgments

We would like to give special thanks to Ben London, Tong Zhao, Arash Einolghozati, Andrew Borthwick and many others at Amazon for helpful comments and discussions. We thank the reviewers for their valuable comments and efforts towards improving our manuscript. This project was supported in part by NSF(IIS-1639792, IIS-1717916).

Abstract

Embedding methods which enforce a partial order or lattice structure over the concept space, such as Order Embeddings (OE) (Vendrov et al., 2016), are a natural way to model transitive relational data (e.g. entailment graphs). However, OE learns a deterministic knowledge base, limiting expressiveness of queries and the ability to use uncertainty for both prediction and learning (e.g. learning from expectations). Probabilistic extensions of OE (Lai and Hockenmaier, 2017) have provided the ability to somewhat calibrate these *denotational probabilities* while retaining the consistency and inductive bias of ordered models, but lack the ability to model the negative correlations found in real-world knowledge. In this work we show that a broad class of models that assign probability measures to OE can never capture negative correlation, which motivates our construction of a novel *box lattice* and accompanying probability measure to capture anticorrelation and even disjoint concepts, while still providing the benefits of probabilistic modeling, such as the ability to perform rich joint and conditional queries over arbitrary sets of concepts, and both learning from and predicting calibrated uncertainty. We show improvements over previous approaches in modeling the Flickr and WordNet entailment graphs, and investigate the power of the model.

* Equal contribution.

1 Introduction

Structured embeddings based on regions, densities, and orderings have gained popularity in recent years for their inductive bias towards the essential asymmetries inherent in problems such as image captioning (Vendrov et al., 2016), lexical and textual entailment (Erk, 2009; Vilnis and McCallum, 2015; Lai and Hockenmaier, 2017; Athiwaratkun and Wilson, 2018), and knowledge graph completion and reasoning (He et al., 2015; Nickel and Kiela, 2017; Li et al., 2017).

Models that easily encode asymmetry, and related properties such as transitivity (the two components of commonplace relations such as partially ordered sets and lattices), have great utility in these applications, leaving less to be learned from the data than arbitrary relational models. At their best, they resemble a hybrid between embedding models and structured prediction. As noted by Vendrov et al. (2016) and Li et al. (2017), while the models learn sets of embeddings, these parameters obey rich structural constraints. The entire set can be thought of as one, sometimes provably consistent, structured prediction, such as an ontology in the form of a single directed acyclic graph.

While the structured prediction analogy applies best to Order Embeddings (OE), which embeds consistent partial orders, other region- and density-based representations have been proposed for the express purpose of inducing a bias towards asymmetric relationships. For example, the Gaussian Embedding (GE) model (Vilnis and McCallum, 2015) aims to represent the asymmetry and uncertainty in an object's relations and attributes by means of uncertainty in the representation. However, while the space of representations is a manifold of probability distributions, the model is not truly probabilistic in that it does not model asymmetries and relations in terms of probabilities, but in terms of asymmetric comparison functions such as the originally proposed KL divergence and the recently proposed *thresholded divergences* (Athiwaratkun and Wilson, 2018).

Probabilistic models are especially compelling for modeling ontologies, entailment graphs, and knowledge graphs. Their desirable properties include an ability to remain consistent in the presence of noisy data, suitability towards semi-supervised training using the expectations and uncertain labels present in these large-scale applications, the naturality of representing the inherent uncertainty of knowledge they store, and the ability to answer complex queries involving more than 2 variables. Note that the final one requires a true joint probabilistic model with a tractable inference procedure, not something provided by e.g. matrix factorization.

We take the dual approach to density-based embeddings and model uncertainty about relationships and attributes as explicitly probabilistic, while basing the probability on a latent space of geometric objects that obey natural structural biases for modeling transitive, asymmetric relations. The most similar work are the probabilistic order embeddings (POE) of Lai (Lai and Hockenmaier, 2017), which apply a probability measure to each order embedding's forward cone (the set of points greater than the embedding in each dimension), assigning a finite and normalized volume to the unbounded space. However, POE suffers severe limitations as a probabilistic model, including an inability to model negative correlations between concepts, which motivates the construction of our box lattice model.

Our model represents objects, concepts, and events as high-dimensional products-of-intervals (*hyperrectangles* or *boxes*), with an event's unary probability coming from the box volume and joint probabilities coming from overlaps. This contrasts with POE's approach of defining events as the forward cones of vectors, extending to infinity, integrated under a probability measure that assigns them finite volume.

One desirable property of a structured representation for ordered data, originally noted in (Vendrov et al., 2016) is a "slackness" shared by OE, POE, and our model: when the model predicts an "edge" or lack thereof (i.e. $P(a|b) = 0$ or 1, or a zero constraint violation in the case of OE), being exposed to that fact again will not update the model. Moreover, there are large degrees of freedom in parameter space that exhibit this slackness, giving the model the ability to embed complex structure with 0 loss when compared to models based on symmetric inner products or distances between embeddings, e.g. bilinear GLMs (Collins et al., 2002), Trans-E (Bordes et al., 2013), and other embedding models which must always be pushing and pulling parameters towards and away from each other.

Our experiments demonstrate the power of our approach to probabilistic ordering-biased relational modeling. First, we investigate an instructive 2-dimensional toy dataset that both demonstrates the way the model self organizes its box event space, and enables sensible answers to queries involving arbitrary numbers of variables, despite being trained on only pairwise data. We achieve a new state of the art in denotational probability modeling on the Flickr entailment dataset (Lai and Hockenmaier, 2017), and a matching state-of-the-art on WordNet hypernymy (Vendrov et al., 2016; Miller, 1995) with the concurrent work on thresholded Gaussian embedding of Athiwaratkun and Wilson (2018), achieving our best results by training on additional co-occurrence expectations aggregated from leaf types.

We find that the strong empirical performance of probabilistic ordering models, and our box lattice model in particular, and their endowment of new forms of training and querying, make them a promising avenue for future research in representing structured knowledge.

2 Related Work

In addition to the related work in structured embeddings mentioned in the introduction, our focus on directed, transitive relational modeling and ontology induction shares much with the rich field of directed graphical models and causal modeling (Pearl, 1988), as well as learning the structure of those models (Heckerman et al., 1995). Work in undirected structure learning such the Graphical Lasso (Friedman et al., 2008) is also relevant due to our desire to learn from pairwise joint/conditional probabilities and moment matrices, which are closely related in the setting of discrete variables.

Especially relevant research in Bayesian networks are applications towards learning taxonomic structure of relational data (Bansal et al., 2014), although this work is often restricted towards tree-shaped ontologies, which allow efficient inference by Chu-Liu-Edmonds' algorithm (Chu and Liu, 1995), while we focus on arbitrary DAGs.

As our model is based on populating a latent "event space" into boxes (products of intervals), it is especially reminiscent of the Mondrian process (Roy and Teh, 2009). However, the Mondrian process partitions the space as a high dimensional tree (a non-parametric kd-tree), while our model allows the arbitrary box placement required for DAG structure, and is much more tractable in high dimensions compared to the Mondrian's Bayesian non-parametric inference.

Embedding applications to relational learning constitute a huge field to which it is impossible to do justice, but one general difference between our approaches is that e.g. a matrix factorization model treats the embeddings as objects to score relation links with, as opposed to POE or our model in which embeddings represent subsets of probabilistic event space which are directly integrated. They are full probabilistic models of the joint set of variables, rather than embedding-based approximations of only low-order joint and conditional probabilities. That is, any set of our parameters can answer any arbitrary probabilistic question (possibly requiring intractable computation), rather than being fixed to modeling only certain subsets of the joint.

Embedding-based learning's large advantage over the combinatorial structure learning presented by classical PGM approaches is its applicability to large-scale probability distributions containing hundreds of thousands of events or more, as in both our WordNet and Flickr experiments.

3 Background

3.1 Partial Orders and Lattices

A non-strict *partial ordered set* (*poset*) is a set P equipped with a binary relation $\preceq$ such that for all $a, b, c \in P$,

- $a \preceq a$ (reflexivity)
- $a \preceq b \preceq a$ implies $a = b$ (antisymmetry)
- $a \preceq b \preceq c$ implies $a \preceq c$ (transitivity)

This is simply a generalization of a totally ordered set that allows some elements to be incomparable, and is a good model for the kind of acyclic directed graph data found in knowledge bases.

A *lattice* is a poset where any subset has a a unique least upper and greatest lower bound, which will be true of all posets (lattices) considered in this paper. The least upper bound of two elements $a, b \in P$ is called the *join*, denoted $a \vee b$, and the greatest lower bound is called the *meet*, denoted $a \wedge b$.

Additionally, in a *bounded lattice* we have two extra elements, called *top*, denoted $\top$ and *bottom*, denoted $\perp$, which are respectively the least upper bound and greatest lower bound of the entire space. Using the extended real number line (adding points at infinity), all lattices considered in this paper are bounded lattices.

3.2 Order Embeddings (OE)

Vendrov et al. (2016) introduced a method for embedding partially ordered sets and a task, *partial order completion*, an abstract term for things like hypernym or entailment prediction (learning transitive relations). The goal is to learn a mapping from the partially-ordered data domain to some other partially-ordered space that will enable generalization.

Definition 1. *Vendrov et al. (2016)*
A function $f : (X, \preceq_X) \to (Y, \preceq_Y)$ is an order-embedding *if for all $u, v \in X$*

$$u \preceq_X v \iff f(u) \preceq_Y f(v)$$

They choose Y to be a vector space, and the order $\preceq_Y$ to be based on the *reverse product order* on $\mathbb{R}^n_+$, which specifies

$$x \preceq y \iff \forall i \in \{1..n\}, \ x_i \geq y_i$$

so an embedding is below another in the hierarchy if all of the coordinates are larger, and 0 provides a top element.

Although Vendrov et al. (2016) do not explicitly discuss it, their model does not just capture partial orderings, but is a standard construction of a vector (Hilbert) lattice, in which the operations of meet and join can be defined as taking the pointwise maximum and minimum of two vectors, respectively (Zaanen, 1997). This observation is also used in (Li et al., 2017) to generate extra constraints for training order embeddings.

As noted in the original work, these single point embeddings can be thought of as regions, i.e. the cone extending out from the vector towards infinity. All concepts "entailed" by a given concept must lie in this cone.

This ordering is optimized from examples of ordered elements and negative samples via a max-margin loss.

3.3 Probabilistic Order Embeddings (POE)

Lai and Hockenmaier (2017) built on the "region" idea to derive a probabilistic formulation (which we will refer to as POE) to model entailment probabilities in a consistent, hierarchical way.

Noting that all of OE's regions obviously have the same infinite area under the standard (Lebesgue) measure of $\mathbb{R}^n_+$, they propose a probabilistic interpretation where the Bernoulli probability of each concept a or joint set of concepts $\{a, b\}$ with corresponding vectors $\{x, y\}$ is given by its volume under the exponential measure:

$$p(a) = \exp(-\sum_i x_i) = \int_{z \preceq x} \exp(-\|z\|_1) dz$$
$$p(a, b) = p(x \wedge y) = \exp(-\|\max(x_i, y_i)\|_1)$$

since the meet of two vectors is simply the intersection of their area cones, and replacing sums with ℓ_1 norms for brevity since all coordinates are positive. While having the intuition of measuring the areas of cones, this also automatically gives a valid probability distribution over concepts since this is just the product likelihood under a coordinatewise exponential distribution.

However, they note a deficiency of their model — it can only model positive (Pearson) correlations between concepts (Bernoulli variables).

Consider two Bernoulli variables a and b, whose probabilities correspond to the areas of cones x and y. Recall the Bernoulli covariance formula (we will deal with covariances instead of correlations when convenient, since they always have the same sign):

$$\text{cov}(a, b) = p(a, b) - p(a)p(b) =$$
$$\exp(-\|\max(x_i, y_i)\|_1) - \exp(-\|x_i + y_i\|_1)$$

Since the sum of two positive vectors can only be greater than the sum of their pointwise maximum, this quantity will always be nonnegative. This has real consequences for probabilistic modeling in KBs: conditioning on more concepts will only make probabilities higher (or unchanged), e.g. $p(\text{dog}|\text{plant}) \geq p(\text{dog})$.

3.4 Probabilistic Asymmetric Transitive Relations

Probabilistic models have pleasing consistency properties for modeling asymmetric transitive relations, in particular compared to density-based embeddings — a pairwise conditional probability table can almost always (in the technical sense) be asymmetrized to produce a DAG by simply taking an edge if $P(a|b) > P(b|a)$. A matrix of pairwise Gaussian KL divergences cannot be consistently asymmetrized in this manner. These claims are proven in Appendix C. While a high $P(a|b)$ does not always indicate an edge in an ontology due to confounding variables, existing graphical model structure learning methods can be used to further prune on the base graph without adding a cycle, such as Graphical Lasso or simple thresholding (Fattahi and Sojoudi, 2017).

4 Method

We develop a probabilistic model for lattices based on hypercube embeddings that can model both positive and negative correlations. Before describing this, we first motivate our choice to abandon OE/POE type cone-based models for this purpose.

4.1 Correlations from Cone Measures

Claim. *For a pair of Bernoulli variables $p(a)$ and $p(b)$, $cov(a, b) \geq 0$ if the Bernoulli probabilities come from the volume of a cone as measured under any product (coordinate-wise) probability measure $p(x) = \prod_i^n p_i(x_i)$ on $\mathbb{R}^n$, where F_i, the associated CDF for p_i, is monotone increasing.*

Proof. For any product measure we have

$$\int_{z \preceq x} p(z) dz = \prod_i^n \int_{x_i \leq z_i} p_i(z_i) dz_i = \prod_i^n 1 - F_i(x_i)$$

This is just the area of the unique box corresponding to $\prod_i^n [F_i(x_i), 1] \in [0, 1]^n$, under the uniform measure. This box is unique as a monotone increasing univariate CDF is bijective with $(0, 1)$ — cones in $\mathbb{R}^n$ can be invertibly mapped to boxes of equivalent measure inside the unit hypercube $[0, 1]^n$. These boxes have only half their degrees of freedom, as they have the form $[F_i(x_i), 1]$ per dimension, (intuitively, they have one end "stuck at infinity" since the cone integrates to infinity.

So W.L.O.G. we can consider two transformed cones x and y corresponding to our Bernoulli variables a and b, and letting $F_i(x_i) = u_i$ and $F_i(y_i) = v_i$, their intersection in the unit hypercube is $\prod_i^n [\max(u_i, v_i), 1]$.

Pairing terms in the right-hand product, we have

$$p(a,b) - p(a)p(b) =$$
$$\prod_i^n (1 - \max(u_i, v_i)) - \prod_i^n (1 - u_i)(1 - v_i) \geq 0$$

since the right contains all the terms of the left and can only grow smaller. This argument is easily modified to the case of the nonnegative orthant, *mutatis mutandis*. □

An open question for future work is what non-product measures this claim also applies to. Note that some non-product measures, such as multivariate Gaussian, can be transformed into product measures easily (*whitening*) and the above proof would still apply. It seems probable that some measures, nonlinearly entangled across dimensions, could encode negative correlations in cone volumes. However, it is not generally tractable to integrate high-dimensional cones under arbitrary non-product measures.

4.2 Box Lattices

The above proof gives us intuition about the possible form of a better representation. Cones can be mapped into boxes within the unit hypercube while preserving their measure, and the lack of negative correlation seems to come from the fact that they always have an overly-large intersection due to "pinning" the maximum in each dimension to 1. To remedy this, we propose to learn representations in the space of *all* boxes (axis-aligned hyperrectangles), gaining back an extra degree of freedom. These representations can be learned with a suitable probability measure in $\mathbb{R}^n$, the nonnegative orthant $\mathbb{R}^n_+$, or directly in the unit hypercube with the uniform measure, which we elect.

We associate each concept with 2 vectors, the minimum and maximum value of the box at each dimension. Practically for numerical reasons these are stored as a minimum, a positive offset plus an ϵ term to prevent boxes from becoming too small and underflowing.

Let us define our box embeddings as a pair of vectors in $[0,1]^n$, (x_m, x_M), representing the maximum and minimum at each coordinate.

Then we can define a partial ordering by inclusion of boxes, and a lattice structure as

$$x \wedge y = \bot \text{ if } x \text{ and } y \text{ disjoint, else}$$
$$x \wedge y = \prod_i [\max(x_{m,i}, y_{m,i}), \min(x_{M,i}, y_{M,i})]$$
$$x \vee y = \prod_i [\min(x_{m,i}, y_{m,i}), \max(x_{M,i}, y_{M,i})]$$

where the meet is the intersecting box, or bottom (the empty set) where no intersection exists, and join is the smallest enclosing box. This lattice, considered on its own terms as a non-probabilistic object, is strictly more general than the order embedding lattice in any dimension, which is proven in Appendix B.

However, the finite sizes of all the lattice elements lead to a natural probabilistic interpretation under the uniform measure. Joint and marginal probabilities are given by the volume of the (intersection) box. For concept a with associated box (x_m, x_M), probability is simply $p(a) = \prod_i^n (x_{M,i} - x_{m,i})$ (under the uniform measure). $p(\bot)$ is of course zero since no probability mass is assigned to the empty set.

It remains to show that this representation can represent both positive and negative correlations.

Claim. *For a pair of Bernoulli variables $p(a)$ and $p(b)$, corr(a,b) can take on any value in $[-1,1]$ if the probabilities come from the volume of associated boxes in $[0,1]^n$.*

Proof. Boxes can clearly model disjointness (exactly -1 correlation if the total volume of the boxes equals 1). Two identical boxes give their concepts exactly correlation 1. The area of the meet is continuous with respect to translations of intersecting boxes, and all other terms in correlation stay constant, so by continuity of the correlation function our model can achieve all possible correlations for a pair of variables. □

This proof can be extended to boxes in $\mathbb{R}^n$ with product measures by the previous reduction.

Limitations: Note that this model cannot perfectly describe all possible probability distributions or concepts as embedded objects. For example, the complement of a box is not a box. However, queries about complemented variables can be calculated by the Inclusion-Exclusion principle, made more efficient by the fact that all non-negated terms can be grouped and calculated exactly. We show some toy exact calculations with negated variables in Appendix A. Also, note that in a knowledge graph often true complements are not required — for example *mortal* and *immortal* are not actually complements, because the concept *color* is neither.

Additionally, requiring the total probability mass covered by boxes to equal 1, or exactly matching marginal box probabilities while modeling all correlations is a difficult box-packing-type problem and not generally possible. Modeling limitations aside, the union of boxes having mass < 1 can be seen as an open-world assumption on our KB (not all points in space have corresponding concepts, yet).

4.3 Learning

While inference (calculation of pairwise joint, unary marginal, and pairwise conditional probabilities) is quite straightforward by taking intersections of boxes and computing volumes (and their ratios), learning does not appear easy at first glance. While the (sub)gradient of the joint probability is well defined when boxes intersect, it is non-differentiable otherwise. Instead we optimize a lower bound.

Clearly $p(a \vee b) \geq p(a \cup b)$, with equality only when $a = b$, so this can give us a lower bound:

$$\begin{aligned} p(a \wedge b) &= p(a) + p(b) - p(a \cup b) \\ &\geq p(a) + p(b) - p(a \vee b) \end{aligned}$$

Where probabilities are always given by the volume of the associated box. This lower bound always exists and is differentiable, even when the joint is not. It is guaranteed to be nonpositive except when a and b intersect, in which case the true joint likelihood should be used.

While a negative bound on a probability is odd, inspecting the bound we see that its gradient will push the enclosing box to be smaller, while increasing areas of the individual boxes, until they intersect, which is a sensible learning strategy.

Since we are working with small probabilities it is advisable to negate this term and maximize the negative logarithm:

$$-\log(p(a \vee b) - p(a) - p(b))$$

This still has an unbounded gradient as the lower bound approaches 0, so it is also useful to add a constant within the logarithm function to avoid numerical problems.

Since the likelihood of the full data is usually intractable to compute as a conjunction of many negations, we optimize binary conditional and unary marginal terms separately by maximum likelihood.

In this work, we parametrize the boxes as $(\min, \Delta = \max - \min)$, with Euclidean projections after gradient steps to keep our parameters in the unit hypercube and maintain the minimum/delta constraints.

Now that we have the ability to compute probabilities and (surrogate) gradients for arbitrary marginals in the model, and by extension conditionals, we will see specific examples in the experiments.

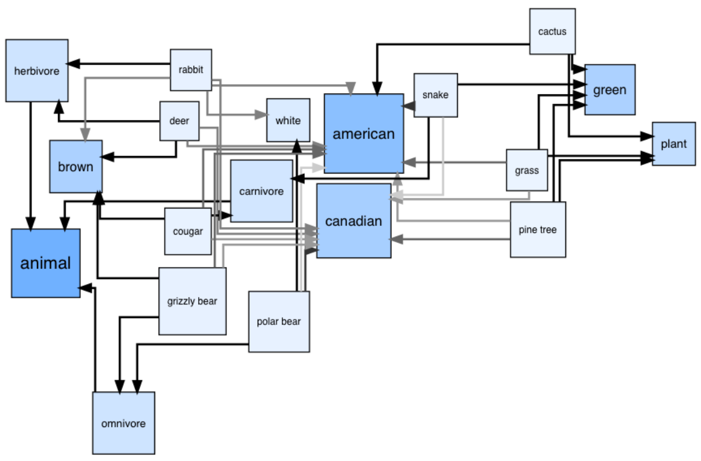
5 Experiments

5.1 Warmup: 2D Embedding of a Toy Lattice

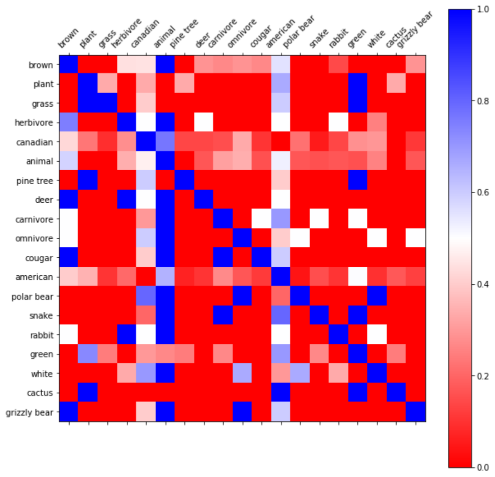
We begin by investigating properties of our model in modeling a small toy problem, consisting of a small hand constructed ontology over 19 concepts, aggregated from atomic synthetic examples first into a probabilistic lattice (e.g. some rabbits are brown, some are white), and then a full CPD. We model it using only 2 dimensions to enable visualization of the way the model self-organizes its "event space", training the model by minimize weighted cross-entropy with both the unary marginals and pairwise conditional probabilities. We also conduct a parallel experiment with POE as embedded in the unit cube, where each representation is constrained to touch the faces $x = 1, y = 1$. In Figure 2, we show the representation of lattice structures by POE and the box lattice model as compared to the abstract probabilistic lattice used to construct the data, shown in Figure 1, and compare the conditional probabilities produced by our model to the ground truth, demonstrating the richer capacity of the box model in capturing strong positive and negative correlations. In Table 1, we perform a series of multivariable conditional queries and demonstrate intuitive results on high-order queries containing up to 4 variables, despite the model being trained on only 2-way information.

5.2 WordNet

We experiment on WordNet hypernym prediction, using the same train, development and test split as Vendrov et al. (2016), created by randomly taking 4,000 hypernym pairs from the 837,888-



(a) Original lattice



(b) Ground truth CPD

Figure 1: Representation of the toy probabilistic lattice used in Section 5.1. Darker color corresponds to more unary marginal probability. The associated CPD is obtained by a weighted aggregation of leaf elements.

edge transitive closure of the WordNet hypernym hierarchy as positive training examples for the development set, 4,000 for the test set, and using the rest as training data. Negative training examples are created by randomly corrupting a train/development/test edge (u, v) by replacing either u or v with a randomly chosen negative node. We use their specific train/dev/test split, while Athiwaratkun and Wilson (2018) use a different train/dev split with the same test set (personal communication) to examine the effect of different negative sampling techniques. We cite their best performing model, called DOE (KL).

Since our model is probabilistic, we would like a sensible value for $P(n)$, where n is a node. We assign these marginal probabilities by looking at the number of descendants in the hierarchy under a node, and normalizing over all nodes, taking $P(n) = \frac{|\textit{ descendants(n) }|}{|\textit{ nodes }|}$.

Furthermore, we use the graph structure (only of the subset of edges in the training set to avoid leaking data) to augment the data with approximate conditional probabilities $P(x|y)$. For each leaf, we consider all of its ancestors as pairwise co-occurences, then aggregate and divide by the number of leaves to get an approximate joint probability distribution, $P(x, y) = \frac{|\textit{ x, y co-occur in ancestor set }|}{|\textit{ leaves }|}$. With this and the unary marginals, we can create a conditional probability table, which we prune based on the difference of $P(x|y)$ and $P(y|x)$ and add cross entropy with these conditional "soft edges" to the training data. We refer to experiments using this additional data as Box + CPD in Table 3.

We use 50 dimensions in our experiments. Since our model has 2 parameters per dimension, we also perform an apples-to-apples comparison with a 100D POE model. As seen in Table 3, we outperform POE significantly even with this added representational power. We also observe sensible negatively correlated examples, shown in 2, in the trained box model, while POE cannot represent such relationships. We tune our models on the development set, with parameters documented in Appendix D.1. We observe that not only does our model outperform POE, it beats all previous results on WordNet, aside from the concurrent work of Athiwaratkun and Wilson (2018) (using different train/dev negative examples), the baseline POE model does as well. This indicates that probabilistic embeddings for transitive relations are a promising avenue for future work. Additionally, the ability of the model to learn from the expected "soft edges" improves it to state-of-the-art level. We expect that co-occurrence counts gathered from real textual corpora, rather than merely aggregating up the WordNet lattice, would further strengthen this effect.

5.3 Flickr Entailment Graph

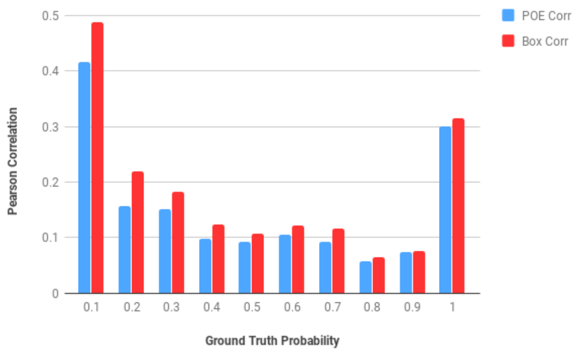

Figure 3: R between model and gold probabilities.

	$P(x\|y)$

POE*	0.084	0.854
Box	**0.050**	**0.900**

Table 4: KL and Pearson correlation between model and gold probability.

We conduct experiments on the large-scale Flickr entailment dataset of 45 million image caption pairs. We use the exactly same train/dev/test from Lai and Hockenmaier (2017). We use a slightly different unseen word pairs and unseen words test data, obtained from the author. We include their published results and also use their published code, marked $*$, for comparison.

For these experiments, we relax our boxes from the unit hypercube to the nonnegative orthant and obtain probabilities under the exponential measure, $p(x) = \exp(-x)$. We enforce the nonnegativity constraints by clipping the LSTM-generated embedding (Hochreiter and Schmidhuber, 1997) for the box minimum with a ReLU, and parametrize our Δ embeddings using a softplus activation to prevent dead units. As in Lai and Hockenmaier (2017), we use 512 hidden units in our LSTM to compose sentence vectors. We then apply two single-layer feed-forward networks with 512 units applied to the final LSTM state to produce the embeddings.

As we can see from Table 4, we note large improvements in KL and Pearson correlation to the ground truth entailment probabilities. In further analysis, Figure 3 demonstrates that while the box model outperforms POE in nearly every regime, the highest gains come from the comparatively difficult to calibrate small entailment probabilities, indicating the greater capability of our model to produce fine-grained distinctions.

6 Conclusion and Future Work

We have only scratched the surface of possible applications. An exciting direction is the incorporation of multi-relational data for general knowledge representation and inference. Secondly, more complex representations, such as $2n$-dimensional products of 2-dimensional convex polyhedra, would offer greater flexibility in tiling event space. Improved inference of the latent boxes, either through better optimization or through Bayesian approaches is another natural extension. Our greatest interest is in the application of this powerful new tool to the many areas where other structured embeddings have shown promise.

7 Acknowledgments

We thank Alice Lai for making the code from her original paper public, and for providing the additional unseen pairs and unseen words data. We also thank Haw-Shiuan Chang, Laurent Dinh, and Ben Poole for helpful discussions. We also thank the anonymous reviewers for their constructive feedback.

Abstract

Many NLP applications can be framed as a graph-to-sequence learning problem. Previous work proposing neural architectures on this setting obtained promising results compared to grammar-based approaches but still rely on linearisation heuristics and/or standard recurrent networks to achieve the best performance. In this work, we propose a new model that encodes the full structural information contained in the graph. Our architecture couples the recently proposed Gated Graph Neural Networks with an input transformation that allows nodes and edges to have their own hidden representations, while tackling the parameter explosion problem present in previous work. Experimental results show that our model outperforms strong baselines in generation from AMR graphs and syntax-based neural machine translation.

1 Introduction

Graph structures are ubiquitous in representations of natural language. In particular, many whole-sentence semantic frameworks employ directed acyclic graphs as the underlying formalism, while most tree-based syntactic representations can also be seen as graphs. A range of NLP applications can be framed as the process of transducing a graph structure into a sequence. For instance, language generation may involve realising a semantic graph into a surface form and syntactic machine translation involves transforming a tree-annotated source sentence to its translation.

Previous work in this setting rely on grammar-based approaches such as tree transducers (Flanigan et al., 2016) and hyperedge replacement grammars (Jones et al., 2012). A key limitation of these approaches is that alignments between graph nodes and surface tokens are required. These alignments are usually automatically generated so they can propagate errors when building the grammar. More recent approaches transform the graph into a linearised form and use off-the-shelf methods such as phrase-based machine translation (Pourdamghani et al., 2016) or neural sequence-to-sequence (henceforth, `s2s`) models (Konstas et al., 2017). Such approaches ignore the full graph structure, discarding key information.

In this work we propose a model for graph-to-sequence (henceforth, `g2s`) learning that leverages recent advances in neural encoder-decoder architectures. Specifically, we employ an encoder based on Gated Graph Neural Networks (Li et al., 2016, GGNNs), which can incorporate the full graph structure without loss of information. Such networks represent edge information as label-wise parameters, which can be problematic even for small sized label vocabularies (in the order of hundreds). To address this limitation, we also introduce a graph transformation that changes edges to additional nodes, solving the parameter explosion problem. This also ensures that edges have graph-specific hidden vectors, which gives more information to the attention and decoding modules in the network.

We benchmark our model in two graph-to-sequence problems, generation from Abstract Meaning Representations (AMRs) and Neural Machine Translation (NMT) with source dependency information. Our approach outperforms strong `s2s` baselines in both tasks *without relying on standard RNN encoders*, in contrast with previous work. In particular, for NMT we show that we avoid the need for RNNs by adding sequential edges between contiguous words in the dependency tree. This illustrates the generality of our

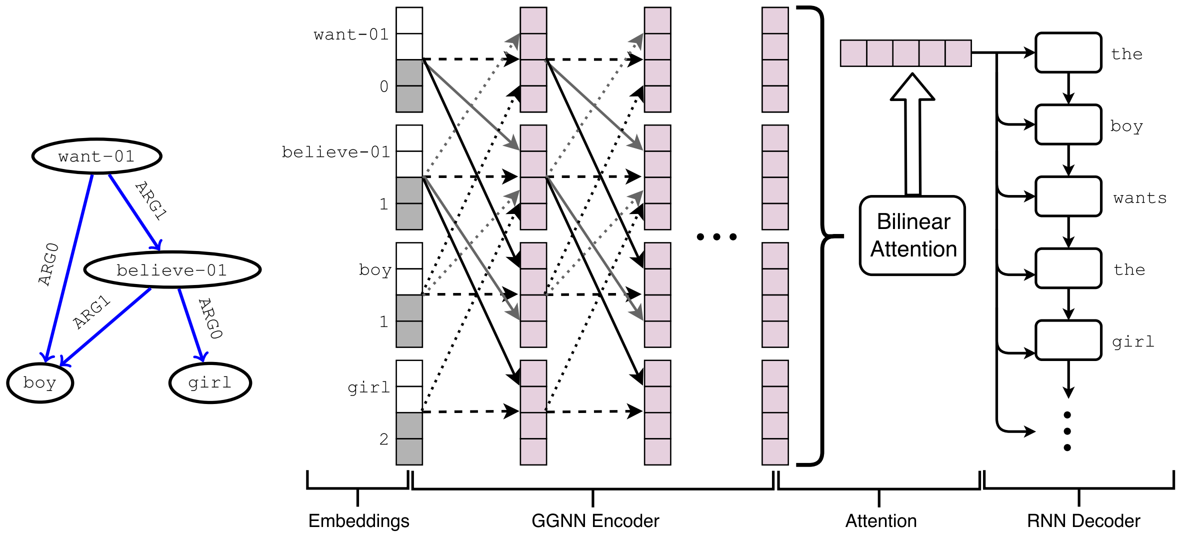

Figure 1: Left: the AMR graph representing the sentence "The boy wants the girl to believe him.". Right: Our proposed architecture using the same AMR graph as input and the surface form as output. The first layer is a concatenation of node and positional embeddings, using distance from the root node as the position. The GGNN encoder updates the embeddings using edge-wise parameters, represented by different colors (in this example, `ARG0` and `ARG1`). The encoder also add corresponding reverse edges (dotted arrows) and self edges for each node (dashed arrows). All parameters are shared between layers. Attention and decoder components are similar to standard `s2s` models. This is a pictorial representation: in our experiments the graphs are transformed before being used as inputs (see §3).

approach: linguistic biases can be added to the inputs by simple graph transformations, without the need for changes to the model architecture.

2 Neural Graph-to-Sequence Model

Our proposed architecture is shown in Figure 1, with an example AMR graph and its transformation into its surface form. Compared to standard `s2s` models, the main difference is in the encoder, where we employ a GGNN to build a graph representation. In the following we explain the components of this architecture in detail.[1]

2.1 Gated Graph Neural Networks

Early approaches for recurrent networks on graphs (Gori et al., 2005; Scarselli et al., 2009) assume a fixed point representation of the parameters and learn using contraction maps. Li et al. (2016) argues that this restricts the capacity of the model and makes it harder to learn long distance relations between nodes. To tackle these issues, they propose Gated Graph Neural Networks, which extend these architectures with gating mechanisms in a similar fashion to Gated Recurrent Units (Cho et al., 2014). This allows the network to be learnt via modern backpropagation procedures.

In following, we formally define the version of GGNNs we employ in this study. Assume a directed graph $\mathcal{G} = \{\mathcal{V}, \mathcal{E}, L_\mathcal{V}, L_\mathcal{E}\}$, where $\mathcal{V}$ is a set of nodes (v, ℓ_v), $\mathcal{E}$ is a set of edges (v_i, v_j, ℓ_e) and $L_\mathcal{V}$ and $L_\mathcal{E}$ are respectively vocabularies for nodes and edges, from which node and edge labels (ℓ_v and ℓ_e) are defined. Given an input graph with nodes mapped to embeddings $\mathbf{X}$, a GGNN is defined as

$$\begin{aligned}
\mathbf{h}_v^0 &= \mathbf{x}_v \\
\mathbf{r}_v^t &= \sigma\left(c_v^r \sum_{u \in \mathcal{N}_v} \mathbf{W}_{\ell_e}^r \mathbf{h}_u^{(t-1)} + \mathbf{b}_{\ell_e}^r\right) \\
\mathbf{z}_v^t &= \sigma\left(c_v^z \sum_{u \in \mathcal{N}_v} \mathbf{W}_{\ell_e}^z \mathbf{h}_u^{(t-1)} + \mathbf{b}_{\ell_e}^z\right) \\
\widetilde{\mathbf{h}}_v^t &= \rho\left(c_v \sum_{u \in \mathcal{N}_v} \mathbf{W}_{\ell_e}\left(\mathbf{r}_u^t \odot \mathbf{h}_u^{(t-1)}\right) + \mathbf{b}_{\ell_e}\right) \\
\mathbf{h}_v^t &= (1 - \mathbf{z}_v^t) \odot \mathbf{h}_v^{(i-1)} + \mathbf{z}_v^t \odot \widetilde{\mathbf{h}}_v^t
\end{aligned}$$

where $e = (u, v, \ell_e)$ is the edge between nodes u and v, $\mathcal{N}(v)$ is the set of neighbour nodes for v, ρ is a non-linear function, σ is the sigmoid function

[1]Our implementation uses MXNet (Chen et al., 2015) and is based on the Sockeye toolkit (Hieber et al., 2017). Code is available at `github.com/beckdaniel/acl2018_graph2seq`.

and $c_v = c_v^z = c_v^r = |\mathcal{N}_v|^{-1}$ are normalisation constants.

Our formulation differs from the original GGNNs from Li et al. (2016) in some aspects: 1) we add bias vectors for the hidden state, reset gate and update gate computations; 2) label-specific matrices do not share any components; 3) reset gates are applied to all hidden states before any computation and 4) we add normalisation constants. These modifications were applied based on preliminary experiments and ease of implementation.

An alternative to GGNNs is the model from Marcheggiani and Titov (2017), which add edge label information to Graph Convolutional Networks (GCNs). According to Li et al. (2016), the main difference between GCNs and GGNNs is analogous to the difference between convolutional and recurrent networks. More specifically, GGNNs can be seen as multi-layered GCNs where layer-wise parameters are tied and gating mechanisms are added. A large number of layers can propagate node information between longer distances in the graph and, unlike GCNs, GGNNs can have an arbitrary number of layers without increasing the number of parameters. Nevertheless, our architecture borrows ideas from GCNs as well, such as normalising factors.

2.2 Using GGNNs in attentional encoder-decoder models

In s2s models, inputs are sequences of tokens where each token is represented by an embedding vector. The encoder then transforms these vectors into hidden states by incorporating context, usually through a recurrent or a convolutional network. These are fed into an attention mechanism, generating a single context vector that informs decisions in the decoder.

Our model follows a similar structure, where the encoder is a GGNN that receives *node* embeddings as inputs and generates *node* hidden states as outputs, using the graph structure as context. This is shown in the example of Figure 1, where we have 4 hidden vectors, one per node in the AMR graph. The attention and decoder components follow similar standard s2s models, where we use a bilinear attention mechanism (Luong et al., 2015) and a 2-layered LSTM (Hochreiter and Schmidhuber, 1997) as the decoder. Note, however, that other decoders and attention mechanisms can be easily employed instead. Bastings et al. (2017) employs a similar idea for syntax-based NMT, but using GCNs instead.

2.3 Bidirectionality and positional embeddings

While our architecture can in theory be used with general graphs, rooted directed acyclic graphs (DAGs) are arguably the most common kind in the problems we are addressing. This means that node embedding information is propagated in a top down manner. However, it is desirable to have information flow from the reverse direction as well, in the same way RNN-based encoders benefit from right-to-left propagation (as in bidirectional RNNs). Marcheggiani and Titov (2017) and Bastings et al. (2017) achieve this by adding reverse edges to the graph, as well as self-loops edges for each node. These extra edges have specific labels, hence their own parameters in the network.

In this work, we also follow this procedure to ensure information is evenly propagated in the graph. However, this raises another limitation: because the graph becomes essentially undirected, the encoder is now unaware of any intrinsic hierarchy present in the input. Inspired by Gehring et al. (2017) and Vaswani et al. (2017), we tackle this problem by adding positional embeddings to every node. These embeddings are indexed by integer values representing the minimum distance from the root node and are learned as model parameters.[2] This kind of positional embedding is restricted to rooted DAGs: for general graphs, different notions of distance could be employed.

3 Levi Graph Transformation

The g2s model proposed in §2 has two key deficiencies. First, GGNNs have three linear transformations *per edge type*. This means that the number of parameters can explode: AMR, for instance, has around 100 different predicates, which correspond to edge labels. Previous work deal with this problem by explicitly grouping edge labels into a single one (Marcheggiani and Titov, 2017; Bastings et al., 2017) but this is not an ideal solution since it incurs in loss of information.

[2]Vaswani et al. (2017) also proposed fixed positional embeddings based on sine and cosine wavelengths. Preliminary experiments showed that this approach did not work in our case: we speculate this is because wavelengths are more suitable to sequential inputs.

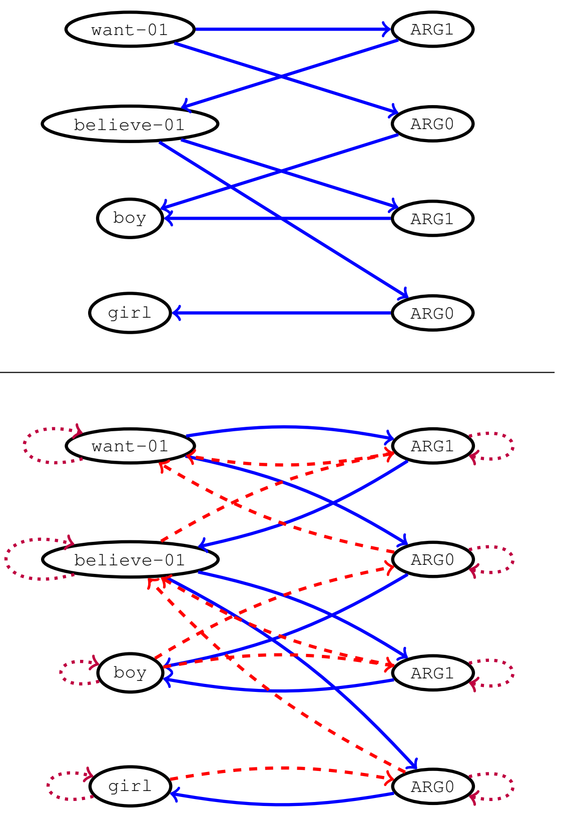

Figure 2: Top: the AMR graph from Figure 1 transformed into its corresponding Levi graph. Bottom: Levi graph with added reverse and self edges (colors represent different edge labels).

The second deficiency is that edge label information is encoded in the form of GGNN parameters in the network. This means that each label will have the same "representation" across all graphs. However, the latent information in edges can depend on the content in which they appear in a graph. Ideally, edges should have instance-specific *hidden states*, in the same way as nodes, and these should also inform decisions made in the decoder through the attention module. For instance, in the AMR graph shown in Figure 1, the `ARG1` predicate between `want-01` and `believe-01` can be interpreted as the preposition "to" in the surface form, while the `ARG1` predicate connecting `believe-01` and `boy` is realised as a pronoun. Notice that edge hidden vectors are already present in `s2s` networks that use linearised graphs: we would like our architecture to also have this benefit.

Instead of modifying the architecture, we propose to transform the input graph into its equivalent Levi graph (Levi, 1942; Gross and Yellen, 2004, p. 765). Given a graph $\mathcal{G} = \{\mathcal{V}, \mathcal{E}, L_{\mathcal{V}}, L_{\mathcal{E}}\}$, a Levi graph[3] is defined as $\mathcal{G} = \{\mathcal{V}', \mathcal{E}', L_{\mathcal{V}'}, L_{\mathcal{E}'}\}$, where $\mathcal{V}' = \mathcal{V} \cup \mathcal{E}$, $L_{\mathcal{V}'} = L_{\mathcal{V}} \cup L_{\mathcal{E}}$ and $L_{\mathcal{E}'} = \varnothing$. The new edge set $\mathcal{E}'$ contains a edge for every (node, edge) pair that is present in the original graph. By definition, the Levi graph is bipartite.

Intuitively, transforming a graph into its Levi graph equivalent turns edges into additional nodes. While simple in theory, this transformation addresses both modelling deficiencies mentioned above in an elegant way. Since the Levi graph has no labelled edges there is no risk of parameter explosion: original edge labels are represented as embeddings, in the same way as nodes. Furthermore, the encoder now naturally generates hidden states for original edges as well.

In practice, we follow the procedure in §2.3 and add reverse and self-loop edges to the Levi graph, so the practical edge label vocabulary is $L_{\mathcal{E}'} = \{\text{default}, \text{reverse}, \text{self}\}$. This still keeps the parameter space modest since we have only three labels. Figure 2 shows the transformation steps in detail, applied to the AMR graph shown in Figure 1. Notice that the transformed graphs are the ones fed into our architecture: we show the original graph in Figure 1 for simplicity.

It is important to note that this transformation can be applied to any graph and therefore is independent of the model architecture. We speculate this can be beneficial in other kinds of graph-based encoder such as GCNs and leave further investigation to future work.

4 Generation from AMR Graphs

Our first `g2s` benchmark is language generation from AMR, a semantic formalism that represents sentences as rooted DAGs (Banarescu et al., 2013). Because AMR abstracts away from syntax, graphs do not have gold-standard alignment information, so generation is not a trivial task. Therefore, we hypothesize that our proposed model is ideal for this problem.

4.1 Experimental setup

Data and preprocessing We use the latest AMR corpus release (LDC2017T10) with the default split of 36521/1368/1371 instances for training,

[3]Formally, a Levi graph is defined over any *incidence structure*, which is a general concept usually considered in a geometrical context. Graphs are an example of incidence structures but so are points and lines in the Euclidean space, for instance.

development and test sets. Each graph is preprocessed using a procedure similar to what is performed by Konstas et al. (2017), which includes entity simplification and anonymisation. This preprocessing is done before transforming the graph into its Levi graph equivalent. For the `s2s` baselines, we also add scope markers as in Konstas et al. (2017). We detail these procedures in the Supplementary Material.

Models Our baselines are attentional `s2s` models which take linearised graphs as inputs. The architecture is similar to the one used in Konstas et al. (2017) for AMR generation, where the encoder is a BiLSTM followed by a unidirectional LSTM. All dimensionalities are fixed to 512.

For the `g2s` models, we fix the number of layers in the GGNN encoder to 8, as this gave the best results on the development set. Dimensionalities are also fixed at 512 except for the GGNN encoder which uses 576. This is to ensure all models have a comparable number of parameters and therefore similar capacity.

Training for all models uses Adam (Kingma and Ba, 2015) with 0.0003 initial learning rate and 16 as the batch size.[4] To regularise our models we perform early stopping on the dev set based on perplexity and apply 0.5 dropout (Srivastava et al., 2014) on the source embeddings. We detail additional model and training hyperparameters in the Supplementary Material.

Evaluation Following previous work, we evaluate our models using BLEU (Papineni et al., 2001) and perform bootstrap resampling to check statistical significance. However, since recent work has questioned the effectiveness of BLEU with bootstrap resampling (Graham et al., 2014), we also report results using sentence-level CHRF++ (Popović, 2017), using the Wilcoxon signed-rank test to check significance. Evaluation is case-insensitive for both metrics.

Recent work has shown that evaluation in neural models can lead to wrong conclusions by just changing the random seed (Reimers and Gurevych, 2017). In an effort to make our conclusions more robust, we run each model 5 times using different seeds. From each pool, we report results using the median model according to performance on the dev set (simulating what is expected from a single run) and using an ensemble of the 5 models.

[4]Larger batch sizes hurt dev performance in our preliminary experiments. There is evidence that small batches can lead to better generalisation performance (Keskar et al., 2017). While this can make training time slower, it was doable in our case since the dataset is small.

	BLEU	CHRF++	#params
Single models			
`s2s`	21.7	49.1	28.4M
`s2s` (-s)	18.4	46.3	28.4M
`g2s`	23.3	50.4	28.3M
Ensembles			
`s2s`	26.6	52.5	142M

KIYCZ17	33.8	–	–
PKH16	26.9	–	–
SPZWG17	25.6	–	–
FDSC16	22.0	–	–

Table 1: Results for AMR generation on the test set. All score differences between our models and the corresponding baselines are significantly different ($p<0.05$). "(-s)" means input without scope marking. KIYCZ17, PKH16, SPZWG17 and FDSC16 are respectively the results reported in Konstas et al. (2017), Pourdamghani et al. (2016), Song et al. (2017) and Flanigan et al. (2016).

Finally, we also report the number of parameters used in each model. Since our encoder architectures are quite different, we try to match the number of parameters between them by changing the dimensionality of the hidden layers (as explained above). We do this to minimise the effects of model capacity as a confounder.

4.2 Results and analysis

Table 1 shows the results on the test set. For the `s2s` models, we also report results without the scope marking procedure of Konstas et al. (2017). Our approach significantly outperforms the `s2s` baselines both with individual models and ensembles, while using a comparable number of parameters. In particular, we obtain these results without relying on scoping heuristics.

On Figure 3 we show an example where our model outperforms the baseline. The AMR graph contains four reentrancies, predicates that refer-

Figure 3: Example showing overgeneration due to reentrancies. Top: original AMR graph with key reentrancies highlighted. Bottom: reference and outputs generated by the s2s and g2s models, highlighting the overgeneration phenomena.

ence previously defined concepts in the graph. In the s2s models including Konstas et al. (2017), reentrant nodes are copied in the linearised form, while this is not necessary for our g2s models. We can see that the s2s prediction overgenerates the "India and China" phrase. The g2s prediction avoids overgeneration, and almost perfectly matches the reference. While this is only a single example, it provides evidence that retaining the full graphical structure is beneficial for this task, which is corroborated by our quantitative results.

Table 1 also show BLEU scores reported in previous work. These results are not strictly comparable because they used different training set versions and/or employ additional unlabelled corpora; nonetheless some insights can be made. In particular, our g2s ensemble performs better than many previous models that combine a smaller training set with a large unlabelled corpus. It is also most informative to compare our s2s model with Konstas et al. (2017), since this baseline is very similar to theirs. We expected our single model baseline to outperform theirs since we use a larger training set but we obtained similar performance. We speculate that better results could be obtained by more careful tuning, but nevertheless we believe such tuning would also benefit our proposed g2s architecture.

The best results with unlabelled data are obtained by Konstas et al. (2017) using Gigaword sentences as additional data and a paired trained procedure with an AMR parser. It is important to note that this procedure is orthogonal to the individual models used for generation and parsing. Therefore, we hypothesise that our model can also benefit from such techniques, an avenue that we leave for future work.

5 Syntax-based Neural Machine Translation

Our second evaluation is NMT, using as graphs source language dependency syntax trees. We focus on a medium resource scenario where additional linguistic information tends to be more beneficial. Our experiments comprise two language pairs: English-German and English-Czech.

5.1 Experimental setup

Data and preprocessing We employ the same data and settings from Bastings et al. (2017),[5] which use the News Commentary V11 corpora from the WMT16 translation task.[6] English text is tokenised and parsed using SyntaxNet[7] while German and Czech texts are tokenised and split into subwords using byte-pair encodings (Sennrich et al., 2016, BPE) (8000 merge operations).

[5]We obtained the data from the original authors to ensure results are comparable without any influence from preprocessing steps.

[6]http://www.statmt.org/wmt16/translation-task.html

[7]https://github.com/tensorflow/models/tree/master/syntaxnet

We refer to Bastings et al. (2017) for further information on the preprocessing steps.

Labelled dependency trees in the source side are transformed into Levi graphs as a preprocessing step. However, unlike AMR generation, in NMT the inputs are originally surface forms that contain important sequential information. This information is lost when treating the input as dependency trees, which might explain why Bastings et al. (2017) obtain the best performance when using an initial RNN layer in their encoder. To investigate this phenomenon, we also perform experiments adding sequential connections to each word in the dependency tree, corresponding to their order in the original surface form (henceforth, `g2s+`). These connections are represented as edges with specific left and right labels, which are added after the Levi graph transformation. Figure 4 shows an example of an input graph for `g2s+`, with the additional sequential edges connecting the words (reverse and self edges are omitted for simplicity).

Models Our `s2s` and `g2s` models are almost the same as in the AMR generation experiments (§4.1). The only exception is the GGNN encoder dimensionality, where we use 512 for the experiments with dependency trees only and 448 when the inputs have additional sequential connections. As in the AMR generation setting, we do this to ensure model capacity are comparable in the number of parameters. Another key difference is that the `s2s` baselines do not use dependency trees: they are trained on the sentences only.

In addition to neural models, we also report results for Phrase-Based Statistical MT (PB-SMT), using Moses (Koehn et al., 2007). The PB-SMT models are trained using the same data conditions as `s2s` (no dependency trees) and use the standard setup in Moses, except for the language model, where we use a 5-gram LM trained on the target side of the respective parallel corpus.[8]

Evaluation We report results in terms of BLEU and CHRF++, using case-sensitive versions of both metrics. Other settings are kept the same as in the AMR generation experiments (§4.1). For PB-SMT, we also report the median result of 5 runs, obtained by tuning the model using MERT (Och and Ney, 2002) 5 times.

[8]Note that target data is segmented using BPE, which is not the usual setting for PB-SMT. We decided to keep the segmentation to ensure data conditions are the same.

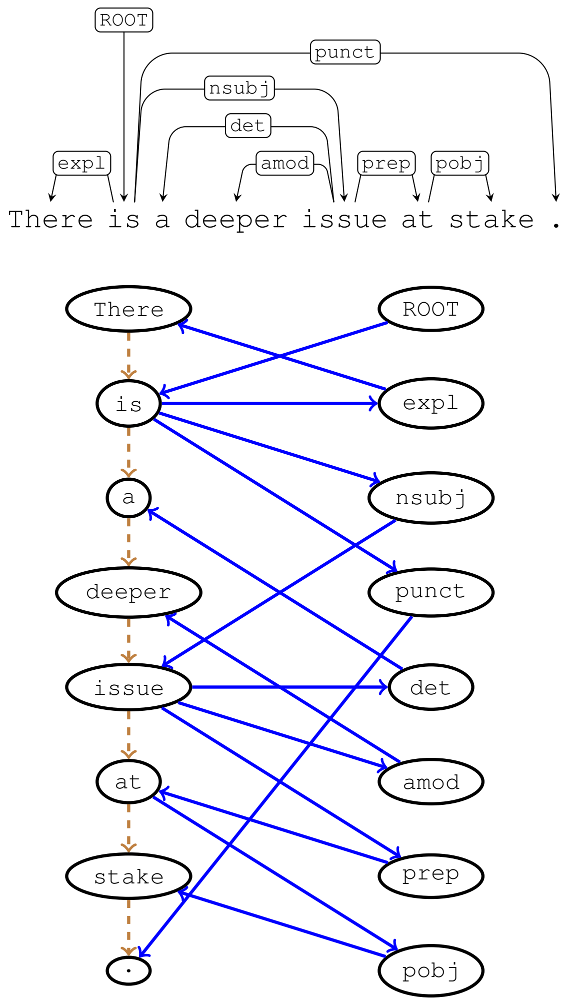

Figure 4: Top: a sentence with its corresponding dependency tree. Bottom: the transformed tree into a Levi graph with additional sequential connections between words (dashed lines). The full graph also contains reverse and self edges, which are omitted in the figure.

5.2 Results and analysis

Table 2 shows the results on the respective test set for both language pairs. The `g2s` models, which do not account for sequential information, lag behind our baselines. This is in line with the findings of Bastings et al. (2017), who found that having a BiRNN layer was key to obtain the best results. However, the `g2s+` models outperform the baselines in terms of BLEU scores under the same parameter budget, in both single model and ensemble scenarios. This result show that it is possible to incorporate sequential biases in our model without relying on RNNs or any other modification in the architecture.

Table 2: Results for syntax-based NMT on the test sets. All score differences between our models and the corresponding baselines are significantly different ($p<0.05$), including the negative CHRF++ result for En-Cs.

Interestingly, we found different trends when analysing the CHRF++ numbers. In particular, this metric favours the PB-SMT models for both language pairs, while also showing improved performance for s2s in En-Cs. CHRF++ has been shown to better correlate with human judgments compared to BLEU, both at system and sentence level for both language pairs (Bojar et al., 2017), which motivated our choice as an additional metric. We leave further investigation of this phenomena for future work.

We also show some of the results reported by Bastings et al. (2017) in Table 2. Note that their results were based on a different implementation, which may explain some variation in performance. Their BoW+GCN model is the most similar to ours, as it uses only an embedding layer and a GCN encoder. We can see that even our simpler g2s model outperforms their results. A key difference between their approach and ours is the Levi graph transformation and the resulting hidden vectors for edges. We believe their architecture would also benefit from our proposed transformation. In terms of baselines, s2s performs better than their BiRNN model for En-De and comparably for En-Cs, which corroborates that our baselines are strong ones. Finally, our g2s+ single models outperform their BiRNN+GCN results, in particular for En-De, which is further evidence that RNNs are not necessary for obtaining the best performance in this setting.

An important point about these experiments is that we did not tune the architecture: we simply employed the same model we used in the AMR generation experiments, only adjusting the dimensionality of the encoder to match the capacity of the baselines. We speculate that even better results would be obtained by tuning the architecture to this task. Nevertheless, we still obtained improved performance over our baselines and previous work, underlining the generality of our architecture.

6 Related work

Graph-to-sequence modelling Early NLP approaches for this problem were based on Hyperedge Replacement Grammars (Drewes et al., 1997, HRGs). These grammars assume the transduction problem can be split into rules that map portions of a graph to a set of tokens in the output sequence. In particular, Chiang et al. (2013) defines a parsing algorithm, followed by a complexity analysis, while Jones et al. (2012) report experiments on semantic-based machine translation using HRGs. HRGs were also used in previous work on AMR parsing (Peng et al., 2015). The main drawback of these grammar-based approaches though is the need for alignments between graph nodes and surface tokens, which are usually not available in gold-standard form.

Neural networks for graphs Recurrent networks on general graphs were first proposed under the name Graph Neural Networks (Gori et al., 2005; Scarselli et al., 2009). Our work is based on the architecture proposed by Li et al. (2016), which add gating mechanisms. The main difference between their work and ours is that they focus on problems that concern the input graph itself such as node classification or path finding while we focus on generating strings. The main alternative for neural-based graph representations is Graph Convolutional Networks (Bruna et al., 2014; Duvenaud et al., 2015; Kipf and Welling, 2017), which have been applied in a range of problems. In NLP, Marcheggiani and Titov (2017) use a similar architecture for Semantic Role Labelling. They use heuristics to mitigate the parameter explosion by grouping edge labels, while we keep the original labels through our Levi graph transformation. An interesting alternative is proposed by Schlichtkrull et al. (2017), which uses tensor factorisation to reduce the number of parameters.

Applications Early work on AMR generation employs grammars and transducers (Flanigan et al., 2016; Song et al., 2017). Linearisation approaches include (Pourdamghani et al., 2016) and (Konstas et al., 2017), which showed that graph simplification and anonymisation are key to good performance, a procedure we also employ in our work. However, compared to our approach, linearisation incurs in loss of information. MT has a long history of previous work that aims at incorporating syntax (Wu, 1997; Yamada and Knight, 2001; Galley et al., 2004; Liu et al., 2006, inter alia). This idea has also been investigated in the context of NMT. Bastings et al. (2017) is the most similar work to ours, and we benchmark against their approach in our NMT experiments. Eriguchi et al. (2016) also employs source syntax, but using constituency trees instead. Other approaches have investigated the use of syntax in the target language (Aharoni and Goldberg, 2017; Eriguchi et al., 2017). Finally, Hashimoto and Tsuruoka (2017) treats source syntax as a latent variable, which can be pretrained using annotated data.

7 Discussion and Conclusion

We proposed a novel encoder-decoder architecture for graph-to-sequence learning, outperforming baselines in two NLP tasks: generation from AMR graphs and syntax-based NMT. Our approach addresses shortcomings from previous work, including loss of information from linearisation and parameter explosion. In particular, we showed how graph transformations can solve issues with graph-based networks without changing the underlying architecture. This is the case of the proposed Levi graph transformation, which ensures the decoder can attend to edges as well as nodes, but also to the sequential connections added to the dependency trees in the case of NMT. Overall, because our architecture can work with general graphs, it is straightforward to add linguistic biases in the form of extra node and/or edge information. We believe this is an interesting research direction in terms of applications.

Our architecture nevertheless has two major limitations. The first one is that GGNNs have a fixed number of layers, even though graphs can vary in size in terms of number of nodes and edges. A better approach would be to allow the encoder to have a dynamic number of layers, possibly based on the diameter (longest path) in the input graph. The second limitation comes from the Levi graph transformation: because edge labels are represented as nodes they end up sharing the vocabulary and therefore, the same semantic space. This is not ideal, as nodes and edges are different entities. An interesting alternative is Weave Module Networks (Kearnes et al., 2016), which explicitly decouples node and edge representations without incurring in parameter explosion. Incorporating both ideas to our architecture is an research direction we plan for future work.

Sharp Nearby, Fuzzy Far Away: How Neural Language Models Use Context

Urvashi Khandelwal, He He, Peng Qi, Dan Jurafsky
Computer Science Department
Stanford University
{urvashik,hehe,pengqi,jurafsky}@stanford.edu

Abstract

We know very little about how neural language models (LM) use prior linguistic context. In this paper, we investigate the role of context in an LSTM LM, through ablation studies. Specifically, we analyze the increase in perplexity when prior context words are shuffled, replaced, or dropped. On two standard datasets, Penn Treebank and WikiText-2, we find that the model is capable of using about 200 tokens of context on average, but sharply distinguishes nearby context (recent 50 tokens) from the distant history. The model is highly sensitive to the order of words within the most recent sentence, but ignores word order in the long-range context (beyond 50 tokens), suggesting the distant past is modeled only as a rough semantic field or topic. We further find that the neural caching model (Grave et al., 2017b) especially helps the LSTM to copy words from within this distant context. Overall, our analysis not only provides a better understanding of how neural LMs use their context, but also sheds light on recent success from cache-based models.

1 Introduction

Language models are an important component of natural language generation tasks, such as machine translation and summarization. They use context (a sequence of words) to estimate a probability distribution of the upcoming word. For several years now, neural language models (NLMs) (Graves, 2013; Jozefowicz et al., 2016; Grave et al., 2017a; Dauphin et al., 2017; Melis et al., 2018; Yang et al., 2018) have consistently outperformed classical n-gram models, an improvement often attributed to their ability to model long-range dependencies in faraway context. Yet, how these NLMs use the context is largely unexplained.

Recent studies have begun to shed light on the information encoded by Long Short-Term Memory (LSTM) networks. They can remember sentence lengths, word identity, and word order (Adi et al., 2017), can capture some syntactic structures such as subject-verb agreement (Linzen et al., 2016), and can model certain kinds of semantic compositionality such as negation and intensification (Li et al., 2016).

However, all of the previous work studies LSTMs at the sentence level, even though they can potentially encode longer context. Our goal is to complement the prior work to provide a richer understanding of the role of context, in particular, long-range context beyond a sentence. We aim to answer the following questions: (i) How much context is used by NLMs, in terms of the number of tokens? (ii) Within this range, are nearby and long-range contexts represented differently? (iii) How do copy mechanisms help the model use different regions of context?

We investigate these questions via ablation studies on a standard LSTM language model (Merity et al., 2018) on two benchmark language modeling datasets: Penn Treebank and WikiText-2. Given a pretrained language model, we perturb the prior context in various ways *at test time*, to study how much the perturbed information affects model performance. Specifically, we alter the context length to study how many tokens are used, permute tokens to see if LSTMs care about word order in both local and global contexts, and drop and replace target words to test the copying abilities of LSTMs with and without an external copy mechanism, such as the neural cache (Grave et al., 2017b). The cache operates by first recording target words and their context representations seen in the history, and then encouraging the model to copy a word from the past when the current context representation matches that word's recorded context vector.

We find that the LSTM is capable of using about 200 tokens of context on average, with no observable differences from changing the hyperparameter settings. Within this context range, word order is only relevant within the 20 most recent tokens or about a sentence. In the long-range context, order has almost no effect on performance, suggesting that the model maintains a high-level, rough semantic representation of faraway words. Finally, we find that LSTMs can regenerate some words seen in the nearby context, but heavily rely on the cache to help them copy words from the long-range context.

2 Language Modeling

Language models assign probabilities to sequences of words. In practice, the probability can be factorized using the chain rule

$$P(w_1, \ldots, w_t) = \prod_{i=1}^{t} P(w_i | w_{i-1}, \ldots, w_1),$$

and language models compute the conditional probability of a *target word* w_t given its preceding context, $w_1, \ldots, w_{t-1}$.

Language models are trained to minimize the negative log likelihood of the training corpus:

$$\text{NLL} = -\frac{1}{T} \sum_{t=1}^{T} \log P(w_t | w_{t-1}, \ldots, w_1),$$

and the model's performance is usually evaluated by perplexity (PP) on a held-out set:

$$\text{PP} = \exp(\text{NLL}).$$

When testing the effect of ablations, we focus on comparing differences in the language model's losses (NLL) on the dev set, which is equivalent to relative improvements in perplexity.

3 Approach

Our goal is to investigate the effect of contextual features such as the length of context, word order and more, on LSTM performance. Thus, we use ablation analysis, during evaluation, to measure changes in model performance in the absence of certain contextual information.

	PTB		**Wiki**	
	Dev	Test	Dev	Test
# Tokens	73,760	82,430	217,646	245,569
Perplexity (no cache)	59.07	56.89	67.29	64.51
Avg. Sent. Len.	20.9	20.9	23.7	22.6

Table 1: Dataset statistics and performance relevant to our experiments.

Typically, when testing the language model on a held-out sequence of words, all tokens prior to the target word are fed to the model; we call this the *infinite-context* setting. In this study, we observe the change in perplexity or NLL when the model is fed a perturbed context $\delta(w_{t-1}, \ldots, w_1)$, at test time. δ refers to the perturbation function, and we experiment with perturbations such as dropping tokens, shuffling/reversing tokens, and replacing tokens with other words from the vocabulary.[1] It is important to note that we do not train the model with these perturbations. This is because the aim is to start with an LSTM that has been trained in the standard fashion, and discover how much context it uses and which features in nearby vs. long-range context are important. Hence, the mismatch in training and test is a necessary part of experiment design, and all measured losses are upper bounds which would likely be lower, were the model also trained to handle such perturbations.

We use a standard LSTM language model, trained and finetuned using the Averaging SGD optimizer (Merity et al., 2018).[2] We also augment the model with a cache *only* for Section 6.2, in order to investigate why an external copy mechanism is helpful. A short description of the architecture and a detailed list of hyperparameters is listed in Appendix A, and we refer the reader to the original paper for additional details.

We analyze two datasets commonly used for language modeling, Penn Treebank (PTB) (Marcus et al., 1993; Mikolov et al., 2010) and Wikitext-2 (Wiki) (Merity et al., 2017). PTB consists of Wall Street Journal news articles with 0.9M tokens for training and a 10K vocabulary. Wiki is a larger and more diverse dataset, containing Wikipedia articles across many topics with 2.1M tokens for training and a 33K vocabulary. Additional dataset statistics are provided in Ta-

[1]Code for our experiments available at `https://github.com/urvashik/lm-context-analysis`

[2]Public release of their code at `https://github.com/salesforce/awd-lstm-lm`

ble 1.

In this paper, we present results only on the dev sets, in order to avoid revealing details about the test sets. However, we have confirmed that all results are consistent with those on the test sets. In addition, for all experiments we report averaged results from three models trained with different random seeds. Some of the figures provided contain trends from only one of the two datasets and the corresponding figures for the other dataset are provided in Appendix B.

4 How much context is used?

LSTMs are designed to capture long-range dependencies in sequences (Hochreiter and Schmidhuber, 1997). In practice, LSTM language models are provided an infinite amount of prior context, which is as long as the test sequence goes. However, it is unclear how much of this history has a direct impact on model performance. In this section, we investigate how many tokens of context achieve a similar loss (or 1-2% difference in model perplexity) to providing the model infinite context. We consider this the *effective context size*.

LSTM language models have an effective context size of about 200 tokens on average. We determine the effective context size by varying the number of tokens fed to the model. In particular, at test time, we feed the model the most recent n tokens:

$$\delta_{\text{truncate}}(w_{t-1}, \ldots, w_1) = (w_{t-1}, \ldots, w_{t-n}), \quad (1)$$

where $n > 0$ and all tokens farther away from the target w_t are dropped.[3] We compare the dev loss (NLL) from truncated context, to that of the infinite-context setting where all previous words are fed to the model. The resulting increase in loss indicates how important the dropped tokens are for the model.

Figure 1a shows that the difference in dev loss, between truncated- and infinite-context variants of the test setting, gradually diminishes as we increase n from 5 tokens to 1000 tokens. In particular, we only see a 1% increase in perplexity as we move beyond a context of 150 tokens on PTB and 250 tokens on Wiki. Hence, we provide empirical evidence to show that LSTM language models do, in fact, model long-range dependencies, without help from extra context vectors or caches.

[3]Words at the beginning of the test sequence with fewer than n tokens in the context are ignored for loss computation.

Changing hyperparameters does not change the effective context size. NLM performance has been shown to be sensitive to hyperparameters such as the dropout rate and model size (Melis et al., 2018). To investigate if these hyperparameters affect the effective context size as well, we train separate models by varying the following hyperparameters one at a time: (1) number of timesteps for truncated back-propogation (2) dropout rate, (3) model size (hidden state size, number of layers, and word embedding size). In Figure 1b, we show that while different hyperparameter settings result in different perplexities in the infinite-context setting, the trend of how perplexity changes as we reduce the context size remains the same.

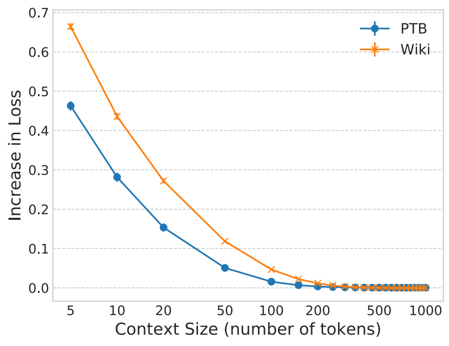
4.1 Do different types of words need different amounts of context?

The effective context size determined in the previous section is aggregated over the entire corpus, which ignores the type of the upcoming word. Boyd-Graber and Blei (2009) have previously investigated the differences in context used by different types of words and found that function words rely on less context than content words. We investigate whether the effective context size varies across different types of words, by categorizing them based on either frequency or parts-of-speech. Specifically, we vary the number of context tokens in the same way as the previous section, and aggregate loss over words within each class separately.

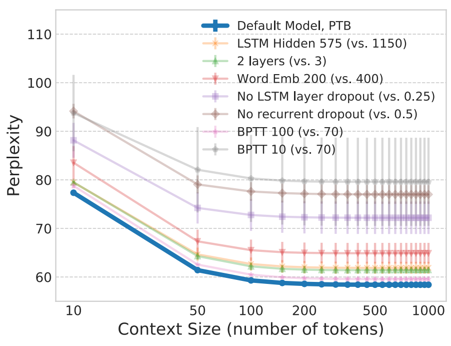
Infrequent words need more context than frequent words. We categorize words that appear at least 800 times in the training set as *frequent*, and the rest as *infrequent*. Figure 1c shows that the loss of frequent words is insensitive to missing context beyond the 50 most recent tokens, which holds across the two datasets. Infrequent words, on the other hand, require more than 200 tokens.

Content words need more context than function words. Given the parts-of-speech of each word, we define *content words* as nouns, verbs and adjectives, and *function words* as prepositions and determiners.[4] Figure 1d shows that the loss of nouns and verbs is affected by distant context, whereas when the target word is a determiner, the model only relies on words within the last 10 tokens.

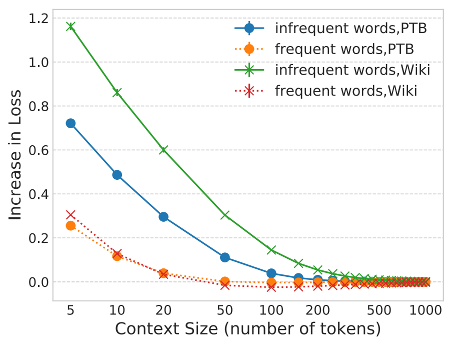
[4]We obtain part-of-speech tags using Stanford CoreNLP (Manning et al., 2014).



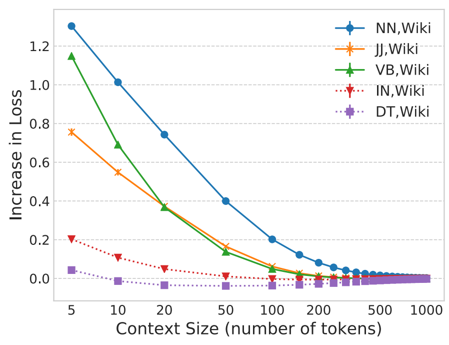
(a) Varying context size.



(b) Changing model hyperparameters.



(c) Frequent vs. infrequent words.



(d) Different parts-of-speech.

Figure 1: Effects of varying the number of tokens provided in the context, as compared to the same model provided with infinite context. Increase in loss represents an absolute increase in NLL over the entire corpus, due to restricted context. All curves are averaged over three random seeds, and error bars represent the standard deviation. **(a)** The model has an effective context size of 150 on PTB and 250 on Wiki. **(b)** Changing model hyperparameters does not change the context usage trend, but does change model performance. We report perplexities to highlight the consistent trend. **(c)** Infrequent words need more context than frequent words. **(d)** Content words need more context than function words.

Discussion. Overall, we find that the model's effective context size is dynamic. It depends on the target word, which is consistent with what we know about language, e.g., determiners require less context than nouns (Boyd-Graber and Blei, 2009). In addition, these findings are consistent with those previously reported for different language models and datasets (Hill et al., 2016; Wang and Cho, 2016).

5 Nearby vs. long-range context

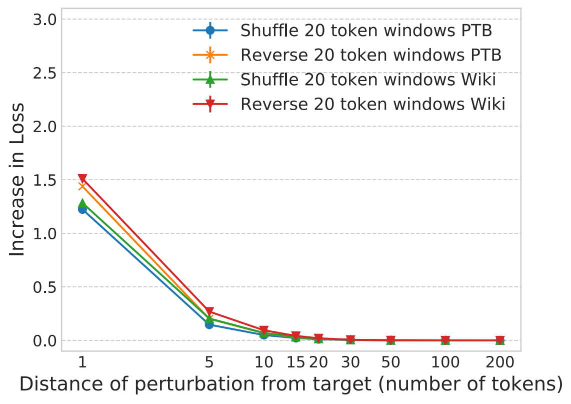
An effective context size of 200 tokens allows for representing linguistic information at many levels of abstraction, such as words, sentences, topics, etc. In this section, we investigate the importance of contextual information such as word order and word identity. Unlike prior work that studies LSTM embeddings at the sentence level, we look at both nearby and faraway context, and analyze how the language model treats contextual information presented in different regions of the context.

5.1 Does word order matter?

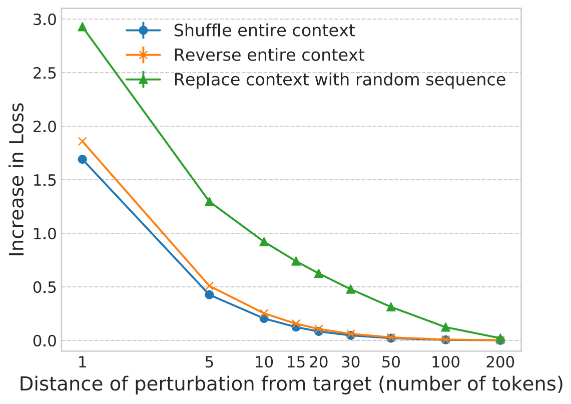
Adi et al. (2017) have shown that LSTMs are aware of word order within a sentence. We investigate whether LSTM language models are sensitive to word order within a larger context window. To determine the range in which word order affects model performance, we permute substrings in the context to observe their effect on dev loss compared to the unperturbed baseline. In particular, we perturb the context as follows,

$$\delta_{\text{permute}}(w_{t-1}, \ldots, w_{t-n}) = (w_{t-1}, .., \rho(w_{t-s_1-1}, .., w_{t-s_2}), .., w_{t-n}) \quad (2)$$

where $\rho \in \{\text{shuffle}, \text{reverse}\}$ and $(s_1, s_2]$ denotes the range of the substring to be permuted. We refer to this substring as the *permutable span*. For



(a) Perturb order locally, within 20 tokens of each point.



(b) Perturb global order, i.e. all tokens in the context before a given point, in Wiki.

Figure 2: Effects of shuffling and reversing the order of words in 300 tokens of context, relative to an unperturbed baseline. All curves are averages from three random seeds, where error bars represent the standard deviation. **(a)** Changing the order of words within a 20-token window has negligible effect on the loss after the first 20 tokens. **(b)** Changing the global order of words within the context does not affect loss beyond 50 tokens.

the following analysis, we distinguish *local word order*, within 20-token permutable spans which are the length of an average sentence, from *global word order*, which extends beyond local spans to include all the farthest tokens in the history. We consider selecting permutable spans within a context of $n = 300$ tokens, which is greater than the effective context size.

Local word order only matters for the most recent 20 tokens. We can locate the region of context beyond which the local word order has no relevance, by permuting word order locally at various points within the context. We accomplish this by varying s_1 and setting $s_2 = s_1 + 20$. Figure 2a shows that local word order matters very much within the most recent 20 tokens, and far less beyond that.

Global order of words only matters for the most recent 50 tokens. Similar to the local word order experiment, we locate the point beyond which the general location of words within the context is irrelevant, by permuting global word order. We achieve this by varying s_1 and fixing $s_2 = n$. Figure 2b demonstrates that after 50 tokens, shuffling or reversing the remaining words in the context has no effect on the model performance.

In order to determine whether this is due to insensitivity to word order or whether the language model is simply not sensitive to any changes in the long-range context, we further replace words in the permutable span with a randomly sampled sequence of the same length from the training set. The gap between the permutation and replacement curves in Figure 2b illustrates that the identity of words in the far away context is still relevant, and only the order of the words is not.

Discussion. These results suggest that word order matters only within the most recent sentence, beyond which the order of sentences matters for 2-3 sentences (determined by our experiments on global word order). After 50 tokens, word order has almost no effect, but the identity of those words is still relevant, suggesting a high-level, rough semantic representation for these faraway words. In light of these observations, we define 50 tokens as the boundary between nearby and long-range context, for the rest of this study. Next, we investigate the importance of different word types in the different regions of context.

5.2 Types of words and the region of context

Open-class or *content words* such as nouns, verbs, adjectives and adverbs, contribute more to the semantic context of natural language than *function words* such as determiners and prepositions. Given our observation that the language model represents long-range context as a rough semantic representation, a natural question to ask is how important are function words in the long-range

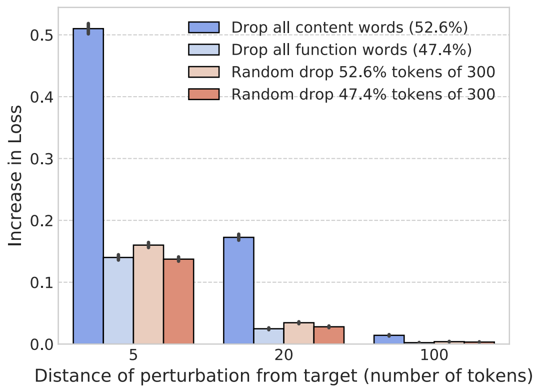


Figure 3: Effect of dropping content and function words from 300 tokens of context relative to an unperturbed baseline, on PTB. Error bars represent 95% confidence intervals. Dropping both content and function words 5 tokens away from the target results in a nontrivial increase in loss, whereas beyond 20 tokens, only content words are relevant.

context? Below, we study the effect of these two classes of words on the model's performance. Function words are defined as all words that are not nouns, verbs, adjectives or adverbs.

Content words matter more than function words. To study the effect of content and function words on model perplexity, we drop them from different regions of the context and compare the resulting change in loss. Specifically, we perturb the context as follows,

$$\delta_{\text{drop}}(w_{t-1}, \ldots, w_{t-n}) = (w_{t-1}, .., w_{t-s_1}, f_{\text{pos}}(y, (w_{t-s_1-1}, .., w_{t-n}))) \tag{3}$$

where $f_{\text{pos}}(y, \text{span})$ is a function that drops all words with POS tag y in a given span. s_1 denotes the starting offset of the perturbed subsequence. For these experiments, we set $s_1 \in \{5, 20, 100\}$. On average, there are slightly more content words than function words in any given text. As shown in Section 4, dropping more words results in higher loss. To eliminate the effect of dropping different fractions of words, for each experiment where we drop a specific word type, we add a control experiment where the same number of tokens are sampled randomly from the context, and dropped.

Figure 3 shows that dropping content words as close as 5 tokens from the target word increases model perplexity by about 65%, whereas dropping the same proportion of tokens at random, results in a much smaller 17% increase. Dropping all function words, on the other hand, is not very different from dropping the same proportion of words at random, but still increases loss by about 15%. This suggests that within the most recent sentence, content words are extremely important but function words are also relevant since they help maintain grammaticality and syntactic structure. On the other hand, beyond a sentence, only content words have a sizeable influence on model performance.

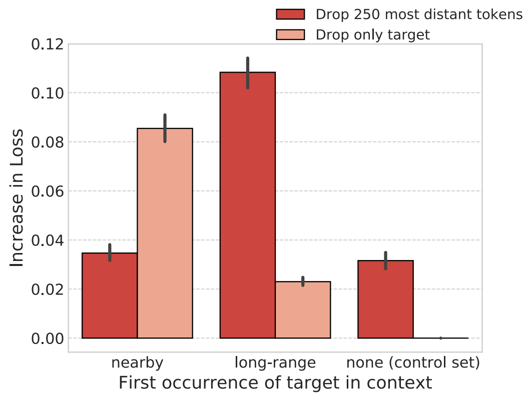
6 To cache or not to cache?

As shown in Section 5.1, LSTM language models use a high-level, rough semantic representation for long-range context, suggesting that they might not be using information from any specific words located far away. Adi et al. (2017) have also shown that while LSTMs are aware of which words appear in their context, this awareness degrades with increasing length of the sequence. However, the success of copy mechanisms such as attention and caching (Bahdanau et al., 2015; Hill et al., 2016; Merity et al., 2017; Grave et al., 2017a,b) suggests that information in the distant context is very useful. Given this fact, can LSTMs copy any words from context without relying on external copy mechanisms? Do they copy words from nearby and long-range context equally? How does the caching model help? In this section, we investigate these questions by studying how LSTMs copy words from different regions of context. More specifically, we look at two regions of context, nearby (within 50 most recent tokens) and long-range (beyond 50 tokens), and study three categories of target words: those that can be copied from nearby context (C_{near}), those that can *only* be copied from long-range context (C_{far}), and those that cannot be copied at all given a limited context (C_{none}).

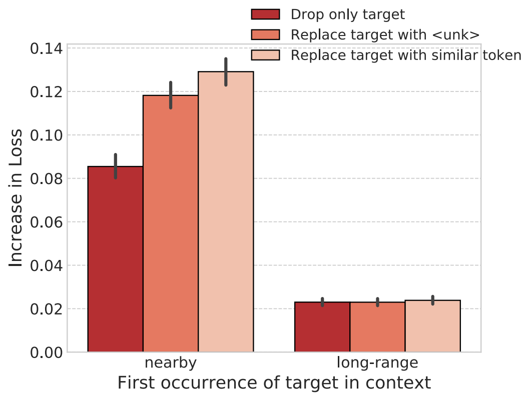
6.1 Can LSTMs copy words without caches?

Even without a cache, LSTMs often regenerate words that have already appeared in prior context. We investigate how much the model relies on the previous occurrences of the upcoming target word, by analyzing the change in loss after dropping and replacing this target word in the context.

LSTMs can regenerate words seen in nearby context. In order to demonstrate the usefulness



(a) Dropping tokens



(b) Perturbing occurrences of target word in context.

Figure 4: Effects of perturbing the target word in the context compared to dropping long-range context altogether, on PTB. Error bars represent 95% confidence intervals. **(a)** Words that can only be copied from long-range context are more sensitive to dropping all the distant words than to dropping the target. For words that can be copied from nearby context, dropping only the target has a much larger effect on loss compared to dropping the long-range context. **(b)** Replacing the target word with other tokens from vocabulary hurts more than dropping it from the context, for words that can be copied from nearby context, but has no effect on words that can only be copied from far away.

of target word occurrences in context, we experiment with dropping all the distant context versus dropping only occurrences of the target word from the context. In particular, we compare removing all tokens after the 50 most recent tokens, (Equation 1 with $n = 50$), versus removing only the target word, in context of size $n = 300$:

$$\delta_{\text{drop}}(w_{t-1}, \ldots, w_{t-n}) = f_{\text{word}}(w_t, (w_{t-1}, \ldots, w_{t-n})), \tag{4}$$

where $f_{\text{word}}(w, \text{span})$ drops words equal to w in a given span. We compare applying both perturbations to a baseline model with unperturbed context restricted to $n = 300$. We also include the target words that never appear in the context (C_{none}) as a control set for this experiment.

The results show that LSTMs rely on the rough semantic representation of the faraway context to generate C_{far}, but direclty copy C_{near} from the nearby context. In Figure 4a, the long-range context bars show that for words that can only be copied from long-range context (C_{far}), removing all distant context is far more disruptive than removing only occurrences of the target word (12% and 2% increase in perplexity, respectively). This suggests that the model relies more on the rough semantic representation of faraway context to predict these C_{far} tokens, rather than directly copying them from the distant context. On the other hand, for words that can be copied from nearby context (C_{near}), removing all long-range context has a smaller effect (about 3.5% increase in perplexity) as seen in Figure 4a, compared to removing the target word which increases perplexity by almost 9%. This suggests that these C_{near} tokens are more often copied from nearby context, than inferred from information found in the rough semantic representation of long-range context.

However, is it possible that dropping the target tokens altogether, hurts the model too much by adversely affecting grammaticality of the context? We test this theory by replacing target words in the context with other words from the vocabulary. This perturbation is similar to Equation 4, except instead of dropping the token, we replace it with a different one. In particular, we experiment with replacing the target with `<unk>`, to see if having the generic word is better than not having any word. We also replace it with a word that has the same part-of-speech tag and a similar frequency in the dataset, to observe how much this change confuses the model. Figure 4b shows that replacing the target with other words results in up to a 14% increase in perplexity for C_{near}, which suggests that the replacement token seems to confuse the model far more than when the token is simply dropped. However, the words that rely on the long-range context, C_{far}, are largely unaffected by these changes, which confirms our conclusion from dropping the target tokens: C_{far}

words are predicted from the rough representation of faraway context instead of specific occurrences of certain words.

6.2 How does the cache help?

If LSTMs can already regenerate words from nearby context, how are copy mechanisms helping the model? We answer this question by analyzing how the neural cache model (Grave et al., 2017b) helps with improving model performance. The cache records the hidden state h_t at each timestep t, and computes a cache distribution over the words in the history as follows:

$$P_{\text{cache}}(w_t|w_{t-1},\dots,w_1;h_t,\dots,h_1) \propto \sum_{i=1}^{t-1} \mathbb{1}[w_i = w_t] \exp(\theta h_i^T h_t), \tag{5}$$

where θ controls the flatness of the distribution. This cache distribution is then interpolated with the model's output distribution over the vocabulary. Consequently, certain words from the history are upweighted, encouraging the model to copy them.

Caches help words that can be copied from long-range context the most. In order to study the effectiveness of the cache for the three classes of words ($C_{\text{near}}, C_{\text{far}}, C_{\text{none}}$), we evaluate an LSTM language model with and without a cache, and measure the difference in perplexity for these words. In both settings, the model is provided all prior context (not just 300 tokens) in order to replicate the Grave et al. (2017b) setup. The amount of history recorded, known as the cache size, is a hyperparameter set to 500 past timesteps for PTB and 3,875 for Wiki, both values very similar to the average document lengths in the respective datasets.

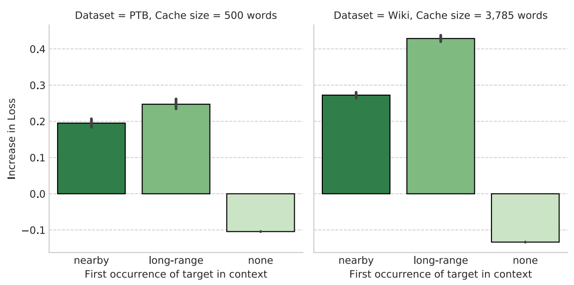

Figure 7: Model performance relative to using a cache. Error bars represent 95% confidence intervals. Words that can only be copied from the distant context benefit the most from using a cache.

We find that the cache helps words that can only be copied from long-range context (C_{far}) more than words that can be copied from nearby (C_{near}). This is illustrated by Figure 7 where without caching, C_{near} words see a 22% increase in perplexity for PTB, and a 32% increase for Wiki, whereas C_{far} see a 28% increase in perplexity for PTB, and a whopping 53% increase for Wiki. Thus, the cache is, in a sense, complementary to the standard model, since it especially helps regenerate words from the long-range context where the latter falls short.

However, the cache also hurts about 36% of the words in PTB and 20% in Wiki, which are words that cannot be copied from context (C_{none}), as illustrated by bars for "none" in Figure 7. We also provide some case studies showing success (Fig. 5) and failure (Fig. 6) modes for the cache. We find that for the successful case, the cache distribution is concentrated on a single word that it wants to copy. However, when the target is not present in the history, the cache distribution is more flat, illustrating the model's confusion, shown in Figure 6. This suggests that the neural cache model might benefit from having the option to ignore the cache when it cannot make a confident choice.

7 Discussion

The findings presented in this paper provide a great deal of insight into how LSTMs model context. This information can prove extremely useful for improving language models. For instance, the discovery that some word types are more important than others can help refine word dropout strategies by making them adaptive to the different word types. Results on the cache also show that we can further improve performance by allowing the model to ignore the cache distribution when it is extremely uncertain, such as in Figure 6. Differences in nearby vs. long-range context suggest that memory models, which feed explicit context representations to the LSTM (Ghosh et al., 2016; Lau et al., 2017), could benefit from representations that specifically capture information orthogonal to that modeled by the LSTM.

In addition, the empirical methods used in this study are model-agnostic and can generalize to models other than the standard LSTM. This opens the path to generating a stronger understanding of model classes beyond test set perplexities, by comparing them across additional axes of information such as how much context they use on average, or how robust they are to shuffled contexts.

Given the empirical nature of this study and the fact that the model and data are tightly coupled, separating model behavior from language characteristics, has proved challenging. More specifically, a number of confounding factors such as vocabulary size, dataset size etc. make this separation difficult. In an attempt to address this, we have chosen PTB and Wiki - two standard language modeling datasets which are diverse in content (news vs. factual articles) and writing style, and are structured differently (eg: Wiki articles are 4-6x longer on average and contain extra information such as titles and paragraph/section markers). Making the data sources diverse in nature, has provided the opportunity to somewhat isolate effects of the model, while ensuring consistency in results. An interesting extension to further study this separation would lie in experimenting with different model classes and even different languages.

Recently, Chelba et al. (2017), in proposing a new model, showed that on PTB, an LSTM language model with 13 tokens of context is similar to the infinite-context LSTM performance, with close to an 8% [5] increase in perplexity. This is compared to a 25% increase at 13 tokens of context in our setup. We believe this difference is attributed to the fact that their model was trained with restricted context and a different error propagation scheme, while ours is not. Further investigation would be an interesting direction for future work.

8 Conclusion

In this analytic study, we have empirically shown that a standard LSTM language model can effectively use about 200 tokens of context on two benchmark datasets, regardless of hyperparameter settings such as model size. It is sensitive to word order in the nearby context, but less so in the long-range context. In addition, the model is able to regenerate words from nearby context, but heavily relies on caches to copy words from far away. These findings not only help us better understand these models but also suggest ways for improving them, as discussed in Section 7. While observations in this paper are reported at the token level, deeper understanding of sentence-level interactions warrants further investigation, which we leave to future work.

Abstract

Recurrent and convolutional neural networks comprise two distinct families of models that have proven to be useful for encoding natural language utterances. In this paper we present SoPa, a new model that aims to bridge these two approaches. SoPa combines neural representation learning with weighted finite-state automata (WFSAs) to learn a soft version of traditional surface patterns. We show that SoPa is an extension of a one-layer CNN, and that such CNNs are equivalent to a restricted version of SoPa, and accordingly, to a restricted form of WFSA. Empirically, on three text classification tasks, SoPa is comparable or better than both a BiLSTM (RNN) baseline and a CNN baseline, and is particularly useful in small data settings.

1 Introduction

Recurrent neural networks (RNNs; Elman, 1990) and convolutional neural networks (CNNs; LeCun, 1998) are two of the most useful text representation learners in NLP (Goldberg, 2016). These methods are generally considered to be quite different: the former encodes an arbitrarily long sequence of text, and is highly expressive (Siegelmann and Sontag, 1995). The latter is more local, encoding fixed length windows, and accordingly less expressive. In this paper, we seek to bridge the gap between RNNs and CNNs, presenting **SoPa** (for **So**ft **Pa**tterns), a model that lies in between them.

SoPa is a neural version of a weighted finite-state automaton (WFSA), with a restricted set of transitions. Linguistically, SoPa is appealing as it

[*]The first two authors contributed equally.

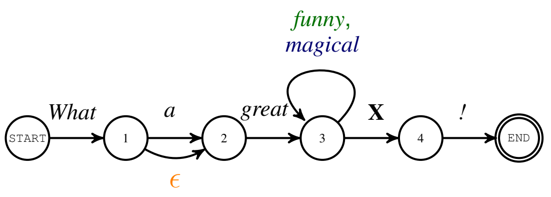

Figure 1: A representation of a surface pattern as a six-state automaton. **Self-loops** allow for repeatedly inserting words (e.g., "*funny*"). **ϵ-transitions** allow for dropping words (e.g., "*a*").

is able to capture a soft notion of surface patterns (e.g., *"what a great X !"*; Hearst, 1992), where some words may be dropped, inserted, or replaced with similar words (see Figure 1). From a modeling perspective, SoPa is interesting because WFSAs are well-studied and come with efficient and flexible inference algorithms (Mohri, 1997; Eisner, 2002) that SoPa can take advantage of.

SoPa defines a set of soft patterns of different lengths, with each pattern represented as a WFSA (Section 3). While the number and lengths of the patterns are hyperparameters, the patterns themselves are learned end-to-end. SoPa then represents a document with a vector that is the aggregate of the scores computed by matching each of the patterns with each span in the document. Because SoPa defines a hidden state that depends on the input token and the previous state, it can be thought of as a simple type of RNN.

We show that SoPa is an extension of a one-layer CNN (Section 4). Accordingly, one-layer CNNs can be viewed as a collection of linear-chain WFSAs, each of which can only match fixed-length spans, while our extension allows matches of flexible-length. As a simple type of RNN that is more expressive than a CNN, SoPa helps to link CNNs and RNNs.

To test the utility of SoPa, we experiment with three text classification tasks (Section 5). We compare against four baselines, including both a bidirectional LSTM and a CNN. Our model performs on par with or better than all baselines on all tasks (Section 6). Moreover, when training with smaller datasets, SoPa is particularly useful, outperforming all models by substantial margins. Finally, building on the connections discovered in this paper, we offer a new, simple method to interpret SoPa (Section 7). This method applies equally well to CNNs. We release our code at `https://github.com/Noahs-ARK/soft_patterns`.

2 Background

Surface patterns. Patterns (Hearst, 1992) are particularly useful tool in NLP (Lin et al., 2003; Etzioni et al., 2005; Schwartz et al., 2015). The most basic definition of a pattern is a sequence of words and wildcards (e.g., "**X** is a **Y**"), which can either be manually defined or extracted from a corpus using cooccurrence statistics. Patterns can then be matched against a specific text span by replacing wildcards with concrete words.

Davidov et al. (2010) introduced a *flexible* notion of patterns, which supports partial matching of the pattern with a given text by skipping some of the words in the pattern, or introducing new words. In their framework, when a sequence of text partially matches a pattern, hard-coded partial scores are assigned to the pattern match. Here, we represent patterns as WFSAs with neural weights, and support these partial matches in a soft manner.

WFSAs. We review weighted finite-state automata with ϵ-transitions before we move on to our special case in Section 3. A WFSA-ϵ with d states over a vocabulary V is formally defined as a tuple $F = \langle \pi, \mathbf{T}, \eta \rangle$, where $\pi \in \mathbb{R}^d$ is an initial weight vector, $\mathbf{T} : (V \cup \{\epsilon\}) \to \mathbb{R}^{d \times d}$ is a transition weight function, and $\eta \in \mathbb{R}^d$ is a final weight vector. Given a sequence of words in the vocabulary $\boldsymbol{x} = \langle x_1, \ldots, x_n \rangle$, the Forward algorithm (Baum and Petrie, 1966) scores $\boldsymbol{x}$ with respect to F. Without ϵ-transitions, Forward can be written as a series of matrix multiplications:

$$p'_{\text{span}}(\boldsymbol{x}) = \pi^\top \left(\prod_{i=1}^{n} \mathbf{T}(x_i) \right) \eta \qquad (1)$$

ϵ-transitions are followed without consuming a word, so Equation 1 must be updated to reflect the possibility of following any number (zero or more) of ϵ-transitions in between consuming each word:

$$p_{\text{span}}(\boldsymbol{x}) = \pi^\top \mathbf{T}(\epsilon)^* \left(\prod_{i=1}^{n} \mathbf{T}(x_i) \mathbf{T}(\epsilon)^* \right) \eta \qquad (2)$$

where * is matrix asteration: $\mathbf{A}^* := \sum_{j=0}^{\infty} \mathbf{A}^j$. In our experiments we use a first-order approximation, $\mathbf{A}^* \approx \mathbf{I} + \mathbf{A}$, which corresponds to allowing zero or one ϵ-transition at a time. When the FSA F is probabilistic, the result of the Forward algorithm can be interpreted as the marginal probability of all paths through F while consuming $\boldsymbol{x}$ (hence the symbol "p").

The Forward algorithm can be generalized to any semiring (Eisner, 2002), a fact that we make use of in our experiments and analysis.[1] The vanilla version of Forward uses the sum-product semiring: $\oplus$ is addition, $\otimes$ is multiplication. A special case of Forward is the Viterbi algorithm (Viterbi, 1967), which sets $\oplus$ to the $\max$ operator. Viterbi finds the *highest scoring* path through F while consuming $\boldsymbol{x}$. Both Forward and Viterbi have runtime $O(d^3 + d^2 n)$, requiring just a single linear pass through the phrase. Using first-order approximate asteration, this runtime drops to $O(d^2 n)$.[2]

Finally, we note that Forward scores are for *exact matches*—the entire phrase must be consumed. We show in Section 3.2 how phrase-level scores can be summarized into a document-level score.

3 SoPa: A Weighted Finite-State Automaton RNN

We introduce SoPa, a WFSA-based RNN, which is designed to represent text as collection of surface pattern occurrences. We start by showing how a single pattern can be represented as a WFSA-ϵ (Section 3.1). Then we describe how to score a complete document using a pattern (Section 3.2), and how multiple patterns can be used to encode a document (Section 3.3). Finally, we show that SoPa can be seen as a simple variant of an RNN (Section 3.4).

[1]The semiring parsing view (Goodman, 1999) has produced unexpected connections in the past (Eisner, 2016). We experiment with max-product and max-sum semirings, but note that our model could be easily updated to use any semiring.

[2]In our case, we also use a sparse transition matrix (Section 3.1), which further reduces our runtime to $O(dn)$.

3.1 Patterns as WFSAs

We describe how a pattern can be represented as a WFSA-ϵ. We first assume a single pattern. A pattern *is* a WFSA-ϵ, but we impose hard constraints on its shape, and its transition weights are given by differentiable functions that have the power to capture concrete words, wildcards, and everything in between. Our model is designed to behave similarly to flexible hard patterns (see Section 2), but to be learnable directly and "end-to-end" through backpropagation. Importantly, it will still be interpretable as simple, almost linear-chain, WFSA-ϵ.

Each pattern has a sequence of d states (in our experiments we use patterns of varying lengths between 2 and 7). Each state i has exactly three possible outgoing transitions: a **self-loop**, which allows the pattern to consume a word without moving states, a **main path** transition to state $i+1$ which allows the pattern to consume one token and move forward one state, and an **ϵ-transition** to state $i+1$, which allows the pattern to move forward one state without consuming a token. All other transitions are given score 0. When processing a sequence of text with a pattern p, we start with a special `START` state, and only move forward (or stay put), until we reach the special `END` state.[3] A pattern with d states will tend to match token spans of length $d-1$ (but possibly shorter spans due to ϵ-transitions, or longer spans due to self-loops). See Figure 1 for an illustration.

Our transition function, $\mathbf{T}$, is a parameterized function that returns a $d \times d$ matrix. For a word x:

$$[\mathbf{T}(x)]_{i,j} = \begin{cases} E(\mathbf{u}_i \cdot \mathbf{v}_x + a_i), & \text{if } j = i \text{ \textit{(self-loop)}} \\ E(\mathbf{w}_i \cdot \mathbf{v}_x + b_i), & \text{if } j = i+1 \\ 0, & \text{otherwise,} \end{cases} \tag{3}$$

where $\mathbf{u}_i$ and $\mathbf{w}_i$ are vectors of parameters, a_i and b_i are scalar parameters, $\mathbf{v}_x$ is a fixed pre-trained word vector for x,[4] and E is an encoding function, typically the identity function or sigmoid. ϵ-transitions are also parameterized, but don't consume a token and depend only on the current state:

$$[\mathbf{T}(\epsilon)]_{i,j} = \begin{cases} E(c_i), & \text{if } j = i+1 \\ 0, & \text{otherwise,} \end{cases} \tag{4}$$

where c_i is a scalar parameter.[5] As we have only three non-zero diagonals in total, the matrix multiplications in Equation 2 can be implemented using vector operations, and the overall runtimes of Forward and Viterbi are reduced to $O(dn)$.[6]

Words vs. wildcards. Traditional *hard* patterns distinguish between words and wildcards. Our model does not explicitly capture the notion of either, but the transition weight function can be interpreted in those terms. Each transition is a logistic regression over the next word vector $\mathbf{v}_x$. For example, for a main path out of state i, $\mathbf{T}$ has two parameters, $\mathbf{w}_i$ and b_i. If $\mathbf{w}_i$ has large magnitude and is close to the word vector for some word y (e.g., $\mathbf{w}_i \approx 100\mathbf{v}_y$), and b_i is a large negative bias (e.g., $b_i \approx -100$), then the transition is essentially matching the specific word y. Whereas if $\mathbf{w}_i$ has small magnitude ($\mathbf{w}_i \approx \mathbf{0}$) and b_i is a large positive bias (e.g., $b_i \approx 100$), then the transition is ignoring the current token and matching a wildcard.[7] The transition could also be something in between, for instance by focusing on specific dimensions of a word's meaning encoded in the vector, such as POS or semantic features like animacy or concreteness (Rubinstein et al., 2015; Tsvetkov et al., 2015).

3.2 Scoring Documents

So far we described how to calculate how well a pattern matches a token span exactly (consuming the whole span). To score a complete document, we prefer a score that aggregates over all matches on subspans of the document (similar to "search" instead of "match" in regular expression parlance). We still assume a single pattern.

Either the Forward algorithm can be used to calculate the expected count of the pattern in the document, $\sum_{1 \le i \le j \le n} p_{\text{span}}(\boldsymbol{x}_{i:j})$, or Viterbi to calculate $s_{\text{doc}}(\boldsymbol{x}) = \max_{1 \le i \le j \le n} s_{\text{span}}(\boldsymbol{x}_{i:j})$, the score of the highest-scoring match. In short documents, we expect patterns to typically occur at most once, so in our experiments we choose the Viterbi algorithm, i.e., the max-product semiring.

Implementation details. We give the specific recurrences we use to score documents in a single

[3] To ensure that we start in the `START` state and end in the `END` state, we fix $\pi = [1, 0, \ldots, 0]$ and $\eta = [0, \ldots, 0, 1]$.

[4] We use GloVe 300d 840B (Pennington et al., 2014).

[5] Adding ϵ-transitions to WFSAs does not increase their expressive power, and in fact slightly complicates the Forward equations. We use them as they require fewer parameters, and make the modeling connection between (hard) flexible patterns and our (soft) patterns more direct and intuitive.

[6] Our implementation is optimized to run on GPUs, so the observed runtime is even *sublinear* in d.

[7] A large bias increases the eagerness to match *any* word.

pass with this model. We define:

$$[\mathrm{maxmul}(\mathbf{A}, \mathbf{B})]_{i,j} = \max_k A_{i,k} B_{k,j}. \quad (5)$$

We also define the following for taking zero or one ϵ-transitions:

$$\mathrm{eps}\,(\mathbf{h}) = \mathrm{maxmul}\,(\mathbf{h}, \max(\mathbf{I}, \mathbf{T}(\epsilon))) \quad (6)$$

where max is element-wise max. We maintain a row vector $\mathbf{h}_t$ at each token:[8]

$$\mathbf{h}_0 = \mathrm{eps}(\pi^\top), \quad (7a)$$
$$\mathbf{h}_{t+1} = \max\left(\mathrm{eps}(\mathrm{maxmul}\,(\mathbf{h}_t, \mathbf{T}(x_{t+1}))), \mathbf{h}_0\right), \quad (7b)$$

and then extract and aggregate END state values:

$$s_t = \mathrm{maxmul}\,(\mathbf{h}_t, \eta), \quad (8a)$$
$$s_{\mathrm{doc}} = \max_{1 \leq t \leq n} s_t. \quad (8b)$$

$[\mathbf{h}_t]_i$ represents the score of the best path through the pattern that ends in state i after consuming t tokens. By including $\mathbf{h}_0$ in Equation 7b, we are accounting for spans that start at time $t+1$. s_t is the maximum of the exact match scores for all spans ending at token t. And s_{doc} is the maximum score of any subspan in the document.

3.3 Aggregating Multiple Patterns

We describe how k patterns are aggregated to score a document. These k patterns give k different s_{doc} scores for the document, which are stacked into a vector $\mathbf{z} \in \mathbb{R}^k$ and constitute the final document representation of SoPa. This vector representation can be viewed as a feature vector. In this paper, we feed it into a multilayer perceptron (MLP), culminating in a softmax to give a probability distribution over document labels. We minimize cross-entropy, allowing the SoPa and MLP parameters to be learned end-to-end.

SoPa uses a total of $(2e+3)dk$ parameters, where e is the word embedding dimension, d is the number of states and k is the number of patterns. For comparison, an LSTM with a hidden dimension of h has $4((e+1)h+h^2)$. In Section 6 we show that SoPa consistently uses fewer parameters than a BiLSTM baseline to achieve its best result.

3.4 SoPa as an RNN

SoPa can be considered an RNN. As shown in Section 3.2, a single pattern with d states has a hidden state vector of size d. Stacking the k hidden state vectors of k patterns into one vector of size $k \times d$ can be thought of as the hidden state of our model. This hidden state is, like in any other RNN, dependent of the input and the previous state. Using self-loops, the hidden state at time point i can in theory depend on the entire history of tokens up to x_i (see Figure 2 for illustration). We do want to discourage the model from following too many self-loops, only doing so if it results in a better fit with the remainder of the pattern. To do this we use the sigmoid function as our encoding function E (see Equation 3), which means that all transitions have scores strictly less than 1. This works to keep pattern matches close to their intended length. Using other encoders, such as the identity function, can result in different dynamics, potentially encouraging rather than discouraging self-loops.

Although even single-layer RNNs are Turing complete (Siegelmann and Sontag, 1995), SoPa's expressive power depends on the semiring. When a WFSA is thought of as a function from finite sequences of tokens to semiring values, it is restricted to the class of functions known as **rational series** (Schützenberger, 1961; Droste and Gastin, 1999; Sakarovitch, 2009).[9] It is unclear how limiting this theoretical restriction is in practice, especially when SoPa is used as a component in a larger network. We defer the investigation of the exact computational properties of SoPa to future work. In the next section, we show that SoPa is an extension of a one-layer CNN, and hence more expressive.

4 SoPa as a CNN Extension

A convolutional neural network (**CNN**; LeCun, 1998) moves a fixed-size sliding window over the document, producing a vector representation for each window. These representations are then often summed, averaged, or max-pooled to produce a document-level representation (Kim, 2014; Yin and Schütze, 2015). In this section, we show that SoPa is an extension of one-layer, max-pooled CNNs.

To recover a CNN from a soft pattern with $d+1$ states, we first remove self-loops and ϵ-transitions,

[8]Here a row vector $\mathbf{h}$ of size n can also be viewed as a $1 \times n$ matrix.

[9]Rational series generalize recognizers of *regular languages*, which are the special case of the Boolean semiring.

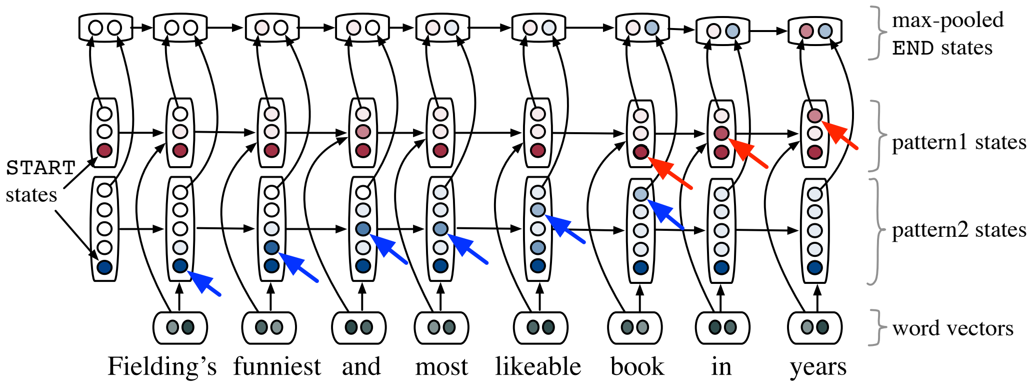

Figure 2: State activations of two patterns as they score a document. pattern1 (length three) matches on *"in years"*. pattern2 (length five) matches on *"funniest and most likeable book"*, using a self-loop to consume the token *"most"*. Active states in the best match are marked with arrow cursors.

retaining only the main path transitions. We also use the identity function as our encoder E (Equation 3), and use the max-sum semiring. With only main path transitions, the network will not match any span that is not exactly d tokens long. Using max-sum, spans of length d will be assigned the score:

$$s_{\text{span}}(\boldsymbol{x}_{i:i+d}) = \sum_{j=0}^{d-1} \mathbf{w}_j \cdot \mathbf{v}_{x_{i+j}} + b_j, \tag{9a}$$

$$= \mathbf{w}_{0:d} \cdot \mathbf{v}_{x_{i:i+d}} + \sum_{j=0}^{d-1} b_j, \tag{9b}$$

where $\mathbf{w}_{0:d} = [\mathbf{w}_0^\top; \ldots; \mathbf{w}_{d-1}^\top]^\top$, $\mathbf{v}_{x_{i:i+d}} = [\mathbf{v}_{x_i}^\top; \ldots; \mathbf{v}_{x_{i+d-1}}^\top]^\top$. Rearranged this way, we recognize the span score as an affine transformation of the concatenated word vectors $\mathbf{v}_{x_{i:i+d}}$. If we use k patterns, then together their span scores correspond to a linear filter with window size d and output dimension k.[10] A single pattern's score for a document is:

$$s_{\text{doc}}(\boldsymbol{x}) = \max_{1 \le i \le n-d+1} s_{\text{span}}(\boldsymbol{x}_{i:i+d}). \tag{10}$$

The $\max$ in Equation 10 is calculated for each pattern independently, corresponding exactly to element-wise max-pooling of the CNN's output layer.

Based on the equivalence between this impoverished version of SoPa and CNNs, we conclude that one-layer CNNs are learning an even more restricted class of WFSAs (linear-chain WFSAs) that capture only fixed-length patterns.

One notable difference between SoPa and arbitrary CNNs is that in general CNNs can use any filter (like an MLP over $\mathbf{v}_{x_{i:i+d}}$, for example). In contrast, in order to efficiently pool over flexible-length spans, SoPa is restricted to operations that follow the semiring laws.[11]

As a model that is more flexible than a one-layer CNN, but (arguably) less expressive than many RNNs, SoPa lies somewhere on the continuum between these two approaches. Continuing to study the bridge between CNNs and RNNs is an exciting direction for future research.

5 Experiments

To evaluate SoPa, we apply it to text classification tasks. Below we describe our datasets and baselines. More details can be found in Appendix A.

Datasets. We experiment with three binary classification datasets.

- **SST**. The Stanford Sentiment Treebank (Socher et al., 2013)[12] contains roughly 10K movie reviews from Rotten Tomatoes,[13] labeled on a scale of 1–5. We consider the binary task, which considers 1 and 2 as negative, and 4 and 5 as positive (ignoring 3s). It is worth noting that this dataset also contains syntactic phrase level annotations, providing a sentiment label to parts of

[10] This variant of SoPa has d bias parameters, which correspond to only a single bias parameter in a CNN. The redundant biases may affect optimization but are an otherwise unimportant difference.

[11] The max-sum semiring corresponds to a linear filter with max-pooling. Other semirings could potentially model more interesting interactions, but we leave this to future work.

[12] `https://nlp.stanford.edu/sentiment/index.html`

[13] `http://www.rottentomatoes.com`

sentences. In order to experiment in a realistic setup, we only consider the complete sentences, and ignore syntactic annotations at train or test time. The number of training/development/test sentences in the dataset is 6,920/872/1,821.

- **Amazon**. The Amazon Review Corpus (McAuley and Leskovec, 2013)[14] contains electronics product reviews, a subset of a larger review dataset. Each document in the dataset contains a review and a summary. Following Yogatama et al. (2015), we only use the reviews part, focusing on positive and negative reviews. The number of training/development/test samples is 20K/5K/25K.
- **ROC**. The ROC story cloze task (Mostafazadeh et al., 2016) is a story understanding task.[15] The task is composed of four-sentence story prefixes, followed by two competing endings: one that makes the joint five-sentence story coherent, and another that makes it incoherent. Following Schwartz et al. (2017), we treat it as a style detection task: we treat all "right" endings as positive samples and all "wrong" ones as negative, and we ignore the story prefix. We split the development set into train and development (of sizes 3,366 and 374 sentences, respectively), and take the test set as-is (3,742 sentences).

Reduced training data. In order to test our model's ability to learn from small datasets, we also randomly sample 100, 500, 1,000 and 2,500 SST training instances and 100, 500, 1,000, 2,500, 5,000, and 10,000 Amazon training instances. Development and test sets remain the same.

Baselines. We compare to four baselines: a BiLSTM, a one-layer CNN, DAN (a simple alternative to RNNs) and a feature-based classifier trained with hard-pattern features.

- **BiLSTM.** Bidirectional LSTMs have been successfully used in the past for text classification tasks (Zhou et al., 2016). We learn a one-layer BiLSTM representation of the document, and feed the average of all hidden states to an MLP.
- **CNN**. CNNs are particularly useful for text classification (Kim, 2014). We train a one-layer CNN with max-pooling, and feed the resulting representation to an MLP.
- **DAN**. We learn a deep averaging network with word dropout (Iyyer et al., 2015), a simple but strong text-classification baseline.
- **Hard**. We train a logistic regression classifier with hard-pattern features. Following Tsur et al. (2010), we replace low frequency words with a special wildcard symbol. We learn sequences of 1–6 concrete words, where any number of wildcards can come between two adjacent words. We consider words occurring with frequency of at least 0.01% of our training set as concrete words, and words occurring in frequency 1% or less as wildcards.[16]

Number of patterns. SoPa requires specifying the number of patterns to be learned, and their lengths. Preliminary experiments showed that the model doesn't benefit from more than a few dozen patterns. We experiment with several configurations of patterns of different lengths, generally considering 0, 10 or 20 patterns of each pattern length between 2–7. The total number of patterns learned ranges between 30–70.[17]

6 Results

Table 1 shows our main experimental results. In two of the cases (SST and ROC), SoPa outperforms all models. On Amazon, SoPa performs within 0.3 points of CNN and BiLSTM, and outperforms the other two baselines. The table also shows the number of parameters used by each model for each task. Given enough data, models with more parameters should be expected to perform better. However, SoPa performs better or roughly the same as a BiLSTM, which has 3–6 times as many parameters.

Figure 3 shows a comparison of all models on the SST and Amazon datasets with varying training set sizes. SoPa is substantially outperforming all baselines, in particular BiLSTM, on small datasets (100 samples). This suggests that SoPa is better fit to learn from small datasets.

Ablation analysis. Table 1 also shows an ablation of the differences between SoPa and CNN: max-product semiring with sigmoid vs. max-sum semiring with identity, self-loops, and ϵ-transitions. The last line is equivalent to a CNN with

Table 2: Six patterns of different lengths learned by SoPa on SST. Each group represents a single pattern p, and shows the five phrases in the training data that have the highest score for p. Columns represent pattern states. Words marked with $_{SL}$ are self-loops. ϵ symbols indicate ϵ-transitions. All other words are from main path transitions.

multiple window sizes. Interestingly, the most notable difference between SoPa and CNN is the semiring and encoder function, while ϵ transitions and self-loops have little effect on performance.[18]

7 Interpretability

We turn to another key aspect of SoPa—its interpretability. We start by demonstrating how we interpret a single pattern, and then describe how to interpret the decisions made by downstream classifiers that rely on SoPa—in this case, a sentence classifier. Importantly, these visualization techniques are equally applicable to CNNs.

Interpreting a single pattern. In order to visualize a pattern, we compute the pattern matching scores with each phrase in our training dataset, and select the k phrases with the highest scores. Table 2 shows examples of six patterns learned using the best SoPa model on the SST dataset, as represented by their five highest scoring phrases in the training set. A few interesting trends can be observed from these examples. First, it seems our patterns encode semantically coherent expressions. A large portion of them correspond to sentiment (the five top examples in the table), but others capture different semantics, e.g., time expressions.

Second, it seems our patterns are relatively soft, and allow lexical flexibility. While some patterns do seem to fix specific words, e.g., "of" in the first example or "minutes" in the last one, even in those cases some of the top matching spans replace these words with other, similar words ("with" and "half-hour", respectively). Encouraging SoPa to have more concrete words, e.g., by jointly learning the word vectors, might make SoPa useful in other contexts, particularly as a decoder. We defer this direction to future work.

Finally, SoPa makes limited but non-negligible use of self-loops and epsilon steps. Interestingly, the second example shows that one of the pat-

Table 3: Documents from the SST training data. Phrases with the largest contribution toward a positive sentiment classification are in **bold green**, and the most negative phrases are in *italic orange*.

terns had an ϵ-transition at the same place in every phrase. This demonstrates a different function of ϵ-transitions than originally designed—they allow a pattern to effectively shorten itself, by learning a high ϵ-transition parameter for a certain state.

Interpreting a document. SoPa provides an interpretable representation of a document—a vector of the maximal matching score of each pattern with any span in the document. To visualize the decisions of our model for a given document, we can observe the patterns and corresponding phrases that score highly within it.

To understand which of the k patterns contributes most to the classification decision, we apply a leave-one-out method. We run the forward method of the MLP layer in SoPa k times, each time zeroing-out the score of a different pattern p. The difference between the resulting score and the original model score is considered p's contribution. We then consider the highest contributing patterns, and attach each one with its highest scoring phrase in that document. Table 3 shows example texts along with their most positive and negative contributing phrases.

8 Related Work

Weighted finite-state automata. WFSAs and hidden Markov models[19] were once popular in automatic speech recognition (Hetherington, 2004; Moore et al., 2006; Hoffmeister et al., 2012) and remain popular in morphology (Dreyer, 2011; Cotterell et al., 2015). Most closely related to this work, neural networks have been combined with weighted finite-state transducers to do morphological reinflection (Rastogi et al., 2016). These prior works learn a single FSA or FST, whereas our model learns a collection of simple but complementary FSAs, together encoding a sequence. We are the first to incorporate neural networks both *before* WFSAs (in their transition scoring functions), and *after* (in the function that turns their vector of scores into a final prediction), to produce an expressive model that remains interpretable.

[19] HMMs are a special case of WFSAs (Mohri et al., 2002).

Recurrent neural networks. The ability of RNNs to represent arbitrarily long sequences of embedded tokens has made them attractive to NLP researchers. The most notable variants, the long short-term memory (LSTM; Hochreiter and Schmidhuber, 1997) and gated recurrent units (GRU; Cho et al., 2014), have become ubiquitous in NLP algorithms (Goldberg, 2016). Recently, several works introduced simpler versions of RNNs, such as recurrent additive networks (Lee et al., 2017) and Quasi-RNNs (Bradbury et al., 2017). Like SoPa, these models can be seen as points along the bridge between RNNs and CNNs.

Other works have studied the expressive power of RNNs, in particular in the context of WFSAs or HMMs (Cleeremans et al., 1989; Giles et al., 1992; Visser et al., 2001; Chen et al., 2018). In this work we relate CNNs to WFSAs, showing that a one-layer CNN with max-pooling can be simulated by a collection of linear-chain WFSAs.

Convolutional neural networks. CNNs are prominent feature extractors in NLP, both for generating character-based embeddings (Kim et al., 2016), and as sentence encoders for tasks like text classification (Yin and Schütze, 2015) and machine translation (Gehring et al., 2017). Similarly to SoPa, several recently introduced variants of CNNs support varying window sizes by either allowing several fixed window sizes (Yin and Schütze, 2015) or by supporting non-consecutive n-gram matching (Lei et al., 2015; Nguyen and Grishman, 2016).

Neural networks and patterns. Some works used patterns as part of a neural network. Schwartz et al. (2016) used pattern contexts for estimating word embeddings, showing improved word similarity results compared to bag-of-word contexts. Shwartz et al. (2016) designed an LSTM representation for dependency patterns, using them to detect hypernymy relations. Here, we learn patterns as a neural version of WFSAs.

Interpretability. There have been several efforts to interpret neural models. The weights of the attention mechanism (Bahdanau et al., 2015) are often used to display the words that are most significant for making a prediction. LIME (Ribeiro et al., 2016) is another approach for visualizing neural models (not necessarily textual). Yogatama and Smith (2014) introduced structured sparsity, which encodes linguistic information into the regularization of a model, thus allowing to visualize the contribution of different bag-of-word features.

Other works jointly learned to encode text and extract the span which best explains the model's prediction (Yessenalina et al., 2010; Lei et al., 2016). Li et al. (2016) and Kádár et al. (2017) suggested a method that erases pieces of the text in order to analyze their effect on a neural model's decisions. Finally, several works presented methods to visualize deep CNNs (Zeiler and Fergus, 2014; Simonyan et al., 2014; Yosinski et al., 2015), focusing on visualizing the different layers of the network, mainly in the context of image and video understanding. We believe these two types of research approaches are complementary: inventing general purpose visualization tools for existing black-box models on the one hand, and on the other, designing models like SoPa that are interpretable by construction.

9 Conclusion

We introduced SoPa, a novel model that combines neural representation learning with WFSAs. We showed that SoPa is an extension of a one-layer CNN. It naturally models flexible-length spans with insertion and deletion, and it can be easily customized by swapping in different semirings. SoPa performs on par with or strictly better than four baselines on three text classification tasks, while requiring fewer parameters than the stronger baselines. On smaller training sets, SoPa outperforms all four baselines. As a simple version of an RNN, which is more expressive than one-layer CNNs, we hope that SoPa will encourage future research on the bridge between these two mechanisms. To facilitate such research, we release our implementation at `https://github.com/Noahs-ARK/soft_patterns`.

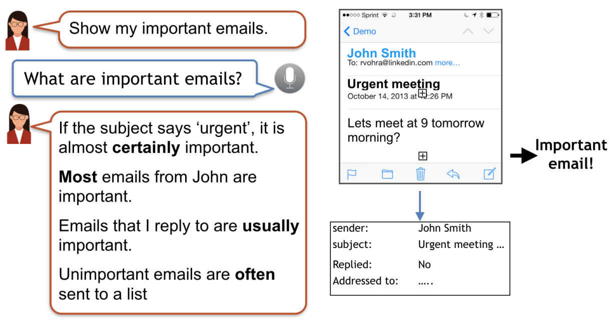
Abstract

Humans can efficiently learn new concepts using language. We present a framework through which a set of explanations of a concept can be used to learn a classifier without access to any labeled examples. We use semantic parsing to map explanations to probabilistic assertions grounded in latent class labels and observed attributes of unlabeled data, and leverage the differential semantics of linguistic quantifiers (e.g., 'usually' vs 'always') to drive model training. Experiments on three domains show that the learned classifiers outperform previous approaches for learning with limited data, and are comparable with fully supervised classifiers trained from a small number of labeled examples.

1 Introduction

As computer systems that interact with us in natural language become pervasive (e.g., Siri, Alexa, Google Home), they suggest the possibility of letting users teach machines in language. The ability to learn from language can enable a paradigm of ubiquitous machine learning, allowing users to teach personalized concepts (e.g., identifying 'important emails' or 'project-related emails') when limited or no training data is available.

In this paper, we take a step towards solving this problem by exploring the use of quantifiers to train classifiers from declarative language. For illustration, consider the hypothetical example of a user explaining the concept of an "important email" through natural language statements (Figure 1). Our framework takes a set of such natural language explanations describing a concept (e.g., "emails that I reply to are usually important") and a set of unlabeled instances as input, and produces



Show my important emails.

What are important emails?

If the subject says 'urgent', it is almost **certainly** important.

Most emails from John are important.

Emails that I reply to are **usually** important.

Unimportant emails are **often** sent to a list

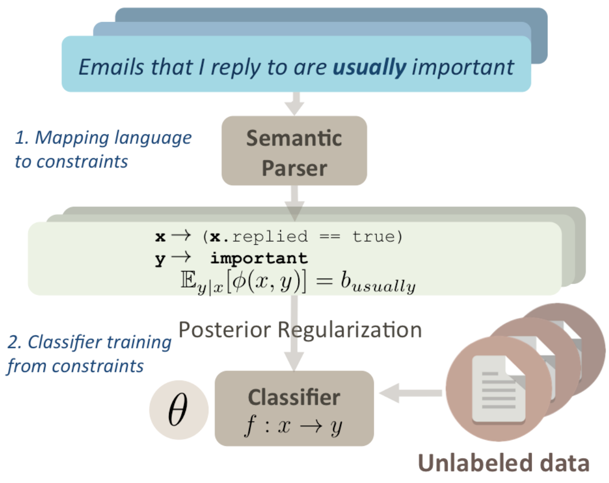
Figure 1: Supervision from language can enable concept learning from limited or even no labeled examples. Our approach assumes the learner has sensors that can extract attributes from data, such as those listed in the table, and language that can refer to these sensors and their values.

a binary classifier (for important emails) as output. Our hypothesis is that language describing concepts encodes key properties that can aid statistical learning. These include specification of relevant attributes (e.g., whether an email was replied to), relationships between such attributes and concept labels (e.g., if a reply implies the class label of that email is 'important'), as well as the strength of these relationships (e.g., via quantifiers like 'often', 'sometimes', 'rarely'). We infer these properties automatically, and use the semantics of linguistic quantifiers to drive the training of classifiers *without labeled examples for any concept*. This is a novel scenario, where previous approaches in semi-supervised and constraint-based learning are not directly applicable. Those approaches require manual pre-specification of expert knowledge for model training. In our approach, this knowledge is automatically inferred from noisy natural language explanations from a user.

Our approach is summarized in the schematic in Figure 2. First, we map the set of natural language explanations of a concept to logical forms



Emails that I reply to are usually important
1. Mapping language to constraints
Semantic Parser
x → (x.replied == true)
y → important
$\mathbb{E}_{y|x}[\phi(x,y)] = b_{usually}$
2. Classifier training from constraints
Posterior Regularization
θ
Classifier $f: x \to y$
Unlabeled data

Figure 2: Our approach to Zero-shot learning from Language. Natural language explanations on how to classify concept examples are parsed into formal constraints relating features to concept labels. The constraints are combined with unlabeled data, using posterior regularization to yield a classifier.

that identify the attributes mentioned in the explanation, and describe the information conveyed about the attribute and the concept label as a quantitative constraint. This mapping is done through semantic parsing. The logical forms denote quantitative constraints, which are probabilistic assertions about observable attributes of the data and unobserved concept labels. Here the strength of a constraint is assumed to be specified by a linguistic quantifier (such as 'all', 'some', 'few', etc., which reflect degrees of generality of propositions). Next, we train a classification model that can assimilate these constraints by adapting the posterior regularization framework (Ganchev et al., 2010).

Intuitively, this can be seen as defining an optimization problem, where the objective is to find parameter estimates for the classifier that do not simply fit the data, but also agree with the human provided natural language advice to the greatest extent possible. Since logical forms can be grounded in a variety of sensors and external resources, an explicit model of semantic interpretation conceptually allows the framework to subsume a flexible range of grounding behaviors. The main contributions of this work are:

1. We introduce the problem of zero-shot learning of classifiers from language, and present an approach towards this.
2. We develop datasets for zero-shot classification from natural descriptions, exhibiting tasks with various levels of difficulty.
3. We empirically show that coarse probability estimates to model linguistic quantifiers can effectively supervise model training across three domains of classification tasks.

2 Related Work

Many notable approaches have explored incorporation of background knowledge into the training of learning algorithms. However, none of them addresses the issue of learning from natural language. Prominent among these are the Constraint-driven learning (Chang et al., 2007a), Generalized Expectation (Mann and McCallum, 2010) and Posterior Regularization (Ganchev et al., 2010) and Bayesian Measurements (Liang et al., 2009) frameworks. All of these require domain knowledge to be manually programmed in before learning. Similarly, Probabilistic Soft Logic (Kimmig et al., 2012) allows users to specify rules in a logical language that can be used for reasoning over graphical models. More recently, multiple approaches have explored few-shot learning from perspective of term or attribute-based transfer (Lampert et al., 2014), or learning representations of instances as probabilistic programs (Lake et al., 2015).

Other work (Lei Ba et al., 2015; Elhoseiny et al., 2013) considers language terms such as colors and textures that can be directly grounded in visual meaning in images. Some previous work (Srivastava et al., 2017) has explored using language explanations for feature space construction in concept learning tasks, where the problem of learning to interpret language, and learning classifiers is treated jointly. However, this approach assumes availability of labeled data for learning classifiers. Also notable is recent work by Andreas et al. (2017), who propose using language descriptions as parameters to model structure in learning tasks in multiple settings. More generally, learning from language has also been previously explored in tasks such as playing games (Branavan et al., 2012), robot navigation (Karamcheti et al., 2017), etc.

Natural language quantification has been studied from multiple perspectives in formal logic (Barwise and Cooper, 1981), linguistics (Löbner, 1987; Bach et al., 2013) and cognitive psychology (Kurtzman and MacDonald, 1993). While quantification has traditionally been defined in set-theoretic terms in linguistic theories[1], our approach joins alternative

[1] e.g., *'some A are B'* $\Leftrightarrow A \cap B \neq \emptyset$

perspectives that represent quantifiers probabilistically (Moxey and Sanford, 1993; Yildirim et al., 2013). To the best of our knowledge, this is the first work to leverage the semantics of quantifiers to guide statistical learning models.

3 Learning Classifiers from Language

Our approach relies on first mapping natural language descriptions to quantitative constraints that specify statistical relationships between observable attributes of instances and their latent concept labels (Step 1 in Figure 2). These quantitative constraints are then imbued into the training of a classifier by guiding predictions from the learned models to concur with them (Step 2). We use semantic parsing to interpret sentences as quantitative constraints, and adapt the posterior regularization principle for our setting to estimate the classifier parameters. Next, we describe these steps in detail. Since learning in this work is largely driven by the semantics of linguistic quantifiers, we call our approach **Learning from Natural Quantification**, or **LNQ**.

3.1 Mapping language to constraints

A key challenge in learning from language is converting free-form language to representations that can be reasoned over, and grounded in data. For example, a description such as '*emails that I reply to are usually important*' may be converted to a mathematical assertion such as $P(important \mid replied : true) = 0.7$', which statistical methods can reason with. Here, we argue that this process can be automated for a large number of real-world descriptions. In interpreting statements describing concepts, we infer the following key elements:

1. *Feature* x, which is grounded in observed attributes of the data. For our example, 'emails replied to' can refer to a predicate such as `replied:true`, which can be evaluated in context of emails to indicate the whether an email was replied to. Incorporating compositional representations enables more complex reasoning. e.g., '*the subject of course-related emails usually mentions CS100*' can map to a composite predicate like '`isStringMatch(field:subject, stringVal('CS100'))`', which can be evaluated for different emails to reflect whether their subject mentions 'CS100'. Mapping language to executable feature functions has been shown to be effective (Srivastava et al., 2017). For sake of simplicity, here we assume that a statement refers to a single feature, but the method can be extended to handle more complex descriptions.
2. *Concept label* y, specifying the class of instances a statement refers to. For binary classes, this reduces to examples or non-examples of a concept. For our running example, y corresponds to the positive class of important emails.
3. *Constraint-type* asserted by the statement. We argue that most concept descriptions belong to one of three categories shown in Table 2, and these constitute our vocabulary of constraint types for this work. For our running example ('emails that I reply to are usually important'), the type corresponds to $P(y \mid x)$, since the syntax of the statement indicates an assertion conditioned on the feature indicating whether an email was replied to. On the other hand, an assertion such as 'I usually reply to important emails' indicates an assertion conditioned on the set important emails, and therefore corresponds to the type $P(x \mid y)$.
4. *Strength* of the constraint. We assume this to be specified by a quantifier. For our running example, this corresponds to the adverb 'usually'. In this work, by *quantifier* we specifically refer to frequency adverbs ('usually','rarely', etc.) and frequency determiners ('few', 'all', etc.).[2] Our thesis is that the semantics of quantifiers can be leveraged to make statistical assertions about relationships involving attributes and concept labels. One way to do this might be to simply associate point estimates of probability values, suggesting the fraction of truth values for assertions described with these quantifiers. Table 1 shows probability values we assign to some common frequency quantifiers for English. These values were set simply based on the authors' intuition about their semantics, and do not reflect any empirical distributions. See Figure 8 for empirical distributions corresponding to some linguistic quantifiers in our data. While these probability values maybe inaccurate, and the semantics of these quantifiers may also change based on context and the speaker, they can still serve as a strong signal for learning classifiers since they are not used as hard constraints, but serve to bias classifiers towards better generalization.

We use a semantic parsing model to map statements to formal semantic representations that specify these aspects. For example, the statement 'Emails that I reply to are usually important' is

[2]This is a significantly restricted definition, and does not address non-frequency determiners (e.g.,'the', 'only', etc.) or mass quantifiers (e.g. 'a lot', 'little'), among other categories.

Frequency quantifier	Probability
all, always, certainly, definitely	0.95
usually, normally, generally, likely, typically	0.70
most, majority	0.60
often, half	0.50
many	0.40
sometimes, frequently, some	0.30
few, occasionally	0.20
rarely, seldom	0.10
never	0.05

Table 1: Probability values we assign to common linguistic quantifiers (hyper-parameters for method)

mapped to a logical form like `(x→replied:true y→positive type:y|x quant:usually)`.

3.1.1 Semantic Parser components

Given a descriptive statement s, the parsing problem consists of predicting a logical form l that best represents its meaning. In turn, we formulate the probability of the logical form l as decomposing into three component factors: (i) probability of observing a feature and concept labels l_{xy} based on the text of the sentence, (ii) probability of the type of the assertion l_{type} based on the identified feature, concept label and syntactic properties of the sentence s, and (iii) identifying the linguistic quantifier, l_{quant}, in the sentence.

$$P(l \mid s) = P(l_{xy} \mid s)\ P(l_{type} \mid l_{xy}, s)\ P(l_{quant} \mid s)$$

We model each of the three components as follows: by using a traditional semantic parser for the first component, training a Max-Ent classifier for the constraint-type for the second component, and looking for an explicit string match to identify the quantifier for the third component.

Identifying features and concept labels, l_{xy}: For identifying the feature and concept label mentioned in a sentence, we presume a linear score $\mathcal{S}(s, l_{xy}) = w^T \psi(s, l_{xy})$ indicating the goodness of assigning a partial logical form, l_{xy}, to a sentence s. Here, $\psi(s, l_{xy}) \in \mathbb{R}^n$ are features that can depend on both the sentence and the partial logical form, and $w \in \mathbb{R}^n$ is a parameter weight-vector for this component. Following recent work in semantic parsing (Liang et al., 2011), we assume a loglinear distribution over interpretations of a sentence.

$$P(l_{xy} \mid s) \propto w^T \psi(s, l_{xy})$$

Provided data consisting of statements labeled with logical forms, the model can be trained via maximum likelihood estimation, and be used to predict interpretations for new statements. For training this component, we use a CCG semantic parsing formalism, and follow the feature-set from Zettlemoyer and Collins (2007), consisting of simple indicator features for occurrences of keywords and lexicon entries. This is also compatible with the semantic parsing formalism in Srivastava et al. (2017), whose data (and accompanying lexicon) are also used in our evaluation. For other datasets with predefined features, this component is learned easily from simple lexicons consisting of trigger words for features and labels.[3] This component is the only part of the parser that is domain-specific. We note that while this component assumes a domain-specific lexicon (and possibly statement annotated with logical forms), this effort is one-time-only, and will find re-use across the possibly large number of concepts in the domain (e.g., email categories).

Identifying assertion type, l_{type}: The principal novelty in our semantic parsing model is in identifying the type of constraint asserted by a statement. For this, we train a MaxEnt classifier, which uses positional and syntactic features based on the text-spans corresponding to feature and concept mentions to predict the constraint type. We extract the following features from a statement:
1. Boolean value indicating whether the text-span corresponding to the feature x precedes the text span for the concept label y.
2. Boolean value indicating if sentence is in passive (rather than active) voice, as identified by the occurrence of `nsubjpass` dependency relation.
3. Boolean value indicating whether head of the text-span for x is a noun, or a verb.
4. Features indicating the occurrence of conditional tokens ('if', 'then' and 'that') preceding or following text-spans for x and y.
5. Features indicating presence of a linguistic quantifier in a `det` or an `advmod` relation with syntactic head of x or y.

Since the constraint type is determined by syntactic and dependency parse features, this

[3]We also identify whether a feature x is negated, through the existence of a `neg` dependency relation with the head of its text-span. e.g., *Important emails are usually not deleted*

Type	Example description	Conversion to Expectation Constraint
$P(y \mid x)$	Emails that I reply to are usually important	$\mathbb{E}[\mathbb{I}_{y=important,reply(x):true}] - p_{usually} \times \mathbb{E}[\mathbb{I}_{reply(x):true}] = 0$
$P(x \mid y)$	I often reply to important emails	$\mathbb{E}[\mathbb{I}_{y=important,reply(x):true}] - p_{often} \times \mathbb{E}[\mathbb{I}_{y=important}] = 0$
$P(y)$	I rarely get important emails	Same as $P(y \vert x_0)$, where x_0 is a constant feature

Table 2: Common constraint-types, and their representation as expectations over feature values

component does not need to be retrained for new domains. In this work, we trained this classifier based on a manually annotated set of 80 sentences describing classes in the small UCI Zoo dataset (Lichman, 2013), and used this model for all experiments.

Identifying quantifiers, l_{quant}: Multiple linguistic quantifiers in a sentence are rare, and we simply look for the first occurrence of a linguistic quantifier in a sentence, i.e. $P(l_{quant}|s)$ is a deterministic function. We note that many real world descriptions of concepts lack an explicit quantifier. e.g., '*Emails from my boss are important*'. In this work, we ignore such statements for the purpose of training. Another treatment might be to models these statements as reflecting a default quantifier, but we do not explore this direction here. Finally, the decoupling of quantification from logical representation is a key decision. At the cost of linguistic coarseness, this allows modeling quantification irrespective of the logical representation (lambda calculus, predicate-argument structures, etc.).

3.2 Classifier training from constraints

In the previous section, we described how individual explanations can be mapped to probabilistic assertions about observable attributes (e.g., the statement 'Emails that I reply to are usually important' may map to $P(y = important \mid replied = true) = p_{usually}$). Here, we describe how a set of such assertions can be used in conjunction with unlabeled data to train classification models.

Our approach relies on having predictions from the classifier on a set of unlabeled examples ($X = \{x_1 \ldots x_n\}$) agree with human-provided advice (in form of constraints). The unobserved concept labels ($Y = \{y_1 \ldots y_n\}$) for the unlabeled data constitute *latent variables* for our method. The training procedure can be seen as iteratively inferring the latent concept labels for unlabeled examples so as to agree with the human advice, and updating the classification models by taking these labels as given. While there are multiple approaches for training statistical models with constraints on latent variables, here we use the Posterior Regularization (PR) framework. The PR objective can be used to optimize a latent variable model subject to a set of constraints, which specify preferences for values of the posterior distributions $p_\theta(Y \mid X)$.

$$J_Q(\theta) = \mathcal{L}(\theta) - \min_{q \in Q} KL(q \mid p_\theta(Y|X))$$

Here, the set Q represents a set of *preferred* posterior distributions over latent variables Y, and is defined as $Q := \{q_X(Y) : \mathbb{E}_q[\phi(X,Y)] \leq \mathbf{b}\}$. The overall objective consists of two components, representing how well does a model θ explain the data (likelihood term $\mathcal{L}(\theta)$), and how far it is from the set Q (KL-divergence term).

In our case, each parsed statement defines a probabilistic constraint. The conjunction of all such constraints defines Q (representing models that exactly agree with human-provided advice). Thus, optimizing the objective reflects a tension between choosing models that increase data likelihood, and emulating language advice.

Converting to PR constraints: The set of constraints that PR can handle can be characterized as bounds on expected values of functions (ϕ) of X and Y (or equivalently, from linearity of expectation, as linear inequalities over expected values of functions of X and Y). To use the framework, we need to ensure that each constraint type in our vocabulary can be expressed in such a form.

Following the plan in Table 2, each constraint type can be converted in an equivalent form $\mathbb{E}_q[\phi(X,Y)] = b$, compatible with PR. In particular, each of these constraint types in our vocabulary can be expressed as equations about expectation values of joint indicator functions of label assignments to instances and their attributes. To explain, consider the assertion $P(y = important \mid replied : true) = p_{usually}$. The probability on the LHS can be expressed as the empirical fraction $\frac{\sum_i \mathbb{E}[\mathbb{I}_{y_i=important,replied:true}]}{\sum_i \mathbb{E}[\mathbb{I}_{replied:true}]}$, which leads to the linear constraints seen in Table 2 (expected values in the table hide summations over instances for brevity). Here, $\mathbb{I}$ denote indicator functions. Thus, we can incorporate probability constraints into our adaptation of the PR scheme.

Learning and Inference: We choose a loglinear parameterization for the concept classifier.

$$p_\theta(y_i \mid x_i) \propto \exp(y\theta^T x)$$

The training of the classifier follows the modified EM procedure described in Ganchev et al. (2010). As proposed in the original work, we solve a relaxed version of the optimization that allows slack variables, and modifies the PR objective with a L_2 regularizer. This allows solutions even when the problem is over-constrained, and the set Q is empty (e.g. due to contradictory advice).

$$J'(\theta, q) = \mathcal{L}(\theta) - KL(q|p_\theta(Y|X)) \\ - \lambda \, ||\mathbb{E}_q[\phi(X,Y)] - b||^2$$

The key step in the training is the computation of the posterior regularizer in the E-step.

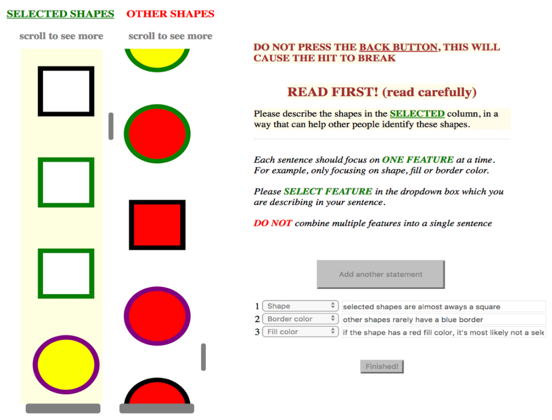
$$\operatorname*{argmin}_q KL(q \mid p_\theta) + \lambda \, ||\mathbb{E}_q[\phi(X,Y)] - b||^2$$

This objective is strictly convex, and all constraints are linear in q. We follow the optimization procedure from Bellare et al. (2009), whereby the minimization problem in the E-step can be efficiently solved through gradient steps in the dual space. In the M-step, we update the model parameters for the classifier based on label distributions q estimated in the E-step. This simply reduces to estimating the parameters θ for the logistic regression classifier, when class label probabilities are known. In all experiments, we run EM for 20 iterations and use a regularization coefficient of $\lambda = 0.1$.

4 Datasets

For evaluating our approach, we created datasets of classification tasks paired with descriptions of the classes, as well as used some existing resources. In this section, we summarize these steps.

Shapes data: To experiment with our approach in a wider range of controlled settings, part of our evaluation focuses on synthetic concepts. For this, we created a set of 50 shape classification tasks that exhibit a range of difficulty, and elicited language descriptions spanning a variety of quantifier expressions. The tasks require classifying geometric shapes with a set of predefined attributes (fill color, border, color, shape, size) into two concept-labels (abstractly named 'selected shape', and 'other'). The datasets were created through a generative process, where features x_i are conditionally independent given the concept-label. Each feature's conditional distribution is sampled from a symmetric



DO NOT PRESS THE BACK BUTTON, THIS WILL CAUSE THE HIT TO BREAK

Please describe the shapes in the SELECTED column, in a way that can help other people identify these shapes.

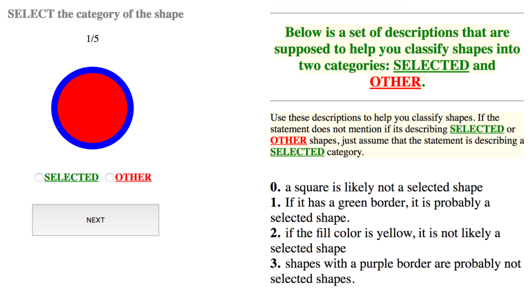
Each sentence should focus on ONE FEATURE at a time. For example, only focusing on shape, fill or border color.

Please SELECT FEATURE in the dropdown box which you are describing in your sentence.

DO NOT combine multiple features into a single sentence

1 Shape: selected shapes are almost aways a square
2 Border color: other shapes rarely have a blue border
3 Fill color: if the shape has a red fill color, it's most likely not a sele

(a) Statement generation task



Below is a set of descriptions that are supposed to help you classify shapes into two categories: SELECTED and OTHER.

Use these descriptions to help you classify shapes. If the statement does not mention if its describing SELECTED or OTHER shapes, just assume that the statement is describing a SELECTED category.

0. a square is likely not a selected shape
1. If it has a green border, it is probably a selected shape.
2. if the fill color is yellow, it is not likely a selected shape
3. shapes with a purple border are probably not selected shapes.

(b) Concept Quiz

Figure 3: Shapes data: Mechanical Turk tasks for (a) collecting concept descriptions, and (b) human evaluation from concept descriptions

Dirichlet distribution, and varying the concentration parameter α allows tuning the noise level of the generated datasets (quantified via their Bayes Optimal accuracy[4]). A dataset is then generated by sampling from these conditional distributions. We sample a total of 50 such datasets, consisting of 100 training and 100 test examples each, where each example is a shape and its assigned label.

For each dataset, we then collected statements from Mechanical Turk workers that describe the concept. The task required turkers to study a sample of shapes presented on the screen for each of the two concept-labels (see Figure 3(a)). They were then asked to write a set of statements that would help others classify these shapes without seeing the data. In total, 30 workers participated in this task, generating a mean of 4.3 statements per dataset.

Email data: Srivastava et al. (2017) provide a dataset of language explanations from human users describing 7 categories of emails, as well as 1030 examples of emails belonging to those categories. While this work uses labeled examples, and focuses

[4]This is the accuracy of a theoretically optimal classifier, which knows the true distribution of the data and labels

Shapes: If a shape doesn't have a blue border, it is probably not a selected shape. Selected shapes occasionally have a yellow fill.
Emails: Emails that mention the word 'meet' in the subject are usually meeting requests Personal reminders almost always have the same recipient and sender
Birds: A specimen that has a striped crown is likely to be a selected bird. Birds in the other category rarely ever have dagger-shaped beaks

Table 3: Examples of explanations for each domain

on mapping natural language explanations (∼30 explanations per email category) to compositional feature functions, we can also use statements in their data for evaluating our approach. While language quantifiers were not studied in the original work, we found about a third of the statements in this data to mention a quantifier.

Birds data: The CUB-200 dataset (Wah et al., 2011) contains images of birds annotated with observable attributes such as size, primary color, wing-patterns, etc. We selected a subset of the data consisting of 10 species of birds and 53 attributes (60 examples per species). Turkers were shown examples of birds from a species, and negative examples consisting of a mix of birds from other species, and were asked to describe the classes (similar to the Shapes data, see Figure 4). During the task, users also had access to a table enumerating groundable attributes they could refer to. In all, 60 workers participated, generating 6.1 statements on average.

Approach	Avg Accuracy	Labels	Descriptions
LNQ	0.751	no	yes
Bayes Optimal	0.831	–	–
FLGE+	0.659	no	yes
FLGE	0.598	no	yes
LR	0.737	yes	no
Random	0.524	–	–
Ablation:			
LNQ (coarse quant)	0.679	no	yes
LNQ (no quant)	0.545	no	yes
Human:			
Human teacher	0.802	yes	writes
Human learner	0.734	no	yes

Table 4: Classification performance on Shapes datasets (averaged over 50 classification tasks).

5 Experiments

Incorporating constraints from language has not been addressed before, and hence previous approaches for learning from limited data such as Mann and McCallum (2010); Chang et al. (2007b) would not directly work for this setting. Our baselines hence consist of extended versions of previous approaches that incorporate output from the parser, as well as fully supervised classifiers trained from a small number of labeled examples.

Classification performance: The top section in Table 4 summarizes performance of various classifiers on the Shape datasets, averaged over all 50 classification tasks. FLGE+ refers to a baseline

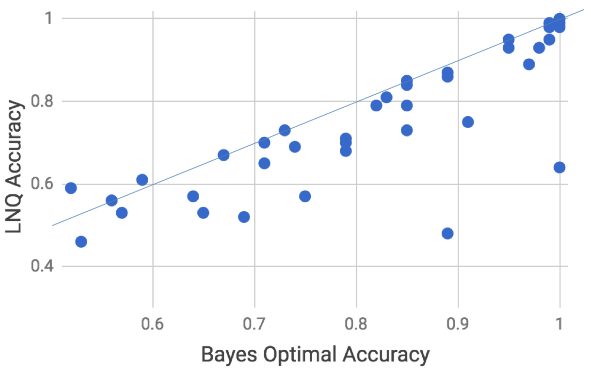

Figure 5: LNQ vs Bayes Optimal Classifier performance for Shape datasets. Each dot represents a dataset generated from a known distribution.

that uses the Feature Labeling through Generalized Expectation criterion, following the approach in Druck et al. (2008); Mann and McCallum (2010). The approach is based on labeling features are indicating specific class-labels, which corresponds to specifiying constraints of type $P(y|x)$[5]. While the original approach (Druck et al., 2008) sets this value to 0.9, we provide the method the quantitative probabilities used by LNQ. Since the original method cannot handle language descriptions, we also provide the approach the concept label y and feature x as identified by the parser. FLGE represents the version that is not provided quantifier probabilities. LR refers to a supervised logistic regression model trained on $n = 8$ randomly chosen labeled instances.[6] We note that LNQ performs substantially better than both FLGE+ and LR on average. This validates our modeling principle for learning classifiers from explanations alone, and also suggests value in our PR-based formulation, which can handle multiple constraint types. We further note that not using quantifier probabilities significantly deteriorates FLGE's performance.

Figure 5 provides a more detailed characterization of LNQ's performance. Each blue dot represents performance on a shape classification task. The horizontal axis represents the accuracy of the Bayes Optimal classifier, and the vertical represents accuracy of the LNQ approach. The blue line represents the trajectory for $x = y$, representing a perfect statistical classifier in the asymptotic case of infinite samples. We note that LNQ is effective in learning competent classifiers for all levels of hardness. Secondly, except for a small number of outliers, the approach works especially well for learning easy concepts (towards the right). From an error-analysis, we found that a majority of these errors are due to problems in parsing (e.g., missed negation, incorrect constraint type) or due to poor explanations from the teacher (bad grammar, or simply incorrect information).

Figure 6 shows results for email classification tasks. In the figure, LN* refers to the approach in Srivastava et al. (2017), which uses natural language descriptions to define compositional features for email classification, but does not incorporate

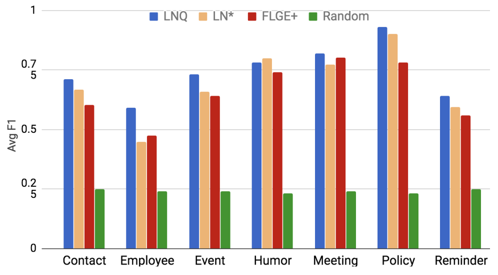

Figure 6: Classification performance (F1) on Email data. (LN* Results from Srivastava et al. (2017))

supervision from quantification. For this task, we found very few of the natural language descriptions to contain quantifiers for some of the individual email categories, making a direct comparison impractical. Thus in this case, we evaluate methods by combining supervision from descriptions in addition to 10 labeled examples (also in line with evaluation in the original paper). We note that additionally incorporating quantification (LNQ) consistently improves classification performance across email categories. On this task, LNQ improves upon FLGE+ and LN* for 6 of the 7 email categories.

Figure 7 shows classification results on the Birds data. Here, LR refers to a logistic regression model trained on n=10 examples. The trends in this case are similar, where LNQ consistently outperforms FLGE+, and is competitive with LR.

Ablating quantification: From Table 4, we further observe that the differential associative strengths of linguistic quantifiers are crucial for our method's classification performance. LNQ (no quant) refers to a variant that assigns the same probability value (average of values in Table 1), irrespective of quantifier. This yields a near random performance, which is what we'd expect if the learning is being driven by the differential strengths of quantifiers. LNQ (coarse quant) refers to a variant that rounds assigned quantifier probabilities in Table 1 to 0 or 1. (i.e., quantifiers such are *rarely* get mapped to 0, while *always* gets mapped to a probability of 1). While its performance (0.679) suggests that simple binary feedback is a substantial signal, the difference from the full model indicates value in using soft probabilities. On the other hand, in a sensitivity study, we found the performance of the approach to be robust to small changes in the probability values of quantifiers.

Comparison with human performance: For the Shapes data, we evaluated human teachers' own understanding of concepts they teach by evaluating

[5]In general, Generalized Expectation can also handle broader constraint types, similar to Posterior Regularization

[6]LNQ models are indistinct from LR w.r.t. parametrization, but trained to maximize a different objective. The choice of n here is arbitrary, but is roughly twice the number of explanations for each task in this domain

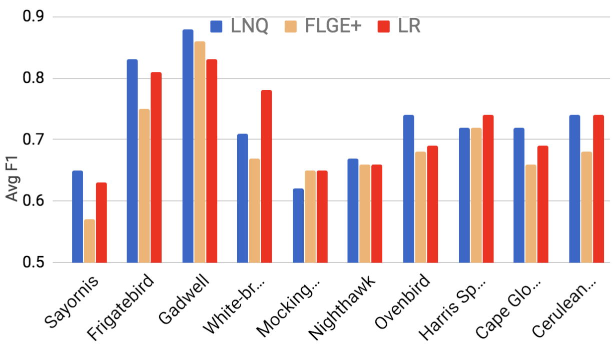

Figure 7: Classification performance on Birds data

them on a quiz based on predicting labels for examples from the test set (see Figure 3(b)). Second, we solicit additional workers that were not exposed to examples from the dataset, and present them only with the statements describing that data (created by a teacher), which is comparable supervision to what LNQ receives. We then evaluate their performance at the same task. From Table 4, we note that a human teacher's average performance is significantly worse ($p < 0.05$, Wilcoxon signed-rank test) than the Bayes Optimal classifier indicating that the teacher's own synthesis of concepts is noisy. The human learner performance is expectedly lower, but interestingly is also significantly worse than LNQ. While this might be potentially be caused by factors such as user fatigue, this might also suggest that automated methods can be better at reasoning with constraints than humans in certain scenarios. These results need to be validated through comprehensive experiments in more domains.

Empirical semantics of quantifiers: We can estimate the distributions of probability values for different quantifiers from our labeled data. For this, we aggregate sentences mentioning a quantifier, and calculate the empirical value of the (conditional) probability associated with the statement, leading to a set of probability values for each quantifier. Figure 8 shows empirical distributions of probability values for six quantifiers. We note that while a few estimates (e.g., 'rarely' and 'often') roughly align with pre-registered beliefs, others are somewhat off (e.g., 'likely' shows a much higher value), and yet others (e.g., 'sometimes') show a large spread of values to be meaningfully modeled as point values. LNQ's performance, inspite of this, shows strong stability in the approach. We don't use these empirical probabilities in experiments, (instead of pre-registered values), so as not to tune the hyperparameters to a specific dataset.

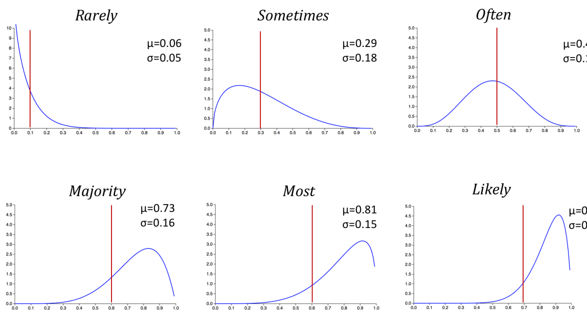

Figure 8: Empirical probability distributions for six quantifiers (Shapes data). Plots show Beta distributions with Method-of-Moment estimates. Red bars correspond to values from Table 1

Such estimates would not be available for a new task without labeled data. Further, using labeled data for estimating these probabilities, and then using the learned model for predicting labels would constitute overfitting, biasing evaluation.

6 Discussion and Future Work

Our approach is surprisingly effective in learning from free-form language. However, it does not address linguistic issues such as modifiers (e.g., *very* likely), nested quantification, etc. On the other hand, we found no instances of nested quantification in the data, suggesting that people might be primed to use simpler language when teaching. While we approximate quantifier semantics as absolute probability values, they may vary significantly based on the context, as shown by cognitive studies such as Newstead and Collis (1987). Future work can model how these parameters can be adapted in a task specific way (e.g., cases such as cancer prediction where base rates are small), and provide better models of quantifier semantics. e.g., as distributions, rather than point values.

Our approach is a step towards the idea of using language to guide learning of statistical models. This is an exciting direction, which contrasts with the predominant theme of using statistical learning methods to advance the field of NLP. We believe that language may have as much to help learning, as statistical learning has helped NLP.

Sentence-State LSTM for Text Representation

Yue Zhang[1], **Qi Liu**[1] and **Linfeng Song**[2]

Abstract

Bi-directional LSTMs are a powerful tool for text representation. On the other hand, they have been shown to suffer various limitations due to their sequential nature. We investigate an alternative LSTM structure for encoding text, which consists of a parallel state for each word. Recurrent steps are used to perform local and global information exchange between words simultaneously, rather than incremental reading of a sequence of words. Results on various classification and sequence labelling benchmarks show that the proposed model has strong representation power, giving highly competitive performances compared to stacked BiLSTM models with similar parameter numbers.

1 Introduction

Neural models have become the dominant approach in the NLP literature. Compared to handcrafted indicator features, neural sentence representations are less sparse, and more flexible in encoding intricate syntactic and semantic information. Among various neural networks for encoding sentences, bi-directional LSTMs (BiLSTM) (Hochreiter and Schmidhuber, 1997) have been a dominant method, giving state-of-the-art results in language modelling (Sundermeyer et al., 2012), machine translation (Bahdanau et al., 2015), syntactic parsing (Dozat and Manning, 2017) and question answering (Tan et al., 2015).

Despite their success, BiLSTMs have been shown to suffer several limitations. For example, their inherently sequential nature endows computation non-parallel within the same sentence (Vaswani et al., 2017), which can lead to a computational bottleneck, hindering their use in the industry. In addition, local ngrams, which have been shown a highly useful source of contextual information for NLP, are not explicitly modelled (Wang et al., 2016). Finally, sequential information flow leads to relatively weaker power in capturing long-range dependencies, which results in lower performance in encoding longer sentences (Koehn and Knowles, 2017).

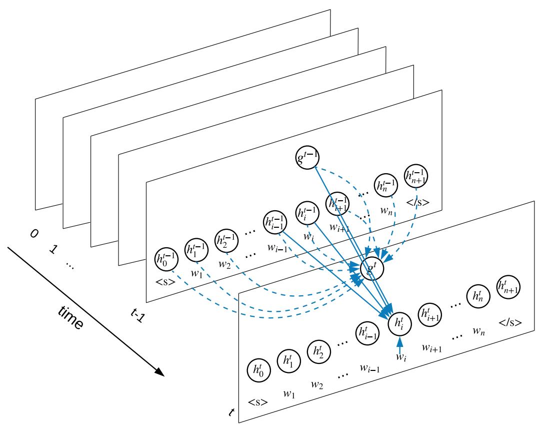

Figure 1: Sentence-State LSTM

We investigate an alternative recurrent neural network structure for addressing these issues. As shown in Figure 1, the main idea is to model the hidden states of all words simultaneously at each recurrent step, rather than one word at a time. In particular, we view the whole sentence as a single state, which consists of sub-states for individual words and an overall sentence-level state. To capture local and non-local contexts, states are updated recurrently by exchanging information between each other. Consequently, we refer to our model as sentence-state LSTM, or S-LSTM in short. Empirically, S-LSTM can give effective sentence encoding after 3 – 6 recurrent steps. In contrast, the number of recurrent steps necessary for BiLSTM scales with the size of the sentence.

At each recurrent step, information exchange is conducted between consecutive words in the sentence, and between the sentence-level state and each word. In particular, each word receives information from its predecessor and successor simultaneously. From an initial state without information exchange, each word-level state can obtain 3-gram, 5-gram and 7-gram information after 1, 2 and 3 recurrent steps, respectively. Being connected with every word, the sentence-level state vector serves to exchange non-local information with each word. In addition, it can also be used as a global sentence-level representation for classification tasks.

Results on both classification and sequence labelling show that S-LSTM gives better accuracies compared to BiLSTM using the same number of parameters, while being faster. We release our code and models at `https://github.com/leuchine/S-LSTM`, which include all baselines and the final model.

2 Related Work

LSTM (Graves and Schmidhuber, 2005) showed its early potentials in NLP when a neural machine translation system that leverages LSTM source encoding gave highly competitive results compared to the best SMT models (Bahdanau et al., 2015). LSTM encoders have since been explored for other tasks, including syntactic parsing (Dyer et al., 2015), text classification (Yang et al., 2016) and machine reading (Hermann et al., 2015). Bi-directional extensions have become a standard configuration for achieving state-of-the-art accuracies among various tasks (Wen et al., 2015; Ma and Hovy, 2016; Dozat and Manning, 2017). S-LSTMs are similar to BiLSTMs in their recurrent bi-directional message flow between words, but different in the design of state transition.

CNNs (Krizhevsky et al., 2012) also allow better parallelisation compared to LSTMs for sentence encoding (Kim, 2014), thanks to parallelism among convolution filters. On the other hand, convolution features embody only fix-sized local n-gram information, whereas sentence-level feature aggregation via pooling can lead to loss of information (Sabour et al., 2017). In contrast, S-LSTM uses a global sentence-level node to assemble and back-distribute local information in the recurrent state transition process, suffering less information loss compared to pooling.

Attention (Bahdanau et al., 2015) has recently been explored as a standalone method for sentence encoding, giving competitive results compared to Bi-LSTM encoders for neural machine translation (Vaswani et al., 2017). The attention mechanism allows parallelisation, and can play a similar role to the sentence-level state in S-LSTMs, which uses neural gates to integrate word-level information compared to hierarchical attention. S-LSTM further allows local communication between neighbouring words.

Hierarchical stacking of CNN layers (LeCun et al., 1995; Kalchbrenner et al., 2014; Papandreou et al., 2015; Dauphin et al., 2017) allows better interaction between non-local components in a sentence via incremental levels of abstraction. S-LSTM is similar to hierarchical attention and stacked CNN in this respect, incrementally refining sentence representations. However, S-LSTM models hierarchical encoding of sentence structure as a *recurrent* state transition process. In nature, our work belongs to the family of LSTM sentence representations.

S-LSTM is inspired by message passing over graphs (Murphy et al., 1999; Scarselli et al., 2009). Graph-structure neural models have been used for computer program verification (Li et al., 2016) and image object detection (Liang et al., 2016). The closest previous work in NLP includes the use of convolutional neural networks (Bastings et al., 2017; Marcheggiani and Titov, 2017) and DAG LSTMs (Peng et al., 2017) for modelling syntactic structures. Compared to our work, their motivations and network structures are highly different. In particular, the DAG LSTM of Peng et al. (2017) is a natural extension of tree LSTM (Tai et al., 2015), and is sequential rather than parallel in nature. To our knowledge, we are the first to investigate a graph RNN for encoding sentences, proposing parallel graph states for integrating word-level and sentence-level information. In this perspective, our contribution is similar to that of Kim (2014) and Bahdanau et al. (2015) in introducing a neural representation to the NLP literature.

3 Model

Given a sentence $\boldsymbol{s} = w_1, w_2, \ldots, w_n$, where w_i represents the ith word and n is the sentence length, our goal is to find a neural representation of $\boldsymbol{s}$, which consists of a hidden vector $\boldsymbol{h}_i$ for each input word w_i, and a global sentence-level hidden vector $\boldsymbol{g}$. Here $\boldsymbol{h}_i$ represents syntactic and semantic features for w_i under the sentential context, while $\boldsymbol{g}$ represents features for the whole sentence. Following previous work, we additionally add $\langle s\rangle$ and $\langle /s\rangle$ to the two ends of the sentence as w_0 and w_{n+1}, respectively.

3.1 Baseline BiLSTM

The baseline BiLSTM model consists of two LSTM components, which process the input in the forward left-to-right and the backward right-to-left directions, respectively. In each direction, the reading of input words is modelled as a recurrent process with a single hidden state. Given an initial value, the state changes its value recurrently, each time consuming an incoming word.

Take the forward LSTM component for example. Denoting the initial state as $\overrightarrow{\boldsymbol{h}}^0$, which is a model parameter, the recurrent state transition step for calculating $\overrightarrow{\boldsymbol{h}}^1, \ldots, \overrightarrow{\boldsymbol{h}}^{n+1}$ is defined as follows (Graves and Schmidhuber, 2005):

$$\begin{aligned}
\hat{\boldsymbol{i}}^t &= \sigma(\boldsymbol{W}_i\boldsymbol{x}_t + \boldsymbol{U}_i\overrightarrow{\boldsymbol{h}}^{t-1} + \boldsymbol{b}_i)\\
\hat{\boldsymbol{f}}^t &= \sigma(\boldsymbol{W}_f\boldsymbol{x}_t + \boldsymbol{U}_f\overrightarrow{\boldsymbol{h}}^{t-1} + \boldsymbol{b}_f)\\
\boldsymbol{o^t} &= \sigma(\boldsymbol{W}_o\boldsymbol{x}_t + \boldsymbol{U}_o\overrightarrow{\boldsymbol{h}}^{t-1} + \boldsymbol{b}_o)\\
\boldsymbol{u^t} &= tanh(\boldsymbol{W}_u\boldsymbol{x}_t + \boldsymbol{U}_u\overrightarrow{\boldsymbol{h}}^{t-1} + \boldsymbol{b}_u)\\
\boldsymbol{i}^t, \boldsymbol{f}^t &= softmax(\hat{\boldsymbol{i}}^t, \hat{\boldsymbol{f}}^t)\\
\boldsymbol{c}^t &= \boldsymbol{c}^{t-1} \odot \boldsymbol{f}^t + \boldsymbol{u}^t \odot \boldsymbol{i}^t\\
\overrightarrow{\boldsymbol{h}}^t &= \boldsymbol{o}^t \odot tanh(\boldsymbol{c}^t)
\end{aligned} \tag{1}$$

where $\boldsymbol{x}_t$ denotes the word representation of w_t; $\boldsymbol{i}^t$, $\boldsymbol{o}^t$, $\boldsymbol{f}^t$ and $\boldsymbol{u}^t$ represent the values of an input gate, an output gate, a forget gate and an actual input at time step t, respectively, which controls the information flow for a recurrent cell $\overrightarrow{\boldsymbol{c}}^t$ and the state vector $\overrightarrow{\boldsymbol{h}}^t$; $\boldsymbol{W}_x$, $\boldsymbol{U}_x$ and $\boldsymbol{b}_x$ ($x \in \{i, o, f, u\}$) are model parameters. σ is the sigmoid function.

The backward LSTM component follows the same recurrent state transition process as described in Eq 1. Starting from an initial state $\boldsymbol{h}^{n+1}$, which is a model parameter, it reads the input $\boldsymbol{x}_n$, $\boldsymbol{x}_{n-1}, \ldots, \boldsymbol{x}_0$, changing its value to $\overleftarrow{\boldsymbol{h}}^n$, $\overleftarrow{\boldsymbol{h}}^{n-1}$, $\ldots$, $\overleftarrow{\boldsymbol{h}}^0$, respectively. A separate set of parameters $\hat{\boldsymbol{W}}_x$, $\hat{\boldsymbol{U}}_x$ and $\hat{\boldsymbol{b}}_x$ ($x \in \{i, o, f, u\}$) are used for the backward component.

The BiLSTM model uses the concatenated value of $\overrightarrow{\boldsymbol{h}}^t$ and $\overleftarrow{\boldsymbol{h}}^t$ as the hidden vector for w_t:

$$\boldsymbol{h}^t = [\overrightarrow{\boldsymbol{h}}^t; \overleftarrow{\boldsymbol{h}}^t]$$

A single hidden vector representation $\boldsymbol{g}$ of the whole input sentence can be obtained using the final state values of the two LSTM components:

$$\boldsymbol{g} = [\overrightarrow{\boldsymbol{h}}^{n+1}; \overleftarrow{\boldsymbol{h}}^0]$$

Stacked BiLSTM Multiple layers of BiLTMs can be stacked for increased representation power, where the hidden vectors of a lower layer are used as inputs for an upper layer. Different model parameters are used in each stacked BiLSTM layer.

3.2 Sentence-State LSTM

Formally, an S-LSTM state at time step t can be denoted by:

$$\boldsymbol{H}^t = \langle \boldsymbol{h}_0^t, \boldsymbol{h}_1^t, \ldots, \boldsymbol{h}_{n+1}^t, \boldsymbol{g}^t\rangle,$$

which consists of a sub state $\boldsymbol{h}_i^t$ for each word w_i and a sentence-level sub state $\boldsymbol{g}^t$.

S-LSTM uses a recurrent state transition process to model information exchange between sub states, which enriches state representations incrementally. For the initial state $\boldsymbol{H}^0$, we set $\boldsymbol{h}_i^0 = \boldsymbol{g}^0 = \boldsymbol{h}^0$, where $\boldsymbol{h}^0$ is a parameter. The state transition from $\boldsymbol{H}^{t-1}$ to $\boldsymbol{H}^t$ consists of sub state transitions from $\boldsymbol{h}_i^{t-1}$ to $\boldsymbol{h}_i^t$ and from $\boldsymbol{g}^{t-1}$ to $\boldsymbol{g}^t$. We take an LSTM structure similar to the baseline BiLSTM for modelling state transition, using a recurrent cell $\boldsymbol{c}_i^t$ for each w_i and a cell $\boldsymbol{c}_g^t$ for $\boldsymbol{g}$.

As shown in Figure 1, the value of each $\boldsymbol{h}_i^t$ is computed based on the values of $\boldsymbol{x}_i$, $\boldsymbol{h}_{i-1}^{t-1}$, $\boldsymbol{h}_i^{t-1}$, $\boldsymbol{h}_{i+1}^{t-1}$ and $\boldsymbol{g}^{t-1}$, together with their corresponding cell values:

$$\begin{aligned}
\boldsymbol{\xi}_i^t &= [\boldsymbol{h}_{i-1}^{t-1}, \boldsymbol{h}_i^{t-1}, \boldsymbol{h}_{i+1}^{t-1}]\\
\hat{\boldsymbol{i}}_i^t &= \sigma(\boldsymbol{W}_i\boldsymbol{\xi}_i^t + \boldsymbol{U}_i\boldsymbol{x}_i + \boldsymbol{V}_i\boldsymbol{g}^{t-1} + \boldsymbol{b}_i)\\
\hat{\boldsymbol{l}}_i^t &= \sigma(\boldsymbol{W}_l\boldsymbol{\xi}_i^t + \boldsymbol{U}_l\boldsymbol{x}_i + \boldsymbol{V}_l\boldsymbol{g}^{t-1} + \boldsymbol{b}_l)\\
\hat{\boldsymbol{r}}_i^t &= \sigma(\boldsymbol{W}_r\boldsymbol{\xi}_i^t + \boldsymbol{U}_r\boldsymbol{x}_i + \boldsymbol{V}_r\boldsymbol{g}^{t-1} + \boldsymbol{b}_r)\\
\hat{\boldsymbol{f}}_i^t &= \sigma(\boldsymbol{W}_f\boldsymbol{\xi}_i^t + \boldsymbol{U}_f\boldsymbol{x}_i + \boldsymbol{V}_f\boldsymbol{g}^{t-1} + \boldsymbol{b}_f)\\
\hat{\boldsymbol{s}}_i^t &= \sigma(\boldsymbol{W}_s\boldsymbol{\xi}_i^t + \boldsymbol{U}_s\boldsymbol{x}_i + \boldsymbol{V}_s\boldsymbol{g}^{t-1} + \boldsymbol{b}_s)\\
\boldsymbol{o}_i^t &= \sigma(\boldsymbol{W}_o\boldsymbol{\xi}_i^t + \boldsymbol{U}_o\boldsymbol{x}_i + \boldsymbol{V}_o\boldsymbol{g}^{t-1} + \boldsymbol{b}_o)\\
\boldsymbol{u}_i^t &= tanh(\boldsymbol{W}_u\boldsymbol{\xi}_i^t + \boldsymbol{U}_u\boldsymbol{x}_i + \boldsymbol{V}_u\boldsymbol{g}^{t-1} + \boldsymbol{b}_u)\\
\boldsymbol{i}_i^t, \boldsymbol{l}_i^t, \boldsymbol{r}_i^t, \boldsymbol{f}_i^t, \boldsymbol{s}_i^t &= softmax(\hat{\boldsymbol{i}}_i^t, \hat{\boldsymbol{l}}_i^t, \hat{\boldsymbol{r}}_i^t, \hat{\boldsymbol{f}}_i^t, \hat{\boldsymbol{s}}_i^t)\\
\boldsymbol{c}_i^t &= \boldsymbol{l}_i^t \odot \boldsymbol{c}_{i-1}^{t-1} + \boldsymbol{f}_i^t \odot \boldsymbol{c}_i^{t-1} + \boldsymbol{r}_i^t \odot \boldsymbol{c}_{i+1}^{t-1}\\
&\quad + \boldsymbol{s}_i^t \odot \boldsymbol{c}_g^{t-1} + \boldsymbol{i}_i^t \odot \boldsymbol{u}_i^t\\
\boldsymbol{h}_i^t &= \boldsymbol{o}_t^i \odot tanh(\boldsymbol{c}_i^t)
\end{aligned} \tag{2}$$

where $\boldsymbol{\xi}_i^t$ is the concatenation of hidden vectors of a context window, and $\boldsymbol{l}_i^t$, $\boldsymbol{r}_i^t$, $\boldsymbol{f}_i^t$, $\boldsymbol{s}_i^t$ and $\boldsymbol{i}_i^t$ are gates that control information flow from $\boldsymbol{\xi}_i^t$ and $\boldsymbol{x}_i$ to $\boldsymbol{c}_i^t$. In particular, $\boldsymbol{i}_i^t$ controls information from the input $\boldsymbol{x}_i$; $\boldsymbol{l}_i^t$, $\boldsymbol{r}_i^t$, $\boldsymbol{f}_i^t$ and $\boldsymbol{s}_i^t$ control information from the left context cell $\boldsymbol{c}_{i-1}^{t-1}$, the right context cell $\boldsymbol{c}_{i+1}^{t-1}$, $\boldsymbol{c}_i^{t-1}$ and the sentence context cell $\boldsymbol{c}_g^{t-1}$, respectively. The values of $\boldsymbol{i}_i^t$, $\boldsymbol{l}_i^t$, $\boldsymbol{r}_i^t$, $\boldsymbol{f}_i^t$ and $\boldsymbol{s}_i^t$ are normalised such that they sum to $\mathbf{1}$. $\boldsymbol{o}_i^t$ is an output gate from the cell state $\boldsymbol{c}_i^t$ to the hidden state $\boldsymbol{h}_i^t$. $\boldsymbol{W}_x$, $\boldsymbol{U}_x$, $\boldsymbol{V}_x$ and $\boldsymbol{b}_x$ ($x \in \{i, o, l, r, f, s, u\}$) are model parameters. σ is the sigmoid function.

The value of $\boldsymbol{g}^t$ is computed based on the values of $\boldsymbol{h}_i^{t-1}$ for all $i \in [0..n+1]$:

$$
\begin{aligned}
\bar{\boldsymbol{h}} &= avg(\boldsymbol{h}_0^{t-1}, \boldsymbol{h}_1^{t-1}, \ldots, \boldsymbol{h}_{n+1}^{t-1}) \\
\hat{\boldsymbol{f}}_g^t &= \sigma(\boldsymbol{W}_g \boldsymbol{g}^{t-1} + \boldsymbol{U}_g \bar{\boldsymbol{h}} + \boldsymbol{b}_g) \\
\hat{\boldsymbol{f}}_i^t &= \sigma(\boldsymbol{W}_f \boldsymbol{g}^{t-1} + \boldsymbol{U}_f \boldsymbol{h}_i^{t-1} + \boldsymbol{b}_f) \\
\boldsymbol{o}^t &= \sigma(\boldsymbol{W}_o \boldsymbol{g}^{t-1} + \boldsymbol{U}_o \bar{\boldsymbol{h}} + \boldsymbol{b}_o) \\
\boldsymbol{f}_0^t, \ldots, \boldsymbol{f}_{n+1}^t, \boldsymbol{f}_g^t &= softmax(\hat{\boldsymbol{f}}_0^t, \ldots, \hat{\boldsymbol{f}}_{n+1}^t, \hat{\boldsymbol{f}}_g^t) \\
\boldsymbol{c}_g^t &= \boldsymbol{f}_g^t \odot \boldsymbol{c}_g^{t-1} + \sum_i \boldsymbol{f}_i^t \odot \boldsymbol{c}_i^{t-1} \\
\boldsymbol{g}^t &= \boldsymbol{o}^t \odot tanh(\boldsymbol{c}_g^t)
\end{aligned}
\tag{3}
$$

where $\boldsymbol{f}_0^t, \ldots, \boldsymbol{f}_{n+1}^t$ and $\boldsymbol{f}_g^t$ are gates controlling information from $\boldsymbol{c}_0^{t-1}, \ldots, \boldsymbol{c}_{n+1}^{t-1}$ and $\boldsymbol{c}_g^{t-1}$, respectively, which are normalised. $\boldsymbol{o}^t$ is an output gate from the recurrent cell $\boldsymbol{c}_g^t$ to $\boldsymbol{g}^t$. $\boldsymbol{W}_x$, $\boldsymbol{U}_x$ and $\boldsymbol{b}_x$ ($x \in \{g, f, o\}$) are model parameters.

Contrast with BiLSTM The difference between S-LSTM and BiLSTM can be understood with respect to their recurrent states. While BiLSTM uses only one state in each direction to represent the subsequence from the beginning to a certain word, S-LSTM uses a structural state to represent the full sentence, which consists of a sentence-level sub state and $n + 2$ word-level sub states, simultaneously. Different from BiLSTMs, for which $\boldsymbol{h}^t$ at different time steps are used to represent $w_0, \ldots, w_{n+1}$, respectively, the word-level states $\boldsymbol{h}_i^t$ and sentence-level state $\boldsymbol{g}^t$ of S-LSTMs directly correspond to the goal outputs $\boldsymbol{h}_i$ and $\boldsymbol{g}$, as introduced in the beginning of this section. As t increases from 0, $\boldsymbol{h}_i^t$ and $\boldsymbol{g}^t$ are enriched with increasingly deeper context information.

From the perspective of information flow, BiLSTM passes information from one end of the sentence to the other. As a result, the number of time steps scales with the size of the input. In contrast, S-LSTM allows bi-directional information flow at each word simultaneously, and additionally between the sentence-level state and every word-level state. At each step, each $\boldsymbol{h}_i$ captures an increasing larger ngram context, while additionally communicating globally to all other $\boldsymbol{h}_j$ via $\boldsymbol{g}$. The optimal number of recurrent steps is decided by the end-task performance, and does not necessarily scale with the sentence size. As a result, S-LSTM can potentially be both more efficient and more accurate compared with BiLSTMs.

Increasing window size. By default S-LSTM exchanges information only between neighbouring words, which can be seen as adopting a 1-word window on each side. The window size can be extended to 2, 3 or more words in order to allow more communication in a state transition, expediting information exchange. To this end, we modify Eq 2, integrating additional context words to $\boldsymbol{\xi}_i^t$, with extended gates and cells. For example, with a window size of 2, $\boldsymbol{\xi}_i^t = [\boldsymbol{h}_{i-2}^{t-1}, \boldsymbol{h}_{i-1}^{t-1}, \boldsymbol{h}_i^{t-1}, \boldsymbol{h}_{i+1}^{t-1}, \boldsymbol{h}_{i+2}^{t-1}]$. We study the effectiveness of window size in our experiments.

Additional sentence-level nodes. By default S-LSTM uses one sentence-level node. One way of enriching the parameter space is to add more sentence-level nodes, each communicating with word-level nodes in the same way as described by Eq 3. In addition, different sentence-level nodes can communicate with each other during state transition. When one sentence-level node is used for classification outputs, the other sentence-level node can serve as hidden memory units, or latent features. We study the effectiveness of multiple sentence-level nodes empirically.

3.3 Task settings

We consider two task settings, namely classification and sequence labelling. For *classification*, $\boldsymbol{g}$ is fed to a *softmax* classification layer:

$$\boldsymbol{y} = softmax(\boldsymbol{W}_c \boldsymbol{g} + \boldsymbol{b}_c)$$

where $\boldsymbol{y}$ is the probability distribution of output class labels and $\boldsymbol{W}_c$ and $\boldsymbol{b}_c$ are model parameters. For *sequence labelling*, each $\boldsymbol{h}_i$ can be used as feature representation for a corresponding word w_i.

External attention It has been shown that summation of hidden states using attention (Bahdanau et al., 2015; Yang et al., 2016) give better accuracies compared to using the end states of BiLSTMs. We study the influence of attention on both S-LSTM and BiLSTM for *classification*. In particular, additive attention (Bahdanau

Table 1: Dataset statistics

et al., 2015) is applied to the hidden states of input words for both BiLSTMs and S-LSTMs calculating a weighted sum

$$\boldsymbol{g} = \sum_t \alpha_t \boldsymbol{h}_t$$

where

$$\alpha_t = \frac{\exp \boldsymbol{u}^T \boldsymbol{\epsilon}_t}{\sum_i \exp \boldsymbol{u}^T \boldsymbol{\epsilon}_i}$$

$$\boldsymbol{\epsilon}_t = tanh(\boldsymbol{W}_\alpha \boldsymbol{h}_t + \boldsymbol{b}_\alpha)$$

Here $\boldsymbol{W}_\alpha$, $\boldsymbol{u}$ and $\boldsymbol{b}_\alpha$ are model parameters.

External CRF For *sequential labelling*, we use a CRF layer on top of the hidden vectors $\boldsymbol{h}_1, \boldsymbol{h}_2, \ldots, \boldsymbol{h}_n$ for calculating the conditional probabilities of label sequences (Huang et al., 2015; Ma and Hovy, 2016):

$$P(\boldsymbol{Y}_1^n | \boldsymbol{h}, \boldsymbol{W}_s, \boldsymbol{b}_s) = \frac{\prod_{i=1}^n \psi_i(y_{i-1}, y_i, \boldsymbol{h})}{\sum_{\boldsymbol{Y}_1^{n\prime}} \prod_{i=1}^n \psi_i(y'_{i-1}, y'_i, \boldsymbol{h})}$$

$$\psi_i(y_{i-1}, y_i, \boldsymbol{h}) = exp(\boldsymbol{W}_s^{y_{i-1}, y_i} h_i + b_s^{y_{i-1}, y_i})$$

where $\boldsymbol{W}_s^{y_{i-1}, y_i}$ and $b_s^{y_{i-1}, y_i}$ are parameters specific to two consecutive labels y_{i-1} and y_i.

For training, standard log-likelihood loss is used with L_2 regularization given a set of gold-standard instances.

4 Experiments

We empirically compare S-LSTMs and BiLSTMs on different classification and sequence labelling tasks. All experiments are conducted using a GeForce GTX 1080 GPU with 8GB memory.

Model	Time (s)	Acc	# Param

With ⟨s⟩, ⟨/s⟩	65	82.64	8,768K

Table 2: Movie review DEV results of S-LSTM

4.1 Experimental Settings

Datasets. We choose the movie review dataset of Pang and Lee (2008), and additionally the 16 datasets of Liu et al. (2017) for classification evaluation. We randomly split the movie review dataset into training (80%), development (10%) and test (10%) sections, and the original split of Liu et al. (2017) for the 16 classification datasets.

For sequence labelling, we choose the Penn Treebank (Marcus et al., 1993) POS tagging task and the CoNLL (Sang et al., 2003) NER task as our benchmarks. For POS tagging, we follow the standard split (Manning, 2011), using sections 0 – 18 for training, 19 – 21 for development and 22 – 24 for test. For NER, we follow the standard split, and use the BIOES tagging scheme (Ratinov and Roth, 2009). Statistics of the four datasets are shown in Table 1.

Hyperparameters. We initialise word embeddings using GloVe (Pennington et al., 2014) 300 dimensional embeddings.[1] Embeddings are fine-tuned during model training for all tasks. Dropout (Srivastava et al., 2014) is applied to embedding hidden states, with a rate of 0.5. All models are optimised using the Adam optimizer (Kingma and Ba, 2014), with an initial learning rate of 0.001 and a decay rate of 0.97. Gradients are clipped at 3 and a batch size of 10 is adopted. Sentences with similar lengths are batched together. The L2 regularization parameter is set to 0.001.

4.2 Development Experiments

We use the movie review development data to investigate different configurations of S-LSTMs and BiLSTMs. For S-LSTMs, the default configuration uses $\langle s \rangle$ and $\langle /s \rangle$ words for augmenting words

[1]https://nlp.stanford.edu/projects/glove/

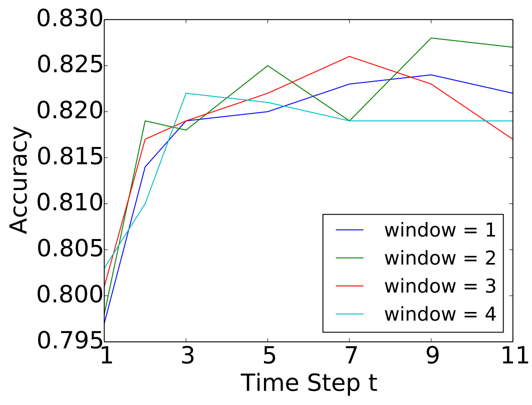

Figure 2: Accuracies with various window sizes and time steps on movie review development set

of a sentence. A hidden layer size of 300 and one sentence-level node are used.

Hyperparameters: Table 2 shows the development results of various S-LSTM settings, where Time refers to training time per epoch. Without the sentence-level node, the accuracy of S-LSTM drops to 81.76%, demonstrating the necessity of global information exchange. Adding one additional sentence-level node as described in Section 3.2 does not lead to accuracy improvements, although the number of parameters and decoding time increase accordingly. As a result, we use only 1 sentence-level node for the remaining experiments. The accuracies of S-LSTM increases as the hidden layer size for each node increases from 100 to 300, but does not further increase when the size increases beyond 300. We fix the hidden size to 300 accordingly. Without using $\langle s \rangle$ and $\langle /s \rangle$, the performance of S-LSTM drops from 82.64% to 82.36%, showing the effectiveness of having these additional nodes. Hyperparameters for BiLSTM models are also set according to the development data, which we omit here.

State transition. In Table 2, the number of recurrent state transition steps of S-LSTM is decided according to the best development performance. Figure 2 draws the development accuracies of S-LSTMs with various window sizes against the number of recurrent steps. As can be seen from the figure, when the number of time steps increases from 1 to 11, the accuracies generally increase, before reaching a maximum value. This shows the effectiveness of recurrent information exchange in S-LSTM state transition.

On the other hand, no significant differences are observed on the peak accuracies given by different window sizes, although a larger window size (e.g. 4) generally results in faster plateauing. This can be be explained by the intuition that information exchange between distant nodes can be achieved using more recurrent steps under a smaller window size, as can be achieved using fewer steps under a larger window size. Considering efficiency, we choose a window size of 1 for the remaining experiments, setting the number of recurrent steps to 9 according to Figure 2.

Table 3: Movie review development results

S-LSTM vs BiLSTM: As shown in Table 3, BiLSTM gives significantly better accuracies compared to uni-directional LSTM[2], with the training time per epoch growing from 67 seconds to 106 seconds. Stacking 2 layers of BiLSTM gives further improvements to development results, with a larger time of 207 seconds. 3 layers of stacked BiLSTM does not further improve the results. In contrast, S-LSTM gives a development result of 82.64%, which is significantly better compared to 2-layer stacked BiLSTM, with a smaller number of model parameters and a shorter time of 65 seconds.

We additionally make comparisons with stacked CNNs and hierarchical attention (Vaswani et al., 2017), shown in Table 3 (the CNN and Transformer rows), where N indicates the number of attention layers. CNN is the most efficient among all models compared, with the smallest model size. On the other hand, a 3-layer stacked CNN gives an accuracy of 81.46%, which is also

[2] $p < 0.01$ using t-test. For the remaining of this paper, we use the same measure for statistical significance.

Model	Accuracy	Train (s)	Test (s)
Socher et al. (2011)	77.70	–	–
Socher et al. (2012)	79.00	–	–
Kim (2014)	81.50	–	–
Qian et al. (2016)	81.50	–	–
BiLSTM	81.61	51	1.62
2 stacked BiLSTM	81.94	98	3.18
3 stacked BiLSTM	81.71	137	4.67
3 stacked CNN	81.59	31	1.04
Transformer (N=8)	81.97	89	2.75
S-LSTM	**82.45***	41	1.53

Table 4: Test set results on movie review dataset (* denotes significance in all tables).

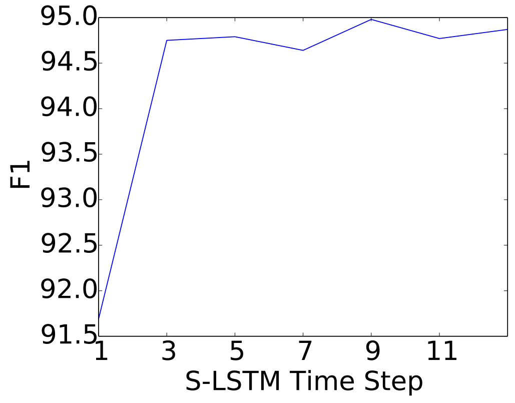
the lowest compared with BiLSTM, hierarchical attention and S-LSTM. The best performance of hierarchical attention is between single-layer and two-layer BiLSTMs in terms of both accuracy and efficiency. S-LSTM gives significantly better accuracies compared with both CNN and hierarchical attention.

Influence of external attention mechanism. Table 3 additionally shows the results of BiLSTM and S-LSTM when external attention is used as described in Section 3.3. Attention leads to improved accuracies for both BiLSTM and S-LSTM in classification, with S-LSTM still outperforming BiLSTM significantly. The result suggests that external techniques such as attention can play orthogonal roles compared with internal recurrent structures, therefore benefiting both BiLSTMs and S-LSTMs. Similar observations are found using external CRF layers for sequence labelling.

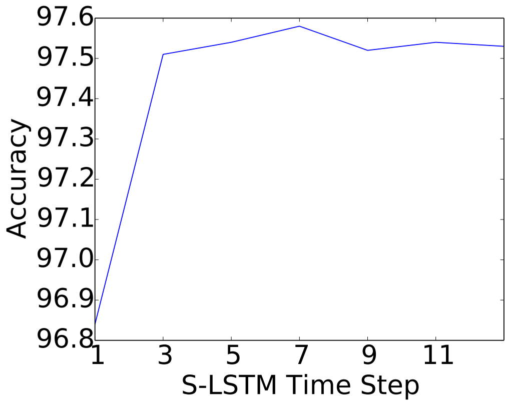
4.3 Final Results for Classification

The final results on the movie review and rich text classification datasets are shown in Tables 4 and 5, respectively. In addition to training time per epoch, test times are additionally reported. We use the best settings on the movie review development dataset for both S-LSTMs and BiLSTMs. The step number for S-LSTMs is set to 9.

As shown in Table 4, the final results on the movie review dataset are consistent with the development results, where S-LSTM outperforms BiLSTM significantly, with a faster speed. Observations on CNN and hierarchical attention are consistent with the development results. S-LSTM also gives highly competitive results when compared with existing methods in the literature.



(a) CoNLL03



(b) WSJ

Figure 3: Sequence labelling development results.

As shown in Table 5, among the 16 datasets of Liu et al. (2017), S-LSTM gives the best results on 12, compared with BiLSTM and 2 layered BiLSTM models. The average accuracy of S-LSTM is 85.6%, significantly higher compared with 84.9% by 2-layer stacked BiLSTM. 3-layer stacked BiLSTM gives an average accuracy of 84.57%, which is lower compared to a 2-layer stacked BiLSTM, with a training time per epoch of 423.6 seconds. The relative speed advantage of S-LSTM over BiLSTM is larger on the 16 datasets as compared to the movie review test test. This is because the average length of inputs is larger on the 16 datasets (see Section 4.5).

4.4 Final Results for Sequence Labelling

Bi-directional RNN-CRF structures, and in particular BiLSTM-CRFs, have achieved the state of the art in the literature for sequence labelling tasks, including POS-tagging and NER. We compare S-LSTM-CRF with BiLSTM-CRF for sequence labelling, using the same settings as decided on the movie review development experiments for both BiLSTMs and S-LSTMs. For the latter, we decide

Table 7: Results on CoNLL03 (NER)

the number of recurrent steps on the respective development sets for sequence labelling. The POS accuracies and NER F1-scores against the number of recurrent steps are shown in Figure 3 (a) and (b), respectively. For POS tagging, the best step number is set to 7, with a development accuracy of 97.58%. For NER, the step number is set to 9, with a development F1-score of 94.98%.

As can be seen in Table 6, S-LSTM gives significantly better results compared with BiLSTM on the WSJ dataset. It also gives competitive accuracies as compared with existing methods in the literature. Stacking two layers of BiLSTMs leads to improved results compared to one-layer BiLSTM, but the accuracy does not further improve with three layers of stacked LSTMs.

For NER (Table 7), S-LSTM gives an F1-score of 91.57% on the CoNLL test set, which is significantly better compared with BiLSTMs. Stacking more layers of BiLSTMs leads to slightly better F1-scores compared with a single-layer BiLSTM. Our BiLSTM results are comparable to the results reported by Ma and Hovy (2016) and Lample et al. (2016), who also use bidirectional RNN-CRF structures. In contrast, S-LSTM gives the best reported results under the same settings.

In the second section of Table 7, Yang et al. (2017) use cross-domain data, obtaining an F-score of 91.26%; Rei (2017) perform multi-task

learning using additional language model objectives, obtaining an F-score of 86.26%; Peters et al. (2017) leverage character-level language models, obtaining an F-score of 91.93%, which is the current best result on the dataset. All the three models are based on BiLSTM-CRF. On the other hand, these semi-supervised learning techniques are orthogonal to our work, and can potentially be used for S-LSTM also.

4.5 Analysis

Figure 4 (a) and (b) show the accuracies against the sentence length on the movie review and CoNLL datasets, respectively, where test samples are binned in batches of 80. We find that the performances of both S-LSTM and BiLSTM decrease as the sentence length increases. On the other hand, S-LSTM demonstrates relatively better robustness compared to BiLSTMs. This confirms our intuition that a sentence-level node can facilitate better non-local communication.

Figure 5 shows the training time per epoch of S-LSTM and BiLSTM on sentences with different lengths on the 16 classification datasets. To make these comparisons, we mix all training instances, order them by the size, and put them into 10 equal groups, the medium sentence lengths of which are shown. As can be seen from the figure, the speed advantage of S-LSTM is larger when the size of the input text increases, thanks to a fixed number of recurrent steps.

Similar to hierarchical attention (Vaswani et al., 2017), there is a relative disadvantage of S-LSTM in comparison with BiLSTM, which is that the memory consumption is relatively larger. For example, over the movie review development set, the actual GPU memory consumption by S-LSTM, BiLSTM, 2-layer stacked BiLSTM and 4-layer stacked BiLSTM are 252M, 89M, 146M and 253M, respectively. This is due to the fact that computation is performed in parallel by S-LSTM and hierarchical attention.

5 Conclusion

We have investigated S-LSTM, a recurrent neural network for encoding sentences, which offers richer contextual information exchange with more parallelism compared to BiLSTMs. Results on a range of classification and sequence labelling tasks show that S-LSTM outperforms BiLSTMs using the same number of parameters, demonstrating that S-LSTM can be a useful addition to the neural toolbox for encoding sentences.

The structural nature in S-LSTM states allows straightforward extension to tree structures, resulting in highly parallelisable tree LSTMs. We leave such investigation to future work. Next directions also include the investigation of S-LSTM to more NLP tasks, such as machine translation.

Abstract

Inductive transfer learning has greatly impacted computer vision, but existing approaches in NLP still require task-specific modifications and training from scratch. We propose Universal Language Model Fine-tuning (ULMFiT), an effective transfer learning method that can be applied to any task in NLP, and introduce techniques that are key for fine-tuning a language model. Our method significantly outperforms the state-of-the-art on six text classification tasks, reducing the error by 18-24% on the majority of datasets. Furthermore, with only 100 labeled examples, it matches the performance of training from scratch on 100× more data. We open-source our pretrained models and code[1].

1 Introduction

Inductive transfer learning has had a large impact on computer vision (CV). Applied CV models (including object detection, classification, and segmentation) are rarely trained from scratch, but instead are fine-tuned from models that have been pretrained on ImageNet, MS-COCO, and other datasets (Sharif Razavian et al., 2014; Long et al., 2015a; He et al., 2016; Huang et al., 2017).

Text classification is a category of Natural Language Processing (NLP) tasks with real-world applications such as spam, fraud, and bot detection (Jindal and Liu, 2007; Ngai et al., 2011; Chu et al., 2012), emergency response (Caragea et al., 2011), and commercial document classification, such as for legal discovery (Roitblat et al., 2010).

While Deep Learning models have achieved state-of-the-art on many NLP tasks, these models are trained from scratch, requiring large datasets, and days to converge. Research in NLP focused mostly on *transductive* transfer (Blitzer et al., 2007). For *inductive* transfer, fine-tuning pretrained word embeddings (Mikolov et al., 2013), a simple transfer technique that only targets a model's first layer, has had a large impact in practice and is used in most state-of-the-art models. Recent approaches that concatenate embeddings derived from other tasks with the input at different layers (Peters et al., 2017; McCann et al., 2017; Peters et al., 2018) still train the main task model from scratch and treat pretrained embeddings as fixed parameters, limiting their usefulness.

In light of the benefits of pretraining (Erhan et al., 2010), we should be able to do better than *randomly initializing* the remaining parameters of our models. However, inductive transfer via fine-tuning has been unsuccessful for NLP (Mou et al., 2016). Dai and Le (2015) first proposed fine-tuning a language model (LM) but require millions of in-domain documents to achieve good performance, which severely limits its applicability.

We show that not the idea of LM fine-tuning but our lack of knowledge of how to train them effectively has been hindering wider adoption. LMs overfit to small datasets and suffered catastrophic forgetting when fine-tuned with a classifier. Compared to CV, NLP models are typically more shallow and thus require different fine-tuning methods.

We propose a new method, Universal Language Model Fine-tuning (ULMFiT) that addresses these issues and enables robust inductive transfer learning for any NLP task, akin to fine-tuning ImageNet models: The same 3-layer LSTM architecture—with the same hyperparameters and no additions other than tuned dropout hyperparameters—outperforms highly engineered models and trans-

[1] http://nlp.fast.ai/ulmfit.
[*] Equal contribution. Jeremy focused on the algorithm development and implementation, Sebastian focused on the experiments and writing.

fer learning approaches on six widely studied text classification tasks. On IMDb, with 100 labeled examples, ULMFiT matches the performance of training from scratch with $10\times$ and—given 50k unlabeled examples—with $100\times$ more data.

Contributions Our contributions are the following: 1) We propose Universal Language Model Fine-tuning (ULMFiT), a method that can be used to achieve CV-like transfer learning for any task for NLP. 2) We propose *discriminative fine-tuning*, *slanted triangular learning rates*, and *gradual unfreezing*, novel techniques to retain previous knowledge and avoid catastrophic forgetting during fine-tuning. 3) We significantly outperform the state-of-the-art on six representative text classification datasets, with an error reduction of 18-24% on the majority of datasets. 4) We show that our method enables extremely sample-efficient transfer learning and perform an extensive ablation analysis. 5) We make the pretrained models and our code available to enable wider adoption.

2 Related work

Transfer learning in CV Features in deep neural networks in CV have been observed to transition from task-*specific* to *general* from the first to the last layer (Yosinski et al., 2014). For this reason, most work in CV focuses on transferring the last layers of the model (Long et al., 2015b). Sharif Razavian et al. (2014) achieve state-of-the-art results using features of an ImageNet model as input to a simple classifier. In recent years, this approach has been superseded by fine-tuning either the last (Donahue et al., 2014) or several of the last layers of a pretrained model and leaving the remaining layers frozen (Long et al., 2015a).

Hypercolumns In NLP, only recently have methods been proposed that go beyond transferring word embeddings. The prevailing approach is to pretrain embeddings that capture additional context via other tasks. Embeddings at different levels are then used as features, concatenated either with the word embeddings or with the inputs at intermediate layers. This method is known as hypercolumns (Hariharan et al., 2015) in CV[2] and is used by Peters et al. (2017), Peters et al. (2018), Wieting and Gimpel (2017), Conneau et al. (2017), and McCann et al. (2017) who use language modeling, paraphrasing, entailment, and Machine Translation (MT) respectively for pretraining. Specifically, Peters et al. (2018) require engineered custom architectures, while we show state-of-the-art performance with the same basic architecture across a range of tasks. In CV, hypercolumns have been nearly entirely superseded by end-to-end fine-tuning (Long et al., 2015a).

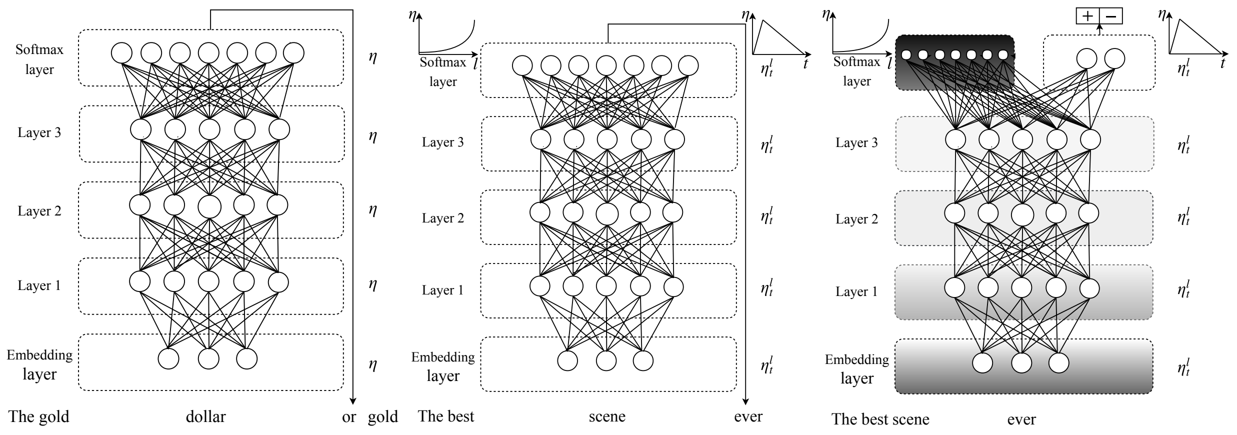
[2]A hypercolumn at a pixel in CV is the vector of activations of all CNN units above that pixel. In analogy, a hypercolumn for a word or sentence in NLP is the concatenation of embeddings at different layers in a pretrained model.

Multi-task learning A related direction is multi-task learning (MTL) (Caruana, 1993). This is the approach taken by Rei (2017) and Liu et al. (2018) who add a language modeling objective to the model that is trained jointly with the main task model. MTL requires the tasks to be trained from scratch every time, which makes it inefficient and often requires careful weighting of the task-specific objective functions (Chen et al., 2017).

Fine-tuning Fine-tuning has been used successfully to transfer between similar tasks, e.g. in QA (Min et al., 2017), for distantly supervised sentiment analysis (Severyn and Moschitti, 2015), or MT domains (Sennrich et al., 2015) but has been shown to fail between unrelated ones (Mou et al., 2016). Dai and Le (2015) also fine-tune a language model, but overfit with 10k labeled examples and require millions of in-domain documents for good performance. In contrast, ULMFiT leverages general-domain pretraining and novel fine-tuning techniques to prevent overfitting even with only 100 labeled examples and achieves state-of-the-art results also on small datasets.

3 Universal Language Model Fine-tuning

We are interested in the most general *inductive* transfer learning setting for NLP (Pan and Yang, 2010): Given a static source task $\mathcal{T}_S$ and *any* target task $\mathcal{T}_T$ with $\mathcal{T}_S \neq \mathcal{T}_T$, we would like to improve performance on $\mathcal{T}_T$. Language modeling can be seen as the ideal source task and a counterpart of ImageNet for NLP: It captures many facets of language relevant for downstream tasks, such as long-term dependencies (Linzen et al., 2016), hierarchical relations (Gulordava et al., 2018), and sentiment (Radford et al., 2017). In contrast to tasks like MT (McCann et al., 2017) and entailment (Conneau et al., 2017), it provides data in near-unlimited quantities for most domains and languages. Additionally, a pretrained LM can be easily adapted to the idiosyncrasies of a target



(a) LM pre-training (b) LM fine-tuning (c) Classifier fine-tuning

Figure 1: ULMFiT consists of three stages: a) The LM is trained on a general-domain corpus to capture general features of the language in different layers. b) The full LM is fine-tuned on target task data using discriminative fine-tuning (‘*Discr*’) and slanted triangular learning rates (STLR) to learn task-specific features. c) The classifier is fine-tuned on the target task using gradual unfreezing, ‘*Discr*’, and STLR to preserve low-level representations and adapt high-level ones (shaded: unfreezing stages; black: frozen).

task, which we show significantly improves performance (see Section 5). Moreover, language modeling already is a key component of existing tasks such as MT and dialogue modeling. Formally, language modeling induces a hypothesis space $\mathcal{H}$ that should be useful for many other NLP tasks (Vapnik and Kotz, 1982; Baxter, 2000).

We propose Universal Language Model Fine-tuning (ULMFiT), which pretrains a language model (LM) on a large general-domain corpus and fine-tunes it on the target task using novel techniques. The method is *universal* in the sense that it meets these practical criteria: 1) It works across tasks varying in document size, number, and label type; 2) it uses a single architecture and training process; 3) it requires no custom feature engineering or preprocessing; and 4) it does not require additional in-domain documents or labels.

In our experiments, we use the state-of-the-art language model AWD-LSTM (Merity et al., 2017a), a regular LSTM (with no attention, short-cut connections, or other sophisticated additions) with various tuned dropout hyperparameters. Analogous to CV, we expect that downstream performance can be improved by using higher-performance language models in the future.

ULMFiT consists of the following steps, which we show in Figure 1: a) General-domain LM pretraining (§3.1); b) target task LM fine-tuning (§3.2); and c) target task classifier fine-tuning (§3.3). We discuss these in the following sections.

3.1 General-domain LM pretraining

An ImageNet-like corpus for language should be large and capture general properties of language. We pretrain the language model on Wikitext-103 (Merity et al., 2017b) consisting of 28,595 preprocessed Wikipedia articles and 103 million words. Pretraining is most beneficial for tasks with small datasets and enables generalization even with 100 labeled examples. We leave the exploration of more diverse pretraining corpora to future work, but expect that they would boost performance. While this stage is the most expensive, it only needs to be performed once and improves performance and convergence of downstream models.

3.2 Target task LM fine-tuning

No matter how diverse the general-domain data used for pretraining is, the data of the target task will likely come from a different distribution. We thus fine-tune the LM on data of the target task. Given a pretrained general-domain LM, this stage converges faster as it only needs to adapt to the idiosyncrasies of the target data, and it allows us to train a robust LM even for small datasets. We propose *discriminative fine-tuning* and *slanted triangular learning rates* for fine-tuning the LM, which we introduce in the following.

Discriminative fine-tuning As different layers capture *different types of information* (Yosinski et al., 2014), they should be fine-tuned to *different extents*. To this end, we propose a novel fine-tuning method, *discriminative fine-tuning*[3].

Instead of using the same learning rate for *all* layers of the model, discriminative fine-tuning allows us to tune *each* layer with different learning rates. For context, the regular stochastic gradient descent (SGD) update of a model's parameters θ at time step t looks like the following (Ruder, 2016):

$$\theta_t = \theta_{t-1} - \eta \cdot \nabla_\theta J(\theta) \tag{1}$$

where η is the learning rate and $\nabla_\theta J(\theta)$ is the gradient with regard to the model's objective function. For discriminative fine-tuning, we split the parameters θ into $\{\theta^1, \ldots, \theta^L\}$ where θ^l contains the parameters of the model at the l-th layer and L is the number of layers of the model. Similarly, we obtain $\{\eta^1, \ldots, \eta^L\}$ where η^l is the learning rate of the l-th layer.

The SGD update with discriminative fine-tuning is then the following:

$$\theta_t^l = \theta_{t-1}^l - \eta^l \cdot \nabla_{\theta^l} J(\theta) \tag{2}$$

We empirically found it to work well to first choose the learning rate η^L of the last layer by fine-tuning only the last layer and using $\eta^{l-1} = \eta^l/2.6$ as the learning rate for lower layers.

Slanted triangular learning rates For adapting its parameters to task-specific features, we would like the model to quickly converge to a suitable region of the parameter space in the beginning of training and then refine its parameters. Using the same learning rate (LR) or an annealed learning rate throughout training is not the best way to achieve this behaviour. Instead, we propose *slanted triangular learning rates* (STLR), which first linearly increases the learning rate and then linearly decays it according to the following update schedule, which can be seen in Figure 2:

$$\begin{aligned} cut &= \lfloor T \cdot cut\_frac \rfloor \\ p &= \begin{cases} t/cut, & \text{if } t < cut \\ 1 - \frac{t-cut}{cut\cdot(ratio-1)}, & \text{otherwise} \end{cases} \\ \eta_t &= \eta_{max} \cdot \frac{1 + p\cdot(ratio-1)}{ratio} \end{aligned} \tag{3}$$

where T is the number of training iterations[4], cut_frac is the fraction of iterations we increase the LR, cut is the iteration when we switch from increasing to decreasing the LR, p is the fraction of the number of iterations we have increased or will decrease the LR respectively, $ratio$ specifies how much smaller the lowest LR is from the maximum LR η_{max}, and η_t is the learning rate at iteration t. We generally use $cut\_frac = 0.1$, $ratio = 32$ and $\eta_{max} = 0.01$.

STLR modifies triangular learning rates (Smith, 2017) with a short increase and a long decay period, which we found key for good performance.[5] In Section 5, we compare against aggressive cosine annealing, a similar schedule that has recently been used to achieve state-of-the-art performance in CV (Loshchilov and Hutter, 2017).[6]

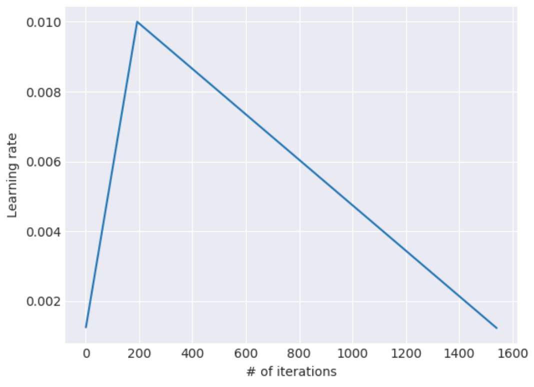


Figure 2: The slanted triangular learning rate schedule used for ULMFiT as a function of the number of training iterations.

3.3 Target task classifier fine-tuning

Finally, for fine-tuning the classifier, we augment the pretrained language model with two additional linear blocks. Following standard practice for CV classifiers, each block uses batch normalization (Ioffe and Szegedy, 2015) and dropout, with ReLU activations for the intermediate layer and a softmax activation that outputs a probability distribution over target classes at the last layer. Note that the parameters in these task-specific classifier layers are the only ones that are learned from scratch. The first linear layer takes as the input the pooled last hidden layer states.

Concat pooling The signal in text classification tasks is often contained in a few words, which may

[3] An unrelated method of the same name exists for deep Boltzmann machines (Salakhutdinov and Hinton, 2009).

[4]In other words, the number of epochs times the number of updates per epoch.

[5]We also credit personal communication with the author.

[6]While Loshchilov and Hutter (2017) use multiple annealing cycles, we generally found one cycle to work best.

occur anywhere in the document. As input documents can consist of hundreds of words, information may get lost if we only consider the last hidden state of the model. For this reason, we concatenate the hidden state at the last time step $\mathbf{h}_T$ of the document with both the max-pooled and the mean-pooled representation of the hidden states over as many time steps as fit in GPU memory $\mathbf{H} = \{\mathbf{h}_1, \ldots, \mathbf{h}_T\}$:

$$\mathbf{h}_c = [\mathbf{h}_T, \texttt{maxpool}(\mathbf{H}), \texttt{meanpool}(\mathbf{H})] \quad (4)$$

where [] is concatenation.

Fine-tuning the target classifier is the most critical part of the transfer learning method. Overly aggressive fine-tuning will cause catastrophic forgetting, eliminating the benefit of the information captured through language modeling; too cautious fine-tuning will lead to slow convergence (and resultant overfitting). Besides discriminative fine-tuning and triangular learning rates, we propose *gradual unfreezing* for fine-tuning the classifier.

Gradual unfreezing Rather than fine-tuning all layers at once, which risks catastrophic forgetting, we propose to gradually unfreeze the model starting from the last layer as this contains the *least general* knowledge (Yosinski et al., 2014): We first unfreeze the last layer and fine-tune all unfrozen layers for one epoch. We then unfreeze the next lower frozen layer and repeat, until we fine-tune all layers until convergence at the last iteration. This is similar to '*chain-thaw*' (Felbo et al., 2017), except that we add a layer at a time to the set of 'thawed' layers, rather than only training a single layer at a time.

While discriminative fine-tuning, slanted triangular learning rates, and gradual unfreezing all are beneficial on their own, we show in Section 5 that they complement each other and enable our method to perform well across diverse datasets.

BPTT for Text Classification (BPT3C) Language models are trained with backpropagation through time (BPTT) to enable gradient propagation for large input sequences. In order to make fine-tuning a classifier for large documents feasible, we propose BPTT for Text Classification (BPT3C): We divide the document into fixed-length batches of size b. At the beginning of each batch, the model is initialized with the final state of the previous batch; we keep track of the hidden states for mean and max-pooling; gradients are back-propagated to the batches whose hidden states contributed to the final prediction. In practice, we use variable length backpropagation sequences (Merity et al., 2017a).

Dataset	Type	# classes	# examples
TREC-6	Question	6	5.5k
IMDb	Sentiment	2	25k
Yelp-bi	Sentiment	2	560k
Yelp-full	Sentiment	5	650k
AG	Topic	4	120k
DBpedia	Topic	14	560k

Table 1: Text classification datasets and tasks with number of classes and training examples.

Bidirectional language model Similar to existing work (Peters et al., 2017, 2018), we are not limited to fine-tuning a unidirectional language model. For all our experiments, we pretrain both a forward and a backward LM. We fine-tune a classifier for each LM independently using BPT3C and average the classifier predictions.

4 Experiments

While our approach is equally applicable to sequence labeling tasks, we focus on text classification tasks in this work due to their important real-world applications.

4.1 Experimental setup

Datasets and tasks We evaluate our method on six widely-studied datasets, with varying numbers of documents and varying document length, used by state-of-the-art text classification and transfer learning approaches (Johnson and Zhang, 2017; McCann et al., 2017) as instances of three common text classification tasks: sentiment analysis, question classification, and topic classification. We show the statistics for each dataset and task in Table 1.

Sentiment Analysis For sentiment analysis, we evaluate our approach on the binary movie review IMDb dataset (Maas et al., 2011) and on the binary and five-class version of the Yelp review dataset compiled by Zhang et al. (2015).

Question Classification We use the six-class version of the small TREC dataset (Voorhees and Tice, 1999) dataset of open-domain, fact-based questions divided into broad semantic categories.

	Model	Test		Model	Test
IMDb	CoVe (McCann et al., 2017)	8.2	TREC-6	CoVe (McCann et al., 2017)	4.2
	oh-LSTM (Johnson and Zhang, 2016)	5.9		TBCNN (Mou et al., 2015)	4.0
	Virtual (Miyato et al., 2016)	5.9		LSTM-CNN (Zhou et al., 2016)	3.9
	ULMFiT (ours)	**4.6**		ULMFiT (ours)	**3.6**

Table 2: Test error rates (%) on two text classification datasets used by McCann et al. (2017).

	AG	DBpedia	Yelp-bi	Yelp-full
Char-level CNN (Zhang et al., 2015)	9.51	1.55	4.88	37.95
CNN (Johnson and Zhang, 2016)	6.57	0.84	2.90	32.39
DPCNN (Johnson and Zhang, 2017)	6.87	0.88	2.64	30.58
ULMFiT (ours)	**5.01**	**0.80**	**2.16**	**29.98**

Table 3: Test error rates (%) on text classification datasets used by Johnson and Zhang (2017).

Topic classification For topic classification, we evaluate on the large-scale AG news and DBpedia ontology datasets created by Zhang et al. (2015).

Pre-processing We use the same pre-processing as in earlier work (Johnson and Zhang, 2017; McCann et al., 2017). In addition, to allow the language model to capture aspects that might be relevant for classification, we add special tokens for upper-case words, elongation, and repetition.

Hyperparameters We are interested in a model that performs robustly across a diverse set of tasks. To this end, if not mentioned otherwise, we use the same set of hyperparameters across tasks, which we tune on the IMDb validation set. We use the AWD-LSTM language model (Merity et al., 2017a) with an embedding size of 400, 3 layers, 1150 hidden activations per layer, and a BPTT batch size of 70. We apply dropout of 0.4 to layers, 0.3 to RNN layers, 0.4 to input embedding layers, 0.05 to embedding layers, and weight dropout of 0.5 to the RNN hidden-to-hidden matrix. The classifier has a hidden layer of size 50. We use Adam with $\beta_1 = 0.7$ instead of the default $\beta_1 = 0.9$ and $\beta_2 = 0.99$, similar to (Dozat and Manning, 2017). We use a batch size of 64, a base learning rate of 0.004 and 0.01 for fine-tuning the LM and the classifier respectively, and tune the number of epochs on the validation set of each task[7]. We otherwise use the same practices used in (Merity et al., 2017a).

[7]On small datasets such as TREC-6, we fine-tune the LM only for 15 epochs without overfitting, while we can fine-tune longer on larger datasets. We found 50 epochs to be a good default for fine-tuning the classifier.

Baselines and comparison models For each task, we compare against the current state-of-the-art. For the IMDb and TREC-6 datasets, we compare against CoVe (McCann et al., 2017), a state-of-the-art transfer learning method for NLP. For the AG, Yelp, and DBpedia datasets, we compare against the state-of-the-art text categorization method by Johnson and Zhang (2017).

4.2 Results

For consistency, we report all results as error rates (lower is better). We show the test error rates on the IMDb and TREC-6 datasets used by McCann et al. (2017) in Table 2. Our method outperforms both CoVe, a state-of-the-art transfer learning method based on hypercolumns, as well as the state-of-the-art on both datasets. On IMDb, we reduce the error dramatically by 43.9% and 22% with regard to CoVe and the state-of-the-art respectively. This is promising as the existing state-of-the-art requires complex architectures (Peters et al., 2018), multiple forms of attention (McCann et al., 2017) and sophisticated embedding schemes (Johnson and Zhang, 2016), while our method employs a regular LSTM with dropout. We note that the language model fine-tuning approach of Dai and Le (2015) only achieves an error of 7.64 vs. 4.6 for our method on IMDb, demonstrating the benefit of transferring knowledge from a large ImageNet-like corpus using our fine-tuning techniques. IMDb in particular is reflective of real-world datasets: Its documents are generally a few

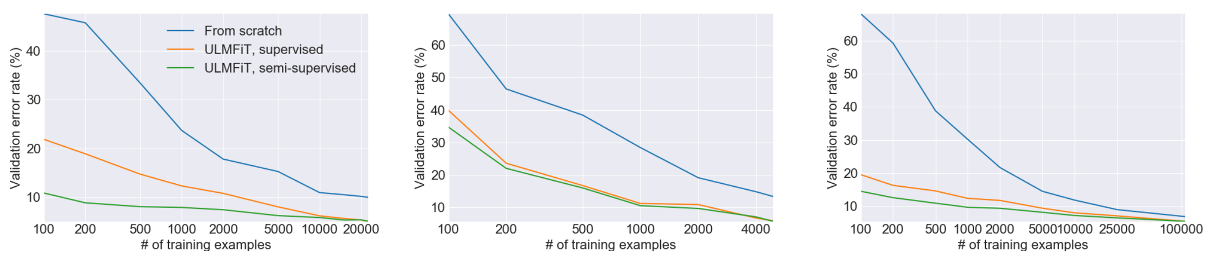

Figure 3: Validation error rates for supervised and semi-supervised ULMFiT vs. training from scratch with different numbers of training examples on IMDb, TREC-6, and AG (from left to right).

paragraphs long—similar to emails (e.g for legal discovery) and online comments (e.g for community management); and sentiment analysis is similar to many commercial applications, e.g. product response tracking and support email routing.

On TREC-6, our improvement—similar as the improvements of state-of-the-art approaches—is not statistically significant, due to the small size of the 500-examples test set. Nevertheless, the competitive performance on TREC-6 demonstrates that our model performs well across different dataset sizes and can deal with examples that range from single sentences—in the case of TREC-6—to several paragraphs for IMDb. Note that despite pretraining on more than two orders of magnitude less data than the 7 million sentence pairs used by McCann et al. (2017), we consistently outperform their approach on both datasets.

We show the test error rates on the larger AG, DBpedia, Yelp-bi, and Yelp-full datasets in Table 3. Our method again outperforms the state-of-the-art significantly. On AG, we observe a similarly dramatic error reduction by 23.7% compared to the state-of-the-art. On DBpedia, Yelp-bi, and Yelp-full, we reduce the error by 4.8%, 18.2%, 2.0% respectively.

5 Analysis

In order to assess the impact of each contribution, we perform a series of analyses and ablations. We run experiments on three corpora, IMDb, TREC-6, and AG that are representative of different tasks, genres, and sizes. For all experiments, we split off 10% of the training set and report error rates on this validation set with unidirectional LMs. We fine-tune the classifier for 50 epochs and train all methods but ULMFiT with early stopping.

Low-shot learning One of the main benefits of transfer learning is being able to train a model for a task with a small number of labels. We evaluate ULMFiT on different numbers of labeled examples in two settings: only labeled examples are used for LM fine-tuning ('*supervised*'); and all task data is available and can be used to fine-tune the LM ('*semi-supervised*'). We compare ULMFiT to training from scratch—which is necessary for hypercolumn-based approaches. We split off balanced fractions of the training data, keep the validation set fixed, and use the same hyperparameters as before. We show the results in Figure 3.

On IMDb and AG, supervised ULMFiT with only 100 labeled examples matches the performance of training from scratch with $10\times$ and $20\times$ more data respectively, clearly demonstrating the benefit of general-domain LM pretraining. If we allow ULMFiT to also utilize unlabeled examples (50k for IMDb, 100k for AG), at 100 labeled examples, we match the performance of training from scratch with $50\times$ and $100\times$ more data on AG and IMDb respectively. On TREC-6, ULMFiT significantly improves upon training from scratch; as examples are shorter and fewer, supervised and semi-supervised ULMFiT achieve similar results.

Pretraining	IMDb	TREC-6	AG
Without pretraining	5.63	10.67	5.52
With pretraining	**5.00**	**5.69**	**5.38**

Table 4: Validation error rates for ULMFiT with and without pretraining.

Impact of pretraining We compare using no pretraining with pretraining on WikiText-103 (Merity et al., 2017b) in Table 4. Pretraining is most useful for small and medium-sized datasets, which are most common in commercial applications. However, even for large datasets, pretraining improves performance.

LM	IMDb	TREC-6	AG
Vanilla LM	5.98	7.41	5.76
AWD-LSTM LM	**5.00**	**5.69**	**5.38**

Table 5: Validation error rates for ULMFiT with a vanilla LM and the AWD-LSTM LM.

LM fine-tuning	IMDb	TREC-6	AG
No LM fine-tuning	6.99	6.38	6.09
Full	5.86	6.54	5.61
Full + discr	5.55	6.36	5.47
Full + discr + stlr	**5.00**	**5.69**	**5.38**

Table 6: Validation error rates for ULMFiT with different variations of LM fine-tuning.

Impact of LM quality In order to gauge the importance of choosing an appropriate LM, we compare a vanilla LM with the same hyperparameters without any dropout[8] with the AWD-LSTM LM with tuned dropout parameters in Table 5. Using our fine-tuning techniques, even a regular LM reaches surprisingly good performance on the larger datasets. On the smaller TREC-6, a vanilla LM without dropout runs the risk of overfitting, which decreases performance.

Impact of LM fine-tuning We compare no fine-tuning against fine-tuning the full model (Erhan et al., 2010) ('*Full*'), the most commonly used fine-tuning method, with and without discriminative fine-tuning ('*Discr*') and slanted triangular learning rates ('*Stlr*') in Table 6. Fine-tuning the LM is most beneficial for larger datasets. '*Discr*' and '*Stlr*' improve performance across all three datasets and are necessary on the smaller TREC-6, where regular fine-tuning is not beneficial.

Impact of classifier fine-tuning We compare training from scratch, fine-tuning the full model ('*Full*'), only fine-tuning the last layer ('*Last*') (Donahue et al., 2014), '*Chain-thaw*' (Felbo et al., 2017), and gradual unfreezing ('*Freez*'). We furthermore assess the importance of discriminative fine-tuning ('*Discr*') and slanted triangular learning rates ('*Stlr*'). We compare the latter to an alternative, aggressive cosine annealing schedule ('*Cos*') (Loshchilov and Hutter, 2017). We use a learning rate $\eta^L = 0.01$ for '*Discr*', learning rates of 0.001 and 0.0001 for the last and all other layers respectively for '*Chain-thaw*' as in (Felbo et al., 2017), and a learning rate of 0.001 otherwise. We show the results in Table 7.

[8]To avoid overfitting, we only train the vanilla LM classifier for 5 epochs and keep dropout of 0.4 in the classifier.

Classifier fine-tuning	IMDb	TREC-6	AG
From scratch	9.93	13.36	6.81
Full	6.87	6.86	5.81
Full + discr	4.57	6.21	5.62
Last	6.49	16.09	8.38
Chain-thaw	5.39	6.71	5.90
Freez	6.37	6.86	5.81
Freez + discr	5.39	5.86	6.04
Freez + stlr	5.04	6.02	5.35
Freez + cos	5.70	6.38	**5.29**
Freez + discr + stlr	**5.00**	**5.69**	5.38

Table 7: Validation error rates for ULMFiT with different methods to fine-tune the classifier.

Fine-tuning the classifier significantly improves over training from scratch, particularly on the small TREC-6. '*Last*', the standard fine-tuning method in CV, severely underfits and is never able to lower the training error to 0. '*Chain-thaw*' achieves competitive performance on the smaller datasets, but is outperformed significantly on the large AG. '*Freez*' provides similar performance as '*Full*'. '*Discr*' consistently boosts the performance of '*Full*' and '*Freez*', except for the large AG. Cosine annealing is competitive with slanted triangular learning rates on large data, but under-performs on smaller datasets. Finally, full ULMFiT classifier fine-tuning (bottom row) achieves the best performance on IMDB and TREC-6 and competitive performance on AG. Importantly, ULMFiT is the only method that shows excellent performance across the board—and is therefore the only *universal* method.

Classifier fine-tuning behavior While our results demonstrate that *how* we fine-tune the classifier makes a significant difference, fine-tuning for inductive transfer is currently under-explored in NLP as it mostly has been thought to be unhelpful (Mou et al., 2016). To better understand the fine-tuning behavior of our model, we compare the validation error of the classifier fine-tuned with ULMFiT and '*Full*' during training in Figure 4.

On all datasets, fine-tuning the full model leads to the lowest error comparatively early in training, e.g. already after the first epoch on IMDb.

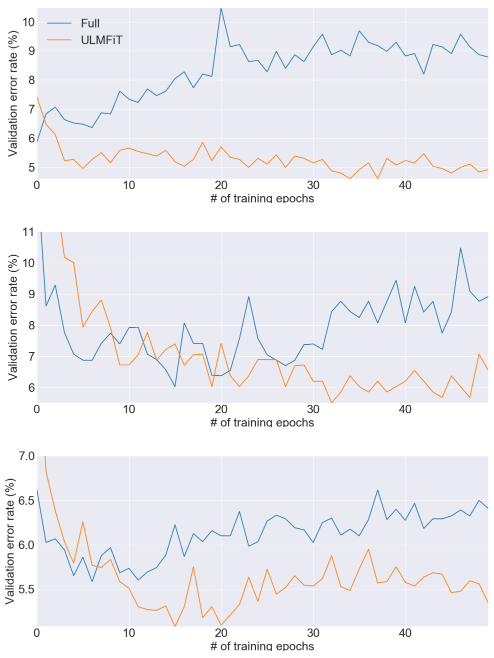

Figure 4: Validation error rate curves for fine-tuning the classifier with ULMFiT and '*Full*' on IMDb, TREC-6, and AG (top to bottom).

The error then increases as the model starts to overfit and knowledge captured through pretraining is lost. In contrast, ULMFiT is more stable and suffers from no such catastrophic forgetting; performance remains similar or improves until late epochs, which shows the positive effect of the learning rate schedule.

Impact of bidirectionality At the cost of training a second model, ensembling the predictions of a forward and backwards LM-classifier brings a performance boost of around 0.5–0.7. On IMDb we lower the test error from 5.30 of a single model to 4.58 for the bidirectional model.

6 Discussion and future directions

While we have shown that ULMFiT can achieve state-of-the-art performance on widely used text classification tasks, we believe that language model fine-tuning will be particularly useful in the following settings compared to existing transfer learning approaches (Conneau et al., 2017; McCann et al., 2017; Peters et al., 2018): a) NLP for non-English languages, where training data for supervised pretraining tasks is scarce; b) new NLP tasks where no state-of-the-art architecture exists; and c) tasks with limited amounts of labeled data (and some amounts of unlabeled data).

Given that transfer learning and particularly fine-tuning for NLP is under-explored, many future directions are possible. One possible direction is to improve language model pretraining and fine-tuning and make them more scalable: for ImageNet, predicting far fewer classes only incurs a small performance drop (Huh et al., 2016), while recent work shows that an alignment between source and target task label sets is important (Mahajan et al., 2018)—focusing on predicting a subset of words such as the most frequent ones might retain most of the performance while speeding up training. Language modeling can also be augmented with additional tasks in a multi-task learning fashion (Caruana, 1993) or enriched with additional supervision, e.g. syntax-sensitive dependencies (Linzen et al., 2016) to create a model that is more general or better suited for certain downstream tasks, ideally in a weakly-supervised manner to retain its universal properties.

Another direction is to apply the method to novel tasks and models. While an extension to sequence labeling is straightforward, other tasks with more complex interactions such as entailment or question answering may require novel ways to pretrain and fine-tune. Finally, while we have provided a series of analyses and ablations, more studies are required to better understand what knowledge a pretrained language model captures, how this changes during fine-tuning, and what information different tasks require.

7 Conclusion

We have proposed ULMFiT, an effective and extremely sample-efficient transfer learning method that can be applied to any NLP task. We have also proposed several novel fine-tuning techniques that in conjunction prevent catastrophic forgetting and enable robust learning across a diverse range of tasks. Our method significantly outperformed existing transfer learning techniques and the state-of-the-art on six representative text classification tasks. We hope that our results will catalyze new developments in transfer learning for NLP.

Evaluating neural network explanation methods using hybrid documents and morphosyntactic agreement

LMU Munich, Germany
poerner@cis.lmu.de

Abstract

The behavior of deep neural networks (DNNs) is hard to understand. This makes it necessary to explore post hoc explanation methods. We conduct the first comprehensive evaluation of explanation methods for NLP. To this end, we design two novel evaluation paradigms that cover two important classes of NLP problems: small context and large context problems. Both paradigms require no manual annotation and are therefore broadly applicable. We also introduce LIMSSE, an explanation method inspired by LIME that is designed for NLP. We show empirically that LIMSSE, LRP and DeepLIFT are the most effective explanation methods and recommend them for explaining DNNs in NLP.

1 Introduction

DNNs are complex models that combine linear transformations with different types of nonlinearities. If the model is deep, i.e., has many layers, then its behavior during training and inference is notoriously hard to understand.

This is a problem for both scientific methodology and real-world deployment. Scientific methodology demands that we understand our models. In the real world, a decision (e.g., "your blog post is offensive and has been removed") by itself is often insufficient; in addition, an explanation of the decision may be required (e.g., "our system flagged the following words as offensive"). The European Union plans to mandate that intelligent systems used for sensitive applications provide such explanations (European General Data Protection Regulation, expected 2018, cf. Goodman and Flaxman (2016)).

A number of post hoc explanation methods for DNNs have been proposed. Due to the complexity of the DNNs they explain, these methods are necessarily approximations and come with their own sources of error. At this point, it is not clear which of these methods to use when reliable explanations for a specific DNN architecture are needed.

Definitions. (i) A *task method* solves an NLP problem, e.g., a GRU that predicts sentiment.

(ii) An *explanation method* explains the behavior of a task method on a specific input. For our purpose, it is a function $\phi(t, k, \mathbf{X})$ that assigns real-valued relevance scores for a target class k (e.g., positive) to positions t in an input text $\mathbf{X}$ (e.g., "great food"). For this example, an explanation method might assign: $\phi(1, k, \mathbf{X}) > \phi(2, k, \mathbf{X})$.

(iii) An *(explanation) evaluation paradigm* quantitatively evaluates explanation methods for a task method, e.g., by assigning them accuracies.

Contributions. (i) We present novel evaluation paradigms for explanation methods for two classes of common NLP tasks (see §2). Crucially, *neither paradigm requires manual annotations* and our methodology is therefore broadly applicable.

(ii) Using these paradigms, we perform a comprehensive evaluation of explanation methods for NLP (§3). We cover the most important classes of task methods, RNNs and CNNs, as well as the recently proposed Quasi-RNNs.

(iii) We introduce LIMSSE (§3.6), an explanation method inspired by LIME (Ribeiro et al.,

tasks	sentiment analysis, morphological prediction, ...
task methods	CNN, GRU, LSTM, ...
explanation methods	LIMSSE, LRP, DeepLIFT, ...
evaluation paradigms	hybrid document, morphosyntactic agreement

2016) that is designed for word-order sensitive task methods (e.g., RNNs, CNNs). We show empirically that LIMSSE, LRP (Bach et al., 2015) and DeepLIFT (Shrikumar et al., 2017) are the most effective explanation methods (§4): LRP and DeepLIFT are the most consistent methods, while LIMSSE wins the hybrid document experiment.

2 Evaluation paradigms

In this section, we introduce two novel evaluation paradigms for explanation methods on two types of common NLP tasks, *small context* tasks and *large context* tasks. Small context tasks are defined as those that can be solved by finding short, self-contained indicators, such as words and phrases, and weighing them up (i.e., tasks where CNNs with pooling can be expected to perform well). We design the *hybrid document paradigm* for evaluating explanation methods on small context tasks. Large context tasks require the correct handling of long-distance dependencies, such as subject-verb agreement.[1] We design the *morphosyntactic agreement paradigm* for evaluating explanation methods on large context tasks.

We could also use **human judgments** for evaluation. While we use Mohseni and Ragan (2018)'s manual relevance benchmark for comparison, there are two issues with it: (i) Due to the *cost of human labor*, it is limited in size and domain. (ii) More importantly, *a good explanation method should not reflect what humans attend to, but what task methods attend to.* For instance, the family name "Kolstad" has 11 out of its 13 appearances in the 20 newsgroups corpus in sci.electronics posts. Thus, task methods probably learn it as a sci.electronics indicator. Indeed, the explanation method in Fig 1 (top) marks "Kolstad" as relevant, but the human annotator does not.

2.1 Small context: Hybrid document paradigm

Given a collection of documents, hybrid documents are created by randomly concatenating document fragments. We assume that, on average, the most relevant input for a class k in a hybrid document is located in a fragment that stems from a document with gold label k. Hence, an explanation method succeeds if it places maximal relevance for k inside the correct fragment.

Formally, let x_t be a word inside hybrid document $\mathbf{X}$ that originates from a document $\mathbf{X}'$ with gold label $y(\mathbf{X}')$. x_t's gold label $y(\mathbf{X}, t)$ is set to $y(\mathbf{X}')$. Let $f(\mathbf{X})$ be the class assigned to the hybrid document by a task method, and let ϕ be an explanation method as defined above. Let $\mathrm{rmax}(\mathbf{X}, \phi)$ denote the position of the maximally relevant word in $\mathbf{X}$ for the predicted class $f(\mathbf{X})$. If this maximally relevant word comes from a document with the correct gold label, the explanation method is awarded a hit:

$$\mathrm{hit}(\phi, \mathbf{X}) = \mathbb{I}[y\big(\mathbf{X}, \mathrm{rmax}(\mathbf{X}, \phi)\big) = f(\mathbf{X})] \quad (1)$$

where $\mathbb{I}[P]$ is 1 if P is true and 0 otherwise. In Fig 1 (bottom), the explanation method $\mathrm{grad}^{\mathrm{L2}}_{1p}$ places rmax outside the correct (underlined) fragment. Therefore, it does not get a hit point, while $\mathrm{limsse}^{\mathrm{ms}}_{s}$ does.

The pointing game accuracy of an explanation method is calculated as its total number of hit points divided by the number of possible hit points. This is a form of the pointing game paradigm from computer vision (Zhang et al., 2016).

2.2 Large context: Morphosyntactic agreement paradigm

Many natural languages display morphosyntactic agreement between words v and w. A DNN that

[1] Consider deciding the number of *[verb]* in "the children in the green house said that the big telescope *[verb]*" vs. "the children in the green house who broke the big telescope *[verb]*". The local contexts of "children" or "*[verb]*" do not suffice to solve this problem, instead, the large context of the entire sentence has to be considered.

$\text{grad}^{\text{dot}}_{\int s}$	the **link** provided by the editor above [encourages ...]
lrp	the **link** provided by the editor above [encourages ...]
$\text{limsse}^{\text{bb}}$	the link provided by the **editor** above [encourages ...]

$\text{grad}^{\text{L2}}_{\int s}$	few if any events in **history** [are ...]
occ_1	few if any **events** in history [are ...]
$\text{limsse}^{\text{ms}}_{s}$	few if any **events** in history [are ...]

Figure 2: **Top:** verb context classified singular. Green: evidence for singular. Task method: GRU. **Bottom:** verb context classified plural. Green: evidence for plural. Task method: LSTM. Underlined: subject. Bold: rmax position.

predicts the agreeing feature in w should pay attention to v. For example, in the sentence "the children with the telescope are home", the number of the verb (plural for "are") can be predicted from the subject ("children") without looking at the verb. If the language allows for v and w to be far apart (Fig 3, top), successful task methods have to be able to handle large contexts.

Linzen et al. (2016) show that English verb number can be predicted by a unidirectional LSTM with accuracy $> 99\%$, based on left context alone. When a task method predicts the correct number, we expect successful explanation methods to place maximal relevance on the subject:

$$\text{hit}_{\text{target}}(\phi, \mathbf{X}) = \mathbb{I}[\text{rmax}(\mathbf{X}, \phi) = \text{target}(\mathbf{X})]$$

where $\text{target}(\mathbf{X})$ is the location of the subject, and rmax is calculated as above. Regardless of whether the prediction is correct, we expect rmax to fall onto a noun that has the predicted number:

$$\text{hit}_{\text{feat}}(\phi, \mathbf{X}) = \mathbb{I}[\text{feat}\big(\mathbf{X}, \text{rmax}(\mathbf{X}, \phi)\big) = f(\mathbf{X})]$$

where $\text{feat}(\mathbf{X}, t)$ is the morphological feature (here: number) of x_t. In Fig 2, rmax on "link" gives a $\text{hit}_{\text{target}}$ point (and a hit_{feat} point), rmax on "editor" gives a hit_{feat} point. $\text{grad}^{\text{L2}}_{\int s}$ does not get any points as "history" is not a plural noun.

Labels for this task can be automatically generated using part-of-speech taggers and parsers, which are available for many languages.

3 Explanation methods

In this section, we define the explanation methods that will be evaluated. For our purpose, explanation methods produce word relevance scores $\phi(t, k, \mathbf{X})$, which are specific to a given class k and a given input $\mathbf{X}$. $\phi(t, k, \mathbf{X}) > \phi(t', k, \mathbf{X})$ means that x_t contributed more than $x_{t'}$ to the task method's (potential) decision to classify $\mathbf{X}$ as k.

3.1 Gradient-based explanation methods

Gradient-based explanation methods approximate the contribution of some DNN input i to some output o with o's gradient with respect to i (Simonyan et al., 2014). In the following, we consider two output functions $o(k, \mathbf{X})$, the unnormalized class score $s(k, \mathbf{X})$ and the class probability $p(k|\mathbf{X})$:

$$s(k, \mathbf{X}) = \vec{w}_k \cdot \vec{h}(\mathbf{X}) + b_k \tag{2}$$

$$p(k|\mathbf{X}) = \frac{\exp\big(s(k, \mathbf{X})\big)}{\sum_{k'=1}^{K} \exp\big(s(k', \mathbf{X})\big)} \tag{3}$$

where k is the target class, $\vec{h}(\mathbf{X})$ the document representation (e.g., an RNN's final hidden layer), $\vec{w}_k$ (resp. b_k) k's weight vector (resp. bias).

The simple gradient of $o(k, \mathbf{X})$ w.r.t. i is:

$$\text{grad}_1(i, k, \mathbf{X}) = \frac{\partial o(k, \mathbf{X})}{\partial i} \tag{4}$$

grad_1 underestimates the importance of inputs that saturate a nonlinearity (Shrikumar et al., 2017). To address this, Sundararajan et al. (2017) integrate over all gradients on a linear interpolation $\alpha \in [0, 1]$ between a baseline input $\bar{\mathbf{X}}$ (here: all-zero embeddings) and $\mathbf{X}$:

$$\begin{aligned}\text{grad}_{\int}(i, k, \mathbf{X}) &= \int_{\alpha=0}^{1} \frac{\partial o(k, \bar{\mathbf{X}} + \alpha(\mathbf{X} - \bar{\mathbf{X}}))}{\partial i} \partial\alpha \\ &\approx \frac{1}{M} \sum_{m=1}^{M} \frac{\partial o(k, \bar{\mathbf{X}} + \frac{m}{M}(\mathbf{X} - \bar{\mathbf{X}}))}{\partial i}\end{aligned} \tag{5}$$

where M is a big enough constant (here: 50).

In NLP, symbolic inputs (e.g., words) are often represented as one-hot vectors $\vec{x}_t \in \{1, 0\}^{|V|}$ and embedded via a real-valued matrix: $\vec{e}_t = \mathbf{M}\vec{x}_t$. Gradients are computed with respect to individual entries of $\mathbf{E} = [\vec{e}_1 \ldots \vec{e}_{|\mathbf{X}|}]$. Bansal et al. (2016) and Hechtlinger (2016) use the L2 norm to reduce vectors of gradients to single values:

$$\phi_{\text{grad}^{\text{L2}}}(t, k, \mathbf{X}) = ||\text{grad}(\vec{e}_t, k, \mathbf{E})|| \tag{6}$$

where $\text{grad}(\vec{e}_t, k, \mathbf{E})$ is a vector of elementwise gradients w.r.t. $\vec{e}_t$. Denil et al. (2015) use the dot product of the gradient vector and the embedding[2], i.e., the gradient of the "hot" entry in $\vec{x}_t$:

$$\phi_{\text{grad}^{\text{dot}}}(t, k, \mathbf{X}) = \vec{e}_t \cdot \text{grad}(\vec{e}_t, k, \mathbf{E}) \tag{7}$$

We use "grad_1" for Eq 4, "$\text{grad}_{\int}$" for Eq 5, "$_p$" for Eq 3, "$_s$" for Eq 2, "L2" for Eq 6 and "dot" for Eq 7. This gives us eight explanation methods: $\text{grad}^{\text{L2}}_{1s}$, $\text{grad}^{\text{L2}}_{1p}$, $\text{grad}^{\text{dot}}_{1s}$, $\text{grad}^{\text{dot}}_{1p}$, $\text{grad}^{\text{L2}}_{\int s}$, $\text{grad}^{\text{L2}}_{\int p}$, $\text{grad}^{\text{dot}}_{\int s}$, $\text{grad}^{\text{dot}}_{\int p}$.

[2]For $\text{grad}^{\text{dot}}_{\int}$, replace $\vec{e}_t$ with $\vec{e}_t - \bar{\vec{e}}_t$. Since our baseline embeddings are all-zeros, this is equivalent.

3.2 Layer-wise relevance propagation

Layer-wise relevance propagation (LRP) is a backpropagation-based explanation method developed for fully connected neural networks and CNNs (Bach et al., 2015) and later extended to LSTMs (Arras et al., 2017b). In this paper, we use Epsilon LRP (Eq 58, Bach et al. (2015)). Remember that the activation of neuron j, a_j, is the sum of weighted upstream activations, $\sum_i a_i w_{i,j}$, plus bias b_j, squeezed through some nonlinearity. We denote the pre-nonlinearity activation of j as a'_j. The relevance of j, $R(j)$, is distributed to upstream neurons i proportionally to the contribution that i makes to a'_j in the forward pass:

$$R(i) = \sum_j R(j) \frac{a_i w_{i,j}}{a'_j + \mathrm{esign}(a'_j)} \quad (8)$$

This ensures that relevance is conserved between layers, with the exception of relevance attributed to b_j. To prevent numerical instabilities, $\mathrm{esign}(a')$ returns $-\epsilon$ if $a' < 0$ and ϵ otherwise. We set $\epsilon = .001$. The full algorithm is:

$$R(L_{k'}) = s(k, \mathbf{X})\mathbb{I}[k' = k]$$

... recursive application of Eq 8 ...

$$\phi_{\mathrm{lrp}}(t, k, \mathbf{X}) = \sum_{j=1}^{\dim(\vec{e}_t)} R(e_{t,j})$$

where L is the final layer, k the target class and $R(e_{t,j})$ the relevance of dimension j in the t'th embedding vector. For $\epsilon \to 0$ and provided that all nonlinearities up to the unnormalized class score are relu, Epsilon LRP is equivalent to the product of input and raw score gradient (here: $\mathrm{grad}_{1s}^{\mathrm{dot}}$) (Kindermans et al., 2016). In our experiments, the second requirement holds only for CNNs.

Experiments by Ancona et al. (2017) (see §6) suggest that LRP does not work well for LSTMs if all neurons – including gates – participate in backpropagation. We therefore use Arras et al. (2017b)'s modification and treat sigmoid-activated gates as time step-specific weights rather than neurons. For instance, the relevance of LSTM candidate vector $\vec{g}_t$ is calculated from memory vector $\vec{c}_t$ and input gate vector $\vec{i}_t$ as

$$R(g_{t,d}) = R(c_{t,d}) \frac{g_{t,d} \cdot i_{t,d}}{c_{t,d} + \mathrm{esign}(c_{t,d})}$$

This is equivalent to applying Eq 8 while treating $\vec{i}_t$ as a diagonal weight matrix. The gate neurons in $\vec{i}_t$ do not receive any relevance themselves. See supplementary material for formal definitions of Epsilon LRP for different architectures.

3.3 DeepLIFT

DeepLIFT (Shrikumar et al., 2017) is another backpropagation-based explanation method. Unlike LRP, it does not explain $s(k, \mathbf{X})$, but $s(k, \mathbf{X}) - s(k, \bar{\mathbf{X}})$, where $\bar{\mathbf{X}}$ is some baseline input (here: all-zero embeddings). Following Ancona et al. (2018) (Eq 4), we use this backpropagation rule:

$$R(i) = \sum_j R(j) \frac{a_i w_{i,j} - \bar{a}_i w_{i,j}}{a'_j - \bar{a}'_j + \mathrm{esign}(a'_j - \bar{a}'_j)}$$

where $\bar{a}$ refers to the forward pass of the baseline. Note that the original method has a different mechanism for avoiding small denominators; we use esign for compatibility with LRP. The DeepLIFT algorithm is started with $R(L_{k'}) = \big(s(k, \mathbf{X}) - s(k, \bar{\mathbf{X}})\big)\mathbb{I}[k' = k]$. On gated (Q)RNNs, we proceed analogous to LRP and treat gates as weights.

3.4 Cell decomposition for gated RNNs

The cell decomposition explanation method for LSTMs (Murdoch and Szlam, 2017) decomposes the unnormalized class score $s(k, \mathbf{X})$ (Eq 2) into additive contributions. For every time step t, we compute how much of $\vec{c}_t$ "survives" until the final step T and contributes to $s(k, \mathbf{X})$. This is achieved by applying all future forget gates $\vec{f}$, the final $\tanh$ nonlinearity, the final output gate $\vec{o}_T$, as well as the class weights of k to $\vec{c}_t$. We call this quantity "net load of t for class k":

$$\mathrm{nl}(t, k, \mathbf{X}) = \vec{w}_k \cdot \Big(\vec{o}_T \odot \tanh\big(\big(\prod_{j=t+1}^{T} \vec{f}_j\big) \odot \vec{c}_t\big)\Big)$$

where $\odot$ and $\prod$ are applied elementwise. The relevance of t is its gain in net load relative to $t-1$: $\phi_{\mathrm{decomp}}(t, k, \mathbf{X}) = \mathrm{nl}(t, k, \mathbf{X}) - \mathrm{nl}(t-1, k, \mathbf{X})$. For GRU, we change the definition of net load:

$$\mathrm{nl}(t, k, \mathbf{X}) = \vec{w}_k \cdot \big(\big(\prod_{j=t+1}^{T} \vec{z}_j\big) \odot \vec{h}_t\big)$$

where $\vec{z}$ are GRU update gates.

3.5 Input perturbation methods

Input perturbation methods assume that the removal or masking of relevant inputs changes the output (Zeiler and Fergus, 2014). Omission-based methods remove inputs completely (Kádár et al., 2017), while occlusion-based methods replace them with a baseline (Li et al., 2016b). In computer vision, perturbations are usually applied to patches, as neighboring pixels tend to correlate (Zintgraf et al., 2017). To calculate the omit_N (resp. occ_N) relevance of word x_t, we delete (resp. occlude), one at a time, all N-grams that contain x_t, and average the change in the unnormalized class score from Eq 2:

$$\phi_{[\mathrm{omit}|\mathrm{occ}]_N}(t,k,\mathbf{X}) = \sum_{j=1}^{N} \big[s(k,[\vec{e}_1 \dots \vec{e}_{|\mathbf{X}|}]) \\ -s(k,[\vec{e}_1 \dots \vec{e}_{t-N-1+j}] \| \bar{\mathbf{E}} \| [\vec{e}_{t+j} \dots \vec{e}_{|\mathbf{X}|}])\big] \frac{1}{N}$$

where $\vec{e}_t$ are embedding vectors, $\|$ denotes concatenation and $\bar{\mathbf{E}}$ is either a sequence of length zero (ϕ_{omit}) or a sequence of N baseline (here: all-zero) embedding vectors (ϕ_{occ}).

3.6 LIMSSE: LIME for NLP

Local Interpretable Model-agnostic Explanations (LIME) (Ribeiro et al., 2016) is a framework for explaining predictions of complex classifiers. LIME approximates the behavior of classifier f in the neighborhood of input $\mathbf{X}$ with an interpretable (here: linear) model. The interpretable model is trained on samples $\mathbf{Z}_1 \dots \mathbf{Z}_N$ (here: $N = 3000$), which are randomly drawn from $\mathbf{X}$, with "gold labels" $f(\mathbf{Z}_1) \dots f(\mathbf{Z}_N)$.

Since RNNs and CNNs respect word order, we cannot use the bag of words sampling method from the original description of LIME. Instead, we introduce Local Interpretable Model-agnostic Substring-based Explanations (LIMSSE). LIMSSE uniformly samples a length l_n (here: $1 \le l_n \le 6$) and a starting point s_n, which define the substring $\mathbf{Z}_n = [\vec{x}_{s_n} \dots \vec{x}_{s_n+l_n-1}]$. To the linear model, $\mathbf{Z}_n$ is represented by a binary vector $\vec{z}_n \in \{0,1\}^{|\mathbf{X}|}$, where $z_{n,t} = \mathbb{I}[s_n \le t < s_n + l_n]$.

We learn a linear weight vector $\hat{\vec{v}}_k \in \mathbb{R}^{|\mathbf{X}|}$, whose entries are word relevances for k, i.e., $\phi_{\mathrm{limsse}}(t,k,\mathbf{X}) = \hat{v}_{k,t}$. To optimize it, we experiment with three loss functions. The first, which we will refer to as $\mathrm{limsse}^{\mathrm{bb}}$, assumes that our DNN is a total black box that delivers only a classification:

$$\hat{\vec{v}}_k = \underset{\vec{v}_k}{\mathrm{argmin}} \sum_n -\big[\log\big(\sigma(\vec{z}_n \cdot \vec{v}_k)\big)\mathbb{I}[f(\mathbf{Z}_n) = k] \\ + \log\big(1 - \sigma(\vec{z}_n \cdot \vec{v}_k)\big)\mathbb{I}[f(\mathbf{Z}_n) \neq k]\big]$$

where $f(\mathbf{Z}_n) = \mathrm{argmax}_{k'}\big(p(k'|\mathbf{Z}_n)\big)$. The black box approach is maximally general, but insensitive to the magnitude of evidence found in $\mathbf{Z}_n$. Hence, we also test magnitude-sensitive loss functions:

$$\hat{\vec{v}}_k = \underset{\vec{v}_k}{\mathrm{argmin}} \sum_n \big(\vec{z}_n \cdot \vec{v}_k - o(k,\mathbf{Z}_n)\big)^2$$

where $o(k,\mathbf{Z}_n)$ is one of $s(k,\mathbf{Z}_n)$ or $p(k|\mathbf{Z}_n)$. We refer to these as $\mathrm{limsse}^{\mathrm{ms}}_s$ and $\mathrm{limsse}^{\mathrm{ms}}_p$.

4 Experiments

4.1 Hybrid document experiment

For the hybrid document experiment, we use the 20 newsgroups corpus (topic classification) (Lang, 1995) and reviews from the 10th yelp dataset challenge (binary sentiment analysis)[3]. We train five DNNs per corpus: a bidirectional GRU (Cho et al., 2014), a bidirectional LSTM (Hochreiter and Schmidhuber, 1997), a 1D CNN with global max pooling (Collobert et al., 2011), a bidirectional Quasi-GRU (QGRU), and a bidirectional Quasi-LSTM (QLSTM). The Quasi-RNNs are 1D CNNs with a feature-wise gated recursive pooling layer (Bradbury et al., 2017). Word embeddings are $\mathbb{R}^{300}$ and initialized with pre-trained GloVe embeddings (Pennington et al., 2014)[4]. The main layer has a hidden size of 150 (bidirectional architectures: 75 dimensions per direction). For the QRNNs and CNN, we use a kernel width of 5. In all five architectures, the resulting document representation is projected to 20 (resp. two) dimensions using a fully connected layer, followed by a softmax. See supplementary material for details on training and regularization.

After training, we sentence-tokenize the test sets, shuffle the sentences, concatenate ten sentences at a time and classify the resulting hybrid documents. Documents that are assigned a class that is not the gold label of at least one constituent word are discarded (yelp: $< 0.1\%$; 20 newsgroups: 14% - 20%). On the remaining documents, we use the explanation methods from §3 to find the maximally relevant word for each prediction. The random baseline samples the maximally relevant word from a uniform distribution.

For reference, we also evaluate on a **human judgment** benchmark (Mohseni and Ragan (2018), Table 2, C11-C15). It contains

Table 2: Pointing game accuracies in hybrid document experiment (left), on manually annotated benchmark (middle) and in morphosyntactic agreement experiment (right). $\text{hit}_{\text{target}}$ (resp. hit_{feat}): maximal relevance on subject (resp. on noun with the predicted number feature). Bold: top explanation method. Underlined: within 5 points of top explanation method.

188 documents from the 20 newsgroups test set (classes sci.med and sci.electronics), with one manually created list of relevant words per document. We discard documents that are incorrectly classified (20% - 27%) and define: $\text{hit}(\phi, \mathbf{X}) = \mathbb{I}[\text{rmax}(\mathbf{X}, \phi) \in \text{gt}(\mathbf{X})]$, where $\text{gt}(\mathbf{X})$ is the manual ground truth.

4.2 Morphosyntactic agreement experiment

For the morphosyntactic agreement experiment, we use automatically annotated English Wikipedia sentences by Linzen et al. (2016)[5]. For our purpose, a sample consists of: all words preceding the verb: $\mathbf{X} = [x_1 \cdots x_T]$; part-of-speech (POS) tags: $\text{pos}(\mathbf{X}, t) \in \{\text{VBZ, VBP, NN, NNS}, \ldots\}$; and the position of the subject: $\text{target}(\mathbf{X}) \in [1, T]$. The number feature is derived from the POS:

$$\text{feat}(\mathbf{X}, t) = \begin{cases} \text{Sg} & \text{if } \text{pos}(\mathbf{X}, t) \in \{\text{VBZ, NN}\} \\ \text{Pl} & \text{if } \text{pos}(\mathbf{X}, t) \in \{\text{VBP, NNS}\} \\ \text{n/a} & \text{otherwise} \end{cases}$$

The gold label of a sentence is the number of its verb, i.e., $y(\mathbf{X}) = \text{feat}(\mathbf{X}, T + 1)$.

As task methods, we replicate Linzen et al. (2016)'s unidirectional LSTM ($\mathbb{R}^{50}$ randomly initialized word embeddings, hidden size 50). We also train unidirectional GRU, QGRU and QLSTM architectures with the same dimensionality. We use the explanation methods from §3 to find the most relevant word for predictions on the test set. As described in §2.2, explanation methods are awarded a $\text{hit}_{\text{target}}$ (resp. hit_{feat}) point if this word is the subject (resp. a noun with the predicted number feature). For reference, we use a random baseline as well as a baseline that assumes that the most relevant word directly precedes the verb.

5 Discussion

5.1 Explanation methods

Our experiments suggest that explanation methods for neural NLP differ in quality.

As in previous work (see §6), **gradient L2 norm** (grad^{L2}) performs poorly, especially on RNNs. We assume that this is due to its inability to distinguish relevances for and against k.

Gradient embedding dot product (grad^{dot}) is competitive on CNN (Table 2, $\text{grad}^{\text{dot}}_{1p}$ C05, $\text{grad}^{\text{dot}}_{1s}$ C10, C15), presumably because relu is linear on positive inputs, so gradients are exact in-

Figure 3: **Top:** verb context classified singular. Task method: LSTM. **Bottom:** hybrid yelp review, classified positive. Task method: QLSTM.

stead of approximate. grad^{dot} also has decent performance for GRU ($\text{grad}^{\text{dot}}_{1p}$ C01, $\text{grad}^{\text{dot}}_{\int s}$ C{06, 11, 16, 20, 24}), perhaps because GRU hidden activations are always in [-1,1], where $\tanh$ and σ are approximately linear.

Integrated gradient ($\text{grad}_{\int}$) mostly outperforms simple gradient (grad_1), though not consistently (C01, C07). Contrary to expectation, integration did not help much with the failure of the gradient method on LSTM on 20 newsgroups ($\text{grad}^{\text{dot}}_1$ vs. $\text{grad}^{\text{dot}}_{\int}$ in C08, C13), which we had assumed to be due to saturation of $\tanh$ on large absolute activations in $\vec{c}$. Smaller intervals may be needed to approximate the integration, however, this means additional computational cost.

The gradient of $s(k, \mathbf{X})$ performs better or similar to the gradient of $p(k|\mathbf{X})$. The main exception is yelp ($\text{grad}^{\text{dot}}_{1s}$ vs. $\text{grad}^{\text{dot}}_{1p}$, C01-C05). This is probably due to conflation by $p(k|\mathbf{X})$ of evidence for k (numerator in Eq 3) and against competitor classes (denominator). In a two-class scenario, there is little incentive to keep classes separate, leading to information flow through the denominator. In future work, we will replace the two-way softmax with a one-way sigmoid such that $\phi(t, 0, \mathbf{X}) := -\phi(t, 1, \mathbf{X})$.

LRP and **DeepLIFT** are the most consistent explanation methods across evaluation paradigms and task methods. (The comparatively low pointing game accuracies on the yelp QRNNs and CNN (C02, C04, C05) are probably due to the fact that they explain $s(k, .)$ in a two-way softmax, see above.) On CNN (C05, C10, C15), LRP and $\text{grad}^{\text{dot}}_{1s}$ perform almost identically, suggesting that they are indeed quasi-equivalent on this architecture (see §3.2). On (Q)RNNs, modified LRP and DeepLIFT appear to be superior to the gradient method (lrp vs. $\text{grad}^{\text{dot}}_{1s}$, deeplift vs. $\text{grad}^{\text{dot}}_{\int s}$, C01-C04, C06-C09, C11-C14, C16-C27).

Decomposition performs well on LSTM, especially in the morphosyntactic agreement experiment, but it is inconsistent on other architectures. Gated RNNs have a long-term additive and a multiplicative pathway, and the decomposition method only detects information traveling via the additive one. Miao et al. (2016) show qualitatively that GRUs often reorganize long-term memory abruptly, which might explain the difference between LSTM and GRU. QRNNs only have additive recurrent connections; however, given that $\vec{c}_t$ (resp. $\vec{h}_t$) is calculated by convolution over several time steps, decomposition relevance can be incorrectly attributed inside that window. This likely is the reason for the stark difference between the performance of decomposition on QRNNs in the hybrid document experiment and on the manually labeled data (C07, C09 vs. C12, C14). Overall, we do not recommend the decomposition method, because it fails to take into account all routes by which information can be propagated.

Omission and occlusion produce inconsistent results in the hybrid document experiment. Shrikumar et al. (2017) show that perturbation methods can lack sensitivity when there are more relevant inputs than the "perturbation window" covers. In the morphosyntactic agreement experiment, omission is not competitive; we assume that this is because it interferes too much with syntactic structure. occ_1 does better (esp. C16-C19), possibly because an all-zero "placeholder" is less disruptive than word removal. But despite some high scores, it is less consistent than other explanation methods.

Magnitude-sensitive **LIMSSE** ($\text{limsse}^{\text{ms}}$) consistently outperforms black-box LIMSSE ($\text{limsse}^{\text{bb}}$), which suggests that numerical outputs should be used for approximation where possible. In the hybrid document experiment, magnitude-sensitive LIMSSE outperforms the other explanation methods (exceptions: C03, C05). However, it fails in the morphosyntactic agreement experiment (C16-C27). In fact, we expect LIMSSE to be unsuited for *large context* problems, as it cannot discover dependencies whose range is bigger than a given text sample. In Fig 3 (top), $\mathrm{limsse}_p^{\mathrm{ms}}$ highlights *any* singular noun without taking into account how that noun fits into the overall syntactic structure.

5.2 Evaluation paradigms

The assumptions made by our automatic evaluation paradigms have exceptions: (i) the correlation between fragment of origin and relevance does not always hold (e.g., a positive review may contain negative fragments, and will almost certainly contain neutral fragments); (ii) in morphological prediction, we cannot always expect the subject to be the only predictor for number. In Fig 2 (bottom) for example, "few" is a reasonable clue for plural despite not being a noun. This imperfect ground truth means that absolute pointing game accuracies should be taken with a grain of salt; but we argue that this does not invalidate them for comparisons.

We also point out that there are characteristics of explanations that may be desirable but are not reflected by the pointing game. Consider Fig 3 (bottom). Both explanations get hit points, but the lrp explanation appears "cleaner" than $\mathrm{limsse}_p^{\mathrm{ms}}$, with relevance concentrated on fewer tokens.

6 Related work

6.1 Explanation methods

Explanation methods can be divided into local and global methods (Doshi-Velez and Kim, 2017). Global methods infer general statements about what a DNN has learned, e.g., by clustering documents (Aubakirova and Bansal, 2016) or n-grams (Kádár et al., 2017) according to the neurons that they activate. Li et al. (2016a) compare embeddings of specific words with reference points to measure how drastically they were changed during training. In computer vision, Simonyan et al. (2014) optimize the input space to maximize the activation of a specific neuron. Global explanation methods are of limited value for explaining a specific prediction as they represent average behavior. Therefore, we focus on local methods.

Local explanation methods explain a decision taken for one specific input at a time. We have attempted to include all important local methods for NLP in our experiments (see §3). We do not address self-explanatory models (e.g., attention (Bahdanau et al., 2015) or rationale models (Lei et al., 2016)), as these are very specific architectures that may not be not applicable to all tasks.

6.2 Explanation evaluation

According to Doshi-Velez and Kim (2017)'s taxonomy of explanation evaluation paradigms, *application-grounded* paradigms test how well an explanation method helps real users solve real tasks (e.g., doctors judge automatic diagnoses); *human-grounded* paradigms rely on proxy tasks (e.g., humans rank task methods based on explanations); *functionally-grounded* paradigms work without human input, like our approach.

Arras et al. (2016) (cf. Samek et al. (2016)) propose a functionally-grounded explanation evaluation paradigm for NLP where words in a correctly (resp. incorrectly) classified document are deleted in descending (resp. ascending) order of relevance. They assume that the fewer words must be deleted to reduce (resp. increase) accuracy, the better the explanations. According to this metric, LRP (§3.2) outperforms $\mathrm{grad}^{\mathrm{L2}}$ on CNNs (Arras et al., 2016) and LSTMs (Arras et al., 2017b) on 20 newsgroups. Ancona et al. (2017) perform the same experiment with a binary sentiment analysis LSTM. Their graph shows occ_1, $\mathrm{grad}_1^{\mathrm{dot}}$ and $\mathrm{grad}_\int^{\mathrm{dot}}$ tied in first place, while LRP, DeepLIFT and the gradient L1 norm lag behind. Note that their treatment of LSTM gates in LRP / DeepLIFT differs from our implementation.

An issue with the word deletion paradigm is that it uses syntactically broken inputs, which may introduce artefacts (Sundararajan et al., 2017). In our hybrid document paradigm, inputs are syntactically intact (though semantically incoherent at the document level); the morphosyntactic agreement paradigm uses unmodified inputs.

Another class of functionally-grounded evaluation paradigms interprets the performance of a secondary task method, on inputs that are derived from (or altered by) an explanation method, as a proxy for the quality of that explanation method. Murdoch and Szlam (2017) build a rule-based classifier from the most relevant phrases in a corpus (task method: LSTM). The classifier based on decomp (§3.4) outperforms the gradient-based classifier, which is in line with our results. Arras et al. (2017a) build document representations by summing over word embeddings weighted by relevance scores (task method: CNN). They show that K-nearest neighbor performs better on document representations derived with LRP than on those derived with grad^{L2}, which also matches our results. Denil et al. (2015) condense documents by extracting top-K relevant sentences, and let the original task method (CNN) classify them. The accuracy loss, relative to uncondensed documents, is smaller for grad^{dot} than for heuristic baselines.

In the domain of human-based evaluation paradigms, Ribeiro et al. (2016) compare different variants of LIME (§3.6) by how well they help non-experts clean a corpus from words that lead to overfitting. Selvaraju et al. (2017) assess how well explanation methods help non-experts identify the more accurate out of two object recognition CNNs. These experiments come closer to real use cases than functionally-grounded paradigms; however, they are less scalable.

7 Summary

We conducted the first comprehensive evaluation of explanation methods for NLP, an important undertaking because there is a need for understanding the behavior of DNNs.

To conduct this study, we introduced evaluation paradigms for explanation methods for two classes of NLP tasks, small context tasks (e.g., topic classification) and large context tasks (e.g., morphological prediction). Neither paradigm requires manual annotations. We also introduced LIMSSE, a substring-based explanation method inspired by LIME and designed for NLP.

Based on our experimental results, we recommend LRP, DeepLIFT and LIMSSE for small context tasks and LRP and DeepLIFT for large context tasks, on all five DNN architectures that we tested. On CNNs and possibly GRUs, the (integrated) gradient embedding dot product is a good alternative to DeepLIFT and LRP.

8 Code

Our implementation of LIMSSE, the gradient, perturbation and decomposition methods can be found in our branch of the `keras` package: `www.github.com/NPoe/keras`. To re-run our experiments, see scripts in `www.github.com/NPoe/neural-nlp-explanation-experiment`. Our LRP implementation (same repository) is adapted from Arras et al. (2017b)[6].

Abstract

To be informative, an evaluation must measure how well systems generalize to realistic unseen data. We identify limitations of and propose improvements to current evaluations of text-to-SQL systems. First, we compare human-generated and automatically generated questions, characterizing properties of queries necessary for real-world applications. To facilitate evaluation on multiple datasets, we release standardized and improved versions of seven existing datasets and one new text-to-SQL dataset. Second, we show that the current division of data into training and test sets measures robustness to variations in the way questions are asked, but only partially tests how well systems generalize to new queries; therefore, we propose a complementary dataset split for evaluation of future work. Finally, we demonstrate how the common practice of anonymizing variables during evaluation removes an important challenge of the task. Our observations highlight key difficulties, and our methodology enables effective measurement of future development.

1 Introduction

Effective natural language interfaces to databases (NLIDB) would give lay people access to vast amounts of data stored in relational databases. This paper identifies key oversights in current evaluation methodology for this task. In the process, we (1) introduce a new, challenging dataset, (2) standardize and fix many errors in existing datasets, and (3) propose a simple yet effective baseline system.[1]

Question-Based Split
Train
Test
how many people are there in iowa?
select population
from state
where state_name = "iowa"
how many people live in utah?
select population
from state
where state_name = "utah"
Query-Based Split
Train
Test

Figure 1: Traditional question-based splits allow queries to appear in both train and test. Our query-based split ensures each query is in only one.

First, we consider query complexity, showing that human-written questions require more complex queries than automatically generated ones. To illustrate this challenge, we introduce *Advising*, a dataset of questions from university students about courses that lead to particularly complex queries.

Second, we identify an issue in the way examples are divided into training and test sets. The standard approach, shown at the top of Fig. 1, divides examples based on the text of each *question*. As a result, many of the queries in the test set are seen in training, albeit with different entity names and with the question phrased differently. This means metrics are mainly measuring robustness to the way a set of known SQL queries can be expressed in English—still a difficult problem, but not a complete test of ability to compose new queries in a familiar domain. We introduce a template-based slot-filling baseline that cannot generalize to new queries, and yet is competitive with prior work on multiple datasets. To measure robustness to new queries, we propose splitting based on the SQL *query*. We show that state-of-the-art systems with excellent performance on traditional question-based splits struggle on query-based splits. We also consider the common practice of variable anonymization, which removes a challenging form of ambiguity from the task. In the process, we apply extensive effort to standardize datasets and fix a range of errors.

Previous NLIDB work has led to impressive systems, but current evaluations provide an incomplete picture of their strengths and weaknesses. In this paper, we provide new and improved data, a new baseline, and guidelines that complement existing metrics, supporting future work.

2 Related Work

The task of generating SQL representations from English questions has been studied in the NLP and DB communities since the 1970s (Androutsopoulos et al., 1995). Our observations about evaluation methodology apply broadly to the systems cited below.

Within the DB community, systems commonly use pattern matching, grammar-based techniques, or intermediate representations of the query (Pazos Rangel et al., 2013). Recent work has explored incorporating user feedback to improve accuracy (Li and Jagadish, 2014). Unfortunately, none of these systems are publicly available, and many rely on domain-specific resources.

In the NLP community, there has been extensive work on semantic parsing to logical representations that query a knowledge base (Zettlemoyer and Collins, 2005; Liang et al., 2011; Beltagy et al., 2014; Berant and Liang, 2014), while work on mapping to SQL has recently increased (Yih et al., 2015; Iyer et al., 2017; Zhong et al., 2017). One of the earliest statistical models for mapping text to SQL was the PRECISE system (Popescu et al., 2003, 2004), which achieved high precision on queries that met constraints linking tokens and database values, attributes, and relations, but did not attempt to generate SQL for questions outside this class. Later work considered generating queries based on relations extracted by a syntactic parser (Giordani and Moschitti, 2012) and applying techniques from logical parsing research (Poon, 2013). However, none of these earlier systems are publicly available, and some required extensive engineering effort for each domain, such as the lexicon used by PRECISE.

More recent work has produced general purpose systems that are competitive with previous results and are also available, such as Iyer et al. (2017). We also adapt a logical form parser with a sequence to tree approach that makes very few assumptions about the output structure (Dong and Lapata, 2016).

One challenge for applying neural models to this task is annotating large enough datasets of question-query pairs. Recent work (Cai et al., 2017; Zhong et al., 2017) has automatically generated large datasets using templates to form random queries and corresponding natural-language-like questions, and then having humans rephrase the question into English. Another option is to use feedback-based learning, where the system alternates between training and making predictions, which a user rates as correct or not (Iyer et al., 2017). Other work seeks to avoid the data bottleneck by using end-to-end approaches (Yin et al., 2016; Neelakantan et al., 2017), which we do not consider here. One key contribution of this paper is standardization of a range of datasets, to help address the challenge of limited data resources.

3 Data

For our analysis, we study a range of text-to-SQL datasets, standardizing them to have a consistent SQL style.

ATIS (Price, 1990; Dahl et al., 1994) User questions for a flight-booking task, manually annotated. We use the modified SQL from Iyer et al. (2017), which follows the data split from the logical form version (Zettlemoyer and Collins, 2007).

GeoQuery (Zelle and Mooney, 1996) User questions about US geography, manually annotated with Prolog. We use the SQL version (Popescu et al., 2003; Giordani and Moschitti, 2012; Iyer et al., 2017), which follows the logical form data split (Zettlemoyer and Collins, 2005).

Restaurants (Tang and Mooney, 2000; Popescu et al., 2003) User questions about restaurants, their food types, and locations.

Scholar (Iyer et al., 2017) User questions about academic publications, with automatically generated SQL that was checked by asking the user if the output was correct.

Academic (Li and Jagadish, 2014) Questions about the Microsoft Academic Search (MAS) database, derived by enumerating every logical query that could be expressed using the search page of the MAS website and writing sentences to match them. The domain is similar to that of Scholar, but their schemas differ.

Yelp and IMDB (Yaghmazadeh et al., 2017) Questions about the Yelp website and the Internet Movie Database, collected from colleagues of the authors who knew the type of information in each database, but not their schemas.

WikiSQL (Zhong et al., 2017) A large collection of automatically generated questions about individual tables from Wikipedia, paraphrased by crowd workers to be fluent English.

Advising (This Work) Our dataset of questions over a database of course information at the University of Michigan, but with fictional student records. Some questions were collected from the EECS department Facebook page and others were written by CS students with knowledge of the database who were instructed to write questions they might ask in an academic advising appointment.

The authors manually labeled the initial set of questions with SQL. To ensure high quality, at least two annotators scored each question-query pair on a two-point scale for accuracy—did the query generate an accurate answer to the question?—and a three-point scale for helpfulness—did the answer provide the information the asker was probably seeking? Cases with low scores were fixed or removed from the dataset.

We collected paraphrases using Jiang et al. (2017)'s method, with manual inspection to ensure accuracy. For a given sentence, this produced paraphrases with the same named entities (e.g. course number EECS 123). To add variation, we annotated entities in the questions and queries with their types—such as course name, department, or instructor—and substituted randomly-selected values of each type into each paraphrase and its corresponding query. This combination of paraphrasing and entity replacement means an original question of "For next semester, who is teaching EECS 123?" can give rise to "Who teaches MATH 456 next semester?" as well as "Who's the professor for next semester's CHEM 789?"

3.1 SQL Canonicalization

SQL writing style varies. To enable consistent training and evaluation across datasets, we canonicalized the queries: (1) we alphabetically ordered fields in `SELECT`, tables in `FROM`, and constraints in `WHERE`; (2) we standardized table aliases in the form `<TABLE_NAME>alias<N>` for the `N`th use of the same table in one query; and (3) we standardized capitalization and spaces between symbols. We confirmed these changes do not alter the meaning of the queries via unit tests of the canonicalization code and manual inspection of the output. We also manually fixed some errors, such as ambiguous mixing of `AND` and `OR` (30 ATIS queries).

	Sets Identified	Affected Queries
ATIS	141	380
GeoQuery	17	39
Scholar	60	152

Table 1: Manually identified duplicate queries (different SQL for equivalent questions).

3.2 Variable Annotation

Existing SQL datasets do not explicitly identify which words in the question are used in the SQL query. Automatic methods to identify these variables, as used in prior work, do not account for ambiguities, such as words that could be either a city or an airport. To provide accurate anonymization, we annotated query variables using a combination of automatic and manual processing.

Our automatic process extracted terms from each side of comparison operations in SQL: one side contains quoted text or numbers, and the other provides a type for those literals. Often quoted text in the query is a direct copy from the question, while in some cases we constructed dictionaries to map common acronyms, like *american airlines*–`AA`, and times, like *2pm*–`1400`. The process flagged cases with ambiguous mappings, which we then manually processed. Often these were mistakes, which we corrected, such as missing constraints (e.g., *papers in 2015* with no date limit in the query), extra constraints (e.g., limiting to a single airline despite no mention in the question), inaccurate constraints (e.g., *more than 5* as `> 4`), and inconsistent use of *this year* to mean different years in different queries.

3.3 Query Deduplication

Three of the datasets had many duplicate queries (i.e., semantically equivalent questions with different SQL). To avoid this spurious ambiguity we manually grouped the data into sets of equivalent questions (Table 1). A second person manually inspected every set and ran the queries. Where multiple queries are valid, we kept them all, though only used the first for the rest of this work.

	Redundancy Measures						Complexity Measures							
	Question count	Unique query count	[1]/[2]	Queries / pattern μ	Queries / pattern Max	Pattern count	Tables / query μ	Tables / query Max	Unique tables / query μ	Unique tables / query Max	SELECTs / query μ	SELECTs / query Max	Nesting Depth μ	Nesting Depth Max
Advising	4570	211	21.7	20.3	90	174	3.2	9	3.0	9	1.23	6	1.18	4
ATIS	5280	947	5.6	7.0	870	751	6.4	32	3.8	12	1.79	8	1.39	8

WikiSQL	80,654	77,840	1.0	165.3	42,816	488	1	1	1	1	1	1	1	1

Table 2: Descriptive statistics for text-to-SQL datasets. Datasets in the first group are human-generated from the NLP community, in the second are human-generated from the DB community, and in the third are automatically-generated. [1]/[2] is Question count / Unique query count.

4 Evaluating on Multiple Datasets Is Necessary

For evaluation to be informative it must use data that is representative of real-world queries. If datasets have biases, robust comparisons of models will require evaluation on multiple datasets. For example, some datasets, such as ATIS and Advising, were collected from users and are task-oriented, while others, such as WikiSQL, were produced by automatically generating queries and engaging people to express the query in language. If these two types of datasets differ systematically, evaluation on one may not reflect performance on the other. In this section, we provide descriptive statistics aimed at understanding how several datasets differ, especially with respect to query redundancy and complexity.

4.1 Measures

We consider a range of measures that capture different aspects of data complexity and diversity:

Question / Unique Query Counts We measure dataset size and how many distinct queries there are when variables are anonymized. We also present the mean number of questions per unique query; a larger mean indicates greater redundancy.

SQL Patterns Complexity can be described as the answer to the question, "How many query-form patterns would be required to generate this dataset?" Fig. 2 shows an example of a pattern, which essentially abstracts away from the specific table and field names. Some datasets were generated from patterns similar to these, including WikiSQL and Cai et al. (2017). This enables the generation of large numbers of queries, but limits the variation between them to only that encompassed by their patterns. We count the number of patterns needed to cover the full dataset, where larger numbers indicate greater diversity. We also report mean queries per pattern; here, larger numbers indicate greater redundancy, showing that many queries fit the same mold.

```
SELECT <table-alias>.<field>
FROM <table> AS <table-alias>
WHERE <table-alias>.<field> = <literal>

SELECT RIVERalias0.RIVER_NAME
FROM RIVER AS RIVERalias0
WHERE RIVERalias0.TRAVERSE = "florida";

SELECT CITYalias0.CITY_NAME
FROM CITY AS CITYalias0
WHERE CITYalias0.STATE_NAME = "alabama";
```

Figure 2: An SQL pattern and example queries.

Counting Tables We consider the total number of tables and the number of unique tables mentioned in a query. These numbers differ in the event of self-joins. In both cases, higher values imply greater complexity.

Nesting A query with nested subqueries may be more complex than one without nesting. We count SELECT statements within each query to determine the number of sub-queries. We also report the depth of query nesting. In both cases, higher values imply greater complexity.

4.2 Analysis

The statistics in Table 2 show several patterns.

First, dataset size is not the best indicator of dataset diversity. Although WikiSQL contains fifteen times as many question-query pairs as ATIS, ATIS contains significantly more patterns than

WikiSQL; moreover, WikiSQL's queries are dominated by one pattern that is more than half of the dataset (`SELECT col AS result FROM table WHERE col = value`). The small, hand-curated datasets developed by the database community—Academic, IMDB, and Yelp—have noticeably less redundancy as measured by questions per unique query and queries per pattern than the datasets the NLP community typically evaluates on.

Second, human-generated datasets exhibit greater complexity than automatically generated data. All of the human-generated datasets except Yelp demonstrate at least some nesting. The average query from any of the human-generated datasets joins more than one table.

In particular, task-oriented datasets require joins and nesting. ATIS and Advising, which were developed with air-travel and student-advising tasks in mind, respectively, both score in the top three for multiple complexity scores.

To accurately predict performance on human-generated or task-oriented questions, it is thus necessary to evaluate on datasets that test the ability to handle nesting and joins. Training and testing NLP systems, particularly deep learning-based methods, benefits from large datasets. However, at present, the largest dataset available does not provide the desired complexity.

Takeaway: Evaluate on multiple datasets, some with nesting and joins, to provide a thorough picture of a system's strengths and weaknesses.

5 Current Data Splits Only Partially Probe Generalizability

It is standard best practice in machine learning to divide data into disjoint training, development, and test sets. Otherwise, evaluation on the test set will not accurately measure how well a model generalizes to new examples. The standard splits of GeoQuery, ATIS, and Scholar treat each pair of a natural language question and its SQL query as a single item. Thus, as long as each question-query pair appears in only one set, the test set is not tainted with training data. We call this a question-based data split.

However, many English questions may correspond to the same SQL query. If at least one copy of every SQL query appears in training, then the task evaluated is classification, not true semantic parsing, of the English questions. We can increase the number of distinct SQL queries by varying what entities our questions ask about; the queries for *what states border Texas* and *what states border Massachusetts* are not identical. Adding this variation changes the task from pure classification to classification plus slot-filling. Does this provide a true evaluation of the trained model's performance on unseen inputs?

It depends on what we wish to evaluate. If we want a system that answers questions within a particular domain, and we have a dataset that we are confident covers everything a user might want to know about that domain, then evaluating on the traditional question-based split tells us whether the system is robust to variation in how a request is expressed. But compositionality is an essential part of language, and a system that has trained on *What courses does Professor Smith teach?* and *What courses meet on Fridays?* should be prepared for *What courses that Professor Smith teaches meet on Fridays?* Evaluation on the question split does not tell us about a model's generalizable knowledge of SQL, or even its generalizable knowledge within the present domain.

To evaluate the latter, we propose a complementary new division, where no SQL query is allowed to appear in more than one set; we call this the *query split*. To generate a query split, we substitute variables for entities in each query in the dataset, as described in § 3.2. Queries that are identical when thus anonymized are treated as a single query and randomly assigned—with all their accompanying questions—to train, dev, or test. We include the original question split and the new query split labeling for the new Advising dataset, as well as ATIS, GeoQuery, and Scholar. For the much smaller Academic, IMDB, Restaurant, and Yelp datasets, we include question- and query- based buckets for cross validation.

5.1 Systems

Recently, a great deal of work has used variations on the seq2seq model. We compare performance of a basic seq2seq model (Sutskever et al., 2014), and seq2seq with attention over the input (Bahdanau et al., 2015), implemented with TensorFlow seq2seq (Britz et al., 2017). We also extend that model to include an attention-based copying option, similar to Jia and Liang (2016). Our output vocabulary for the decoder includes a special token, `COPY`. If `COPY` has the highest probability at step t, we replace it with the input token with the

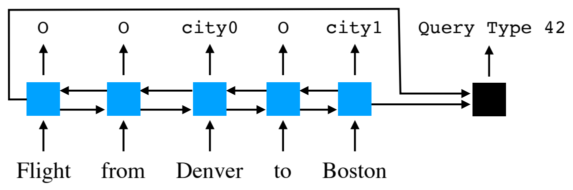

Figure 3: Baseline: blue boxes are LSTM cells and the black box is a feed-forward network. Outputs are the query template to use (right) and which tokens to fill it with (left).

max of the normalized attention scores. Our loss function is the sum of two terms: first, the categorical cross entropy for the model's probability distribution over the output vocabulary tokens; and second, the loss for word copying. When the correct output token is `COPY`, the second loss term is the categorical cross entropy of the distribution of attention scores at time t. Otherwise it is zero.

For comparison, we include systems from two recent papers. Dong and Lapata (2016) used an attention-based seq2tree model for semantic parsing of logical forms; we apply their code here to SQL datasets. Iyer et al. (2017) use a seq2seq model with automatic dataset expansion through paraphrasing and SQL templates.[2]

We could not find publicly available code for the non-neural text-to-SQL systems discussed in Section 2. Also, most of those approaches require development of specialized grammars or templates for each new dataset they are applied to, so we do not compare such systems.

5.2 New Template Baseline

In addition to the seq2seq models, we develop a new baseline system for text-to-SQL parsing which exploits repetitiveness in data. First, we automatically generate SQL templates from the training set. The system then makes two predictions: (1) which template to use, and (2) which words in the sentence should fill slots in the template. This system is not able to generalize beyond the queries in the training set, so it will fail completely on the new query-split data setting.

Fig. 3 presents the overall architecture, which we implemented in DyNet (Neubig et al., 2017). A bidirectional LSTM provides a prediction for each word, either `O` if the word is not used in the final query, or a symbol such as `city1` to indicate that it fills a slot. The hidden states of the LSTM at each end of the sentence are passed through a small feed-forward network to determine the SQL template to use. This architecture is simple and enables a joint choice of the tags and the template, though we do not explicitly enforce agreement.

To train the model, we automatically construct a set of templates and slots. Slots are determined based on the variables in the dataset, with each SQL variable that is explicitly given in the question becoming a slot. We can construct these templates because our new version of the data explicitly defines all variables, their values, and where they appear in both question and query.

For completeness, we also report on an oracle version of the template-based system (performance if it always chose the correct template from the train set and filled all slots correctly).

5.3 Oracle Entity Condition

Some systems, such as Dong and Lapata's model, are explicitly designed to work on anonymized data (i.e., data where entity names are replaced with a variable indicating their type). Others, such as attention-based copying models, treat identification of entities as an inextricable component of the text-to-SQL task. We therefore describe results on both the actual datasets with entities in place and a version anonymized using the variables described in § 3.2. We refer to the latter as the oracle entity condition.

5.4 Results and Analysis

We hypothesized that even a system unable to generalize can achieve good performance on question-based splits of datasets, and the results in Table 3 substantiate that for the NLP community's datasets. The template-based, slot-filling baseline was competitive with state-of-the-art systems for question split on the four datasets from the NLP community. The template-based oracle performance indicates that for these datasets anywhere from 70-100% accuracy on question-based split could be obtained by selecting a template from the training set and filling in the right slots.

For the three datasets developed by the databases community, the effect of question-query split is far less pronounced. The small sizes of these datasets cannot account for the difference,

[2] We enable Iyer et al. (2017)'s paraphrasing data augmentation, but not their template-based augmentation because templates do not exist for most of the datasets (though they also found it did not significantly improve performance). Note, on ATIS and Geo their evaluation assumed no ambiguity in entity identification, which is equivalent to our Oracle Entities condition (§5.3).

Table 3: Accuracy of neural text-to-SQL systems on English question splits ('?' columns) and SQL query splits ('Q' columns). The vertical line separates datasets from the NLP (left) and DB (right) communities. Results for Iyer et al. (2017) are slightly lower here than in the original paper because we evaluate on SQL output, not the database response.

since even the oracle baseline did not have much success on these question splits, and since the baseline was able to handle the small Restaurants dataset. Looking back at Section 4, however, we see that these are the datasets with the least redundancy in Table 2. Because their question:unique-query ratios are nearly 1:1, the question splits and query splits of these datasets were quite similar.

Reducing redundancy does not improve performance on query split, though; at most, it reduces the difference between performance on the two splits. IMDB and Yelp both show weak results on query split despite their low redundancy. Experiments on a non-redundant version of query split for Advising, ATIS, GeoQuery, and Restaurant that contained only one question for each query confirmed this: in each case, accuracy remained the same or declined relative to regular query split.

Having ruled out redundancy as a cause for the exceptional performance on Academic's query split, we suspect the simplicity of its questions and the compositionality of its queries may be responsible. Every question in the dataset begins *return me* followed by a phrase indicating the desired field, optionally followed by one or more constraints; for instance, *return me the papers by 'author_name0'* and *return me the papers by 'author_name0' on journal_name0.*

None of this, of course, is to suggest that question-based split is an easy problem, even on the NLP community's datasets. Except for the Advising and Restaurants datasets, even the oracle version of the template-based system is far from perfect. Access to oracle entities helps performance of non-copying systems substantially, as we would expect. Entity matching is thus a non-trivial component of the task.

But the query-based split is certainly more difficult than the question-based split. Across datasets and systems, performance suffered on query split. Access to oracle entities did not remove this effect.

Many of the seq2seq models do show some ability to generalize, though. Unlike the template-based baseline, many were able to eek out some performance on query split.

On question split, ATIS is the most difficult of the NLP datasets, yet on query split, it is among the easiest. To understand this apparent contradiction, we must consider what kinds of mistakes systems make and the contexts in which they appear. We therefore analyze the output of the attention-based-copying model in greater detail.

We categorize each output as shown in column one of Table 4. The "Correct" category is self-explanatory. "Entity problem only" means that the query would have been correct but for a mistake in one or more entity names. "Different template" means that the system output was the same as another query from the dataset but for the entity names; however, it did not match the correct query for this question. "No template match" contains both the most mundane and the most interesting errors. Here, the system output a query that is not copied from training data. Sometimes, this is a simple error, such as inserting an extra comma in the `WHERE` clause. Other times, it is recombining

		Advising		ATIS		GeoQuery		Scholar

Table 4: Types of errors by the attention-based copying model for question and query splits, with (Count)s of queries in each category, and the (μ Length) of gold queries in the category.

segments of queries it has seen into new queries. This is necessary but not sufficient model behavior in order to do well on the query split. In at least one case, this category includes a semantically equivalent query marked as incorrect by the exact-match accuracy metric.[3] Table 4 shows the number of examples from the test set that fell into each category, as well as the mean length of gold queries ("length") for each category.

Short queries are easier than long ones in the question-based condition. In most cases, length in "correct" is shorter than length in either "different template" or "no template match" categories.

In addition, for short queries, the model seems to prefer to copy a query it has seen before; for longer ones, it generates a new query. In every case but one, mean length in "different template" is less than in "No template match."

Interestingly, in ATIS and GeoQuery, where the model performs tolerably well on query split, the length for correct queries in query split is higher than the length for correct queries from the question split. Since, as noted above, recombination of template pieces (as we see in "no template match") is a necessary step for success on query split, it may be that longer queries have a higher probability of recombination, and therefore a better chance of being correct in query split. The data from Scholar does not support this position; however, note that only 17 queries were correct in Scholar query split, suggesting caution in making generalizations from this set.

These results also seem to indicate that our copying mechanism effectively deals with entity identification. Across all datasets, we see only a small number of entity-problem-only examples. However, comparing the rows from Table 3 for seq2seq+Copy at the top and seq2seq+Attention in the oracle entities condition, it is clear that having oracle entities provides a useful signal, with consistent gains in performance.

Takeaways: Evaluate on both question-based and query-based dataset splits. Additionally, variable anonymization noticeably decreases the difficulty of the task; thus, thorough evaluations should include results on datasets without anonymization.

5.5 Logic Variants

To see if our observations on query and question split performance apply beyond SQL, we also considered the logical form annotations for ATIS and GeoQuery (Zettlemoyer and Collins, 2005, 2007). We retrained Jia and Liang (2016)'s baseline and full system. Interestingly, we founnd limited impact on performance, measured with either logical forms or denotations. To understand why, we inspected the logical form datasets. In both ATIS and GeoQuery, the logical form version has a larger set of queries after variable identification. This seems to be because the logic abstracts away from the surface form less than SQL does. For example, these questions have the same SQL in our data, but different logical forms:

what state has the largest capital

```
(A, (state(A), loc(B, A), largest(B, capital(B))))
```

which state 's capital city is the largest

```
(A, largest(B, (state(A), capital(A, B), city(B))))
```

```
SELECT CITYalias0.STATE_NAME
FROM CITY AS CITYalias0
WHERE CITYalias0.POPULATION = (
  SELECT MAX( CITYalias1.POPULATION )
  FROM CITY AS CITYalias1 ,
       STATE AS STATEalias0
  WHERE STATEalias0.CAPITAL =
        CITYalias1.CITY_NAME ) ;
```

Other examples include variation in the logical form between sentences with *largest* and *largest*

[3]For the question *which of the states bordering pennsylvania has the largest population*, the gold query ranked the options by population and kept the top result, while the system output used a subquery to find the max population then selected states that had that population.

population even though the associated dataset only has population figures for cities (not area or any other measure of size). Similarly in ATIS, the logical form will add `(flight $0)` if the question mentions flights explicitly, making these two queries different, even though they convey the same user intent:

what flights do you have from bwi to sfo
i need a reservation from bwi to sfo

By being closer to a syntactic representation, the queries end up being more compositional, which encourages the model to learn more compositionality than the SQL models do.

6 Conclusion

In this work, we identify two issues in current datasets for mapping questions to SQL queries. First, by analyzing question and query complexity we find that human-written datasets require properties that have not yet been included in large-scale automatically generated query sets. Second, we show that the generalizability of systems is overstated by the traditional data splits. In the process we also identify and fix hundreds of mistakes across multiple datasets and homogenize the SQL query structures to enable effective multi-domain experiments.

Our analysis has clear implications for future work. Evaluating on multiple datasets is necessary to ensure coverage of the types of questions humans generate. Developers of future large-scale datasets should incorporate joins and nesting to create more human-like data. And new systems should be evaluated on both question- and query-based splits, guiding the development of truly general systems for mapping natural language to structured database queries.

Abstract

We present a generative model to map natural language questions into SQL queries. Existing neural network based approaches typically generate a SQL query word-by-word, however, a large portion of the generated results is incorrect or not executable due to the mismatch between question words and table contents. Our approach addresses this problem by considering the structure of table and the syntax of SQL language. The quality of the generated SQL query is significantly improved through (1) learning to replicate content from column names, cells or SQL keywords; and (2) improving the generation of WHERE clause by leveraging the column-cell relation. Experiments are conducted on WikiSQL, a recently released dataset with the largest question-SQL pairs. Our approach significantly improves the state-of-the-art execution accuracy from 69.0% to 74.4%.

1 Introduction

We focus on semantic parsing that maps natural language utterances to executable programs (Zelle and Mooney, 1996; Wong and Mooney, 2007; Zettlemoyer and Collins, 2007; Kwiatkowski et al., 2011; Pasupat and Liang, 2015; Iyer et al., 2017; Iyyer et al., 2017). In this work, we regard SQL as the programming language, which could be executed on a table or a relational database to obtain an outcome. Datasets are the main driver of progress for statistical approaches in semantic parsing (Liang, 2016). Recently, Zhong et al. (2017) release WikiSQL, the largest hand-annotated semantic parsing dataset which is an order of magnitude larger than other datasets in terms of both the number of logical forms and the number of tables. Pointer network (Vinyals et al., 2015) based approach is developed, which generates a SQL query word-by-word through replicating from a word sequence consisting of question words, column names and SQL keywords. However, a large portion of generated results is incorrect or not executable due to the mismatch between question words and column names (or cells). This also reflects the real scenario where users do not always use exactly the same column name or cell content to express the question.

To address the aforementioned problem, we present a generative semantic parser that considers the structure of table and the syntax of SQL language. The approach is partly inspired by the success of structure/grammar driven neural network approaches in semantic parsing (Xiao et al., 2016; Krishnamurthy et al., 2017). Our approach is based on pointer networks, which encodes the question into continuous vectors, and synthesizes the SQL query with three channels. The model learns when to generate a column name, a cell or a SQL keyword. We further incorporate column-cell relation to mitigate the ill-formed outcomes.

We conduct experiments on WikiSQL. Results show that our approach outperforms existing systems, improving state-of-the-art execution accuracy to 74.4% and logical form accuracy to 60.7%. An extensive analysis reveals the advantages and limitations of our approach.

2 Task Formulation and Dataset

As shown in Figure 1, we focus on sequence-to-SQL generation in this work. Formally, the task takes a question q and a table t consisting of n col-

Question :
what 's the total number of songs originally performed by anna nalick ?
Table
Sequence-to-SQL Generation
SELECT clause
WHERE clause
SQL : SELECT COUNT Song choice WHERE Original artist = anna christine nalick
Execution
SELECT aggregator
WHERE column
WHERE operator
SELECT column
WHERE value
1
Answer

Episode	Song choice	Original artist
Top 80	I Try	Macy Gray
Top 40	Breathe (2 AM)	Anna Christine Nalick
Top 22	Put Your Records On	Corinne Bailey Rae
Top 18	Sweet Ones	Sarah Slean
Top 10	Inside and Out	Bee Gees

Figure 1: An brief illustration of the task. The focus of this work is sequence-to-SQL generation.

umn names and $n \times m$ cells as the input, and outputs a SQL query y. We do not consider the join operation over multiple relational tables, which we leave in the future work.

We use WikiSQL (Zhong et al., 2017), the largest hand-annotated semantic parsing dataset to date which consists of 87,726 questions and SQL queries distributed across 26,375 tables from Wikipedia.

3 Related Work

Semantic Parsing. Semantic parsing aims to map natural language utterances to programs (e.g., logical forms), which will be executed to obtain the answer (denotation) (Zettlemoyer and Collins, 2005; Liang et al., 2011; Berant et al., 2013; Poon, 2013; Krishnamurthy and Kollar, 2013; Pasupat and Liang, 2016; Sun et al., 2016; Jia and Liang, 2016; Kočiský et al., 2016; Lin et al., 2017). Existing studies differ from (1) the form of the knowledge base, e.g. facts from Freebase, a table (or relational database), an image (Suhr et al., 2017; Johnson et al., 2017; Hu et al., 2017; Goldman et al., 2017) or a world state (Long et al., 2016); (2) the programming language, e.g. first-order logic, lambda calculus, lambda DCS, SQL, parameterized neural programmer (Yin et al., 2015; Neelakantan et al., 2016), or coupled distributed and symbolic executors (Mou et al., 2017); (3) the supervision used for learning the semantic parser, e.g. question-denotation pairs, binary correct/incorrect feedback (Artzi and Zettlemoyer, 2013), or richer supervision of question-logical form pairs (Dong and Lapata, 2016). In this work, we study semantic parsing over tables, which is critical for users to access relational databases with natural language, and could serve users' information need for structured data on the web. We use SQL as the programming language, which has a broad acceptance to programmers.

Natural Language Interface for Databases. Our work relates to the area of accessing database with natural language interface (Dahl et al., 1994; Brad et al., 2017). Popescu et al. (2003) use a parser to parse the question, and then use lexicon matching between question and the table column names/cells. Giordani and Moschitti (2012) parse the question with dependency parser, compose candidate SQL queries with heuristic rules, and use kernel based SVM ranker to rank the results. Li and Jagadish (2014) translate natural language utterances into SQL queries based on dependency parsing results, and interact with users to ensure the correctness of the interpretation process. Yaghmazadeh et al. (2017) build a semantic parser on the top of SEMPRE (Pasupat and Liang, 2015) to get a SQL sketch, which only has the SQL shape and will be subsequently completed based on the table content. Iyer et al. (2017) maps utterances to SQL queries through sequence-to-sequence learning. User feedbacks are incorporated to reduce the number of queries to be labeled. Zhong et al. (2017) develop an augmented pointer network, which is further improved with reinforcement learning for SQL sequence prediction. Xu et al. (2017) adopts a sequence-to-set model to predict WHERE columns, and uses an attentional model to predict the slots in where clause.

Different from (Iyer et al., 2017; Zhong et al., 2017), our approach leverages SQL syntax and table structure. Compared to (Popescu et al., 2003; Giordani and Moschitti, 2012; Yaghmazadeh et al., 2017), our approach is end-to-end learning and independent of a syntactic parser or manually designed templates. We are aware of existing studies that combine reinforcement learning and maximum likelihood estimation (MLE) (Guu et al., 2017; Mou et al., 2017; Liang et al., 2017). However, the focus of this work is the design of the neural architecture, despite we also implement an RL strategy (refer to §4.4).

Structure/Grammar Guided Neural Decoder Our approach could be viewed as an extension of the sequence-to-sequence learning (Sutskever et al., 2014; Bahdanau et al., 2015) with a tailored neural decoder driven by the characteristic of the target language (Yin and Neubig, 2017; Rabinovich et al., 2017). Methods with similar intuitions have been developed for language modeling (Dyer et al., 2016), neural machine translation (Wu et al., 2017) and lambda calculus based semantic parsing (Dong and Lapata, 2016; Krishnamurthy et al., 2017). The difference is that our model is developed for sequence-to-SQL generation, in which table structure and SQL syntax are considered.

4 Methodology

We first describe the background on pointer networks, and then present our approach that considers the table structure and the SQL syntax.

4.1 Background: Pointer Networks

Pointer networks is originally introduced by (Vinyals et al., 2015), which takes a sequence of elements as the input and outputs a sequence of discrete tokens corresponding to positions in the input sequence. The approach has been successfully applied in reading comprehension (Kadlec et al., 2016) for pointing to the positions of answer span from the document, and also in sequence-to-sequence based machine translation (Gulcehre et al., 2016) and text summarization (Gu et al., 2016) for replicating rare words from the source sequence to the target sequence.

The approach of Zhong et al. (2017) is based on pointer networks. The encoder is a recurrent neural network (RNN) with gated recurrent unit (GRU) (Cho et al., 2014), whose input is the concatenation of question words, words from column names and SQL keywords. The decoder is another GRU based RNN, which works in a sequential way and generates a word at each time step. The generation of a word is actually selectively replicating a word from the input sequence, the probability distribution of which is calculated with an attention mechanism (Bahdanau et al., 2015). The probability of generating the i-th word x_i in the input sequence at the t-th time step is calculated as Equation 1, where h_t^{dec} is the decoder hidden state at the t-th time step, h_i^{enc} is the encoder hidden state of the word x_i, W_a is the model parameter.

$$p(y_t = x_i | y_{<t}, x) \propto exp(W_a[h_t^{dec}; h_i^{enc}]) \quad (1)$$

It is worth to note that if a column name consists of multiple words (such as "original artist" in Figure 1), these words are separated in the input sequence. The approach has no guarantee that a multi-word column name could be successively generated, which would affect the executability of the generated SQL query.

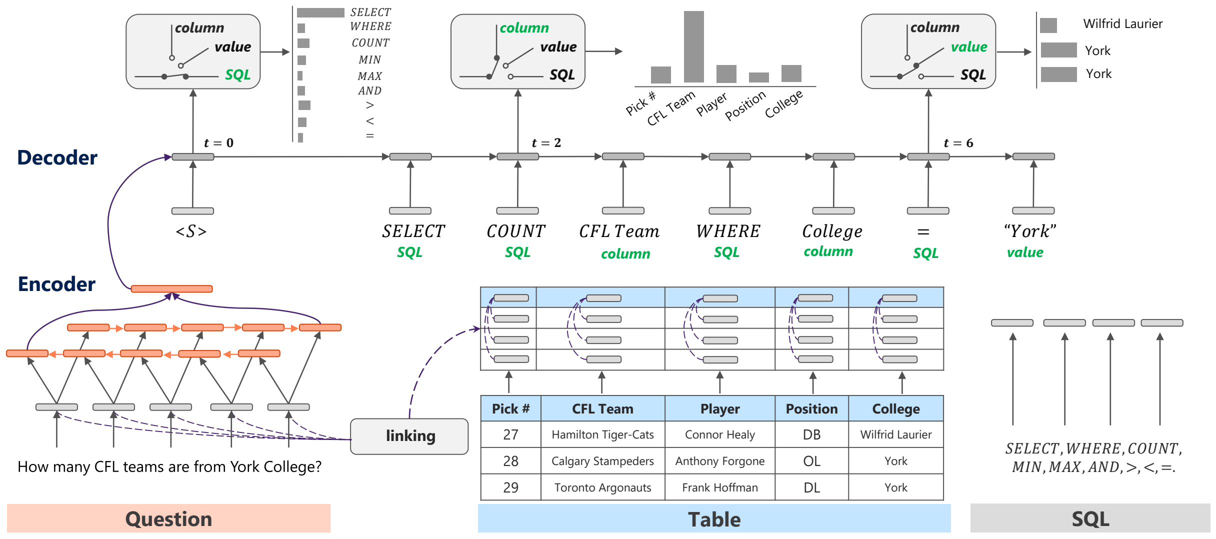
4.2 STAMP: Syntax- and Table- Aware seMantic Parser

Figure 2 illustrates an overview of the proposed model, which is abbreviated as STAMP. Different from Zhong et al. (2017), the word is not the basic unit to be generated in STAMP. As is shown, there are three "channels" in STAMP, among which the column channel predicts a column name, the value channel predicts a table cell and the SQL channel predicts a SQL keyword. Accordingly, the probability of generating a target token is formulated in Equation 2, where z_t stands for the channel selected by the switching gate, $p_z(\cdot)$ is the probability to choose a channel, and $p_w(\cdot)$ is similar to Equation 1 which is a probability distribution over the tokens from one of the three channels.

$$p(y_t | y_{<t}, x) = \sum_{z_t} p_w(y_t | z_t, y_{<t}, x) p_z(z_t | y_{<t}, x) \quad (2)$$

One advantage of this architecture is that it inherently addresses the problem of generating partial column name/cell because an entire column name/cell is the basic unit to be generated. Another advantage is that the column-cell relation and question-cell connection can be naturally integrated in the model, which will be described below.

Specifically, our encoder takes a question as the input. Bidirectional RNN with GRU unit is applied to the question, and the concatenation of both ends is used as the initial state of the decoder. Another bidirectional RNN is used to compute the representation of a column name (or a cell), in case that each unit contains multiple words (Dong



Pick #	CFL Team	Player	Position	College
27	Hamilton Tiger-Cats	Connor Healy	DB	Wilfrid Laurier
28	Calgary Stampeders	Anthony Forgone	OL	York
29	Toronto Argonauts	Frank Hoffman	DL	York

Figure 2: An illustration of the proposed approach. At each time step, a switching gate selects a channel to predict a column name (maybe composed of multiple words), a cell or a SQL keyword. The words in green below the SQL tokens stand for the results of the switching gate at each time step.

et al., 2015). Essentially, each channel is an attentional neural network. For cell and SQL channels, the input of the attention module only contains the decoder hidden state and the representation of the token to be calculated as follows,

$$p_w^{sql}(i) \propto exp(W_{sql}[h_t^{dec}; e_i^{sql}]) \qquad (3)$$

where e_i^{sql} stands for the representation of the i-th SQL keyword. As suggested by (Zhong et al., 2017), we also concatenate the question representation into the input of the column channel in order to improve the accuracy of the SELECT column. We implement the switching gate with a feed-forward neural network, in which the output is a $softmax$ function and the input is the decoder hidden state h_t^{dec}.

4.3 Improved with Column-Cell Relation

We further improve the STAMP model by considering the column-cell relation, which is important for predicting the WHERE clause.

On one hand, the column-cell relation could improve the prediction of SELECT column. We observe that a cell or a part of it typically appears at the question acting as the WHERE value, such as *"anna nalick"* for "*anna christine nalick*"). However, a column name might be represented with a totally different utterance, which is a "semantic gap". Supposing the question is "How many schools did player number 3 play at?" and the SQL query is "Select count School Club Team where No. = 3". We could see that the column names "School Club Team" and "No." are different from their corresponding utterances "schools", "number" in natural language question. Thus, table cells could be regarded as the pivot that connects the question and column names (the "linking" component in Figure 2). For instance, taking the question from Figure 2, the word "*York*" would help to predict the column name as "*College*" rather than "*Player*". There might be different possible ways to implement this intuition. We use cell information to enhance the column name representation in this work. The vector of a column name is further concatenated with a question-aware cell vector, which is weighted averaged over the cell vectors belonging to the same column. The probability distribution in the column channel is calculated as Equation 4. We use the number of cell words occurring in the question to measure the importance of a cell, which is further normalized through a $softmax$ function to yield the final weight $\alpha_j^{cell} \in [0, 1]$. An alternative measurement is to use an additional attention model whose input contains the question vector and the cell vector. We favor to the intuitive and efficient way in this work.

$$p_w^{col}(i) \propto exp(W_{col}[h_t^{dec}; h_i^{col}; \sum_{j \in col_i} \alpha_j^{cell} h_j^{cell}]) \qquad (4)$$

On the other hand, the column-cell relation could improve the prediction of the WHERE value. To yield an executable SQL, the WHERE value should be a cell that belongs to the same WHERE column[1]. Taking Figure 2 as an example, it should be avoided to predict a where clause like "*Player* = *York*" because the cell "*York*" does not belong to the column name "*Player*". To achieve this, we incorporate a global variable to memorize the last predicted column name. When the switching gate selects the value channel, the cell distribution is only calculated over the cells belonging to the last predicted column name. Furthermore, we incorporate an additional probability distribution over cells based on the aforementioned word co-occurrence between the question and cells, and weighted average two cell distributions, which is calculated as follows.

$$p_w^{cell}(j) = \lambda \hat{p}_w^{cell}(j) + (1-\lambda)\alpha_j^{cell} \qquad (5)$$

where $\hat{p}_w^{cell}(j)$ is the standard probability distribution obtained from the attentional neural network, and λ is a hyper parameter which is tuned on the dev set.

4.4 Improved with Policy Gradient

The model described so far could be conventionally learned via cross-entropy loss over question-SQL pairs. However, different SQL queries might be executed to yield the same result, and possible SQL queries of different variations could not be exhaustively covered in the training dataset. Two possible ways to handle this are (1) shuffling the WHERE clause to generate more SQL queries, and (2) using reinforcement learning (RL) which regards the correctness of the executed output as the goodness (reward) of the generated SQL query. We follow Zhong et al. (2017) and adopt a policy gradient based approach. We use a baseline strategy (Zaremba and Sutskever, 2015) to decrease the learning variance. The expected reward (Williams, 1992) for an instance is calculated as $\mathbb{E}(y_g) = \sum_{j=1}^{k} logp(y_j)R(y_j, y^g)$, where y^g is the ground truth SQL query, y_j is a generated SQL query, $p(y_j)$ is the probability of y_j being generated by our model, and k is the number of sampled SQL queries. $R(y_j, y^g)$ is the same reward function defined by Zhong et al. (2017), which is $+1$ if y_j is executed to yield the correct answer; -1 if y_j is a valid SQL query and is executed to get an incorrect answer; and -2 if y_j is not a valid SQL query. In this way, model parameters could be updated with policy gradient over question-answer pairs.

4.5 Training and Inference

As the WikiSQL data contains rich supervision of question-SQL pairs, we use them to train model parameters. The model has two cross-entropy loss functions, as given below. One is for the switching gate classifier (p_z) and another is for the attentional probability distribution of a channel (p_w).

$$l = -\sum_t logp_z(z_t|y_{<t}, x) - \sum_t logp_w(y_t|z_t, y_{<t}, x) \qquad (6)$$

Our parameter setting strictly follows Zhong et al. (2017). We represent each word using word embedding[2] (Pennington et al., 2014) and the mean of the sub-word embeddings of all the n-grams in the word (Hashimoto et al., 2016)[3]. The dimension of the concatenated word embedding is 400. We clamp the embedding values to avoid over-fitting. We set the dimension of encoder and decoder hidden state as 200. During training, we randomize model parameters from a uniform distribution with fan-in and fan-out, set batch size as 64, set the learning rate of SGD as 0.5, and update the model with stochastic gradient descent. Greedy search is used in the inference process. We use the model trained from question-SQL pairs as initialization and use RL strategy to fine-tune the model. SQL queries used for training RL are sampled based on the probability distribution of the model learned from question-SQL pairs. We tune the best model on the dev set and do inference on the test set for only once. This protocol is used in model comparison as well as in ablations.

5 Experiment

We conduct experiments on the WikiSQL dataset[4], which includes $61,297/9,145/17,284$ examples in the training/dev/test sets. Each instance consists of a question, a table, a SQL query and a result. Following Zhong et al. (2017), we use two

[1]This constraint is suitable in this work as we do not consider the nested query in the where clause, such as "*where College = select College from table*", which is also the case not included in the WikiSQL dataset. We leave generating nested SQL query in the future work.

evaluation metrics. One metric is logical form accuracy (Acc_{lf}), which measures the percentage of the generated SQL queries that have exact string match with the ground truth SQL queries. Since different SQL queries might obtain the same result, another metric is execution accuracy (Acc_{ex}), which measures the percentage of the generated SQL queries that obtain the correct answer.

5.1 Model Comparisons

After released, WikiSQL dataset has attracted a lot of attentions from both industry and research communities. Zhong et al. (2017) develop following methods, including (1) Aug.PntNet which is an end-to-end learning pointer network approach; (2) Seq2SQL (no RL), in which two separate classifiers are trained for SELECT aggregator and SELECT column, separately; and (3) Seq2SQL, in which reinforcement learning is further used for model training. Results of tattentional sequence-to-sequence learning baseline (Attentional Seq2Seq) are also reported in (Zhong et al., 2017). Xu et al. (2017) develop SQLNet, which predicts SELECT clause and WHERE clause separately. Sequence-to-set neural architecture and column attention are adopted to predict the WHERE clause. Similarly, Guo and Gao (2018) develop tailored modules to handle three components of SQL queries, respectively. A parallel work from (Yu et al., 2018) obtains higher execution accuracy (82.6%) on WikiSQL, however, its model is slot-filling based which is designed specifically for the "select-aggregator-where" type and utilizes external knowledge base (such as Freebase) to tag the question words. We believe this mechanism could improve our model as well, we leave this as a potential future work.

Our model is abbreviated as (**STAMP**), which is short for Syntax- and Table- Aware seMantic Parser. The STAMP model in Table 1 stands for the model we describe in §4.2 plus §4.3. STAMP+RL is the model that is fine-tuned with the reinforcement learning strategy as described in §4.4. We implement a simplified version of our approach (w/o cell), in which WHERE values come from the question. Thus, this setting differs from Aug.PntNet in the generation of WHERE column. We also study the influence of the relation-cell relation (w/o column-cell relation) through removing the enhanced column vector, which is calculated by weighted averaging cell vectors.

From Table 1, we can see that STAMP performs better than existing systems on WikiSQL. Incorporating RL strategy does not significantly improve the performance. Our simplified model, STAMP (w/o cell), achieves better accuracy than Aug.PntNet, which further reveals the effects of the column channel. Results also demonstrate the effects of incorporating the column-cell relation, removing which leads to about 4% performance drop in terms of Acc_{ex}.

5.2 Model Analysis: Fine-Grained Accuracy

We analyze the STAMP model from different perspectives in this part.

Firstly, since SQL queries in WikiSQL consists of SELECT column, SELECT aggregator, and WHERE clause, we report the results with regard

Methods	Dev			Test		
	Acc$_{sel}$	Acc$_{agg}$	Acc$_{where}$	Acc$_{sel}$	Acc$_{agg}$	Acc$_{where}$
Aug.PntNet (reimplemented by us)	80.9%	89.3%	62.1%	81.3%	89.7%	62.1%
Seq2SQL (Zhong et al., 2017)	89.6%	90.0%	62.1%	88.9%	90.1%	60.2%
SQLNet (Xu et al., 2017)	91.5%	90.1%	74.1%	90.9%	90.3%	71.9%
Guo and Gao (2018)	92.5%	90.1%	74.7%	91.9%	90.3%	72.8%
STAMP (w/o cell)	89.9%	89.2%	72.1%	89.2%	89.3%	71.2%
STAMP (w/o column-cell relation)	89.3%	89.2%	73.2%	88.8%	89.2%	71.8%
STAMP	89.4%	89.5%	77.1%	88.9%	89.7%	76.0%
STAMP+RL	89.6%	89.7%	77.3%	90.0%	89.9%	76.3%

Table 2: Fine-grained accuracies on the WikiSQL dev and test sets. Accuracy (Acc$_{lf}$) is evaluated on SELECT column (Acc$_{sel}$) , SELECT aggregator (Acc$_{agg}$), and WHERE clause (Acc$_{where}$), respectively.

to more fine-grained evaluation metrics over these aspects. Results are given in Table 2, in which the numbers of Seq2SQL and SQLNet are reported in (Xu et al., 2017). We can see that the main improvement of STAMP comes from the WHERE clause, which is also the key challenge of the WikiSQL dataset. This is consistent with our primary intuition on improving the prediction of WHERE column and WHERE value. The accuracies of STAMP on SELECT column and SELECT aggregator are not as high as SQLNet. The main reason is that these two approaches train the SELECT clause separately while STAMP learns all these components in a unified paradigm.

5.3 Model Analysis: Difficulty Analysis

We study the performance of STAMP on different portions of the test set according to the difficulties of examples. We compare between Aug.PntNet (re-implemented by us) and STAMP. In this work, the difficulty of an example is reflected by the number of WHERE columns.

Method	#where	Dev	Test
	$= 1$	63.4%	63.8%
Aug.PntNet	$= 2$	51.0%	51.8%
	≥ 3	38.5%	38.1%
	$= 1$	80.9%	80.2%
STAMP	$= 2$	65.1%	65.4%
	≥ 3	44.1%	48.2%

Table 3: Execution accuracy (Acc$_{ex}$) on different groups of WikiSQL dev and test sets.

From Table 3, we can see that STAMP outperforms Aug.PntNet in all these groups. The accuracy decreases with the increase of the number of WHERE conditions.

5.4 Model Analysis: Executable Analysis

We study the percentage of executable SQL queries in the generated results. As shown in Table 4, STAMP significantly outperforms Aug.PntNet. Almost all the results of STAMP are executable. This is because STAMP avoids generating incomplete column names or cells, and guarantees the correlation between WHERE conditions and WHERE values in the table.

	Dev	Test
Aug.PntNet	77.9%	78.7%
STAMP	99.9%	99.9%

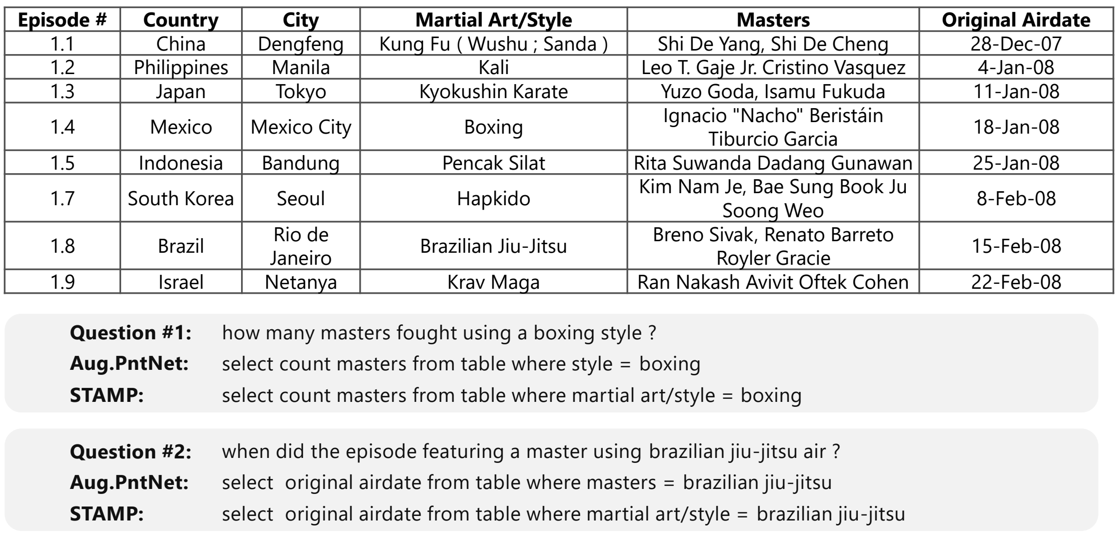
Table 4: Percentage of the executable SQL queries on WikiSQL dev and test sets.

5.5 Model Analysis: Case Study

We give a case study to illustrate the generated results by STAMP, with a comparison to Aug.PntNet. Results are given in Figure 3. In the first example, Aug.PntNet generates incomplete column name (“*style*”), which is addressed in STAMP through replicating an entire column name. In the second example, the WHERE value (“*brazilian jiu-jitsu*”) does not belong to the generated WHERE column (“*Masters*”) in Aug.PntNet. This problem is avoided in STAMP through incorporating the table content.

5.6 Error Analysis

We conduct error analysis on the dev set of WikiSQL to show the limitation of the STAMP model and where is the room for making further improvements. We analyze the 2,302 examples which are executed to wrong answers by the STAMP model, and find that 33.6% of them have wrong SE-



Episode #	Country	City	Martial Art/Style	Masters	Original Airdate
1.1	China	Dengfeng	Kung Fu (Wushu ; Sanda)	Shi De Yang, Shi De Cheng	28-Dec-07
1.2	Philippines	Manila	Kali	Leo T. Gaje Jr. Cristino Vasquez	4-Jan-08
1.3	Japan	Tokyo	Kyokushin Karate	Yuzo Goda, Isamu Fukuda	11-Jan-08
1.4	Mexico	Mexico City	Boxing	Ignacio "Nacho" Beristáin Tiburcio Garcia	18-Jan-08
1.5	Indonesia	Bandung	Pencak Silat	Rita Suwanda Dadang Gunawan	25-Jan-08
1.7	South Korea	Seoul	Hapkido	Kim Nam Je, Bae Sung Book Ju Soong Weo	8-Feb-08
1.8	Brazil	Rio de Janeiro	Brazilian Jiu-Jitsu	Breno Sivak, Renato Barreto Royler Gracie	15-Feb-08
1.9	Israel	Netanya	Krav Maga	Ran Nakash Avivit Oftek Cohen	22-Feb-08

Question #1:	how many masters fought using a boxing style ?
Aug.PntNet:	select count masters from table where style = boxing
STAMP:	select count masters from table where martial art/style = boxing

Question #2:	when did the episode featuring a master using brazilian jiu-jitsu air ?
Aug.PntNet:	select original airdate from table where masters = brazilian jiu-jitsu
STAMP:	select original airdate from table where martial art/style = brazilian jiu-jitsu

Figure 3: Case study on the dev set between Aug.PntNet and STAMP. These two questions are based on the same table. Each question is followed by the generated SQL queries from the two approaches.

LECT columns, 15.7% of them have a different number of conditions in the WHERE clause, and 53.7% of them have a different WHERE column set compared to the ground truth. Afterwards, we analyze a portion of randomly sampled dissatisfied examples. Consistent with the qualitative results, most problems come from column prediction, including both SELECT clause and WHERE clause. Even though the overall accuracy of the SELECT column prediction is about 90% and we also use cell information to enhance the column representation, this semantic gap is still the main bottleneck. Extracting and incorporating various expressions for a table column (i.e. relation in a relational database) might be a potential way to mitigate this problem. Compared to column prediction, the quality of cell prediction is much better because cell content typically (partially) appears in the question.

5.7 Transfers to WikiTableQuestions

WikiTableQuestions (Pasupat and Liang, 2015) is a widely used dataset for semantic parsing. To further test the performance of our approach, we conduct an additional transfer learning experiment. Firstly, we directly apply the STAMP model trained on WikiSQL to WikiTableQuestions, which is an unsupervised learning setting for the WikiTableQuestions dataset. Results show that the test accuracy of STAMP in this setting is 14.5%, which has a big gap between best systems on WikiTableQuestions, where Zhang et al. (2017) and Krishnamurthy et al. (2017) yield 43.3% and 43.7%, respectively. Furthermore, we apply the learnt STAMP model to generate SQL queries on natural language questions from WikiTableQuestions, and regard the generated SQL queries which could be executed to correct answers as additional pseudo question-SQL pairs. In this way, the STAMP model learnt from a combination of WikiSQL and pseudo question-SQL pairs could achieve 21.0% on the test set. We find that this big gap is caused by the difference between the two datasets. Among 8 types of questions in WikiTableQuestions, half of them including {"*Union*", "*Intersection*", "*Reverse*", "*Arithmetic*"} are not covered in the WikiSQL dataset. It is an interesting direction to leverage algorithms developed from two datasets to improve one another.

5.8 Discussion

Compared to slot-filling based models that restrict target SQL queries to fixed forms of "select-aggregator-where", our model is less tailored. We believe that it is easy to expand our model to generate nested SQL queries or JOIN clauses, which could also be easily trained with back-propagation if enough training instances of these SQL types are available. For example, we could incorporate a hierarchical "value" channel to handle nest queries. Let us suppose our decoder works horizontally that next generated token is at the right hand of the current token. Inspired by chunk-based decoder for neural machine translation (Ishiwatari et al., 2017), we could increase the depth of the "value" channel to generates tokens of a nested WHERE value along the vertical axis. During inference, an addition gating function might be necessary to determine whether to generate a nested query, followed by the generation of WHERE value. An intuitive way that extends our model to handle JOIN clauses is to add the 4th channel, which predicts a table from a collection of tables. Therefore, the decoder should learn to select one of the four channels at each time step. Accordingly, we need to add "from" as a new SQL keyword in order to generate SQL queries including "from xxxTable".

In terms of the syntax of SQL, the grammar we used in this work could be regarded as shallow syntax, such as three channels and column-cell relation. We do not use deep syntax, such as the sketch of SQL language utilized in some slot-filling models, because incorporating them would make the model clumpy. Instead, we let the model to learn the sequential and compositional relations of SQL queries automatically from data. Empirical results show that our model learns these patterns well.

6 Conclusion and Future Work

In this work, we develop STAMP, a Syntax- and Table- Aware seMantic Parser that automatically maps natural language questions to SQL queries, which could be executed on web table or relational dataset to get the answer. STAMP has three channels, and it learns to switch to which channel at each time step. STAMP considers cell information and the relation between cell and column name in the generation process. Experiments are conducted on the WikiSQL dataset. Results show that STAMP achieves the new state-of-the-art performance on WikiSQL. We conduct extensive experiment analysis to show advantages and limitations of our approach, and where is the room for others to make further improvements.

SQL language has more complicated queries than the cases included in the WikiSQL dataset, including (1) querying over multiple relational databases, (2) nested SQL query as condition value, (3) more operations such as "*group by*" and "*order by*", etc. In this work, the STAMP model is not designed for the first and second cases, but it could be easily adapted to the third case through incorporating additional SQL keywords and of course the learning of which requires dataset of the same type. In the future, we plan to improve the accuracy of the column prediction component. We also plan to build a large-scale dataset that considers more sophisticated SQL queries. We also plan to extend the approach to low-resource scenarios (Feng et al., 2018).

Acknowledgments

We thank Yaming Sun for her great help. We also would like to thank three anonymous reviewers for their valuable comments and suggestions. This research was partly supported by National Natural Science Foundation of China(No. 61632011 and No.61772156, and No.61472107).

Multitask Parsing Across Semantic Representations

Daniel Hershcovich[1,2] **Omri Abend**[2] **Ari Rappoport**[2]

Abstract

The ability to consolidate information of different types is at the core of intelligence, and has tremendous practical value in allowing learning for one task to benefit from generalizations learned for others. In this paper we tackle the challenging task of improving semantic parsing performance, taking UCCA parsing as a test case, and AMR, SDP and Universal Dependencies (UD) parsing as auxiliary tasks. We experiment on three languages, using a uniform transition-based system and learning architecture for all parsing tasks. Despite notable conceptual, formal and domain differences, we show that multitask learning significantly improves UCCA parsing in both in-domain and out-of-domain settings. Our code is publicly available.[1]

1 Introduction

Semantic parsing has arguably yet to reach its full potential in terms of its contribution to downstream linguistic tasks, partially due to the limited amount of semantically annotated training data. This shortage is more pronounced in languages other than English, and less researched domains.

Indeed, recent work in semantic parsing has targeted, among others, Abstract Meaning Representation (AMR; Banarescu et al., 2013), bilexical Semantic Dependencies (SDP; Oepen et al., 2016) and Universal Conceptual Cognitive Annotation (UCCA; Abend and Rappoport, 2013). While these schemes are formally different and focus on different distinctions, much of their semantic content is shared (Abend and Rappoport, 2017).

Multitask learning (MTL; Caruana, 1997) allows exploiting the overlap between tasks to effectively extend the training data, and has greatly advanced with neural networks and representation learning (see §2). We build on these ideas and propose a general transition-based DAG parser, able to parse UCCA, AMR, SDP and UD (Nivre et al., 2016). We train the parser using MTL to obtain significant improvements on UCCA parsing over single-task training in (1) in-domain and (2) out-of-domain settings in English; (3) an in-domain setting in German; and (4) an in-domain setting in French, where training data is scarce.

The novelty of this work is in proposing a general parsing and learning architecture, able to accommodate such widely different parsing tasks, and in leveraging it to show benefits from learning them jointly.

2 Related Work

MTL has been used over the years for NLP tasks with varying degrees of similarity, examples including joint classification of different arguments in semantic role labeling (Toutanova et al., 2005), and joint parsing and named entity recognition (Finkel and Manning, 2009). Similar ideas, of parameter sharing across models trained with different datasets, can be found in studies of domain adaptation (Blitzer et al., 2006; Daume III, 2007; Ziser and Reichart, 2017). For parsing, domain adaptation has been applied successfully in parser combination and co-training (McClosky et al., 2010; Baucom et al., 2013).

Neural MTL has mostly been effective in tackling formally similar tasks (Søgaard and Goldberg, 2016), including multilingual syntactic dependency parsing (Ammar et al., 2016; Guo et al., 2016), as well as multilingual (Duong et al., 2017), and cross-domain semantic parsing (Herzig and Berant, 2017; Fan et al., 2017).

Sharing parameters with a low-level task has

[1]http://github.com/danielhers/tupa

shown great benefit for transition-based syntactic parsing, when jointly training with POS tagging (Bohnet and Nivre, 2012; Zhang and Weiss, 2016), and with lexical analysis (Constant and Nivre, 2016; More, 2016). Recent work has achieved state-of-the-art results in multiple NLP tasks by jointly learning the tasks forming the NLP standard pipeline using a single neural model (Collobert et al., 2011; Hashimoto et al., 2017), thereby avoiding cascading errors, common in pipelines.

Much effort has been devoted to joint learning of syntactic and semantic parsing, including two CoNLL shared tasks (Surdeanu et al., 2008; Hajič et al., 2009). Despite their conceptual and practical appeal, such joint models rarely outperform the pipeline approach (Lluís and Màrquez, 2008; Henderson et al., 2013; Lewis et al., 2015; Swayamdipta et al., 2016, 2017).

Peng et al. (2017a) performed MTL for SDP in a closely related setting to ours. They tackled three tasks, annotated over the same text and sharing the same formal structures (bilexical DAGs), with considerable edge overlap, but differing in target representations (see §3). For all tasks, they reported an increase of 0.5-1 labeled F_1 points. Recently, Peng et al. (2018) applied a similar approach to joint frame-semantic parsing and semantic dependency parsing, using disjoint datasets, and reported further improvements.

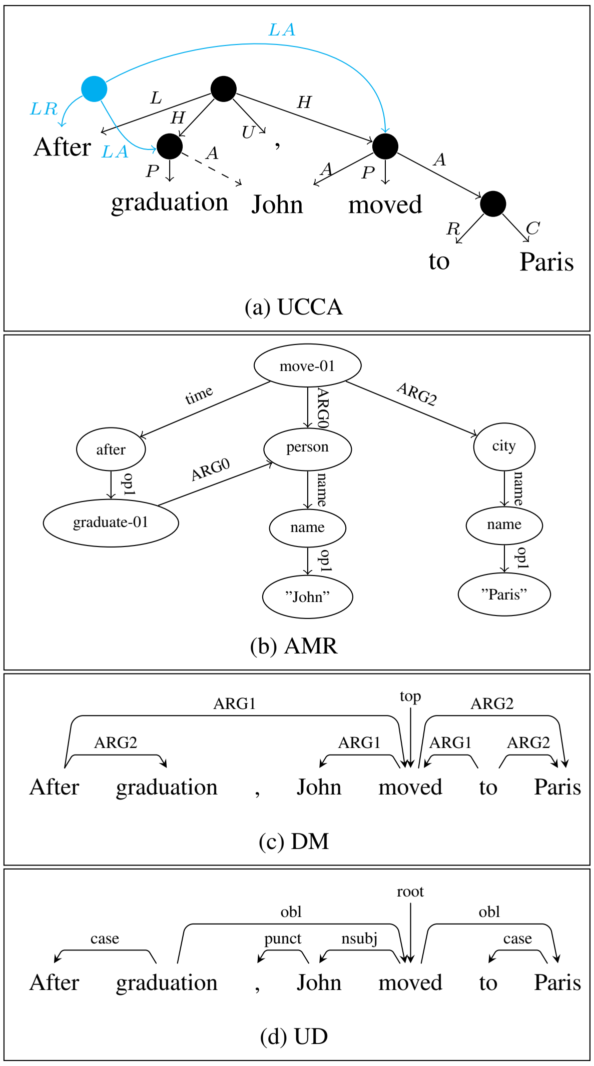

Figure 1: Example graph for each task. Figure 1a presents a UCCA graph. The dashed edge is remote, while the blue node and its outgoing edges represent inter-Scene linkage. Pre-terminal nodes and edges are omitted for brevity. Figure 1b presents an AMR graph. Text tokens are not part of the graph, and must be matched to concepts and constants by alignment. Variables are represented by their concepts. Figure 1c presents a DM semantic dependency graph, containing multiple roots: "After", "moved" and "to", of which "moved" is marked as *top*. Punctuation tokens are excluded from SDP graphs. Figure 1d presents a UD tree. Edge labels express syntactic relations.

3 Tackled Parsing Tasks

In this section, we outline the parsing tasks we address. We focus on representations that produce full-sentence analyses, i.e., produce a graph covering all (content) words in the text, or the lexical concepts they evoke. This contrasts with "shallow" semantic parsing, primarily semantic role labeling (SRL; Gildea and Jurafsky, 2002; Palmer et al., 2005), which targets argument structure phenomena using flat structures. We consider four formalisms: UCCA, AMR, SDP and Universal Dependencies. Figure 1 presents one sentence annotated in each scheme.

Universal Conceptual Cognitive Annotation. UCCA (Abend and Rappoport, 2013) is a semantic representation whose main design principles are ease of annotation, cross-linguistic applicability, and a modular architecture. UCCA represents the semantics of linguistic utterances as directed acyclic graphs (DAGs), where terminal (childless) nodes correspond to the text tokens, and non-terminal nodes to semantic units that participate in some super-ordinate relation. Edges are labeled, indicating the role of a child in the relation the parent represents. Nodes and edges belong to one of several *layers*, each corresponding to a "module" of semantic distinctions. UCCA's *foundational layer* (the only layer for which annotated data exists) mostly covers predicate-argument structure, semantic heads and inter-Scene relations.

UCCA distinguishes *primary* edges, corresponding to explicit relations, from *remote* edges (appear dashed in Figure 1a) that allow for a unit to participate in several super-ordinate relations. Primary edges form a tree in each layer, whereas remote edges enable reentrancy, forming a DAG.

Abstract Meaning Representation. AMR (Banarescu et al., 2013) is a semantic representation that encodes information about named entities, argument structure, semantic roles, word sense and co-reference. AMRs are rooted directed graphs, in which both nodes and edges are labeled. Most AMRs are DAGs, although cycles are permitted.

AMR differs from the other schemes we consider in that it does not anchor its graphs in the words of the sentence (Figure 1b). Instead, AMR graphs connect variables, concepts (from a predefined set) and constants (which may be strings or numbers). Still, most AMR nodes are alignable to text tokens, a tendency used by AMR parsers, which align a subset of the graph nodes to a subset of the text tokens (concept identification). In this work, we use pre-aligned AMR graphs.

Despite the brief period since its inception, AMR has been targeted by a number of works, notably in two SemEval shared tasks (May, 2016; May and Priyadarshi, 2017). To tackle its variety of distinctions and unrestricted graph structure, AMR parsers often use specialized methods. Graph-based parsers construct AMRs by identifying concepts and scoring edges between them, either in a pipeline fashion (Flanigan et al., 2014; Artzi et al., 2015; Pust et al., 2015; Foland and Martin, 2017), or jointly (Zhou et al., 2016). Another line of work trains machine translation models to convert strings into linearized AMRs (Barzdins and Gosko, 2016; Peng et al., 2017b; Konstas et al., 2017; Buys and Blunsom, 2017b). Transition-based AMR parsers either use dependency trees as pre-processing, then mapping them into AMRs (Wang et al., 2015a,b, 2016; Goodman et al., 2016), or use a transition system tailored to AMR parsing (Damonte et al., 2017; Ballesteros and Al-Onaizan, 2017). We differ from the above approaches in addressing AMR parsing using the same general DAG parser used for other schemes.

Semantic Dependency Parsing. SDP uses a set of related representations, targeted in two recent SemEval shared tasks (Oepen et al., 2014, 2015), and extended by Oepen et al. (2016). They correspond to four semantic representation schemes, referred to as DM, PAS, PSD and CCD, representing predicate-argument relations between content words in a sentence. All are based on semantic formalisms converted into bilexical dependencies—directed graphs whose nodes are text tokens. Edges are labeled, encoding semantic relations between the tokens. Non-content tokens, such as punctuation, are left out of the analysis (see Figure 1c). Graphs containing cycles have been removed from the SDP datasets.

We use one of the representations from the SemEval shared tasks: DM (DELPH-IN MRS), converted from DeepBank (Flickinger et al., 2012), a corpus of hand-corrected parses from LinGO ERG (Copestake and Flickinger, 2000), an HPSG (Pollard and Sag, 1994) using Minimal Recursion Semantics (Copestake et al., 2005).

Universal Dependencies. UD (Nivre et al., 2016, 2017) has quickly become the dominant dependency scheme for syntactic annotation in many languages, aiming for cross-linguistically consistent and coarse-grained treebank annotation. Formally, UD uses bilexical trees, with edge labels representing syntactic relations between words.

We use UD as an auxiliary task, inspired by previous work on joint syntactic and semantic parsing (see §2). In order to reach comparable analyses cross-linguistically, UD often ends up in annotation that is similar to the common practice in semantic treebanks, such as linking content words to content words wherever possible. Using UD further allows conducting experiments on languages other than English, for which AMR and SDP annotated data is not available (§7).

In addition to basic UD trees, we use the *enhanced*++ UD graphs available for English, which are generated by the Stanford CoreNLP converters (Schuster and Manning, 2016).[2] These include additional and augmented relations between content words, partially overlapping with the notion of remote edges in UCCA: in the case of control verbs, for example, a direct relation is added in enhanced++ UD between the subordinated verb and its controller, which is similar to the semantic schemes' treatment of this construction.

4 General Transition-based DAG Parser

All schemes considered in this work exhibit reentrancy and discontinuity (or non-projectivity), to varying degrees. In addition, UCCA and AMR

[2]http://github.com/stanfordnlp/CoreNLP

contain non-terminal nodes. To parse these graphs, we extend TUPA (Hershcovich et al., 2017), a transition-based parser originally developed for UCCA, as it supports all these structural properties. TUPA's transition system can yield any labeled DAG whose terminals are anchored in the text tokens. To support parsing into AMR, which uses graphs that are not anchored in the tokens, we take advantage of existing alignments of the graphs with the text tokens during training (§5).

First used for projective syntactic dependency tree parsing (Nivre, 2003), transition-based parsers have since been generalized to parse into many other graph families, such as (discontinuous) constituency trees (e.g., Zhang and Clark, 2009; Maier and Lichte, 2016), and DAGs (e.g., Sagae and Tsujii, 2008; Du et al., 2015). Transition-based parsers apply *transitions* incrementally to an internal state defined by a buffer B of remaining tokens and nodes, a stack S of unresolved nodes, and a labeled graph G of constructed nodes and edges. When a terminal state is reached, the graph G is the final output. A classifier is used at each step to select the next transition, based on features that encode the current state.

4.1 TUPA's Transition Set

Given a sequence of tokens $w_1, \ldots, w_n$, we predict a rooted graph G whose terminals are the tokens. Parsing starts with the root node on the stack, and the input tokens in the buffer.

The TUPA transition set includes the standard SHIFT and REDUCE operations, NODE$_X$ for creating a new non-terminal node and an X-labeled edge, LEFT-EDGE$_X$ and RIGHT-EDGE$_X$ to create a new primary X-labeled edge, LEFT-REMOTE$_X$ and RIGHT-REMOTE$_X$ to create a new remote X-labeled edge, SWAP to handle discontinuous nodes, and FINISH to mark the state as terminal.

Although UCCA contains nodes without any text tokens as descendants (called *implicit units*), these nodes are infrequent and only cover 0.5% of non-terminal nodes. For this reason we follow previous work (Hershcovich et al., 2017) and discard implicit units from the training and evaluation, and so do not include transitions for creating them.

In AMR, implicit units are considerably more common, as any unaligned concept with no aligned descendents is implicit (about 6% of the nodes). Implicit AMR nodes usually result from alignment errors, or from abstract concepts which

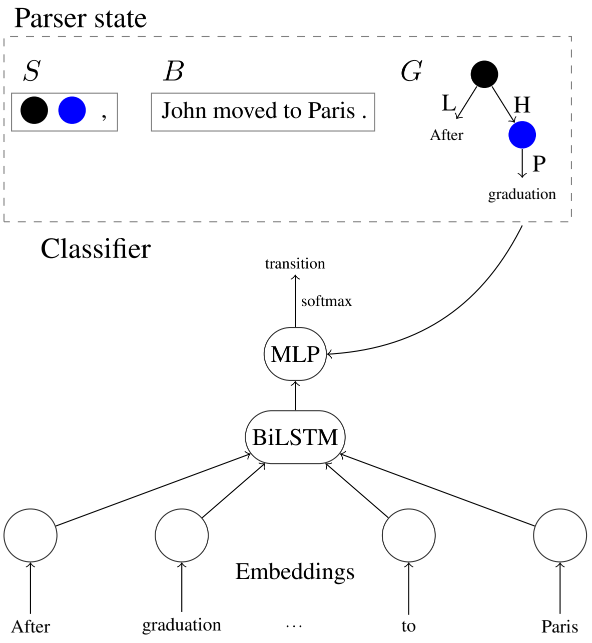

Figure 2: Illustration of the TUPA model, adapted from Hershcovich et al. (2017). Top: parser state. Bottom: BiLTSM architecture.

have no explicit realization in the text (Buys and Blunsom, 2017a). We ignore implicit nodes when training on AMR as well. TUPA also does not support node labels, which are ubiquitous in AMR but absent in UCCA structures (only edges are labeled in UCCA). We therefore only produce edge labels and not node labels when training on AMR.

4.2 Transition Classifier

To predict the next transition at each step, we use a BiLSTM with embeddings as inputs, followed by an MLP and a softmax layer for classification (Kiperwasser and Goldberg, 2016). The model is illustrated in Figure 2. Inference is performed greedily, and training is done with an oracle that yields the set of all optimal transitions at a given state (those that lead to a state from which the gold graph is still reachable). Out of this set, the actual transition performed in training is the one with the highest score given by the classifier, which is trained to maximize the sum of log-likelihoods of all optimal transitions at each step.

Features. We use the original TUPA features, representing the words, POS tags, syntactic dependency relations, and previously predicted edge labels for nodes in specific locations in the parser state. In addition, for each token we use embeddings representing the one-character prefix, three-character suffix, shape (capturing orthographic

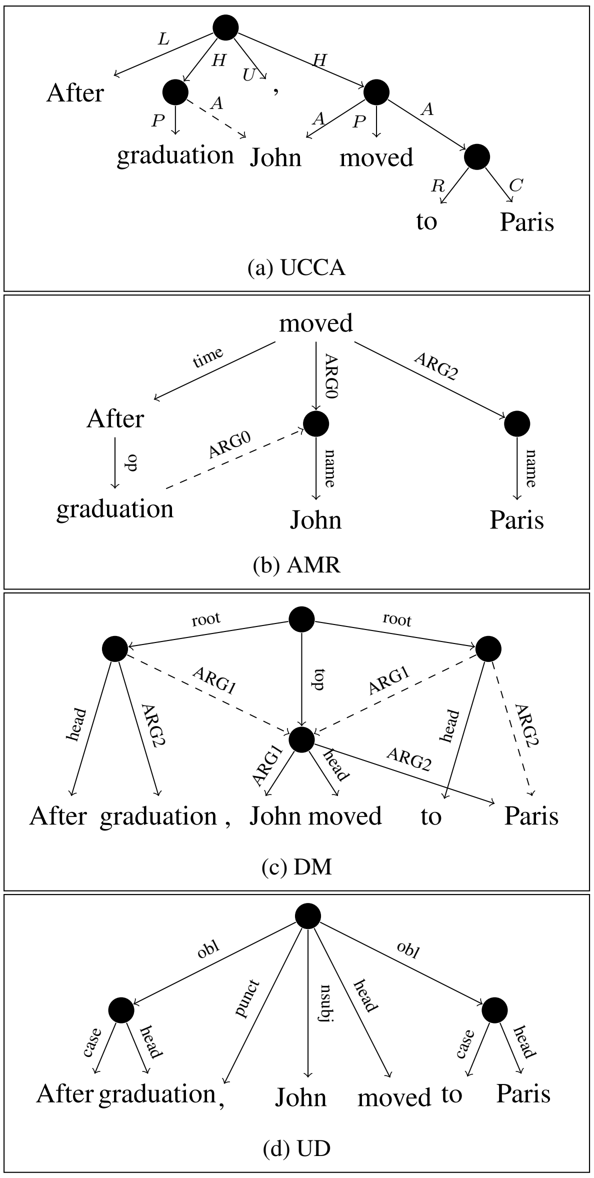

Figure 3: Graphs from Figure 1, after conversion to the unified DAG format (with pre-terminals omitted: each terminal drawn in place of its parent). Figure 3a presents a converted UCCA graph. Linkage nodes and edges are removed, but the original graph is otherwise preserved. Figure 3b presents a converted AMR graph, with text tokens added according to the alignments. Numeric suffixes of *op* relations are removed, and names collapsed. Figure 3c presents a converted SDP graph (in the DM representation), with intermediate non-terminal *head* nodes introduced. In case of reentrancy, an arbitrary reentrant edge is marked as remote. Figure 3d presents a converted UD graph. As in SDP, intermediate non-terminals and *head* edges are introduced. While converted UD graphs form trees, enhanced++ UD graphs may not.

features, e.g., "Xxxx"), and named entity type,[3] all provided by spaCy (Honnibal and Montani, 2018).[4] To the learned word vectors, we concatenate the 250K most frequent word vectors from fastText (Bojanowski et al., 2017),[5] pre-trained over Wikipedia and updated during training.

Constraints. As each annotation scheme has different constraints on the allowed graph structures, we apply these constraints separately for each task. During training and parsing, the relevant constraint set rules out some of the transitions according to the parser state. Some constraints are task-specific, others are generic. For example, in UCCA, a terminal may only have one parent. In AMR, a concept corresponding to a PropBank frame may only have the core arguments defined for the frame as children. An example of a generic constraint is that stack nodes that have been swapped should not be swapped again.[6]

5 Unified DAG Format

To apply our parser to the four target tasks (§3), we convert them into a unified DAG format, which is inclusive enough to allow representing any of the schemes with very little loss of information.[7]

The format consists of a rooted DAG, where the tokens are the terminal nodes. As in the UCCA format, edges are labeled (but not nodes), and are divided into *primary* and *remote* edges, where the primary edges form a tree (all nodes have at most one primary parent, and the root has none). Remote edges enable reentrancy, and thus together with primary edges form a DAG. Figure 3 shows examples for converted graphs. Converting UCCA into the unified format consists simply of removing linkage nodes and edges (see Figure 3a), which were also discarded by Hershcovich et al. (2017).

Converting bilexical dependencies. To convert DM and UD into the unified DAG format, we add a pre-terminal for each token, and attach the pre-terminals according to the original dependency edges: traversing the tree from the root down, for each head token we create a non-terminal parent with the edge label *head*, and add the node's dependents as children of the created non-terminal node (see Figures 3c and 3d). Since DM allows multiple roots, we form a single root node, whose

[3]See Supplementary Material for a full listing of features.

[4]`http://spacy.io`

[5]`http://fasttext.cc`

[6] To implement this constraint, we define a *swap index* for each node, assigned when the node is created. At initialization, only the root node and terminals exist. We assign the root a swap index of 0, and for each terminal, its position in the text (starting at 1). Whenever a node is created as a result of a NODE transition, its swap index is the arithmetic mean of the swap indices of the stack top and buffer head.

[7]See Supplementary Material for more conversion details.

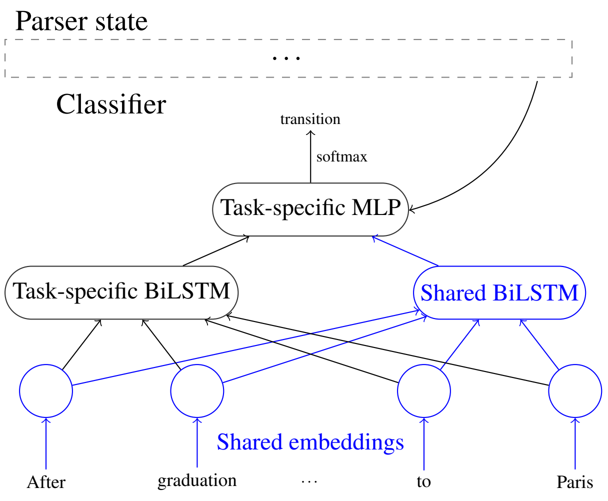

Figure 4: MTL model. Token representations are computed both by a task-specific and a shared BiLSTM. Their outputs are concatenated with the parser state embedding, identical to Figure 2, and fed into the task-specific MLP for selecting the next transition. Shared parameters are shown in blue.

children are the original roots. The added edges are labeled *root*, where top nodes are labeled *top* instead. In case of reentrancy, an arbitrary parent is marked as primary, and the rest as remote (denoted as dashed edges in Figure 3).

Converting AMR. In the conversion from AMR, node labels are dropped. Since alignments are not part of the AMR graph (see Figure 3b), we use automatic alignments (see §7), and attach each node with an edge to each of its aligned terminals.

Named entities in AMR are represented as a subgraph, whose *name*-labeled root has a child for each token in the name (see the two *name* nodes in Figure 1b). We collapse this subgraph into a single node whose children are the name tokens.

6 Multitask Transition-based Parsing

Now that the same model can be applied to different tasks, we can train it in a multitask setting. The fairly small training set available for UCCA (see §7) makes MTL particularly appealing, and we focus on it in this paper, treating AMR, DM and UD parsing as auxiliary tasks.

Following previous work, we share only some of the parameters (Klerke et al., 2016; Søgaard and Goldberg, 2016; Bollmann and Søgaard, 2016; Plank, 2016; Braud et al., 2016; Martínez Alonso and Plank, 2017; Peng et al., 2017a, 2018), leaving task-specific sub-networks as well. Concretely, we keep the BiLSTM used by TUPA for the main task (UCCA parsing), add a BiLSTM that is shared across all tasks, and replicate the MLP (feedforward sub-network) for each task. The BiLSTM outputs (concatenated for the main task) are fed into the task-specific MLP (see Figure 4). Feature embeddings are shared across tasks.

Unlabeled parsing for auxiliary tasks. To simplify the auxiliary tasks and facilitate generalization (Bingel and Søgaard, 2017), we perform unlabeled parsing for AMR, DM and UD, while still predicting edge labels in UCCA parsing. To support unlabeled parsing, we simply remove all labels from the EDGE, REMOTE and NODE transitions output by the oracle. This results in a much smaller number of transitions the classifier has to select from (no more than 10, as opposed to 45 in labeled UCCA parsing), allowing us to use no BiLSTMs and fewer dimensions and layers for task-specific MLPs of auxiliary tasks (see §7). This limited capacity forces the network to use the shared parameters for all tasks, increasing generalization (Martínez Alonso and Plank, 2017).

7 Experimental Setup

We here detail a range of experiments to assess the value of MTL to UCCA parsing, training the parser in single-task and multitask settings, and evaluating its performance on the UCCA test sets in both in-domain and out-of-domain settings.

Data. For UCCA, we use v1.2 of the English Wikipedia corpus (*Wiki*; Abend and Rappoport, 2013), with the standard train/dev/test split (see Table 1), and the *Twenty Thousand Leagues Under the Sea* corpora (*20K*; Sulem et al., 2015), annotated in English, French and German.[8] For English and French we use 20K v1.0, a small parallel corpus comprising the first five chapters of the book. As in previous work (Hershcovich et al., 2017), we use the English part only as an out-of-domain test set. We train and test on the French part using the standard split, as well as the German corpus (v0.9), which is a pre-release and still contains a considerable amount of noisy annotation. Tuning is performed on the respective development sets.

For AMR, we use LDC2017T10, identical to the dataset targeted in SemEval 2017 (May and Priyadarshi, 2017).[9] For SDP, we use the DM representation from the SDP 2016 dataset (Oepen

et al., 2016).[10] For Universal Dependencies, we use all English, French and German treebanks from UD v2.1 (Nivre et al., 2017).[11] We use the enhanced++ UD representation (Schuster and Manning, 2016) in our English experiments, henceforth referred to as UD^{++}. We use only the AMR, DM and UD training sets from standard splits.

While UCCA is annotated over Wikipedia and over a literary corpus, the domains for AMR, DM and UD are blogs, news, emails, reviews, and Q&A. This domain difference between training and test is particularly challenging (see §9). Unfortunately, none of the other schemes have available annotation over Wikipedia text.

Settings. We explore the following settings: (1) in-domain setting in English, training and testing on Wiki; (2) out-of-domain setting in English, training on Wiki and testing on 20K; (3) French in-domain setting, where available training dataset is small, training and testing on 20K; (4) German in-domain setting on 20K, with somewhat noisy annotation. For MTL experiments, we use unlabeled AMR, DM and UD^{++} parsing as auxiliary tasks in English, and unlabeled UD parsing in French and German.[12] We also report baseline results training only the UCCA training sets.

Training. We create a unified corpus for each setting, shuffling all sentences from relevant datasets together, but using only the UCCA development set F_1 score as the early stopping criterion. In each training epoch, we use the same number of examples from each task—the UCCA training set size. Since training sets differ in size, we sample this many sentences from each one. The model is implemented using DyNet (Neubig et al., 2017).[13]

[10]`http://sdp.delph-in.net/osdp-12.tgz`

[11]`http://hdl.handle.net/11234/1-2515`

[12]We did not use AMR, DM or UD^{++} in French and German, as these are only available in English.

Table 2: Hyperparameter settings. Middle column shows hyperparameters used for the single-task architecture, described in §4.2, and right column for the multitask architecture, described in §6. **Main** refers to parameters specific to the main task—UCCA parsing (task-specific MLP and BiLSTM, and edge label embedding), **Aux** to parameters specific to each auxiliary task (task-specific MLP, but no edge label embedding since the tasks are unlabeled), and **Shared** to parameters shared among all tasks (shared BiLSTM and embeddings).

Hyperparameters. We initialize embeddings randomly. We use dropout (Srivastava et al., 2014) between MLP layers, and recurrent dropout (Gal and Ghahramani, 2016) between BiLSTM layers, both with $p = 0.4$. We also use word ($\alpha = 0.2$), tag ($\alpha = 0.2$) and dependency relation ($\alpha = 0.5$) dropout (Kiperwasser and Goldberg, 2016).[14] In addition, we use a novel form of dropout, *node dropout*: with a probability of 0.1 at each step, all features associated with a single node in the parser state are replaced with zero vectors. For optimization we use a minibatch size of 100, decaying all weights by 10^{-5} at each update, and train with stochastic gradient descent for N epochs with a learning rate of 0.1, followed by AMSGrad (Sashank J. Reddi, 2018) for N epochs with $\alpha = 0.001, \beta_1 = 0.9$ and $\beta_2 = 0.999$. We use $N = 50$ for English and German, and $N = 400$ for French. We found this training strategy better than using only one of the optimization methods,

[14]In training, the embedding for a feature value w is replaced with a zero vector with a probability of $\frac{\alpha}{\#(w)+\alpha}$, where $\#(w)$ is the number of occurrences of w observed.

similar to findings by Keskar and Socher (2017). We select the epoch with the best average labeled F_1 score on the UCCA development set. Other hyperparameter settings are listed in Table 2.

Evaluation. We evaluate on UCCA using labeled precision, recall and F_1 on primary and remote edges, following previous work (Hershcovich et al., 2017). Edges in predicted and gold graphs are matched by terminal yield and label. Significance testing of improvements over the single-task model is done by the bootstrap test (Berg-Kirkpatrick et al., 2012), with $p < 0.05$.

8 Results

Table 3 presents our results on the English in-domain Wiki test set. MTL with all auxiliary tasks and their combinations improves the primary F_1 score over the single task baseline. In most settings the improvement is statistically significant. Using all auxiliary tasks contributed less than just DM and UD^{++}, the combination of which yielded the best scores yet in in-domain UCCA parsing, with 74.9% F_1 on primary edges. Remote F_1 is improved in some settings, but due to the relatively small number of remote edges (about 2% of all edges), none of the differences is significant. Note that our baseline single-task model (*Single*) is slightly better than the current state-of-the-art (HAR17; Hershcovich et al., 2017), due to the incorporation of additional features (see §4.2).

Table 4 presents our experimental results on the 20K corpora in the three languages. For English out-of-domain, improvements from using MTL are even more marked. Moreover, the improvement is largely additive: the best model, using all three auxiliary tasks (*All*), yields an error reduction of 2.9%. Again, the single-task baseline is slightly better than HAR17.

The contribution of MTL is also apparent in French and German in-domain parsing: 3.7% error reduction in French (having less than 10% as much UCCA training data as English) and 1% in German, where the training set is comparable in size to the English one, but is noisier (see §7). The best MTL models are significantly better than single-task models, demonstrating that even a small training set for the main task may suffice, given enough auxiliary training data (as in French).

9 Discussion

Quantifying the similarity between tasks. Task similarity is an important factor in MTL success (Bingel and Søgaard, 2017; Martínez Alonso and Plank, 2017). In our case, the main and auxiliary tasks are annotated on different corpora from different domains (§7), and the target representations vary both in form and in content.

To quantify the domain differences, we follow Plank and van Noord (2011) and measure the L1 distance between word distributions in the English training sets and 20K test set (Table 5). All auxiliary training sets are more similar to 20K than Wiki is, which may contribute to the benefits observed on the English 20K test set.

As a measure of the formal similarity of the different schemes to UCCA, we use unlabeled F_1 score evaluation on both primary and remote edges (ignoring edge labels). To this end, we annotated 100 English sentences from Section 02 of the Penn Treebank Wall Street Journal (PTB WSJ). Anno-

	20K	AMR	DM	UD
Wiki	1.047	0.895	0.913	0.843
20K		0.949	0.971	0.904
AMR			0.757	0.469
DM				0.754

UD^{++}	82.7	84.6	83.6	12.5	12.7	12.6

Table 6: Unlabeled F_1 scores between the representations of the same English sentences (from PTB WSJ), converted to the unified DAG format, and annotated UCCA graphs.

tation was carried out by a single expert UCCA annotator, and is publicly available.[15] These sentences had already been annotated by the AMR, DM and PTB schemes,[16] and we convert their annotation to the unified DAG format.

Unlabeled F_1 scores between the UCCA graphs and those converted from AMR, DM and UD^{++} are presented in Table 6. UD^{++} is highly overlapping with UCCA, while DM less so, and AMR even less (cf. Figure 3).

Comparing the average improvements resulting from adding each of the tasks as auxiliary (see §8), we find AMR the least beneficial, UD^{++} second, and DM the most beneficial, in both in-domain and out-of-domain settings. This trend is weakly correlated with the formal similarity between the tasks (as expressed in Table 6), but weakly negatively correlated with the word distribution similarity scores (Table 5). We conclude that other factors should be taken into account to fully explain this effect, and propose to address this in future work through controlled experiments, where corpora of the same domain are annotated with the various formalisms and used as training data for MTL.

AMR, SDP and UD parsing. Evaluating the full MTL model (*All*) on the unlabeled auxiliary tasks yielded 64.7% unlabeled Smatch F_1 (Cai and Knight, 2013) on the AMR development set, when using oracle concept identification (since the auxiliary model does not predict node labels), 27.2% unlabeled F_1 on the DM development set, and 4.9% UAS on the UD development set. These poor results reflect the fact that model selection was based on the score on the UCCA development set, and that the model parameters dedicated to auxiliary tasks were very limited (to encourage using the shared parameters). However, preliminary experiments using our approach produced promising results on each of the tasks' respective English development sets, when treated as a single task: 67.1% labeled Smatch F_1 on AMR (adding a transition for implicit nodes and classifier for node labels), 79.1% labeled F_1 on DM, and 80.1% LAS F_1 on UD. For comparison, the best results on these datasets are 70.7%, 91.2% and 82.2%, respectively (Foland and Martin, 2017; Peng et al., 2018; Dozat et al., 2017).

10 Conclusion

We demonstrate that semantic parsers can leverage a range of semantically and syntactically annotated data, to improve their performance. Our experiments show that MTL improves UCCA parsing, using AMR, DM and UD parsing as auxiliaries. We propose a unified DAG representation, construct protocols for converting these schemes into the unified format, and generalize a transition-based DAG parser to support all these tasks, allowing it to be jointly trained on them.

While we focus on UCCA in this work, our parser is capable of parsing any scheme that can be represented in the unified DAG format, and preliminary results on AMR, DM and UD are promising (see §9). Future work will investigate whether a single algorithm and architecture can be competitive on all of these parsing tasks, an important step towards a joint many-task model for semantic parsing.

Abstract

Character-level models have become a popular approach specially for their accessibility and ability to handle unseen data. However, little is known on their ability to reveal the underlying morphological structure of a word, which is a crucial skill for high-level semantic analysis tasks, such as semantic role labeling (SRL). In this work, we train various types of SRL models that use word, character and morphology level information and analyze how performance of characters compare to words and morphology for several languages. We conduct an in-depth error analysis for each morphological typology and analyze the strengths and limitations of character-level models that relate to out-of-domain data, training data size, long range dependencies and model complexity. Our exhaustive analyses shed light on important characteristics of character-level models and their semantic capability.

1 Introduction

Encoding of words is perhaps the most important step towards a successful end-to-end natural language processing application. Although word embeddings have been shown to provide benefit to such models, they commonly treat words as the smallest meaning bearing unit and assume that each word type has its own vector representation. This assumption has two major shortcomings especially for languages with rich morphology: (1) inability to handle unseen or out-of-vocabulary (OOV) word-forms (2) inability to exploit the regularities among word parts.

The limitations of word embeddings are particularly pronounced in sentence-level semantic tasks, especially in languages where word parts play a crucial role. Consider the Turkish sentences "*Köy+**lü-ler** (villagers) şehr+**e** (to town) geldi (came)*" and "*Sendika+**lı-lar** (union members) meclis+**e** (to council) geldi (came)*". Here the stems *köy (village)* and *sendika (union)* function similarly in semantic terms with respect to the verb *come* (as *the origin of the agents of the verb*), where *şehir (town)* and *meclis (council)* both function as *the end point*. These semantic similarities are determined by the common word parts shown in **bold**. However ortographic similarity does not always correspond to semantic similarity. For instance the ortographically similar words *knight* and *night* have large semantic differences. Therefore, for a successful semantic application, the model should be able to capture both the regularities, *i.e, morphological tags* and the irregularities, *i.e, lemmas* of the word.

Morphological analysis already provides the aforementioned information about the words. However access to useful morphological features may be problematic due to software licensing issues, lack of robust morphological analyzers and high ambiguity among analyses. Character-level models (CLM), being a cheaper and accessible alternative to morphology, have been reported as performing competitively on various NLP tasks (Ling et al., 2015; Plank et al., 2016; Lee et al., 2017). However the extent to which these tasks depend on morphology is small; and their relation to semantics is weak. Hence, little is known on their true ability to reveal the underlying morphological structure of a word and their semantic capabilities. Furthermore, their behaviour across languages from different families; and their limitations and strengths such as handling of long-range dependencies, reaction to model complexity or performance on out-of-domain data are unknown. Analyzing such issues is a key to fully understanding the character-level models.

To achieve this, we perform a case study on semantic role labeling (SRL), a sentence-level semantic analysis task that aims to identify predicate-argument structures and assign meaningful labels to them as follows:

[Villagers]$_{\text{comers}}$ came [to town]$_{\text{end point}}$

We use a simple method based on bidirectional LSTMs to train three types of base semantic role labelers that employ (1) words (2) characters and character sequences and (3) gold morphological analysis. The gold morphology serves as the upper bound for us to compare and analyze the performances of character-level models on languages of varying morphological typologies. We carry out an exhaustive error analysis for each language type and analyze the strengths and limitations of character-level models compared to morphology. In regard to the diversity hypothesis which states that *diversity* of systems in ensembles lead to further improvement, we combine character and morphology-level models and measure the performance of the ensemble to better understand how similar they are.

We experiment with several languages with varying degrees of morphological richness and typology: Turkish, Finnish, Czech, German, Spanish, Catalan and English. Our experiments and analysis reveal insights such as:

- CLMs provide great improvements over whole-word-level models despite not being able to match the performance of morphology-level models (MLMs) for *in-domain* datasets. However their performance surpass all MLMs on *out-of-domain* data,
- Limitations and strengths differ by morphological typology. Their limitations for agglutinative languages are related to rich *derivational morphology* and high *contextual ambiguity*; whereas for fusional languages they are related to *number of morphological tags* (morpheme ambiguity) ,
- CLMs can handle long-range dependencies equally well as MLMs,
- In presence of more training data, CLM's performance is expected to improve faster than of MLM.

2 Related Work

Neural SRL Methods: Neural networks have been first introduced to the SRL scene by Collobert et al. (2011), where they use a unified end-to-end convolutional network to perform various NLP tasks. Later, the combination of neural networks (LSTMs in particular) with traditional SRL features (categorical and binary) has been introduced (FitzGerald et al., 2015). Recently, it has been shown that careful design and tuning of deep models can achieve state-of-the-art with no or minimal syntactic knowledge for English and Chinese SRL. Although the architectures vary slightly, they are mostly based on a variation of bi-LSTMs. Zhou and Xu (2015); He et al. (2017) connect the layers of LSTM in an interleaving pattern where in (Wang et al., 2015; Marcheggiani et al., 2017) regular bi-LSTM layers are used. Commonly used features for the encoding layer are: pretrained word embeddings; distance from the predicate; predicate context; predicate region mark or flag; POS tag; and predicate lemma embedding. Only a few of the models (Marcheggiani et al., 2017; Marcheggiani and Titov, 2017) perform dependency-based SRL. Furthermore, all methods focus on languages with rich resources and less morphological complexity like English and Chinese.

Character-level Models: Character-level models have proven themselves useful for many NLP tasks such as language modeling (Ling et al., 2015; Kim et al., 2016), POS tagging (Santos and Zadrozny, 2014; Plank et al., 2016), dependency parsing (Dozat et al., 2017) and machine translation (Lee et al., 2017). However the number of comparative studies that analyze their relation to morphology are rather limited. Recently, Vania and Lopez (2017) presented a unified framework, where they investigated the performances of different subword units, namely characters, morphemes and morphological analysis on language modeling task. They experimented with languages of varying morphological typologies and concluded that the performance of character models can not yet match the morphological models, albeit very close. Similarly, Belinkov et al. (2017) analyzed how different word representations help learn better morphology and model rare words on a neural MT task and concluded that character-based representations are much better for learning morphology.

3 Method

Formally, we generate a label sequence $\vec{l}$ for each sentence and predicate pair: (s, p). Each $l_t \in \vec{l}$ is chosen from $\mathcal{L} = \{roles \cup nonrole\}$, where $roles$ are language-specific semantic roles (mostly consistent with PropBank) and $nonrole$ is a symbol to present tokens that are not arguments. Given θ as model parameters and g_t as gold label for t_{th} token, we find the parameters that minimize the negative log likelihood of the sequence:

$$\hat{\theta} = \arg\min_{\theta} \left(-\sum_{t=1}^{n} log(p(g_t|\theta, s, p)) \right) \quad (1)$$

Label probabilities, $p(l_t|\theta, s, p)$, are calculated with equations given below.First, the word encoding layer splits tokens into subwords via ρ function.

$$\rho(w) = s_0, s_1, .., s_n \quad (2)$$

As proposed by Ling et al. (2015), we treat words as a sequence of subword units. Then, the sequence is fed to a simple bi-LSTM network (Graves and Schmidhuber, 2005; Gers et al., 2000) and hidden states from each direction are weighted with a set of parameters which are also learned during training. Finally, the weighted vector is used as the word embedding given in Eq. 4.

$$hs_f, hs_b = \text{bi-LSTM}(s_0, s_1, .., s_n) \quad (3)$$
$$\vec{w} = W_f \cdot hs_f + W_b \cdot hs_b + b \quad (4)$$

There may be more than one predicate in the sentence so it is crucial to inform the network of which arguments we aim to label. In order to mark the predicate of interest, we concatenate a predicate flag pf_t to the word embedding vector.

$$\vec{x_t} = [\vec{w}; pf_t] \quad (5)$$

Final vector, $\vec{x_t}$ serves as an input to another bi-LSTM unit.

$$\vec{h_f}, \vec{h_b} = \text{bi-LSTM}(x_t) \quad (6)$$

Finally, the label distribution is calculated via softmax function over the concatenated hidden states from both directions.

$$p(\vec{l_t}|s, p) = softmax(W_l \cdot [\vec{h_f}; \vec{h_b}] + \vec{b_l}) \quad (7)$$

For simplicity, we assign the label with the highest probability to the input token. [1].

3.1 Subword Units

We use three types of units: (1) words (2) characters and character sequences and (3) outputs of morphological analysis. Words serve as a lower bound; while morphology is used as an upper bound for comparison. Table 1 shows sample outputs of various ρ functions. Here, *char* function

ρ	**word**	**output**
char	available	<-a-v-a-i-l-a-b-l-e->
char3	available	<av-ava-vai-ail-ila-lab-abl-ble-le>
morph-DEU	prächtiger	[*prächtig*;Pos;Nom;Sg;Masc]
morph-SPA	las	[*el*;postype=article;gen=f;num=p]
morph-CAT	la	[*el*;postype=article;gen=f;num=s]
morph-TUR	boyundaki	[*boy*;NOUN;A3sg;P3sg;Loc;DB;ADJ]
morph-FIN	tyhjyyttä	[*tyhjyys*;Case=Par;Number=Sing]
morph-CZE	si	[*se*;SubPOS=7;Num=X;Cas=3]

Table 1: Sample outputs of different ρ functions

simply splits the token into its characters. Similar to n-gram language models, *char3* slides a character window of width $n = 3$ over the token. Finally, gold morphological features are used as outputs of *morph-language*. Throughout this paper, we use *morph* and *oracle* interchangably, i.e., morphology-level models (MLM) have access to gold tags unless otherwise is stated. For all languages, *morph* outputs the *lemma* of the token followed by language specific morphological tags. As an exception, it outputs additional information for some languages, such as parts-of-speech tags for Turkish. Word segmenters such as Morfessor and Byte Pair Encoding (BPE) are other commonly used subword units. Due to low scores obtained from our preliminary experiments and unsatisfactory results from previous studies (Vania and Lopez, 2017), we excluded these units.

4 Experiments

We use the datasets distributed by LDC for Catalan (CAT), Spanish (SPA), German (DEU), Czech (CZE) and English (ENG) (Hajič et al., 2012b,a); and datasets made available by Haverinen et al. (2015); Şahin and Adalı (2017) for Finnish (FIN) and Turkish (TUR) respectively [2]. Datasets are

[1]Our implementation can be found at https://github.com/gozdesahin/Subword_Semantic_Role_Labeling

[2]Turkish PropBank is based on previous efforts (Atalay et al., 2003; Sulubacak et al., 2016; Sulubacak and Eryiğit, 2018; Oflazer et al., 2003; Şahin, 2016b,a)

	#sent	#token	#pred	#role	type
CZE	39K	653K	414K	51	F
ENG	39K	958K	179K	38	F
DEU	36K	649K	17K	9	F
SPA	14K	419K	44K	34	F
CAT	13K	384K	37K	35	F
FIN	12K	163K	27K	20	A
TUR	4K	39K	8K	26	A

Table 2: Training data statistics. A: Agglutinative, F: Fusional

provided with syntactic dependency annotations and semantic roles of verbal predicates. In addition, English supplies nominal predicates annotated with semantic roles and does not provide any morphological feature. Statistics for the training split for all languages are given in Table 2. Here, **#pred** is number of predicates, and **#role** refers to number distinct semantic roles that occur more than 10 times. More detailed statistics about the datasets can be found in Hajič et al. (2009); Haverinen et al. (2015); Şahin and Adalı (2017).

4.1 Experimental Setup

To fit the requirements of the SRL task and of our model, we performed the following:

Spanish, Catalan: Multiword expressions (MWE) are represented as a single token, *(e.g., Confederación_Francesa_del_Trabajo)*, that causes notably long character sequences which are hard to handle by LSTMs. For the sake of memory efficiency and performance, we used an abbreviation *(e.g., CFdT)* for each MWE during training and testing.

Finnish: Original dataset defines its own format of semantic annotation, such as 17:PBArgM_mod|19:PBArgM_mod meaning the node is an argument of 17_{th} and 19_{th} tokens with *ArgM-mod* (temporary modifier) semantic role. They have been converted into CoNLL-09 tabular format, where each predicate's arguments are given in a specific column.

Turkish: Words are splitted from derivational boundaries in the original dataset, where each inflectional group is represented as a separate token. We first merge boundaries of the same word, *i.e, tokens of the word*, then we use our own ρ function to split words into subwords.

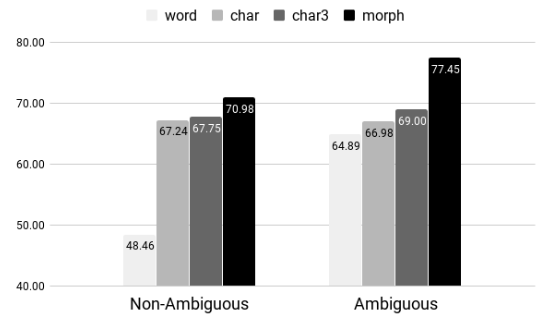
Training and Evaluation: We lowercase all tokens beforehand and place special start and end of the token characters. For all experiments, we initialized weight parameters orthogonally and used one layer bi-LSTMs both for subword composition and argument labeling with hidden size of 200. Subword embedding size is chosen as 200. We used gradient clipping and early stopping to prevent overfitting. Stochastic gradient descent is used as the optimizer. The initial learning rate is set to 1 and reduced by half if scores on development set do not improve after 3 epochs. We use the provided splits and evaluate the results with the official evaluation script provided by CoNLL-09 shared task. In this work (and in most of the recent SRL works), only the scores for argument labeling are reported, which may cause confusions for the readers while comparing with older SRL studies. Most of the early SRL work report combined scores (argument labeling with predicate sense disambiguation (PSD)). However, PSD is considered a simpler task with higher F1 scores [3]. Therefore, we believe omitting PSD helps us gain more useful insights on character level models.

5 Results and Analysis

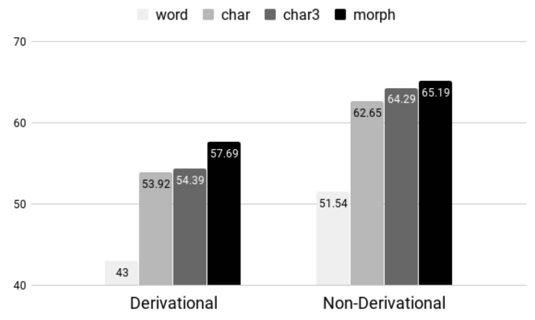
Our main results on test and development sets for models that use words, characters (*char*), character trigrams (*char3*) and morphological analyses (*morph*) are given in Table 3. We calculate *improvement over word (IOW)* for each subword model and *improvement over the best character model (IOC)* for the *morph*. *IOW* and *IOC* values are calculated on the test set.

The biggest improvement over the word baseline is achieved by the models that have access to morphology for all languages (except for English) as expected. Character trigrams consistently outperformed characters by a small margin. Same pattern is observed on the results of the development set. *IOW* has the values between 0% to 38% while *IOC* values range between 2%-10% dependending on the properties of the language and the dataset. We analyze the results separately for agglutinative and fusional languages and reveal the links between certain linguistic phenomena and the *IOC*, *IOW* values.

[3]For instance in English CoNLL-09 dataset, 87% of the predicates are annotated with their first sense, hence even a dummy classifier would achieve 87% accuracy. The best system from CoNLL-09 shared task reports 85.63 F1 on English evaluation dataset, however when the results of PSD are discarded, it drops down to 81.



(a) Finnish - Contextual ambiguity



(b) Turkish - Derivational morphology

Table 3: F1 scores of word, character, character trigram and morphology models for argument labeling. Best F1 for each language is shown in **bold**. First row: results on test, Second row: results on development.

Agglutinative languages have many morphemes attached to a word like beads on a string. This leads to high number of OOV words and cause word lookup models to fail. Hence, the highest *IOW*s by character models are achieved on these languages: Finnish and Turkish. This language family has one-to-one morpheme to meaning mapping with small orthographic differences *(e.g., mış, miş, muş, müş for past perfect tense)*, that can be easily extracted from the data. Even though each morpheme has only one interpretation, each word (consisting of many morphemes) has usually more than one. For instance two possible analyses for the Turkish word “dolar” are (1) “dol+Verb+Positive+Aorist+3sg” *(it fills)*, (2) “dola+Verb+Positive+Aorist+3sg” *(he/she wraps)*. For a syntactic task, models are not obliged to learn the difference between the two; whereas for a semantic task like SRL, they are. We will refer to this issue as *contextual ambiguity*. Another important linguistic issue for agglutinative languages is the complex interaction between morphology and syntax, which is usually achieved via derivational morphemes. In other words, unlike *inflectional* morphemes that only give information on *word-level semantics*, derivational morphemes provide more clues on *sentence-level semantics*. The effects of these two phenomena on model performances is shown in Fig. 1. Scores given in Fig. 1 are absolute F1 scores for each model. For the analysis in Fig. 1a, we separately calculated F1 scores of each model on words that have been observed with at least two different set of morphological features (*ambiguous*), and one set of features (*non-ambiguous*). Due to the low number of ambiguous words in Turkish dataset ($\leq$100), it has been calculated for Finnish only. Similarly, for the derivational morphology analysis in Fig. 1b, we have separately calculated scores for sentences containing derived words (*derivational*), and simple sentences without any derivations. Both analyses show that access to gold morphological tags (*oracle*) provided big performance gains on arguments with contextual ambiguity and sentences with derived words. Moderate *IOC* signals that *char* and *char3* learns to imitate the “beads” and their “predictable order” on the string (in the absence of the aforementioned issues).

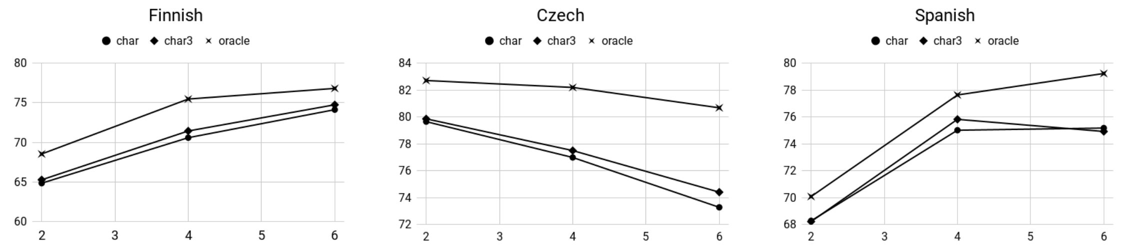

Figure 2: *x axis*: Number of morphological features; *y axis*: Targeted F1 scores

Fusional languages *may* have many morphemes in a word. Spanish and Catalan have relatively low morpheme per word ratio that results with low OOV% (5.63 and 5.40 for Spanish and Catalan respectively); whereas, German and Czech have OOV% of 7.93 and 7.98 (Hajič et al., 2009). We observe that *IOW* by character models are well aligned with OOV percentages of the datasets. Unlike agglutinative languages, single morpheme can serve multiple purposes in fusional languages. For instance, "o" (e.g., *habl-o*) may signal 1_{st} person singular present tense, or 3_{rd} person singular past tense. We count the number of surface forms with at least two different features and use their ratio *(#ambiguous forms/#total forms)* as a proxy to morphological complexity of the language. The *complexities* are approximated as 22%, 16%, 15% for Czech, Spanish and Catalan respectively; which are aligned with the observed *IOC*s. Since there is no unique morpheme to meaning mapping, generally multiple morphological tags are used to resolve the *morpheme ambiguity*. Therefore there is an indirect relation between the number of morphological tags used and the ambiguity of the word. To demonstrate this phenomena, we calculate targeted F1 scores on arguments with varying number of morphological features. Results using feature bins of [1-2], [3-4] and [5-6] are given in Fig. 2. As the number of features increase, the performance gap between oracle and character models grows dramatically for Czech and Spanish, while it stays almost fixed for Finnish. This finding suggests that high number of morphological tags signal the vagueness/complex cases in fusional languages where character models struggle; and also shows that the complexity can not be directly explained by number of morphological tags for agglutinative languages. German is known for having many compound words and compound lemmas that lead to high OOV% for lemma; and also is less ambiguous (9%). Therefore we would expect a lower *IOC*. However, the evaluation set consists only of 550 predicates and 1073 arguments, hence small changes in prediction lead to dramatic percentage changes.

5.1 Similarity between models

One way to infer similarity is to measure *diversity*. Consider a set of baseline models that are not diverse, i.e., making similar errors with similar inputs. In such a case, combination of these models would not be able to overcome the biases of the learners, hence the combination would not achieve a better result. In order to test if character and morphological models are *similar*, we combine them and measure the performance of the ensemble. Suppose that a prediction p_i is generated for each token by a model m_i, $i \in n$, then the final prediction is calculated from these predictions by:

$$p_{final} = f(p_0, p_1, .., p_n | \phi) \tag{8}$$

where f is the combining function with parameter ϕ. The simplest global approach is *averaging (AVG)*, where f is simply the mean function and p_is are the log probabilities. Mean function combines model outputs linearly, therefore ignores the nonlinear relation between base models/units. In order to exploit nonlinear connections, we learn the parameters ϕ of f via a simple linear layer followed by sigmoid activation. In other words, we train a new model that learns how to best combine the predictions from subword models. This ensemble technique is generally referred to as *stacking* or *stacked generalization (SG)*. [4]

Although not guaranteed, diverse models can be achieved by altering the input representation,

[4]To train the SG model, we have used one linear layer with 64 hidden units followed by sigmoid nonlinear activation. Weights are orthogonally initialized and optimized via adam algorithm with a learning rate of 0.02 for 25 epochs.

	char+char3			char+oracle			char3+oracle		
	Avg	SG	*IOB%*	Avg	SG	*IOB%*	Avg	SG	*IOB%*
Czech	76.24	76.26	**2.03**	80.36	81.06	*0.49*	80.57	81.10	*0.55*
Finnish	70.31	70.29	**4.58**	72.73	72.88	*2.42*	72.72	73.02	*2.62*
Turkish	59.43	59.39	**6.34**	61.98	62.07	*4.53*	60.56	60.74	*2.28*
Spanish	70.01	70.05	*3.16*	71.80	71.75	**3.47**	71.64	71.62	**3.24**

German	66.84	66.97	*2.15*	71.02	71.16	**2.62**	71.31	71.25	**2.84**

Table 4: Results of ensembling via averaging (Avg) and stack generalization (SG). *IOB: Improvement Over Best of baseline models*

the learning algorithm, training data or the hyper-parameters. To ensure that the only factor contributing to the diversity of the learners is the input representation, all parameters, training data and model settings are left unchanged.

Our results are given in Table 4. *IOB* shows the improvement over the best of the baseline models in the ensemble. Averaging and stacking methods gave similar results, meaning that there is no immediate nonlinear relations between units. We observe two language clusters: (1) Czech and agglutinative languages (2) Spanish, Catalan, German and English. The common property of that separate clusters are (1) high OOV% and (2) relatively low OOV%. Amongst the first set, we observe that the improvement gained by character-morphology ensembles is higher (shown with green) than ensembles between characters and character trigrams (shown with red), whereas the opposite is true for the second set of languages. It can be interpreted as character level models being more similar to the morphology level models for the first cluster, i.e., languages with high OOV%, and characters and morphology being more diverse for the second cluster.

6 Limitations and Strengths

To expand our understanding and reveal the limitations and strengths of the models, we analyze their ability to handle long range dependencies, their relation with training data and model size; and measure their performances on out of domain data.

6.1 Long Range Dependencies

Long range dependency is considered as an important linguistic issue that is hard to solve. Therefore the ability to handle it is a strong performance indicator. To gain insights on this issue, we measure how models perform as the distance between the predicate and the argument increases. The unit of measure is number of tokens between the two; and argument is defined as the head of the argument phrase in accordance with dependency-based SRL task. For that purpose, we created bins of [0-4], [5-9], [10-14] and [15-19] distances. Then, we have calculate F1 scores for arguments in each bin. Due to low number of predicate-argument pairs in buckets, we could not analyze German and Turkish; and also the bin [15-19] is only used for Czech. Our results are shown in Fig. 3. We observe that either *char* or *char3* closely follows the *oracle* for all languages. The gap between the two does not increase with the distance, suggesting that the performance gap is not related to long range dependencies. In other words, both characters and the oracle handle long range dependencies equally well.

6.2 Training Data Size

We analyzed how *char3* and *oracle* models perform with respect to the training data size. For that purpose, we trained them on chunks of increasing size and evaluate on the provided test split. We used units of 2000 sentences for German and Czech; and 400 for Turkish. Results are shown in Fig. 4. Apparently as the data size increases, the performances of both models logarithmically increase - with a varying speed. To speak in statistical terms, we fit a logarithmic curve to the observed F1 scores (shown with transparent lines) and check the x coefficients, where x refers to the number of sentences. This coefficient can be considered as an approximation to the speed of growth with data size. We observe that the coefficient is higher for *char3* than *oracle* for all languages. It can be interpreted as: in the presence of more training data, *char3* may surpass the *oracle*; i.e., *char3* relies on data more than the *oracle*.

6.3 Out-of-Domain (OOD) Data

As part of the CoNLL09 shared task (Hajič et al., 2009), out of domain test sets are provided for

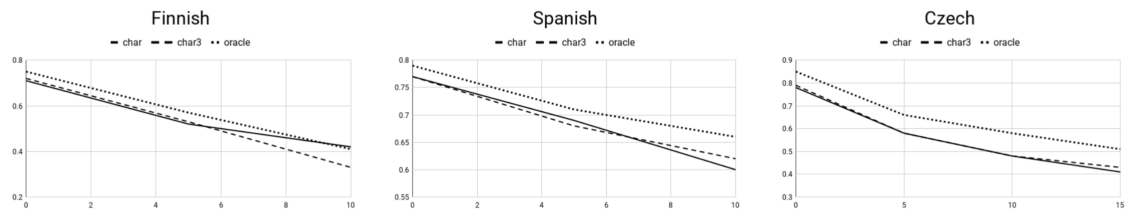

Figure 3: *X axis*: Distance between the predicate and the argument, *Y axis*: F1 scores on argument labels

three languages: Czech, German and English. We test our models trained on regular training dataset on these OOD data. The results are given in Table 5. Here, we clearly see that the best model has shifted from oracle to character based models. The dramatic drop in German oracle model is due to the high lemma OOV rate which is a consequence of keeping compounds as a single lemma. Czech oracle model performs reasonably however is unable to beat the generalization power of the *char3* model. Furthermore, the scores of the character models in Table 5 are higher than the best OOD scores reported in the shared task (Hajič et al., 2009); even though our main results on evaluation set are not (except for Czech). This shows that character-level models have increased robustness to out-of-domain data due to their ability to learn regularities among data.

6.4 Model Size

Throughout this paper, our aim was to gain insights on how models perform on different languages rather than scoring the highest F1. For this reason, we used a model that can be considered small when compared to recent neural SRL models and avoided parameter search. However,

		char3		**oracle**	
		F1	*I* (%)	F1	*I* (%)
Finnish	$\ell = 1$	67.78		71.15	
	$\ell = 2$	67.62	*-0.2*	75.71	*6.4*
Turkish	$\ell = 1$	56.60		59.38	
	$\ell = 2$	56.93	*0.5*	61.02	*2.7*
Spanish	$\ell = 1$	68.43		69.39	
	$\ell = 2$	69.30	*1.3*	71.56	*3.1*
Catalan	$\ell = 1$	71.34		73.24	
	$\ell = 2$	71.71	*0.5*	74.84	*2.2*

Table 6: Effect of layer size on model performances. *I*: Improvement over model with one layer.

we wonder how the models behave when given a larger network. To answer this question, we trained *char3* and *oracle* models with more layers for two fusional languages (Spanish, Catalan), and two agglutinative languages (Finnish, Turkish). The results given in Table 6 clearly shows that model complexity provides relatively more benefit to morphological models. This indicates that morphological signals help to extract more complex linguistic features that have semantic clues.

6.5 Predicted Morphological Tags

Although models with access to gold morphological tags achieve better F1 scores than character models, they can be less useful a in real-life scenario since they require gold tags at test time. To predict the performance of morphology-level models in such a scenario, we train the same models with the same parameters with predicted morphological features. Predicted tags

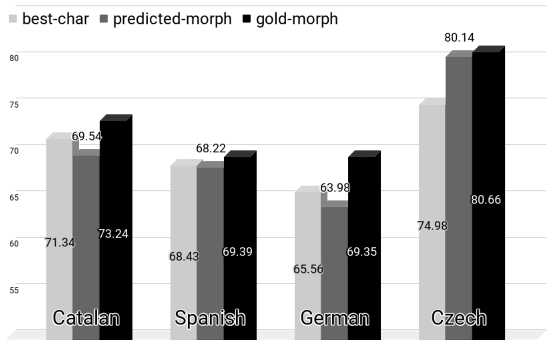

Figure 5: F1 scores for *best-char* (best of the CLMs) and model with predicted (*predicted-morph*) and gold morphological tags (*gold-morph*).

were only available for German, Spanish, Catalan and Czech. Our results given in Fig. 5, show that (except for Czech), predicted morphological tags are not as useful as characters alone.

7 Conclusion

Character-level neural models are becoming the *defacto* standard for NLP problems due to their accessibility and ability to handle unseen data. In this work, we investigated how they compare to models with access to gold morphological analysis, on a sentence-level semantic task. We evaluated their quality on *semantic role labeling* in a number of agglutinative and fusional languages. Our results lead to the following conclusions:

- For in-domain data, character-level models cannot yet match the performance of morphology-level models. However, they still provide considerable advantages over whole-word models,
- Their shortcomings depend on the morphology type. For agglutinative languages, their performance is limited on data with rich *derivational morphology* and high *contextual ambiguity* (morphological disambiguation); and for fusional languages, they struggle on tokens with high number of morphological tags,
- Similarity between character and morphology-level models is higher than the similarity within character-level (char and char-trigram) models on languages with high OOV%; and vice versa,
- Their ability to handle long-range dependencies is very similar to morphology-level models,
- They rely relatively more on training data size. Therefore, given more training data their performance will improve faster than morphology-level models,
- They perform *substantially* well on out of domain data, surpassing all morphology-level models. However, relatively less improvement is expected when model complexity is increased,
- They generally perform better than models that only have access to predicted/silver morphological tags.

AMR Parsing as Graph Prediction with Latent Alignment

Chunchuan Lyu[1] **Ivan Titov**[1,2]
[1]ILCC, School of Informatics, University of Edinburgh
[2]ILLC, University of Amsterdam

Abstract

Abstract meaning representations (AMRs) are broad-coverage sentence-level semantic representations. AMRs represent sentences as rooted labeled directed acyclic graphs. AMR parsing is challenging partly due to the lack of annotated alignments between nodes in the graphs and words in the corresponding sentences. We introduce a neural parser which treats alignments as latent variables within a joint probabilistic model of concepts, relations and alignments. As exact inference requires marginalizing over alignments and is infeasible, we use the variational auto-encoding framework and a continuous relaxation of the discrete alignments. We show that joint modeling is preferable to using a pipeline of align and parse. The parser achieves the best reported results on the standard benchmark (74.4% on LDC2016E25).

1 Introduction

Abstract meaning representations (AMRs) (Banarescu et al., 2013) are broad-coverage sentence-level semantic representations. AMR encodes, among others, information about semantic relations, named entities, co-reference, negation and modality. The semantic representations can be regarded as rooted labeled directed acyclic graphs (see Figure 1). As AMR abstracts away from details of surface realization, it is potentially beneficial in many semantic related NLP tasks, including text summarization (Liu et al., 2015; Dohare and Karnick, 2017), machine translation (Jones et al., 2012) and question answering (Mitra and Baral, 2016).

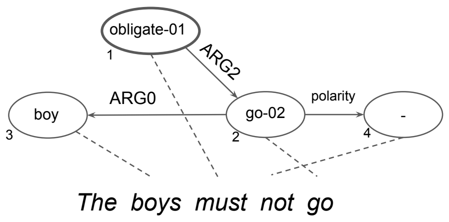

Figure 1: An example of AMR, the dashed lines denote latent alignments, *obligate-01* is the root. Numbers indicate depth-first traversal order.

AMR parsing has recently received a lot of attention (e.g., (Flanigan et al., 2014; Artzi et al., 2015; Konstas et al., 2017)). One distinctive aspect of AMR annotation is the lack of explicit alignments between nodes in the graph (*concepts*) and words in the sentences. Though this arguably simplified the annotation process (Banarescu et al., 2013), it is not straightforward to produce an effective parser without relying on an alignment. Most AMR parsers (Damonte et al., 2017; Flanigan et al., 2016; Werling et al., 2015; Wang and Xue, 2017; Foland and Martin, 2017) use a pipeline where the aligner training stage precedes training a parser. The aligners are not directly informed by the AMR parsing objective and may produce alignments suboptimal for this task.

In this work, we demonstrate that the alignments can be treated as latent variables in a joint probabilistic model and induced in such a way as to be beneficial for AMR parsing. Intuitively, in our probabilistic model, every node in a graph is assumed to be aligned to a word in a sentence: each concept is predicted based on the corresponding RNN state. Similarly, graph edges (i.e. relations) are predicted based on representations of concepts and aligned words (see Figure 2). As alignments are latent, exact inference requires marginalizing over latent alignments, which is infeasible. Instead we use variational inference, specifically the variational autoencoding framework of Kingma and Welling (2014). Using discrete latent variables in deep learning has proven to be challenging (Mnih and Gregor, 2014; Bornschein and Bengio, 2015). We use a continuous relaxation of the alignment problem, relying on the recently introduced Gumbel-Sinkhorn construction (Mena et al., 2018). This yields a computationally-efficient approximate method for estimating our joint probabilistic model of concepts, relations and alignments.

We assume injective alignments from concepts to words: every node in the graph is aligned to a single word in the sentence and every word is aligned to at most one node in the graph. This is necessary for two reasons. First, it lets us treat concept identification as sequence tagging at test time. For every word we would simply predict the corresponding concept or predict *NULL* to signify that no concept should be generated at this position. Secondly, Gumbel-Sinkhorn can only work under this assumption. This constraint, though often appropriate, is problematic for certain AMR constructions (e.g., named entities). In order to deal with these cases, we re-categorized AMR concepts. Similar recategorization strategies have been used in previous work (Foland and Martin, 2017; Peng et al., 2017).

The resulting parser achieves 74.4% Smatch score on the standard test set when using LDC2016E25 training set,[1] an improvement of 3.4% over the previous best result (van Noord and Bos, 2017). We also demonstrate that inducing alignments within the joint model is indeed beneficial. When, instead of inducing alignments, we follow the standard approach and produce them on preprocessing, the performance drops by 0.9% Smatch. Our main contributions can be summarized as follows:

- we introduce a joint probabilistic model for alignment, concept and relation identification;
- we demonstrate that a continuous relaxation can be used to effectively estimate the model;
- the model achieves the best reported results.[2]

[1]The standard deviation across multiple training runs was 0.16%.

[2]The code can be accessed from `https://github.com/ChunchuanLv/AMR_AS_GRAPH_PREDICTION`

2 Probabilistic Model

In this section we describe our probabilistic model and the estimation technique. In section 3, we describe preprocessing and post-processing (including concept re-categorization, sense disambiguation, wikification and root selection).

2.1 Notation and setting

We will use the following notation throughout the paper. We refer to words in the sentences as $\mathbf{w} = (w_1, \dots, w_n)$, where n is sentence length, $w_k \in \mathcal{V}$ for $k \in \{1 \dots, n\}$. The concepts (i.e. labeled nodes) are $\mathbf{c} = (c_1, \dots, c_m)$, where m is the number of concepts and $c_i \in \mathcal{C}$ for $i \in \{1 \dots, m\}$. For example, in Figure 1, $\mathbf{c} = (\textit{obligate}, \textit{go}, \textit{boy}, \text{-})$.[3] Note that senses are predicted at post-processing, as discussed in Section 3.2 (i.e. *go* is labeled as *go-02*).

A relation between 'predicate concept' i and 'argument concept' j is denoted by $r_{ij} \in \mathcal{R}$; it is set to *NULL* if j is not an argument of i. In our example, $r_{2,3} = \textit{ARG0}$ and $r_{1,3} = \textit{NULL}$. We will use R to denote all relations in the graph.

To represent alignments, we will use $\mathbf{a} = \{a_1, \dots, a_m\}$, where $a_i \in \{1, \dots, n\}$ returns the index of a word aligned to concept i. In our example, $a_1 = 3$.

All three model components rely on bidirectional LSTM encoders (Schuster and Paliwal, 1997). We denote states of BiLSTM (i.e. concatenation of forward and backward LSTM states) as $\mathbf{h}_k \in \mathbb{R}^d$ $(k \in \{1, \dots, n\})$. The sentence encoder takes pre-trained fixed word embeddings, randomly initialized lemma embeddings, part-of-speech and named-entity tag embeddings.

2.2 Method overview

We believe that using discrete alignments, rather than attention-based models (Bahdanau et al., 2015) is crucial for AMR parsing. AMR banks are a lot smaller than parallel corpora used in machine translation (MT) and hence it is important to inject a useful inductive bias. We constrain our alignments from concepts to words to be injective. First, it encodes the observation that concepts are mostly triggered by single words (especially, after re-categorization, Section 3.1). Second, it implies

[3]The probabilistic model is invariant to the ordering of concepts, though the order affects the inference algorithm (see Section 2.5). We use depth-first traversal of the graph to generate the ordering.

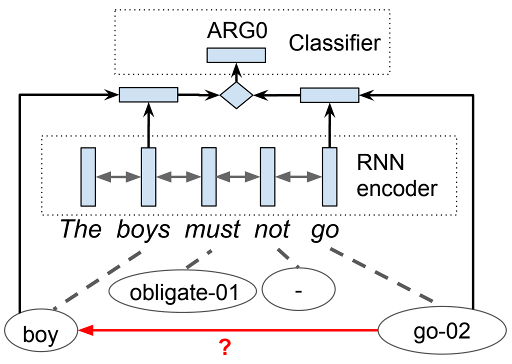

Figure 2: Relation identification: predicting a relation between *boy* and *go-02* relying on the two concepts and corresponding RNN states.

that each word corresponds to at most one concept (if any). This encourages competition: alignments are mutually-repulsive. In our example, *obligate* is not lexically similar to the word *must* and may be hard to align. However, given that other concepts are easy to predict, alignment candidates other than *must* and *the* will be immediately ruled out. We believe that these are the key reasons for why attention-based neural models do not achieve competitive results on AMR (Konstas et al., 2017) and why state-of-the-art models rely on aligners. Our goal is to combine best of two worlds: to use alignments (as in state-of-the-art AMR methods) and to induce them while optimizing for the end goal (similarly to the attention component of encoder-decoder models).

Our model consists of three parts: (1) the concept identification model $P_\theta(\mathbf{c}|\mathbf{a},\mathbf{w})$; (2) the relation identification model $P_\phi(R|\mathbf{a},\mathbf{w},\mathbf{c})$ and (3) the alignment model $Q_\psi(\mathbf{a}|\mathbf{c},R,\mathbf{w})$.[4] Formally, (1) and (2) together with the uniform prior over alignments $P(\mathbf{a})$ form the generative model of AMR graphs. In contrast, the alignment model $Q_\psi(\mathbf{a}|\mathbf{c},R,\mathbf{w})$, as will be explained below, is approximating the intractable posterior $P_{\theta,\phi}(\mathbf{a}|\mathbf{c},R,\mathbf{w})$ within that probabilistic model.

In other words, we assume the following model for generating the AMR graph:

$$P_{\theta,\phi}(\mathbf{c},R|\mathbf{w}) = \sum_{\mathbf{a}} P(\mathbf{a}) P_\theta(\mathbf{c}|\mathbf{a},\mathbf{w}) P_\phi(R|\mathbf{a},\mathbf{w},\mathbf{c})$$

$$= \sum_{\mathbf{a}} P(\mathbf{a}) \prod_{i=1}^{m} P(c_i|\mathbf{h}_{a_i}) \prod_{i,j=1}^{m} P(r_{ij}|\mathbf{h}_{a_i},\mathbf{c}_i,\mathbf{h}_{a_j},\mathbf{c}_j)$$

AMR concepts are assumed to be generated conditional independently relying on the BiLSTM states and surface forms of the aligned words. Similarly, relations are predicted based only on AMR concept embeddings and LSTM states corresponding to words aligned to the involved concepts. Their combined representations are fed into a bi-affine classifier (Dozat and Manning, 2017) (see Figure 2).

The expression involves intractable marginalization over all valid alignments. As standard in variational autoencoders, VAEs (Kingma and Welling, 2014), we lower-bound the log-likelihood as

$$\begin{aligned} &\log P_{\theta,\phi}(\mathbf{c},R|\mathbf{w}) \\ &\geq E_Q[\log P_\theta(\mathbf{c}|\mathbf{a},\mathbf{w}) P_\phi(R|\mathbf{a},\mathbf{w},\mathbf{c})] \\ &- D_{KL}(Q_\psi(\mathbf{a}|\mathbf{c},R,\mathbf{w}) || P(\mathbf{a})), \end{aligned} \quad (1)$$

where $Q_\psi(\mathbf{a}|\mathbf{c},R,\mathbf{w})$ is the variational posterior (aka the inference network), $E_Q[\ldots]$ refers to the expectation under $Q_\psi(\mathbf{a}|\mathbf{c},R,\mathbf{w})$ and D_{KL} is the Kullback-Liebler divergence. In VAEs, the lower bound is maximized both with respect to model parameters (θ and ϕ in our case) and the parameters of the inference network (ψ). Unfortunately, gradient-based optimization with discrete latent variables is challenging. We use a continuous relaxation of our optimization problem, where real-valued vectors $\hat{\mathbf{a}}_i \in \mathbb{R}^n$ (for every concept i) approximate discrete alignment variables a_i. This relaxation results in low-variance estimates of the gradient using the parameterization trick (Kingma and Welling, 2014), and ensures fast and stable training. We will describe the model components and the relaxed inference procedure in detail in sections 2.6 and 2.7.

Though the estimation procedure requires the use of the relaxation, the learned parser is straightforward to use. Given our assumptions about the alignments, we can independently choose for each word w_k ($k = 1, \ldots, m$) the most probably concept according to $P_\theta(c|\mathbf{h}_k)$. If the highest scoring option is *NULL*, no concept is introduced. The relations could then be predicted relying on $P_\phi(R|\mathbf{a},\mathbf{w},\mathbf{c})$. This would have led to generating inconsistent AMR graphs, so instead we search for the highest scoring valid graph (see Section 3.2). Note that the alignment model Q_ψ is not used at test time and only necessary to train accurate concept and relation identification models.

[4] θ, ϕ and ψ denote all parameters of the models.

2.3 Concept identification model

The concept identification model chooses a concept c (i.e. a labeled node) conditioned on the aligned word k or decides that no concept should be introduced (i.e. returns *NULL*). Though it can be modeled with a softmax classifier, it would not be effective in handling rare or unseen words. First, we split the decision into estimating the probability of concept category $\tau(c) \in \mathcal{T}$ (e.g. 'number', 'frame') and estimating the probability of the specific concept within the chosen category. Second, based on a lemmatizer and training data[5] we prepare one candidate concept e_k for each word k in vocabulary (e.g., it would propose *want* if the word is *wants*). Similar to Luong et al. (2015), our model can then either copy the candidate e_k or rely on the softmax over potential concepts of category τ. Formally, the concept prediction model is defined as

$$P_\theta(c|\mathbf{h}_k, w_k) = P(\tau(c)|\mathbf{h}_k, w_k) \times \frac{[[e_k = c]] \times \exp(\mathbf{v}_{copy}^T \mathbf{h_k}) + \exp(\mathbf{v}_c^T \mathbf{h_k})}{Z(\mathbf{h_k}, \theta)},$$

where the first multiplicative term is a softmax classifier over categories (including *NULL*); $\mathbf{v}_{copy}, \mathbf{v}_c \in \mathbb{R}^d$ (for $c \in \mathcal{C}$) are model parameters; $[[\ldots]]$ denotes the indicator function and equals 1 if its argument is true and 0, otherwise; $Z(\mathbf{h}, \theta)$ is the partition function ensuring that the scores sum to 1.

2.4 Relation identification model

We use the following arc-factored relation identification model:

$$P_\phi(R|\mathbf{a}, \mathbf{w}, \mathbf{c}) = \prod_{i,j=1}^{m} P(r_{ij}|\mathbf{h}_{a_i}, \mathbf{c}_i, \mathbf{h}_{a_j}, \mathbf{c}_j) \quad (2)$$

Each term is modeled in exactly the same way:

1. for both endpoints, embedding of the concept c is concatenated with the RNN state $\mathbf{h}$;

2. they are linearly projected to a lower dimension separately through $M_h(\mathbf{h}_{a_i} \circ c_i) \in \mathbb{R}^{d_f}$ and $M_d(\mathbf{h}_{a_j} \circ c_j) \in \mathbb{R}^{d_f}$, where $\circ$ denotes concatenation;

3. a log-linear model with bilinear scores $M_h(\mathbf{h}_{a_i} \circ c_i)^T C_r M_d(\mathbf{h}_{a_j} \circ c_j)$, $C_r \in \mathbb{R}^{d_f \times d_f}$ is used to compute the probabilities.

[5]See supplementary materials.

In the above discussion, we assumed that BiLSTM encodes a sentence once and the BiLSTM states are then used to predict concepts and relations. In semantic role labeling, the task closely related to the relation identification stage of AMR parsing, a slight modification of this approach was shown more effective (Zhou and Xu, 2015; Marcheggiani et al., 2017). In that previous work, the sentence was encoded by a BiLSTM once per each predicate (i.e. verb) and the encoding was in turn used to identify arguments of that predicate. The only difference across the re-encoding passes was a binary flag used as input to the BiLSTM encoder at each word position. The flag was set to 1 for the word corresponding to the predicate and to 0 for all other words. In that way, BiLSTM was encoding the sentence specifically for predicting arguments of a given predicate. Inspired by this approach, when predicting label r_{ij} for $j \in \{1, \ldots m\}$, we input binary flags $\mathbf{p}_1, \ldots \mathbf{p}_n$ to the BiLSTM encoder which are set to 1 for the word indexed by a_i ($\mathbf{p}_{a_i} = 1$) and to 0 for other words ($\mathbf{p}_j = 0$, for $j \neq a_i$). This also means that BiLSTM encoders for predicting relations and concepts end up being distinct. We use this multi-pass approach in our experiments.[6]

2.5 Alignment model

Recall that the alignment model is only used at training, and hence it can rely both on input (states $\mathbf{h}_1, \ldots, \mathbf{h}_n$) and on the list of concepts $c_1, \ldots, c_m$.

Formally, we add $(m-n)$ *NULL* concepts to the list.[7] Aligning a word to any *NULL*, would correspond to saying that the word is not aligned to any 'real' concept. Note that each one-to-one alignment (i.e. permutation) between n such concepts and n words implies a valid injective alignment of n words to m 'real' concepts. This reduction to permutations will come handy when we turn to the Gumbel-Sinkhorn relaxation in the next section. Given this reduction, from now on, we will assume that $m = n$.

As with sentences, we use a BiLSTM model to encode concepts $\mathbf{c}$, where $\mathbf{g}_i \in \mathcal{R}^{d_g}$, $i \in \{1, \ldots, n\}$. We use a globally-normalized align-

[6]Using the vanilla one-pass model from equation (2) results in 1.4% drop in Smatch score.

[7]After re-categorization (Section 3.1), $m \geq n$ holds for most cases. For exceptions, we append *NULL* to the sentence.

ment model:

$$Q_\psi(\mathbf{a}|\mathbf{c}, R, \mathbf{w}) = \frac{\exp(\sum_{i=1}^{n} \varphi(\mathbf{g}_i, \mathbf{h}_{a_i}))}{Z_\psi(\mathbf{c}, \mathbf{w})},$$

where $Z_\psi(\mathbf{c}, \mathbf{w})$ is the intractable partition function and the terms $\varphi(\mathbf{g}_i, \mathbf{h}_{a_i})$ score each alignment link according to a bilinear form

$$\varphi(\mathbf{g}_i, \mathbf{h}_{a_i}) = \mathbf{g}_i^T B \mathbf{h}_{a_i}, \qquad (3)$$

where $B \in \mathbb{R}^{d_g \times d}$ is a parameter matrix.

2.6 Estimating model with Gumbel-Sinkhorn

Recall that our learning objective (1) involves expectation under the alignment model. The partition function of the alignment model $Z_\psi(\mathbf{c}, \mathbf{w})$ is intractable, and it is tricky even to draw samples from the distribution. Luckily, the recently proposed relaxation (Mena et al., 2018) lets us circumvent this issue. First, note that exact samples from a categorical distribution can be obtained using the perturb-and-max technique (Papandreou and Yuille, 2011). For our alignment model, it would correspond to adding independent noise to the score for every possible alignment and choosing the highest scoring one:

$$\mathbf{a}^\star = \operatorname*{argmax}_{\mathbf{a} \in \mathcal{P}} \sum_{i=1}^{n} \varphi(\mathbf{g}_i, \mathbf{h}_{a_i}) + \epsilon_{\mathbf{a}}, \qquad (4)$$

where $\mathcal{P}$ is the set of all permutations of n elements, $\epsilon_{\mathbf{a}}$ is a noise drawn independently for each $\mathbf{a}$ from the fixed Gumbel distribution ($\mathcal{G}(0,1)$). Unfortunately, this is also intractable, as there are $n!$ permutations. Instead, in perturb-and-max an approximate schema is used where noise is assumed factorizable. In other words, first noisy scores are computed as $\hat{\varphi}(\mathbf{g}_i, \mathbf{h}_{a_i}) = \varphi(\mathbf{g}_i, \mathbf{h}_{a_i}) + \epsilon_{i,a_i}$, where $\epsilon_{i,a_i} \sim \mathcal{G}(0,1)$ and an approximate sample is obtained by $\mathbf{a}^\star = \operatorname{argmax}_{\mathbf{a}} \sum_{i=1}^{n} \hat{\varphi}(\mathbf{g}_i, \mathbf{h}_{a_i})$,

Such sampling procedure is still intractable in our case and also non-differentiable. The main contribution of Mena et al. (2018) is approximating this argmax with a simple differentiable computation $\hat{\mathbf{a}} = S_t(\Phi, \Sigma)$ which yields an approximate (i.e. relaxed) permutation. We use Φ and Σ to denote the $n \times n$ matrices of alignment scores $\varphi(\mathbf{g}_i, \mathbf{h}_k)$ and noise variables ϵ_{ik}, respectively. Instead of returning index a_i for every concept i, it would return a (peaky) distribution over words $\hat{\mathbf{a}}_i$. The peakiness is controlled by the temperature parameter t of Gumbel-Sinkhorn which balances smoothness ('differentiability') vs. bias of the estimator. For further details and the derivation, we refer the reader to the original paper (Mena et al., 2018).

Note that Φ is a function of the alignment model Q_ψ, so we will write Φ_ψ in what follows. The variational bound (1) can now be approximated as

$$\begin{aligned} E_{\Sigma \sim \mathcal{G}(0,1)} & [\log P_\theta(c|S_t(\Phi_\psi, \Sigma), \mathbf{w}) \\ & + \log P_\phi(R|S_t(\Phi_\psi, \Sigma), \mathbf{w}, \mathbf{c})] \\ & - D_{KL}(\frac{\Phi_\psi + \Sigma}{t} || \frac{\Sigma}{t_0}) \end{aligned} \qquad (5)$$

Following Mena et al. (2018), the original KL term from equation (1) is approximated by the KL term between two $n \times n$ matrices of i.i.d. Gumbel distributions with different temperature and mean. The parameter t_0 is the 'prior temperature'.

Using the Gumbel-Sinkhorn construction unfortunately does not guarantee that $\sum_i \hat{\mathbf{a}}_{ij} = 1$. To encourage this equality to hold, and equivalently to discourage overlapping alignments, we add another regularizer to the objective (5):

$$\Omega(\hat{\mathbf{a}}, \lambda) = \lambda \sum_j \max(\sum_i (\hat{\mathbf{a}}_{ij}) - 1, 0). \qquad (6)$$

Our final objective is fully differentiable with respect to all parameters (i.e. θ, ϕ and ψ) and has low variance as sampling is performed from the fixed non-parameterized distribution, as in standard VAEs.

2.7 Relaxing concept and relation identification

One remaining question is how to use the soft input $\hat{\mathbf{a}} = S_t(\Phi_\psi, \Sigma)$ in the concept and relation identification models in equation (5). In other words, we need to define how we compute $P_\theta(c|S_t(\Phi_\psi, \Sigma), \mathbf{w})$ and $P_\phi(R|S_t(\Phi_\psi, \Sigma), \mathbf{w}, \mathbf{c})$.

The standard technique would be to pass to the models expectations under the relaxed variables $\sum_{k=1}^{n} \hat{\mathbf{a}}_{ik} \mathbf{h}_k$, instead of the vectors $\mathbf{h}_{a_i}$ (Maddison et al., 2017; Jang et al., 2017). This is what we do for the relation identification model. We use this approach also to relax the one-hot encoding of the predicate position ($\mathbf{p}$, see Section 2.4).

However, the concept prediction model $\log P_\theta(c|S_t(\Phi_\psi, \Sigma), \mathbf{w})$ relies on the pointing mechanism, i.e. directly exploits the words $\mathbf{w}$ rather than relies only on biLSTM states $\mathbf{h}_k$. So

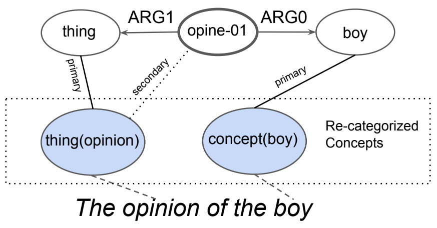

Figure 3: An example of re-categorized AMR. AMR graph at the top, re-categorized concepts in the middle, and the sentence is at the bottom.

instead we treat $\hat{\mathbf{a}}_i$ as a prior in a hierarchical model:

$$\log P_\theta(c_i|\hat{\mathbf{a}}_\mathbf{i}, \mathbf{w}) \approx \log \sum_{k=1}^{n} \hat{\mathbf{a}}_{ik} P_\theta(c_i|a_i = k, \mathbf{w}) \quad (7)$$

As we will show in our experiments, a softer version of the loss is even more effective:

$$\log P_\theta(c_i|\hat{\mathbf{a}}_\mathbf{i}, \mathbf{w}) \approx \log \sum_{k=1}^{n} (\hat{\mathbf{a}}_{ik} P_\theta(c_i|a_i = k, \mathbf{w}))^\alpha, \quad (8)$$

where we set the parameter $\alpha = 0.5$. We believe that using this loss encourages the model to more actively explore the alignment space. Geometrically, the loss surface shaped as a ball in the 0.5-norm space would push the model away from the corners, thus encouraging exploration.

3 Pre- and post-pocessing

3.1 Re-Categorization

AMR parsers often rely on a pre-processing stage, where specific subgraphs of AMR are grouped together and assigned to a single node with a new compound category (e.g., Werling et al. (2015); Foland and Martin (2017); Peng et al. (2017)); this transformation is reversed at the post-processing stage. Our approach is very similar to the Factored Concept Label system of Wang and Xue (2017), with one important difference that we unpack our concepts before the relation identification stage, so the relations are predicted between original concepts (all nodes in each group share the same alignment distributions to the RNN states). Intuitively, the goal is to ensure that concepts rarely lexically triggered (e.g., *thing* in Figure 3) get grouped together with lexically triggered nodes. Such 'primary' concepts get encoded in the category of the concept (the set of categories is τ, see also section 2.3). In Figure 3, the re-categorized concept *thing(opinion)* is produced from *thing* and *opine-01*. We use *concept* as the dummy category type. There are 8 templates in our system which extract re-categorizations for fixed phrases (e.g. *thing(opinion)*), and a deterministic system for grouping lexically flexible, but structurally stable sub-graphs (e.g., named entities, *have-rel-role-91* and *have-org-role-91* concepts).

Details of the re-categorization procedure and other pre-processing are provided in appendix.

3.2 Post-processing

For post-processing, we handle sense-disambiguation, wikification and ensure legitimacy of the produced AMR graph. For sense disambiguation we pick the most frequent sense for that particular concept ('-01', if unseen). For wikification we again look-up in the training set and default to "-". There is certainly room for improvement in both stages. Our probability model predicts edges conditional independently and thus cannot guarantee the connectivity of AMR graph, also there are additional constraints which are useful to impose. We enforce three constraints: (1) specific concepts can have only one neighbor (e.g., 'number' and 'string'; see appendix for details); (2) each predicate concept can have at most one argument for each relation $r \in \mathcal{R}$; (3) the graph should be connected. Constraint (1) is addressed by keeping only the highest scoring neighbor. In order to satisfy the last two constraints we use a simple greedy procedure. First, for each edge, we pick-up the highest scoring relation and edge (possibly *NULL*). If the constraint (2) is violated, we simply keep the highest scoring edge among the duplicates and drop the rest. If the graph is not connected (i.e. constraint (3) is violated), we greedily choose edges linking the connected components until the graph gets connected (MSCG in Flanigan et al. (2014)).

Finally, we need to select a root node. Similarly to relation identification, for each candidate concept c_i, we concatenate its embedding with the corresponding LSTM state ($\mathbf{h}_{a_i}$) and use these scores in a softmax classifier over all the concepts.

4 Experiments and Discussion

4.1 Data and setting

We primarily focus on the most recent LDC2016E25 (R2) dataset, which consists of 36521, 1368 and 1371 sentences in training, development and testing sets, respectively. The earlier LDC2015E86 (R1) dataset has been used by much of the previous work. It contains 16833 training sentences, and same sentences for development and testing as R2.[8]

We used the development set to perform model selection and hyperparameter tuning. The hyperparameters, as well as information about embeddings and pre-processing, are presented in the supplementary materials.

We used Adam (Kingma and Ba, 2014) to optimize the loss (5) and to train the root classifier. Our best model is trained fully jointly, and we do early stopping on the development set scores. Training takes approximately 6 hours on a single GeForce GTX 1080 Ti with Intel Xeon CPU E5-2620 v4.

4.2 Experiments and discussion

We start by comparing our parser to previous work (see Table 1). Our model substantially outperforms all the previous models on both datasets. Specifically, it achieves 74.4% Smatch score on LDC2016E25 (R2), which is an improvement of 3.4% over character seq2seq model relying on silver data (van Noord and Bos, 2017). For LDC2015E86 (R1), we obtain 73.7% Smatch score, which is an improvement of 3.0% over the previous best model, multi-BiLSTM parser of Foland and Martin (2017).

In order to disentangle individual phenomena, we use the AMR-evaluation tools (Damonte et al., 2017) and compare to systems which reported these scores (Table 2). We obtain the highest scores on most subtasks. The exception is negation detection. However, this is not too surprising as many negations are encoded with morphology, and character models, unlike our word-level model, are able to capture predictive morphological features (e.g., detect prefixes such as "un-" or "im-").

Now, we turn to ablation tests (see Table 3). First, we would like to see if our latent alignment framework is beneficial. In order to test this, we create a baseline version of our system ('pre-align') which relies on the JAMR aligner (Flani-

[8]Annotation in R2 has also been slightly revised.

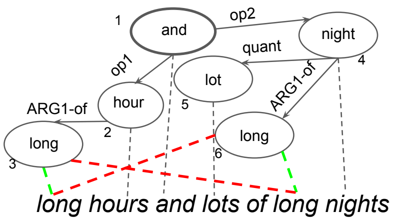

Figure 4: When modeling concepts alone, the posterior probability of the correct (green) and wrong (red) alignment links will be the same.

gan et al., 2014), rather than induces alignments as latent variables. Recall that in our model we used training data and a lemmatizer to produce candidates for the concept prediction model (see Section 2.3, the copy function). In order to have a fair comparison, if a concept is not aligned after JAMR, we try to use our copy function to align it. If an alignment is not found, we make the alignment uniform across the unaligned words. In preliminary experiments, we considered alternatives versions (e.g., dropping concepts unaligned by JAMR or dropping concepts unaligned after both JAMR and the matching heuristic), but the chosen strategy was the most effective. These scores of pre-align are superior to the results from Foland and Martin (2017) which also relies on JAMR alignments and uses BiLSTM encoders. There are many potential reasons for this difference in performance. For example, their relation identification model is different (e.g., single pass, no bi-affine modeling), they used much smaller networks than us, they use plain JAMR rather than a combination of JAMR and our copy function, they use a different recategorization system. These results confirm that we started with a strong basic model, and that our variational alignment framework provided further gains in performance.

Now we would like to confirm that joint training of alignments with both concepts and relations is beneficial. In other words, we would like to see if alignments need to be induced in such a way as to benefit the relation identification task. For this ablation we break the full joint training into two stages. We start by jointly training the alignment model and the concept identification model. When these are trained, we optimizing the relation model but keep the concept identification model and alignment models fixed ('2 stages' in see Table 4). When compared to our joint model ('full model'), we observe a substantial drop in Smatch score (-0.8%). In another version ('2 stages, tune align') we also use two stages but we fine-tune the alignment model on the second stage. This approach appears slightly more accurate but still -0.5% below the full model. In both cases, the drop is more substantial for relations ('SRL'). In order to see why relations are potentially useful in learning alignments, consider Figure 4. The example contains duplicate concepts *long*. The concept prediction model factorizes over concepts and does not care which way these duplicates are aligned: correctly (green edges) or not (red edges). Formally, the true posterior under the concept-only model in '2 stages' assigns exactly the same probability to both configurations, and the alignment model Q_ψ will be forced to mimic it (even though it relies on an LSTM model of the graph). The spurious ambiguity will have a detrimental effect on the relation identification stage.

Ablation	Concepts	SRL	Smatch
No Sinkhorn	85.7	69.3	73.8
No Sinkhorn reg	85.6	69.5	74.2
No soft loss	85.2	69.1	73.7
Full model	**85.9**	**69.8**	**74.4**

Table 5: Ablation studies: alignment modeling and relaxation (all on R2). Scores on ablations are averaged over 2 runs.

It is interesting to see the contribution of other modeling decisions we made when modeling and relaxing alignments. First, instead of using Gumbel-Sinkhorn, which encourages mutually-repulsive alignments, we now use a factorized alignment model. Note that this model ('No Sinkhorn' in Table 5) still relies on (relaxed) discrete alignments (using Gumbel softmax) but does not constrain the alignments to be injective. A substantial drop in performance indicates that the prior knowledge about the nature of alignments appears beneficial. Second, we remove the additional regularizer for Gumbel-Sinkhorn approximation (equation (6)). The performance drop in

Smatch score ('No Sinkhorn reg') is only moderate. Finally, we show that using the simple hierarchical relaxation (equation (7)) rather than our softer version of the loss (equation (8)) results in a substantial drop in performance ('No soft loss', -0.7% Smatch). We hypothesize that the softer relaxation favors exploration of alignments and helps to discover better configurations.

5 Additional Related Work

Alignment performance has been previously identified as a potential bottleneck affecting AMR parsing (Damonte et al., 2017; Foland and Martin, 2017). Some recent work has focused on building aligners specifically for training their parsers (Werling et al., 2015; Wang and Xue, 2017). However, those aligners are trained independently of concept and relation identification and only used at pre-processing.

Treating alignment as discrete variables has been successful in some sequence transduction tasks with neural models (Yu et al., 2017, 2016). Our work is similar in that we also train discrete alignments jointly but the tasks, the inference framework and the decoders are very different.

The discrete alignment modeling framework has been developed in the context of traditional (i.e. non-neural) statistical machine translation (Brown et al., 1993). Such translation models have also been successfully applied to semantic parsing tasks (e.g., (Andreas et al., 2013)), where they rivaled specialized semantic parsers from that period. However, they are considerably less accurate than current state-of-the-art parsers applied to the same datasets (e.g., (Dong and Lapata, 2016)).

For AMR parsing, another way to avoid using pre-trained aligners is to use seq2seq models (Konstas et al., 2017; van Noord and Bos, 2017). In particular, van Noord and Bos (2017) used character level seq2seq model and achieved the previous state-of-the-art result. However, their model is very data demanding as they needed to train it on additional 100K sentences parsed by other parsers. This may be due to two reasons. First, seq2seq models are often not as strong on smaller datasets. Second, recurrent decoders may struggle with predicting the linearized AMRs, as many statistical dependencies are highly non-local.

6 Conclusions

We introduced a neural AMR parser trained by jointly modeling alignments, concepts and relations. We make such joint modeling computationally feasible by using the variational autoencoding framework and continuous relaxations. The parser achieves state-of-the-art results and ablation tests show that joint modeling is indeed beneficial.

We believe that the proposed approach may be extended to other parsing tasks where alignments are latent (e.g., parsing to logical form (Liang, 2016)). Another promising direction is integrating character seq2seq to substitute the copy function. This should also improve the handling of negation and rare words. Though our parsing model does not use any linearization of the graph, we relied on LSTMs and somewhat arbitrary linearization (depth-first traversal) to encode the AMR graph in our alignment model. A better alternative would be to use graph convolutional networks (Marcheggiani and Titov, 2017; Kipf and Welling, 2017): neighborhoods in the graph are likely to be more informative for predicting alignments than the neighborhoods in the graph traversal.

Accurate SHRG-Based Semantic Parsing

Yufei Chen, Weiwei Sun and **Xiaojun Wan**
Institute of Computer Science and Technology, Peking University
The MOE Key Laboratory of Computational Linguistics, Peking University
{yufei.chen,ws,wanxiaojun}@pku.edu.cn

Abstract

We demonstrate that an SHRG-based parser can produce semantic graphs much more accurately than previously shown, by relating synchronous production rules to the syntacto-semantic composition process. Our parser achieves an accuracy of 90.35 for EDS (89.51 for DMRS) in terms of ELEMENTARY DEPENDENCY MATCH, which is a 4.87 (5.45) point improvement over the best existing data-driven model, indicating, in our view, the importance of linguistically-informed derivation for data-driven semantic parsing. This accuracy is equivalent to that of English Resource Grammar guided models, suggesting that (recurrent) neural network models are able to effectively learn deep linguistic knowledge from annotations.

1 Introduction

Graph-structured semantic representations, e.g. Semantic Dependency Graphs (SDG; Clark et al., 2002; Ivanova et al., 2012), Elementary Dependency Structure (EDS; Oepen and Lønning, 2006), Abstract Meaning Representation (AMR; Banarescu et al., 2013), Dependency-based Minimal Recursion Semantics (DMRS; Copestake, 2009), and Universal Conceptual Cognitive Annotation (UCCA; Abend and Rappoport, 2013), provide a lightweight yet effective way to encode rich semantic information of natural language sentences (Kuhlmann and Oepen, 2016). Parsing to semantic graphs has been extensively studied recently.

At the risk of oversimplifying, work in this area can be divided into three types, according to how much structural information of a target graph is explicitly modeled. Parsers of the first type throw an input sentence into a sequence-to-sequence model and leverage the power of deep learning technologies to obtain auxiliary symbols to transform the output sequence into a graph (Peng et al., 2017b; Konstas et al., 2017). The strategy of the second type is to gradually generate a graph in a greedy search fashion (Zhang et al., 2016; Buys and Blunsom, 2017). Usually, a transition system is defined to handle graph construction. The last solution explicitly associates each basic part with a target graph score, and casts parsing as the search for the graphs with highest sum of partial scores (Flanigan et al., 2014; Cao et al., 2017). Although many parsers achieve encouraging results, they are very hard for linguists to interpret and understand, partially because they do not explicitly model the syntacto-semantic composition process which is a significant characteristic of natural languages.

In theory, Synchronous Hyperedge Replacement Grammar (SHRG; Drewes et al., 1997) provides a mathematically sound framework to construct semantic graphs. In practice, however, initial results on the utility of SHRG for semantic parsing were somewhat disappointing (Peng et al., 2015; Peng and Gildea, 2016). In this paper, we show that the performance that can be achieved by an SHRG-based parser is far higher than what has previously been demonstrated. We focus here on relating SHRG rules to the syntacto-semantic composition process because we feel that information about syntax-semantics interface has been underexploited in the data-driven parsing architecture. We demonstrate the feasibility of inducing a high-quality, linguistically-informed SHRG from compositional semantic annotations licensed by English Resource Grammar (ERG; Flickinger, 2000), dubbed English Resource Semantics[1] (ERS). Coupled with RNN-based pars-

Model	Grammar	SDG	EDS	DMRS
Data-driven	NO	89.4	85.48	84.16
ERG-based	Unification	92.80	89.58	89.64
SHRG-based	Rewriting	- -	90.39	89.51

Table 1: Parsing accuracy of the best existing grammar-free and -based models as well as our SHRG-based model. Results are copied from (Oepen et al., 2015; Peng et al., 2017a; Buys and Blunsom, 2017).

ing techniques, we build a robust SHRG parser that is able to produce semantic analysis for all sentences. Our parser achieves an accuracy of 90.35 for EDS and 89.51 for DMRS in terms of ELEMENTARY DEPENDENCY MATCH (EDM) which outperforms the best existing grammar-free model (Buys and Blunsom, 2017) by a significant margin (see Table 1). This marked result affirms the value of modeling the syntacto-semantic composition process for semantic parsing.

On sentences that can be parsed by ERG-guided parsers, e.g. PET[2] or ACE[3], significant accuracy gaps between ERG-guided parsers and data-driven parsers are repeatedly reported (see Table 1). The main challenge for ERG-guided parsing is limited coverage. Even for treebanking on WSJ sentences from PTB, such a parser lacks analyses for c.a. 11% of sentences (Oepen et al., 2015). Our parser yields equivalent accuracy to ERG-guided parsers and equivalent coverage, full-coverage in fact, to data-driven parsers. We see this investigation as striking a balance between data-driven and grammar-driven parsing. It is not our goal to argue against the use of unification grammar in high-performance deep linguistic processing. Nevertheless, we do take it as a reflection of two points: (1) (recurrent) neural network models are able to effectively learn deep linguistic knowledge from annotations; (2) practical parsing may benefit from transforming a model-theoretic grammar into a generative-enumerative grammar.

The architecture of our parser has potential uses beyond establishing a strong string-to-graph parser. Our grammar extraction algorithm has some freedom to induce different SHRGs following different linguistic hypothesis, and allows some issues in theoretical linguistics to be empirically investigated. In this paper, we examine the

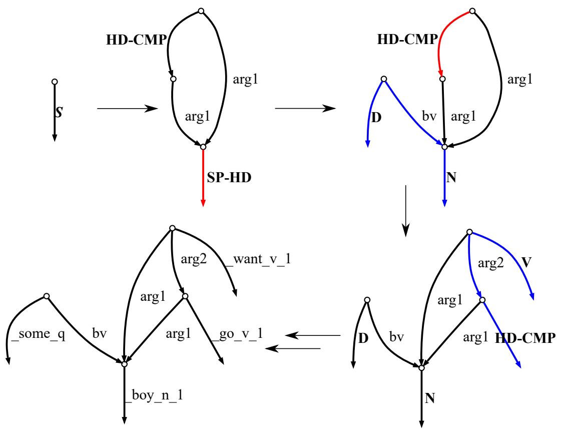

Figure 1: A partial rewriting process of HRG on the semantic graph associated with "Some boys want to go." Lowercase symbols indicate terminal edges, while bold, uppercase symbols indicate nonterminal edges. Red edges are the hyperedges that will be replaced in the next step, while the blue edges in the next step constitute their corresponding RHS graphs.

lexicalist/constructivist hypothesis, a divide across a variety of theoretical frameworks, in an empirical setup. The lexicalist tradition traces its origins to Chomsky (1970) and is widely accepted by various computational grammar formalisms, including CCG, LFG, HPSG and LTAG. A lexicalist approach argues that the lexical properties of words determine their syntactic and semantic behaviors. The constructivist perspective, e.g. Borer's Exo-Skeletal approach (2005b; 2005a; 2013), emphasizes the role of syntax in constructing meanings. In this paper, we focus on lexicalist and constructivist hypotheses for syntacto-semantic composition. We present our computation-oriented analysis in §6. Under the architecture of our neural parser, a construction grammar works much better than a lexicalized grammar.

Our parser is available at https://github.com/draplater/hrg-parser/.

2 Hyperedge Replacement Grammar

Hyperedge replacement grammar (HRG) is a context-free rewriting formalism for graph generation (Drewes et al., 1997). An edge-labeled, directed hypergraph is a tuple $H = \langle V, E, l, X \rangle$, where V is a finite set of nodes, and $E \subseteq V^+$ is a finite set of hyperedges. A hyperedge is an extension of a normal edge which can connect to more than two nodes or only one node. $l : E \rightarrow L$

Algorithm 1 Hyperedge Replacement Grammar Extraction Algorithm

```
Require: Input syntactic tree $T$, hypergraph $g$
 1: RULES $\leftarrow \{\}$
 2: for tree node $n$ in postorder traversal of $T$ do
Ensure: Rewriting rule of node $n$ is A $\rightarrow$ B + C, spans of node A, B, C are SPAN-A, SPAN-B, SPAN-C
 3:     SPANS $\leftarrow$ {SPAN-A, SPAN-B, SPAN-C}
 4:     C-EDGES $\leftarrow \{e|e \in \text{EDGES}(g) \wedge \text{SPAN}(e) \in \text{SPANS}\}$
 5:     ALL-NODES $\leftarrow \{s|s \in \text{NODES}(g) \wedge \exists e \in \text{C-EDGES s.t. } s \in \text{NODES}(e)\}$
 6:     S-EDGES $\leftarrow \{e|e \in \text{EDGES}(g) \wedge e \text{ is structual edge} \wedge \forall s \in \text{NODES}(e) \implies s \in \text{C-EDGES}\}$
 7:     ALL-EDGES = C-EDGES $\cup$ S-EDGES
 8:     INTERNAL-NODES $\leftarrow \{\}$
 9:     EXTERNAL-NODES $\leftarrow \{\}$
10:     for node $s$ in ALL-NODES do
11:         if $\forall e \in \text{EDGES}(g), s \in \text{NODES}(e) \implies e \in \text{ALL-EDGES}$ then
12:             INTERNAL-NODES $\leftarrow$ INTERNAL-NODES $\cup \{s\}$
13:         else
14:             EXTERNAL-NODES $\leftarrow$ EXTERNAL-NODES $\cup \{s\}$
15:         end if
16:     end for
17:     RULES $\leftarrow$ RULES $\cup$ {(A, ALL-EDGES, INTERNAL-NODES, EXTERNAL-NODES)}
18: end for
```

assigns a label from a finite set L to each edge. $X \in V^*$ defines an ordered list of nodes, i.e., **external nodes**, which specify the connecting parts when replacing a hyperedge.

An HRG $G = \langle N, T, P, S \rangle$ is a graph rewriting system, where N and T are two disjoint finite sets of nonterminal and terminal symbols respectively. $S \in N$ is the start symbol. P is a finite set of productions of the form $A \rightarrow R$, where the left hand side (LHS) $A \in N$, and the right hand side (RHS) R is a hypergraph with edge labels over $N \cup T$. The rewriting process replaces a nonterminal hyperedge with the graph fragment specified by a production's RHS, attaching each external node to the matched node of the corresponding LHS. An example is shown in Figure 1. Following Chiang et al. (2013), we make the nodes only describe connections between edges and store no other information.

A synchronous grammar defines mappings between different grammars. Here we focus on relating a string grammar, CFG in our case, to a graph grammar, i.e., HRG. SHRG can be represented as tuple $G = \langle N, T, T', P, S \rangle$. N is a finite set of nonterminal symbols in both CFG and HRG. T' and T are finite sets of terminal symbols in CFG and HRG, respectively. $S \in N$ is the start symbol. P is a finite set of productions of the form $A \rightarrow \langle R, R', \sim \rangle$, where $A \in N$, R is a hypergraph fragment with edge labels over $N \cup T$, and R' is a symbol sequence over $N \cup T'$. $\sim$ is a mapping between the nonterminals in R and R'. When a coherent CFG derivation is ready, we can *interpret* it using the corresponding HRG and get a semantic graph.

3 Grammar Extraction

3.1 Graph Representations for ERS

ERS are richly detailed semantic representations produced by the ERG, a hand-crafted, linguistically-motivated HPSG grammar for English. Beyond basic predicate–argument structures, ERS also includes other information about various complex phenomena such as the distinction between scopal and non-scopal arguments, conditionals, comparatives, and many others. ERS are in the formalism of Minimal Recursion Semantics (MRS; Copestake et al., 2005), but can be expressed in different ways. Semantic graphs, including EDS and DMRS, can be reduced from the standard feature structure encoded representations, with or without a loss of information. In this paper, we conduct experiments on ERS data, but our grammar extraction algorithm and the parser are not limited to ERS.

One distinguished characteristic of ERS is that the construction of ERS strictly follows the prin-

	①	②	③	④	⑤
Shared LHS	SP-HD	HD↓V	HD-CMP	HD-CMP	S↓SP-HD
RHS (syntax)	D + N	V + PUNCT	CM + HD↓V	V + HD-CMP	SP-HD + HD-CMP
RHS (semantics)					
Figure 2: The grammar extraction process of the running example. Conceptual edges which are directly aligned with the syntactic rules are painted in green. The span-based alignment is shown in the parentheses. Structural edges that connect conceptual edges are painted in brown. Green edges and brown edges together form the subgraph, which acts as RHS in the HRG rule. External nodes are represented as solid dots.

ciple of compositionality (Bender et al., 2015). A precise syntax-semantics interface is introduced to guarantee compositionality and therefore all meaning units can be traced back to linguistic signals, including both lexical and constructional ones. Take Figure 2 for example. Every concept, e.g. the existence quantifier _some_q, is associated with a surface string. We favor such correspondence not because it eases extraction of SHRGs, but because we emphasize sentence meanings that are from forms. The connection between syntax (sentence form) and semantics (word and sentence meaning) is fundamental to the study of language.

3.2 The Algorithm

We introduce a novel SHRG extraction algorithm, which requires and only requires alignments between conceptual edges and surface strings. A tree is also required, but this tree does not have to be a gold-standard syntactic tree. All trees that are compatible with an alignment can be used. The syntactic part of DeepBank is a phrase structure which describes HPSG derivation. The vast majority of syntactic rules in DeepBank are binary, and the rest are unary. In §5, we report evaluation results based on DeepBank trees.

A conceptual graph is composed by two kinds of edges: 1) **conceptual edges** that carry semantic concept information and are connected with only one node, and 2) **structural edges** that build relationships among concepts by connecting nodes. The grammar extraction process repeatedly replaces a subgraph with a nonterminal hyperedge, defining the nonterminal symbol as LHS and the subgraph as RHS. The key problem is to identify an appropriate subgraph in each step. To this end, we take advantage of DeepBank's accurate and fine-grained alignments between the surface string in syntactic tree and concepts in semantic graphs.

To extract the HRG rule synchronized with the syntactic rewriting rule A → B + C, we assume that conceptual edges sharing common spans with A, B or C are in the same subgraph. This subgraph acts as the RHS of the HRG rule. We make the extraction process go in the direction of postorder traversal of the syntactic tree, to ensure that all sub-spans of A, B or C are already replaced with hyperedges. We then add the structural edges that connect the above conceptual edges to RHS. After the subgraph is identified, it is easy to distinguish between internal nodes and external nodes.

If all edges connected to a node are in the subgraph, this node is an internal node. Otherwise, it is external node. Finally, the subgraph is replaced with a nonterminal edge. Algorithm 1 presents a precise demonstration and Figure 2 illustrates an example.

4 A Neural SHRG Parser

Under the SHRG formalism, semantic parsing can be divided into two steps: syntactic parsing and semantic interpretation. Syntactic parsing utilizes the CFG part to get a derivation that is shared by the HRG part. At one derivation step, there may be more than one HRG rule applicable. In this case, we need a semantic disambiguation model to choose a good one.

4.1 Syntactic Parsing

Following the LSTM-Minus approach proposed by Cross and Huang (2016), we build a constituent parser with a CKY decoder. We denote the output vectors of forward and backward LSTM as $\boldsymbol{f}_i$ and $\boldsymbol{b}_i$. The feature $\boldsymbol{s}_{i,j}$ of a span (i, j) can be calculated from the differences of LSTM encodings:

$$\boldsymbol{s}_{i,j} = (\boldsymbol{f}_j - \boldsymbol{f}_i) \oplus (\boldsymbol{b}_i - \boldsymbol{b}_j)$$

The operator $\oplus$ indicates the concatenation of two vectors. Constituency parsing can be regarded as predicting scores for spans and labels, and getting the best syntactic tree with dynamic programming. Following Stern et al. (2017)'s approach, We calculate the span scores $\textsc{Score}_{\text{span}}(i, j)$ and labels scores $\textsc{Score}_{\text{label}}(i, j, l)$ from $\boldsymbol{s}_{i,j}$ with multilayer perceptrons (MLPs):

$$\textsc{Score}_{\text{span}}(i, j) = \text{MLP}_{\text{span}}(\boldsymbol{s}_{i,j})$$

$$\textsc{Score}_{\text{label}}(i, j, l) = \text{MLP}_{\text{label}}(\boldsymbol{s}_{i,j})[l]$$

$\boldsymbol{x}[i]$ indicates the ith element of a vector $\boldsymbol{x}$. We condense the unary chains into one label to ensure that only one rule is corresponds with a specific span. Because the construction rules from DeepBank are either unary or binary, we do not deal with binarization.

Because the SHRG synchronizes at rule level, we need to restrict the parser to ensure that the output agrees with the known rules. The restriction can be directly added into the CKY decoder. To simplify the semantic interpretation process, we add extra label information to enrich the nonterminals in CFG rules. In particular, we consider the count of external nodes of a corresponding HRG rule. For example, the LHS of rule ④ in Figure 2 will be labeled as "`HD-CMP#2`", since the RHS of its HRG counterpart has two external nodes.

4.2 Semantic Interpretation

When a phrase structure tree, i.e., a derivation tree, T is available, semantic interpretation can be regarded as *translating* T to the derivation of graph construction by assigning a corresponding HRG rule to each syntactic counterpart. Our approach to finding the optimal HRG rule combination $\hat{R} = \{r_1, r_2, ...\}$ from the search space $\mathcal{R}(T)$:

$$\hat{R} = \text{argmax}_{R \in \mathcal{R}(T)} \textsc{Score}(R|T) \qquad (1)$$

To solve this optimization problem, we implement a greedy search decoder and a bottom-up beam search decoder. The final semantic graph G is read off from $\hat{R}$.

4.2.1 Greedy Search Model

In this model, we assume that each HRG rule is selected independently of the others. The score of G is defined as the sum of all rule scores:

$$\textsc{Score}(R = \{r_1, r_2, ...\}|T) = \sum_{r \in R} \textsc{Score}(r|T)$$

The maximization of the graph score can be decomposed into the maximization of each rule score. $\textsc{Score}(r|T)$ can be calculated in many ways. Count-based approach is the simplest one, where the rule score is estimated by its frequency in the training data. We also evaluate a sophisticated scoring method, i.e., training a classifier based on rule embedding:

$$\textsc{Score}(r|T) = \text{MLP}(\boldsymbol{s}_{i,j} \oplus \boldsymbol{r})$$

Inspired by the bag-of-words model, we represent the rule as bag of edge labels. The i-th position in $\boldsymbol{r}$ indicates the number of times the i-th label appears in the rule.

4.2.2 Bottom-Up Beam Search Model

We can also leverage structured prediction to approximate $\textsc{Score}(R|T)$ and employ principled decoding algorithms to solve the optimization problem (1). We propose a factorization model to assign scores to the graph and subgraphs in the intermediate state. The score of a certain graph can be seen as the sum of each factor score.

$$\textsc{Score}(R|T) = \sum_{i \in \textsc{Part}(R,T)} \textsc{ScorePart}(i)$$

We use predicates and arguments as factors for scoring. There are two kinds of factors: 1) A conceptual edge aligned with span (i, j) taking predicate name p. We use the span embedding $\boldsymbol{s}_{i,j}$ as features, and scoring with non-linear transformation:

$$\textsc{ScorePart}_{\text{pred}}(i, j, p) = \text{MLP}_{\text{pred}}(\boldsymbol{s}_{i,j})[p]$$

2) A structural edge with label L connects with predicates p_a and p_b, which are aligned with spans (i_1, j_1) and (i_2, j_2) respectively. We use the span embedding $\boldsymbol{s}_{i_1,j_1}$, $\boldsymbol{s}_{i_2,j_2}$ and random initialized predicate embedding $\boldsymbol{p}_a$, $\boldsymbol{p}_b$ as features, and scoring with non-linear transformation:

$$\textsc{ScorePart}_{\text{arg}}(i_1, j_1, i_2, j_2, \boldsymbol{p}_a, \boldsymbol{p}_b, L)$$
$$= \text{MLP}_{\text{arg}}(\boldsymbol{s}_{i_1,j_1} \oplus \boldsymbol{s}_{i_2,j_2} \oplus \boldsymbol{p}_a \oplus \boldsymbol{p}_b)[L]$$

We assign a beam to each node in the syntactic tree. To ensure that we always get a subgraph which does not contain any nonterminal edges during the search process, we perform the beam search in the bottom-up direction. We only reserve top k subgraphs in each beam. Figure 3 illustrates the process.

4.3 Training

The objective of training is to make the score of the correct graph higher than incorrect graphs. We use the score difference between the correct graph R_g and the highest scoring incorrect graph as the loss:

$$\text{loss} = \max_{\hat{R} \neq R_g} \textsc{Score}(\hat{R}|T) - \textsc{Score}(R_g|T)$$

Following (Kiperwasser and Goldberg, 2016)'s experience of loss augmented inference, in order to update graphs which have high model scores but are very wrong, we augment each factor belonging to the gold graph by adding a penalty term c to its score. Finally the *loss* term is:

$$\text{loss} = \textsc{Score}(R_g|T) - \sum_{i \in \textsc{Part}(R_g,T)} c -$$
$$\max(\textsc{Score}(\hat{R}|T) - \sum_{i \in \textsc{Part}(\hat{R},T) \cap \textsc{Part}(R_g,T)} c)$$

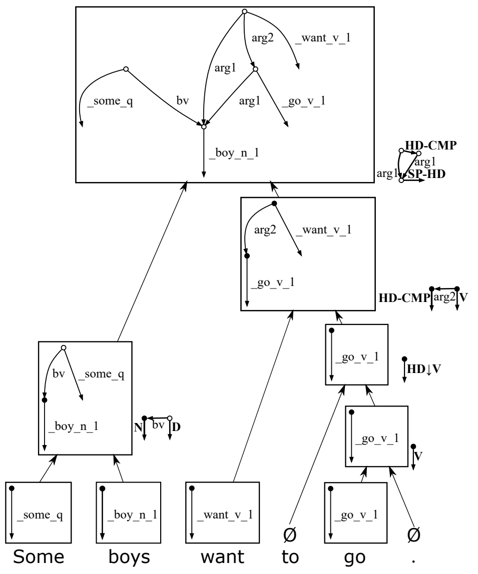

Figure 3: The semantic interpretation process. The interpretation performs bottom-up beam search to get a bunch of high-scored subgraphs for each node in the derivation tree.

5 Experiments

5.1 Set-up

DeepBank is an annotation of the Penn TreeBank Wall Street Journal which is annotated under the formalism of HPSG. We use DeepBank version 1.1, corresponding to ERG 1214, and use the *standard* data split. Therefore the numeric performance can be directly compared to results reported in Buys and Blunsom (2017). We use the pyDelphin library to extract DMRS and EDS graphs and use the tool provided by jigsaw[4] to separate punctuation marks from the words they attach to. We use DyNet[5] to implement our neural models, and automatic batch technique (Neubig et al., 2017) in DyNet to perform mini-batch gradient descent training. The detailed network hyper-parameters can be seen in Table 2. The same pre-trained word embedding as (Kiperwasser and Goldberg, 2016) is employed.

5.2 Results of Grammar Extraction

DeepBank provides fine-grained syntactic trees with rich information. For example, the label `SP-HD_HC_C` denotes that this is a "head+specifier" construction, where the semantic head is also the syntactic head. But there

	4	1237	873	299	2561
	5+	669	557	297	901

Table 3: Statistics of SHRG rules with different label type by the count of external points in EDS and DMRS representations.

is also the potential for data sparseness. In our experiments, we extract SHRG with three kinds of labels: fine-grained labels, coarse-grained labels and single Xs (meaning unlabeled parsing). The fine-grained labels are the original labels, namely fine-grained construction types. We use the part before the first underscore of each label, e.g. SP-HD, as a coarse-grained label. The coarse-grained labels are more like the highly generalized rule schemata proposed by Pollard and Sag (1994). Some statistics are shown in Table 3.

Instead of using gold-standard trees to extract a synchronous grammar, we also tried randomly-generated alignment-compatible trees. The result is shown in Table 4. Gold standard trees exhibit a low entropy, indicating a high regularity.

5.3 Results of Syntactic Parsing

In addition to the standard evaluation method for phrase-structure parsing, we find a more suitable measurement, i.e. condensed score, for our task. Because we condense unary rule chains into one label and extract synchronous grammar under this condensed syntactic tree, it is better to calculate the correctness of the condensed label rather than a single label. The additional label "#N" that indicates the number of external points is also considered in our condensed score evaluation method. The result is shown in Table 5.

Tree Type	1	2	3	4	5+
Gold	1476	488	280	248	251
Fuzzy 1	12710	7591	7963	6578	8998
Fuzzy 2	13606	7355	7228	6090	9112
Fuzzy 3	12278	8228	8462	7039	9946

Table 4: Comparison of grammars extracted from unlabeled gold trees and randomly-generated alignment-compatible trees (”fuzzy” trees).

Label	Standard				Condensed	
	P	R	F	POS	BCKT	POS
Fine	90.81	91.19	91.00	94.40	87.09	92.98
Coarse	90.78	91.24	91.01	98.30	87.93	95.98

Table 5: Accuracy of syntactic parsing under different labels on development data. We add the count of external nodes of corresponding HRG rule. "POS" concerns the prediction of preterminals, while "BCKT" denotes bracketing.

5.4 Results of Semantic Interpretation

Dridan and Oepen (2011) proposed the EDM metric to evaluate the performance the ERS-based graphs. EDM uses the alignment between the nodes in a graph and the spans in a string to detect the common parts between two graphs. It converts the predicate and predicate–argument relationship to comparable triples and calculates the correctness in these triples. A predicate of label L and span S is denoted as triple (S, NAME, L) and a relationship R between the predicate labelled P and argument labelled A is denoted as triple (P, R, A). We calculate the F_1 value of the total triples as EDM score. Similarity, we compute the F_1 score of only predicate triples and only the relation triples as EDM_P and EDM_A.

We reuse the word embeddings and bidirectional LSTM in the trained syntactic parsing model to extract span embedding $\boldsymbol{s}_{i,j}$. The results of the count-based model, rule embedding model and structured model with beam decoder are summarized in Table 6. We report the standard EDM metrics. The count-based model can achieve considerably good results, showing the correctness of our grammar extraction method. We also try different labels for the syntactic trees. The results

Model	EDM$_P$	EDM$_A$	EDM
Count Based	90.12	81.96	86.03
Rule Embedding	93.41	84.84	89.11
Beam Search	93.48	87.88	90.67

Table 6: The EDM score on EDS development data with different model: count based greedy search, rule embedding greedy search and beam search. We use syntactic trees with coarse-grained labels.

Data	Label	EDM$_P$	EDM$_A$	EDM
EDS	Fine	92.70	87.77	90.23
	Coarse	93.48	87.88	90.67
DMRS	Fine	92.52	86.47	89.46
	Coarse	93.60	86.62	90.07

Table 7: Accuracy on the development data under different labels of syntactic tree and beam search.

are shown in Table 7. Models based on coarse-grained labels achieve optimal performance. The results on test set of EDS data are shown in Table 8. We achieve state-of-the-art performance with a remarkable improvement over Buys and Blunsom (2017)'s neural parser.

6 On Syntax-Semantics Interface

In this paper, we empirically study the lexicalist/constructivist hypothesis, a divide across a variety of theoretical frameworks, taking semantic parsing as a case study. Although the original grammar that guides the annotation of ERS data, namely ERG, is highly lexicalized in that the majority of information is encoded in lexical entries (or lexical rules) as opposed to being represented in constructions (i.e., rules operating on phrases), our grammar extraction algorithm has some freedom to induce different SHRGs that choose between the lexicalist and constructivist approaches. We modify algorithm 1 to follow the key insights of the lexicalist approach. This is done by considering all outgoing edges when finding the subgraph of the lexical rules. The differences between two kinds of grammars is shown in Table 9.

Different grammars allow the lexicalist/constructivist issue in theoretical linguistics to be empirically examined. The comparison of the counts of rules in each grammar is summarized in Table 11, from which we can see that the sizes of the grammars are comparable. However, the parsing results are quite different, as shown

	Model	EDM$_P$	EDM$_A$	EDM
EDS	Buys and Blunsom	88.14	82.20	85.48
	ACE	91.82	86.92	89.58
	Ours	93.15	87.59	90.35
DMRS	Buys and Blunsom	87.54	80.10	84.16
	ACE	92.08	86.77	89.64
	Ours	93.11	86.01	89.51

Table 8: Accuracy on the test set. We use syntactic trees of coarse-grained labels and beam search.

in Table 10. A construction grammar works much better than a lexicalized grammar under the architecture of our neural parser. We take this comparison as informative since lexicalist approaches are more widely accepted by various computational grammar formalisms, including CCG, LFG, HPSG and LTAG.

We think that the success of applying SHRG to resolve semantic parsing highly relies on the compositionality nature of ERS' sentence-level semantic annotation. This is the property that makes sure the extracted rules are consistent and regular. Previous investigation by Peng et al. (2015) on SHRG-based semantic parsing utilizes AMR-Bank which lacks this property to some extent (see Bender et al.'s argument). We think this may be one reason for the disappointing parsing performance. Think about the AMR graph associated "John wants Bob to believe that he saw him." The AMR's annotation for co-reference is a kind of non-compositional, speaker meaning, and results in grammar sparseness.

7 On Deep Linguistic Knowledge

Semantic annotations have a tremendous impact on semantic parsing. In parallel with developing new semantic annotations, e.g. AMRBank, there is a resurgence of interest in exploring existing annotations grounded under deep grammar formalisms, such as semantic analysis provided by ERS (Flickinger, 2000). In stark contrast, it seems that only the annotation results gain interests, but not the core annotation engine—knowledge-extensive grammar.

The tendency to continually ignore the positive impact of precision grammar on semantic parsing is somewhat strange. For sentences that can be parsed by an ERG-guided parser, there is a significant accuracy gap which is repeatedly reported. See Table 1 for recent results. The main challenges for precision grammar-guided parsing are unsat-

Lexicon	Construction	Lexicalized	CFG Counterpart	Construction	Lexicalized
some			SP-HD → D + N		want			HD-CMP → V + HD-CMP		go			S↓SP-HD → SP-HD + HD-CMP		
Table 9: Rules of lexicalized and construction grammars that are extracted from the running example.

Grammar	EDM$_P$	EDM$_A$	EDM
Construction	93.48	87.88	90.67
Lexicalized	92.14	81.05	86.63

Table 10: The EDM score on EDS development data with construction grammar and lexicalized grammar using syntax trees of coarse-grained labels and beam search.

Grammar	1	2	3	4	5+
Construction	14234	3424	1486	732	418
Lexicalized	11653	5938	2358	396	11

Table 11: Comparison of the construction grammar and the lexicalized grammar extracted from EDS data. We use syntax trees of coarse-grained labels.

isfactory coverage and efficiency that limit their uses in NLP applications. Even for treebanking on newswire data, i.e., Wall Street Journal data from Penn TreeBank (Marcus et al., 1993), ERG lacks analyses for c.a. 11% of sentences (Oepen et al., 2015). For text data from the web, e.g. tweets, this problem is even more serious. Moreover, checking all possible linguistic constraints makes a grammar-guided parser too slow for many realistic NLP applications. Robustness and efficiency, thus, are two major problems for practical NLP applications.

Recent encouraging progress achieved with purely data-driven models helps resolve the above two problems. Nevertheless, it seems too radical to remove all explicit linguistic knowledge about the syntacto-semantic composition process, the key characteristics of natural languages. In this paper, we introduce a neural SHRG-based semantic parser that strikes a balance between data-driven and grammar-guided parsing. We encode deep linguistic knowledge partially in a symbolic way and partially in a statistical way. It is worth noting that the symbolic system is a derivational, generative-enumerative grammar, while the origin of the data source is grounded under a representational, model-theoretic grammar. While grammar writers may favor the convenience provided by a unification grammar formalism, a practical parser may re-use algorithms by another formalism by *translating* grammars through *data*. Experiments also suggest that (recurrent) neural network models are able to effectively gain some deep linguistic knowledge from annotations.

8 Conclusion

The advantages of using graph grammars to resolve semantic parsing is clear in concept but underexploited in practice. Here, we have shown ways to improve SHRG-based string-to-semantic-graph parsing. Especially, we emphasize the importance of modeling syntax-semantic interface and the compositional property of semantic annotations. Just like recent explorations on many other NLP tasks, we also show that neural network models are very powerful to advance deep language understanding.

Abstract

To solve math word problems, previous statistical approaches attempt at learning a direct mapping from a problem description to its corresponding equation system. However, such mappings do not include the information of a few higher-order operations that cannot be explicitly represented in equations but are required to solve the problem. The gap between natural language and equations makes it difficult for a learned model to generalize from limited data. In this work we present an intermediate meaning representation scheme that tries to reduce this gap. We use a sequence-to-sequence model with a novel attention regularization term to generate the intermediate forms, then execute them to obtain the final answers. Since the intermediate forms are latent, we propose an iterative labeling framework for learning by leveraging supervision signals from both equations and answers. Our experiments show using intermediate forms outperforms directly predicting equations.

1 Introduction

There is a growing interest in math word problem solving (Kushman et al., 2014; Koncel-Kedziorski et al., 2015; Huang et al., 2017; Roy and Roth, 2018). It requires reasoning with respect to sets of numbers or variables, which is an essential capability in many other natural language understanding tasks. Consider the math problems shown in Table 1. To solve the problems, one needs to know how many numbers to be summed up (e.g. "2 numbers/3 numbers"), and the relation between variables ("the first/second number"). However, an equation system does not encode these information explicitly. For example, an equation represents "the sum of 2 numbers" as $(x + y)$ and "the sum of 3 numbers" as $(x + y + z)$. This makes it difficult to generalize to cases unseen from data (e.g. "the sum of 100 numbers").

1) <u>**The sum of 2 numbers**</u> is 18. **The first number** is 4 more than **the second number**. Find the two numbers. **Equations:** $x + y = 18, x = y + 4$
2) <u>**The sum of 3 numbers**</u> is 15. **The larger number** is 4 times **the smallest** and **the middle number** is 5. What are the numbers? **Equations:** $x + y + z = 15, x = 4 * z, y = 5$

Table 1: Math word problems. Equations have lost the information of *count, max, ordinal* operations.

This paper presents a new intermediate meaning representation scheme for solving math problems, aiming at closing the semantic gap between natural language and equations. To generate the intermediate forms, we adapt a sequence-to-sequence (seq2seq) network following recent work that tries to generate equations from problem descriptions for this task. Wang et al. (2017) have shown that seq2seq models have the power to generate equations of which problem types do not exist in training data. In this paper, we propose a new method which adds an extra meaning representation and generate an intermediate form as output. Additionally, we observe that the attention weights of the seq2seq model repetitively concentrates on numbers in the problem description. To address the issue, we further propose to use a form of attention regularization.

To train the model without explicit annotations of intermediate forms, we propose an iterative la-

*Work done while this author was an intern at Microsoft Research.

beling framework to leverage signals from both equations and their solutions. We first derive possible intermediate forms with ambiguity using the gold-standard equation systems, and use these forms for training to get a pre-trained model. Then we iteratively refine the intermediate forms using the learned model and the signals from the gold-standard answers.

We conduct experiments on two publicly available math problem datasets. Our experimental results show that using the intermediate forms for training performs significantly better than directly mapping problems to equation systems. Furthermore, our iterative labeling framework creates better labeled data with intermediate forms for training, which leads to improved performance.

To summarize, our contributions include:

- We present a new intermediate meaning representation scheme for solving math problems.
- We design an iterative labeling framework to automatically augment training data with intermediate meaning representation.
- We propose using attention regularization in training to address the issue of incorrect attention in the seq2seq model.
- We verify the effectiveness of our proposed solutions by conducting experiments and analysis on real-world datasets.

2 Meaning Representation

In this section, we will compare meaning representations for solving math problems and introduce the proposed intermediate meaning representation.

2.1 Meaning Representations for Math Problem Solving

We first discuss two meaning representation schemes for math problem solving.

An **equation system** is a collection of one or more equations involving the same set of variables, which should be considered as highly abstractive symbolic representation.

The **Dolphin Language** is introduced by Shi et al. (2015). It contains about 35 math-related classes and over 200 math-related functions, with additional classes and functions automatically mined from Freebase.

Unfortunately, these representation schemes do not generalize well. Consider the two problems listed in Table 2. They belong to the same type of problems asking about the summation of consecutive integers. However, their meaning representations are very different in the Dolphin language and in equations. On one hand, the Dolphin language aligns too closely with natural utterances. Since the math problem descriptions are diverse in using various nouns and verbs, Dolphin language may represent the same type of problems differently. On the other hand, an equation system does not explicitly represent useful problem solving information such as "*number of variables*" and "*numbers are consecutive*"

2.2 Intermediate Meaning Representation

To bridge the semantic gap between the two meaning representations, we present a new intermediate meaning representation scheme for math problem solving. It consists of 6 *classes* and 23 *functions*. Here a *class* is the set of entities with the same semantic properties and can be inherited (e.g. $2 \in int$, $int \sqsubseteq num$). A *function* is comprised of a name, a list of arguments with corresponding types, and a return type. For example, there are two overloaded definitions for the function *math#sum* (Table 3). These forms can be constructed by recursively applying joint operations on functions with class type constraints. Our representation scheme attempts to borrow the explicit use of higher-order functions from the Dolphin language, while avoiding to be too specific. Meanwhile, the intermediate forms are not as concise as the equation systems (Table 2). We leave more detailed definitions to the supplement material due to space limit.

3 Problem Statement

Given a math word problem p, our goal is to predict its answer A_p. For each problem we have annotations of both the equation system E_p and the answer A_p available for training. The latent intermediate form will be denoted as LF_p.

We formulate math problem solving as a sequence prediction task, taking the sequence of words in a math problem as input and generating a sequence of tokens in its corresponding intermediate form as output. We then execute the intermediate form to obtain the final answer. We evaluate the task using answer accuracy on two publicly

Problem 1: Find three consecutive integers with a sum of 267.
Dolphin Language: vf.find(cat('integers'), count:3, adj.consecutive, (math#sum(pron.that, 267, det.a)))
Equation: $x + (x + 1) + (x + 2) = 267$
This work: math#consecutive(3), math#sum(cnt: 3) = 267
Problem 2: What are 5 consecutive numbers total 95?
Dolphin Language: wh.vf.math.total((cat('numbers'), count:5, pron.what, adj.consecutive), 95)
Equation: $x + (x + 1) + (x + 2) + (x + 3) + (x + 4) = 95$
This work: math#consecutive(5), math#sum(cnt: 5) = 95

Table 2: Different representations for math problems. Dolphin language is detailed ('all words'). Equation system is coarse that it represents many functions implicitly, such as "*count*", "*consecutive*".

Classes
int, float, num, unk, var, list
Functions
ret:int count($1:list): number of variables in $1
ret:var max($1:list): variable of max value in $1
ret:var math#product($1,$2:var): $1 times $2
ret:var math#sum($1:list): sum of variables in $1
ret:var math#sum(cnt:$1:int): sum of $1 unks
Example
Four times the sum of three and a number is 10. -> math#product(4, math#sum(3, m))=10

Table 3: Examples of classes and functions in our intermediate representation. "ret" stands for return type. $1, $2 are arguments with its types.

available math word problem datasets[1]:

- **Number Word Problem** (NumWord) is created by Shi et al. (2015). It contains 1,878 number word problems (verbally expressed number problems, such as the examples in Table 1). Its linear subset (subset of problems that can be solved by linear equation systems) has 986 problems, only involving four basic operations $\{+, -, *, /\}$.

- **Dolphin18K** is created by Huang et al. (2016). It contains 18,711 math word problems collected from Yahoo! Answers[2]. Since it contains some problems without equations, we only use the subset of 10,644 problems which are paired with their equation systems.

[1]Other small datasets with 4 basic operations $\{+, -, *, /\}$ and only one unknown variable are considered as subsets of our datasets.

[2]https://answers.yahoo.com/

4 Model

In this section, we describe (1) the basic sequence-to-sequence model, and (2) attention regularization.

4.1 Sequence-to-Sequence RNN Model

Our baseline model is based on sequence-to-sequence learning (Sutskever et al., 2014) with attention (Bahdanau et al., 2015) and copy mechanism (Gulcehre et al., 2016; Gu et al., 2016).

Encoder: The encoder is implemented as a single-layer bidirectional RNN with gated recurrent units (GRUs). It reads words one-by-one from the input problem, producing a sequence of hidden states $h_i = [h_i^F, h_i^B]$ with:

$$h_i^F = GRU(\phi^{in}(x_i), h_{i-1}^F), \quad (1)$$

$$h_i^B = GRU(\phi^{in}(x_i), h_{i+1}^B), \quad (2)$$

where ϕ^{in} maps each input word x_i to a fixed-dimensional vector.

Decoder with Copying: At each decoding step j, the decoder receives the word embedding of the previous word, and an attention function is applied to attend over the input words as follows:

$$e_{ji} = v^T \tanh(W_h h_i + W_s s_j + b_{attn}), \quad (3)$$

$$a_{ji} = \frac{\exp(e_{ji})}{\sum_{i'=1}^{m} \exp(e_{ji'})}, \quad (4)$$

$$c_j = \sum_{i=1}^{m} a_{ji} h_i, \quad (5)$$

where s_j is the decoder hidden state. Intuitively, a_{ji} defines the probability distribution of attention over the input words. They are computed from the unnormalized attention scores e_{ji}. c_j is the context vector, which is the weighted sum of the encoder hidden states.

At each step, the model has to decide whether to *generate a word* from target vocabulary or to *copy a number* from the problem description. The generation probability p_{gen} is modeled by:

$$p_{gen} = \sigma(w_c^T c_j + w_s^T s_j + b_{ptr}), \quad (6)$$

where w_c, w_s and b_{ptr} are model parameters. Next, p_{gen} is used as a soft switch: with probability p_{gen} the model decides to generate from the decoder state. The probability distribution over all words in the vocabulary is:

$$P_{RNN} = \text{softmax}(W[s_j, c_j] + b); \quad (7)$$

with probability $1 - p_{gen}$ the model decides to directly copy an input word according to its attention weight. This leads to the final distribution of decoder state outputs:

$$P(w_j = w|\cdot) = p_{gen}P_{RNN}(w) + (1 - p_{gen})a_{ji} \quad (8)$$

4.2 Attention Regularization

In preliminary experiments, we observed that the attention weights in the baseline model repetitively concentrate on the numbers in the math problem description (will be discussed in later sections with Figure 1(a)). To address this issue, we regularize the accumulative attention weights for each input token using a rectified linear unit (ReLU) layer, leading to the regularization term:

$$\text{AttReg} = \sum_i \text{ReLU}(\sum_{j=0}^{T} a_{ji} - 1), \quad (9)$$

where $\text{ReLU}(x) = \max(x, 0)$. This term penalizes the accumulated attention weights on specific locations if it exceeds 1. Adding this term to the primary loss to get the final objective function:

$$Loss = -\sum_i \log p(\mathbf{y}^i|\mathbf{x}^i; \theta) + \lambda * \text{AttReg} \quad (10)$$

where λ is a hyper-parameter that controls the contribution of attention regularization in the loss.

The format of our attention regularization term resembles the coverage mechanism used in neural machine translation (Tu et al., 2016; Cohn et al., 2016), which encourages the coverage or fertility control for input tokens.

5 Iterative Labeling

Since explicit annotations of our intermediate forms do not exist, we propose an iterative labeling framework for training.

5.1 Deriving Latent Forms From Equations

We use the annotated equation systems to derive possible latent forms. First we define some simple rules that map an expression to our intermediate form. For example, we use regular expressions to match numbers and unknown variables. Example rules are shown in Table 4 (see Section 2 of the Supplement Material for all rules).

Regex/Rules	**Class/Function**
`\-?[0-9\.]+`	num
`[a-z]`	unk
`<num>|<unk>`	var
`(<var>\+)+<var>`	math#sum($1:list)
`(<unk>\+)+<unk>` $1=count of unk	math#sum (cnt:$1:int)

Table 4: Example rules for deriving latent forms from equation system.

5.2 Ambiguity in Derivation

For one equation system, several latent form derivations are possible. Take the following math problem as an example:

*Find **3** consecutive integers that **3** times the sum of the first and the third is 79.*

Given the annotation of its equation $3 * (x + (x + 2)) = 79$, there are two possible latent intermediate forms:
1) math#consecutive(3), math#product(3, math#sum(ordinal(1), ordinal(3)))=79
2) math#consecutive(3), math#product(3, math#sum(min(), max()))=79

There exist two types of ambiguities: a) **operator ambiguity**. $(x + 2)$ may correspond to the operator "*ordinal(3)*" or "*max()*"; b) **alignment ambiguity**. For each "3" in the intermediate form, it is unclear which "3" in the input to be copied. Therefore, we may derive multiple intermediate forms with spurious ones for a training problem.

We can see from Table 5 that both datasets we used have the issue of ambiguity, containing about 20% of problems with operator ambiguity and 10% of problems with alignment ambiguity.

5.3 Iterative Labeling

To address the issue of ambiguity, we perform an iterative procedure where we search for correct intermediate forms to refine the training data. The

Dataset	Ambiguous		Ambig. #LF
	oper	align	(per prob)
NumWord (Linear)	28.0%	10.2%	3.67
NumWord (All)	26.9%	9.5%	4.29
Dolphin18K	35.9%	9.6%	3.86

Table 5: Statistics of latent forms on two datasets. The percentage of problems with operator and alignment ambiguity is shown in the 2*nd* and 3*rd* columns respectively. We also show the average number of intermediate forms of problems with derivation ambiguity in the rightmost column.

intuition is that a better model will lead to more correct latent form outputs, and more correct latent forms in training data will lead to a better model.

Algorithm 1 Iterative Labeling

```
Require:
  (1) Tuples of (math problem description, equation system, answer) $D_n = \{(p_i, E_{p_i}, A_{p_i})\}$
  (2) Possible latent forms $P_{LF} = \{(p_0, LF^1_{p_0}), (p_0, LF^2_{p_0}), ..., (p_n, LF^m_{p_n})\}$
  (3) Beam size $B$
  (4) training iterations $N_{iter}$, pre-training iterations $N_{pre}$
  Procedure:
  for $iter = 1$ to $N_{iter}$ do
      if $iter < N_{pre}$ then
          $\theta \leftarrow$ MLE with $P_{LF}$
      else
          for $(p, LF)$ in $P_{LF}$ do
              C = Decode $B$ latent forms given $p$
              for j in 1...B do
                  if Ans($C_j$) is correct then
                      $LF \Leftarrow C_j$
                      break
          $\theta \leftarrow$ MLE with relabeled $P_{LF}$
```

Algorithm 1 describes our training procedure. As pre-training, we first update our model by maximum likelihood estimation (MLE) with all possible latent forms for N_{pre} iterations. Ambiguous and wrong latent forms may appear at this stage. This pre-training is to ensure faster convergence and a more stable model. After N_{pre} iterations, iterative labeling starts. We decode on each training instance with beam search. We declare C_j to be the *consistent form* in the beam if it can be executed to yield the correct answer. Therefore we can relabel the latent form LF with C_j for problem p and use the new pairs for training. If there is no consistent form in the beam, we keep it unchanged. With iterative labeling, we update our model by MLE with relabeled latent forms. There are two conditions of N_{pre} to consider:
(1) $N_{pre} = 0$, the training starts iterative labeling without pre-training.
(2) $N_{pre} = N_{iter}$, the training is pure MLE without iterative labeling.

6 Experiments

In this section, we compare our method against several strong baseline systems.

6.1 Experiment Setting

Following previous work, experiments are done in 5-fold cross validation: in each run, 20% is used for testing, 70% for training and 10% for validation.

Representation To make the task easier with less auxiliary nuisances (e.g. bracket pairs), we represent the intermediate forms in Polish notation. [3]

Implementation details The dimension of encoder hidden state, decoder hidden state and embeddings are 100 in NumWord, 512 in Dolphin18K. All model parameters are initialized randomly with Gaussian distribution. The hyper-parameter λ for the weight of attention regularization is set to 1.0 on NumWord and 0.4 on Dolphin18K. We use SGD optimizer with decaying learning rate initialized as 0.5. Dropout rate is set to 0.5. The stopping criterion for training is validation accuracy with the maximum number of iterations no more than 150. The vocabulary consists of words observed no less than N times in training set. We set $N = 1$ for NumWord and $N = 5$ for Dolphin18K. The beam size is set to 20 in the decoding stage. For iterative training, we first train a model for $N_{pre} = 50$ iterations for pre-training. We tune the hyper-parameters on a separate dev set.

We consider the following models for comparisons:

- **Wang et al. (2017):** a seq2seq model with attention mechanism. As preprocessing, it replaces numbers in the math problem with tokens $\{n_1, n_2, ...\}$. It generates **equation**

[3]https://en.wikipedia.org/wiki/Polish_notation

as output and recovers $\{n_1, n_2, ...\}$ to corresponding numbers in the post-processing.

- **Seq2Seq_Equ:** we implement a seq2seq model with attention and copy mechanism. Different from Wang et al. (2017), it has the ability to copy numbers from problem description.
- **Shi et al. (2015):** a rule-based system. It parses math problems into Dolphin language trees with predefined grammars and reasons across trees to get the equations with rules. We report numbers from their paper as the Dolphin language is not publicly available.
- **Huang et al. (2017):** the current state-of-the-art model on Dolphin18K. It is a feature-based model. It generates candidate equations and find the most probable equation by ranking with predefined features.

6.2 Results

Overall results are shown in Table 6. From the table, we can see that our final model (**Seq2Seq_LF+AttReg+Iter**) outperforms the neural-based baseline models (Wang et al. (2017)[4] and **Seq2Seq_Equ**). On Number word problem dataset, our model already outperforms the state-of-the-art feature-based model (Huang et al., 2017) by 40.8% and is comparable to the ruled-based model (Shi et al., 2015)[5].

Advantage of intermediate forms: From the first two rows, we can see that the seq2seq model which is trained to generate intermediate forms (**Seq2Seq_LF**) greatly outperforms the same model trained to generate equations (**Seq2Seq_Equ**). The use of intermediate forms helps more on NumWord than on Dolphin18K. This result is expected as the Dolphin18K dataset is more challenging, containing many other types of difficulties discussed in Section 6.3.

Effect of Attention Regularization: Attention regularization improves the seq2seq model on the two datasets as expected. Figure 1 shows an example. The attention regularization does meet the expectation: the alignments in Fig 1(b) are less concentrated on the numbers in the input and more importantly and alignments are more reasonable. For example, when generating "*math#product*" in the output, the attention is now correctly focused on the input token "*times*".

[4]We re-implement this since it is not publicly available.

[5]The system reports precision and recall. Since all the problems have answers, its recall equals to our accuracy.

Effect of Iterative Labeling: We can see from Table 6 that iterative labeling clearly contributes to the accuracy increase on the two datasets. Now we compare the performance with and without pre-training in Table 7. When $N_{pre} = 0$ in Algorithm 1, the model starts iterative labeling from the first iteration without pre-training. We find that training with pre-training is substantially better, as the model without pre-training can be unstable and may generate misleading spurious candidate forms.

Next, we compare the performance with pure MLE training on NumWord (Linear) in Figure 2. The difference is that after 50 iterations of MLE training, iterative labeling would refine the latent forms of training data. In pure MLE training, the accuracy converges after 130 iterations. By using iterative labeling, the model achieves the accuracy of 61.6% at $110th$ iterations, which is faster to converge and leads to better performance.

Furthermore, to check whether iterative labeling actually resolves ambiguities in the intermediate forms of the training data, we manually sample 100 math problems with derivation ambiguity. **78%** of them are relabeled with correct latent forms as we have checked. From Table 8, we can see the latent form of one training problem is iteratively refined to the correct one.

6.3 Model Comparisons

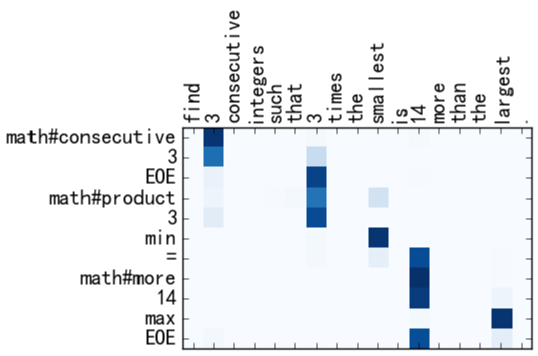
To explore the generalization ability of the neural approach and better guide our future work, we compare the problems solved by our neural-based model with the rule-based model (Shi et al., 2015) and the feature-based model (Huang et al., 2017).

Neural-based v. Rule-based: On NumWord (ALL), **41.6%** of problems can be solved by both models. **15.5%** can only be solved by our neural model, while the rule-based model generates an empty or a wrong semantic tree due to the limitations of the predefined grammar. The neural model is more consistent with flexible word order and insertion of lexical items (e.g. rule-based model cannot handle the extra word 'whole' in "Find two consecutive **whole** numbers").

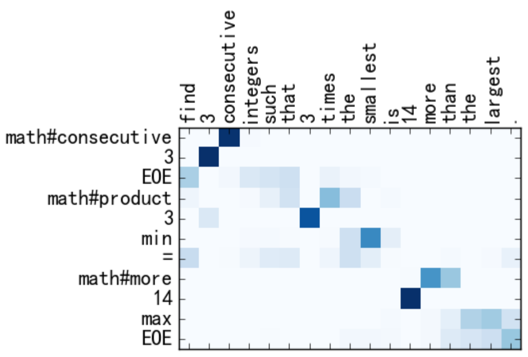
Neural-based v. Feature-based: On Dolphin18K, **9.2%** of problems can be solved by both models. **7.6%** can only be solved by our neural model, which indicates that the neural model

Models	NumWord (Linear)	NumWord (ALL)	Dolphin18K (Linear)
Wang et al. (2017)	19.7%	14.6%	10.2%
Seq2Seq_Equ	26.8%	20.1%	13.1%
Seq2Seq_LF	50.8%	45.2%	13.9%
Seq2Seq_LF+AttReg	56.7%	54.0%	15.1%
Seq2Seq_LF+AttReg+Iter	61.6%	57.1%	16.8%
Shi et al. (2015)	63.6%	60.2%	n/a
Huang et al. (2017)	20.8%	n/a	28.4%

Table 6: Performances on two datasets. "**LF**" means that the model generates latent intermediate forms instead of equation systems. "**AttReg**" means attention regularization. "**Iter**" means iterative labeling. "**n/a**" means that the model does not run on the dataset.



(a) **seq2seq_LF**



(b) **seq2seq_LF+AttReg**

Figure 1: Example alignments for one problem (darker color represents higher attention score).

	NumWord (Linear)	NumWord (ALL)	Dolphin18K (Linear)
-pre	58.1%	54.9%	14.9%
+pre	61.6%	57.1%	16.8%

Table 7: Performance with and without pre-training in iterative labeling.

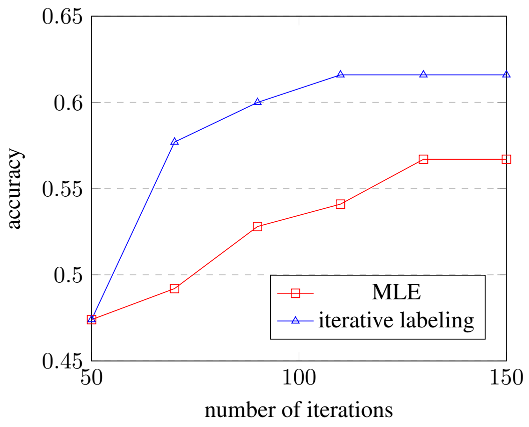


Figure 2: Accuracy with different iterations of training on NumWord (Linear).

can capture novel features that the feature-based model is missing.

While our neural model is complementary to the above mentioned models, we observe two main types of errors (more examples are shown in the supplementary material):

1. Natural language variations: Same type of problems can be described in different scenarios. The two problems: (1) "What is 10 minus 2?" and (2) "John has 10 apples. How many apples does John have after giving Mary 2 apples", lead to the same equation $x = 10 - 2$ but with very different descriptions. With limited size of data, we could not be expected to cover all possible ways to ask the same underlining math problems. Although the feature-based model has considered this with some features (e.g. POS Tag), the challenge is not well-addressed.

2. Nested operations: Some problems require multiple nested operations (e.g. "I think of a number, double it, add 3, multiply the answer by 3 and then add on the original number"). The rule-based model performs more consistently on this.

Training Problem:
Find **2_0** *consecutive integers which the first number is* **2_1** *more than* **2_2** *times the second number.*
Intermediate form in 1*st* iteration
(✗) math#consecutive(**2_0**), ordinal(1) = math#sum("**2_0**", math#product("**2_0**", "**max()**")
Intermediate form in 51*st* iteration
(✗) math#consecutive(**2_0**), ordinal(1) = math#sum(**2_1**, math#product("**2_0**", ordinal(2))
Intermediate form in 101*st* iteration
(✓) math#consecutive(**2_0**), ordinal(1) = math#sum(**2_1**, math#product(**2_2**, ordinal(2))

Table 8: Instance check of intermediate form for one math problem in several training iterations. **2_0** means the the first '2' in the input and so on. Tokens with quote marks mean that they are incorrect.

7 Related Work

Our work is related to two research areas: math word problem solving and semantic parsing.

7.1 Math Word Problem Solving

There are two major components in this task: (1) meaning representation; (2) learning framework.

Semantic Representation With the annotation of equation system, most approaches attempt at learning a direct mapping from math problem description to an equation system. There are other approaches considering an intermediate representation that bridges the semantic gap between natural language and equation system. Bakman (2007) defines a table of schema (e.g. Transfer-In-Place, Transfer-In-Ownership) with associated formulas in natural utterance. A math problem can be mapped into a list of schema instantiations, then converted to equations. Liguda and Pfeiffer (2012) use augmented semantic network to represent math problems, where nodes represent concepts of quantities and edges represent transition states. Shi et al. (2015) design a new meaning representation language called Dolphin Language (DOL) with over 200 math-related functions and more additional noun functions. With predefined rules, these approaches accept limited well-format input sentences. Inspired by these representations, our work describes a new formal language which is more compact and is effective in facilitating better machine learning performance.

Learning Framework In rule-based approaches (Bakman, 2007; Liguda and Pfeiffer, 2012; Shi et al., 2015), they map math problem description into structures with predefined grammars and rules.

Feature-based approaches contain two stages: (1) generate equation candidates; They either replace numbers of existing equations in the training data as new equations (Kushman et al., 2014; Zhou et al., 2015; Upadhyay et al., 2016), or enumerate possible combinations of math operators and numbers and variables (Koncel-Kedziorski et al., 2015), which leads to intractably huge search space. (2) predict equation with features. For example, Hosseini et al. (2014) design features to classify verbs to addition or subtraction. Roy and Roth (2015); Roy et al. (2016) leverage the tree structure of equations. Mitra and Baral (2016); Roy and Roth (2018) design features for a few math concepts (e.g. Part-Whole, Comparison). Roy and Roth (2017) focus on the dependencies between number units. These approaches requires manual feature design and the features may be difficult to be generalized to other tasks.

Recently, there are a few works trying to build an end-to-end system with neural models. Ling et al. (2017) consider multiple-choice math problems and use a seq2seq model to generate rationale and the final choice (i.e. A, B, C, D). Wang et al. (2017) apply a seq2seq model to generate equations with the constraint of single unknown variable. Similarly, we use the seq2seq model but with novel attention regularization to address incorrect attention weights in the seq2seq model.

7.2 Semantic Parsing

Our work is also related to the classic settings of learning executable semantic parsers from indirect supervision (Clarke et al., 2010; Liang et al., 2011; Artzi and Zettlemoyer, 2011, 2013; Berant et al., 2013; Pasupat and Liang, 2016). Maximum marginal likelihood with beam search (Kwiatkowski et al., 2013; Pasupat and Liang, 2016; Ling et al., 2017) is traditionally used. It maximizes the marginal likelihood of all consistent logical forms being observed. Recently reinforcement learning (Guu et al., 2017; Liang et al., 2017) has also been considered, which maximizes the expected reward over all possible logical forms. Different from them, we only consider one single consistent latent form per training instance by leveraging training signals from both the answer and the equation system, which should be more efficient for our task.

8 Conclusion

This paper presents an intermediate meaning representation scheme for math problem solving that bridges the semantic gap between natural language and equation systems. To generate intermediate forms, we propose a seq2seq model with novel attention regularization. Without explicit annotations of latent forms, we design an iterative labeling framework for training. Experimental result shows that using intermediate forms is more effective than directly using equations. Furthermore, our iterative labeling effectively resolves ambiguities and leads to better performances.

As shown in the error analysis, same types of problems can have different natural language expressions. In the future, we will focus on tackling this challenge. In addition, we plan to expand the coverage of our meaning representation to support more mathematic concepts.

Abstract

We introduce an open-domain neural semantic parser which generates formal meaning representations in the style of Discourse Representation Theory (DRT; Kamp and Reyle 1993). We propose a method which transforms Discourse Representation Structures (DRSs) to trees and develop a structure-aware model which decomposes the decoding process into three stages: basic DRS structure prediction, condition prediction (i.e., predicates and relations), and referent prediction (i.e., variables). Experimental results on the Groningen Meaning Bank (GMB) show that our model outperforms competitive baselines by a wide margin.

1 Introduction

Semantic parsing is the task of mapping natural language to machine interpretable meaning representations. A variety of meaning representations have been adopted over the years ranging from functional query language (FunQL; Kate et al. 2005) to dependency-based compositional semantics (λ-DCS; Liang et al. 2011), lambda calculus (Zettlemoyer and Collins, 2005), abstract meaning representations (Banarescu et al., 2013), and minimal recursion semantics (Copestake et al., 2005).

Existing semantic parsers are for the most part data-driven using annotated examples consisting of utterances and their meaning representations (Zelle and Mooney, 1996; Wong and Mooney, 2006; Zettlemoyer and Collins, 2005). The successful application of encoder-decoder models (Sutskever et al., 2014; Bahdanau et al., 2015) to a variety of NLP tasks has provided strong impetus to treat semantic parsing as a sequence transduction problem where an utterance is mapped to a target meaning representation in string format (Dong and Lapata, 2016; Jia and Liang, 2016; Kočiskỳ et al., 2016). The fact that meaning representations do not naturally conform to a linear ordering has also prompted efforts to develop recurrent neural network architectures tailored to tree or graph-structured decoding (Dong and Lapata, 2016; Cheng et al., 2017; Yin and Neubig, 2017; Alvarez-Melis and Jaakkola, 2017; Rabinovich et al., 2017; Buys and Blunsom, 2017)

Most previous work focuses on building semantic parsers for question answering tasks, such as querying a database to retrieve an answer (Zelle and Mooney, 1996; Cheng et al., 2017), or conversing with a flight booking system (Dahl et al., 1994). As a result, parsers trained on query-based datasets work on restricted domains (e.g., restaurants, meetings; Wang et al. 2015), with limited vocabularies, exhibiting limited compositionality, and a small range of syntactic and semantic constructions. In this work, we focus on open-domain semantic parsing and develop a general-purpose system which generates formal meaning representations in the style of Discourse Representation Theory (DRT; Kamp and Reyle 1993).

DRT is a popular theory of meaning representation designed to account for a variety of linguistic phenomena, including the interpretation of pronouns and temporal expressions within and across sentences. Advantageously, it supports meaning representations for entire texts rather than isolated sentences which in turn can be translated into first-order logic. The Groningen Meaning Bank (GMB; Bos et al. 2017) provides a large collection of English texts annotated with Discourse Representation Structures (see Figure 1 for an example). GMB integrates various levels of semantic annotation (e.g., anaphora, named entities, thematic roles, rhetorical relations) into a unified formalism providing expressive meaning representations for open-domain texts.

We treat DRT parsing as a structure prediction problem. We develop a method to transform DRSs to tree-based representations which can be further linearized to bracketed string format. We examine a series of encoder-decoder models (Bahdanau et al., 2015) differing in the way tree-

continuation(k_1,k_2), parallel(k_1,k_2)

Figure 1: DRT meaning representation for the sentence *The statement says each of the dead men wore magazine vests and carried two hand grenades.*

structured logical forms are generated and show that a structure-aware decoder is paramount to open-domain semantic parsing. Our proposed model decomposes the decoding process into three stages. The first stage predicts the structure of the meaning representation omitting details such as predicates or variable names. The second stage fills in missing predicates and relations (e.g., thing, Agent) conditioning on the natural language input and the previously predicted structure. Finally, the third stage predicts variable names based on the input and the information generated so far.

Decomposing decoding into these three steps reduces the complexity of generating logical forms since the model does not have to predict deeply nested structures, their variables, and predicates all at once. Moreover, the model is able to take advantage of the GMB annotations more efficiently, e.g., examples with similar structures can be effectively used in the first stage despite being very different in their lexical make-up. Finally, a piecemeal mode of generation yields more accurate predictions; since the output of every decoding step serves as input to the next one, the model is able to refine its predictions taking progressively more global context into account. Experimental results on the GMB show that our three-stage decoder outperforms a vanilla encoder-decoder model and a related variant which takes shallow structure into account, by a wide margin.

Our contributions in this work are three-fold: an open-domain semantic parser which yields discourse representation structures; a novel end-to-end neural model equipped with a structured decoder which decomposes the parsing process into three stages; a DRS-to-tree conversion method which transforms DRSs to tree-based representations allowing for the application of structured decoders as well as sequential modeling. We release our code[1] and tree formatted version of the GMB in the hope of driving further research in open-domain semantic parsing.

2 Discourse Representation Theory

In this section we provide a brief overview of the representational semantic formalism used in the GMB. We refer the reader to Bos et al. (2017) and Kamp and Reyle (1993) for more details.

Discourse Representation Theory (DRT; Kamp and Reyle 1993) is a general framework for representing the meaning of sentences and discourse which can handle multiple linguistic phenomena including anaphora, presuppositions, and temporal expressions. The basic meaning-carrying units in DRT are Discourse Representation Structures (DRSs), which are recursive formal meaning structures that have a model-theoretic interpretation and can be translated into first-order logic (Kamp and Reyle, 1993). Basic DRSs consist of discourse referents (e.g., x, y) representing entities in the discourse and discourse conditions (e.g., man(x), magazine(y)) representing information about discourse referents. Following conventions in the DRT literature, we visualize DRSs in a box-like format (see Figure 1).

GMB adopts a variant of DRT that uses a neo-Davidsonian analysis of events (Kipper et al., 2008), i.e., events are first-order entities characterized by one-place predicate symbols (e.g., say(e_1) in Figure 1). In addition, it follows Projective Discourse Representation Theory (PDRT; Venhuizen et al. 2013) an extension of DRT specifically developed to account for the interpretation of presuppositions and related projection phenomena

[1] https://github.com/EdinburghNLP/EncDecDRSparsing

(e.g., conventional implicatures). In PDRT, each basic DRS introduces a label, which can be bound by a pointer indicating the interpretation site of semantic content. To account for the rhetorical structure of texts, GMB adopts Segmented Discourse Representation Theory (SDRT; Asher and Lascarides 2003). In SDRT, discourse segments are linked with rhetorical relations reflecting different characteristics of textual coherence, such as temporal order and communicative intentions (see continuation(k_1, k_2) in Figure 1).

More formally, DRSs are expressions of type $\langle exp_e \rangle$ (denoting individuals or discourse referents) and $\langle exp_t \rangle$ (i.e., truth values):

$$\langle exp_e \rangle ::= \langle ref \rangle, \quad \langle exp_t \rangle ::= \langle drs \rangle | \langle sdrs \rangle, \tag{1}$$

discourse referents $\langle ref \rangle$ are in turn classified into six categories, namely common referents (x_n), event referents (e_n), state referents (s_n), segment referents (k_n), proposition referents (π_n), and time referents (t_n). $\langle drs \rangle$ and $\langle sdrs \rangle$ denote basic and segmented DRSs, respectively:

$$\langle drs \rangle ::= \langle pvar \rangle : \boxed{\begin{array}{c} (\langle pvar \rangle, \langle ref \rangle))^* \\ \hline (\langle pvar \rangle, \langle condition \rangle))^* \end{array}}, \tag{2}$$

$$\langle sdrs \rangle ::= \boxed{\begin{array}{c} k_1 : \langle exp_t \rangle, k_2 : \langle exp_t \rangle \\ \hline coo(k_1, k_2) \end{array}} \; | \; \boxed{\begin{array}{c} k_1 : \langle exp_t \rangle \\ k_2 : \langle exp_t \rangle \\ \hline sub(k_1, k_2) \end{array}}, \tag{3}$$

Basic DRSs consist of a set of referents ($\langle ref \rangle$) and conditions ($\langle condition \rangle$), whereas segmented DRSs are *recursive* structures that combine two $\langle exp_t \rangle$ by means of coordinating (*coo*) or subordinating (*sub*) relations. DRS conditions can be basic or complex:

$$\langle condition \rangle ::= \langle basic \rangle | \langle complex \rangle, \tag{4}$$

Basic conditions express properties of discourse referents or relations between them:

$$\begin{aligned} \langle basic \rangle ::= \; & \langle sym_1 \rangle(\langle exp_e \rangle) \mid \langle sym_2 \rangle(\langle exp_e \rangle, \langle exp_e \rangle) \\ & \mid \langle exp_e \rangle = \langle exp_e \rangle \mid \langle exp_e \rangle = \langle num \rangle \\ & \mid timex(\langle exp_e \rangle, \langle sym_0 \rangle) \\ & \mid named(\langle exp_e \rangle, \langle sym_0 \rangle, class). \end{aligned} \tag{5}$$

where $\langle sym_n \rangle$ denotes n-place predicates, $\langle num \rangle$ denotes cardinal numbers, *timex* expresses temporal information (e.g., timex(x_7, 2005) denotes the year 2005), and *class* refers to named entity classes (e.g., location).

Complex conditions are unary or binary. Unary conditions have one DRS as argument and represent negation ($\neg$) and modal operators expressing necessity ($\Box$) and possibility ($\Diamond$). Condition

sections	# doc	# sent	# token	avg
00-99	10,000	62,010	1,354,149	21.84
20-99	7,970	49,411	1,078,953	21.83
10-19	1,038	6,483	142,344	21.95
00-09	992	6,116	132,852	21.72

Table 1: Statistics on the GMB (avg denotes the average number of tokens per sentence).

$\langle ref \rangle : \langle exp_t \rangle$ represents verbs with propositional content (e.g., factive verbs). Binary conditions are conditional statements ($\rightarrow$) and questions.

$$\begin{aligned} \langle complex \rangle &::= \langle unary \rangle \mid \langle binary \rangle, \\ \langle unary \rangle &::= \neg\langle exp_t \rangle \mid \Box\langle exp_t \rangle | \Diamond\langle exp_t \rangle | \langle ref \rangle : \langle exp_t \rangle \\ \langle binary \rangle &::= \langle exp_t \rangle \rightarrow \langle exp_t \rangle | \langle exp_t \rangle \vee \langle exp_t \rangle | \langle exp_t \rangle ? \langle exp_t \rangle \end{aligned} \tag{6}$$

3 The Groningen Meaning Bank Corpus

Corpus Creation DRSs in GMB were obtained from Boxer (Bos, 2008, 2015), and then refined using expert linguists and crowdsourcing methods. Boxer constructs DRSs based on a pipeline of tools involving POS-tagging, named entity recognition, and parsing. Specifically, it relies on the syntactic analysis of the C&C parser (Clark and Curran, 2007), a general-purpose parser using the framework of Combinatory Categorial Grammar (CCG; Steedman 2001). DRSs are obtained from CCG parses, with semantic composition being guided by the CCG syntactic derivation.

Documents in the GMB were collected from a variety of sources including *Voice of America* (a newspaper published by the US Federal Government), the Open American National Corpus, Aesop's fables, humorous stories and jokes, and country descriptions from the *CIA World Factbook*. The dataset consists of 10,000 documents each annotated with a DRS. Various statistics on the GMB are shown in Table 1. Bos et al. (2017) recommend sections 20–99 for training, 10–19 for tuning, and 00–09 for testing.

DRS-to-Tree Conversion As mentioned earlier, DRSs in the GMB are displayed in a box-like format which is intuitive and easy to read but not particularly amenable to structure modeling. In this section we discuss how DRSs were post-processed and simplified into a tree-based format, which served as input to our models.

The GMB provides DRS annotations per-document. Our initial efforts have focused on sentence-level DRS parsing which is undoubtedly a necessary first step for more global semantic representations. It is relatively, straightforward to obtain sentence-level DRSs from document-level annotations since referents and conditions are indexed to tokens. We match each sentence in a document with the DRS whose content bears the same indices as the tokens occurring in the sentence. This matching process yields 52,268 sentences for training (sections 20–99), 5,172 sentences for development (sections 10–19), (development), and 5,440 sentences for testing (sections 00–09).

In order to simplify the representation, we omit referents in the top part of the DRS (e.g., x_1, e_1 and π_1 in Figure 1) but preserve them in conditions without any information loss. Also we ignore pointers to DRSs since this information is implicitly captured through the typing and co-indexing of referents. Definition (1) is simplified to:

$$\langle drs \rangle ::= \text{DRS}(\langle condition \rangle^*), \tag{7}$$

where DRS() denotes a basic DRS. We also modify discourse referents to SDRSs (e.g., k_1, k_2 in Figure 1) which we regard as elements bearing scope over expressions $\langle exp_t \rangle$ and add a 2-place predicate $\langle sym_2 \rangle$ to describe the discourse relation between them. So, definition (3) becomes:

$$\begin{aligned} \langle sdrs \rangle ::= &\text{SDRS}((\langle ref \rangle(\langle exp_t \rangle))^* \\ &(\langle sym_2 \rangle(\langle ref \rangle, \langle ref \rangle))^*), \end{aligned} \tag{8}$$

where SDRS() denotes a segmented DRS, and $\langle ref \rangle$ are segment referents.

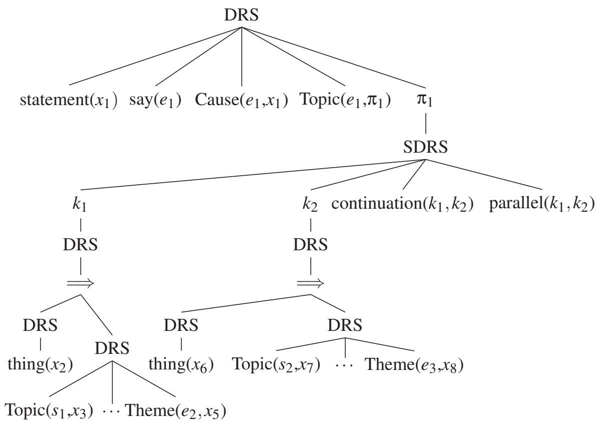
We treat cardinal numbers $\langle num \rangle$ and $\langle sym_0 \rangle$ in relation *timex* as constants. We introduce the binary predicate "card" to represent cardinality (e.g., $|x_8| = 2$ is card(x_8,NUM)). We also simplify $\langle exp_e \rangle = \langle exp_e \rangle$ to eq($\langle exp_e \rangle, \langle exp_e \rangle$) using the binary relation "eq" (e.g., $x_1 = x_2$ becomes eq(x_1,x_2)). Moreover, we ignore *class* in *named* and transform *named*($\langle exp_e \rangle, \langle sym_0 \rangle$, *class*) into $\langle sym_1 \rangle(\langle exp_e \rangle)$ (e.g., named(x_2, mongolia, *geo*) becomes mongolia(x_2)). Consequently, basic conditions (see definition (5)) are simplified to:

$$\langle basic \rangle ::= \langle sym_1 \rangle(\langle exp_e \rangle) | \langle sym_2 \rangle(\langle exp_e \rangle, \langle exp_e \rangle) \tag{9}$$

Analogously, we treat *unary* and *binary* conditions as scoped functions, and definition (6) becomes:

$$\begin{aligned} \langle unary \rangle ::= &\ \neg \mid \Box \mid \Diamond \mid \langle ref \rangle(\langle exp_t \rangle) \\ \langle binary \rangle ::= &\ \rightarrow \mid \vee \mid ?(\langle exp_t \rangle, \langle exp_t \rangle), \end{aligned} \tag{10}$$

Following the transformations described above, the DRS in Figure 1 is converted into the tree in



DRS(statement(x_1) say(e_1) Cause(e_1,x_1) Topic(e_1,π_1) π_1(SDRS(k_1 (DRS ($\Longrightarrow$(DRS(thing(x_2)) DRS (Topic(s_1,x_3) dead(s_1) man(x_3) of(x_2,x_3) magazine(x_4) on(x_5,x_4) vest(x_5) wear(e_2) Agent(e_2,x_2) Theme(e_2,x_5))))) k_2(DRS $\Longrightarrow$(DRS(thing(x_6)) DRS(Topic(s_2,x_7) dead(s_2) man(x_7) of(x_6,x_7) card(x_8,NUM) hand(x_9) in(x_8,x_9) carry(e_3) Agent(e_3,x6) Theme(e3,x8))))) continuation(k_1,k_2) parallel(k_1,k_2)

Figure 2: Tree-based representation (top) of the DRS in Figure 1 and its linearization (bottom).

Figure 2, which can be subsequently linearized into a PTB-style bracketed sequence. It is important to note that the conversion does not diminish the complexity of DRSs. The average tree width in the training set is 10.39 and tree depth is 4.64.

4 Semantic Parsing Models

We present below three encoder-decoder models which are increasingly aware of the structure of the DRT meaning representations. The models take as input a natural language sentence X represented as $w_1, w_2, \ldots, w_n$, and generate a sequence $Y = (y_1, y_2, ..., y_m)$, which is a linearized tree (see Figure 2 bottom), where n is the length of the sentence, and m the length of the generated DRS sequence. We aim to estimate $p(Y|X)$, the conditional probability of the semantic parse tree Y given natural language input X:

$$p(Y|X) = \prod_j p(y_j | Y_1^{j-1}, X_1^n)$$

4.1 Encoder

An encoder is used to represent the natural language input X into vector representations. Each token in a sentence is represented by a vector x_k which is the concatenation of randomly initialized embeddings e_{w_i}, pre-trained word embeddings $\bar{e}_{w_i}$, and lemma embeddings e_{l_i}: $x_k = \tanh([e_{w_i}; \bar{e}_{w_i}; e_{l_i}] * W_1 + b_1)$, where $W_1 \in \mathbb{R}^{\mathcal{D}}$ and $\mathcal{D}$ is a shorthand for $(d_w + d_p + d_l) \times d_{input}$ (subscripts w, p, and l denote the dimensions of word embeddings, pre-trained embeddings, and lemma embeddings, respectively); $b_1 \in \mathbb{R}^{d_{input}}$ and the symbol ; denotes concatenation. Embeddings e_{w_i}

and e_{l_i} are randomly initialized and tuned during training, while $\bar{e}_{w_i}$ are fixed.

We use a bidirectional recurrent neural network with long short-term memory units (bi-LSTM; Hochreiter and Schmidhuber 1997) to encode natural language sentences:

$$[h_{e_1} : h_{e_n}] = \text{bi-LSTM}(x_1 : x_n),$$

where h_{e_i} denotes the hidden representation of the encoder, and x_i refers to the input representation of the ith token in the sentence. Table 2 summarizes the notation used throughout this paper.

4.2 Sequence Decoder

We employ a sequential decoder (Bahdanau et al., 2015) as our baseline model with the architecture shown in Figure 3(a). Our decoder is a (forward) LSTM, which is conditionally initialized with the hidden state of the encoder, i.e., we set $h_{d_0} = h_{e_n}$ and $c_{d_0} = c_{e_n}$, where c is a memory cell:

$$h_{d_j} = \text{LSTM}(e_{y_{j-1}}),$$

where h_{d_j} denotes the hidden representation of y_j, e_{y_j} are randomly initialized embeddings tuned during training, and y_0 denotes the start of sequence.

The decoder uses the contextual representation of the encoder together with the embedding of the previously predicted token to output the next token from the vocabulary V:

$$s_j = [h_{ct_j}; e_{y_{j-1}}] * W_2 + b_2,$$

where $W_2 \in \mathbb{R}^{(d_{enc}+d_y)\times|V|}$, $b_2 \in \mathbb{R}^{|V|}$, d_{enc} and d_y are the dimensions of the encoder hidden unit and output representation, respectively, and h_{ct_j} is obtained using an attention mechanism:

$$h_{ct_j} = \sum_{i=1}^{n} \beta_{ji} h_{e_i},$$

where the weight β_{ji} is computed by:

$$\beta_{ji} = \frac{e^{f(h_{d_j}, h_{e_i})}}{\sum_k e^{f(h_{d_j}, h_{e_k})}},$$

and f is the dot-product function. We obtain the probability distribution over the output tokens as:

$$p_j = p(y_j | Y_1^{j-1}, X_1^n) = \textsc{SoftMax}(s_j)$$

Symbol	Description
X; Y	sequence of words; outputs
w_i; y_i	the ith word; output
X_i^j; Y_i^j	word; output sequence from position i to j
e_{w_i}; e_{y_i}	random embedding of word w_i; of output y_i
$\bar{e}_{w_i}$	fixed pretrained embedding of word w_i
e_{l_i}	random embedding for lemma l_i
d_w	dimension of random word embedding
d_p	dimension of pretrained word embedding
d_l	the dimension of random lemma embedding
d_{input}	input dimension of encoder
d_{enc}; d_{dec}	hidden dimension of encoder; decoder
W_i	matrix of model parameters
b_i	vector of model parameters
x_i	representation of ith token
h_{e_i}	hidden representation of ith token
c_{e_i}	memory cell of ith token in encoder
h_{d_i}	hidden representation of ith token in decoder
c_{d_i}	memory cell of ith token in decoder
s_j	score vector of jth output in decoder
h_{ct_j}	context representation of jth output
β_j^i	alignment from jth output to ith token
o_j^i	copy score of jth output from ith token
$\hat{}$	indicates tree structure (e.g. $\hat{Y}, \hat{y}_i, \hat{s}_j$)
$\bar{}$	indicates DRS conditions (e.g. $\bar{Y}, \bar{y}_i, \bar{s}_j$)
$\dot{}$	indicates referents (e.g. $\dot{Y}, \dot{y}_i, \dot{s}_j$)

Table 2: Notation used throughout this paper.

4.3 Shallow Structure Decoder

The baseline decoder treats all conditions in a DRS uniformly and has no means of distinguishing between conditions corresponding to tokens in a sentence (e.g., the predicate say(e_1) refers to the verb *said*) and semantic relations (e.g., Cause(e_1,x_1)). Our second decoder attempts to take this into account by distinguishing conditions which are local and correspond to words in a sentence from items which are more global and express semantic content (see Figure 3(b)). Specifically, we model sentence specific conditions using a copying mechanism, and all other conditions $\mathcal{G}$ which do not correspond to sentential tokens (e.g., thematic roles, rhetorical relations) with an insertion mechanism.

Each token in a sentence is assigned a copying score o_{ji}:

$$o_{ji} = h_{d_j}^\top W_3 h_{e_i},$$

where subscript ji denotes the ith token at jth time step, and $W_3 \in \mathbb{R}^{d_{dec}\times d_{enc}}$. All other conditions $\mathcal{G}$ are assigned an insertion score:

$$s_j = [h_{ct_j}; e_{y_{j-1}}] * W_4 + b_4,$$

where $W_4 \in \mathbb{R}^{(d_{enc}+d_y)\times|\mathcal{G}|}$, $b_4 \in \mathbb{R}^{|\mathcal{G}|}$, and h_{ct_j} are the same with the baseline decoder. We obtain the probability distribution over output tokens as:

$$p_j = p(y_j | Y_1^{j-1}, X_1^n) = \textsc{SoftMax}([o_j; s_j])$$

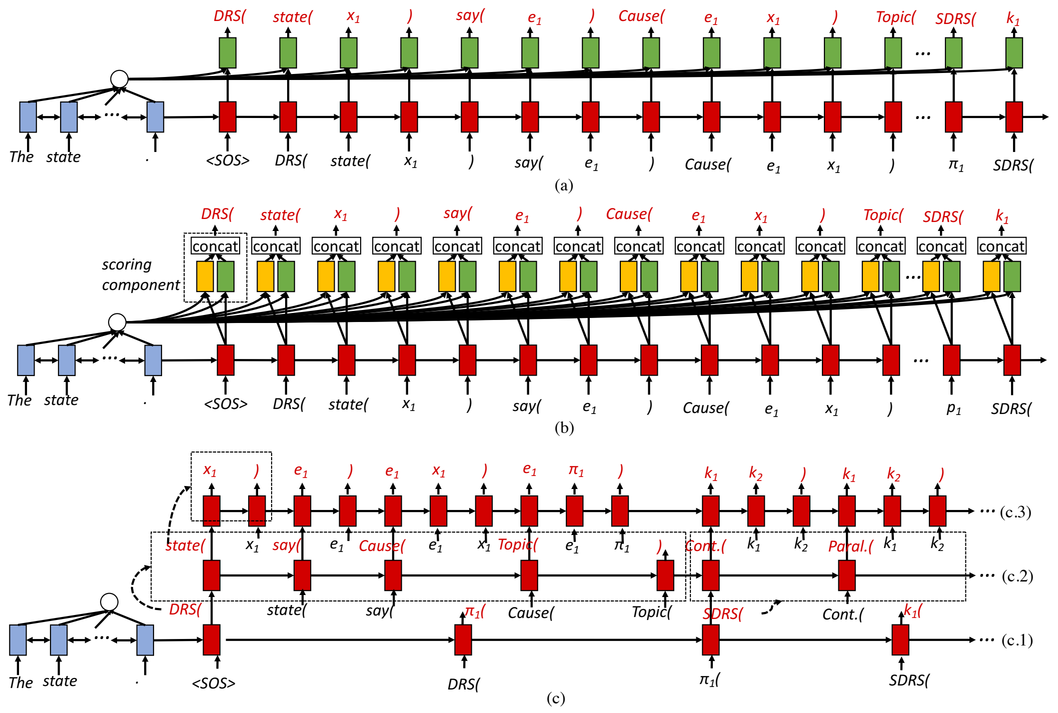


Figure 3: (a) baseline model; (b) shallow structure model; (c) deep structure model (scoring components are not displayed): (c.1) predicts DRS structure, (c.2) predicts conditions, and (c.3) predicts referents. Blue boxes are encoder hidden units, red boxes are decoder LSTM hidden units, green and yellow boxes represent copy and insertion scores, respectively.

4.4 Deep Structure Decoder

As explained previously, our structure prediction problem is rather challenging: the length of a bracketed DRS is nearly five times longer than its corresponding sentence. As shown in Figure 1, a bracketed DRS, $y_1, y_2, ..., y_n$ consists of three parts: internal structure $\hat{Y} = \hat{y}_1, \hat{y}_2, ...\hat{y}_t$ (e.g., DRS(π_1(SDRS(k_1(DRS($\rightarrow$(DRS( )DRS( ))) k_2(DRS($\rightarrow$(DRS( ) DRS ( ))))))))), conditions $\bar{Y} = \bar{y}_1, \bar{y}_2, ..., \bar{y}_r$ (e.g., statement, say, Topic), and referents $\dot{Y} = \dot{y}_1, \dot{y}_2, ..., \dot{y}_v$ (e.g., x_1, e_1, π_1), where $t + r * 2 + v = n$.[2]

Our third decoder (see Figure 3(c)) first predicts the structural make-up of the DRS, then the conditions, and finally their referents in an end-to-end framework. The probability distribution of structured output Y given natural language input X is rewritten as:

$$\begin{aligned} p(Y|X) = & \; p(\hat{Y}, \bar{Y}, \dot{Y}|X) \\ = & \; \prod_j p(\hat{y}_j|\hat{Y}_1^{j-1}, X) \\ & \times \prod_j p(\bar{y}_j|\bar{Y}_1^{j-1}, \hat{Y}_1^{j'}, X) \\ & \times \prod_j p(\dot{y}_j|\dot{Y}_1^{j-1}, \bar{Y}_1^{j'}, \hat{Y}_1^{j''}, X) \end{aligned} \quad (11)$$

where $\hat{Y}_1^{j-1}$, $\bar{Y}_1^{j-1}$, and $\dot{Y}_1^{j-1}$ denote the tree structure, conditions, and referents predicted so far. $\hat{Y}_1^{j'}$ denotes the structure predicted *before* conditions $\bar{y}_j$; $\hat{Y}_1^{j''}$ and $\bar{Y}_1^{j'}$ are the structures and conditions predicted *before* referents $\dot{y}_j$. We next discuss how each decoder is modeled.

Structure Prediction To model basic DRS structure we apply the shallow decoder discussed in Section 4.3 and also shown in Figure 3(c.1). Tokens in such structures correspond to parent nodes in a tree; in other words, they are all inserted from $\mathcal{G}$, and subsequently predicted tokens are only scored with the insert score, i.e., $\hat{s}_i = s_i$. The hidden units of the decoder are:

$$\hat{h}_{d_j} = \text{LSTM}(e_{\hat{y}_{j-1}}),$$

And the probabilistic distribution over structure denoting tokens is:

$$p(y_j|Y_1^{j-1}, X) = \text{SoftMax}(\hat{s}_j)$$

Condition Prediction DRS conditions are generated by taking previously predicted structures into account, e.g., when "DRS(" or "SDRS(" are predicted, their conditions will be generated next. By mapping j to (k, m_k), the sequence of conditions can be rewritten as $\bar{y}_1, \ldots, \bar{y}_j, \ldots, \bar{y}_r = \bar{y}_{(1,1)}, \bar{y}_{(1,2)}, \ldots, \bar{y}_{(k,m_k)}, \ldots,$ where $\bar{y}_{(k,m_k)}$ is m_kth

[2]Each condition has one and only one right bracket.

condition of structure token $\hat{y}_k$. The corresponding hidden units $\hat{h}_{d_k}$ act as conditional input to the decoder. Structure denoting tokens (e.g., "DRS(" or "SDRS(") are fed into the decoder one by one to generate the corresponding conditions as:

$$e_{\bar{y}_{(k,0)}} = \hat{h}_{d_k} * W_5 + b_5,$$

where $W_5 \in \mathbb{R}^{d_{dec} \times d_y}$ and $b_5 \in \mathbb{R}^{d_y}$. The hidden unit of the conditions decoder is computed as:

$$\bar{h}_{d_j} = \bar{h}_{d_{(k,m_k)}} = \text{LSTM}(e_{\bar{y}_{(k,m_k-1)}}),$$

Given hidden unit $\bar{h}_{d_j}$, we obtain the copy score $\bar{o}_j$ and insert score $\bar{s}_j$. The probabilistic distribution over conditions is:

$$p(\bar{y}_j | \bar{Y}_1^{j-1}, \hat{Y}_1^{j'}, X) = \text{SoftMax}([\bar{o}_j; \bar{s}_j])$$

Referent Prediction Referents are generated based on the structure and conditions of the DRS. Each condition has at least one referent. Similar to condition prediction, the sequence of referents can be rewritten as $\dot{y}_1, \ldots, \dot{y}_j, \ldots, \dot{y}_v = \dot{y}_{(1,1)}, \dot{y}_{(1,2)}, \ldots, \dot{y}_{(k,m_k)}, \ldots$ The hidden units of the conditions decoder are fed into the referent decoder $e_{\dot{y}_{(k,0)}} = \bar{h}_{d_k} * W_6 + b_6$, where $W_6 \in \mathbb{R}^{d_{dec} \times d_y}$, $b_6 \in \mathbb{R}^{d_y}$. The hidden unit of the referent decoder is computed as:

$$\dot{h}_{d_j} = \dot{h}_{d_{(k,m_k)}} = \text{LSTM}(e_{\dot{y}_{(k,m_k-1)}}),$$

All referents are inserted from $\mathcal{G}$, given hidden unit $\dot{h}_{d_j}$ (we only obtain the insert score $\dot{s}_j$). The probabilistic distribution over predicates is:

$$p(\dot{y}_j | \dot{Y}_1^{j-1}, \bar{Y}_1^{j'}, \hat{Y}_1^{j''}, X) = \text{SoftMax}(\dot{s}_j).$$

Note that a single LSTM is adopted for structure, condition and referent prediction. The mathematic symbols are summarized in Table 2.

4.5 Training

The models are trained to minimize a cross-entropy loss objective with ℓ_2 regularization:

$$L(\theta) = -\sum_j \log p_j + \frac{\lambda}{2} ||\theta||^2,$$

where θ is the set of parameters, and λ is a regularization hyper-parameter ($\lambda = 10^{-6}$). We used stochastic gradient descent with Adam (Kingma and Ba, 2014) to adjust the learning rate.

5 Experimental Setup

Settings Our experiments were carried out on the GMB following the tree conversion process discussed in Section 3. We adopted the training, development, and testing partitions recommended in Bos et al. (2017). We compared the three models introduced in Section 4, namely the baseline sequence decoder, the shallow structured decoder and the deep structure decoder. We used the same empirical hyper-parameters for all three models. The dimensions of word and lemma embeddings were 64 and 32, respectively. The dimensions of hidden vectors were 256 for the encoder and 128 for the decoder. The encoder used two hidden layers, whereas the decoder only one. The dropout rate was 0.1. Pre-trained word embeddings (100 dimensions) were generated with Word2Vec trained on the AFP portion of the English Gigaword corpus.[3]

Evaluation Due to the complex nature of our structured prediction task, we cannot expect model output to exactly match the gold standard. For instance, the numbering of the referents may be different, but nevertheless valid, or the order of the children of a tree node (e.g., "DRS(india(x_1) say(e_1))" and "DRS(say(e_1) india(x_1))" are the same). We thus use F_1 instead of exact match accuracy. Specifically, we report D-match[4] a metric designed to evaluate scoped meaning representations and released as part of the distribution of the Parallel Meaning Bank corpus (Abzianidze et al., 2017). D-match is based on Smatch[5], a metric used to evaluate AMR graphs (Cai and Knight, 2013); it calculates F_1 on discourse representation graphs (DRGs), i.e., triples of nodes, arcs, and their referents, applying multiple restarts to obtain a good referent (node) mapping between graphs.

We converted DRSs (predicted and goldstandard) into DRGs following the top-down procedure described in Algorithm 1.[6] IsCondition returns *true* if the child is a condition (e.g., india(x_1)), where three arcs are created, one is connected to a parent node and the other two are connected to arg1 and arg2, respectively (lines 7–12). IsQuantifier returns *true* if the child is a quantifier (e.g., π_1, $\neg$ and $\Box$) and three arcs are created; one is connected to the parent node, one to the referent that is created if and only

[3]The models are trained on a single GPU without batches.

Algorithm 1 DRS to DRG Conversion

```
Input: $T$, tree-like DRS
Output: $G$, a set of edges
 1: $n_b \leftarrow 0$; $n_c \leftarrow 0$; $G \leftarrow \emptyset$
 2: $stack \leftarrow []$; $R \leftarrow \emptyset$
 3: procedure TRAVELDRS(parent)
 4:     $stack.append(b_{n_b})$; $n_b \leftarrow n_b + 1$
 5:     $node_p \leftarrow stack.top$
 6:     for $child$ in $parent$ do
 7:         if ISCONDITION($child$) then
 8:             $G \leftarrow G \cup \{node_p \xrightarrow{child.rel} c_{n_c}\}$
 9:             $G \leftarrow G \cup \{c_{n_c} \xrightarrow{\text{arg1}} child.arg1\}$
10:             $G \leftarrow G \cup \{c_{n_c} \xrightarrow{\text{arg2}} child.arg2\}$
11:             $n_c \leftarrow n_c + 1$
12:             ADDREFERENT($node_p, child$)
13:         else if ISQUANTIFIER($child$) then
14:             $G \leftarrow G \cup \{node_p \xrightarrow{child.class} c_{n_c}\}$
15:             $G \leftarrow G \cup \{c_{n_c} \xrightarrow{\text{arg1}} child.arg1\}$
16:             $G \leftarrow G \cup \{c_{n_c} \xrightarrow{\text{arg1}} b_{n_b+1}\}$
17:             $n_c \leftarrow n_c + 1$
18:             if ISPROPSEG($child$) then
19:                 ADDREFERENT($node_p, child$)
20:             end if
21:             TRAVELDRS($child.nextDRS$)
22:         end if
23:     end for
24:     $stack.pop()$
25: end procedure
26: procedure ADDREFERENT($node_p, child$)
27:     if $child.arg1$ not in $R$ then
28:         $G \leftarrow G \cup \{node_p \xrightarrow{\text{ref}} child.arg1\}$
29:         $R \leftarrow R \cup child.arg1$
30:     end if
31:     if $child.arg2$ not in $R$ then
32:         $G \leftarrow G \cup \{node_p \xrightarrow{\text{ref}} child.arg2\}$
33:         $R \leftarrow R \cup child.arg2$
34:     end if
35: end procedure
36: TRAVELDRS($T$)
37: return $G$
```

if the child is a proposition or segment (e.g., π_1 and k_1), and one is connected to the next DRS or SDRS nodes (lines 13–20). The algorithm will recursively travel all DRS or SDRS nodes (line 21). Furthermore, arcs are introduced to connect DRS or SDRS nodes to the referents that first appear in a condition (lines 26–35).

When comparing two DRGs, we calculate the F_1 over their arcs. For example consider the two DRGs (a) and (b) shown in Figure 4. Let $\{b_0 : b_0, x_1 : x_2, x_2 : x_3, c_0 : c_0, c_1 : c_2, c_2 : c_3\}$ denote the node alignment between them. The number of matching arcs is eight, the number of arcs in the gold DRG is nine, and the number of arcs in the predicted DRG is 12. So recall is 8/9, precision is 8/12, and F_1 is 76.19.

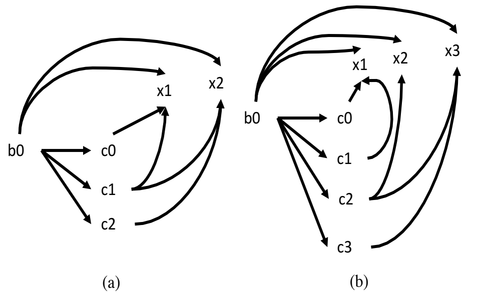

Figure 4: (a) is the gold DRS and (b) is the predicted DRS (condition names are not shown).

6 Results

Table 3 compares our three models on the development set. As can be seen, the shallow structured decoder performs better than the baseline decoder, and the proposed deep structure decoder outperforms both of them. Ablation experiments show that without pre-trained word embeddings or word lemma embeddings, the model generally performs worse. Compared to lemma embeddings, pretrained word embeddings contribute more.

Table 4 shows our results on the test set. To assess the degree to which the various decoders contribute to DRS parsing, we report results when predicting the full DRS structure (second block), when ignoring referents (third block), and when ignoring both referents and conditions (fourth block). Overall, we observe that the shallow structure model improves precision over the baseline with a slight loss in recall, while the deep structure model performs best by a large margin. When referents are not taken into account (compare the second and third blocks in Table 4), performance improves across the board. When conditions are additionally omitted, we observe further performance gains. This is hardly surprising, since errors propagate from one stage to the next when predicting full DRS structures. Further analysis revealed that the parser performs slightly better on (copy) conditions which correspond to natural language tokens compared to (insert) conditions (e.g., Topic, Agent) which are generated from global semantic content (83.22 vs 80.63 F_1). The parser is also better on sentences which do not represent SDRSs (79.12 vs 68.36 F_1) which is expected given that they usually correspond to more elaborate structures. We also found that rhetorical relations (linking segments) are predicted fairly accurately, especially if they are frequently attested (e.g., Continuation, Parallel), while the parser has difficulty with relations denoting contrast.

Model	P (%)	R (%)	F_1 (%)
baseline	51.35	63.85	56.92
shallow	67.88	63.53	65.63
deep	79.01	75.65	77.29
deep (–pre)	78.47	73.43	75.87
deep (–pre & lem)	78.21	72.82	75.42

Table 3: GMB development set.

Model	DRG			DRG w/o refs			DRG w/o refs & conds		
	P	R	F_1	P	R	F_1	P	R	F_1
baseline	52.21	64.46	57.69	47.20	58.93	52.42	52.89	71.80	60.91
shallow	66.61	63.92	65.24	66.05	62.93	64.45	83.30	62.91	71.68
deep	79.27	75.88	77.54	82.87	79.40	81.10	93.91	88.51	91.13

Table 4: GMB test set.

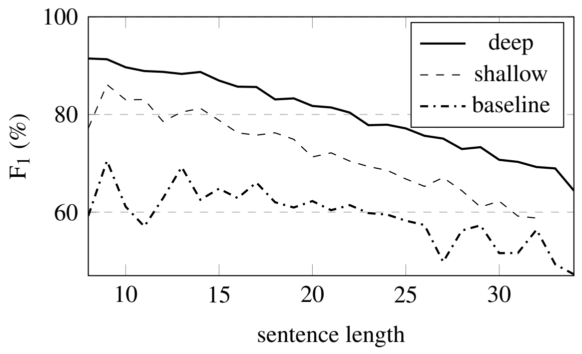

Figure 5: F_1 score as a function of sentence length.

Figure 5 shows F_1 performance for the three parsers on sentences of different length. We observe a similar trend for all models: as sentence length increases, model performance decreases. The baseline and shallow models do not perform well on short sentences which despite containing fewer words, can still represent complex meaning which is challenging to capture sequentially. On the other hand, the performance of the deep model is relatively stable. LSTMs in this case function relatively well, as they are faced with the easier task of predicting meaning in different stages (starting with a tree skeleton which is progressively refined). We provide examples of model output in the supplementary material.

7 Related Work

Tree-structured Decoding A few recent approaches develop structured decoders which make use of the syntax of meaning representations. Dong and Lapata (2016) and Alvarez-Melis and Jaakkola (2017) generate trees in a top-down fashion, while in other work (Xiao et al., 2016; Krishnamurthy et al., 2017) the decoder generates from a grammar that guarantees that predicted logical forms are well-typed. In a similar vein, Yin and Neubig (2017) generate abstract syntax trees (ASTs) based on the application of production rules defined by the grammar. Rabinovich et al. (2017) introduce a modular decoder whose various components are dynamically composed according to the generated tree structure. In comparison, our model does not use grammar information explicitly. We first decode the structure of the DRS, and then fill in details pertaining to its semantic content. Our model is not strictly speaking top-down, we generate partial trees sequentially, and then expand non-terminal nodes, ensuring that when we generate the children of a node, we have already obtained the structure of the entire tree.

Wide-coverage Semantic Parsing Our model is trained on the GMB (Bos et al., 2017), a richly annotated resource in the style of DRT which provides a unique opportunity for bootstrapping wide-coverage semantic parsers. Boxer (Bos, 2008) was a precursor to the GMB, the first semantic parser of this kind, which deterministically maps CCG derivations onto formal meaning representations. Le and Zuidema (2012) were the first to train a semantic parser on an early release of the GMB (2,000 documents; Basile et al. 2012), however, they abandon lambda calculus in favor of a graph based representation. The latter is closely related to AMR, a general-purpose meaning representation language for broad-coverage text. In AMR the meaning of a sentence is represented as a rooted, directed, edge-labeled and leaf-labeled graph. AMRs do not resemble classical meaning representations and do not have a model-theoretic interpretation. However, see Bos (2016) and Artzi et al. (2015) for translations to first-order logic.

8 Conclusions

We introduced a new end-to-end model for open-domain semantic parsing. Experimental results on the GMB show that our decoder is able to recover discourse representation structures to a good degree (77.54 F_1), albeit with some simplifications. In the future, we plan to model document-level representations which are more in line with DRT and the GMB annotations.

Acknowledgments We thank the anonymous reviewers for their feedback and Johan Bos for answering several questions relating to the GMB. We gratefully acknowledge the support of the European Research Council (Lapata, Liu; award number 681760) and the EU H2020 project SUMMA (Cohen, Liu; grant agreement 688139).

Abstract

Many deep learning architectures have been proposed to model the *compositionality* in text sequences, requiring a substantial number of parameters and expensive computations. However, there has not been a rigorous evaluation regarding the added value of sophisticated compositional functions. In this paper, we conduct a point-by-point comparative study between Simple Word-Embedding-based Models (SWEMs), consisting of parameter-free pooling operations, relative to word-embedding-based RNN/CNN models. Surprisingly, SWEMs exhibit comparable or even superior performance in the majority of cases considered. Based upon this understanding, we propose two additional pooling strategies over learned word embeddings: (i) a max-pooling operation for improved interpretability; and (ii) a hierarchical pooling operation, which preserves spatial (n-gram) information within text sequences. We present experiments on 17 datasets encompassing three tasks: (i) (long) document classification; (ii) text sequence matching; and (iii) short text tasks, including classification and tagging.

1 Introduction

Word embeddings, learned from massive unstructured text data, are widely-adopted building blocks for Natural Language Processing (NLP). By representing each word as a fixed-length vector, these embeddings can group semantically similar words, while implicitly encoding rich linguistic regularities and patterns (Bengio et al., 2003; Mikolov et al., 2013; Pennington et al., 2014). Leveraging the word-embedding construct, many deep architectures have been proposed to model the *compositionality* in variable-length text sequences. These methods range from simple operations like addition (Mitchell and Lapata, 2010; Iyyer et al., 2015), to more sophisticated compositional functions such as Recurrent Neural Networks (RNNs) (Tai et al., 2015; Sutskever et al., 2014), Convolutional Neural Networks (CNNs) (Kalchbrenner et al., 2014; Kim, 2014; Zhang et al., 2017a) and Recursive Neural Networks (Socher et al., 2011a).

Models with more expressive compositional functions, *e.g.*, RNNs or CNNs, have demonstrated impressive results; however, they are typically computationally expensive, due to the need to estimate hundreds of thousands, if not millions, of parameters (Parikh et al., 2016). In contrast, models with simple compositional functions often compute a sentence or document embedding by simply adding, or averaging, over the word embedding of each sequence element obtained via, *e.g.*, *word2vec* (Mikolov et al., 2013), or *GloVe* (Pennington et al., 2014). Generally, such a Simple Word-Embedding-based Model (SWEM) does not explicitly account for spatial, word-order information within a text sequence. However, they possess the desirable property of having significantly fewer parameters, enjoying much faster training, relative to RNN- or CNN-based models. Hence, there is a computation-*vs.*-expressiveness tradeoff regarding how to model the compositionality of a text sequence.

In this paper, we conduct an extensive experimental investigation to understand when, and why, simple pooling strategies, operated over word embeddings alone, already carry sufficient information for natural language understanding. To account for the distinct nature of various NLP tasks that may require different semantic features, we compare SWEM-based models with existing recurrent and convolutional networks in a point-by-point manner. Specifically, we consider 17 datasets, including three distinct NLP tasks: *document classification* (Yahoo news, Yelp reviews, *etc.*), *natural language sequence matching* (SNLI, WikiQA, *etc.*) and *(short) sentence classification/tagging* (Stanford sentiment treebank, TREC, *etc.*). Surprisingly, SWEMs exhibit comparable or even superior performance in the majority of cases considered.

In order to validate our experimental findings, we conduct additional investigations to understand to what extent *the word-order information* is utilized/required to make predictions on different tasks. We observe that in text representation tasks, many words (*e.g.*, stop words, or words that are not related to sentiment or topic) do not meaningfully contribute to the final predictions (*e.g.*, sentiment label). Based upon this understanding, we propose to leverage a *max-pooling* operation directly over the word embedding matrix of a given sequence, to select its most *salient* features. This strategy is demonstrated to extract complementary features relative to the standard averaging operation, while resulting in a more interpretable model. Inspired by a case study on sentiment analysis tasks, we further propose a *hierarchical pooling* strategy to abstract and preserve the spatial information in the final representations. This strategy is demonstrated to exhibit comparable empirical results to LSTM and CNN on tasks that are sensitive to word-order features, while maintaining the favorable properties of not having compositional parameters, thus fast training.

Our work presents a simple yet strong baseline for text representation learning that is widely ignored in benchmarks, and highlights the general computation-*vs.*-expressiveness tradeoff associated with appropriately selecting compositional functions for distinct NLP problems. Furthermore, we quantitatively show that the word-embedding-based text classification tasks can have the similar level of difficulty regardless of the employed models, using the subspace training (Li et al., 2018) to constrain the trainable parameters. Thus, according to Occam's razor, simple models are preferred.

2 Related Work

A fundamental goal in NLP is to develop expressive, yet computationally efficient compositional functions that can capture the linguistic structure of natural language sequences. Recently, several studies have suggested that on certain NLP applications, much simpler word-embedding-based architectures exhibit comparable or even superior performance, compared with more-sophisticated models using recurrence or convolutions (Parikh et al., 2016; Vaswani et al., 2017). Although complex compositional functions are avoided in these models, additional modules, such as attention layers, are employed on top of the word embedding layer. As a result, the specific role that the word embedding plays in these models is not emphasized (or explicit), which distracts from understanding how important the word embeddings alone are to the observed superior performance. Moreover, several recent studies have shown empirically that the advantages of distinct compositional functions are highly dependent on the specific task (Mitchell and Lapata, 2010; Iyyer et al., 2015; Zhang et al., 2015a; Wieting et al., 2015; Arora et al., 2016). Therefore, it is of interest to study the practical value of the additional expressiveness, on a wide variety of NLP problems.

SWEMs bear close resemblance to Deep Averaging Network (DAN) (Iyyer et al., 2015) or fastText (Joulin et al., 2016), where they show that average pooling achieves promising results on certain NLP tasks. However, there exist several key differences that make our work unique. First, we explore a series of pooling operations, rather than only average-pooling. Specifically, a *hierarchical* pooling operation is introduced to incorporate spatial information, which demonstrates superior results on sentiment analysis, relative to average pooling. Second, our work not only explores when simple pooling operations are enough, but also investigates the underlying reasons, *i.e.*, what semantic features are required for distinct NLP problems. Third, DAN and fastText only focused on one or two problems at a time, thus a comprehensive study regarding the effectiveness of various compositional functions on distinct NLP tasks, *e.g.*, categorizing short sentence/long documents, matching natural language sentences, has heretofore been absent. In response, our work seeks to perform a comprehensive comparison with respect to simple-*vs.*-complex compositional functions, across a wide range of NLP problems, and reveals some general rules for rationally selecting models to tackle different tasks.

3 Models & training

Consider a text sequence represented as X (either a sentence or a document), composed of a sequence of words: $\{w_1, w_2, ..., w_L\}$, where L is the number of tokens, *i.e.*, the sentence/document length. Let $\{v_1, v_2, ..., v_L\}$ denote the respective word embeddings for each token, where $v_l \in \mathbb{R}^K$. The compositional function, $X \rightarrow z$, aims to combine word embeddings into a fixed-length sentence/document representation z. These representations are then used to make predictions about sequence X. Below, we describe different types of functions considered in this work.

3.1 Recurrent Sequence Encoder

A widely adopted compositional function is defined in a recurrent manner: the model successively takes word vector v_t at position t, along with the hidden unit h_{t-1} from the last position $t-1$, to update the current hidden unit via $h_t = f(v_t, h_{t-1})$, where $f(\cdot)$ is the transition function.

To address the issue of learning long-term dependencies, $f(\cdot)$ is often defined as Long Short-Term Memory (LSTM) (Hochreiter and Schmidhuber, 1997), which employs *gates* to control the flow of information abstracted from a sequence. We omit the details of the LSTM and refer the interested readers to the work by Graves et al. (2013) for further explanation. Intuitively, the LSTM encodes a text sequence considering its word-order information, but yields additional compositional parameters that must be learned.

3.2 Convolutional Sequence Encoder

The Convolutional Neural Network (CNN) architecture (Kim, 2014; Collobert et al., 2011; Gan et al., 2017; Zhang et al., 2017b; Shen et al., 2018) is another strategy extensively employed as the compositional function to encode text sequences. The convolution operation considers windows of n consecutive words within the sequence, where a set of filters (to be learned) are applied to these word windows to generate corresponding *feature maps*. Subsequently, an aggregation operation (such as max-pooling) is used on top of the feature maps to abstract the most salient semantic features, resulting in the final representation. For most experiments, we consider a single-layer CNN text model. However, Deep CNN text models have also been developed (Conneau et al., 2016), and are considered in a few of our experiments.

3.3 Simple Word-Embedding Model (SWEM)

To investigate the raw modeling capacity of word embeddings, we consider a class of models with no additional compositional parameters to encode natural language sequences, termed SWEMs. Among them, the simplest strategy is to compute the element-wise average over word vectors for a given sequence (Wieting et al., 2015; Adi et al., 2016):

$$z = \frac{1}{L} \sum_{i=1}^{L} v_i \, . \tag{1}$$

The model in (1) can be seen as an average pooling operation, which takes the mean over each of the K dimensions for all word embeddings, resulting in a representation z with the same dimension as the embedding itself, termed here SWEM-*aver*. Intuitively, z takes the information of every sequence element into account via the addition operation.

Max Pooling Motivated by the observation that, in general, only a small number of key words contribute to final predictions, we propose another SWEM variant, that extracts the most salient features from every word-embedding dimension, by taking the maximum value along each dimension of the word vectors. This strategy is similar to the max-over-time pooling operation in convolutional neural networks (Collobert et al., 2011):

$$z = \text{Max-pooling}(v_1, v_2, ..., v_L) \, . \tag{2}$$

We denote this model variant as SWEM-*max*. Here the j-th component of z is the maximum element in the set $\{v_{1j}, \ldots, v_{Lj}\}$, where v_{1j} is, for example, the j-th component of v_1. With this pooling operation, those words that are unimportant or unrelated to the corresponding tasks will be ignored in the encoding process (as the components of the embedding vectors will have small amplitude), unlike SWEM-*aver* where every word contributes equally to the representation.

Considering that SWEM-*aver* and SWEM-*max* are complementary, in the sense of accounting for different types of information from text sequences, we also propose a third SWEM variant, where the two abstracted features are concatenated together to form the sentence embeddings, denoted here as SWEM-*concat*. For all SWEM variants, there are no additional compositional parameters to be

Model	Parameters	Complexity	Sequential Ops
CNN	$n \cdot K \cdot d$	$\mathcal{O}(n \cdot L \cdot K \cdot d)$	$\mathcal{O}(1)$
LSTM	$4 \cdot d \cdot (K + d)$	$\mathcal{O}(L \cdot d^2 + L \cdot K \cdot d)$	$\mathcal{O}(L)$
SWEM	0	$\mathcal{O}(L \cdot K)$	$\mathcal{O}(1)$

Table 1: Comparisons of CNN, LSTM and SWEM architectures. Columns correspond to the number of *compositional* parameters, computational complexity and sequential operations, respectively.

learned. As a result, the models only exploit intrinsic word embedding information for predictions.

Hierarchical Pooling Both SWEM-*aver* and SWEM-*max* do not take word-order or spatial information into consideration, which could be useful for certain NLP applications. So motivated, we further propose a *hierarchical* pooling layer. Let $v_{i:i+n-1}$ refer to the *local* window consisting of n consecutive words words, $v_i, v_{i+1}, ..., v_{i+n-1}$. First, an average-pooling is performed on each local window, $v_{i:i+n-1}$. The extracted features from all windows are further down-sampled with a *global* max-pooling operation on top of the representations for every window. We call this approach SWEM-*hier* due to its layered pooling.

This strategy preserves the local spatial information of a text sequence in the sense that it keeps track of how the sentence/document is constructed from individual word windows, *i.e.*, n-grams. This formulation is related to bag-of-n-grams method (Zhang et al., 2015b). However, SWEM-*hier* learns fixed-length representations for the n-grams that appear in the corpus, rather than just capturing their occurrences via count features, which may potentially advantageous for prediction purposes.

3.4 Parameters & Computation Comparison

We compare CNN, LSTM and SWEM wrt their parameters and computational speed. K denotes the dimension of word embeddings, as above. For the CNN, we use n to denote the filter width (assumed constant for all filters, for simplicity of analysis, but in practice variable n is commonly used). We define d as the dimension of the final sequence representation. Specifically, d represents the dimension of hidden units or the number of filters in LSTM or CNN, respectively.

We first examine the number of *compositional parameters* for each model. As shown in Table 1, both the CNN and LSTM have a large number of parameters, to model the semantic compositionality of text sequences, whereas SWEM has no such parameters. Similar to Vaswani et al. (2017), we then consider the computational complexity and the minimum number of sequential operations required for each model. SWEM tends to be more efficient than CNN and LSTM in terms of computation complexity. For example, considering the case where $K = d$, SWEM is faster than CNN or LSTM by a factor of nd or d, respectively. Further, the computations in SWEM are highly parallelizable, unlike LSTM that requires $\mathcal{O}(L)$ sequential steps.

4 Experiments

We evaluate different compositional functions on a wide variety of supervised tasks, including document categorization, text sequence matching (given a sentence pair, X_1, X_2, predict their relationship, y) as well as (short) sentence classification. We experiment on 17 datasets concerning natural language understanding, with corresponding data statistics summarized in the Supplementary Material. Our code will be released to encourage future research.

We use GloVe word embeddings with $K = 300$ (Pennington et al., 2014) as initialization for all our models. Out-Of-Vocabulary (OOV) words are initialized from a uniform distribution with range $[-0.01, 0.01]$. The GloVe embeddings are employed in two ways to learn refined word embeddings: (i) directly updating each word embedding during training; and (ii) training a 300-dimensional Multilayer Perceptron (MLP) layer with ReLU activation, with GloVe embeddings as input to the MLP and with output defining the refined word embeddings. The latter approach corresponds to learning an MLP model that adapts GloVe embeddings to the dataset and task of interest. The advantages of these two methods differ from dataset to dataset. We choose the better strategy based on their corresponding performances on the validation set. The final classifier is implemented as an MLP layer with dimension selected from the set $[100, 300, 500, 1000]$, followed by a sigmoid or softmax function, depending on the specific task.

Adam (Kingma and Ba, 2014) is used to optimize all models, with learning rate selected from the set $[1 \times 10^{-3}, 3 \times 10^{-4}, 2 \times 10^{-4}, 1 \times 10^{-5}]$ (with cross-validation used to select the appropriate parameter for a given dataset and task). Dropout regularization (Srivastava et al., 2014) is

4.1 Document Categorization

We begin with the task of categorizing documents (with approximately 100 words in average per document). We follow the data split in Zhang et al. (2015b) for comparability. These datasets can be generally categorized into three types: *topic categorization* (represented by Yahoo! Answer and AG news), *sentiment analysis* (represented by Yelp Polarity and Yelp Full) and *ontology classification* (represented by DBpedia). Results are shown in Table 2. Surprisingly, on topic prediction tasks, our SWEM model exhibits stronger performances, relative to both LSTM and CNN compositional architectures, this by leveraging both the average and max-pooling features from word embeddings. Specifically, our SWEM-*concat* model even outperforms a 29-layer deep CNN model (Conneau et al., 2016), when predicting topics. On the ontology classification problem (DBpedia dataset), we observe the same trend, that SWEM exhibits comparable or even superior results, relative to CNN or LSTM models.

Since there are no compositional parameters in SWEM, our models have an order of magnitude fewer parameters (excluding embeddings) than LSTM or CNN, and are considerably more computationally efficient. As illustrated in Table 4, SWEM-*concat* achieves better results on Yahoo! Answer than CNN/LSTM, with only 61K parameters (one-tenth the number of LSTM parameters, or one-third the number of CNN parameters), while taking a fraction of the training time relative to the CNN or LSTM.

Model	Parameters	Speed
CNN	541K	171s
LSTM	1.8M	598s
SWEM	**61K**	**63s**

Table 4: Speed & Parameters on Yahoo! Answer dataset.

Interestingly, for the sentiment analysis tasks, both CNN and LSTM compositional functions perform better than SWEM, suggesting that word-order information may be required for analyzing sentiment orientations. This finding is consistent with Pang et al. (2002), where they hypothesize that the positional information of a word in text sequences may be beneficial to predict sentiment. This is intuitively reasonable since, for instance, the phrase "not really good" and "really not good" convey different levels of negative sentiment, while being different only by their word orderings. Contrary to SWEM, CNN and

LSTM models can both capture this type of information via convolutional filters or recurrent transition functions. However, as suggested above, such word-order patterns may be much less useful for predicting the topic of a document. This may be attributed to the fact that word embeddings alone already provide sufficient topic information of a document, at least when the text sequences considered are relatively long.

4.1.1 Interpreting model predictions

Although the proposed SWEM-*max* variant generally performs a slightly worse than SWEM-*aver*, it extracts complementary features from SWEM-*aver*, and hence in most cases SWEM-*concat* exhibits the best performance among all SWEM variants. More importantly, we found that the word embeddings learned from SWEM-*max* tend to be sparse. We trained our SWEM-*max* model on the Yahoo datasets (randomly initialized). With the learned embeddings, we plot the values for each of the word embedding dimensions, for the entire vocabulary. As shown in Figure 1, most of the values are highly concentrated around zero, indicating that the word embeddings learned are very sparse. On the contrary, the GloVe word embeddings, for the same vocabulary, are considerably denser than the embeddings learned from SWEM-*max*. This suggests that the model may only depend on a few key words, among the entire vocabulary, for predictions (since most words do not contribute to the max-pooling operation in SWEM-*max*). Through the embedding, the model learns the important words for a given task (those words with non-zero embedding components).

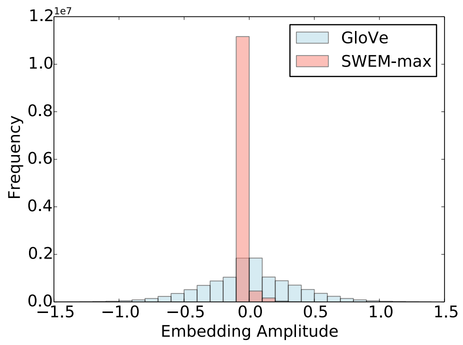

Figure 1: Histograms for learned word embeddings (randomly initialized) of SWEM-*max* and GloVe embeddings for the same vocabulary, trained on the Yahoo! Answer dataset.

In this regard, the nature of max-pooling process gives rise to a more interpretable model. For a document, only the word with largest value in each embedding dimension is employed for the final representation. Thus, we suspect that semantically similar words may have large values in some shared dimensions. So motivated, after training the SWEM-*max* model on the Yahoo dataset, we selected five words with the largest values, among the entire vocabulary, for each word embedding dimension (these words are selected preferentially in the corresponding dimension, by the max operation). As shown in Table 3, the words chosen wrt each embedding dimension are indeed highly relevant and correspond to a common topic (the topics are inferred from words). For example, the words in the first column of Table 3 are all political terms, which could be assigned to the *Politics & Government* topic. Note that our model can even learn locally interpretable structure that is not explicitly indicated by the label information. For instance, all words in the fifth column are *Chemistry*-related. However, we do not have a chemistry label in the dataset, and regardless they should belong to the *Science* topic.

4.2 Text Sequence Matching

To gain a deeper understanding regarding the modeling capacity of word embeddings, we further investigate the problem of sentence matching, including natural language inference, answer sentence selection and paraphrase identification. The corresponding performance metrics are shown in Table 5. Surprisingly, on most of the datasets considered (except WikiQA), SWEM demonstrates the best results compared with those with CNN or the LSTM encoder. Notably, on SNLI dataset, we observe that SWEM-*max* performs the best among all SWEM variants, consistent with the findings in Nie and Bansal (2017); Conneau et al. (2017), that *max-pooling* over BiLSTM hidden units outperforms average pooling operation on SNLI dataset. As a result, with only 120K parameters, our SWEM-*max* achieves a test accuracy of 83.8%, which is very competitive among state-of-the-art sentence encoding-based models (in terms of both performance and number of parameters)[1].

The strong results of the SWEM approach on these tasks may stem from the fact that when matching natural language sentences, it is sufficient in most cases to simply model the word-level

[1]See leaderboard at `https://nlp.stanford.edu/projects/snli/` for details.

Model	SNLI	MultiNLI Matched	MultiNLI Mismatched	WikiQA		Quora	MSRP

SWEM-*concat*	83.3	67.9	67.6	0.6788	0.6908	**83.03**	**71.5**	**81.3**

Table 5: Performance of different models on matching natural language sentences. Results with * are for Bidirectional LSTM, reported in Williams et al. (2017). Our reported results on MultiNLI are only trained MultiNLI training set (without training data from SNLI). For MSRP dataset, we follow the setup in Hu et al. (2014) and do not use any additional features.

alignments between two sequences (Parikh et al., 2016). From this perspective, word-order information becomes much less useful for predicting relationship between sentences. Moreover, considering the simpler model architecture of SWEM, they could be much easier to be optimized than LSTM or CNN-based models, and thus give rise to better empirical results.

4.2.1 Importance of word-order information

One possible disadvantage of SWEM is that it ignores the word-order information within a text sequence, which could be potentially captured by CNN- or LSTM-based models. However, we empirically found that except for sentiment analysis, SWEM exhibits similar or even superior performance as the CNN or LSTM on a variety of tasks. In this regard, one natural question would be: how important are word-order features for these tasks? To this end, we randomly shuffle the words for every sentence in the training set, while keeping the original word order for samples in the test set. The motivation here is to remove the word-order features from the training set and examine how sensitive the performance on different tasks are to word-order information. We use LSTM as the model for this purpose since it can captures word-order information from the original training set.

Datasets	Yahoo	Yelp P.	SNLI
Original	72.78	95.11	78.02
Shuffled	72.89	93.49	77.68

Table 6: Test accuracy for LSTM model trained on original/shuffled training set.

The results on three distinct tasks are shown in Table 6. Somewhat surprisingly, for Yahoo and SNLI datasets, the LSTM model trained on shuffled training set shows comparable accuracies to those trained on the original dataset, indicating that word-order information does not contribute significantly on these two problems, *i.e.*, topic categorization and textual entailment. However, on the Yelp polarity dataset, the results drop noticeably, further suggesting that word-order does matter for sentiment analysis (as indicated above from a different perspective).

Negative:	Friendly staff and nice selection of vegetarian options. Food **is just okay**, **not great**. **Makes me wonder why everyone likes** food fight so much.
Positive:	The store is small, but it carries specialties that are difficult to find in Pittsburgh. I **was particularly excited** to find middle eastern chili sauce and chocolate covered turkish delights.

Table 7: Test samples from Yelp Polarity dataset for which LSTM gives wrong predictions with shuffled training data, but predicts correctly with the original training set.

Notably, the performance of LSTM on the Yelp dataset with a shuffled training set is very close to our results with SWEM, indicating that the main difference between LSTM and SWEM may be due to the ability of the former to capture word-order features. Both observations are in consistent with our experimental results in the previous section.

Case Study To understand what type of sentences are sensitive to word-order information, we further show those samples that are wrongly predicted because of the shuffling of training data in Table 7. Taking the first sentence as an example, several words in the review are generally positive, *i.e. friendly*, *nice*, *okay*, *great* and *likes*. However, the most vital features for predicting the sentiment of this sentence could be the phrase/sentence *'is just okay'*, *'not great'* or *'makes me wonder why everyone likes'*, which cannot be captured without

considering word-order features. It is worth noting the hints for predictions in this case are actually n-gram phrases from the input document.

4.3 SWEM-*hier* for sentiment analysis

As demonstrated in Section 4.2.1, word-order information plays a vital role for sentiment analysis tasks. However, according to the case study above, the most important features for sentiment prediction may be some key n-gram phrase/words from the input document. We hypothesize that incorporating information about the local word-order, *i.e.*, n-gram features, is likely to largely mitigate the limitations of the above three SWEM variants. Inspired by this observation, we propose using another simple pooling operation termed as hierarchical (SWEM-*hier*), as detailed in Section 3.3. We evaluate this method on the two document-level sentiment analysis tasks and the results are shown in the last row of Table 2.

SWEM-*hier* greatly outperforms the other three SWEM variants, and the corresponding accuracies are comparable to the results of CNN or LSTM (Table 2). This indicates that the proposed hierarchical pooling operation manages to abstract spatial (word-order) information from the input sequence, which is beneficial for performance in sentiment analysis tasks.

4.4 Short Sentence Processing

We now consider sentence-classification tasks (with approximately 20 words on average). We experiment on three sentiment classification datasets, *i.e.*, MR, SST-1, SST-2, as well as subjectivity classification (Subj) and question classification (TREC). The corresponding results are shown in Table 8. Compared with CNN/LSTM compositional functions, SWEM yields inferior accuracies on sentiment analysis datasets, consistent with our observation in the case of document categorization. However, SWEM exhibits comparable performance on the other two tasks, again with much less parameters and faster training. Further, we investigate two sequence tagging tasks: the standard CoNLL2000 chunking and CoNLL2003 NER datasets. Results are shown in the Supplementary Material, where LSTM and CNN again perform better than SWEMs. Generally, SWEM is less effective at extracting representations from *short* sentences than from *long* documents. This may be due to the fact that for a shorter text sequence, word-order features tend to be more important since the semantic information provided by word embeddings alone is relatively limited.

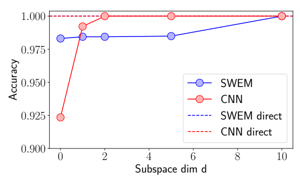
Moreover, we note that the results on these relatively small datasets are highly sensitive to model regularization techniques due to the overfitting issues. In this regard, one interesting future direction may be to develop specific regularization strategies for the SWEM framework, and thus make them work better on small sentence classification datasets.

5 Discussion

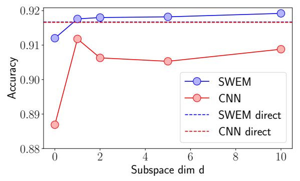
5.1 Comparison via subspace training

We use *subspace training* (Li et al., 2018) to measure the model complexity in text classification problems. It constrains the optimization of the trainable parameters in a subspace of low dimension d, the intrinsic dimension d_{int} defines the minimum d that yield a good solution. Two models are studied: the SWEM-*max* variant, and the CNN model including a convolutional layer followed by a FC layer. We consider two settings:

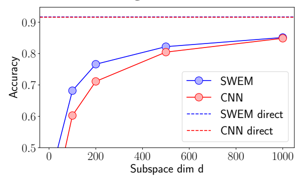
(1) The word embeddings are randomly intialized, and optimized jointly with the model parameters. We show the performance of direct and subspace training on AG News dataset in Figure 2 (a)(b). The two models trained via direct method share almost identical perfomrnace on training and



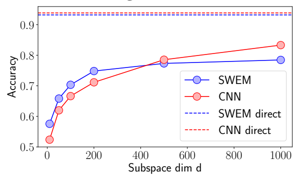
(a) Training on AG News



(b) Testing on AG News



(c) Testing on AG News



(d)Testing on Yelp P.

Figure 2: Performance of subspace training. Word embeddings are optimized in (a)(b), and frozen in (c)(d).

testing. The subspace training yields similar accuracy with direct training for very small d, even when model parameters are not trained at all ($d = 0$). This is because the word embeddings have the full degrees of freedom to adjust to achieve good solutions, regardless of the employed models. SWEM seems to have an easier loss landscape than CNN for word embeddings to find the best solutions. According to Occam's razor, simple models are preferred, if all else are the same.

(2) The pre-trained GloVe are frozen for the word embeddings, and only the model parameters are optimized. The results on testing datasets of AG News and Yelp P. are shown in Figure 2 (c)(d), respectively. SWEM shows significantly higher accuracy than CNN for a large range of low subspace dimension, indicating that SWEM is more parameter-efficient to get a decent solution. In Figure 2(c), if we set the performance threshold as 80% testing accuracy, SWEM exhibits a lower d_{int} than CNN on AG News dataset. However, in Figure 2(d), CNN can leverage more trainable parameters to achieve higher accuracy when d is large.

5.2 Linear classifiers

To further investigate the quality of representations learned from SWEMs, we employ a linear classifier on top of the representations for prediction, instead of a non-linear MLP layer as in the previous section. It turned out that utilizing a linear classifier only leads to a very small performance drop for both Yahoo! Ans. (from 73.53% to 73.18%) and Yelp P. datasets (from 93.76% to 93.66%) . This observation highlights that SWEMs are able to extract robust and informative sentence representations despite their simplicity.

5.3 Extension to other languages

We have also tried our SWEM-concat and SWEM-hier models on Sogou news corpus (with the same experimental setup as (Zhang et al., 2015b)), which is a *Chinese* dataset represented by Pinyin (a phonetic romanization of Chinese). SWEM-concat yields an accuracy of 91.3%, while SWEM-hier (with a local window size of 5) obtains an accuracy of 96.2% on the test set. Notably, the performance of SWEM-hier is comparable to the best accuracies of CNN (95.6%) and LSTM (95.2%), as reported in (Zhang et al., 2015b). This indicates that hierarchical pooling is more suitable than average/max pooling for Chinese text classification, by taking spatial information into account. It also implies that Chinese is more sensitive to local word-order features than English.

6 Conclusions

We have performed a comparative study between SWEM (with parameter-free pooling operations) and CNN or LSTM-based models, to represent text sequences on 17 NLP datasets. We further validated our experimental findings through additional exploration, and revealed some general rules for rationally selecting compositional functions for distinct problems. Our findings regarding when (and why) simple pooling operations are enough for text sequence representations are summarized as follows:

• Simple pooling operations are surprisingly effective at representing longer documents (with hundreds of words), while recurrent/convolutional compositional functions are most effective when constructing representations for short sentences.

• Sentiment analysis tasks are more sensitive to word-order features than topic categorization tasks. However, a simple *hierarchical pooling layer* proposed here achieves comparable results to LSTM/CNN on sentiment analysis tasks.

• To match natural language sentences, *e.g.*, textual entailment, answer sentence selection, *etc.*, simple pooling operations already exhibit similar or even superior results, compared to CNN and LSTM.

• In SWEM with max-pooling operation, each *individual dimension* of the word embeddings contains interpretable semantic patterns, and groups together words with a common theme or *topic*.

ParaNMT-50M: Pushing the Limits of Paraphrastic Sentence Embeddings with Millions of Machine Translations

John Wieting[1] **Kevin Gimpel**[2]
[1]Carnegie Mellon University, Pittsburgh, PA, 15213, USA
[2]Toyota Technological Institute at Chicago, Chicago, IL, 60637, USA
jwieting@cs.cmu.edu, kgimpel@ttic.edu

Abstract

We describe ParaNMT-50M, a dataset of more than 50 million English-English sentential paraphrase pairs. We generated the pairs automatically by using neural machine translation to translate the non-English side of a large parallel corpus, following Wieting et al. (2017). Our hope is that ParaNMT-50M can be a valuable resource for paraphrase generation and can provide a rich source of semantic knowledge to improve downstream natural language understanding tasks. To show its utility, we use ParaNMT-50M to train paraphrastic sentence embeddings that outperform all supervised systems on every SemEval semantic textual similarity competition, in addition to showing how it can be used for paraphrase generation.[1]

1 Introduction

While many approaches have been developed for generating or finding paraphrases (Barzilay and McKeown, 2001; Lin and Pantel, 2001; Dolan et al., 2004), there do not exist any freely-available datasets with millions of sentential paraphrase pairs. The closest such resource is the Paraphrase Database (PPDB; Ganitkevitch et al., 2013), which was created automatically from bilingual text by pivoting over the non-English language (Bannard and Callison-Burch, 2005). PPDB has been used to improve word embeddings (Faruqui et al., 2015; Mrkšić et al., 2016). However, PPDB is less useful for learning *sentence* embeddings (Wieting and Gimpel, 2017).

In this paper, we describe the creation of a dataset containing more than 50 million sentential paraphrase pairs. We create it automatically by scaling up the approach of Wieting et al. (2017). We use neural machine translation (NMT) to translate the Czech side of a large Czech-English parallel corpus. We pair the English translations with the English references to form paraphrase pairs. We call this dataset ParaNMT-50M. It contains examples illustrating a broad range of paraphrase phenomena; we show examples in Section 3. ParaNMT-50M has the potential to be useful for many tasks, from linguistically controlled paraphrase generation, style transfer, and sentence simplification to core NLP problems like machine translation.

We show the utility of ParaNMT-50M by using it to train paraphrastic sentence embeddings using the learning framework of Wieting et al. (2016b). We primarily evaluate our sentence embeddings on the SemEval semantic textual similarity (STS) competitions from 2012-2016. Since so many domains are covered in these datasets, they form a demanding evaluation for a general purpose sentence embedding model.

Our sentence embeddings learned from ParaNMT-50M outperform all systems in every STS competition from 2012 to 2016. These tasks have drawn substantial participation; in 2016, for example, the competition attracted 43 teams and had 119 submissions. Most STS systems use curated lexical resources, the provided supervised training data with manually-annotated similarities, and joint modeling of the sentence pair. We use none of these, simply encoding each sentence independently using our models and computing cosine similarity between their embeddings.

We experiment with several compositional architectures and find them all to work well. We find benefit from making a simple change to learning ("mega-batching") to better leverage the large training set, namely, increasing the search space

[1] Dataset, code, and embeddings are available at `https://www.cs.cmu.edu/~jwieting`.

of negative examples. In the supplementary, we evaluate on general-purpose sentence embedding tasks used in past work (Kiros et al., 2015; Conneau et al., 2017), finding our embeddings to perform competitively.

Finally, in Section 6, we briefly report results showing how PARANMT-50M can be used for paraphrase generation. A standard encoder-decoder model trained on PARANMT-50M can generate paraphrases that show effects of "canonicalizing" the input sentence. In other work, fully described by Iyyer et al. (2018), we used PARANMT-50M to generate paraphrases that have a specific syntactic structure (represented as the top two levels of a linearized parse tree).

We release the PARANMT-50M dataset, our trained sentence embeddings, and our code. PARANMT-50M is the largest collection of sentential paraphrases released to date. We hope it can motivate new research directions and be used to create powerful NLP models, while adding a robustness to existing ones by incorporating paraphrase knowledge. Our paraphrastic sentence embeddings are state-of-the-art by a significant margin, and we hope they can be useful for many applications both as a sentence representation function and as a general similarity metric.

2 Related Work

We discuss work in automatically building paraphrase corpora, learning general-purpose sentence embeddings, and using parallel text for learning embeddings and similarity functions.

Paraphrase discovery and generation. Many methods have been developed for generating or finding paraphrases, including using multiple translations of the same source material (Barzilay and McKeown, 2001), using distributional similarity to find similar dependency paths (Lin and Pantel, 2001), using comparable articles from multiple news sources (Dolan et al., 2004; Dolan and Brockett, 2005; Quirk et al., 2004), aligning sentences between standard and Simple English Wikipedia (Coster and Kauchak, 2011), crowdsourcing (Xu et al., 2014, 2015; Jiang et al., 2017), using diverse MT systems to translate a single source sentence (Suzuki et al., 2017), and using tweets with matching URLs (Lan et al., 2017).

The most relevant prior work uses bilingual corpora. Bannard and Callison-Burch (2005) used methods from statistical machine translation to find lexical and phrasal paraphrases in parallel text. Ganitkevitch et al. (2013) scaled up these techniques to produce the Paraphrase Database (PPDB). Our goals are similar to those of PPDB, which has likewise been generated for many languages (Ganitkevitch and Callison-Burch, 2014) since it only needs parallel text. In particular, we follow the approach of Wieting et al. (2017), who used NMT to translate the non-English side of parallel text to get English-English paraphrase pairs. We scale up the method to a larger dataset, produce state-of-the-art paraphrastic sentence embeddings, and release all of our resources.

Sentence embeddings. Our learning and evaluation setting is the same as that of our recent work that seeks to learn paraphrastic sentence embeddings that can be used for downstream tasks (Wieting et al., 2016b,a; Wieting and Gimpel, 2017; Wieting et al., 2017). We trained models on noisy paraphrase pairs and evaluated them primarily on semantic textual similarity (STS) tasks. Prior work in learning general sentence embeddings has used autoencoders (Socher et al., 2011; Hill et al., 2016), encoder-decoder architectures (Kiros et al., 2015; Gan et al., 2017), and other sources of supervision and learning frameworks (Le and Mikolov, 2014; Pham et al., 2015; Arora et al., 2017; Pagliardini et al., 2017; Conneau et al., 2017).

Parallel text for learning embeddings. Prior work has shown that parallel text, and resources built from parallel text like NMT systems and PPDB, can be used for learning embeddings for words and sentences. Several have used PPDB as a knowledge resource for training or improving embeddings (Faruqui et al., 2015; Wieting et al., 2015; Mrkšić et al., 2016). NMT architectures and training settings have been used to obtain better embeddings for words (Hill et al., 2014a,b) and words-in-context (McCann et al., 2017). Hill et al. (2016) evaluated the encoders of English-to-X NMT systems as sentence representations. Mallinson et al. (2017) adapted trained NMT models to produce sentence similarity scores in semantic evaluations.

3 The PARANMT-50M Dataset

To create our dataset, we used back-translation of bitext (Wieting et al., 2017). We used a Czech-English NMT system to translate Czech sentences

Dataset	Avg. Length	Avg. IDF	Avg. Para. Score	Vocab. Entropy	Parse Entropy	Total Size
Common Crawl	24.0$\pm$34.7	7.7$\pm$1.1	0.83$\pm$0.16	7.2	3.5	0.16M
CzEng 1.6	13.3$\pm$19.3	7.4$\pm$1.2	0.84$\pm$0.16	6.8	4.1	51.4M
Europarl	26.1$\pm$15.4	7.1$\pm$0.6	0.95$\pm$0.05	6.4	3.0	0.65M
News Commentary	25.2$\pm$13.9	7.5$\pm$1.1	0.92$\pm$0.12	7.0	3.4	0.19M

greetings, all!	hello everyone!
but she doesn't have much of a case.	but as far as the case goes, she doesn't have much.
it was good in spite of the taste.	despite the flavor, it felt good.

Table 2: Example paraphrase pairs from PARANMT-50M, where each consists of an English reference translation and the machine translation of the Czech source sentence (not shown).

from the training data into English. We paired the translations with the English references to form English-English paraphrase pairs.

We used the pretrained Czech-English model from the NMT system of Sennrich et al. (2017). Its training data includes four sources: Common Crawl, CzEng 1.6 (Bojar et al., 2016), Europarl, and News Commentary. We did not choose Czech due to any particular linguistic properties. Wieting et al. (2017) found little difference among Czech, German, and French as source languages for back-translation. There were much larger differences due to data domain, so we focus on the question of domain in this section. We leave the question of investigating properties of back-translation of different languages to future work.

3.1 Choosing a Data Source

To assess characteristics that yield useful data, we randomly sampled 100K English reference translations from each data source and computed statistics. Table 1 shows the average sentence length, the average inverse document frequency (IDF) where IDFs are computed using Wikipedia sentences, and the average paraphrase score for the two sentences. The paraphrase score is calculated by averaging PARAGRAM-PHRASE embeddings (Wieting et al., 2016b) for the two sentences in each pair and then computing their cosine similarity. The table also shows the entropies of the vocabularies and constituent parses obtained using the Stanford Parser (Manning et al., 2014).[2]

Europarl exhibits the least diversity in terms of rare word usage, vocabulary entropy, and parse entropy. This is unsurprising given its formulaic and repetitive nature. CzEng has shorter sentences than the other corpora and more diverse sentence structures, as shown by its high parse entropy. In terms of vocabulary use, CzEng is not particularly more diverse than Common Crawl and News Commentary, though this could be due to the prevalence of named entities in the latter two.

In Section 5.3, we empirically compare these data sources as training data for sentence embeddings. The CzEng corpus yields the strongest performance when controlling for training data size. Since its sentences are short, we suspect this helps ensure high-quality back-translations. A large portion of it is movie subtitles which tend to use a wide vocabulary and have a diversity of sentence structures; however, other domains are included as well. It is also the largest corpus, containing over 51 million sentence pairs. In addition to providing a large number of training examples for downstream tasks, this means that the NMT system should be able to produce quality translations for this subset of its training data.

For all of these reasons, we chose the CzEng corpus to create PARANMT-50M. When doing so, we used beam search with a beam size of 12 and selected the highest scoring translation from the beam. It took over 10,000 GPU hours to back-translate the CzEng corpus. We show illustrative examples in Table 2.

3.2 Manual Evaluation

We conducted a manual analysis of our dataset in order to quantify its noise level and assess how the

[2]To mitigate sparsity in the parse entropy, we used only the top two levels of each parse tree.

Para. Score Range	# (M)	Avg. Tri. Overlap	Paraphrase 1	2	3	Fluency 1	2	3
(-0.1, 0.2]	4.0	0.00±0.0	92	6	2	1	5	94
(0.2, 0.4]	3.8	0.02±0.1	53	32	15	1	12	87
(0.4, 0.6]	6.9	0.07±0.1	22	45	33	2	9	89
(0.6, 0.8]	14.4	0.17±0.2	1	43	56	11	0	89
(0.8, 1.0]	18.0	0.35±0.2	1	13	86	3	0	97

Table 3: Manual evaluation of PARANMT-50M. 100-pair samples were drawn from five ranges of the automatic paraphrase score (first column). Paraphrase strength and fluency were judged on a 1-3 scale and counts of each rating are shown.

noise can be ameliorated with filtering. Two native English speakers annotated a sample of 100 examples from each of five ranges of the Paraphrase Score.[3] We obtained annotations for both the strength of the paraphrase relationship and the fluency of the translations.

To annotate paraphrase strength, we adopted the annotation guidelines used by Agirre et al. (2012). The original guidelines specify six classes, which we reduced to three for simplicity. We combined the top two into one category, left the next, and combined the bottom three into the lowest category. Therefore, for a sentence pair to have a rating of 3, the sentences must have the same meaning, but some unimportant details can differ. To have a rating of 2, the sentences are roughly equivalent, with some important information missing or that differs slightly. For a rating of 1, the sentences are not equivalent, even if they share minor details.

For fluency of the back-translation, we use the following: A rating of 3 means it has no grammatical errors, 2 means it has one to two errors, and 1 means it has more than two grammatical errors or is not a natural English sentence.

Table 3 summarizes the annotations. For each score range, we report the number of pairs, the mean trigram overlap score, and the number of times each paraphrase/fluency label was present in the sample of 100 pairs. There is noise but it is largely confined to the bottom two ranges which together comprise only 16% of the entire dataset. In the highest paraphrase score range, 86% of the pairs possess a strong paraphrase relationship. The annotations suggest that PARANMT-50M contains approximately 30 million strong paraphrase pairs, and that the paraphrase score is a good indicator of quality. At the low ranges, we inspected the data and found there to be many errors in the sentence alignment in the original bitext. With regards to fluency, approximately 90% of the back-translations are fluent, even at the low end of the paraphrase score range. We do see an outlier at the second-highest range of the paraphrase score, but this may be due to the small number of annotated examples.

[3]Even though the similarity score lies in $[-1, 1]$, most observed scores were positive, so we chose the five ranges shown in Table 3.

4 Learning Sentence Embeddings

To show the usefulness of the PARANMT-50M dataset, we will use it to train sentence embeddings. We adopt the learning framework from Wieting et al. (2016b), which was developed to train sentence embeddings from pairs in PPDB. We first describe the compositional sentence embedding models we will experiment with, then discuss training and our modification ("mega-batching").

Models. We want to embed a word sequence s into a fixed-length vector. We denote the tth word in s as s_t, and we denote its word embedding by x_t. We focus on three model families, though we also experiment with combining them in various ways. The first, which we call WORD, simply averages the embeddings x_t of all words in s. This model was found by Wieting et al. (2016b) to perform strongly for semantic similarity tasks.

The second is similar to WORD, but instead of word embeddings, we average character trigram embeddings (Huang et al., 2013). We call this TRIGRAM. Wieting et al. (2016a) found this to work well for sentence embeddings compared to other n-gram orders and to word averaging.

The third family includes long short-term memory (LSTM) networks (Hochreiter and Schmidhuber, 1997). We average the hidden states to produce the final sentence embedding. For regularization during training, we scramble words with a small probability (Wieting and Gimpel, 2017). We also experiment with bidirectional LSTMs (BLSTM), averaging the forward and backward hidden states with no concatenation.[4]

Training. The training data is a set S of paraphrase pairs $\langle s, s' \rangle$ and we minimize a margin-

[4]Unlike Conneau et al. (2017), we found this to outperform max-pooling for both semantic similarity and general sentence embedding tasks.

based loss $\ell(s, s') =$

$$\max(0, \delta - \cos(g(s), g(s')) + \cos(g(s), g(t)))$$

where g is the model (WORD, TRIGRAM, etc.), δ is the margin, and t is a "negative example" taken from a mini-batch during optimization. The intuition is that we want the two texts to be more similar to each other than to their negative examples. To select t we choose the most similar sentence in some set. For simplicity we use the mini-batch for this set, i.e.,

$$t = \operatorname*{argmax}_{t' : \langle t', \cdot \rangle \in S_b \setminus \{\langle s, s' \rangle\}} \cos(g(s), g(t'))$$

where $S_b \subseteq S$ is the current mini-batch.

Modification: mega-batching. By using the mini-batch to select negative examples, we may be limiting the learning procedure. That is, if all potential negative examples in the mini-batch are highly dissimilar from s, the loss will be too easy to minimize. Stronger negative examples can be obtained by using larger mini-batches, but large mini-batches are sub-optimal for optimization.

Therefore, we propose a procedure we call "mega-batching." We aggregate M mini-batches to create one mega-batch and select negative examples from the mega-batch. Once each pair in the mega-batch has a negative example, the mega-batch is split back up into M mini-batches and training proceeds. We found that this provides more challenging negative examples during learning as shown in Section 5.5. Table 6 shows results for different values of M, showing consistently higher correlations with larger M values.

5 Experiments

We now investigate how best to use our generated paraphrase data for training paraphrastic sentence embeddings.

5.1 Evaluation

We evaluate sentence embeddings using the SemEval semantic textual similarity (STS) tasks from 2012 to 2016 (Agirre et al., 2012, 2013, 2014, 2015, 2016) and the STS Benchmark (Cer et al., 2017). Given two sentences, the aim of the STS tasks is to predict their similarity on a 0-5 scale, where 0 indicates the sentences are on different topics and 5 means they are completely equivalent. As our test set, we report the average Pearson's r over each year of the STS tasks from 2012-2016. We use the small (250-example) English dataset from SemEval 2017 (Cer et al., 2017) as a development set, which we call STS2017 below.

Training Corpus	WORD	TRIGRAM	LSTM
Common Crawl	80.9	80.2	79.1
CzEng 1.6	**83.6**	**81.5**	**82.5**
Europarl	78.9	78.0	80.4
News Commentary	80.2	78.2	80.5

Table 4: Pearson's $r \times 100$ on STS2017 when training on 100k pairs from each back-translated parallel corpus. CzEng works best for all models.

The supplementary material contains a description of a method to obtain a paraphrase lexicon from PARANMT-50M that is on par with that provided by PPDB 2.0. We also evaluate our sentence embeddings on a range of additional tasks that have previously been used for evaluating sentence representations (Kiros et al., 2015).

5.2 Experimental Setup

For training sentence embeddings on PARANMT-50M, we follow the experimental procedure of Wieting et al. (2016b). We use PARAGRAM-SL999 embeddings (Wieting et al., 2015) to initialize the word embedding matrix for all models that use word embeddings. We fix the mini-batch size to 100 and the margin δ to 0.4. We train all models for 5 epochs. For optimization we use Adam (Kingma and Ba, 2014) with a learning rate of 0.001. For the LSTM and BLSTM, we fixed the scrambling rate to 0.3.[5]

5.3 Dataset Comparison

We first compare parallel data sources. We evaluate the quality of a data source by using its back-translations paired with its English references as training data for paraphrastic sentence embeddings. We compare the four data sources described in Section 3. We use 100K samples from each corpus and trained 3 different models on each: WORD, TRIGRAM, and LSTM. Table 4 shows that CzEng provides the best training data for all models, so we used it to create PARANMT-50M and for all remaining experiments.

[5]As in our prior work (Wieting and Gimpel, 2017), we found that scrambling significantly improves results, even with our much larger training set. But while we previously used a scrambling rate of 0.5, we found that a smaller rate of 0.3 worked better when training on PARANMT-50M, presumably due to the larger training set.

Filtering Method	Model Avg.
Translation Score	83.2
Trigram Overlap	83.1
Paraphrase Score	**83.3**

Table 5: Pearson's $r \times 100$ on STS2017 for the best training fold across the average of WORD, TRIGRAM, and LSTM models for each filtering method.

CzEng is diverse in terms of both vocabulary and sentence structure. It has significantly shorter sentences than the other corpora, and has much more training data, so its translations are expected to be better than those in the other corpora. Wieting et al. (2017) found that sentence length was the most important factor in filtering quality training data, presumably due to how NMT quality deteriorates with longer sentences. We suspect that better translations yield better data for training sentence embeddings.

5.4 Data Filtering

Since the PARANMT-50M dataset is so large, it is computationally demanding to train sentence embeddings on it in its entirety. So, we filter the data to create a training set for sentence embeddings.

We experiment with three simple methods: (1) the length-normalized translation score from decoding, (2) trigram overlap (Wieting et al., 2017), and (3) the paraphrase score from Section 3. Trigram overlap is calculated by counting trigrams in the reference and translation, then dividing the number of shared trigrams by the total number in the reference or translation, whichever has fewer.

We filtered the back-translated CzEng data using these three strategies. We ranked all 51M+ paraphrase pairs in the dataset by the filtering measure under consideration and then split the data into tenths (so the first tenth contains the bottom 10% under the filtering criterion, the second contains those in the bottom 10-20%, etc.).

We trained WORD, TRIGRAM, and LSTM models for a single epoch on 1M examples sampled from each of the ten folds for each filtering criterion. We averaged the correlation on the STS2017 data across models for each fold. Table 5 shows the results of the filtering methods. Filtering based on the paraphrase score produces the best data for training sentence embeddings.

We randomly selected 5M examples from the top two scoring folds using paraphrase score filtering, ensuring that we only selected examples in which both sentences have a maximum length of 30 tokens.[6] These resulting 5M examples form the training data for the rest of our experiments. Note that many more than 5M pairs from the dataset are useful, as suggested by our human evaluations in Section 3.2. We have experimented with doubling the training data when training our best sentence similarity model and found the correlation increased by more than half a percentage point on average across all datasets.

M	WORD	TRIGRAM	LSTM
1	82.3	81.5	81.5
20	84.0	83.1	84.6
40	**84.1**	**83.4**	**85.0**

Table 6: Pearson's $r \times 100$ on STS2017 with different mega-batch sizes M.

original	sir, i'm just trying to protect.
negative examples:	
$M = 1$	i mean, colonel...
$M = 20$	i only ask that the baby be safe.
$M = 40$	just trying to survive. on instinct.
original	i'm looking at him, you know?
$M = 1$	they know that i've been looking for her.
$M = 20$	i'm keeping him.
$M = 40$	i looked at him with wonder.
original	i'il let it go a couple of rounds.
$M = 1$	sometimes the ball doesn't go down.
$M = 20$	i'll take two.
$M = 40$	i want you to sit out a couple of rounds, all right?

Table 7: Negative examples for various mega-batch sizes M with the BLSTM model.

5.5 Effect of Mega-Batching

Table 6 shows the impact of varying the mega-batch size M when training for 5 epochs on our 5M-example training set. For all models, larger mega-batches improve performance. There is a smaller gain when moving from 20 to 40, but all models show clear gains over $M = 1$.

Table 7 shows negative examples with different mega-batch sizes M. We use the BLSTM model and show the negative examples (nearest neighbors from the mega-batch excluding the current training example) for three sentences. Using larger mega-batches improves performance, presumably by producing more compelling negative examples for the learning procedure. This is likely more important when training on sentences than

[6] Wieting et al. (2017) found that sentence length cutoffs were effective for filtering back-translated parallel text.

Table 9: Results on STS Benchmark test set.

prior work on learning from text snippets (Wieting et al., 2015, 2016b; Pham et al., 2015).

5.6 Model Comparison

Table 8 shows results on the 2012-2016 STS tasks and Table 9 shows results on the STS Benchmark.[7] Our best models outperform all STS competition systems and all related work of which we are aware on the 2012-2016 STS datasets. Note that the large improvement over BLEU and METEOR suggests that our embeddings could be useful for evaluating machine translation output.

[7]Baseline results are from http://ixa2.si.ehu.es/stswiki/index.php/STSbenchmark, except for the unsupervised InferSent result which we computed.

Models	Mean Pearson Abs. Diff.
Word / Trigram	2.75
Word / LSTM	2.17
Trigram / LSTM	2.89

Table 10: The means (over all 25 STS competition datasets) of the absolute differences in Pearson's r between each pair of models.

Overall, our individual models (Word, Trigram, LSTM) perform similarly. Using 300 dimensions appears to be sufficient; increasing dimensionality does not necessarily improve correlation. When examining particular STS tasks, we found that our individual models showed marked differences on certain tasks. Table 10 shows the mean absolute difference in Pearson's r over all 25 datasets. The Trigram model shows the largest differences from the other two, both of which use word embeddings. This suggests that Trigram may be able to complement the other two by providing information about words that are unknown to models that rely on word embeddings.

We experiment with two ways of combining models. The first is to define additive architectures

Target Syntax	Paraphrase
original	with the help of captain picard, the borg will be prepared for everything.
`(SBARQ(ADVP)(,)(S)(,)(SQ))`	now, the borg will be prepared by picard, will it?
`(S(NP)(ADVP)(VP))`	the borg here will be prepared for everything.
original	you seem to be an excellent burglar when the time comes.
`(S(SBAR)(,)(NP)(VP))`	when the time comes, you'll be a great thief.
``(S(``)(UCP)('')(NP)(VP))``	"you seem to be a great burglar, when the time comes." you said.

Table 11: Syntactically controlled paraphrases generated by the SCPN trained on PARANMT-50M.

that form the embedding for a sentence by adding the embeddings computed by two (or more) individual models. All parameters are trained jointly just like when we train individual models; that is, we do not first train two simple models and add their embeddings. The second way is to define concatenative architectures that form a sentence embedding by concatenating the embeddings computed by individual models, and again to train all parameters jointly.

In Table 8 and Table 9, these combinations show consistent improvement over the individual models as well as the larger LSTM and BLSTM. Concatenating WORD and TRIGRAM results in the best performance on average across STS tasks, outperforming the best supervised systems from each year. We have released the pretrained model for these "WORD, TRIGRAM" embeddings. In addition to providing a strong baseline for future STS tasks, these embeddings offer the advantages of being extremely efficient to compute and being robust to unknown words.

We show the usefulness of PARANMT by also reporting the results of training the "WORD, TRIGRAM" model on SimpWiki, a dataset of aligned sentences from Simple English and standard English Wikipedia (Coster and Kauchak, 2011). It has been shown useful for training sentence embeddings in past work (Wieting and Gimpel, 2017). However, Table 8 shows that training on PARANMT leads to gains in correlation of 3 to 6 points compared to SimpWiki.

6 Paraphrase Generation

In addition to powering state-of-the-art paraphrastic sentence embeddings, our dataset is useful for paraphrase generation. We briefly describe two efforts in paraphrase generation here.

We have found that training an encoder-decoder model on PARANMT-50M can produce a paraphrase generation model that canonicalizes text. For this experiment, we used a bidirectional LSTM encoder and a two-layer LSTM decoder with soft attention over the encoded states (Bahdanau et al., 2015). The attention computation consists of a bilinear product with a learned parameter matrix. Table 12 shows examples of output generated by this model, showing how the model is able to standardize the text and correct grammatical errors. This model would be interesting to evaluate for automatic grammar correction as it does so without any direct supervision. Future work could also use this canonicalization to improve performance of models by standardizing inputs and removing noise from data.

original	overall, i that it's a decent buy, and am happy that i own it.
paraphrase	it's a good buy, and i'm happy to own it.
original	oh, that's a handsome women, that is.
paraphrase	that's a beautiful woman.

Table 12: Examples from our paraphrase generation model that show the ability to canonicalize text and correct grammatical errors.

PARANMT-50M has also been used for syntactically-controlled paraphrase generation; this work is described in detail by Iyyer et al. (2018). A syntactically controlled paraphrase network (SCPN) is trained to generate a paraphrase of a sentence whose constituent structure follows a provided parse template. A parse template contains the top two levels of a linearized parse tree. Table 11 shows example outputs using the SCPN. The paraphrases mostly preserve the semantics of the input sentences while changing their syntax to fit the target syntactic templates. The SCPN was used for augmenting training data and finding adversarial examples.

We believe that PARANMT-50M and future datasets like it can be used to generate rich paraphrases that improve the performance and robustness of models on a multitude of NLP tasks.

7 Discussion

One way to view PARANMT-50M is as a way to represent the learned translation model in a monolingual generated dataset. This raises the question of whether we could learn an effective sentence embedding model from the original parallel text used to train the NMT system, rather than requiring the intermediate step of generating a paraphrase training set.

However, while Hill et al. (2016) and Mallinson et al. (2017) used trained NMT models to produce sentence similarity scores, their correlations are considerably lower than ours (by 10% to 35% absolute in terms of Pearson). It appears that NMT encoders form representations that do not necessarily encode the semantics of the sentence in a way conducive to STS evaluations. They must instead create representations suitable for a decoder to generate a translation. These two goals of representing sentential semantics and producing a translation, while likely correlated, evidently have some significant differences.

Our use of an intermediate dataset leads to the best results, but this may be due to our efforts in optimizing learning for this setting (Wieting et al., 2016b; Wieting and Gimpel, 2017). Future work will be needed to develop learning frameworks that can leverage parallel text directly to reach the same or improved correlations on STS tasks.

8 Conclusion

We described the creation of ParaNMT-50M, a dataset of more than 50M English sentential paraphrase pairs. We showed how to use ParaNMT-50M to train paraphrastic sentence embeddings that outperform supervised systems on STS tasks, as well as how it can be used for generating paraphrases for purposes of data augmentation, robustness, and even grammar correction.

The key advantage of our approach is that it only requires parallel text. There are hundreds of millions of parallel sentence pairs, and more are being generated continually. Our procedure is immediately applicable to the wide range of languages for which we have parallel text.

We release ParaNMT-50M, our code, and pretrained sentence embeddings, which also exhibit strong performance as general-purpose representations for a multitude of tasks. We hope that ParaNMT-50M, along with our embeddings, can impart a notion of meaning equivalence to improve NLP systems for a variety of tasks. We are actively investigating ways to apply these two new resources to downstream applications, including machine translation, question answering, and additional paraphrase generation tasks.

Acknowledgments

We thank the anonymous reviewers, the developers of Theano (Theano Development Team, 2016), the developers of PyTorch (Paszke et al., 2017), and NVIDIA Corporation for donating GPUs used in this research.

Abstract

We investigate a new commonsense inference task: given an event described in a short free-form text ("X drinks coffee in the morning"), a system reasons about the likely intents ("X wants to stay awake") and reactions ("X feels alert") of the event's participants. To support this study, we construct a new crowdsourced corpus of 25,000 event phrases covering a diverse range of everyday events and situations. We report baseline performance on this task, demonstrating that neural encoder-decoder models can successfully compose embedding representations of previously unseen events and reason about the likely intents and reactions of the event participants. In addition, we demonstrate how commonsense inference on people's intents and reactions can help unveil the implicit gender inequality prevalent in modern movie scripts.

1 Introduction

Understanding a narrative requires commonsense reasoning about the mental states of people in relation to events. For example, if "Alex is dragging his feet at work", pragmatic implications about Alex's *intent* are that "Alex wants to avoid doing things" (Figure 1). We can also infer that Alex's *emotional reaction* might be feeling "lazy" or "bored". Furthermore, while not explicitly mentioned, we can infer that people other than Alex are affected by the situation, and these people are likely to feel "frustrated" or "impatient".

This type of pragmatic inference can potentially be useful for a wide range of NLP applications

[*]These two authors contributed equally.

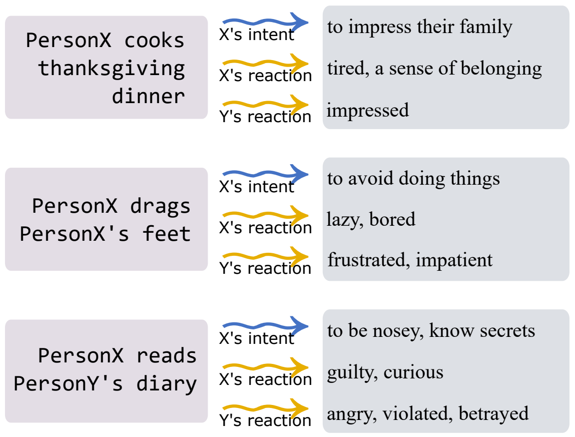

Figure 1: Examples of commonsense inference on mental states of event participants. In the third example event, common sense tells us that Y is likely to feel betrayed as a result of X reading their diary.

that require accurate anticipation of people's intents and emotional reactions, even when they are not explicitly mentioned. For example, an ideal dialogue system should react in empathetic ways by reasoning about the human user's mental state based on the events the user has experienced, without the user explicitly stating how they are feeling. Similarly, advertisement systems on social media should be able to reason about the emotional reactions of people after events such as mass shootings and remove ads for guns which might increase social distress (Goel and Isaac, 2016). Also, pragmatic inference is a necessary step toward automatic narrative understanding and generation (Tomai and Forbus, 2010; Ding and Riloff, 2016; Ding et al., 2017). However, this type of social commonsense reasoning goes far beyond the widely studied entailment tasks (Bowman et al., 2015; Dagan et al., 2006) and thus falls outside the scope of existing benchmarks.

In this paper, we introduce a new task, corpus,

PersonX's Intent	Event Phrase	PersonX's Reaction	Others' Reactions
to express anger to vent their frustration to get PersonY's full attention	**PersonX starts to yell at PersonY**	mad frustrated annoyed	shocked humiliated mad at PersonX
to communicate something without being rude to let the other person think for themselves to be subtle	**PersonX drops a hint**	sly secretive frustrated	oblivious surprised grateful
to catch the criminal to be civilized justice	**PersonX reports ___ to the police**	anxious worried nervous	sad angry regret
to wake up to feel more energized	**PersonX drinks a cup of coffee**	alert awake refreshed	NONE
to be feared to be taken seriously to exact revenge	**PersonX carries out PersonX's threat**	angry dangerous satisfied	sad afraid angry
NONE	**It starts snowing**	NONE	calm peaceful cold

Table 1: Example annotations of intent and reactions for 6 event phrases. Each annotator could fill in up to three free-responses for each mental state.

and model, supporting commonsense inference on events with a specific focus on modeling stereotypical intents and reactions of people, described in short free-form text. Our study is in a similar spirit to recent efforts of Ding and Riloff (2016) and Zhang et al. (2017), in that we aim to model aspects of commonsense inference via natural language descriptions. Our new contributions are: (1) a new corpus that supports commonsense inference about people's intents and reactions over a diverse range of everyday events and situations, (2) inference about even those people who are not directly mentioned by the event phrase, and (3) a task formulation that aims to *generate* the textual descriptions of intents and reactions, instead of classifying their polarities or classifying the inference relations between two given textual descriptions.

Our work establishes baseline performance on this new task, demonstrating that, given the phrase-level inference dataset, neural encoder-decoder models can successfully compose phrasal embeddings for previously unseen events and reason about the mental states of their participants.

Furthermore, in order to showcase the practical implications of commonsense inference on events and people's mental states, we apply our model to modern movie scripts, which provide a new insight into the gender bias in modern films beyond what previous studies have offered (England et al., 2011; Agarwal et al., 2015; Ramakrishna et al., 2017; Sap et al., 2017). The resulting corpus includes around 25,000 event phrases, which combine automatically extracted phrases from stories and blogs with all idiomatic verb phrases listed in the Wiktionary. Our corpus is publicly available.[1]

2 Dataset

One goal of our investigation is to probe whether it is feasible to build computational models that can perform limited, but well-scoped commonsense inference on short free-form text, which we refer to as *event phrases*. While there has been much prior research on phrase-level paraphrases (Pavlick et al., 2015) and phrase-level entailment (Dagan et al., 2006), relatively little prior work focused on phrase-level inference that requires prag-

[1]https://tinyurl.com/event2mind

matic or commonsense interpretation. We scope our study to two distinct types of inference: given a phrase that describes an event, we want to reason about the likely intents and emotional reactions of people who caused or affected by the event. This complements prior work on more general commonsense inference (Speer and Havasi, 2012; Li et al., 2016; Zhang et al., 2017), by focusing on the causal relations between events and people's mental states, which are not well covered by most existing resources.

We collect a wide range of phrasal event descriptions from stories, blogs, and Wiktionary idioms. Compared to prior work on phrasal embeddings (Wieting et al., 2015; Pavlick et al., 2015), our work generalizes the phrases by introducing (typed) variables. In particular, we replace words that correspond to entity mentions or pronouns with typed variables such as `PersonX` or `PersonY`, as shown in examples in Table 1. More formally, the phrases we extract are a combination of a verb predicate with partially instantiated arguments. We keep specific arguments together with the predicate, if they appear frequently enough (e.g., `PersonX eats pasta for dinner`). Otherwise, the arguments are replaced with an untyped blank (e.g., `PersonX eats ___ for dinner`). In our work, only person mentions are replaced with typed variables, leaving other types to future research.

Inference types The first type of pragmatic inference is about *intent*. We define intent as an explanation of why the agent causes a volitional event to occur (or "none" if the event phrase was unintentional). The intent can be considered a mental pre-condition of an action or an event. For example, if the event phrase is `PersonX takes a stab at ___`, the annotated intent might be that "PersonX wants to solve a problem".

The second type of pragmatic inference is about *emotional reaction*. We define reaction as an explanation of how the mental states of the agent and other people involved in the event would change as a result. The reaction can be considered a mental post-condition of an action or an event. For example, if the event phrase is that `PersonX gives PersonY ___ as a gift`, PersonX might "feel good about themselves" as a result, and PersonY might "feel grateful" or "feel thankful".

Source	# Unique Events	# Unique Verbs	Average κ
