$$P_{copy}(w) = \sum_{i=1}^{n} \alpha_t^i * \mathbb{1}\{w == w_i\} \tag{11}$$

Finally, we obtain the probability distribution over the dynamic vocabulary (i.e., union of original target side and source sentence vocabulary) by summing over P_{copy} and P_{vocab},

$$P(w) = \lambda_t^{copy} P_{copy}(w) + (1 - \lambda_t^{copy}) P_{vocab}(w) \tag{12}$$

where σ is the sigmoid function, and $\mathbf{W}_d$, $\mathbf{W}_e$, $\mathbf{W}_f$ are weight matrices.

4.2 Answer Span Identification

We frame the problem of identifying candidate answer spans from a paragraph as a sequence labeling task and base our model on the BiLSTM-CRF approach for named entity recognition (Huang et al., 2015). Given a paragraph of n tokens, instead of directly feeding the sequence of word vectors $\mathbf{x} = (x_1, ..., x_n)$ to the LSTM units, we first construct the feature-rich embedding $\mathbf{x}'$ for each token, which is the concatenation of the word embedding, an NER feature embedding, and a character-level representation of the word (Lample et al., 2016). We use the concatenated vector as the "final" embedding $\mathbf{x}'$ for the token,

$$x_i' = \text{concat}(x_i, \text{CharRep}_i, \text{NER}_i) \tag{13}$$

where CharRep_i is the concatenation of the last hidden states of a character-based biLSTM. The intuition behind the use of NER features is that SQuAD answer spans contain a large number of named entities, numeric phrases, etc.

Then a multi-layer Bi-directional LSTM is applied to $(x_1', ..., x_n')$ and we obtain the output state

z_t for time step t by concatenation of the hidden states (forward and backward) at time step t from the last layer of the BiLSTM. We apply the softmax to $(z_1, ..., z_n)$ to get the normalized score representation for each token, which is of size $n \times k$, where k is the number of tags.

Instead of using a softmax training objective that minimizes the cross-entropy loss for each individual word, the model is trained with a CRF (Lafferty et al., 2001) objective, which minimizes the negative log-likelihood for the entire correct sequence: $-\log(p_{\mathbf{y}})$,

$$p_{\mathbf{y}} = \frac{\exp(q(\mathbf{x}', \mathbf{y}))}{\sum_{\mathbf{y}' \in \mathbf{Y}'} \exp(q(\mathbf{x}', \mathbf{y}'))} \quad (14)$$

where $q(\mathbf{x}', \mathbf{y}) = \sum_{t=1}^{n} P_{t,y_t} + \sum_{t=0}^{n-1} A_{y_t, y_{t+1}}$, P_{t,y_t} is the score of assigning tag y_t to the t^{th} token, and $A_{y_t,y_{t+1}}$ is the transition score from tag y_t to y_{t+1}, the scoring matrix A is to be learned. $\mathbf{Y}'$ represents all the possible tagging sequences.

5 Experiments

5.1 Dataset

We use the SQuAD dataset (Rajpurkar et al., 2016) to train our models. It is one of the largest general purpose QA datasets derived from Wikipedia with over 100k questions posed by crowdworkers on a set of Wikipedia articles. The answer to each question is a segment of text from the corresponding Wiki passage. The crowdworkers were users of Amazon's Mechanical Turk located in the US or Canada. To obtain high-quality articles, the authors sampled 500 articles from the top 10,000 articles obtained by Nayuki's Wikipedia's internal PageRanks. The question-answer pairs were generated by annotators from a paragraph; and although the dataset is typically used to evaluate reading comprehension, it has also been used in an open domain QA setting (Chen et al., 2017; Wang et al., 2018). For training/testing answer extraction systems, we pair each paragraph in the dataset with the gold answer spans that it contains. For the question generation system, we pair each sentence that contains an answer span with the corresponding gold question as in Du et al. (2017).

To quantify the effect of using predicted (rather than gold standard) answer spans on question generation (e.g., predicted answer span boundaries can be inaccurate), we also train the models on an augmented "Training set w/ noisy examples" (see Table 2). This training set contains all of the original training examples *plus* new examples for predicted answer spans (from the top-performing answer extraction model, bottom row of Table 3) that *overlap* with a gold answer span. We pair the new training sentence (w/ predicted answer span) with the gold question. The added examples comprise 42.21% of the noisy example training set.

For generation of our one million QA pair corpus, we apply our systems to the 10,000 top-ranking articles of Wikipedia.

5.2 Evaluation Metrics

For question generation evaluation, we use BLEU (Papineni et al., 2002) and METEOR (Denkowski and Lavie, 2014).[1] BLEU measures average n-gram precision vs. a set of reference questions and penalizes for overly short sentences. METEOR is a recall-oriented metric that takes into account synonyms, stemming, and paraphrases.

For answer candidate extraction evaluation, we use precision, recall and F-measure vs. the gold standard SQuAD answers. Since answer boundaries are sometimes ambiguous, we compute *Binary Overlap* and *Proportional Overlap* metrics in addition to *Exact Match*. Binary Overlap counts every predicted answer that overlaps with a gold answer span as correct, and Proportional Overlap give partial credit proportional to the amount of overlap (Johansson and Moschitti, 2010; Irsoy and Cardie, 2014).

5.3 Baselines and Ablation Tests

For question generation, we compare to the state-of-the-art baselines and conduct ablation tests as follows: **Du et al. (2017)**'s model is an attention-based RNN sequence-to-sequence neural network (without using the answer location information feature). **Seq2seq + copy$_{\text{w/ answer}}$** is the attention-based sequence-to-sequence model augmented with a copy mechanism, with answer features concatenated with the word embeddings during encoding. **Seq2seq + copy$_{\text{w/ full context + answer}}$** is the same model as the previous one, but we allow access to the full context (i.e., all the preceding sentences and the input sentence itself). We denote it as **ContextNQG** henceforth for simplicity. **CorefNQG** is the coreference-based model proposed in this paper. **CorefNQG–gating** is an

[1]We use the evaluation scripts of Du et al. (2017).

Models	Training set			Training set w/ noisy examples		
	BLEU-3	BLEU-4	METEOR	BLEU-3	BLEU-4	METEOR
Baseline (Du et al., 2017) (w/o answer)	17.50	12.28	16.62	15.81	10.78	15.31
Seq2seq + copy (w/ answer)	20.01	14.31	18.50	19.61	13.96	18.19
ContextNQG: Seq2seq + copy (w/ full context + answer)	20.31	14.58	18.84	19.57	14.05	18.19
CorefNQG	**20.90**	**15.16**	**19.12**	**20.19**	**14.52**	18.59
- gating	20.68	14.84	18.98	20.08	14.40	**18.64**
- mention-pair score	20.56	14.75	18.85	19.73	14.13	18.38

Table 2: Evaluation results for question generation.

Models	Precision			Recall			F-measure		
	Prop.	Bin.	Exact	Prop.	Bin.	Exact	Prop.	Bin.	Exact
NER	24.54	25.94	12.77	**58.20**	**67.66**	**38.52**	34.52	37.50	19.19
BiLSTM	43.54	45.08	22.97	28.43	35.99	18.87	34.40	40.03	20.71
BiLSTM w/ NER	44.35	46.02	25.33	33.30	40.81	23.32	38.04	43.26	24.29
BiLSTM-CRF w/ char	**49.35**	**51.92**	**38.58**	30.53	32.75	24.04	37.72	40.16	29.62
BiLSTM-CRF w/ char w/ NER	45.96	51.61	33.90	41.05	43.98	28.37	**43.37**	**47.49**	**30.89**

Table 3: Evaluation results of answer extraction systems.

ablation test, the gating network is removed and the coreference position embedding is not refined. **CorefNQG–mention-pair score** is also an ablation test where all mention-pair $score_i$ are set to zero.

For answer span extraction, we conduct experiments to compare the performance of an off-the-shelf NER system and BiLSTM based systems.

For **training and implementation details**, please see the Supplementary Material.

6 Results and Analysis

6.1 Automatic Evaluation

Table 2 shows the BLEU-$\{3, 4\}$ and METEOR scores of different models. Our CorefNQG outperforms the seq2seq baseline of Du et al. (2017) by a large margin. This shows that the copy mechanism, answer features and coreference resolution all aid question generation. In addition, CorefNQG outperforms both Seq2seq+Copy models significantly, whether or not they have access to the full context. This demonstrates that the coreference knowledge encoded with the gating network explicitly helps with the training and generation: it is more difficult for the neural sequence model to learn the coreference knowledge in a latent way. (See input 1 in Figure 3 for an example.) Building end-to-end models that take into account coreference knowledge in a latent way is an interesting direction to explore. In the ablation tests, the performance drop of CorefNQG–gating

	BLEU-3	BLEU-4	METEOR
Seq2seq + copy (w/ ans.)	17.81	12.30	17.11
ContextNQG	18.05	12.53	17.33
CorefNQG	**18.46**	**12.96**	**17.58**

Table 4: Evaluation results for question generation on the portion that requires coreference knowledge (36.42% examples of the original test set).

shows that the gating network is playing an important role for getting *refined* coreference position feature embedding, which helps the model learn the importance of an antecedent. The performance drop of CorefNQG–mention-pair score shows the mention-pair score introduced from the external system (Clark and Manning, 2016) helps the neural network better encode coreference knowledge.

To better understand the effect of coreference resolution, we also evaluate our model and the baseline models on just that portion of the test set that requires pronoun resolution (36.42% of the examples) and show the results in Table 4. The gaps of performance between our model and the baseline models are still significant. Besides, we see that all three systems' performance drop on this partial test set, which demonstrates the hardness of generating questions for the cases that require pronoun resolution (passage context).

We also show in Table 2 the results of the QG models trained on the training set augmented with noisy examples with predicted answer spans.

Input 1: The elizabethan navigator, sir francis drake was born in the nearby town of tavistock and was the mayor of plymouth. ... . he died of dysentery in 1596 off the coast of puerto rico.
Human: In what year did Sir Francis Drake die ?
ContextNQG: When did he die ?
CorefNQG: When did sir francis drake die ?

Input 2: american idol is an american singing competition ... . it began airing on fox on june 11 , 2002, as an addition to the idols format based on the british series pop idol and has since become one of the most successful shows in the history of american television.
Human: When did american idol first air on tv ?
ContextNQG: When did fox begin airing ?
CorefNQG: When did american idol begin airing ?

Input 3: ... the a38 dual-carriageway runs from east to west across the north of the city . within the city it is designated as ' the parkway ' and represents the boundary between the urban parts of the city and the generally more recent suburban areas .
Human: What is the a38 called inside the city ?
ContextNQG: What is another name for the city ?
CorefNQG: What is the city designated as ?

Figure 3: Example questions (with answers highlighted) generated by human annotators (ground truth questions), by our system CorefNQG, and by the Seq2seq+Copy model trained with full context (i.e., ContextNQG).

There is a consistent but acceptable drop for each model on this new training set, given the inaccuracy of predicted answer spans. We see that CorefNQG still outperforms the baseline models across all metrics.

Figure 3 provides sample output for input sentences that require contextual coreference knowledge. We see that ContextNQG fails in all cases; our model misses only the third example due to an error introduced by coreference resolution — the "city" and "it" are considered coreferent. We can also see that human-generated questions are more natural and varied in form with better paraphrasing.

In Table 3, we show the evaluation results for different answer extraction models. First we see that all variants of BiLSTM models outperform the off-the-shelf NER system (that proposes all NEs as answer spans), though the NER system has a higher recall. The BiLSTM-CRF that encodes the character-level and NER features for each token performs best in terms of F-measure.

6.2 Human Study

We hired four native speakers of English to rate the systems' outputs. Detailed guidelines for the raters are listed in the supplementary materials.

	Grammaticality	Making Sense	Answerability	Avg. rank
ContextNQG	3.793	3.836	3.892	1.768
CorefNQG	3.804*	3.847**	3.895*	1.762
Human	**3.807**	**3.850**	**3.902**	**1.758**

Table 5: Human evaluation results for question generation. "Grammaticality", "Making Sense" and "Answerability" are rated on a 1–5 scale (5 for the best, see the supplementary materials for a detailed rating scheme), "Average rank" is rated on a 1–3 scale (1 for the most preferred, ties are allowed.) Two-tailed t-test results are shown for our method compared to ContextNQG (stat. significance is indicated with $^{*}(p < 0.05)$, $^{**}(p < 0.01)$.)

The evaluation can also be seen as a measure of the quality of the generated dataset (Section 6.3). We randomly sampled 11 passages/paragraphs from the test set; there are in total around 70 question-answer pairs for evaluation.

We consider three metrics — "grammaticality", "making sense" and "answerability". The evaluators are asked to first rate the grammatical correctness of the generated question (before being shown the associated input sentence or any other textual context). Next, we ask them to rate the degree to which the question "makes sense" given the input sentence (i.e., without considering the correctness of the answer span). Finally, evaluators rate the "answerability" of the question given the full context.

Table 5 shows the results of the human evaluation. Bold indicates top scores. We see that the original human questions are preferred over the two NQG systems' outputs, which is understandable given the examples in Figure 3. The human-generated questions make more sense and correspond better with the provided answers, particularly when they require information in the preceding context. How exactly to capture the preceding context so as to *ask* better and more diverse questions is an interesting future direction for research. In terms of grammaticality, however, the neural models do quite well, achieving very close to human performance. In addition, we see that our method (CorefNQG) performs statistically significantly better across all metrics in comparison to the baseline model (ContextNQG), which has access to the entire preceding context in the passage.

6.3 The Generated Corpus

Our system generates in total 1,259,691 question-answer pairs, nearly 126 questions per article. Figure 5 shows the distribution of different types of

	Exact Match		F-1	
	Dev	Test	Dev	Test
DocReader (Chen et al., 2017)	82.33	81.65	88.20	87.79

Table 6: Performance of the neural machine reading comprehension model (no initialization with pretrained embeddings) on our generated corpus.

The United States of America (USA), commonly referred to as the United States (U.S.) or America, is a federal republic composed of states, a federal district, five major self-governing territories, and various possessions. ... . The territories are scattered about the Pacific Ocean and the Caribbean Sea. Nine time zones are covered. The geography, climate and wildlife of the country are extremely diverse.
Q1: What is another name for the united states of america ?
Q2: How many major territories are in the united states?
Q3: What are the territories scattered about ?

Figure 4: Example question-answer pairs from our generated corpus.

questions in our dataset vs. the SQuAD training set. We see that the distribution for "In what", "When", "How long", "Who", "Where", "What does" and "What do" questions in the two datasets is similar. Our system generates more "What is", "What was" and "What percentage" questions, while the proportions of "What did", "Why" and "Which" questions in SQuAD are larger than ours. One possible reason is that the "Why", "What did" questions are more *complicated* to ask (sometimes involving world knowledge) and the answer spans are longer phrases of various types that are harder to identify. "What is" and "What was" questions, on the other hand, are often *safer* for the neural networks systems to ask.

In Figure 4, we show some examples of the generated question-answer pairs. The answer extractor identifies the answer span boundary well and all three questions correspond to their answers. Q2 is valid but not entirely accurate. For more examples, please refer to our supplementary materials.

Table 6 shows the performance of a top-performing system for the SQuAD dataset (Document Reader (Chen et al., 2017)) when applied to the development and test set portions of our generated dataset. The system was trained on the training set portion of our dataset. We use the SQuAD evaluation scripts, which calculate exact match (EM) and F-1 scores.[2] Performance of the

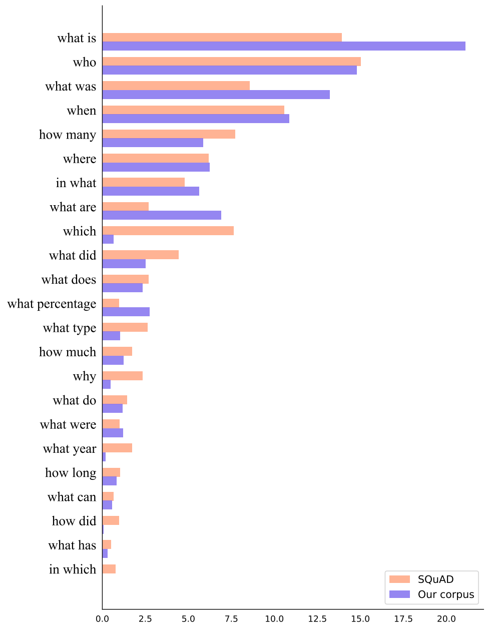

Figure 5: Distribution of question types of our corpus and SQuAD training set. The categories are the ones used in Wang et al. (2016), we add one more category: "what percentage".

neural machine reading model is reasonable. We also train the DocReader on our training set and test the models' performance on the *original* dev set of SQuAD; for this, the performance is around 45.2% on EM and 56.7% on F-1 metric. DocReader trained on the *original* SQuAD training set achieves 69.5% EM, 78.8% F-1 indicating that our dataset is more difficult and/or less natural than the crowd-sourced QA pairs of SQuAD.

7 Conclusion

We propose a new neural network model for better encoding coreference knowledge for paragraph-level question generation. Evaluations with different metrics on the SQuAD machine reading dataset show that our model outperforms state-of-the-art baselines. The ablation study shows the effectiveness of different components in our model. Finally, we apply our question generation framework to produce a corpus of 1.26 million question-answer pairs, which we hope will benefit the QA research community. It would also be interesting to apply our approach to incorporating coreference knowledge to other text generation tasks.

Acknowledgments

We thank the anonymous reviewers and members of Cornell NLP group for helpful comments.

[2]F-1 measures the average overlap between the predicted answer span and ground truth answer (Rajpurkar et al., 2016).

Abstract

Machine reading comprehension (MRC) on real web data usually requires the machine to answer a question by analyzing multiple passages retrieved by search engine. Compared with MRC on a single passage, multi-passage MRC is more challenging, since we are likely to get multiple confusing answer candidates from different passages. To address this problem, we propose an end-to-end neural model that enables those answer candidates from different passages to verify each other based on their content representations. Specifically, we jointly train three modules that can predict the final answer based on three factors: the answer boundary, the answer content and the cross-passage answer verification. The experimental results show that our method outperforms the baseline by a large margin and achieves the state-of-the-art performance on the English MS-MARCO dataset and the Chinese DuReader dataset, both of which are designed for MRC in real-world settings.

1 Introduction

Machine reading comprehension (MRC), empowering computers with the ability to acquire knowledge and answer questions from textual data, is believed to be a crucial step in building a general intelligent agent (Chen et al., 2016). Recent years have seen rapid growth in the MRC community. With the release of various datasets, the MRC task has evolved from the early cloze-style test (Hermann et al., 2015; Hill et al., 2015) to answer extraction from a single passage (Rajpurkar et al., 2016) and to the latest more complex question answering on web data (Nguyen et al., 2016; Dunn et al., 2017; He et al., 2017).

*This work was done while the first author was doing internship at Baidu Inc.

Great efforts have also been made to develop models for these MRC tasks , especially for the answer extraction on single passage (Wang and Jiang, 2016; Seo et al., 2016; Pan et al., 2017). A significant milestone is that several MRC models have exceeded the performance of human annotators on the SQuAD dataset[1] (Rajpurkar et al., 2016). However, this success on single Wikipedia passage is still not adequate, considering the ultimate goal of reading the whole web. Therefore, several latest datasets (Nguyen et al., 2016; He et al., 2017; Dunn et al., 2017) attempt to design the MRC tasks in more realistic settings by involving search engines. For each question, they use the search engine to retrieve multiple passages and the MRC models are required to read these passages in order to give the final answer.

One of the intrinsic challenges for such multi-passage MRC is that since all the passages are question-related but usually independently written, it's probable that multiple confusing answer candidates (correct or incorrect) exist. Table 1 shows an example from MS-MARCO. We can see that all the answer candidates have semantic matching with the question while they are literally different and some of them are even incorrect. As is shown by Jia and Liang (2017), these confusing answer candidates could be quite difficult for MRC models to distinguish. Therefore, special consideration is required for such multi-passage MRC problem.

In this paper, we propose to leverage the answer candidates from different passages to verify the final correct answer and rule out the noisy incorrect answers. Our hypothesis is that the cor-

Question: What is the difference between a mixed and pure culture?

Passages:

[1] **A culture is a society's total way of living and a society is a group that live in a defined territory and participate in common culture.** While the answer given is in essence true, societies originally form for the express purpose to enhance . . .

[2] . . . There has been resurgence in the economic system known as capitalism during the past two decades. 4. **The mixed economy is a balance between socialism and capitalism.** As a result, some institutions are owned and maintained by . . .

[3] **A pure culture is one in which only one kind of microbial species is found whereas in mixed culture two or more microbial species formed colonies.** Culture on the other hand, is the lifestyle that the people in the country . . .

[4] Best Answer: **A pure culture comprises a single species or strains. A mixed culture is taken from a source and may contain multiple strains or species.** A contaminated culture contains organisms that derived from some place . . .

[5] . . . It will be at that time when we can truly obtain a pure culture. **A pure culture is a culture consisting of only one strain.** You can obtain a pure culture by picking out a small portion of the mixed culture . . .

[6] **A pure culture is one in which only one kind of microbial species is found whereas in mixed culture two or more microbial species formed colonies.** A pure culture is a culture consisting of only one strain. . . .

. . . . . .

Reference Answer: A pure culture is one in which only one kind of microbial species is found whereas in mixed culture two or more microbial species formed colonies.

Table 1: An example from MS-MARCO. The text in bold is the predicted answer candidate from each passage according to the boundary model. The candidate from [1] is chosen as the final answer by this model, while the correct answer is from [6] and can be verified by the answers from [3], [4], [5].

rect answers could occur more frequently in those passages and usually share some commonalities, while incorrect answers are usually different from one another. The example in Table 1 demonstrates this phenomenon. We can see that the answer candidates extracted from the last four passages are all valid answers to the question and they are semantically similar to each other, while the answer candidates from the other two passages are incorrect and there is no supportive information from other passages. As human beings usually compare the answer candidates from different sources to deduce the final answer, we hope that MRC model can also benefit from the cross-passage answer verification process.

The overall framework of our model is demonstrated in Figure 1 , which consists of three modules. First, we follow the boundary-based MRC models (Seo et al., 2016; Wang and Jiang, 2016) to find an answer candidate for each passage by identifying the start and end position of the answer (Figure 2). Second, we model the meanings of the answer candidates extracted from those passages and use the content scores to measure the quality of the candidates from a second perspective. Third, we conduct the answer verification by enabling each answer candidate to attend to the other candidates based on their representations. We hope that the answer candidates can collect supportive information from each other according to their semantic similarities and further decide whether each candidate is correct or not. Therefore, the final answer is determined by three factors: the boundary, the content and the cross-passage answer verification. The three steps are modeled using different modules, which can be jointly trained in our end-to-end framework.

We conduct extensive experiments on the MS-MARCO (Nguyen et al., 2016) and DuReader (He et al., 2017) datasets. The results show that our answer verification MRC model outperforms the baseline models by a large margin and achieves the state-of-the-art performance on both datasets.

2 Our Approach

Figure 1 gives an overview of our multi-passage MRC model which is mainly composed of three modules including answer boundary prediction, answer content modeling and answer verification. First of all, we need to model the question and passages. Following Seo et al. (2016), we compute the question-aware representation for each passage (Section 2.1). Based on this representation, we employ a Pointer Network (Vinyals et al., 2015) to predict the start and end position of the answer in the module of answer boundary prediction (Section 2.2). At the same time, with the answer content model (Section 2.3), we estimate whether each word should be included in the answer and thus obtain the answer representations. Next, in the answer verification module (Section 2.4), each answer candidate can attend to the other answer candidates to collect supportive information and we compute one score for each candidate

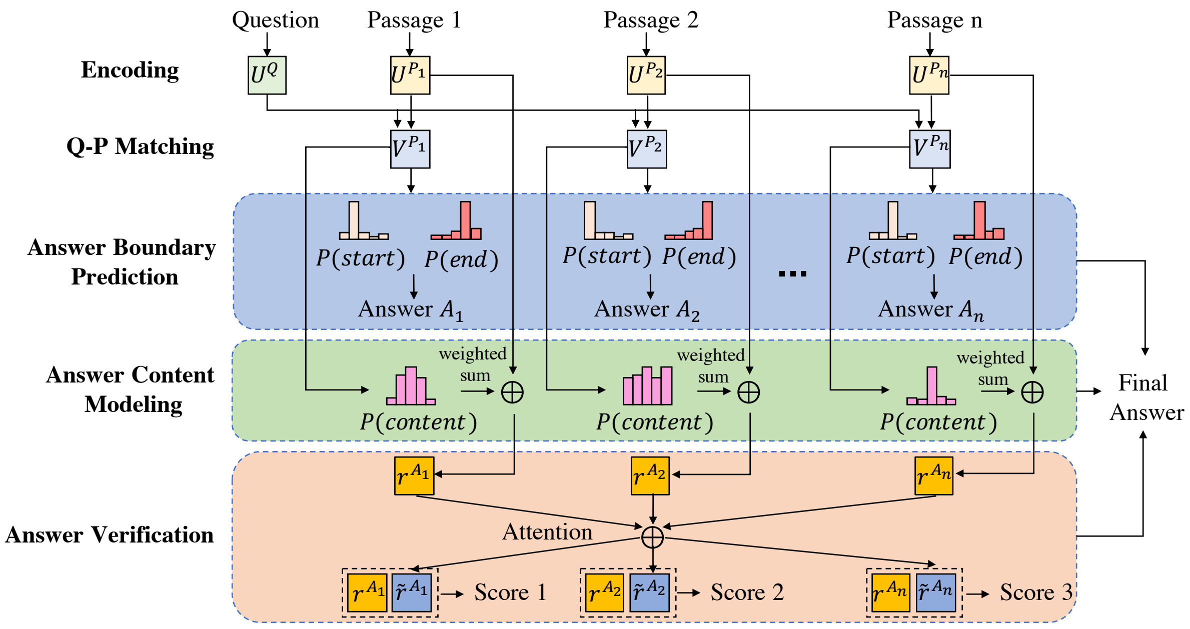

Figure 1: Overview of our method for multi-passage machine reading comprehension

to indicate whether it is correct or not according to the verification. The final answer is determined by not only the boundary but also the answer content and its verification score (Section 2.5).

2.1 Question and Passage Modeling

Given a question $\mathbf{Q}$ and a set of passages $\{\mathbf{P}_i\}$ retrieved by search engines, our task is to find the best concise answer to the question. First, we formally present the details of modeling the question and passages.

Encoding We first map each word into the vector space by concatenating its word embedding and sum of its character embeddings. Then we employ bi-directional LSTMs (BiLSTM) to encode the question $\mathbf{Q}$ and passages $\{\mathbf{P}_i\}$ as follows:

$$\mathbf{u}_t^Q = \text{BiLSTM}_Q(\mathbf{u}_{t-1}^Q, [\mathbf{e}_t^Q, \mathbf{c}_t^Q]) \quad (1)$$

$$\mathbf{u}_t^{P_i} = \text{BiLSTM}_P(\mathbf{u}_{t-1}^{P_i}, [\mathbf{e}_t^{P_i}, \mathbf{c}_t^{P_i}]) \quad (2)$$

where $\mathbf{e}_t^Q$, $\mathbf{c}_t^Q$, $\mathbf{e}_t^{P_i}$, $\mathbf{c}_t^{P_i}$ are the word-level and character-level embeddings of the t^{th} word. $\mathbf{u}_t^Q$ and $\mathbf{u}_t^{P_i}$ are the encoding vectors of the t^{th} words in $\mathbf{Q}$ and $\mathbf{P}_i$ respectively. Unlike previous work (Wang et al., 2017c) that simply concatenates all the passages, we process the passages independently at the encoding and matching steps.

Q-P Matching One essential step in MRC is to match the question with passages so that important information can be highlighted. We use the Attention Flow Layer (Seo et al., 2016) to conduct the Q-P matching in two directions. The similarity matrix $\mathbf{S} \in \mathbb{R}^{|\mathbf{Q}|\times|\mathbf{P}_i|}$ between the question and passage i is changed to a simpler version, where the similarity between the t^{th} word in the question and the k^{th} word in passage i is computed as:

$$\mathbf{S}_{t,k} = \mathbf{u}_t^{Q\top} \cdot \mathbf{u}_k^{P_i} \quad (3)$$

Then the context-to-question attention and question-to-context attention is applied strictly following Seo et al. (2016) to obtain the question-aware passage representation $\{\tilde{\mathbf{u}}_t^{P_i}\}$. We do not give the details here due to space limitation. Next, another BiLSTM is applied in order to fuse the contextual information and get the new representation for each word in the passage, which is regarded as the match output:

$$\mathbf{v}_t^{P_i} = \text{BiLSTM}_M(\mathbf{v}_{t-1}^{P_i}, \tilde{\mathbf{u}}_t^{P_i}) \quad (4)$$

Based on the passage representations, we introduce the three main modules of our model.

2.2 Answer Boundary Prediction

To extract the answer span from passages, mainstream studies try to locate the boundary of the answer, which is called boundary model. Following (Wang and Jiang, 2016), we employ Pointer Network (Vinyals et al., 2015) to compute the probability of each word to be the start or end position of the span:

$$g_k^t = \mathbf{w}_1^{a\intercal} \tanh(\mathbf{W}_2^a[\mathbf{v}_k^P, \mathbf{h}_{t-1}^a]) \quad (5)$$

$$\alpha_k^t = \exp(g_k^t) / \sum\nolimits_{j=1}^{|\mathbf{P}|} \exp(g_j^t) \quad (6)$$

$$\mathbf{c}_t = \sum\nolimits_{k=1}^{|\mathbf{P}|} \alpha_k^t \mathbf{v}_k^P \quad (7)$$

$$\mathbf{h}_t^a = \text{LSTM}(\mathbf{h}_{t-1}^a, \mathbf{c}_t) \quad (8)$$

By utilizing the attention weights, the probability of the k^{th} word in the passage to be the start and end position of the answer is obtained as α_k^1 and α_k^2. It should be noted that the pointer network is applied to the concatenation of all passages, which is denoted as P so that the probabilities are comparable across passages. This boundary model can be trained by minimizing the negative log probabilities of the true start and end indices:

$$\mathcal{L}_{boundary} = -\frac{1}{N}\sum_{i=1}^{N}(\log \alpha_{y_i^1}^1 + \log \alpha_{y_i^2}^2) \quad (9)$$

where N is the number of samples in the dataset and y_i^1, y_i^2 are the gold start and end positions.

2.3 Answer Content Modeling

Previous work employs the boundary model to find the text span with the maximum boundary score as the final answer. However, in our context, besides locating the answer candidates, we also need to model their meanings in order to conduct the verification. An intuitive method is to compute the representation of the answer candidates separately after extracting them, but it could be hard to train such model end-to-end. Here, we propose a novel method that can obtain the representation of the answer candidates based on probabilities.

Specifically, we change the output layer of the classic MRC model. Besides predicting the boundary probabilities for the words in the passages, we also predict whether each word should be included in the content of the answer. The content probability of the k^{th} word is computed as:

$$p_k^c = \text{sigmoid}(\mathbf{w}_1^{c\intercal}\text{ReLU}(\mathbf{W}_2^c \mathbf{v}_k^{P_i})) \quad (10)$$

Training this content model is also quite intuitive. We transform the boundary labels into a continuous segment, which means the words within the answer span will be labeled as 1 and other words will be labeled as 0. In this way, we define the loss function as the averaged cross entropy:

$$\mathcal{L}_{content} = -\frac{1}{N}\frac{1}{|\text{P}|}\sum_{i=1}^{N}\sum_{j=1}^{|P|}[y_k^c \log p_k^c + (1-y_k^c)\log(1-p_k^c)] \quad (11)$$

The content probabilities provide another view to measure the quality of the answer in addition to the boundary. Moreover, with these probabilities, we can represent the answer from passage i as a weighted sum of all the word embeddings in this passage:

$$\mathbf{r}^{A_i} = \frac{1}{|\mathbf{P}_i|}\sum\nolimits_{k=1}^{|\mathbf{P}_i|} p_k^c[\mathbf{e}_k^{P_i}, \mathbf{c}_k^{P_i}] \quad (12)$$

2.4 Cross-Passage Answer Verification

The boundary model and the content model focus on extracting and modeling the answer within a single passage respectively, with little consideration of the cross-passage information. However, as is discussed in Section 1, there could be multiple answer candidates from different passages and some of them may mislead the MRC model to make an incorrect prediction. It's necessary to aggregate the information from different passages and choose the best one from those candidates. Therefore, we propose a method to enable the answer candidates to exchange information and verify each other through the cross-passage answer verification process.

Given the representation of the answer candidates from all passages $\{\mathbf{r}^{A_i}\}$, each answer candidate then attends to other candidates to collect supportive information via attention mechanism:

$$s_{i,j} = \begin{cases} 0, & \text{if } i = j, \\ \mathbf{r}^{A_i\intercal} \cdot \mathbf{r}^{A_j}, & \text{otherwise} \end{cases} \quad (13)$$

$$\alpha_{i,j} = \exp(s_{i,j}) / \sum\nolimits_{k=1}^{n} \exp(s_{i,k}) \quad (14)$$

$$\tilde{\mathbf{r}}^{A_i} = \sum\nolimits_{j=1}^{n} \alpha_{i,j}\mathbf{r}^{A_j} \quad (15)$$

Here $\tilde{\mathbf{r}}^{A_i}$ is the collected verification information from other passages based on the attention weights. Then we pass it together with the original representation $\mathbf{r}^{A_i}$ to a fully connected layer:

$$g_i^v = \mathbf{w}^{v\intercal}[\mathbf{r}^{A_i}, \tilde{\mathbf{r}}^{A_i}, \mathbf{r}^{A_i} \odot \tilde{\mathbf{r}}^{A_i}] \quad (16)$$

We further normalize these scores over all passages to get the verification score for answer candidate A_i:

$$p_i^v = \exp(g_i^v) / \sum\nolimits_{j=1}^{n} \exp(g_j^v) \quad (17)$$

In order to train this verification model, we take the answer from the gold passage as the gold answer. And the loss function can be formulated as the negative log probability of the correct answer:

$$\mathcal{L}_{verify} = -\frac{1}{N}\sum_{i=1}^{N} \log p^v_{y_i^v} \tag{18}$$

where y_i^v is the index of the correct answer in all the answer candidates of the i^{th} instance .

2.5 Joint Training and Prediction

As is described above, we define three objectives for the reading comprehension model over multiple passages: 1. finding the boundary of the answer; 2. predicting whether each word should be included in the content; 3. selecting the best answer via cross-passage answer verification. According to our design, these three tasks can share the same embedding, encoding and matching layers. Therefore, we propose to train them together as multi-task learning (Ruder, 2017). The joint objective function is formulated as follows:

$$\mathcal{L} = \mathcal{L}_{boundary} + \beta_1\mathcal{L}_{content} + \beta_2\mathcal{L}_{verify} \tag{19}$$

where β_1 and β_2 are two hyper-parameters that control the weights of those tasks.

When predicting the final answer, we take the boundary score, content score and verification score into consideration. We first extract the answer candidate A_i that has the maximum boundary score from each passage i. This boundary score is computed as the product of the start and end probability of the answer span. Then for each answer candidate A_i, we average the content probabilities of all its words as the content score of A_i. And we can also predict the verification score for A_i using the verification model. Therefore, the final answer can be selected from all the answer candidates according to the product of these three scores.

3 Experiments

To verify the effectiveness of our model on multi-passage machine reading comprehension, we conduct experiments on the MS-MARCO (Nguyen et al., 2016) and DuReader (He et al., 2017) datasets. Our method achieves the state-of-the-art performance on both datasets.

3.1 Datasets

We choose the MS-MARCO and DuReader datasets to test our method, since both of them are designed from real-world search engines and involve a large number of passages retrieved from the web. One difference of these two datasets is that MS-MARCO mainly focuses on the English web data, while DuReader is designed for Chinese MRC. This diversity is expected to reflect the generality of our method. In terms of the data size, MS-MARCO contains 102023 questions, each of which is paired up with approximately 10 passages for reading comprehension. As for DuReader, it keeps the top-5 search results for each question and there are totally 201574 questions.

	MS-MARCO	DuReader
Multiple Answers	9.93%	67.28%
Multiple Spans	40.00%	56.38%

Table 2: Percentage of questions that have multiple valid answers or answer spans

One prerequisite for answer verification is that there should be multiple correct answers so that they can verify each other. Both the MS-MARCO and DuReader datasets require the human annotators to generate multiple answers if possible. Table 2 shows the proportion of questions that have multiple answers. However, the same answer that occurs many times is treated as one single answer here. Therefore, we also report the proportion of questions that have multiple answer spans to match with the human-generated answers. A span is taken as valid if it can achieve F1 score larger than 0.7 compared with any reference answer. From these statistics, we can see that the phenomenon of multiple answers is quite common for both MS-MARCO and DuReader. These answers will provide strong signals for answer verification if we can leverage them properly.

3.2 Implementation Details

For MS-MARCO, we preprocess the corpus with the reversible tokenizer from Stanford CoreNLP (Manning et al., 2014) and we choose the span that achieves the highest ROUGE-L score with the reference answers as the gold span for training. We employ the 300-D pre-trained Glove embeddings (Pennington et al., 2014) and keep it fixed during training. The character embeddings are randomly initialized with its dimension as 30. For DuReader, we follow the preprocessing described in He et al. (2017).

We tune the hyper-parameters according to the

Model	ROUGE-L	BLEU-1

R-Net (Wang et al., 2017c)	42.89	42.22
S-Net (Tan et al., 2017)	45.23	43.78
Our Model	**46.15**	**44.47**
S-Net (Ensemble)	46.65	44.78
Our Model (Ensemble)	**46.66**	**45.41**
Human	47	46

Table 3: Performance of our method and competing models on the MS-MARCO test set

validation performance on the MS-MARCO development set. The hidden size is set to be 150 and we apply $L2$ regularization with its weight as 0.0003. The task weights β_1, β_2 are both set to be 0.5. To train our model, we employ the Adam algorithm (Kingma and Ba, 2014) with the initial learning rate as 0.0004 and the mini-batch size as 32. Exponential moving average is applied on all trainable variables with a decay rate 0.9999.

Two simple yet effective technologies are employed to improve the final performance on these two datasets respectively. For MS-MARCO, approximately 8% questions have the answers as Yes or No, which usually cannot be solved by extractive approach (Tan et al., 2017). We address this problem by training a simple Yes/No classifier for those questions with certain patterns (e.g., starting with "is"). Concretely, we simply change the output layer of the basic boundary model so that it can predict whether the answer is "Yes" or "No". For DuReader, the retrieved document usually contains a large number of paragraphs that cannot be fed into MRC models directly (He et al., 2017). The original paper employs a simple a simple heuristic strategy to select a representative paragraph for each document, while we train a paragraph ranking model for this. We will demonstrate the effects of these two technologies later.

3.3 Results on MS-MARCO

Table 3 shows the results of our system and other state-of-the-art models on the MS-MARCO test set. We adopt the official evaluation metrics, including ROUGE-L (Lin, 2004) and BLEU-1 (Papineni et al., 2002). As we can see, for both metrics, our single model outperforms all the other competing models with an evident margin, which is extremely hard considering the near-human performance. If we ensemble the models trained with different random seeds and hyper-parameters, the results can be further improved and outperform the ensemble model in Tan et al. (2017), especially in terms of the BLEU-1.

Model	BLEU-4	ROUGE-L
Match-LSTM	31.8	39.0
BiDAF	31.9	39.2
PR + BiDAF	37.55	41.81

Joint Training	44.12	-1.53
YesNo Classification	41.87	-3.78
Boundary Baseline	**38.95**	**-6.70**

Table 5: Ablation study on MS-MARCO development set

3.4 Results on DuReader

The results of our model and several baseline systems on the test set of DuReader are shown in Table 4. The BiDAF and Match-LSTM models are provided as two baseline systems (He et al., 2017). Based on BiDAF, as is described in Section 3.2, we tried a new paragraph selection strategy by employing a paragraph ranking (PR) model. We can see that this paragraph ranking can boost the BiDAF baseline significantly. Finally, we implement our system based on this new strategy, and our system (single model) achieves further improvement by a large margin.

4 Analysis and Discussion

4.1 Ablation Study

To get better insight into our system, we conduct in-depth ablation study on the development set of MS-MARCO, which is shown in Table 5. Following Tan et al. (2017), we mainly focus on the ROUGE-L score that is averaged case by case.

We first evaluate the answer verification by ablating the cross-passage verification model so that the verification loss and verification score will not be used during training and testing. Then we remove the content model in order to test the necessity of modeling the content of the answer. Since we don't have the content scores, we use the boundary probabilities instead to compute the answer representation for verification. Next, to show the benefits of joint training, we train the boundary model separately from the other two models. Finally, we remove the yes/no classification in order to show the real improvement of our end-to-end model compared with the baseline method that predicts the answer with only the boundary model.

From Table 5, we can see that the answer verification makes a great contribution to the overall improvement, which confirms our hypothesis that cross-passage answer verification is useful for the multi-passage MRC. For the ablation of the content model, we analyze that it will not only affect the content score itself, but also violate the verification model since the content probabilities are necessary for the answer representation, which will be further analyzed in Section 4.3. Another discovery is that jointly training the three models can provide great benefits, which shows that the three tasks are actually closely related and can boost each other with shared representations at bottom layers. At last, comparing our method with the baseline, we achieve an improvement of nearly 3 points without the yes/no classification. This significant improvement proves the effectiveness of our approach.

4.2 Case Study

To demonstrate how each module of our model takes effect when predicting the final answer, we conduct a case study in Table 6 with the same example that we discussed in Section 1. For each answer candidate, we list three scores predicted by the boundary model, content model and verification model respectively.

On the one hand, we can see that these three scores generally have some relevance. For example, the second candidate is given lowest scores by all the three models. We analyze that this is because the models share the same encoding and matching layers at bottom level and this relevance guarantees that the content and verification models will not violate the boundary model too much. On the other hand, we also see that the verification score can really make a difference here when the boundary model makes an incorrect decision among the confusing answer candidates ([1], [3], [4], [6]). Besides, as we expected, the verification model tends to give higher scores for those answers that have semantic commonality with each other ([3], [4], [6]), which are all valid answers in this case. By multiplying the three scores, our model finally predicts the answer correctly.

4.3 Necessity of the Content Model

In our model, we compute the answer representation based on the content probabilities predicted by a separate content model instead of directly using the boundary probabilities. We argue that this content model is necessary for our answer verification process. Figure 2 plots the predicted content probabilities as well as the boundary probabilities

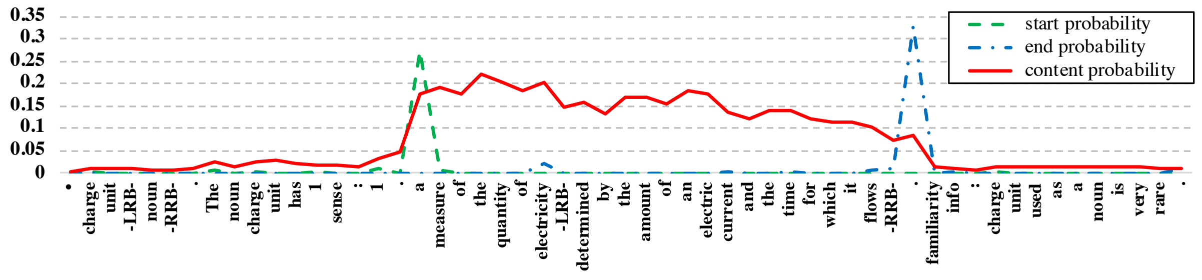

Figure 2: The boundary probabilities and content probabilities for the words in a passage

for a passage. We can see that the boundary and content probabilities capture different aspects of the answer. Since answer candidates usually have similar boundary words, if we compute the answer representation based on the boundary probabilities, it's difficult to model the real difference among different answer candidates. On the contrary, with the content probabilities, we pay more attention to the content part of the answer, which can provide more distinguishable information for verifying the correct answer. Furthermore, the content probabilities can also adjust the weights of the words within the answer span so that unimportant words (e.g. "and" and ".") get lower weights in the final answer representation. We believe that this refined representation is also good for the answer verification process.

5 Related Work

Machine reading comprehension made rapid progress in recent years, especially for single-passage MRC task, such as SQuAD (Rajpurkar et al., 2016). Mainstream studies (Seo et al., 2016; Wang and Jiang, 2016; Xiong et al., 2016) treat reading comprehension as extracting answer span from the given passage, which is usually achieved by predicting the start and end position of the answer. We implement our boundary model similarly by employing the boundary-based pointer network (Wang and Jiang, 2016). Another inspiring work is from Wang et al. (2017c), where the authors propose to match the passage against itself so that the representation can aggregate evidence from the whole passage. Our verification model adopts a similar idea. However, we collect information across passages and our attention is based on the answer representation, which is much more efficient than attention over all passages. For the model training, Xiong et al. (2017) argues that the boundary loss encourages exact answers at the cost of penalizing overlapping answers. Therefore they propose a mixed objective that incorporates rewards derived from word overlap. Our joint training approach has a similar function. By taking the content and verification loss into consideration, our model will give less loss for overlapping answers than those unmatched answers, and our loss function is totally differentiable.

Recently, we also see emerging interests in multi-passage MRC from both the academic (Dunn et al., 2017; Joshi et al., 2017) and industrial community (Nguyen et al., 2016; He et al., 2017). Early studies (Shen et al., 2017; Wang et al., 2017c) usually concat those passages and employ the same models designed for single-passage MRC. However, more and more latest studies start to design specific methods that can read multiple passages more effectively. In the aspect of passage selection, Wang et al. (2017a) introduced a pipelined approach that rank the passages first and then read the selected passages for answering questions. Tan et al. (2017) treats the passage ranking as an auxiliary task that can be trained jointly with the reading comprehension model. Actually, the target of our answer verification is very similar to that of the passage selection, while we pay more attention to the answer content and the answer verification process. Speaking of the answer verification, Wang et al. (2017b) has a similar motivation to ours. They attempt to aggregate the evidence from different passages and choose the final answer from n-best candidates. However, they implement their idea as a separate reranking step after reading comprehension, while our answer verification is a component of the whole model that can be trained end-to-end.

6 Conclusion

In this paper, we propose an end-to-end framework to tackle the multi-passage MRC task . We creatively design three different modules in our model, which can find the answer boundary, model the answer content and conduct cross-passage answer verification respectively. All these three modules can be trained with different forms of the answer labels and training them jointly can provide further improvement. The experimental results demonstrate that our model outperforms the baseline models by a large margin and achieves the state-of-the-art performance on two challenging datasets, both of which are designed for MRC on real web data.

Abstract

A DAG automaton is a formal device for manipulating graphs. By augmenting a DAG automaton with transduction rules, a DAG transducer has potential applications in fundamental NLP tasks. In this paper, we propose a novel DAG transducer to perform graph-to-program transformation. The target structure of our transducer is a program licensed by a declarative programming language rather than linguistic structures. By executing such a program, we can easily get a surface string. Our transducer is designed especially for natural language generation (NLG) from type-logical semantic graphs. Taking Elementary Dependency Structures, a format of English Resource Semantics, as input, our NLG system achieves a BLEU-4 score of 68.07. This remarkable result demonstrates the feasibility of applying a DAG transducer to resolve NLG, as well as the effectiveness of our design.

1 Introduction

The recent years have seen an increased interest as well as rapid progress in semantic parsing and surface realization based on graph-structured semantic representations, e.g. Abstract Meaning Representation (AMR; Banarescu et al., 2013), Elementary Dependency Structure (EDS; Oepen and Lønning, 2006) and Depedendency-based Minimal Recursion Semantics (DMRS; Copestake, 2009). Still underexploited is a formal framework for manipulating graphs that parallels automata, tranducers or formal grammars for strings and trees. Two such formalisms have recently been proposed and applied for NLP. One is graph grammar, e.g. Hyperedge Replacement Grammar (HRG; Ehrig et al., 1999). The other is DAG automata, originally studied by Kamimura and Slutzki (1982) and extended by Chiang et al. (2018). In this paper, we study DAG transducers in depth, with the goal of building accurate, efficient yet robust natural language generation (NLG) systems.

The meaning representation studied in this work is what we call type-logical semantic graphs, i.e. semantic graphs grounded under type-logical semantics (Carpenter, 1997), one dominant theoretical framework for modeling natural language semantics. In this framework, adjuncts, such as adjective and adverbal phrases, are analyzed as (higher-order) functors, the function of which is to consume complex arguments (Kratzer and Heim, 1998). In the same spirit, generalized quantifiers, prepositions and function words in many languages other than English are also analyzed as higher-order functions. Accordingly, all the linguistic elements are treated as roots in type-logical semantic graphs, such as EDS and DMRS. This makes the typological structure quite flat rather than hierachical, which is an essential distinction between natural language semantics and syntax.

To the best of our knowledge, the only existing DAG transducer for NLG is the one proposed by Quernheim and Knight (2012). Quernheim and Knight introduced a DAG-to-tree transducer that can be applied to AMR-to-text generation. This transducer is designed to handle hierarchical structures with limited reentrencies, and it is unsuitable for meaning graphs transformed from type-logical semantics. Furthermore, Quernheim and Knight did not describe how to acquire graph recognition and transduction rules from linguistic data, and reported no result of practical generation. It is still unknown to what extent a DAG transducer suits realistic NLG.

The design for string and tree transducers

(Comon et al., 1997) focuses on not only the logic of the computation for a new data structure, but also the corresponding control flow. This is very similar the imperative programming paradigm: implementing algorithms with exact details in explicit steps. This design makes it very difficult to transform a type-logical semantic graph into a string, due to the fact their internal structures are highly diverse. We borrow ideas from declarative programming, another programming paradigm, which describes what a program must accomplish, rather than how to accomplish it. We propose a novel DAG transducer to perform graph-to-program transformation (§3). The input of our transducer is a semantic graph, while the output is a program licensed by a declarative programming language rather than linguistic structures. By executing such a program, we can easily get a surface string. This idea can be extended to other types of linguistic structures, e.g. syntactic trees or semantic representations of another language.

We conduct experiments on richly detailed semantic annotations licensed by English Resource Grammar (ERG; Flickinger, 2000). We introduce a principled method to derive transduction rules from DeepBank (Flickinger et al., 2012). Furthermore, we introduce a fine-to-coarse strategy to ensure that at least one sentence is generated for any input graph. Taking EDS graphs, a variable-free ERS format, as input, our NLG system achieves a BLEU-4 score of 68.07. On average, it produces more than 5 sentences in a second on an x86_64 GNU/Linux platform with two Intel Xeon E5-2620 CPUs. Since the data for experiments is newswire data, i.e. WSJ sentences from PTB (Marcus et al., 1993), the input graphs are quite large on average. The remarkable accuracy, efficiency and robustness demonstrate the feasibility of applying a DAG transducer to resolve NLG, as well as the effectiveness of our transducer design.

2 Previous Work and Challenges

2.1 Preliminaries

A node-labeled **simple** graph over alphabet Σ is a triple $G = (V, E, \ell)$, where V is a finite set of nodes, $E \subseteq V \times V$ is an finite set of edges and $\ell : V \rightarrow \Sigma$ is a labeling function. For a node $v \in V$, sets of its incoming and outgoing edges are denoted by $in(v)$ and $out(v)$ respectively. For an edge $e \in E$, its source node and target node are denoted by $src(e)$ and $tar(e)$ respectively. Generally speaking, a DAG is a **directed acyclic simple graph**. Different from trees, a DAG allows nodes to have multiple incoming edges. In this paper, we only consider DAGs that are **unordered**, **node-labeled**, **multi-rooted**[1] and **connected**.

Conceptual graphs, including AMR and EDS, are both node-labeled and edge-labeled. It seems that without edge labels, a DAG is inadequate, but this problem can be solved easily by using the strategies introduced in (Chiang et al., 2018). Take a labeled edge $\texttt{proper\_q} \xrightarrow{\texttt{BV}} \texttt{named}$ for example[2]. We can represent the same information by replacing it with two unlabeled edges and a new labeled node: $\texttt{proper\_q} \rightarrow \texttt{BV} \rightarrow \texttt{named}$.

2.2 Previous Work

DAG automata are the core engines of graph transducers (Bohnet and Wanner, 2010; Quernheim and Knight, 2012). In this work, we adopt Chiang et al. (2018)'s design and define a weighted DAG automaton as a tuple $M = \langle \Sigma, Q, \delta, \mathbb{K} \rangle$:

- Σ is an alphabet of node labels.
- Q is a finite set of states.
- $(\mathbb{K}, \oplus, \otimes, 0, 1)$ is a semiring of weights.
- $\delta : \Theta \rightarrow \mathbb{K}\backslash\{0\}$ is a weight function that assigns nonzero weights to a finite transition set Θ. Every transition $t \in \Theta$ is of the form

  $$\{q_1, \cdots, q_m\} \xrightarrow{\sigma} \{r_1, \cdots, r_n\}$$

  where q_i and r_j are states in Q. A transition t gets m states on the incoming edges of a node and puts n states on the outgoing edges. A transition that does not belong to Θ recieves a weight of zero.

A *run* of M on a DAG $D = \langle V, E, \ell \rangle$ is an edge labeling function $\rho : E \rightarrow Q$. The weight of a run ρ (denoted as $\delta'(\rho)$) is the product of all weights of local transitions:

$$\delta'(\rho) = \bigotimes_{v \in V} \delta\left(\rho(in(v)) \xrightarrow{\ell(v)} \rho(out(v))\right)$$

Here, for a function f, we use $f(\{a_1, \cdots, a_n\})$ to represent $\{f(a_1), \cdots, f(a_n)\}$. If $\mathbb{K}$ is a boolean semiring, the automata fall backs to an unweighted

[1] A node without incoming edges is called *root* and a node without outgoing edges is called *leaf*.

[2] proper_q and named are node labels, while BV is the edge label.

DAG automata or DAG acceptor. A *accepting run* or *recognition* is a run, the weight of which is 1, meaning *true*.

2.3 Challenges

The DAG automata defined above can only be used for recognition. In order to generate sentences from semantic graphs, we need DAG transducers. A DAG transducer is a DAG automata-augmented computation model for transducing well-formed DAGs to other data structures. Quernheim and Knight (2012) focused on feature structures and introduced a *DAG-to-Tree* transducer to perform graph-to-tree transformation. The input of their transducer is limited to single-rooted DAGs. When the labels of the leaves of an output tree in order are interpreted as words, this transducer can be applied to generate natural language sentences.

When applying Quernheim and Knight's DAG-to-Tree transducer on type-logic semantic graphs, e.g. ERS, there are some significant problems. First, it lacks the ability to *reverse* the direction of edges during transduction because it is difficult to keep acyclicy anymore if edge reversing is allowed. Second, it cannot handle multiple roots. But we have discussed and reached the conclusion that multi-rootedness is a necessary requirement for representing type-logical semantic graphs. It is difficult to decide which node should be the tree root during a 'top-down' transduction and it is also difficult to merge multiple unconnected nodes into one during a 'bottom-up' transduction. At the risk of oversimplifying, we argue that the function of the existing DAG-to-Tree transducer is to transform a hierachical structure into another hierarchical structure. Since the type-local semantic graphs are so flat, it is extremely difficult to adopt Quernheim and Knight's design to handle such graphs. Third, there are unconnected nodes with direct dependencies, meaning that their correpsonding surface expressions appear to be very close. The conceptual nodes `_even_x_deg` and `_steep_a_1` in Figure 4 are an example. It is extremely difficult for the DAG-to-Tree transducer to handle this situation.

3 A New DAG Transducer

3.1 Basic Idea

In this paper, we introduce a design of transducers that can perform structure transformation towards many data structures, including but not limited to trees. The basic idea is to give up the *rewritting* method to directly generate a new data structure piece by piece, while recognizing an input DAG. Instead, our transducer obtains target structures based on side effects of DAG recognition. The output of our transducer is no longer the target data structure itself, e.g. a tree or another DAG, and is now a program, i.e. a bunch of statements licensed by a particular **declarative** programming language. The target structures are constructed by executing such programs.

Since our main concern of this paper is natural language generation, we take strings, namely sequences of words, as our target structures. In this section, we introduce an extremely simple programming language for string concatenation and then details about how to leverage the power of declarative programming to perform DAG-to-string transformation.

3.2 A Declarative Programming Language

The syntax in the BNF format of our declarative programming language, denoted as $\mathcal{L}_c$, for string calculation is:

$$\begin{aligned} \langle program\rangle &::= \langle statement\rangle * \\ \langle statement\rangle &::= \langle variable\rangle = \langle expr\rangle \\ \langle expr\rangle &::= \langle variable\rangle \mid \langle string\rangle \\ &\quad \mid \langle expr\rangle + \langle expr\rangle \end{aligned}$$

Here a *string* is a sequence of characters selected from an alphabet (denoted as Σ_{out}) and can be empty (denoted as ϵ). The semantics of '=' is *value assignment*, while the semantics of '+' is *string concatenation*. The value of variables are strings. For every statement, the left hand side is a variable and the right hand side is a sequence of string literals and variables that are combined through '+'. Equation (1) presents an exmaple program licensed by this language.

$$\begin{aligned} S &= x_{21} + \texttt{want} + x_{11} \\ x_{11} &= \texttt{to} + \texttt{go} \\ x_{21} &= x_{41} + \texttt{John} \\ x_{41} &= \epsilon \end{aligned} \tag{1}$$

After solving these statements, we can query the values of all variables. In particular, we are interested in S, which is related to the desired natural language expression `John want to go`[3].

[3] The expression is a sequence of lemmas rather than inflected words. Refer to §4 for more details.

Using the relation between the variables, we can easily convert the statements in (1) to a rooted tree. The result is shown in Figure 1. This tree is significantly different from the target structures discussed by Quernheim and Knight (2012) or other normal tree transducers (Comon et al., 1997). This tree represents calculation to solve the program. Constructing such *internal* trees is an essential function of the *compiler* of our programming language.

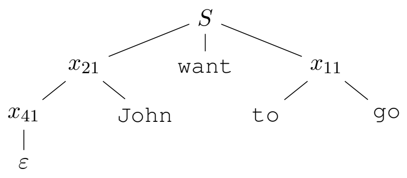

Figure 1: Variable relation tree.

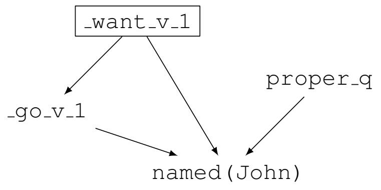

Figure 2: An input graph. The intended reading is *John wants to go*.

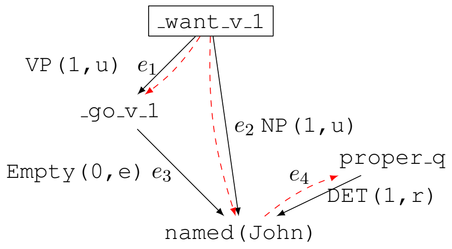

Figure 3: A run of the graph in Figure 2.

3.3 Informal Illustration

We introduce our DAG transducer using a simple example. Figure 2 shows the original input graph $D = (V, E, \ell)$. Without any loss of generality, we remove edge labels. Table 1 lists the rule set—R—for this example. Every row represents an applicable transduction rule that consists of two parts. The left column is the recognition part displayed in the form $I \xrightarrow{\sigma} O$, where I, O and σ decode the state set of incoming edges, the state set of outgoing edges and the node label respectively. The right column is the generation part which consists of (multiple) templates of statements licensed by the programming language defined in the previous section. In practice, two different rules may have a same recognition part but different generation parts.

Every state q is of the form $l(n, d)$ where l is the finite state label, n is the count of possible variables related to q, and d denotes the direction. The value of d can only be `r` (reversed), `u` (unchanged) or `e`(empty). Variable $v_{l(j,d)}$ represents the jth ($1 \le j \le n$) variable related to state q. For example, $v_{\texttt{X(2,r)}}$ means the second variable of state `X(3,r)`. There are two special variables: S, which corresponds to the whole sentence and L, which corresponds to the output string associated to current node label. It is reasonable to assume that there exists a function $\psi : \Sigma \to \Sigma^*_{\text{out}}$ that maps a particular node label, i.e. concept, to a surface string. Therefore L is determined by ψ.

Now we are ready to apply transduction rules to translate D into a string. The transduction consists of two steps:

Recognition The goal of this step is to find an edge labeling function $\rho : E \to Q$ which satisfies that for every node v, $\rho(in(v)) \xrightarrow{\ell(v)} \rho(out(v))$ matches the recognition part of a rule in R. The recognition result is shown in Figure 3. The red dashed edges in Figure 3 make up an *intermediate graph* $T(\rho)$, which is a subgraph of D if edge direction is not taken into account. Sometimes, $T(\rho)$ paralles the syntactic structure of an output sentence. For a labeling function ρ, we can construct *intermediate graph* $T(\rho)$ by checking the direction parameter of every edge state. For an edge $e = (u, v) \in E$, if the direction of $\rho(e)$ is `r`, then (v, u) is in $T(\rho)$. If the direction is `u`, then (u, v) is in $T(\rho)$. If the direction is `e`, neither (u, v) nor (v, u) is included. The recognition process is slightly different from the one in Chiang et al. (2018). Since incoming edges with an `Empty(0,e)` state carry no semantic information, they will be ignored during recognition. For example, in Figure 3, we will only use e_2 and e_4 to match transducation rules for node `named(John)`.

Instantiation We use $rule(v)$ to denotes the rule used on node v. Assume s is the generation part of $rule(v)$. For every edge e_i adjacent to v, assume $\rho(e_i) = l(n, d)$. We replace L with $\psi(\ell(v))$ and replace every occurrence of $v_{l(j,d)}$ in s with a new variable x_{ij} ($1 \le j \le n$). Then we

$Q = \{$`DET(1,r)`,`Empty(0,e)`,`VP(1,u)`,`NP(1,u)`$\}$		
Rule	For Recognition	For Generation
1	$\{\} \xrightarrow{\texttt{proper\_q}} \{\texttt{DET(1,r)}\}$	$v_{\texttt{DET(1,r)}} = \epsilon$
2	$\{\} \xrightarrow{\texttt{\_want\_v\_1}} \{\texttt{VP(1,u),NP(1,u)}\}$	$S = v_{\texttt{NP(1,u)}} + L + v_{\texttt{VP(1,u)}}$
3	$\{\texttt{VP(1,u)}\} \xrightarrow{\texttt{\_go\_v\_1}} \{\texttt{Empty(0,e)}\}$	$v_{\texttt{VP(1,u)}} = \texttt{to} + L$
4	$\{\texttt{NP(1,u),DET(1,r)}\} \xrightarrow{\texttt{named}} \{\}$	$v_{\texttt{NP(1,u)}} = v_{\texttt{DET(1,r)}} + L$

Table 1: Sets of states (Q) and rules (R) that can be used to process the graph in Figure 2.

get a newly generated expression for v. For example, node `_want_v_1` is recognized using Rule 2, so we replace $v_{\texttt{NP(1,u)}}$ with x_{21}, $v_{\texttt{VP(1,u)}}$ with x_{11} and L with `want`. After instantiation, we get all the statements in Equation (1).

Our transducer is suitable for type-logical semantic graphs. Because declarative programming brings in more freedom for graph transduction. We can arrange the variables in almost any order without regard to the edge directions in original graphs. Meanwhile, the multi-rooted problem can be solved easily because the generation is based on side effects. We do not need to decide which node is the tree root.

3.4 Definition

The formal definition of our DAG transducer described above is a tuple $M = (\Sigma, Q, R, w, V, S)$ where:

- Σ is an alphabet of node labels.
- Q is a finite set of edge states. Every state $q \in Q$ is of the form $l(n, d)$ where l is the state label, n is the variable count and d is the direction of state which can be `r`, `u` or `e`.
- R is a finite set of rules. Every rule is of the form $I \xrightarrow{\sigma} \langle O, E\rangle$. E can be any kind of statement in a declarative programming language. It is called the generation part. I, σ and O have the same meanings as they do in the previous section and they are called the recognition part.
- w is a score function. Given a particular run and an anchor node, w assigns a score to measure the preference for a particular rule at this anchor node.
- V is the set of parameterized variables that can be used in every expression.
- $S \in V$ is a distinguished, global variable. It is like the 'goal' of a program.

4 DAG Transduction-based NLG

Different languages exhibit different morpho-syntactic and syntactico-semantic properties. For example, Russian and Arabic are morphologically-rich languages and heavily utilize grammatical markers to indicate grammatical as well as semantic functions. On the contrary, Chinese, as an analytic language, encodes grammatical and semantic information in a highly configurational rather than either inflectional or derivational way. Such differences affects NLG significantly. Considering generating Chinese sentences, it seems sufficient to employ our DAG transducer to obtain a sequence of lemmas, since no morpholical production is needed. But for morphologically-rich languages, we do need to model complex morphological changes.

To unify a general framework for DAG transduction-based NLG, we propose a two-step strategy to achive meaning-to-text transformation.

- In the first phase, we are concerned with syntactico-semantic properties and utilize our DAG transducer to translate a semantic graph into sequential lemmas. Information such as tense, apsects, gender, etc. is attached to anchor lemmas. Actually, our transducer generates "`want.PRES`" rather than "`wants`". Here, "PRES" indicates a particular tense.
- In the second phase, we are concerned with morpho-syntactic properties and utilize a neural sequence-to-sequence model to obtain final surface strings from the outputs of the DAG transducer.

5 Inducing Transduction Rules

We present an empirical study on the feasibility of DAG transduction-based NLG. We focus on

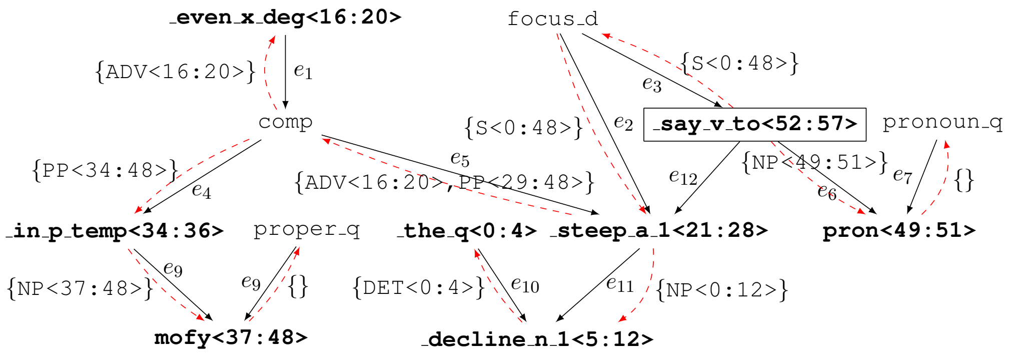

Figure 4: An example graph. The intended reading is *"the decline is even steeper than in September", he said.* Original edge labels are removed for clarity. Every edge is associated with a span list, and spans are written in the form `label<begin:end>`. The red dashed edges belong to the intermediate graph T.

variable-free MRS representations, namely EDS (Oepen and Lønning, 2006). The data set used in this work is DeepBank 1.1 (Flickinger et al., 2012).

5.1 EDS-specific Constraints

In order to generate reasonable strings, three constraints must be kept during transduction. First, for a rule $I \xrightarrow{\sigma} \langle O, E\rangle$, a state with direction `u` in I or a state with direction `r` in O is called *head state* and its variables are called *head variables*. For example, the head state of rule 3 in Table 1 is `VP(1,u)` and the head state of rule 2 is `DET(1,r)`. There is at most one head state in a rule and only head variables or S can be the left sides of statements. If there is no head state, we assign the global S as its head. Otherwise, the number of statements is equal to the number of head variables and each statement has a distinguished left side variable. An empty state does not have any variables. Second, every rule has no-copying, no-deleting statements. In other words, all variables must be used exactly once in a statement. Third, during recognition, a labeling function ρ is valid only if $T(\rho)$ is a rooted tree.

After transduction, we get result ρ^*. The first and second constraints ensure that for all nodes, there is at most one incoming red dashed edge in $T(\rho^*)$ and 'data' carried by variables of the only incoming red dashed edge or S is separated into variables of outgoing red dashed edges. The last constraint ensures that we can solve all statements by a bottom-up process on tree $T(\rho^*)$.

5.2 Fine-to-Coarse Transduction

Almost all NLG systems that heavily utilize a symbolic system to encode deep syntactico-semantic information lack some robustness, meaning that some input graphs may not be successfully processed. There are two reasons: (1) some explicit linguistic constraints are not included; (2) exact decoding is too time-consuming while inexact decoding cannot cover the whole search space. To solve the robustness problem, we introduce a fine-to-coarse strategy to ensure that at least one sentence is generated for any input graph. There are three types of rules in our system, namely *induced rules*, *extended rules* and *dynamic rules*. The most fine-grained rules are applied to bring us precision, while the most coarse-grained rules are for robustness.

In order to extract reasonable rules, we will use both EDS graphs and the corresponding derivation trees provided by ERG. The details will be described step-by-step in the following sections.

5.3 Induced Rules

Figure 4 shows an example for obtaining induced rules. The *induced rules* are directly obtained by following three steps:

Finding intermediate tree T EDS graphs are highly regular semantic graphs. It is not difficult to generate T based on a highly customized 'breadth-first' search. The generation starts from the 'top' node (`_say_v_to` in Figure 4) given by the EDS graph and traverse the whole graph. No more than thirty heuristic rules are used to decide the visiting order of nodes.

Assigning states EDS graphs also provide span information for nodes. We select a group of *lexical* nodes which have corresponding substrings in the original sentence. In Figure 4, these nodes are in bold font and directly followed by a span. Then we merge spans from the bottom of T to the top to assign each red edge a span list. For each node n in T, we collect spans of every outgoing dashed edge of n into a list s. Some additional spans may be inserted into s. These spans do not occur in the EDS graph but they do occur in the sentence, i.e. `than<29:33>`. Then we merge continuous spans in s and assign the remaining spans in s to the incoming red dashed edge of n. We apply a similar method to the derivation tree. As a result, every inner node of the derivation tree is associated with a span. Then we align the edges in T to nodes of the inner derivation tree by comparing their spans. Finally edge labels in Figure 4 are generated.

We use the concatenation of the edge labels in a span list as the state label. The edge labels are joined in order with '_'. `Empty(0,e)` is the state of the edges that do not belong to T (ignoring direction), such as e_{12}. The variable count of a state is equal to the size of the span list and the direction of a state is decided by whether the edge in T related to the state and its corresponding edge in D have different directions. For example, the state of e_5 should be `ADV_PP(2,r)`.

Generating statements After the above two steps, we are ready to generate statements according to how spans are merged. For all nodes, spans of the incoming edges represent the left hand side and the outgoing edges represent the right hand side. For example, the rule for node `comp` will be:

$$\{\texttt{ADV(1,r)}\} \xrightarrow{\texttt{comp}} \{\texttt{PP(1,u)}, \texttt{ADV\_PP(2,r)}\}$$

$$v_{\texttt{ADV\_PP(1,r)}} = v_{\texttt{ADV(1,r)}}$$

$$v_{\texttt{ADV\_PP(2,r)}} = \texttt{than} + v_{\texttt{PP(1,u)}}$$

5.4 Extended Rules

Extended rules are used when no induced rules can cover a given node. In theory, there can be unlimited modifier nodes pointing to a given node, such as `PP` and `ADJ`. We use some manually written rules to slightly change an induced rule (prototype) by addition or deletion to generate a group of extended rules. The motivation here is to deal with the data sparseness problem.

For a group of selected non-head states in I, such as `PP` and `ADJ`. We can produce new rules by removing or duplicating more of them. For example:

$$\{\texttt{NP(1,u)},\texttt{ADJ(1,r)}\} \xrightarrow{\texttt{\_X\_n\_1}} \{\}$$
$$v_{\texttt{NP(1,u)}} = v_{\texttt{ADJ(1,r)}} + L$$

As a result, we get the two rules below:

$$\{\texttt{NP(1,u)}\} \xrightarrow{\texttt{\_X\_n\_1}} \{\} \quad v_{\texttt{NP(1,u)}} = L$$

$$\{\texttt{NP(1,u)},\texttt{ADJ(1,r)}_1, \texttt{ADJ(1,r)}_2\} \xrightarrow{\texttt{\_X\_n\_1}} \{\}$$
$$v_{\texttt{NP(1,u)}} = v_{\texttt{ADJ(1,r)}_1} + v_{\texttt{ADJ(1,r)}_2} + L$$

5.5 Dynamic Rules

During decoding, when neither induced nor extended rule is applicable, we *create* a dynamic rule on-the-fly. Our rule creator builds a new rule following the Markov assumption:

$$P(O|C) = P(q_1|C)\prod_{i=2}^{n} P(q_i|C)P(q_i|q_{i-1}, C)$$

$C = \langle I, D\rangle$ represents the context. $O = \{q_1, \cdots, q_n\}$ denotes the outgoing states and I, D have the same meaning as before. Though they are unordered multisets, we can give them an explicit alphabet order by their edge labels. There is also a group of hard constraints to make sure that the predicted rules are well-formed as the definition in §5 requires. This Markovization strategy is widely utilized by lexicalized and unlexicalized PCFG parsers (Collins, 1997; Klein and Manning, 2003). For a dynamic rule, all variables in this rule will appear in the statement. We use a simple perceptron-based scorer to assign every variable a score and arrange them in an decreasing order.

6 Evaluation and Analysis

6.1 Set-up

We use DeepBank 1.1 (Flickinger et al., 2012), i.e. gold-standard ERS annotations, as our main experimental data set to train a DAG transducer as well as a sequence-to-sequence morpholyzer, and wikiwoods (Flickinger et al., 2010), i.e. automatically-generated ERS annotations by ERG, as additional data set to enhance the sequence-to-sequence morpholyzer. The training, development and test data sets are from DeepBank and split according to DeepBank's recommendation. There are 34,505, 1,758 and 1,444 sentences (all disconnected graphs as well as their associated sentences are removed) in the training, development and test data sets. We use a small portion of wikiwoods data, c.a. 300K sentences, for experiments.

37,537 induced rules are directly extracted from the training data set, and 447,602 extended rules are obtained. For DAG recognition, at one particular position, there may be more than one rule applicable. In this case, we need a disambiguation model as well as a decoder to search for a globally optimal solution. In this work, we train a structured perceptron model (Collins, 2002) for disambiguation and employ a beam decoder. The perceptron model used by our dynamic rule generator are trained with the induced rules. To get a sequence-to-sequence model, we use the open source tool—OpenNMT[4].

6.2 The Decoder

We implement a fine-to-coarse beam search decoder. Given a DAG D, our goal is to find the highest scored labeling function ρ:

$$\rho = \arg\max_{\rho} \prod_{i=1}^{n} \sum_{j} w_j \cdot f_j(rule(v_i), D)$$

$$\text{s.t.} \quad rule(v_i) = \rho(in(v_i)) \xrightarrow{\ell(v_i)} \langle \rho(out(v_i)), E_i \rangle$$

where n is the node count and $f_j(\cdot,\cdot)$ and w_j represent a feature and the corresponding weight, respectively. The features are chosen from the context of the given node v_i. We perform 'top-down' search to translate an input DAG into a morphology-function-enhanced lemma sequence. Each hypothesis consists of the current DAG graph, the partial labeling function, the current hypothesis score and other graph information used to perform rule selection. The decoder will keep the corresponding partial intermediate graph T acyclic when decoding. The algorithm used by our decoder is displayed in Algorithm 1. Function `FindRules`(h, n, R) will use hard constraints to select rules from the rule set R according to the contextual information. It will also perform an acyclic check on T. Function `Insert`(h, r, n, B) will create and score a new hypothesis made from the given context and then insert it into beam B.

[4]https://github.com/OpenNMT/OpenNMT/

After we get the edge labeling function ρ, we use a simple linear equation solver to convert all statements to a sequence of lemmas.

Algorithm 1: Algorithm for our decoder.

```
Input: $D$ is the EDS graph. $R_I$ and $R_E$
       are induced-rules and
       extended-rules respectively.
Result: The edge labeling function $\rho$.
1  $Q \leftarrow$ all the roots in $D$
2  $B1 \leftarrow$ empty beam
3  $E \leftarrow \varnothing$
4  Insert initial hypothesis into $B1$
5  while $Q$ is not empty:
6      $B2 \leftarrow$ empty beam
7      $n \leftarrow$ dequeue a node from $Q$
8      for $h \in B1$:
9          $rules \leftarrow$ FindRules$(h, n, R_I)$
10         if $rules$ is not empty:
11             for $r \in rules$:
12                 Insert$(h, r, n, B2)$
           else:
13             $rules \leftarrow$ FindRules$(h, n, R_E)$
14             for $r \in rules$:
15                 Insert$(h, r, n, B2)$
16     if $B2$ is still empty:
17         for $h \in B1$:
18             $r \leftarrow$ RuleGenerator$(h, n)$
19             Insert$(h, r, n, B2)$
20     $B1 \leftarrow B2$
21     for $e \in out(n)$:
22         $E \leftarrow E \cup \{e\}$
23         if $in(tar(e)) \subseteq E$:
24             $Q \leftarrow Q \cup \{tar(e)\}$
25 Extract $\rho$ from best hypothesis in $B1$
```

6.3 Accuracy

In order to evaluate the effectiveness of our transducer for NLG, we try a group of tests showed in Table 2. All sequence-to-sequence models (either from lemma sequences to lemma sequences or lemma sequences to sentences) are trained on DeepBank and wikiwoods data set and tuned on the development data. The second column shows the BLEU-4 scores between generated lemma sequences and golden sequences of lemmas. The third column shows the BLEU-4 scores between generated sentences and golden sentences. The fourth column shows the fraction of graphs in the test data set that can reach output sentences.

Transducer	Lemmas	Sentences	Coverage
I	89.44	74.94	67%
I+E	88.41	74.03	77%
I+E+D	82.04	68.07	100%
DFS-NN	50.45		100%
AMR-NN		33.8	100%
AMR-NRG		25.62	100%

Table 2: Accuracy (BLEU-4 score) and coverage of different systems. *I* denotes transduction only using induced rules; *I+E* denotes transduction using both induced and extended rules; *I+E+D* denotes transduction using all kinds of rules. *DFS-NN* is a rough implementation of Konstas et al. (2017) but with the EDS data, while *AMR-NN* includes the results originally reported by Konstas et al., which are evaluated on the AMR data. *AMR-NRG* includes the results obtained by a synchronous graph grammar (Song et al., 2017).

The graphs that cannot received any natural language sentences are removed while conducting the BLEU evaluation.

As we can conclude from Table 2, using only induced rules achieves the highest accuracy but the coverage is not satisfactory. Extended rules lead to a slight accuracy drop but with a great improvement of coverage (c.a. 10%). Using dynamic rules, we observe a significant accuracy drop. Nevertheless, we are able to handle all EDS graphs. The full-coverage robustness may benefit many NLP applications. The lemma sequences generated by our transducer are really close to the golden one. This means that our model actually works and most reordering patterns are handled well by induced rules.

Compared to the AMR generation task, our transducer on EDS graphs achieves much higher accuracies. To make clear how much improvement is from the data and how much is from our DAG transducer, we implement a purely neural baseline. The baseline converts a DAG into a concept sequence by a pre-order DFS traversal on the intermediate tree of this DAG. Then we use a sequence-to-sequence model to transform this concept sequence to the lemma sequence for comparison. This is a kind of implementation of Konstas et al.'s model but evaluated on the EDS data. We can see that on this task, our transducer is much better than a pure sequence-to-sequence model on DeepBank data.

Transducer	Average (s)	Maximal (s)
I	0.090	0.40
I+E	0.093	0.46
I+E+D	0.18	3.2

Table 3: Efficiency of our NL generator.

6.4 Efficiency

Table 3 shows the efficiency of the beam search decoder with a beam size of 128. The platform for this experiment is x86_64 GNU/Linux with two Intel Xeon E5-2620 CPUs. The second and third columns represent the average and the maximal time (in seconds) to translate an EDS graph. Using dynamic rules slow down the decoder to a great degree. Since the data for experiments is newswire data, i.e. WSJ sentences from PTB (Marcus et al., 1993), the input graphs are quite large on average. On average, it produces more than 5 sentences per second on CPU. We consider this a promising speed.

7 Conclusion

We extend the work on DAG automata in Chiang et al. (2018) and propose a general method to build flexible DAG transducer. The key idea is to leverage a declarative programming language to minimize the computation burden of a graph transducer. We think may NLP tasks that involve graph manipulation may benefit from this design. To exemplify our design, we develop a practical system for the semantic-graph-to-string task. Our system is accurate (BLEU 68.07), efficient (more than 5 sentences per second on a CPU) and robust (full-coverage). The empirical evaluation confirms the usefulness a DAG transducer to resolve NLG, as well as the effectiveness of our design.

A Distributional and Orthographic Aggregation Model for English Derivational Morphology

Daniel Deutsch*, **John Hewitt*** **and Dan Roth**
Department of Computer and Information Science
University of Pennsylvania
{ddeutsch,johnhew,danroth}@seas.upenn.edu

Abstract

Modeling derivational morphology to generate words with particular semantics is useful in many text generation tasks, such as machine translation or abstractive question answering. In this work, we tackle the task of derived word generation. That is, given the word "run," we attempt to generate the word "runner" for "someone who runs." We identify two key problems in generating derived words from root words and transformations: suffix ambiguity and orthographic irregularity. We contribute a novel aggregation model of derived word generation that learns derivational transformations both as orthographic functions using sequence-to-sequence models and as functions in distributional word embedding space. Our best open-vocabulary model, which can generate novel words, and our best closed-vocabulary model, show 22% and 37% relative error reductions over current state-of-the-art systems on the same dataset.

1 Introduction

The explicit modeling of morphology has been shown to improve a number of tasks (Seeker and Çetinoglu, 2015; Luong et al., 2013). In a large number of the world's languages, many words are composed through morphological operations on subword units. Some languages are rich in *inflectional* morphology, characterized by syntactic transformations like pluralization. Similarly, languages like English are rich in *derivational* morphology, where the semantics of words are composed from smaller parts. The AGENT derivational transformation, for example, answers the question, *what is the word for 'someone who runs'?* with the answer, a *runner*.[1] Here, AGENT is spelled out as suffixing *-ner* onto the root verb *run*.

*These authors contributed equally; listed alphabetically.

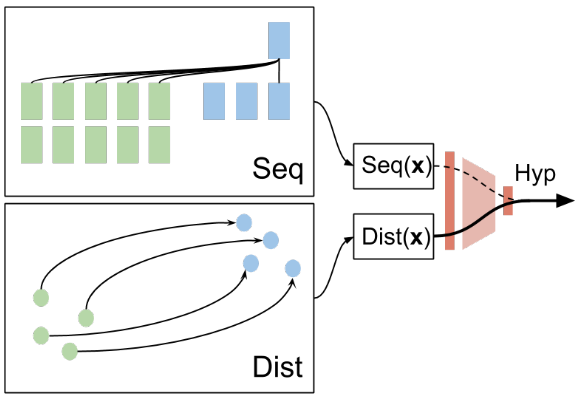

Figure 1: Diagram depicting the flow of our aggregation model. Two models generate a hypothesis according to orthogonal information; then one is chosen as the final model generation. Here, the hypothesis from the distributional model is chosen.

We tackle the task of derived word generation. In this task, a root word $\mathbf{x}$ and a derivational transformation t are given to the learner. The learner's job is to produce the result of the transformation on the root word, called the derived word $\mathbf{y}$. Table 1 gives examples of these transformations.

Previous approaches to derived word generation model the task as a character-level sequence-to-sequence (seq2seq) problem (Cotterell et al., 2017b). The letters from the root word and some encoding of the transformation are given as input to a neural encoder, and the decoder is trained to produce the derived word, one letter at a time. We identify the following problems with these approaches:

First, because these models are unconstrained, they can generate sequences of characters that do

[1]We use the verb *run* as a demonstrative example; the transformation can be applied to most verbs.

$\mathbf{x}$	t		$\mathbf{y}$
wise	ADVERB	→	wise*ly*
simulate	RESULT	→	simula*tion*
approve	RESULT	→	approv*al*
overstate	RESULT	→	overstate*ment*
yodel	AGENT	→	yodel*er*
survive	AGENT	→	surviv*or*
intense	NOMINAL	→	intens*ity*
effective	NOMINAL	→	effective*ness*
pessimistic	NOMINAL	→	pessim*ism*

Table 1: The goal of derived word generation is to produce the derived word, $\mathbf{y}$, given both the root word, $\mathbf{x}$, and the transformation t, as demonstrated here with examples from the dataset.

not form actual words. We argue that requiring the model to generate a known word is a reasonable constraint in the special case of English derivational morphology, and doing so avoids a large number of common errors.

Second, sequence-based models can only generalize string manipulations (such as "add *-ment*") if they appear frequently in the training data. Because of this, they are unable to generate derived words that do not follow typical patterns, such as generating *truth* as the nominative derivation of *true*. We propose to learn a function for each transformation in a low dimensional vector space that corresponds to mapping from representations of the root word to the derived word. This eliminates the reliance on orthographic information, unlike related approaches to distributional semantics, which operate at the suffix level (Gupta et al., 2017).

We contribute an aggregation model of derived word generation that produces hypotheses independently from two separate learned models: one from a seq2seq model with only orthographic information, and one from a feed-forward network using only distributional semantic information in the form of pretrained word vectors. The model learns to choose between the hypotheses according to the relative confidence of each. This system can be interpreted as learning to decide between positing an orthographically regular form or a semantically salient word. See Figure 1 for a diagram of our model.

We show that this model helps with two open problems with current state-of-the-art seq2seq derived word generation systems, suffix ambiguity and orthographic irregularity (Section 2). We also improve the accuracy of seq2seq-only derived word systems by adding external information through constrained decoding and hypothesis rescoring. These methods provide orthogonal gains to our main contribution.

We evaluate models in two categories: open vocabulary models that can generate novel words unattested in a preset vocabulary, and closed-vocabulary models, which cannot. Our best open-vocabulary and closed-vocabulary models demonstrate 22% and 37% relative error reductions over the current state of the art.

2 Background: Derivational Morphology

Derivational transformations generate novel words that are semantically composed from the root word and the transformation. We identify two unsolved problems in derived word transformation, each of which we address in Sections 3 and 4.

First, many plausible choices of suffix for a single pair of root word and transformation. For example, for the verb *ground*, the RESULT transformation could plausibly take as many forms as[2]

$$\begin{aligned}
&(\text{ground}, \textsc{Result}) \to \text{ground}\textit{ing}\\
&(\text{ground}, \textsc{Result}) \to {}^*\text{ground}\textit{ation}\\
&(\text{ground}, \textsc{Result}) \to {}^*\text{ground}\textit{ment}\\
&(\text{ground}, \textsc{Result}) \to {}^*\text{ground}\textit{al}
\end{aligned}$$

However, only one is correct, even though each suffix appears often in the RESULT transformation of other words. We will refer to this problem as "suffix ambiguity."

Second, many derived words seem to lack a generalizable orthographic relationship to their root words. For example, the RESULT of the verb *speak* is *speech*. It is unlikely, given an orthographically similar verb *creak*, that the RESULT be *creech* instead of, say, *creaking*. Seq2seq models must grapple with the problem of derived words that are the result of unlikely or potentially unseen string transformations. We refer to this problem as "orthographic irregularity."

3 Sequence Models and Corpus Knowledge

In this section, we introduce the prior state-of-the-art model, which serves as our baseline system. Then we build on top of this system by incorporating a dictionary constraint and rescoring the

[2]The * indicates a non-word.

model's hypotheses with token frequency information to address the suffix ambiguity problem.

3.1 Baseline Architecture

We begin by formalizing the problem and defining some notation. For source word $\mathbf{x} = x_1, x_2, \ldots x_m$, a derivational transformation t, and target word $\mathbf{y} = y_1, y_2, \ldots y_n$, our goal is to learn some function from the pair $(\mathbf{x}, t)$ to $\mathbf{y}$. Here, x_i and y_j are the ith and jth characters of the input strings $\mathbf{x}$ and $\mathbf{y}$. We will sometimes use $\mathbf{x}_{1:i}$ to denote $x_1, x_2, \ldots x_i$, and similarly for $\mathbf{y}_{1:j}$.

The current state-of-the-art model for derived-form generation approaches this problem by learning a character-level encoder-decoder neural network with an attention mechanism (Cotterell et al., 2017b; Bahdanau et al., 2014).

The input to the bidirectional LSTM encoder (Hochreiter and Schmidhuber, 1997; Graves and Schmidhuber, 2005) is the sequence #, $x_1, x_2, \ldots x_m$, #, t, where # is a special symbol to denote the start and end of a word, and the encoding of the derivational transformation t is concatenated to the input characters. The model is trained to minimize the cross entropy of the training data. We refer to our reimplementation of this model as SEQ.

For a more detailed treatment of neural sequence-to-sequence models with attention, we direct the reader to Luong et al. (2015).

3.2 Dictionary Constraint

The suffix ambiguity problem poses challenges for models which rely exclusively on input characters for information. As previously demonstrated, words derived via the same transformation may take different suffixes, and it is hard to select among them based on character information alone. Here, we describe a process for restricting our inference procedure to only generate known English words, which we call a dictionary constraint. We believe that for English morphology, a large enough corpus will contain the vast majority of derived forms, so while this approach is somewhat restricting, it removes a significant amount of ambiguity from the problem.

To describe how we implemented this dictionary constraint, it is useful first to discuss how decoding in a seq2seq model is equivalent to solving a shortest path problem. The notation is specific to our model, but the argument is applicable to seq2seq models in general.

The goal of decoding is to find the most probable structure $\hat{\mathbf{y}}$ conditioned on some observation $\mathbf{x}$ and transformation t. That is, the problem is to solve

$$\hat{\mathbf{y}} = \arg\max_{\mathbf{y} \in \mathcal{Y}} p(\mathbf{y} \mid \mathbf{x}, t) \tag{1}$$

$$= \arg\min_{\mathbf{y} \in \mathcal{Y}} -\log p(\mathbf{y} \mid \mathbf{x}, t) \tag{2}$$

where $\mathcal{Y}$ is the set of valid structures. Sequential models have a natural ordering $\mathbf{y} = y_1, y_2, \ldots y_n$ over which $-\log p(\mathbf{y} \mid \mathbf{x}, t)$ can be decomposed

$$-\log p(\mathbf{y} \mid \mathbf{x}, t) = \sum_{t=1}^{n} -\log p(y_t \mid \mathbf{y}_{1:t-1}, \mathbf{x}, t) \tag{3}$$

Solving Equation 2 can be viewed as solving a shortest path problem from a special starting state to a special ending state via some path which uniquely represents $\mathbf{y}$. Each vertex in the graph represents some sequence $\mathbf{y}_{1:i}$, and the weight of the edge from $\mathbf{y}_{1:i}$ to $\mathbf{y}_{1:i+1}$ is given by

$$-\log p(y_{i+1} \mid \mathbf{y}_{1:i-1}, \mathbf{x}, t) \tag{4}$$

The weight of the path from the start state to the end state via the unique path that describes $\mathbf{y}$ is exactly equal to Equation 3. When the vocabulary size is too large, the exact shortest path is intractable, and approximate search methods, such as beam search, are used instead.

In derived word generation, $\mathcal{Y}$ is an infinite set of strings. Since $\mathcal{Y}$ is unrestricted, almost all of the strings in $\mathcal{Y}$ are not valid words. Given a dictionary $\mathcal{Y}_{\mathcal{D}}$, the search space is restricted to only those words in the dictionary by searching over the trie induced from $\mathcal{Y}_{\mathcal{D}}$, which is a subgraph of the unrestricted graph. By limiting the search space to $\mathcal{Y}_{\mathcal{D}}$, the decoder is guaranteed to generate some known word. Models which use this dictionary-constrained inference procedure will be labeled with +DICT. Algorithm 1 has the pseudocode for our decoding procedure.

We discuss specific details of the search procedure and interesting observations of the search space in Section 6. Section 5.2 describes how we obtained the dictionary of valid words.

3.3 Word Frequency Knowledge through Rescoring

We also consider the inclusion of explicit word frequency information to help solve suffix ambiguity, using the intuition that "real" derived words are likely to be frequently attested. This permits a high-recall, potentially noisy dictionary.

We are motivated by very high top-10 accuracy compared to top-1 accuracy, even among dictionary-constrained models. By rescoring the hypotheses of a model using word frequency (a word-global signal) as a feature, attempt to recover a portion of this top-10 accuracy.

When a model has been trained, we query it for its top-10 most likely hypotheses. The union of all hypotheses for a subset of the training observations forms the training set for a classifier that learns to predict whether a hypothesis generated by the model is correct. Each hypothesis is labelled with its correctness, a value in $\{\pm 1\}$. We train a simple combination of two scores: the seq2seq model score for the hypothesis, and the log of the word frequency of the hypothesis.

To permit a nonlinear combination of word frequency and model score, we train a small multilayer perceptron with the model score and the frequency of a derived word hypothesis as features.

At testing time, the 10 hypotheses generated by a single seq2seq model for a single observation are rescored. The new model top-1 hypothesis, then, is the argmax over the 10 hypotheses according to the rescorer. In this way, we are able to incorporate word-global information, e.g. word frequency, that is ill-suited for incorporation at each character prediction step of the seq2seq model. We label models that are rescored in this way +FREQ.

4 Distributional Models

So far, we have presented models that learn derivational transformations as orthographic operations. Such models struggle by construction with the orthographic irregularity problem, as they are trained to generalize orthographic information. However, the semantic relationships between root words and derived words are the same even when the orthography is dissimilar. It is salient, for example, that irregular word *speech* is related to its root *speak* in about the same way as how *exploration* is related to the word *explore*.

We model distributional transformations as functions in dense distributional word embedding spaces, crucially learning a function per derivational transformation, not per suffix pair. In this way, we aim to explicitly model the semantic transformation, not the othographic information.

4.1 Feed-forward derivational transformations

For all source words $\mathbf{x}$ and all target words $\mathbf{y}$, we look up static distributional embeddings $v_{\mathbf{x}}, v_{\mathbf{y}} \in \mathbb{R}^d$. For each derivational transformation t, we learn a function $f_t : \mathbb{R}^d \to \mathbb{R}^d$ that maps $v_{\mathbf{x}}$ to $v_{\mathbf{y}}$. f_t is parametrized as two-layer perceptron, trained using a squared loss,

$$\mathcal{L} = \mathbf{b}^{\mathrm{T}}\mathbf{b} \tag{5}$$

$$\mathbf{b} = f_t(v_{\mathbf{x}}) - v_{\mathbf{y}} \tag{6}$$

We perform inference by nearest neighbor search in the embedding space. This inference strategy requires a subset of strings for our embedding dictionary, $\mathcal{Y}_V$.

Upon receiving $(\mathbf{x}, t)$ at test time, we compute $f_t(v_{\mathbf{x}})$ and find the most similar embeddings in $\mathcal{Y}_V$. Specifically, we find the top-k most similar embeddings, and take the most similar derived word that starts with the same 4 letters as the root word, and is not identical to it. This heuristic filters out highly implausible hypotheses.

We use the single-word subset of the Google News vectors (Mikolov et al., 2013) as $\mathcal{Y}_V$, so the size of the vocabulary is 929k words.

4.2 SEQ and DIST Aggregation

The seq2seq and distributional models we have presented learn with disjoint information to solve separate problems. We leverage this intuition to build a model that chooses, for each observation, whether to generate according to orthographic information via the SEQ model, or produce a potentially irregular form via the DIST model.

To train this model, we use a held-out portion of the training set, and filter it to only observations for which exactly one of the two models produces the correct derived form. Finally, we make the strong assumption that the probability of a derived form being generated correctly according to 1 model as opposed to the other is dependent only on the unnormalized model score from each. We model this as a logistic regression (t is omitted for clarity):

$$P(\cdot|\mathbf{y_D}, \mathbf{y_S}, \mathbf{x}) = \\ \mathrm{softmax}(\mathbf{W}_e \left[\textsc{Dist}(\mathbf{y_D}|\mathbf{x}); \textsc{Seq}(\mathbf{y_S}|\mathbf{x})\right] + \mathbf{b}_e)$$

where $\mathbf{W_e}$ and $\mathbf{b_e}$ are learned parameters, $\mathbf{y_D}$ and $\mathbf{y_S}$ are the hypotheses of the distributional and seq2seq models, and $\textsc{Dist}(\cdot)$ and $\textsc{Seq}(\cdot)$ are the models' likelihood functions. We denote this aggregate AGGR in our results.

5 Datasets

In this section we describe the derivational morphology dataset used in our experiments and how we collected the dictionary and token frequencies used in the dictionary constraint and rescorer.

5.1 Derivational Morphology

In our experiments, we use the derived word generation derivational morphology dataset released in Cotterell et al. (2017b). The dataset, derived from NomBank (Meyers et al., 2004) , consists of 4,222 training, 905 validation, and 905 test triples of the form $(\mathbf{x}, t, \mathbf{y})$. The transformations are from the following categories: ADVERB (ADJ $\rightarrow$ ADV), RESULT (V $\rightarrow$ N), AGENT (V $\rightarrow$ N), and NOMINAL (ADJ $\rightarrow$ N). Examples from the dataset can be found in Table 1.

5.2 Dictionary and Token Frequency Statistics

The dictionary and token frequency statistics used in the dictionary constraint and frequency reranking come from the Google Books NGram corpus (Michel et al., 2011). The unigram frequency counts were aggregated across years, and any tokens which appear fewer than approximately 2,000 times, do not end in a known possible suffix, or contain a character outside of our vocabulary were removed.

The frequency threshold was determined using development data, optimizing for high recall. We collect a set of known suffixes from the training data by removing the longest common prefix between the source and target words from the target word. The result is a dictionary with frequency information for around 360k words, which covers 98% of the target words in the training data.[3]

6 Inference Procedure Discussion

In many sequence models where the vocabulary size is large, exact inference by finding the true shortest path in the graph discussed in Section 3.2 is intractable. As a result, approximate inference techniques such as beam search are often used, or the size of the search space is reduced, for example, by using a Markov assumption. We, however, observed that exact inference via a shortest path algorithm is not only tractable in our model, but only slightly more expensive than greedy search and significantly less expensive than beam search.

[3] The remaining 2% is mostly words with hyphens or mistakes in the dataset.

Method	Accuracy	Avg. #States
GREEDY	75.9	11.8
BEAM	76.2	101.2
SHORTEST	76.2	11.8
DICT+GREEDY	77.2	11.7
DICT+BEAM	82.6	91.2
DICT+SHORTEST	82.6	12.4

Table 2: The average accuracies and number of states explored in the search graph of 30 runs of the SEQ model with various search procedures. The BEAM models use a beam size of 10.

To quantify this claim, we measured the accuracy and number of states explored by greedy search, beam search, and shortest path with and without a dictionary constraint on the development data. Table 2 shows the results averaged over 30 runs. As expected, beam search and shortest path have higher accuracies than greedy search and explore more of the search space. Surprisingly, beam search and shortest path have nearly identical accuracies, but shortest path explores significantly fewer hypotheses.

At least two factors contribute to the tractability of exact search in our model. First, our character-level sequence model has a vocabulary size of 63, which is significantly smaller than token-level models, in which a vocabulary of 50k words is not uncommon. The search space of sequence models is dependent upon the size of the vocabulary, so the model's search space is dramatically smaller than for a token-level model.

Second, the inherent structure of the task makes it easy to eliminate large subgraphs of the search space. The first several characters of the input word and output word are almost always the same, so the model assigns very low probability to any sequence with different starting characters than the input. Then, the rest of the search procedure is dedicated to deciding between suffixes. Any suffix which does not appear frequently in the training data receives a low score, leaving the search to decide between a handful of possible options. The result is that the learned probability distribution is very spiked; it puts very high probability on just a few output sequences. It is empirically true that the top few most probable sequences have significantly higher scores than the next most probable sequences, which supports this hypothesis.

In our subsequent experiments, we decode using

Algorithm 1 The decoding procedure uses a shortest-path algorithm to find the most probable output sequence. The dictionary constraint is (optionally) implemented on line 9 by only considering prefixes that are contained in some trie T.

```
1: procedure DECODE($\mathbf{x}$, $t$, $V$, $T$)
2:     $H \leftarrow$ Heap()
3:     $H$.insert(0, #)
4:     while $H$ is not empty do
5:         $\mathbf{y} \leftarrow H$.remove()
6:         if $\mathbf{y}$ is a complete word then return $\mathbf{y}$
7:         for $y \in V$ do
8:             $\mathbf{y}' \leftarrow \mathbf{y} + y$
9:             if $\mathbf{y}' \in T$ then
10:                $s \leftarrow$ FORWARD($\mathbf{x}, t, \mathbf{y}'$)
11:                $H$.insert($s$, $\mathbf{y}'$)
```

exact inference by running a shortest path algorithm (see Algorithm 1). For reranking models, instead of typically using a beam of size k, we use the top k most probable sequences.

7 Results

In all of our experiments, we use the training, development, and testing splits provided by Cotterell et al. (2017b) and average over 30 random restarts. Table 3 displays the accuracies and average edit distances on the test set of each of the systems presented in this work and the state-of-the-art model from Cotterell et al. (2017b).

First, we observed that SEQ outperforms the results reported in Cotterell et al. (2017b) by a large margin, despite the fact that the model architectures are the same. We attribute this difference to better hyperparameter settings and improved learning rate annealing.

Then, it is clear that the accuracy of the distributional model, DIST, is significantly lower than any seq2seq model. We believe the orthography-informed models perform better because most observations in the dataset are orthographically regular, providing low-hanging fruit.

Open-vocabulary models Our open-vocabulary aggregation model AGGR improves performance by 3.8 points accuracy over SEQ, indicating that the sequence models and the distributional model are contributing complementary signals. AGGR is an open-vocabulary model like Cotterell et al. (2017b) and improves upon it by 6.3 points, making it our best comparable model. We provide an in-depth analysis of the strengths of SEQ and DIST in Section 7.1.

Model	Accuracy	Edit
Cotterell et al. (2017b)	71.7	0.97
DIST	54.9	3.23
SEQ	74.2	0.88
AGGR	78.0	0.83
SEQ+FREQ	79.3	0.71
DUAL+FREQ	**82.0**	**0.64**
SEQ+DICT	80.4	0.72
AGGR+DICT	81.0	0.78
SEQ+FREQ+DICT	81.2	0.71
AGGR+FREQ+DICT	**82.4**	**0.67**

Table 3: The accuracies and edit distances of the models presented in this paper and prior work. For edit distance, lower is better. The dictionary-constrained models are on the lower half of the table.

Closed-vocabulary models We now consider closed-vocabulary models that improve upon the seq2seq model in AGGR. First, we see that restricting the decoder to only generate known words is extremely useful, with SEQ+DICT improving over SEQ by 6.2 points. Qualitatively, we note that this constraint helps solve the suffix ambiguity problem, since orthographically plausible incorrect hypotheses are pruned as non-words. See Table 6 for examples of this phenomenon. Additionally, we observe that the dictionary-constrained model outperforms the unconstrained model according to top-10 accuracy (see Table 5).

Rescoring (+FREQ) provides further improvement of 0.8 points, showing that the decoding dictionary constraint provides a higher-quality beam that still has room for top-1 improvement. All together, AGGR+FREQ+DICT provides a 4.4 point improvement over the best open-vocabulary model, AGGR. This shows the disambiguating power of assuming a closed vocabulary.

Edit Distance One interesting side effect of the dictionary constraint appears when comparing AGGR+FREQ with and without the dictionary constraint. Although the accuracy of the dictionary-constrained model is better, the average edit distance is worse. The unconstrained model is free to put invalid words which are orthographically similar to the target word in its top-k, however the constrained model can only choose valid words. This means it is easier for the unconstrained model to generate words which have a low edit distance to the ground truth, whereas the constrained model

can only do that if such a word exists. The result is a more accurate, yet more orthographically diverse, set of hypotheses.

Results by Transformation Next, we compare our best open vocabulary and closed vocabulary models to previous work across each derivational transformation. These results are in Table 4.

The largest improvement over the baseline system is for NOMINAL transformations, in which the AGGR has a 49% reduction in error. We attribute most of this gain to the difficulty of this particular transformation. NOMINAL is challenging because there are several plausible endings (e.g. *-ity*, *-ness*, *-ence*) which occur at roughly the same rate. Additionally, NOMINAL examples are the least frequent transformation in the dataset, so it is challenging for a sequential model to learn to generalize. The distributional model, which does not rely on suffix information, does not have this same weakness, so the aggregation AGGR model has better results.

The performance of AGGR+FREQ+DICT is worse than AGGR, however. This is surprising because, in all other transformations, adding dictionary information improves the accuracies. We believe this is due to the ambiguity of the ground truth: Many root words have seemingly multiple plausible nominal transformations, such as *rigid* $\rightarrow$ {*rigidness*, *rigidity*} and *equivalent* $\rightarrow$ {*equivalence*, *equivalency*}. The dictionary constraint produces a better set of hypotheses to rescore, as demonstrated in Table 5. Therefore, the dictionary-constrained model is likely to have more of these ambiguous cases, which makes the task more difficult.

7.1 Strengths of SEQ and DIST

In this subsection we explore why AGGR improves consistently over SEQ even though it maintains an open vocabulary. We have argued that DIST is able to correctly produce derived words that are orthographically irregular or infrequent in the training data. Figure 2 quantifies this phenomenon, analyzing the difference in accuracy between the two models, and plotting this in relationship to the frequency of the suffix in the training data. The plot shows that SEQ excels at generating derived words ending in *-ly, -ion*, and other suffixes that appeared frequently in the training data. DIST's improvements over SEQ are generally much less frequent in the training data, or as in the case of *-ment*, are less frequent than other suffixes for the same transformation (like *-ion*.) By producing derived words whose suffixes show up rarely in the training data, DIST helps solve the orthographic irregularity problem.

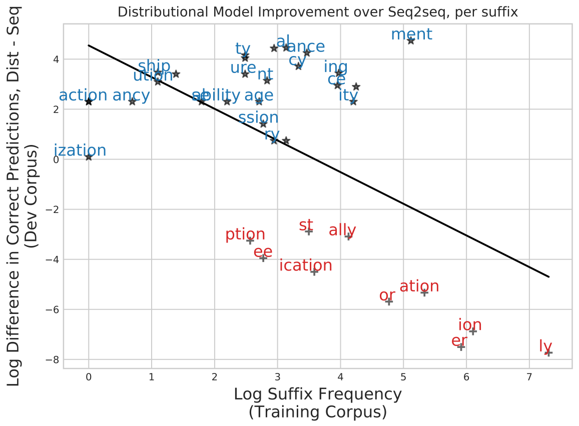

Figure 2: Aggregating across 30 random restarts, we tallied when SEQ and DIST correctly produced derived forms of each suffix. The y-axis shows the logarithm of the difference, per suffix, between the tally for DIST and the tally for SEQ. On the x-axis is the logarithm of the frequency of derived words with each suffix in the training data. A linear regression line is plotted to show the relationship between log suffix frequency and log difference in correct predictions. Suffixes that differ only by the first letter, as with *-ger* and *-er*, have been merged and represented by the more frequent of the two.

8 Prior Work

There has been much work on the related task of inflected word generation (Durrett and DeNero,

2013; Rastogi et al., 2016; Hulden et al., 2014). It is a structurally similar task to ours, but does not have the same difficulty of challenges (Cotterell et al., 2017a,b), which we have addressed in our work. The paradigm completion for derivational morphology dataset we use in this work was introduced in Cotterell et al. (2017b). They apply the model that won the 2016 SIGMORPHON shared task on inflectional morphology to derivational morphology (Kann and Schütze, 2016; Cotterell et al., 2016). We use this as our baseline.

Our implementation of the dictionary constraint is an example of a special constraint which can be directly incorporated into the inference algorithm at little additional cost. Roth and Yih (2004, 2007) propose a general inference procedure that naturally incorporates constraints through recasting inference as solving an integer linear program.

Beam or hypothesis rescoring to incorporate an expensive or non-decomposable signal into search has a history in machine translation (Huang and Chiang, 2007). In inflectional morphology, Nicolai et al. (2015) use this idea to rerank hypotheses using orthographic features and Faruqui et al. (2016) use a character-level language model. Our approach is similar to Faruqui et al. (2016) in that we use statistics from a raw corpus, but at the token level.

There have been several attempts to use distributional information in morphological generation and analysis. Soricut and Och (2015) collect pairs of words related by any morphological change in an unsupervised manner, then select a vector offset which best explains their observations. There has been subsequent work exploring the vector offset method, finding it unsuccessful in capturing derivational transformations (Gladkova et al., 2016). However, we use more expressive, nonlinear functions to model derivational transformations and report positive results. Gupta et al. (2017) then learn a linear transformation per orthographic rule to solve a word analogy task. Our distributional model learns a function per derivational transformation, not per orthographic rule, which allows it to generalize to unseen orthography.

9 Implementation Details

Our models are implemented in Python using the DyNet deep learning library (Neubig et al., 2017). The code is freely available for download.[4]

Sequence Model The sequence-to-sequence model uses character embeddings of size 20, which are shared across the encoder and decoder, with a vocabulary size of 63. The hidden states of the LSTMs are of size 40.

For training, we use Adam with an initial learning rate of 0.005, a batch size of 5, and train for a maximum of 30 epochs. If after one epoch of the training data, the loss on the validation set does not decrease, we anneal the learning rate by half and revert to the previous best model.

During decoding, we find the top 1 most probable sequence as discussed in Section 6 unless rescoring is used, in which we use the top 10.

Rescorer The rescorer is a 1-hidden-layer perceptron with a `tanh` nonlinearity and 4 hidden units. It is trained for a maximum of 5 epochs.

Distributional Model The DIST model is a 1-hidden-layer perceptron with a `tanh` nonlinearity

[4] https://github.com/danieldeutsch/acl2018

and 100 hidden units. It is trained for a maximum of 25 epochs.

10 Conclusion

In this work, we present a novel aggregation model for derived word generation. This model learns to choose between the predictions of orthographically- and distributionally-informed models. This ameliorates suffix ambiguity and orthographic irregularity, the salient problems of the generation task. Concurrently, we show that derivational transformations can be usefully modeled as nonlinear functions on distributional word embeddings. The distributional and orthographic models aggregated contribute orthogonal information to the aggregate, as shown by substantial improvements over state-of-the-art results, and qualitative analysis. Two ways of incorporating corpus knowledge – constrained decoding and rescoring – demonstrate further improvements to our main contribution.

Abstract

In this paper, we propose a joint architecture that captures language, rhyme and meter for sonnet modelling. We assess the quality of generated poems using crowd and expert judgements. The stress and rhyme models perform very well, as generated poems are largely indistinguishable from human-written poems. Expert evaluation, however, reveals that a vanilla language model captures meter implicitly, and that machine-generated poems still underperform in terms of readability and emotion. Our research shows the importance expert evaluation for poetry generation, and that future research should look beyond rhyme/meter and focus on poetic language.

1 Introduction

With the recent surge of interest in deep learning, one question that is being asked across a number of fronts is: can deep learning techniques be harnessed for creative purposes? Creative applications where such research exists include the composition of music (Humphrey et al., 2013; Sturm et al., 2016; Choi et al., 2016), the design of sculptures (Lehman et al., 2016), and automatic choreography (Crnkovic-Friis and Crnkovic-Friis, 2016). In this paper, we focus on a creative textual task: automatic poetry composition.

A distinguishing feature of poetry is its *aesthetic forms*, e.g. rhyme and rhythm/meter.[1] In this work, we treat the task of poem generation as a constrained language modelling task, such that lines of a given poem rhyme, and each line follows a canonical meter and has a fixed number of stresses. Specifically, we focus on sonnets and generate quatrains in iambic pentameter (e.g. see Figure 1), based on an unsupervised model of language, rhyme and meter trained on a novel corpus of sonnets.

Shall I compare thee to a summer's day?
Thou art more lovely and more temperate:
Rough winds do shake the darling buds of May,
And summer's lease hath all too short a date:

Figure 1: 1st quatrain of Shakespeare's *Sonnet 18*.

Our findings are as follows:

- our proposed stress and rhyme models work very well, generating sonnet quatrains with stress and rhyme patterns that are indistinguishable from human-written poems and rated highly by an expert;
- a vanilla language model trained over our sonnet corpus, surprisingly, captures meter implicitly at human-level performance;
- while crowd workers rate the poems generated by our best model as nearly indistinguishable from published poems by humans, an expert annotator found the machine-generated poems to lack readability and emotion, and our best model to be only comparable to a vanilla language model on these dimensions;
- most work on poetry generation focuses on meter (Greene et al., 2010; Ghazvininejad et al., 2016; Hopkins and Kiela, 2017); our results suggest that future research should look beyond meter and focus on improving readability.

In this, we develop a new annotation framework for the evaluation of machine-generated poems, and release both a novel data of sonnets and the full source code associated with this research.[2]

[1]Noting that there are many notable divergences from this in the work of particular poets (e.g. Walt Whitman) and poetry types (such as free verse or haiku).

2 Related Work

Early poetry generation systems were generally rule-based, and based on rhyming/TTS dictionaries and syllable counting (Gervás, 2000; Wu et al., 2009; Netzer et al., 2009; Colton et al., 2012; Toivanen et al., 2013). The earliest attempt at using statistical modelling for poetry generation was Greene et al. (2010), based on a language model paired with a stress model.

Neural networks have dominated recent research. Zhang and Lapata (2014) use a combination of convolutional and recurrent networks for modelling Chinese poetry, which Wang et al. (2016) later simplified by incorporating an attention mechanism and training at the character level. For English poetry, Ghazvininejad et al. (2016) introduced a finite-state acceptor to explicitly model rhythm in conjunction with a recurrent neural language model for generation. Hopkins and Kiela (2017) improve rhythm modelling with a cascade of weighted state transducers, and demonstrate the use of character-level language model for English poetry. A critical difference over our work is that we jointly model both poetry content and forms, and unlike previous work which use dictionaries (Ghazvininejad et al., 2016) or heuristics (Greene et al., 2010) for rhyme, we learn it automatically.

3 Sonnet Structure and Dataset

The sonnet is a poem type popularised by Shakespeare, made up of 14 lines structured as 3 quatrains (4 lines) and a couplet (2 lines);[3] an example quatrain is presented in Figure 1. It follows a number of *aesthetic forms*, of which two are particularly salient: stress and rhyme.

A sonnet line obeys an alternating stress pattern, called the iambic pentameter, e.g.:

$$\begin{array}{cccccccccc} S^- & S^+ & S^- & S^+ & S^- & S^+ & S^- & S^+ & S^- & S^+ \\ \textit{Shall} & \textit{I} & \textit{com} & \textit{pare} & \textit{thee} & \textit{to} & \textit{a} & \textit{sum} & \textit{mer's} & \textit{day?} \end{array}$$

where S^- and S^+ denote unstressed and stressed syllables, respectively.

A sonnet also rhymes, with a typical rhyming scheme being *ABAB CDCD EFEF GG*. There are a number of variants, however, mostly seen in the quatrains; e.g. *AABB* or *ABBA* are also common.

We build our sonnet dataset from the latest image of Project Gutenberg.[4] We first create a (generic) poetry document collection using the GutenTag tool (Brooke et al., 2015), based on its inbuilt poetry classifier and rule-based structural tagging of individual poems.

Given the poems, we use word and character statistics derived from Shakespeare's 154 sonnets to filter out all non-sonnet poems (to form the "BACKGROUND" dataset), leaving the sonnet corpus ("SONNET").[5] Based on a small-scale manual analysis of SONNET, we find that the approach is sufficient for extracting sonnets with high precision. BACKGROUND serves as a large corpus (34M words) for pre-training word embeddings, and SONNET is further partitioned into training, development and testing sets. Statistics of SONNET are given in Table 1.[6]

Partition	#Sonnets	#Words
Train	2685	367K
Dev	335	46K
Test	335	46K

Table 1: SONNET dataset statistics.

4 Architecture

We propose modelling both content and forms jointly with a neural architecture, composed of 3 components: (1) a language model; (2) a pentameter model for capturing iambic pentameter; and (3) a rhyme model for learning rhyming words.

Given a sonnet line, the language model uses standard categorical cross-entropy to predict the next word, and the pentameter model is similarly trained to learn the alternating iambic stress patterns.[7] The rhyme model, on the other hand, uses a margin-based loss to separate rhyming word pairs from non-rhyming word pairs in a quatrain. For generation we use the language model to generate one word at a time, while applying the pentame-

[3]There are other forms of sonnets, but the Shakespearean sonnet is the dominant one. Hereinafter "sonnet" is used to specifically mean Shakespearean sonnets.

[4]`https://www.gutenberg.org/`.

[5]The following constraints were used to select sonnets: $8.0 \leqslant$ mean words per line $\leqslant 11.5$; $40 \leqslant$ mean characters per line $\leqslant 51.0$; min/max number of words per line of 6/15; min/max number of characters per line of 32/60; and min letter ratio per line $\geqslant 0.59$.

[6]The sonnets in our collection are largely in Modern English, with possibly a small number of poetry in Early Modern English. The potentially mixed-language dialect data might add noise to our system, and given more data it would be worthwhile to include time period as a factor in the model.

[7]There are a number of variations in addition to the standard pattern (Greene et al., 2010), but our model uses only the standard pattern as it is the dominant one.

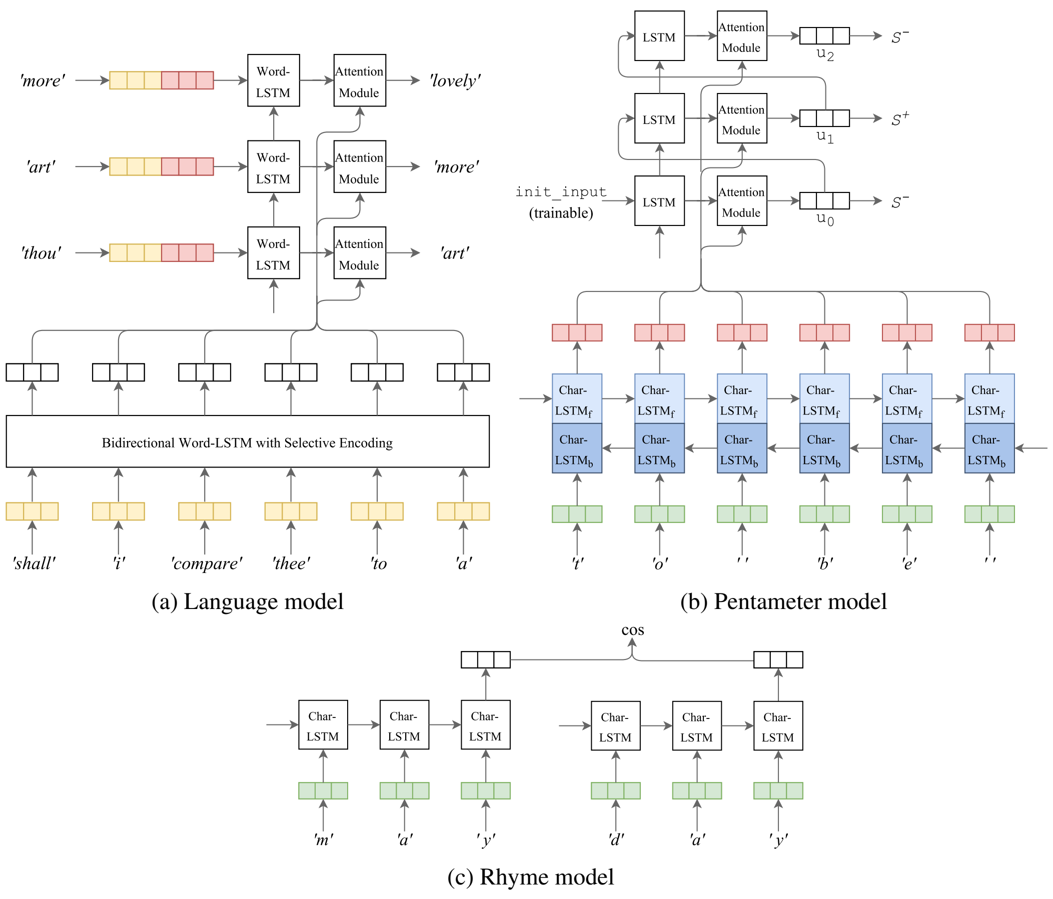

Figure 2: Architecture of the language, pentameter and rhyme models. Colours denote shared weights.

ter model to sample meter-conforming sentences and the rhyme model to enforce rhyme. The architecture of the joint model is illustrated in Figure 2. We train all the components together by treating each component as a sub-task in a multi-task learning setting.[8]

4.1 Language Model

The language model is a variant of an LSTM encoder–decoder model with attention (Bahdanau et al., 2015), where the encoder encodes the preceding context (i.e. all sonnet lines before the current line) and the decoder decodes one word at a time for the current line, while attending to the preceding context.

In the encoder, we embed context words z_i using embedding matrix $\mathbf{W}_{wrd}$ to yield $\mathbf{w}_i$, and feed them to a biLSTM[9] to produce a sequence of encoder hidden states $\mathbf{h}_i = [\vec{\mathbf{h}}_i; \overleftarrow{\mathbf{h}}_i]$. Next we apply a selective mechanism (Zhou et al., 2017) to each $\mathbf{h}_i$. By defining the representation of the whole context $\overline{\mathbf{h}} = [\vec{\mathbf{h}}_C; \overleftarrow{\mathbf{h}}_1]$ (where C is the number of words in the context), the selective mechanism filters the hidden states $\mathbf{h}_i$ using $\overline{\mathbf{h}}$ as follows:

$$\mathbf{h}'_i = \mathbf{h}_i \odot \sigma(\mathbf{W}_a \mathbf{h}_i + \mathbf{U}_a \overline{\mathbf{h}} + \mathbf{b}_a)$$

where $\odot$ denotes element-wise product. Hereinafter $\mathbf{W}$, $\mathbf{U}$ and $\mathbf{b}$ are used to refer to model parameters. The intuition behind this procedure is to selectively filter less useful elements from the context words.

In the decoder, we embed words x_t in the current line using the encoder-shared embedding matrix ($\mathbf{W}_{wrd}$) to produce $\mathbf{w}_t$. In addition to the word embeddings, we also embed the characters of a word using embedding matrix $\mathbf{W}_{chr}$ to produce $\mathbf{c}_{t,i}$, and feed them to a bidirectional (character-level) LSTM:

$$\begin{aligned} \vec{\mathbf{u}}_{t,i} &= \mathrm{LSTM}_f(\mathbf{c}_{t,i}, \vec{\mathbf{u}}_{t,i-1}) \\ \overleftarrow{\mathbf{u}}_{t,i} &= \mathrm{LSTM}_b(\mathbf{c}_{t,i}, \overleftarrow{\mathbf{u}}_{t,i+1}) \end{aligned} \qquad (1)$$

We represent the character encoding of a word by concatenating the last forward and first back-

[8]We stress that although the components appear to be disjointed, the shared parameters allow the components to mutually influence each other during joint training. To exemplify this, we found that the pentameter model performs very poorly when we train each component separately.

[9]We use a single layer for all LSTMs.

ward hidden states $\overline{\mathbf{u}}_t = [\vec{\mathbf{u}}_{t,L}; \overleftarrow{\mathbf{u}}_{t,1}]$, where L is the length of the word. We incorporate character encodings because they provide orthographic information, improve representations of unknown words, and are shared with the pentameter model (Section 4.2).[10] The rationale for sharing the parameters is that we see word stress and language model information as complementary.

Given the word embedding $\mathbf{w}_t$ and character encoding $\overline{\mathbf{u}}_t$, we concatenate them together and feed them to a unidirectional (word-level) LSTM to produce the decoding states:

$$\mathbf{s}_t = \text{LSTM}([\mathbf{w}_t; \overline{\mathbf{u}}_t], \mathbf{s}_{t-1}) \tag{2}$$

We attend $\mathbf{s}_t$ to encoder hidden states $\mathbf{h}'_i$ and compute the weighted sum of $\mathbf{h}'_i$ as follows:

$$\begin{aligned} e^t_i &= \mathbf{v}_b^\intercal \tanh(\mathbf{W}_b\mathbf{h}'_i + \mathbf{U}_b\mathbf{s}_t + \mathbf{b}_b) \\ \mathbf{a}^t &= \text{softmax}(\mathbf{e}^t) \\ \mathbf{h}^*_t &= \sum_i a^t_i \mathbf{h}'_i \end{aligned}$$

To combine $\mathbf{s}_t$ and $\mathbf{h}^*_t$, we use a gating unit similar to a GRU (Cho et al., 2014; Chung et al., 2014): $\mathbf{s}'_t = \text{GRU}(\mathbf{s}_t, \mathbf{h}^*_t)$. We then feed $\mathbf{s}'_t$ to a linear layer with softmax activation to produce the vocabulary distribution (i.e. softmax$(\mathbf{W}_{out}\mathbf{s}'_t + \mathbf{b}_{out})$, and optimise the model with standard categorical cross-entropy loss. We use dropout as regularisation (Srivastava et al., 2014), and apply it to the encoder/decoder LSTM outputs and word embedding lookup. The same regularisation method is used for the pentameter and rhyme models.

As our sonnet data is relatively small for training a neural language model (367K words; see Table 1), we pre-train word embeddings and reduce parameters further by introducing weight-sharing between output matrix $\mathbf{W}_{out}$ and embedding matrix $\mathbf{W}_{wrd}$ via a projection matrix $\mathbf{W}_{prj}$ (Inan et al., 2016; Paulus et al., 2017; Press and Wolf, 2017):

$$\mathbf{W}_{out} = \tanh(\mathbf{W}_{wrd}\mathbf{W}_{prj})$$

4.2 Pentameter Model

This component is designed to capture the alternating iambic stress pattern. Given a sonnet line, the pentameter model learns to attend to the appropriate characters to predict the 10 binary stress symbols sequentially.[11] As punctuation is not pronounced, we preprocess each sonnet line to remove all punctuation, leaving only spaces and letters. Like the language model, the pentameter model is fashioned as an encoder–decoder network.

In the encoder, we embed the characters using the shared embedding matrix $\mathbf{W}_{chr}$ and feed them to the shared bidirectional character-level LSTM (Equation (1)) to produce the character encodings for the sentence: $\mathbf{u}_j = [\vec{\mathbf{u}}_j; \overleftarrow{\mathbf{u}}_j]$.

In the decoder, it attends to the characters to predict the stresses sequentially with an LSTM:

$$\mathbf{g}_t = \text{LSTM}(\mathbf{u}^*_{t-1}, \mathbf{g}_{t-1})$$

where $\mathbf{u}^*_{t-1}$ is the weighted sum of character encodings from the previous time step, produced by an attention network which we describe next,[12] and $\mathbf{g}_t$ is fed to a linear layer with softmax activation to compute the stress distribution.

The attention network is designed to focus on stress-producing characters, whose positions are monotonically increasing (as stress is predicted sequentially). We first compute μ_t, the mean position of focus:

$$\begin{aligned} \mu'_t &= \sigma(\mathbf{v}_c^\intercal \tanh(\mathbf{W}_c\mathbf{g}_t + \mathbf{U}_c\mu_{t-1} + \mathbf{b}_c)) \\ \mu_t &= M \times \min(\mu'_t + \mu_{t-1}, 1.0) \end{aligned}$$

where M is the number of characters in the sonnet line. Given μ_t, we can compute the (unnormalised) probability for each character position:

$$p^t_j = \exp\left(\frac{-(j-\mu_t)^2}{2T^2}\right)$$

where standard deviation T is a hyper-parameter. We incorporate this position information when computing $\mathbf{u}^*_t$:[13]

$$\begin{aligned} \mathbf{u}'_j &= p^t_j \mathbf{u}_j \\ d^t_j &= \mathbf{v}_d^\intercal \tanh(\mathbf{W}_d\mathbf{u}'_j + \mathbf{U}_d\mathbf{g}_t + \mathbf{b}_d) \\ \mathbf{f}^t &= \text{softmax}(\mathbf{d}^t + \log \mathbf{p}^t) \\ \mathbf{u}^*_t &= \sum_j b^t_j \mathbf{u}_j \end{aligned}$$

[10] We initially shared the character encodings with the rhyme model as well, but found sub-par performance for the rhyme model. This is perhaps unsurprising, as rhyme and stress are qualitatively very different aspects of forms.

[11] That is, given the input line *Shall I compare thee to a summer's day?* the model is required to output S^- S^+ S^- S^+ S^- S^+ S^- S^+ S^- S^+, based on the syllable boundaries from Section 3.

[12] Initial input ($\mathbf{u}^*_0$) and state ($\mathbf{g}_0$) is a trainable vector and zero vector respectively.

[13] Spaces are masked out, so they always yield zero attention weights.

Intuitively, the attention network incorporates the position information at two points, when computing: (1) d_j^t by weighting the character encodings; and (2) $\mathbf{f}^t$ by adding the position log probabilities. This may appear excessive, but preliminary experiments found that this formulation produces the best performance.

In a typical encoder–decoder model, the attended encoder vector $\mathbf{u}_t^*$ would be combined with the decoder state $\mathbf{g}_t$ to compute the output probability distribution. Doing so, however, would result in a zero-loss model as it will quickly learn that it can simply ignore $\mathbf{u}_t^*$ to predict the alternating stresses based on $\mathbf{g}_t$. For this reason we use only $\mathbf{u}_t^*$ to compute the stress probability:

$$P(S^-) = \sigma(\mathbf{W}_e\mathbf{u}_t^* + b_e)$$

which gives the loss $\mathcal{L}_{ent} = \sum_t -\log P(S_t^\star)$ for the whole sequence, where $S_t^\star$ is the target stress at time step t.

We find the decoder still has the tendency to attend to the same characters, despite the incorporation of position information. To regularise the model further, we introduce two loss penalties: repeat and coverage loss.

The repeat loss penalises the model when it attends to previously attended characters (See et al., 2017), and is computed as follows:

$$\mathcal{L}_{rep} = \sum_t \sum_j \min(f_j^t, \sum_{t=1}^{t-1} f_j^t)$$

By keeping a sum of attention weights over all previous time steps, we penalise the model when it focuses on characters that have non-zero history weights.

The repeat loss discourages the model from focussing on the same characters, but does not assure that the appropriate characters receive attention. Observing that stresses are aligned with the vowels of a syllable, we therefore penalise the model when vowels are ignored:

$$\mathcal{L}_{cov} = \sum_{j \in V} \text{ReLU}(C - \sum_{t=1}^{10} f_j^t)$$

where V is a set of positions containing vowel characters, and C is a hyper-parameter that defines the minimum attention threshold that avoids penalty.

To summarise, the pentameter model is optimised with the following loss:

$$\mathcal{L}_{pm} = \mathcal{L}_{ent} + \alpha\mathcal{L}_{rep} + \beta\mathcal{L}_{cov} \tag{3}$$

where α and β are hyper-parameters for weighting the additional loss terms.

4.3 Rhyme Model

Two reasons motivate us to learn rhyme in an unsupervised manner: (1) we intend to extend the current model to poetry in other languages (which may not have pronunciation dictionaries); and (2) the language in our SONNET data is not Modern English, and so contemporary dictionaries may not accurately reflect the rhyme of the data.

Exploiting the fact that rhyme exists in a quatrain, we feed sentence-ending word pairs of a quatrain as input to the rhyme model and train it to learn how to separate rhyming word pairs from non-rhyming ones. Note that the model does not assume any particular rhyming scheme — it works as long as quatrains have rhyme.

A training example consists of a number of word pairs, generated by pairing one target word with 3 other reference words in the quatrain, i.e. $\{(x_t, x_r), (x_t, x_{r+1}), (x_t, x_{r+2})\}$, where x_t is the target word and x_{r+i} are the reference words.[14] We assume that in these 3 pairs there should be one rhyming and 2 non-rhyming pairs. From preliminary experiments we found that we can improve the model by introducing additional non-rhyming or negative reference words. Negative reference words are sampled uniform randomly from the vocabulary, and the number of additional negative words is a hyper-parameter.

For each word x in the word pairs we embed the characters using the shared embedding matrix $\mathbf{W}_{chr}$ and feed them to an LSTM to produce the character states $\mathbf{u}_j$.[15] Unlike the language and pentameter models, we use a unidirectional forward LSTM here (as rhyme is largely determined by the final characters), and the LSTM parameters are not shared. We represent the encoding of the whole word by taking the last state $\overline{\mathbf{u}} = \mathbf{u}_L$, where L is the character length of the word.

Given the character encodings, we use a

[14]E.g. for the quatrain in Figure 1, a training example is $\{$(*day*, *temperate*), (*day*, *may*), (*day*, *date*)$\}$.

[15]The character embeddings are the only shared parameters in this model.

margin-based loss to optimise the model:

$$Q = \{\cos(\overline{\mathbf{u}}_t, \overline{\mathbf{u}}_r), \cos(\overline{\mathbf{u}}_t, \overline{\mathbf{u}}_{r+1}), ...\}$$
$$\mathcal{L}_{rm} = \max(0, \delta - \text{top}(Q, 1) + \text{top}(Q, 2))$$

where $\text{top}(Q, k)$ returns the k-th largest element in Q, and δ is a margin hyper-parameter.

Intuitively, the model is trained to learn a sufficient margin (defined by δ) that separates the best pair with *all others*, with the second-best being used to quantify *all others*. This is the justification used in the multi-class SVM literature for a similar objective (Wang and Xue, 2014).

With this network we can estimate whether two words rhyme by computing the cosine similarity score during generation, and resample words as necessary to enforce rhyme.

4.4 Generation Procedure

We focus on quatrain generation in this work, and so the aim is to generate 4 lines of poetry. During generation we feed the hidden state from the previous time step to the language model's decoder to compute the vocabulary distribution for the current time step. Words are sampled using a temperature between 0.6 and 0.8, and they are resampled if the following set of words is generated: (1) UNK token; (2) non-stopwords that were generated before;[16] (3) any generated words with a frequency $\geqslant 2$; (4) the preceding 3 words; and (5) a number of symbols including parentheses, single and double quotes.[17] The first sonnet line is generated without using any preceding context.

We next describe how to incorporate the pentameter model for generation. Given a sonnet line, the pentameter model computes a loss $\mathcal{L}_{pm}$ (Equation (3)) that indicates how well the line conforms to the iambic pentameter. We first generate 10 candidate lines (all initialised with the same hidden state), and then sample one line from the candidate lines based on the pentameter loss values ($\mathcal{L}_{pm}$). We convert the losses into probabilities by taking the softmax, and a sentence is sampled with temperature $= 0.1$.

To enforce rhyme, we randomly select one of the rhyming schemes (*AABB*, *ABAB* or *ABBA*) and resample sentence-ending words as necessary. Given a pair of words, the rhyme model produces a cosine similarity score that estimates how well the two words rhyme. We resample the second word of a rhyming pair (e.g. when generating the second *A* in *AABB*) until it produces a cosine similarity $\geqslant$ 0.9. We also resample the second word of a non-rhyming pair (e.g. when generating the first *B* in *AABB*) by requiring a cosine similarity $\leqslant$ 0.7.[18]

When generating in the forward direction we can never be sure that any particular word is the last word of a line, which creates a problem for resampling to produce good rhymes. This problem is resolved in our model by reversing the direction of the language model, i.e. generating the last word of each line first. We apply this inversion trick at the word level (character order of a word is not modified) and only to the language model; the pentameter model receives the original word order as input.

5 Experiments

We assess our sonnet model in two ways: (1) component evaluation of the language, pentameter and rhyme models; and (2) poetry generation evaluation, by crowd workers and an English literature expert. A sample of machine-generated sonnets are included in the supplementary material.

We tune the hyper-parameters of the model over the development data (optimal configuration in the supplementary material). Word embeddings are initialised with pre-trained skip-gram embeddings (Mikolov et al., 2013a,b) on the BACKGROUND dataset, and are updated during training. For optimisers, we use Adagrad (Duchi et al., 2011) for the language model, and Adam (Kingma and Ba, 2014) for the pentameter and rhyme models. We truncate backpropagation through time after 2 sonnet lines, and train using 30 epochs, resetting the network weights to the weights from the previous epoch whenever development loss worsens.

5.1 Component Evaluation

5.1.1 Language Model

We use standard perplexity for evaluating the language model. In terms of model variants, we have:[19]

- **`LM`:** Vanilla LSTM language model;
- **`LM`*:** LSTM language model that incorporates character encodings (Equation (2));

[16]We use the NLTK stopword list (Bird et al., 2009).

[17]We add these constraints to prevent the model from being too repetitive, in generating the same words.

[18]Maximum number of resampling steps is capped at 1000. If the threshold is exceeded the model is reset to generate from scratch again.

[19]All models use the same (applicable) hyper-parameter configurations.

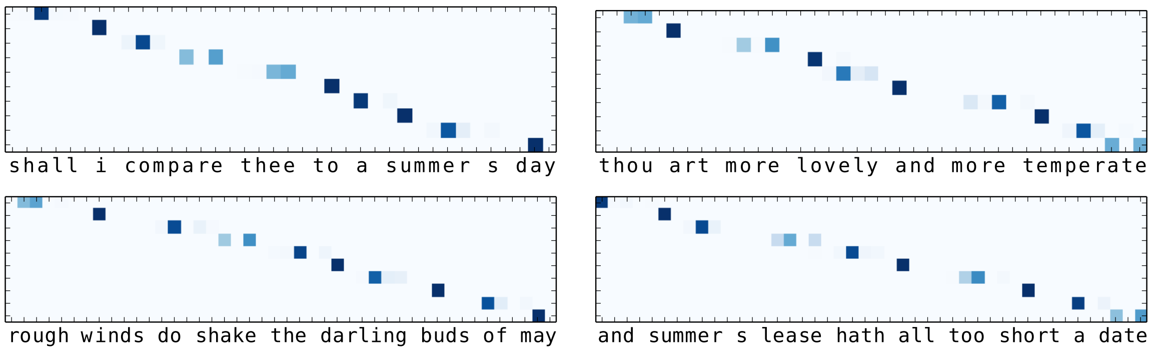

Figure 3: Character attention weights for the first quatrain of Shakespeare's *Sonnet 18*.

Model	Ppl	Stress Acc	Rhyme F1
`LM`	90.13	–	–
`LM`*	84.23	–	–
`LM`**	80.41	–	–
`LM`**`-C`	83.68	–	–
`LM`**`+PM+RM`	80.22	0.74	0.91
`Stress-BL`	–	0.80	–
`Rhyme-BL`	–	–	0.74
`Rhyme-EM`	–	–	0.71

Table 2: Component evaluation for the language model ("Ppl" = perplexity), pentameter model ("Stress Acc"), and rhyme model ("Rhyme F1"). Each number is an average across 10 runs.

- **`LM`**:** LSTM language model that incorporates both character encodings and preceding context;
- **`LM`**`-C`:** Similar to `LM`**, but preceding context is encoded using convolutional networks, inspired by the poetry model of Zhang and Lapata (2014);[20]
- **`LM`**`+PM+RM`:** the full model, with joint training of the language, pentameter and rhyme models.

Perplexity on the test partition is detailed in Table 2. Encouragingly, we see that the incorporation of character encodings and preceding context improves performance substantially, reducing perplexity by almost 10 points from `LM` to `LM`**. The inferior performance of `LM`**`-C` compared to `LM`** demonstrates that our approach of processing context with recurrent networks with selective encoding is more effective than convolutional networks. The full model `LM`**`+PM+RM`, which learns stress and rhyme patterns simultaneously, also appears to improve the language model slightly.

5.1.2 Pentameter Model

To assess the pentameter model, we use the attention weights to predict stress patterns for words in the test data, and compare them against stress patterns in the CMU pronunciation dictionary.[21] Words that have no coverage or have non-alternating patterns given by the dictionary are discarded. We use accuracy as the metric, and a predicted stress pattern is judged to be correct if it matches any of the dictionary stress patterns.

To extract a stress pattern for a word from the model, we iterate through the pentameter (10 time steps), and append the appropriate stress (e.g. 1st time step $= S^-$) to the word if any of its characters receives an attention $\geqslant 0.20$.

For the baseline (`Stress-BL`) we use the pre-trained weighted finite state transducer (WFST) provided by Hopkins and Kiela (2017).[22] The WFST maps a sequence word to a sequence of stresses by assuming each word has 1–5 stresses and the full word sequence produces iambic pentameter. It is trained using the EM algorithm on a sonnet corpus developed by the authors.

We present stress accuracy in Table 2. `LM`**`+PM+RM` performs competitively, and informal inspection reveals that a number of mistakes are due to dictionary errors. To understand the predicted stresses qualitatively, we display attention heatmaps for the the first quatrain of Shakespeare's *Sonnet 18* in Figure 3. The y-axis represents the ten stresses of the iambic pentameter, and

[20]In Zhang and Lapata (2014), the authors use a series of convolutional networks with a width of 2 words to convert 5/7 poetry lines into a fixed size vector; here we use a standard convolutional network with max-pooling operation (Kim, 2014) to process the context.

[21]`http://www.speech.cs.cmu.edu/cgi-bin/cmudict`. Note that the dictionary provides 3 levels of stresses: 0, 1 and 2; we collapse 1 and 2 to S^+.

[22]`https://github.com/JackHopkins/ACLPoetry`

CMU Rhyming Pairs		**CMU Non-Rhyming Pairs**	
Word Pair	Cos	Word Pair	Cos

Table 3: Rhyming errors produced by the model. Examples on the left (right) side are rhyming (non-rhyming) word pairs — determined using the CMU dictionary — that have low (high) cosine similarity. “Cos” denote the system predicted cosine similarity for the word pair.

x-axis the characters of the sonnet line (punctuation removed). The attention network appears to perform very well, without any noticeable errors. The only minor exception is *lovely* in the second line, where it predicts 2 stresses but the second stress focuses incorrectly on the character *e* rather than *y*. Additional heatmaps for the full sonnet are provided in the supplementary material.

5.1.3 Rhyme Model

We follow a similar approach to evaluate the rhyme model against the CMU dictionary, but score based on F1 score. Word pairs that are not included in the dictionary are discarded. Rhyme is determined by extracting the final stressed phoneme for the paired words, and testing if their phoneme patterns match.

We predict rhyme for a word pair by feeding them to the rhyme model and computing cosine similarity; if a word pair is assigned a score $\geqslant 0.8$,[23] it is considered to rhyme. As a baseline (`Rhyme-BL`), we first extract for each word the last vowel and all following consonants, and predict a word pair as rhyming if their extracted sequences match. The extracted sequence can be interpreted as a proxy for the last syllable of a word.

Reddy and Knight (2011) propose an unsupervised model for learning rhyme schemes in poems via EM. There are two latent variables: ϕ specifies the distribution of rhyme schemes, and θ defines the pairwise rhyme strength between two words. The model's objective is to maximise poem likelihood over all possible rhyme scheme assignments under the latent variables ϕ and θ. We train this model (`Rhyme-EM`) on our data[24] and use the learnt θ to decide whether two words rhyme.[25]

Table 2 details the rhyming results. The rhyme model performs very strongly at F1 > 0.90, well above both baselines. `Rhyme-EM` performs poorly because it operates at the word level (i.e. it ignores character/orthographic information) and hence does not generalise well to unseen words and word pairs.[26]

To better understand the errors qualitatively, we present a list of word pairs with their predicted cosine similarity in Table 3. Examples on the left side are rhyming word pairs as determined by the CMU dictionary; right are non-rhyming pairs. Looking at the rhyming word pairs (left), it appears that these words tend not to share any word-ending characters. For the non-rhyming pairs, we spot several CMU errors: (*sire*, *ire*) and (*queen*, *been*) clearly rhyme.

5.2 Generation Evaluation

5.2.1 Crowdworker Evaluation

Following Hopkins and Kiela (2017), we present a pair of quatrains (one machine-generated and one human-written, in random order) to crowd workers on CrowdFlower, and ask them to guess which is the human-written poem. Generation quality is estimated by computing the accuracy of workers at correctly identifying the human-written poem (with lower values indicate better results for the model).

We generate 50 quatrains each for `LM`, `LM`** and `LM`**`+PM+RM` (150 in total), and as a control, generate 30 quatrains with `LM` trained for one epoch. An equal number of human-written quatrains was sampled from the training partition. A HIT contained 5 pairs of poems (of which one is a control), and workers were paid \$0.05 for each HIT. Workers who failed to identify the human-written poem in the control pair reliably (minimum accuracy $= 70\%$) were removed by CrowdFlower automati-

[23]0.8 is empirically found to be the best threshold based on development data.

[24]We use the original authors' implementation: `https://github.com/jvamvas/rhymediscovery`.

[25]A word pair is judged to rhyme if $\theta_{w_1,w_2} \geqslant 0.02$; the threshold (0.02) is selected based on development performance.

[26]Word pairs that did not co-occur in a poem in the training data have rhyme strength of zero.

Model	Accuracy
LM	0.742
LM**	0.672
LM**+PM+RM	0.532
LM**+RM	0.532

Table 4: Crowdworker accuracy performance.

Model	Meter	Rhyme	Read.	Emotion
LM	4.00±0.73	1.57±0.67	2.77±0.67	2.73±0.51
LM**	4.07±1.03	1.53±0.88	3.10±1.04	2.93±0.93
LM**+PM+RM	4.10±0.91	4.43±0.56	2.70±0.69	2.90±0.79
Human	3.87±1.12	4.10±1.35	4.80±0.48	4.37±0.71

Table 5: Expert mean and standard deviation ratings on several aspects of the generated quatrains.

cally, and they were restricted to do a maximum of 3 HITs. To dissuade workers from using search engines to identify real poems, we presented the quatrains as images.

Accuracy is presented in Table 4. We see a steady decrease in accuracy (= improvement in model quality) from LM to LM** to LM**+PM+RM, indicating that each model generates quatrains that are less distinguishable from human-written ones. Based on the suspicion that workers were using rhyme to judge the poems, we tested a second model, LM**+RM, which is the full model without the pentameter component. We found identical accuracy (0.532), confirming our suspicion that crowd workers depend on only rhyme in their judgements. These observations demonstrate that meter is largely ignored by lay persons in poetry evaluation.

5.2.2 Expert Judgement

To better understand the qualitative aspects of our generated quatrains, we asked an English literature expert (a Professor of English literature at a major English-speaking university; the last author of this paper) to directly rate 4 aspects: meter, rhyme, readability and emotion (i.e. amount of emotion the poem evokes). All are rated on an ordinal scale between 1 to 5 (1 = worst; 5 = best). In total, 120 quatrains were annotated, 30 each for LM, LM**, LM**+PM+RM, and human-written poems (Human). The expert was blind to the source of each poem. The mean and standard deviation of the ratings are presented in Table 5.

We found that our full model has the highest ratings for both rhyme and meter, even higher than human poets. This might seem surprising, but in fact it is well established that real poets regularly break rules of form to create other effects (Adams, 1997). Despite excellent form, the output of our model can easily be distinguished from human-written poetry due to its lower emotional impact and readability. In particular, there is evidence here that our focus on form actually hurts the readability of the resulting poems, relative even to the simpler language models. Another surprise is how well simple language models do in terms of their grasp of meter: in this expert evaluation, we see only marginal benefit as we increase the sophistication of the model. Taken as a whole, this evaluation suggests that future research should look beyond forms, towards the substance of good poetry.

6 Conclusion

We propose a joint model of language, meter and rhyme that captures language and form for modelling sonnets. We provide quantitative analyses for each component, and assess the quality of generated poems using judgements from crowdworkers and a literature expert. Our research reveals that vanilla LSTM language model captures meter implicitly, and our proposed rhyme model performs exceptionally well. Machine-generated generated poems, however, still underperform in terms of readability and emotion.

Abstract

Traditionally, Referring Expression Generation (REG) models first decide on the form and then on the content of references to discourse entities in text, typically relying on features such as salience and grammatical function. In this paper, we present a new approach (NeuralREG), relying on deep neural networks, which makes decisions about form and content in one go without explicit feature extraction. Using a delexicalized version of the WebNLG corpus, we show that the neural model substantially improves over two strong baselines. Data and models are publicly available[1].

1 Introduction

Natural Language Generation (NLG) is the task of automatically converting non-linguistic data into coherent natural language text (Reiter and Dale, 2000; Gatt and Krahmer, 2018). Since the input data will often consist of entities and the relations between them, generating references for these entities is a core task in many NLG systems (Dale and Reiter, 1995; Krahmer and van Deemter, 2012). Referring Expression Generation (REG), the task responsible for generating these references, is typically presented as a two-step procedure. First, the referential form needs to be decided, asking whether a reference at a given point in the text should assume the form of, for example, a proper name ("Frida Kahlo"), a pronoun ("she") or description ("the Mexican painter"). In addition, the REG model must account for the different ways in which a particular referential form can be realized. For example, both "Frida" and "Kahlo" are name-variants that may occur in a text, and she can alternatively also be described as, say, "the famous female painter".

Most of the earlier REG approaches focus either on selecting referential form (Orita et al., 2015; Castro Ferreira et al., 2016), or on selecting referential content, typically zooming in on one specific kind of reference such as a pronoun (e.g., Henschel et al., 2000; Callaway and Lester, 2002), definite description (e.g., Dale and Haddock, 1991; Dale and Reiter, 1995) or proper name generation (e.g., Siddharthan et al., 2011; van Deemter, 2016; Castro Ferreira et al., 2017b). Instead, in this paper, we propose NeuralREG: an end-to-end approach addressing the full REG task, which given a number of entities in a text, produces corresponding referring expressions, simultaneously selecting both form and content. Our approach is based on neural networks which generate referring expressions to discourse entities relying on the surrounding linguistic context, without the use of any feature extraction technique.

Besides its use in traditional pipeline NLG systems (Reiter and Dale, 2000), REG has also become relevant in modern "end-to-end" NLG approaches, which perform the task in a more integrated manner (see e.g. Konstas et al., 2017; Gardent et al., 2017b). Some of these approaches have recently focused on inputs which references to entities are delexicalized to general tags (e.g., ENTITY-1, ENTITY-2) in order to decrease data sparsity. Based on the delexicalized input, the model generates outputs which may be likened to templates in which references to the discourse entities are not realized (as in "The ground of ENTITY-1 is located in ENTITY-2.").

While our approach, dubbed as NeuralREG, is compatible with different applications of REG models, in this paper, we concentrate on the last one, relying on a specifically constructed set of

[1]https://github.com/ThiagoCF05/NeuralREG

78,901 referring expressions to 1,501 entities in the context of the semantic web, derived from a (delexicalized) version of the WebNLG corpus (Gardent et al., 2017a,b). Both this data set and the model will be made publicly available. We compare NeuralREG against two baselines in an automatic and human evaluation, showing that the integrated neural model is a marked improvement.

2 Related work

In recent years, we have seen a surge of interest in using (deep) neural networks for a wide range of NLG-related tasks, as the generation of (first sentences of) Wikipedia entries (Lebret et al., 2016), poetry (Zhang and Lapata, 2014), and texts from abstract meaning representations (e.g., Konstas et al., 2017; Castro Ferreira et al., 2017a). However, the usage of deep neural networks for REG has remained limited and we are not aware of any other integrated, end-to-end model for generating referring expressions in discourse.

There is, however, a lot of earlier work on selecting the form and content of referring expressions, both in psycholinguistics and in computational linguistics. In psycholinguistic models of reference, various linguistic factors have been proposed as influencing the form of referential expressions, including cognitive status (Gundel et al., 1993), centering (Grosz et al., 1995) and information density (Jaeger, 2010). In models such as these, notions like *salience* play a central role, where it is assumed that entities which are salient in the discourse are more likely to be referred to using shorter referring expressions (like a pronoun) than less salient entities, which are typically referred to using longer expressions (like full proper names).

Building on these ideas, many REG models for generating references in texts also strongly rely on the concept of salience and factors contributing to it. Reiter and Dale (2000) for instance, discussed a straightforward rule-based method based on this notion, stating that full proper names can be used for initial references, typically less salient than subsequent references, which, according to the study, can be realized by a pronoun in case there is no mention to any other entity of same person, gender and number between the reference and its antecedents. More recently, Castro Ferreira et al. (2016) proposed a data-driven, non-deterministic model for generating referential forms, taking into account salience features extracted from the discourse such as grammatical position, givenness and recency of the reference. Importantly, these models do not specify which contents a particular reference, be it a proper name or description, should have. To this end, separate models are typically used, including, for example, Dale and Reiter (1995) for generating descriptions, and Siddharthan et al. (2011); van Deemter (2016) for proper names.

Of course, when texts are generated in practical settings, both form and content need to be chosen. This was the case, for instance, in the GREC shared task (Belz et al., 2010), which aimed to evaluate models for automatically generated referring expressions grounded in discourse. The input for the models were texts in which the referring expressions to the topic of the relevant Wikipedia entry were removed and appropriate references throughout the text needed to be generated (by selecting, for each gap, from a list of candidate referring expressions of different forms and with different contents). Some participating systems approached this with traditional pipelines for selecting referential form, followed by referential content, while others proposed more integrated methods. More details about the models can be seen on Belz et al. (2010).

In sum, existing REG models for text generation strongly rely on abstract features such as the salience of a referent for deciding on the form or content of a referent. Typically, these features are extracted automatically from the context, and engineering relevant ones can be complex. Moreover, many of these models only address part of the problem, either concentrating on the choice of referential form or on deciding on the contents of, for example, proper names or definite descriptions. In contrast, we introduce NeuralREG, an end-to-end approach based on neural networks which generates referring expressions to discourse entities directly from a delexicalized/wikified text fragment, without the use of any feature extraction technique. Below we describe our model in more detail, as well as the data on which we develop and evaluate it.

3 Data and processing

3.1 WebNLG corpus

Our data is based on the WebNLG corpus (Gardent et al., 2017a), which is a parallel resource ini-

Subject	**Predicate**	**Object**
108_St_Georges_Terrace	location	Perth
Perth	country	Australia
108_St_Georges_Terrace	completionDate	1988@*year*
108_St_Georges_Terrace	cost	120 million (Australian dollars)@*USD*
108_St_Georges_Terrace	floorCount	50@*Integer*

↓

108 St Georges Terrace was completed in 1988 in Perth, Australia. It has a total of 50 floors and cost 120m Australian dollars.

Figure 1: Example of a set of triples (top) and corresponding text (bottom).

tially released for the eponymous NLG challenge. In this challenge, participants had to automatically convert non-linguistic data from the Semantic Web into a textual format (Gardent et al., 2017b). The source side of the corpus are sets of *Resource Description Framework* (RDF) triples. Each RDF triple is formed by a Subject, Predicate and Object, where the Subject and Object are constants or Wikipedia entities, and predicates represent a relation between these two elements in the triple. The target side contains English texts, obtained by *crowdsourcing*, which describe the source triples. Figure 1 depicts an example of a set of 5 RDF triples and the corresponding text.

The corpus consists of 25,298 texts describing 9,674 sets of up to 7 RDF triples (an average of 2.62 texts per set) in 15 domains (Gardent et al., 2017b). In order to be able to train and evaluate our models for referring expression generation (the topic of this study), we produced a delexicalized version of the original corpus.

3.2 Delexicalized WebNLG

We delexicalized the training and development parts of the WebNLG corpus by first automatically mapping each entity in the source representation to a general tag. All entities that appear on the left and right side of the triples were mapped to AGENTs and PATIENTs, respectively. Entities which appear on both sides in the relations of a set were represented as BRIDGEs. To distinguish different AGENTs, PATIENTs and BRIDGEs in a set, an ID was given to each entity of each kind (PATIENT-1, PATIENT-2, etc.). Once all entities in the text were mapped to different roles, the first two authors of this study manually replaced the referring expressions in the original target texts by their respective tags. Figure 2 shows the entity mapping and the delexicalized template for the example in Figure 1 in its versions representing the references with general tags and Wikipedia IDs.

We delexicalized 20,198 distinct texts describing 7,812 distinct sets of RDF triples, resulting in 16,628 distinct templates. While this dataset (which we make available) has various uses, we used it to extract a collection of referring expressions to Wikipedia entities in order to evaluate how well our REG model can produce references to entities throughout a (small) text.

3.3 Referring expression collection

Using the delexicalized version of the WebNLG corpus, we automatically extracted all referring expressions by tokenizing the original and delexicalized versions of the texts and then finding the non overlapping items. For instance, by processing the text in Figure 1 and its delexicalized template in Figure 2, we would extract referring expressions like "108 St Georges Terrace" and "It" to ⟨ *AGENT-1, 108_St_Georges_Terrace* ⟩, "Perth" to ⟨ *BRIDGE-1, Perth* ⟩, "Australia" to ⟨ *PATIENT-1, Australia* ⟩ and so on.

Once all texts were processed and the referring expressions extracted, we filtered only the ones referring to Wikipedia entities, removing references to constants like dates and numbers, for which no references are generated by the model. In total, the final version of our dataset contains 78,901 referring expressions to 1,501 Wikipedia entities, in which 71.4% (56,321) are proper names, 5.6% (4,467) pronouns, 22.6% (17,795) descriptions and 0.4% (318) demonstrative referring expressions. We split this collection in training, developing and test sets, totaling 63,061, 7,097 and 8,743 referring expressions in each one of them.

Each instance of the final dataset consists of a truecased tokenized referring expression, the target entity (distinguished by its Wikipedia ID), and the discourse context preceding and following the relevant reference (we refer to these as the pre- and pos-context). Pre- and pos-contexts are the lowercased, tokenized and delexicalized

Tag	**Entity**
AGENT-1	108_St_Georges_Terrace
BRIDGE-1	Perth
PATIENT-1	Australia
PATIENT-2	1988@*year*
PATIENT-3	"120 million (Australian dollars)"@*USD*
PATIENT-4	50@*Integer*

AGENT-1 was completed in **PATIENT-2** in **BRIDGE-1** , **PATIENT-1** . **AGENT-1** has a total of **PATIENT-4** floors and cost **PATIENT-3** .

$\downarrow_{Wiki}$

108_St_Georges_Terrace was completed in **1988** in **Perth** , **Australia** . **108_St_Georges_Terrace** has a total of **50** floors and cost **20_million_(Australian_dollars)** .

Figure 2: Mapping between tags and entities for the related delexicalized/wikified templates.

pieces of text before and after the target reference. References to other discourse entities in the pre- and pos-contexts are represented by their Wikipedia ID, whereas constants (numbers, dates) are represented by a one-word ID removing quotes and replacing white spaces with underscores (e.g., *120_million_(Australian_dollars)* for "120 million (Australian dollars)" in Figure 2).

Although the references to discourse entities are represented by general tags in a delexicalized template produced in the generation process (AGENT-1, BRIDGE-1, etc.), for the purpose of disambiguation, NeuralREG's inputs have the references represented by the Wikipedia ID of their entities. In this context, it is important to observe that the conversion of the general tags to the Wikipedia IDs can be done in constant time during the generation process, since their mapping, like the first representation in Figure 2, is the first step of the process. In the next section, we show in detail how NeuralREG models the problem of generating a referring expression to a discourse entity.

4 NeuralREG

NeuralREG aims to generate a referring expression $y = \{y_1, y_2, ..., y_T\}$ with T tokens to refer to a target entity token $x^{(wiki)}$ given a discourse pre-context $X^{(pre)} = \{x_1^{(pre)}, x_2^{(pre)}, ..., x_m^{(pre)}\}$ and pos-context $X^{(pos)} = \{x_1^{(pos)}, x_2^{(pos)}, ..., x_l^{(pos)}\}$ with m and l tokens, respectively. The model is implemented as a multi-encoder, attention-decoder network with bidirectional (Schuster and Paliwal, 1997) Long-Short Term Memory Layers (LSTM) (Hochreiter and Schmidhuber, 1997) sharing the same input word-embedding matrix V, as explained further.

4.1 Context encoders

Our model starts by encoding the pre- and pos-contexts with two separate bidirectional LSTM encoders (Schuster and Paliwal, 1997; Hochreiter and Schmidhuber, 1997). These modules learn feature representations of the text surrounding the target entity $x^{(wiki)}$, which are used for the referring expression generation. The pre-context $X^{(pre)} = \{x_1^{(pre)}, x_2^{(pre)}, ..., x_m^{(pre)}\}$ is represented by forward and backward hidden-state vectors $(\overrightarrow{h}_1^{(pre)}, \cdots, \overrightarrow{h}_m^{(pre)})$ and $(\overleftarrow{h}_1^{(pre)}, \cdots, \overleftarrow{h}_m^{(pre)})$. The final annotation vector for each encoding timestep t is obtained by the concatenation of the forward and backward representations $h_t^{(pre)} = [\overrightarrow{h}_t^{(pre)}, \overleftarrow{h}_t^{(pre)}]$. The same process is repeated for the pos-context resulting in representations $(\overrightarrow{h}_1^{(pos)}, \cdots, \overrightarrow{h}_l^{(pos)})$ and $(\overleftarrow{h}_1^{(pos)}, \cdots, \overleftarrow{h}_l^{(pos)})$ and annotation vectors $h_t^{(pos)} = [\overrightarrow{h}_t^{(pos)}, \overleftarrow{h}_t^{(pos)}]$. Finally, the encoding of target entity $x^{(wiki)}$ is simply its entry in the shared input word-embedding matrix V_{wiki}.

4.2 Decoder

The referring expression generation module is an LSTM decoder implemented in 3 different versions: `Seq2Seq`, `CAtt` and `HierAtt`. All decoders at each timestep i of the generation process take as input features their previous state s_{i-1}, the target entity-embedding V_{wiki}, the embedding of the previous word of the referring expression $V_{y_{i-1}}$ and finally the summary vector of the pre- and pos-contexts c_i. The difference between the decoder variations is the method to compute c_i.

`Seq2Seq` models the context vector c_i at each timestep i concatenating the pre- and pos-context annotation vectors averaged over time:

$$\hat{h}^{(pre)} = \frac{1}{N}\sum_{i}^{N} h_i^{(pre)} \tag{1}$$

$$\hat{h}^{(pos)} = \frac{1}{N}\sum_{i}^{N} h_i^{(pos)} \tag{2}$$

$$c_i = [\hat{h}^{(pre)}, \hat{h}^{(pos)}] \tag{3}$$

CAtt is an LSTM decoder augmented with an attention mechanism (Bahdanau et al., 2015) over the pre- and pos-context encodings, which is used to compute c_i at each timestep. We compute energies $e_{ij}^{(pre)}$ and $e_{ij}^{(pos)}$ between encoder states $h_i^{(pre)}$ and $h_i^{(post)}$ and decoder state s_{i-1}. These scores are normalized through the application of the softmax function to obtain the final attention probability $\alpha_{ij}^{(pre)}$ and $\alpha_{ij}^{(post)}$. Equations 4 and 5 summarize the process with k ranging over the two encoders ($k \in [pre, pos]$), being the projection matrices $W_a^{(k)}$ and $U_a^{(k)}$ and attention vectors $v_a^{(k)}$ trained parameters.

$$e_{ij}^{(k)} = v_a^{(k)T} \tanh(W_a^{(k)} s_{i-1} + U_a^{(k)} h_j^{(k)}) \tag{4}$$

$$\alpha_{ij}^{(k)} = \frac{\exp(e_{ij}^{(k)})}{\sum_{n=1}^{N} \exp(e_{in}^{(k)})} \tag{5}$$

In general, the attention probability $\alpha_{ij}^{(k)}$ determines the amount of contribution of the jth token of k-context in the generation of the ith token of the referring expression. In each decoding step i, a final summary-vector for each context $c_i^{(k)}$ is computed by summing the encoder states $h_j^{(k)}$ weighted by the attention probabilities $\alpha_i^{(k)}$:

$$c_i^{(k)} = \sum_{j=1}^{N} \alpha_{ij}^{(k)} h_j^{(k)} \tag{6}$$

To combine $c_i^{(pre)}$ and $c_i^{(pos)}$ into a single representation, this model simply concatenate the pre- and pos-context summary vectors $c_i = [c_i^{(pre)}, c_i^{(pos)}]$.

HierAtt implements a second attention mechanism inspired by Libovický and Helcl (2017) in order to generate attention weights for the pre- and pos-context summary-vectors $c_i^{(pre)}$ and $c_i^{(pos)}$ instead of concatenate them. Equations 7, 8 and 9 depict the process, being the projection matrices $W_b^{(k)}$ and $U_b^{(k)}$ as well as attention vectors $v_b^{(k)}$ trained parameters ($k \in [pre, pos]$).

$$e_i^{(k)} = v_b^{(k)T} \tanh(W_b^{(k)} s_{i-1} + U_b^{(k)} c_i^{(k)}) \tag{7}$$

$$\beta_i^{(k)} = \frac{\exp(e_i^{(k)})}{\sum_n \exp(e_i^{(n)})} \tag{8}$$

$$c_i = \sum_k \beta_i^{(k)} U_b^{(k)} c_i^{(k)} \tag{9}$$

Decoding Given the summary-vector c_i, the embedding of the previous referring expression token $V_{y_{i-1}}$, the previous decoder state s_{i-1} and the entity-embedding V_{wiki}, the decoders predict their next state which later is used to compute a probability distribution over the tokens in the output vocabulary for the next timestep as Equations 10 and 11 show.

$$s_i = \Phi_{\text{dec}}(s_{i-1}, [c_i, V_{y_{i-1}}, V_{wiki}]) \tag{10}$$

$$p(y_i | y_{<i}, X^{(pre)}, x^{(wiki)}, X^{(pos)}) = \text{softmax}(W_c s_i + b) \tag{11}$$

In Equation 10, s_0 and c_0 are zero-initialized vectors. In order to find the referring expression y that maximizes the likelihood in Equation 11, we apply a beam search with length normalization with $\alpha = 0.6$ (Wu et al., 2016):

$$lp(y) = \frac{(5 + |y|)^\alpha}{(5+1)^\alpha} \tag{12}$$

The decoder is trained to minimize the negative log likelihood of the next token in the target referring expression:

$$J(\theta) = -\sum_i \log \text{p}(y_i | y_{<i}, X^{(pre)}, x^{(wiki)}, X^{(pos)}) \tag{13}$$

5 Models for Comparison

We compared the performance of NeuralREG against two baselines: *OnlyNames* and a model based on the choice of referential form method of Castro Ferreira et al. (2016), dubbed *Ferreira*.

OnlyNames is motivated by the similarity among the Wikipedia ID of an element and a proper name reference to it. This method refers to each entity by their Wikipedia ID, replacing each underscore in the ID for whitespaces (e.g., *Appleton_International_Airport* to *"Appleton International Airport"*).

Ferreira works by first choosing whether a reference should be a proper name, pronoun, description or demonstrative. The choice is made by a Naive Bayes method as Equation 14 depicts.

$$P(f \mid X) \propto \frac{P(f) \prod\limits_{x \in X} P(x \mid f)}{\sum\limits_{f' \in F} P(f') \prod\limits_{x \in X} P(x \mid f')} \tag{14}$$

The method calculates the likelihood of each referential form f given a set of features X, consisting of grammatical position and information status (new or given in the text and sentence). Once the choice of referential form is made, the most frequent variant is chosen in the training corpus given the referent, syntactic position and information status. In case a referring expression for a wiki target is not found in this way, a backoff method is applied by removing one factor at a time in the following order: sentence information status, text information status and grammatical position. Finally, if a referring expression is not found in the training set for a given entity, the same method as *OnlyNames* is used. Regarding the features, syntactic position distinguishes whether a reference is the subject, object or subject determiner (genitive) in a sentence. Text and sentence information statuses mark whether a reference is a initial or a subsequent mention to an entity in the text and the sentence, respectively. All features were extracted automatically from the texts using the sentence tokenizer and dependency parser of Stanford CoreNLP (Manning et al., 2014).

6 Automatic evaluation

Data We evaluated our models on the training, development and test referring expression sets described in Section 3.3.

Metrics We compared the referring expressions produced by the evaluated models with the gold-standards ones using accuracy and String Edit Distance (Levenshtein, 1966). Since pronouns are highlighted as the most likely referential form to be used when a referent is salient in the discourse, as argued in the introduction, we also computed pronoun accuracy, precision, recall and F1-score in order to evaluate the performance of the models for capturing discourse salience. Finally, we lexicalized the original templates with the referring expressions produced by the models and compared them with the original texts in the corpus using accuracy and BLEU score (Papineni et al., 2002) as a measure of fluency. Since our model does not handle referring expressions for constants (dates and numbers), we just copied their source version into the template.

Post-hoc McNemar's and Wilcoxon signed ranked tests adjusted by the Bonferroni method were used to test the statistical significance of the models in terms of accuracy and string edit distance, respectively. To test the statistical significance of the BLEU scores of the models, we used a bootstrap resampling together with an approximate randomization method (Clark et al., 2011)[2].

Settings NeuralREG was implemented using Dynet (Neubig et al., 2017). Source and target word embeddings were 300D each and trained jointly with the model, whereas hidden units were 512D for each direction, totaling 1024D in the bidirection layers. All non-recurrent matrices were initialized following the method of Glorot and Bengio (2010). Models were trained using stochastic gradient descent with Adadelta (Zeiler, 2012) and mini-batches of size 40. We ran each model for 60 epochs, applying early stopping for model selection based on accuracy on the development set with patience of 20 epochs. For each decoding version (`Seq2Seq`, `CAtt` and `HierAtt`), we searched for the best combination of drop-out probability of 0.2 or 0.3 in both the encoding and decoding layers, using beam search with a size of 1 or 5 with predictions up to 30 tokens or until 2 ending tokens were predicted (*EOS*). The results described in the next section were obtained on the test set by the NeuralREG version with the highest accuracy on the development set over the epochs.

Results Table 1 summarizes the results for all models on all metrics on the test set and Table 2 depicts a text example lexicalized by each model. The first thing to note in the results of the first table is that the baselines in the top two rows performed quite strong on this task, generating more than half of the referring expressions exactly as in the gold-standard. The method based on Castro Ferreira et al. (2016) performed statistically better than *OnlyNames* on all metrics due to its capability, albeit to a limited extent, to predict pronominal references (which *OnlyNames* obviously cannot).

We reported results on the test set for NeuralREG+`Seq2Seq` and NeuralREG+`CAtt` using

[2]`https://github.com/jhclark/multeval`

	All References		Pronouns				Text	
	Acc.	SED	Acc.	Prec.	Rec.	F-Score	Acc.	BLEU
OnlyNames	0.53^{D}	4.05^{D}	-	-	-	-	0.15^{D}	69.03^{D}
Ferreira	0.61^{C}	3.18^{C}	0.43^{B}	0.57	0.54	0.55	0.19^{C}	72.78^{C}
NeuralREG+`Seq2Seq`	$0.74^{A,B}$	$2.32^{A,B}$	0.75^{A}	0.77	0.78	0.78	0.28^{B}	$79.27^{A,B}$
NeuralREG+`CAtt`	0.74^{A}	2.25^{A}	0.75^{A}	0.73	0.78	0.75	0.30^{A}	79.39^{A}
NeuralREG+`HierAtt`	0.73^{B}	2.36^{B}	0.73^{A}	0.74	0.77	0.75	$0.28^{A,B}$	79.01^{B}

Table 1: (1) Accuracy (Acc.) and String Edit Distance (SED) results in the prediction of all referring expressions; (2) Accuracy (Acc.), Precision (Prec.), Recall (Rec.) and F-Score results in the prediction of pronominal forms; and (3) Accuracy (Acc.) and BLEU score results of the texts with the generated referring expressions. Rankings were determined by statistical significance.

dropout probability 0.3 and beam size 5, and NeuralREG+`HierAtt` with dropout probability of 0.3 and beam size of 1 selected based on the highest accuracy on the development set. Importantly, the three NeuralREG variant models statistically outperformed the two baseline systems. They achieved BLEU scores, text and referential accuracies as well as string edit distances in the range of 79.01-79.39, 28%-30%, 73%-74% and 2.25-2.36, respectively. This means that NeuralREG predicted 3 out of 4 references completely correct, whereas the incorrect ones needed an average of 2 post-edition operations in character level to be equal to the gold-standard. When considering the texts lexicalized with the referring expressions produced by NeuralREG, at least 28% of them are similar to the original texts. Especially noteworthy was the score on pronoun accuracy, indicating that the model was well capable of predicting when to generate a pronominal reference in our dataset.

The results for the different decoding methods for NeuralREG were similar, with the NeuralREG+`CAtt` performing slightly better in terms of the BLEU score, text accuracy and String Edit Distance. The more complex NeuralREG+`HierAtt` yielded the lowest results, even though the differences with the other two models were small and not even statistically significant in many of the cases.

7 Human Evaluation

Complementary to the automatic evaluation, we performed an evaluation with human judges, comparing the quality judgments of the original texts to the versions generated by our various models.

Material We quasi-randomly selected 24 instances from the delexicalized version of the WebNLG corpus related to the test part of the referring expression collection. For each of the selected instances, we took into account its source triple set and its 6 target texts: one original (randomly chosen) and its versions with the referring expressions generated by each of the 5 models introduced in this study (two baselines, three neural models). Instances were chosen following 2 criteria: the number of triples in the source set (ranging from 2 to 7) and the differences between the target texts.

For each size group, we randomly selected 4 instances (of varying degrees of variation between the generated texts) giving rise to 144 trials (= 6 triple set sizes $*$ 4 instances $*$ 6 text versions), each consisting of a set of triples and a target text describing it with the lexicalized referring expressions highlighted in yellow.

Method The experiment had a latin-square design, distributing the 144 trials over 6 different lists such that each participant rated 24 trials, one for each of the 24 corpus instances, making sure that participants saw equal numbers of triple set sizes and generated versions. Once introduced to a trial, the participants were asked to rate the fluency ("does the text flow in a natural, easy to read manner?"), grammaticality ("is the text grammatical (no spelling or grammatical errors)?") and clarity ("does the text clearly express the data?") of each target text on a 7-Likert scale, focussing on the highlighted referring expressions. The experiment is available on the website of the author[3].

Participants We recruited 60 participants, 10 per list, via Mechanical Turk. Their average age was 36 years and 27 of them were females. The majority declared themselves native speakers of

Original	5.41^{A}	5.17^{A}	5.42^{A}

Table 3: Fluency, Grammaticality and Clarity results obtained in the human evaluation. Rankings were determined by statistical significance.

English (44), while 14 and 2 self-reported as fluent or having a basic proficiency, respectively.

Results Table 3 summarizes the results. Inspection of the Table reveals a clear pattern: all three neural models scored higher than the baselines on all metrics, with especially NeuralREG+`CAtt` approaching the ratings for the original sentences, although – again – differences between the neural models were small. Concerning the size of the triple sets, we did not find any clear pattern.

To test the statistical significance of the pairwise comparisons, we used the Wilcoxon signed-rank test corrected for multiple comparisons using the Bonferroni method. Different from the automatic evaluation, the results of both baselines were not statistically significant for the three metrics. In comparison with the neural models, NeuralREG+`CAtt` significantly outperformed the baselines in terms of fluency, whereas the other comparisons between baselines and neural models were not statistically significant. The results for the 3 different decoding methods of NeuralREG also did not reveal a significant difference. Finally, the original texts were rated significantly higher than both baselines in terms of the three metrics, also than NeuralREG+`Seq2Seq` and NeuralREG+`HierAtt` in terms of fluency, and than NeuralREG+`Seq2Seq` in terms of clarity.

8 Discussion

This study introduced NeuralREG, an end-to-end approach based on neural networks which tackles the full Referring Expression Generation process. It generates referring expressions for discourse entities by simultaneously selecting form and content without any need of feature extraction techniques. The model was implemented using an encoder-decoder approach where a target referent and its surrounding linguistic contexts were first encoded and combined into a single vector representation which subsequently was decoded into a referring expression to the target, suitable for the specific discourse context. In an automatic evaluation on a collection of 78,901 referring expressions to 1,501 Wikipedia entities, the different versions of the model all yielded better results than the two (competitive) baselines. Later in a complementary human evaluation, the texts with referring expressions generated by a variant of our novel model were considered statistically more fluent than the texts lexicalized by the two baselines.

Data The collection of referring expressions used in our experiments was extracted from a novel, delexicalized and publicly available version of the WebNLG corpus (Gardent et al., 2017a,b), where the discourse entities were replaced with general tags for decreasing the data sparsity. Besides the REG task, these data can be useful for many other tasks related to, for instance, the NLG process (Reiter and Dale, 2000; Gatt and Krahmer, 2018) and Wikification (Moussallem et al., 2017).

Baselines We introduced two strong baselines which generated roughly half of the referring expressions identical to the gold standard in an automatic evaluation. These baselines performed relatively well because they frequently generated full names, which occur often for our wikified references. However, they performed poorly when it came to pronominalization, which is an important ingredient for fluent, coherent text. *OnlyNames*, as the name already reveals, does not manage to generate any pronouns. However, the approach of Castro Ferreira et al. (2016) also did not perform well in the generation of pronouns, revealing a poor capacity to detect highly salient entities in a text.

NeuralREG was implemented with 3 different decoding architectures: `Seq2Seq`, `CAtt` and `HierAtt`. Although all the versions performed relatively similar, the concatenative-attention (`CAtt`) version generated the closest referring expressions from the gold-standard ones and presented the highest textual accuracy in the automatic evaluation. The texts lexicalized by this variant were also considered statistically more fluent than the ones generated by the two proposed baselines in the human evaluation.

Surprisingly, the most complex variant (`HierAtt`) with a hierarchical-attention mechanism gave lower results than `CAtt`, producing lexicalized texts which were rated as less fluent than the original ones and not significantly more fluent from the ones generated by the baselines. This result appears to be not consistent with the findings of Libovický and Helcl (2017), who reported better results on multi-modal machine translation with hierarchical-attention as opposed to the flat variants (Specia et al., 2016).

Finally, our NeuralREG variant with the lowest results were our 'vanilla' sequence-to-sequence (`Seq2Seq`), whose the lexicalized texts were significantly less fluent and clear than the original ones. This shows the importance of the attention mechanism in the decoding step of NeuralREG in order to generate fine-grained referring expressions in discourse.

Conclusion We introduced a deep learning model for the generation of referring expressions in discourse texts. NeuralREG decides both on referential form and on referential content in an integrated, end-to-end approach, without using explicit features. Using a new delexicalized version of the WebNLG corpus (made publicly available), we showed that the neural model substantially improves over two strong baselines in terms of accuracy of the referring expressions and fluency of the lexicalized texts.

yumo.xu@ed.ac.uk, scohen@inf.ed.ac.uk

Abstract

Stock movement prediction is a challenging problem: the market is highly *stochastic*, and we make *temporally-dependent* predictions from *chaotic* data. We treat these three complexities and present a novel deep generative model jointly exploiting text and price signals for this task. Unlike the case with discriminative or topic modeling, our model introduces recurrent, continuous latent variables for a better treatment of stochasticity, and uses neural variational inference to address the intractable posterior inference. We also provide a hybrid objective with temporal auxiliary to flexibly capture predictive dependencies. We demonstrate the state-of-the-art performance of our proposed model on a new stock movement prediction dataset which we collected.[1]

1 Introduction

Stock movement prediction has long attracted both investors and researchers (Frankel, 1995; Edwards et al., 2007; Bollen et al., 2011; Hu et al., 2018). We present a model to predict stock price movement from tweets and historical stock prices.

In natural language processing (NLP), public news and social media are two primary content resources for stock market prediction, and the models that use these sources are often discriminative. Among them, classic research relies heavily on feature engineering (Schumaker and Chen, 2009; Oliveira et al., 2013). With the prevalence of deep neural networks (Le and Mikolov, 2014), event-driven approaches were studied with structured event representations (Ding et al., 2014, 2015). More recently, Hu et al. (2018) propose to mine news sequence directly from text with hierarchical attention mechanisms for stock trend prediction.

However, stock movement prediction is widely considered difficult due to the high stochasticity of the market: stock prices are largely driven by new information, resulting in a random-walk pattern (Malkiel, 1999). Instead of using only deterministic features, generative topic models were extended to jointly learn topics and sentiments for the task (Si et al., 2013; Nguyen and Shirai, 2015). Compared to discriminative models, generative models have the natural advantage in depicting the generative process from market information to stock signals and introducing randomness. However, these models underrepresent chaotic social texts with bag-of-words and employ simple discrete latent variables.

In essence, stock movement prediction is a time series problem. The significance of the temporal dependency between movement predictions is not addressed in existing NLP research. For instance, when a company suffers from a major scandal on a trading day d_1, generally, its stock price will have a downtrend in the coming trading days until day d_2, i.e. $[d_1, d_2]$.[2] If a stock predictor can recognize this decline pattern, it is likely to benefit all the predictions of the movements during $[d_1, d_2]$. Otherwise, the accuracy in this interval might be harmed. This predictive dependency is a result of the fact that public information, e.g. a company scandal, needs time to be absorbed into movements over time (Luss and d'Aspremont, 2015), and thus is largely shared across temporally-close predictions.

Aiming to tackle the above-mentioned outstanding research gaps in terms of modeling *high market stochasticity*, *chaotic market information* and *temporally-dependent prediction*, we propose

[1] https://github.com/yumoxu/stocknet-dataset

[2] We use the notation $[a, b]$ to denote the interval of integer numbers between a and b.

StockNet, a deep generative model for stock movement prediction.

To better incorporate stochastic factors, we generate stock movements from *latent driven factors* modeled with recurrent, continuous latent variables. Motivated by Variational Auto-Encoders (VAEs; Kingma and Welling, 2013; Rezende et al., 2014), we propose a novel decoder with a variational architecture and derive a recurrent variational lower bound for end-to-end training (Section 5.2). To the best of our knowledge, StockNet is the first deep generative model for stock movement prediction.

To fully exploit market information, StockNet directly learns from data without pre-extracting structured events. We build market sources by referring to both fundamental information, e.g. tweets, and technical features, e.g. historical stock prices (Section 5.1).[3] To accurately depict predictive dependencies, we assume that the movement prediction for a stock can benefit from learning to predict its historical movements in a lag window. We propose trading-day alignment as the framework basis (Section 4), and further provide a novel multi-task learning objective (Section 5.3).

We evaluate StockNet on a stock movement prediction task with a new dataset that we collected. Compared with strong baselines, our experiments show that StockNet achieves state-of-the-art performance by incorporating both data from Twitter and historical stock price listings.

2 Problem Formulation

We aim at predicting the movement of a target stock s in a pre-selected stock collection $\mathcal{S}$ on a target trading day d. Formally, we use the market information comprising of relevant social media corpora $\mathcal{M}$, i.e. tweets, and historical prices, in the lag $[d - \Delta d,\ d - 1]$ where Δd is a *fixed* lag size. We estimate the binary movement where 1 denotes rise and 0 denotes fall,

$$y = \mathbb{1}\left(p_d^c > p_{d-1}^c\right) \tag{1}$$

where p_d^c denotes the adjusted closing price adjusted for corporate actions affecting stock prices, e.g. dividends and splits.[4] The adjusted closing price is widely used for predicting stock price movement (Xie et al., 2013) or financial volatility (Rekabsaz et al., 2017).

3 Data Collection

In finance, stocks are categorized into 9 industries: *Basic Materials*, *Consumer Goods*, *Healthcare*, *Services*, *Utilities*, *Conglomerates*, *Financial*, *Industrial Goods* and *Technology*.[5] Since high-trade-volume-stocks tend to be discussed more on Twitter, we select the two-year price movements from 01/01/2014 to 01/01/2016 of 88 stocks to target, coming from all the 8 stocks in *Conglomerates* and the top 10 stocks in capital size in each of the other 8 industries (see supplementary material).

We observe that there are a number of targets with exceptionally minor movement ratios. In a three-way stock trend prediction task, a common practice is to categorize these movements to another "preserve" class by setting upper and lower thresholds on the stock price change (Hu et al., 2018). Since we aim at the binary classification of stock changes identifiable from social media, we set two particular thresholds, -0.5% and 0.55% and simply remove 38.72% of the selected targets with the movement percents between the two thresholds. Samples with the movement percents $\leq$-0.5% and $>$0.55% are labeled with 0 and 1, respectively. The two thresholds are selected to balance the two classes, resulting in 26,614 prediction targets in the whole dataset with 49.78% and 50.22% of them in the two classes. We split them temporally and 20,339 movements between 01/01/2014 and 01/08/2015 are for training, 2,555 movements from 01/08/2015 to 01/10/2015 are for development, and 3,720 movements from 01/10/2015 to 01/01/2016 are for test.

There are two main components in our dataset:[6] a Twitter dataset and a historical price dataset. We access Twitter data under the official license of Twitter, then retrieve stock-specific tweets by querying regexes made up of NASDAQ ticker symbols, e.g. "\$GOOG\b" for *Google Inc.*. We preprocess tweet texts using the NLTK package (Bird et al., 2009) with the particular Twitter

[3]To a fundamentalist, stocks have their intrinsic values that can be derived from the behavior and performance of their company. On the contrary, technical analysis considers only the trends and patterns of the stock price.

[4] Technically, $d - 1$ may not be an eligible trading day and thus has no available price information. In the rest of this paper, the problem is solved by keeping the notational consistency with our recurrent model and using its time step t to index trading days. Details will be provided in Section 4. We use d here to make the formulation easier to follow.

[6]Our dataset is available at `https://github.com/yumoxu/stocknet-dataset`.

mode, including for tokenization and treatment of hyperlinks, hashtags and the "@" identifier. To alleviate sparsity, we further filter samples by ensuring there is at least one tweet for each corpus in the lag. We extract historical prices for the 88 selected stocks to build the historical price dataset from Yahoo Finance.[7]

4 Model Overview

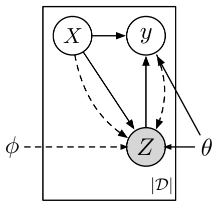

Figure 1: Illustration of the generative process from observed market information to stock movements. We use solid lines to denote the generation process and dashed lines to denote the variational approximation to the intractable posterior.

We provide an overview of data alignment, model factorization and model components.

As explained in Section 1, we assume that predicting the movement on trading day d can benefit from predicting the movements on its former trading days. However, due to the general principle of sample independence, building connections directly across samples with temporally-close target dates is problematic for model training.

As an alternative, we notice that within a sample with a target trading day d there are likely to be other trading days than d in its lag that can simulate the prediction targets close to d. Motivated by this observation and multi-task learning (Caruana, 1998), we make movement predictions not only for d, but also other trading days existing in the lag. For instance, as shown in Figure 2, for a sample targeting 07/08/2012 and a 5-day lag, 03/08/2012 and 06/08/2012 are eligible trading days in the lag and we also make predictions for them using the market information in this sample. The relations between these predictions can thus be captured within the scope of a sample.

As shown in the instance above, not every single date in a lag is an eligible trading day, e.g. weekends and holidays. To better organize and use the input, we regard the trading day, instead of the calendar day used in existing research, as the basic unit for building samples. To this end, we first find all the T eligible trading days referred in a sample, in other words, existing in the time interval $[d - \Delta d + 1,\ d]$. For clarity, in the scope of one sample, we index these trading days with $t \in [1, T]$,[8] and each of them maps to an actual (absolute) trading day d_t. We then propose *trading-day alignment*: we reorganize our inputs, including the tweet corpora and historical prices, by aligning them to these T trading days. Specifically, on the tth trading day, we recognize market signals from the corpus $\mathcal{M}_t$ in $[d_{t-1}, d_t)$ and the historical prices p_t on d_{t-1}, for predicting the movement y_t on d_t. We provide an aligned sample for illustration in Figure 2. As a result, every single unit in a sample is a trading day, and we can predict a sequence of movements $y = [y_1, \ldots, y_T]$. The *main target* is y_T while the remainder $y^* = [y_1, \ldots, y_{T-1}]$ serves as the *temporal auxiliary target*. We use these in addition to the main target to improve prediction accuracy (Section 5.3).

We model the generative process shown in Figure 1. We encode observed market information as a random variable $X = [x_1; \ldots; x_T]$, from which we generate the *latent driven factor* $Z = [z_1; \ldots; z_T]$ for our prediction task. For the aforementioned multi-task learning purpose, we aim at modeling the conditional probability distribution $p_\theta(y|X) = \int_Z p_\theta(y, Z|X)$ instead of $p_\theta(y_T|X)$. We write the following factorization for generation,

$$p_\theta(y, Z|X) = p_\theta(y_T|X, Z)\, p_\theta(z_T|z_{<T}, X) \prod_{t=1}^{T-1} p_\theta(y_t|x_{\le t}, z_t)\, p_\theta(z_t|z_{<t}, x_{\le t}, y_t) \quad (2)$$

where for a given indexed matrix of T vectors $[v_1; \ldots; v_T]$, we denote by $v_{<t}$ and $v_{\le t}$ the submatrix $[v_1; \ldots; v_{t-1}]$ and the submatrix $[v_1; \ldots; v_t]$, respectively. Since y^* is known in generation, we use the posterior $p_\theta(z_t|z_{<t}, x_{\le t}, y_t)$, $t < T$ to incorporate market signals more accurately and only use the prior $p_\theta(z_T|z_{<T}, X)$ when generating z_T. Besides, when $t < T$, y_t is independent of $z_{<t}$ while our main prediction target, y_T is made dependent on $z_{<T}$ through a temporal attention mechanism (Section 5.3).

We show StockNet modeling the above generative process in Figure 2. In a nutshell, StockNet

[7]http://finance.yahoo.com

[8]It holds that $T \ge 1$ since d is undoubtedly a trading day.

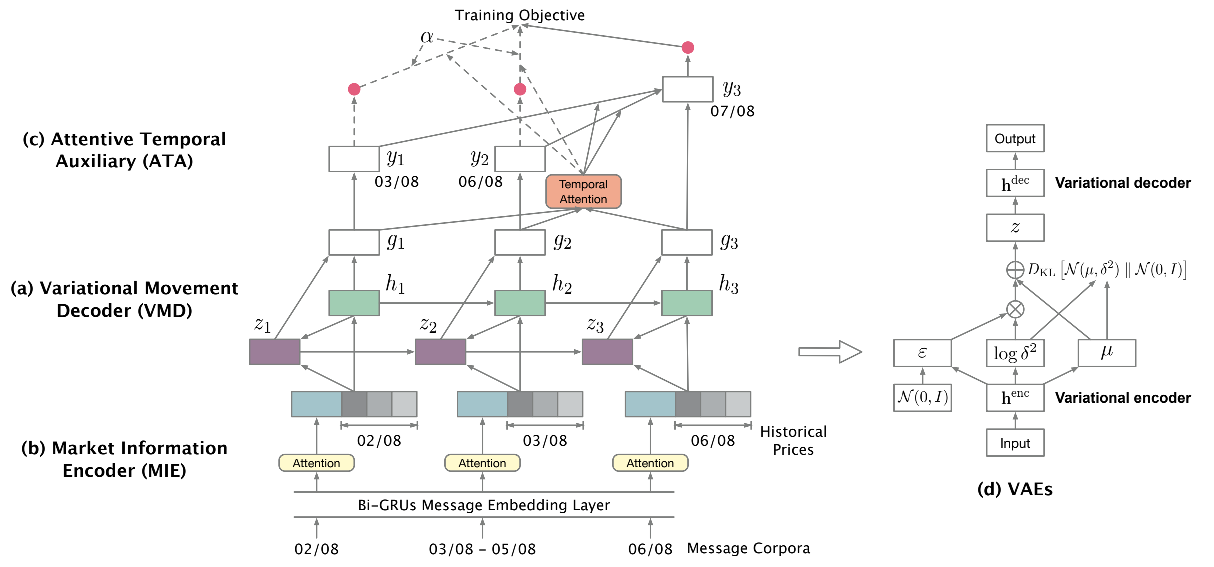

Figure 2: The architecture of StockNet. We use the main target of 07/08/2012 and the lag size of 5 for illustration. Since 04/08/2012 and 05/08/2012 are not trading days (a weekend), trading-day alignment helps StockNet to organize message corpora and historical prices for the other three trading days in the lag. We use dashed lines to denote auxiliary components. Red points denoting temporal objectives are integrated with a temporal attention mechanism to acquire the final training objective.

comprises three primary components following a bottom-up fashion,

1. Market Information Encoder (MIE) that encodes tweets and prices to X;

2. Variational Movement Decoder (VMD) that infers Z with X, y and decodes stock movements y from X, Z;

3. Attentive Temporal Auxiliary (ATA) that integrates temporal loss through an attention mechanism for model training.

5 Model Components

We detail next the components of our model (MIE, VMD, ATA) and the way we estimate our model parameters.

5.1 Market Information Encoder

MIE encodes information from social media and stock prices to enhance market information quality, and outputs the market information input X for VMD. Each temporal input is defined as

$$x_t = [c_t, p_t] \tag{3}$$

where c_t and p_t are the corpus embedding and the historical price vector, respectively.

The basic strategy of acquiring c_t is to first feed messages into the Message Embedding Layer for their low-dimensional representations, then selectively gather them according to their quality. To handle the circumstance that multiple stocks are discussed in one single message, in addition to text information, we incorporate the position information of stock symbols mentioned in messages as well. Specifically, the layer consists of a forward GRU and a backward GRU for the preceding and following contexts of a stock symbol, s, respectively. Formally, in the message corpus of the tth trading day, we denote the word sequence of the kth message, $k \in [1, K]$, as $\mathcal{W}$ where $\mathcal{W}_{\ell^\star} = s, \ell^\star \in [1, L]$, and its word embedding matrix as $E = [e_1; e_2; \ldots; e_L]$. We run the two GRUs as follows,

$$\overrightarrow{h}_f = \overrightarrow{\text{GRU}}(e_f, \overrightarrow{h}_{f-1}) \tag{4}$$

$$\overleftarrow{h}_b = \overleftarrow{\text{GRU}}(e_b, \overleftarrow{h}_{b+1}) \tag{5}$$

$$m = (\overrightarrow{h}_{\ell^\star} + \overleftarrow{h}_{\ell^\star})/2 \tag{6}$$

where $f \in [1, \ldots, \ell^\star]$, $b \in [\ell^\star, \ldots, L]$. The stock symbol is regarded as the last unit in both the preceding and the following contexts where the hidden values, $\overrightarrow{h}_{l^\star}$, $\overleftarrow{h}_{l^\star}$, are averaged to acquire the message embedding m. Gathering all message embeddings for the tth trading day, we have a message embedding matrix $M_t \in \mathbb{R}^{d_m \times K}$. In practice, the layer takes as inputs a five-rank tensor for a mini-batch, and yields all M_t in the batch with shared parameters.

Tweet quality varies drastically. Inspired by the news-level attention (Hu et al., 2018), we weight messages with their respective salience in collective intelligence measurement. Specifically, we first project M_t non-linearly to u_t, the normalized attention weight over the corpus,

$$u_t = \zeta(w_u^\intercal \tanh(W_{m,u} M_t)) \tag{7}$$

where $\zeta(\cdot)$ is the softmax function and $W_{m,u} \in \mathbb{R}^{d_m \times d_m}, w_u \in \mathbb{R}^{d_m \times 1}$ are model parameters. Then we compose messages accordingly to acquire the corpus embedding,

$$c_t = M_t u_t^\intercal. \tag{8}$$

Since it is the price change that determines the stock movement rather than the absolute price value, instead of directly feeding the raw price vector $\tilde{p}_t = \left[\tilde{p}_t^c, \tilde{p}_t^h, \tilde{p}_t^l\right]$ comprising of the adjusted closing, highest and lowest price on a trading day t, into the networks, we normalize it with its last adjusted closing price, $p_t = \tilde{p}_t / \tilde{p}_{t-1}^c - 1$. We then concatenate c_t with p_t to form the final market information input x_t for the decoder.

5.2 Variational Movement Decoder

The purpose of VMD is to recurrently infer and decode the latent driven factor Z and the movement y from the encoded market information X.

Inference

While latent driven factors help to depict the market status leading to stock movements, the posterior inference in the generative model shown in Eq. (2) is intractable. Following the spirit of the VAE, we use deep neural networks to fit latent distributions, i.e. the prior $p_\theta\left(z_t|z_{<t}, x_{\le t}\right)$ and the posterior $p_\theta\left(z_t|z_{<t}, x_{\le t}, y_t\right)$, and sidestep the intractability through *neural approximation* and *reparameterization* (Kingma and Welling, 2013; Rezende et al., 2014). We first employ a variational approximator $q_\phi\left(z_t|z_{<t}, x_{\le t}, y_t\right)$ for the intractable posterior. We observe the following factorization,

$$q_\phi\left(Z|X, y\right) = \prod_{t=1}^{T} q_\phi\left(z_t|z_{<t}, x_{\le t}, y_t\right). \tag{9}$$

Neural approximation aims at minimizing the Kullback-Leibler divergence between the $q_\phi\left(Z|X, y\right)$ and $p_\theta\left(Z|X, y\right)$. Instead of optimizing it directly, we observe that the following equation naturally holds,

$$\begin{aligned} &\log p_\theta\left(y|X\right) \\ =&D_{\text{KL}}\left[q_\phi\left(Z|X, y\right) \parallel p_\theta\left(Z|X, y\right)\right] \\ +&\mathbb{E}_{q_\phi(Z|X,y)}\left[\log p_\theta\left(y|X, Z\right)\right] \\ -&D_{\text{KL}}\left[q_\phi\left(Z|X, y\right) \parallel p_\theta\left(Z|X\right)\right] \end{aligned} \tag{10}$$

where $D_{\text{KL}}\left[q \parallel p\right]$ is the Kullback-Leibler divergence between the distributions q and p. Therefore, we equivalently maximize the following variational recurrent lower bound by plugging Eq. (2, 9) into Eq. (10),

$$\begin{aligned} &\mathcal{L}\left(\theta, \phi; X, y\right) \\ =&\sum_{t=1}^{T} \mathbb{E}_{q_\phi\left(z_t|z_{<t}, x_{\le t}, y_t\right)} \Big\{ \log p_\theta\left(y_t|x_{\le t}, z_{\le t}\right) - \\ &D_{\text{KL}}\left[q_\phi\left(z_t|z_{<t}, x_{\le t}, y_t\right) \parallel p_\theta\left(z_t|z_{<t}, x_{\le t}\right)\right] \Big\} \\ \le&\log p_\theta\left(y|X\right) \end{aligned} \tag{11}$$

where the likelihood term

$$p_\theta\left(y_t|x_{\le t}, z_{\le t}\right) = \begin{cases} p_\theta\left(y_t|x_{\le t}, z_t\right), & \text{if } t < T \\ p_\theta\left(y_T|X, Z\right), & \text{if } t = T. \end{cases} \tag{12}$$

Li et al. (2017) also provide a lower bound for inferring directly-connected recurrent latent variables in text summarization. In their work, priors are modeled with $p_\theta\left(z_t\right) \sim \mathcal{N}(0, I)$, which, in fact, turns the KL term into a static regularization term encouraging sparsity. In Eq. (11), we provide a more theoretically rigorous lower bound where the KL term with $p_\theta\left(z_t|z_{<t}, x_{\le t}\right)$ plays a dynamic role in inferring dependent latent variables for every different model input and latent history.

Decoding

As per time series, VMD adopts an RNN with a GRU cell to extract features and decode stock signals recurrently,

$$h_t^s = \text{GRU}(x_t, h_{t-1}^s). \tag{13}$$

We let the approximator $q_\phi\left(z_t|z_{<t}, x_{\le t}, y_t\right)$ subject to a standard multivariate Gaussian distribution $\mathcal{N}(\mu, \delta^2 I)$. We calculate μ and δ as

$$\mu_t = W_{z,\mu}^\phi h_t^z + b_\mu^\phi \tag{14}$$

$$\log \delta_t^2 = W_{z,\delta}^\phi h_t^z + b_\delta^\phi \tag{15}$$

and the shared hidden representation h_t^z as

$$h_t^z = \tanh(W_z^\phi[z_{t-1}, x_t, h_t^s, y_t] + b_z^\phi) \quad (16)$$

where $W_{z,\mu}^\phi, W_{z,\delta}^\phi, W_z^\phi$ are weight matrices and $b_\mu^\phi, b_\delta^\phi, b_z^\phi$ are biases.

Since Gaussian distribution belongs to the "location-scale" distribution family, we can further *reparameterize* z_t as

$$z_t = \mu_t + \delta_t \odot \epsilon \quad (17)$$

where $\odot$ denotes an element-wise product. The noise term $\epsilon \sim \mathcal{N}(0, I)$ naturally involves stochastic signals in our model.

Similarly, We let the prior $p_\theta\left(z_t | z_{<t}, x_{\le t}\right) \sim \mathcal{N}(\mu', {\delta'}^2 I)$. Its calculation is the same as that of the posterior except the absence of y_t and independent model parameters,

$$\mu'_t = W_{o,\mu}^\theta h_t^{z\prime} + b_\mu^\theta \quad (18)$$

$$\log {\delta'}_t^2 = W_{o,\delta}^\theta h_t^{z\prime} + b_\delta^\theta \quad (19)$$

where

$$h_t^{z\prime} = \tanh(W_z^\theta[z_{t-1}, x_t, h_t^s] + b_z^\theta). \quad (20)$$

Following Zhang et al. (2016), differently from the posterior, we set the prior $z_t = \mu'_t$ during decoding. Finally, we integrate deterministic features and the final prediction hypothesis is given as

$$g_t = \tanh(W_g[x_t, h_t^s, z_t] + b_g) \quad (21)$$

$$\tilde{y}_t = \zeta(W_y g_t + b_y), t < T \quad (22)$$

where W_g, W_y are weight matrices and b_g, b_y are biases. The softmax function $\zeta(\cdot)$ outputs the confidence distribution over up and down. As introduced in Section 4, the decoding of the main target y_T depends on $z_{<T}$ and thus lies at the interface between VMD and ATA. We will elaborate on it in the next section.

5.3 Attentive Temporal Auxiliary

With the acquisition of a sequence of auxiliary predictions $\tilde{Y}^* = [\tilde{y}_1; \ldots; \tilde{y}_{T-1}]$, we incorporate two-folded auxiliary effects into the main prediction and the training objective flexibly by first introducing a shared *temporal attention* mechanism.

Since each hypothesis of a temporal auxiliary contributes unequally to the main prediction and model training, as shown in Figure 3, temporal attention calculates their weights in these two contributions by employing two scoring components: an

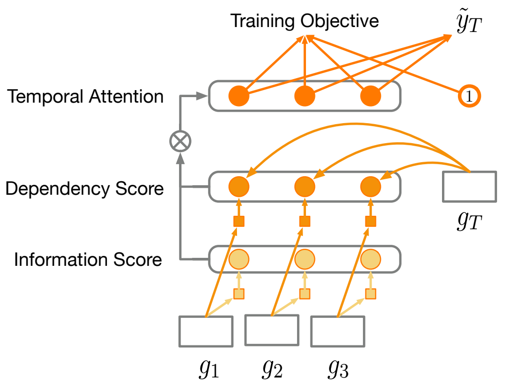

Figure 3: The temporal attention in our model. Squares are the non-linear projections of g_t and points are scores or normalized weights.

information score and a *dependency score*. Specifically,

$$v'_i = w_i^\intercal \tanh(W_{g,i} G^*) \quad (23)$$

$$v'_d = g_T^\intercal \tanh(W_{g,d} G^*) \quad (24)$$

$$v^* = \zeta(v'_i \odot v'_d) \quad (25)$$

where $W_{g,i}, W_{g,d} \in \mathbb{R}^{d_g \times d_g}, w_i \in \mathbb{R}^{d_g \times 1}$ are model parameters. The integrated representations $G^* = [g_1; \ldots; g_{T-1}]$ and g_T are reused as the final representations of temporal market information. The information score v'_i evaluates historical trading days as per their own information quality, while the dependency score v'_d captures their dependencies with our main target. We integrate the two and acquire the final normalized attention weight $v^* \in \mathbb{R}^{1 \times (T-1)}$ by feeding their element-wise product into the softmax function.

As a result, the main prediction can benefit from temporally-close hypotheses have been made and we decode our main hypothesis $\tilde{y}_T$ as

$$\tilde{y}_T = \zeta(W_T[\tilde{Y}^* v^{*\intercal}, g_T] + b_T) \quad (26)$$

where W_T is a weight matrix and b_T is a bias.

As to the model objective, we use the Monte Carlo method to approximate the expectation term in Eq. (11) and typically only one sample is used for gradient computation. To incorporate varied temporal importance at the objective level, we first break down the approximated $\mathcal{L}$ into a series of temporal objectives $f \in \mathbb{R}^{T \times 1}$ where f_t comprises a likelihood term and a KL term for a trading day t,

$$f_t = \log p_\theta\left(y_t | x_{\le t}, z_{\le t}\right) - \lambda D_{\mathrm{KL}}\left[q_\phi\left(z_t | z_{<t}, x_{\le t}, y_t\right) \parallel p_\theta\left(z_t | z_{<t}, x_{\le t}\right)\right] \quad (27)$$

where we adopt the KL term annealing trick (Bowman et al., 2016; Semeniuta et al., 2017) and add a linearly-increasing KL term weight $\lambda \in (0, 1]$ to gradually release the KL regularization effect in the training procedure. Then we reuse v^* to build the final temporal weight vector $v \in \mathbb{R}^{1 \times T}$,

$$v = [\alpha v^*, 1] \tag{28}$$

where 1 is for the main prediction and we adopt the auxiliary weight $\alpha \in [0, 1]$ to control the overall auxiliary effects on the model training. α is tuned on the development set and its effects will be discussed at length in Section 6.5. Finally, we write the training objective $\mathcal{F}$ by recomposition,

$$\mathcal{F}(\theta, \phi; X, y) = \frac{1}{N} \sum_{n}^{N} v^{(n)} f^{(n)} \tag{29}$$

where our model can learn to generalize with the selective attendance of temporal auxiliary. We take the derivative of $\mathcal{F}$ with respect to all the model parameters $\{\theta, \phi\}$ through backpropagation for the update.

6 Experiments

In this section, we detail our experimental setup and results.

6.1 Training Setup

We use a 5-day lag window for sample construction and 32 shuffled samples in a batch.[9] The maximal token number contained in a message and the maximal message number on a trading day are empirically set to 30 and 40, respectively, with the excess clipped. Since all tweets in the batched samples are simultaneously fed into the model, we set the word embedding size to 50 instead of larger sizes to control memory costs and make model training feasible on one single GPU (11GB memory). We set the hidden size of Message Embedding Layer to 100 and that of VMD to 150. All weight matrices in the model are initialized with the fan-in trick and biases are initialized with zero. We train the model with an Adam optimizer (Kingma and Ba, 2014) with the initial learning rate of 0.001. Following Bowman et al. (2016), we use the input dropout rate of 0.3 to regularize latent variables. Tensorflow (Abadi et al., 2016) is used to construct the computational graph of StockNet and hyper-parameters are tweaked on the development set.

6.2 Evaluation Metrics

Following previous work for stock prediction (Xie et al., 2013; Ding et al., 2015), we adopt the standard measure of accuracy and Matthews Correlation Coefficient (MCC) as evaluation metrics. MCC avoids bias due to data skew. Given the confusion matrix $\left(\begin{smallmatrix} \mathrm{tp} & \mathrm{fn} \\ \mathrm{fp} & \mathrm{tn} \end{smallmatrix}\right)$ containing the number of samples classified as true positive, false positive, true negative and false negative, MCC is calculated as

$$\mathrm{MCC} = \frac{\mathrm{tp} \times \mathrm{tn} - \mathrm{fp} \times \mathrm{fn}}{\sqrt{(\mathrm{tp} + \mathrm{fp})(\mathrm{tp} + \mathrm{fn})(\mathrm{tn} + \mathrm{fp})(\mathrm{tn} + \mathrm{fn})}}. \tag{30}$$

6.3 Baselines and Proposed Models

We construct the following five baselines in different genres,[10]

- RAND: a naive predictor making random guess in up or down.
- ARIMA: Autoregressive Integrated Moving Average, an advanced technical analysis method using only price signals (Brown, 2004) .
- RANDFOREST: a discriminative Random Forest classifier using Word2vec text representations (Pagolu et al., 2016).
- TSLDA: a generative topic model jointly learning topics and sentiments (Nguyen and Shirai, 2015).
- HAN: a state-of-the-art discriminative deep neural network with hierarchical attention (Hu et al., 2018).

To make a detailed analysis of all the primary components in StockNet, in addition to HEDGEFUNDANALYST, the fully-equipped StockNet, we also construct the following four variations,

- TECHNICALANALYST: the generative StockNet using only historical prices.
- FUNDAMENTALANALYST: the generative StockNet using only tweet information.
- INDEPENDENTANALYST: the generative StockNet without temporal auxiliary targets.

[9]Typically the lag size is set between 3 and 10. As introduced in Section 4, trading days are treated as basic units in StockNet and 3 calendar days are thus too short to guarantee the existence of more than one trading day in a lag, e.g. the prediction for the movement of Monday. We also experiment with 7 and 10 but they do not yield better results than 5.

[10]We do not treat event-driven models as comparable methods since our model uses no event pre-extraction tool.

6.4 Results

Since stock prediction is a challenging task and a minor improvement usually leads to large potential profits, the accuracy of 56% is generally reported as a satisfying result for binary stock movement prediction (Nguyen and Shirai, 2015). We show the performance of the baselines and our proposed models in Table 1. TLSDA is the best baseline in MCC while HAN is the best baseline in accuracy. Our model, HEDGEFUNDANALYST achieves the best performance of 58.23 in accuracy and 0.080796 in MCC, outperforming TLSDA and HAN with 4.16, 0.59 in accuracy, and 0.015414, 0.028996 in MCC, respectively.

Though slightly better than random guess, classic technical analysis, e.g. ARIMA, does not yield satisfying results. Similar in using only historical prices, TECHNICALANALYST shows an obvious advantage in this task compared ARIMA. We believe there are two major reasons: (1) TECHNICALANALYST learns from training data and incorporates more flexible non-linearity; (2) our test set contains a large number of stocks while ARIMA is more sensitive to peculiar sequence stationarity. It is worth noting that FUNDAMENTALANALYST gains exceptionally competitive results with only 0.009092 less in MCC than HEDGEFUNDANALYST. The performance of FUNDAMENTALANALYST and TECHNICALANALYST confirm the positive effects from tweets and historical prices in stock movement prediction, respectively. As an effective ensemble of the two market information, HEDGEFUNDANALYST gains even better performance.

Compared with DISCRIMINATIVEANALYST, the performance improvements of HEDGEFUNDANALYST are not from enlarging the networks, demonstrating that modeling underlying market status explicitly with latent driven factors indeed benefits stock movement prediction. The comparison with INDEPENDENTANALYST also shows the effectiveness of capturing temporal dependencies between predictions with the temporal auxiliary. However, the effects of the temporal auxiliary are more complex and will be analyzed further in the next section.

6.5 Effects of Temporal Auxiliary

We provide a detailed discuss of how the temporal auxiliary affects model performance. As introduced in Eq. (28), the temporal auxiliary weight α controls the overall effects of the objective-level temporal auxiliary to our model. Figure 4 presents how the performance of HEDGEFUNDANALYST and DISCRIMINATIVEANALYST fluctuates with α.

As shown in Figure 4, enhanced by the temporal auxiliary, HEDGEFUNDANALYST approaches the best performance at 0.5, and DISCRIMINATIVEANALYST achieves its maximum at 0.7. In fact, objective-level auxiliary can be regarded as a denoising regularizer: for a sample with a specific movement as the main target, the market source in the lag can be heterogeneous, e.g. affected by bad news, tweets on earlier days are negative but turn to positive due to timely crises management. Without temporal auxiliary tasks, the model tries to identify positive signals on earlier days only for the main target of rise movement, which is likely to result in pure noise. In such cases, temporal auxiliary tasks help to filter market sources in the lag as per their respective aligned auxiliary movements. Besides, from the perspective of training variational models, the temporal auxiliary helps HEDGEFUNDANALYST to encode more useful information into the latent driven factor Z, which is consistent with recent research in VAEs (Semeniuta et al., 2017). Compared with HEDGEFUNDANALYST that contains a KL term performing dynamic regularization, DISCRIMINATIVEANALYST requires stronger regularization effects coming with a bigger α to achieve its best performance.

Since y^* also involves in generating y_T through the temporal attention, tweaking α acts as a trade-off between focusing on the main target and generalizing by denoising. Therefore, as shown in Figure 4, our models do not linearly benefit from incorporating temporal auxiliary. In fact, the two models follow a similar pattern in terms of performance change: the curves first drop down with the increase of α, except the MCC curve for DISCRIMINATIVEANALYST rising up temporarily at 0.3. After that, the curves ascend abruptly to their maximums, then keep descending till $\alpha = 1$. Though the start phase of increasing α even leads to worse performance, when auxiliary effects are properly introduced, the two models finally gain better results than those with no involvement of auxiliary effects, e.g. INDEPENDENTANALYST.

7 Conclusion

We demonstrated the effectiveness of deep generative approaches for stock movement prediction from social media data by introducing StockNet, a neural network architecture for this task. We tested our model on a new comprehensive dataset and showed it performs better than strong baselines, including implementation of previous work. Our comprehensive dataset is publicly available at `https://github.com/yumoxu/stocknet-dataset`.

Abstract

Automatic rumor detection is technically very challenging. In this work, we try to learn discriminative features from tweets content by following their non-sequential propagation structure and generate more powerful representations for identifying different type of rumors. We propose two *recursive* neural models based on a *bottom-up* and a *top-down* tree-structured neural networks for rumor representation learning and classification, which naturally conform to the propagation layout of tweets. Results on two public Twitter datasets demonstrate that our recursive neural models 1) achieve much better performance than state-of-the-art approaches; 2) demonstrate superior capacity on detecting rumors at very early stage.

1 Introduction

Rumors have always been a social disease. In recent years, it has become unprecedentedly convenient for the "evil-doers" to create and disseminate rumors in massive scale with low cost thanks to the popularity of social media outlets on Twitter, Facebook, etc. The worst effect of false rumors could be devastating to individual and/or society.

Research pertaining rumors spans multiple disciplines, such as philosophy and humanities (DiFonzo and Bordia, 2007; Donovan, 2007), social psychology (Allport and Postman, 1965; Jaeger et al., 1980; Rosnow and Foster, 2005), political studies (Allport and Postman, 1946; Berinsky, 2017), management science (DiFonzo et al., 1994; Kimmel, 2004) and recently computer science and artificial intelligence (Qazvinian et al., 2011; Ratkiewicz et al., 2011; Castillo et al., 2011; Hannak et al., 2014; Zhao et al., 2015; Ma et al., 2015). Rumor is commonly defined as information that emerge and spread among people whose truth value is unverified or intentionally false (DiFonzo and Bordia, 2007; Qazvinian et al., 2011). Analysis shows that people tend to stop spreading a rumor if it is known as false (Zubiaga et al., 2016b). However, identifying such misinformation is non-trivial and needs investigative journalism to fact check the suspected claim, which is labor-intensive and time-consuming. The proliferation of social media makes it worse due to the ever-increasing information load and dynamics. Therefore, it is necessary to develop automatic and assistant approaches to facilitate real-time rumor tracking and debunking.

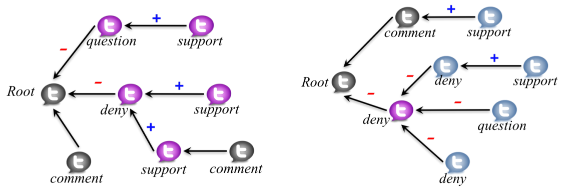
For automating rumor detection, most of the previous studies focused on text mining from sequential microblog streams using supervised models based on feature engineering (Castillo et al., 2011; Kwon et al., 2013; Liu et al., 2015; Ma et al., 2015), and more recently deep neural models (Ma et al., 2016; Chen et al., 2017; Ruchansky et al., 2017). These methods largely ignore or oversimplify the structural information associated with message propagation which however has been shown conducive to provide useful clues for identifying rumors. Kernel-based method (Wu et al., 2015; Ma et al., 2017) was thus proposed to model the structure as propagation trees in order to differentiate rumorous and non-rumorous claims by comparing their tree-based similarities. But such kind of approach cannot directly classify a tree without pairwise comparison with all other trees imposing unnecessary overhead, and it also cannot automatically learn any high-level feature representations out of the noisy surface features.

In this paper, we present a neural rumor detection approach based on recursive neural networks (RvNN) to bridge the content semantics and propagation clues. RvNN and its variants were originally used to compose phrase or sentence representation for syntactic and semantic parsing (Socher et al., 2011, 2012). Unlike parsing, the input into our model is a propagation tree rooted from a source post rather than the parse tree of an individual sentence, and each tree node is a responsive post instead of an individual words. The content semantics of posts and the responsive relationship among them can be jointly captured via the recursive feature learning process along the tree structure.

So, why can such neural model do better for the task? Analysis has generally found that Twitter could "self-correct" some inaccurate information as users share opinions, conjectures and evidences (Zubiaga et al., 2017). To illustrate our intuition, Figure 1 exemplifies the propagation trees of two rumors in our dataset, one being false and the other being true[1]. Structure-insensitive methods basically relying on the relative ratio of different stances in the text cannot do well when such clue is unclear like this example. However, it can be seen that when a post denies the false rumor, it tends to spark supportive or affirmative replies confirming the denial; in contrast, denial to a true rumor tends to trigger question or denial in its replies. This observation may suggest a more general hypothesis that the repliers tend to disagree with (or question) who support a false rumor or deny a true rumor, and also they tend to agree with who deny a false rumor or support a true rumor. Meanwhile, a reply, rather than directly responding to the source tweet (i.e., the root), is usually responsive to its immediate ancestor (Lukasik et al., 2016; Zubiaga et al., 2016a), suggesting obvious local characteristic of the interaction. The recursive network naturally models such structures for learning to capture the rumor indicative signals and enhance the representation by recursively aggregating the signals from different branches.

To this end, we extend the standard RvNN into two variants, i.e., a *bottom-up* (BU) model and a *top-down* (TD) model, which represent the propagation tree structure from different angles, in order to visit the nodes and combine their representations following distinct directions. The important merit of such architecture is that the node features can be selectively refined by the recursion given the connection and direction of all paths of the

[1]False (true) rumor means the veracity of the rumorous claim is false (true).



(a) False rumor (b) True rumor

Figure 1: Propagation trees of two rumorous source tweets. Nodes may express stances on their parent as commenting, supporting, questioning or denying. The edge arrow indicates the direction from a response to its responded node, and the polarity is marked as '+' ('-') for support (denial). The same node color indicates the same stance on the veracity of root node (i.e., source tweet).

tree. As a result, it can be expected that the discriminative signals are better embedded into the learned representations.

We evaluate our proposed approach based on two public Twitter datasets. The results show that our method outperforms strong rumor detection baselines with large margin and also demonstrate much higher effectiveness for detection at early stage of propagation, which is promising for real-time intervention and debunking. Our contributions are summarized as follows in three folds:

- This is the first study that deeply integrates both structure and content semantics based on tree-structured recursive neural networks for detecting rumors from microblog posts.
- We propose two variants of RvNN models based on bottom-up and top-down tree structures to generate better integrated representations for a claim by capturing both structural and textural properties signaling rumors.
- Our experiments based on real-world Twitter datasets achieve superior improvements over state-of-the-art baselines on both rumor classification and early detection tasks. We make the source codes in our experiments publicly accessible [2].

2 Related Work

Most previous automatic approaches for rumor detection (Castillo et al., 2011; Yang et al., 2012; Liu

[2]https://github.com/majingCUHK/Rumor_RvNN

et al., 2015) intended to learn a supervised classifier by utilizing a wide range of features crafted from post contents, user profiles and propagation patterns. Subsequent studies were then conducted to engineer new features such as those representing rumor diffusion and cascades (Friggeri et al., 2014; Hannak et al., 2014) characterized by comments with links to debunking websites. Kwon et al. (2013) introduced a time-series-fitting model based on the volume of tweets over time. Ma et al. (2015) extended their model with more chronological social context features. These approaches typically require heavy preprocessing and feature engineering.

Zhao et al. (2015) alleviated the engineering effort by using a set of regular expressions (such as "really?", "not true", etc) to find questing and denying tweets, but the approach was oversimplified and suffered from very low recall. Ma et al. (2016) used recurrent neural networks (RNN) to learn automatically the representations from tweets content based on time series. Recently, they studied to mutually reinforce stance detection and rumor classification in a neural multi-task learning framework (Ma et al., 2018). However, the approaches cannot embed features reflecting how the posts are propagated and requires careful data segmentation to prepare for time sequence.

Some kernel-based methods were exploited to model the propagation structure. Wu et al. (2015) proposed a hybrid SVM classifier which combines a RBF kernel and a random-walk-based graph kernel to capture both flat and propagation patterns for detecting rumors on Sina Weibo. Ma et al. (2017) used tree kernel to capture the similarity of propagation trees by counting their similar substructures in order to identify different types of rumors on Twitter. Compared to their studies, our model can learn the useful features via a more natural and general approach, i.e., the tree-structured neural network, to jointly generate representations from both structure and content.

RvNN has demonstrated state-of-the-art performances in a variety of tasks, e.g., images segmentation (Socher et al., 2011), phrase representation from word vectors (Socher et al., 2012), and sentiment classification in sentences (Socher et al., 2013). More recently, a deep RvNN was proposed to model the compositionality in natural language for fine-grained sentiment classification by stacking multiple recursive layers (Irsoy and Cardie, 2014). In order to avoid gradient vanishing, some studies integrated Long Short Term Memory (LSTM) (Hochreiter and Schmidhuber, 1997) to RvNN (Zhu et al., 2015; Tai et al., 2015). Mou et al. (2015) used a convolutional network over tree structures for syntactic tree parsing of natural language sentences.

3 Problem Statement

We define a Twitter rumor detection dataset as a set of claims $\mathcal{C} = \{C_1, C_2, \cdots, C_{|\mathcal{C}|}\}$, where each claim C_i corresponds to a source tweet r_i which consists of ideally all its relevant responsive tweets in chronological order, i.e., $C_i = \{r_i, x_{i1}, x_{i2}, \cdots, x_{im}\}$ where each x_{i*} is a responsive tweet of the root r_i. Note that although the tweets are notated sequentially, there are connections among them based on their reply or repost relationships, which can form a propagation tree structure (Wu et al., 2015; Ma et al., 2017) with r_i being the root node.

We formulate this task as a supervised classification problem, which learns a classifier f from labeled claims, that is $f : C_i \to Y_i$, where Y_i takes one of the four finer-grained classes: *non-rumor*, *false rumor*, *true rumor*, and *unverified rumor* that are introduced in the literature (Ma et al., 2017; Zubiaga et al., 2016b).

An important issue of the tree structure is concerned about the direction of edges, which can result in two different architectures of the model: 1) a bottom-up tree; 2) a top-down tree, which are defined as follows:

- **Bottom-up tree** takes the similar shape as shown in Figure 1, where responsive nodes always point to their responded nodes and leaf nodes not having any response are laid out at the furthest level. We represent a tree as $\mathcal{T}_i = \langle V_i, E_i \rangle$, where $V_i = C_i$ which consists of all relevant posts as nodes, and E_i denotes a set of all directed links, where for any $u, v \in V_i$, $u \leftarrow v$ exists if v *responses to* u. This structure is similar to a citation network where a response mimics a reference.

- **Top-down tree** naturally conforms to the direction of information propagation, in which a link $u \to v$ means the information flows from u to v and v sees it and provides a response to u. This structure reverses bottom-up tree and simulates how information cas-

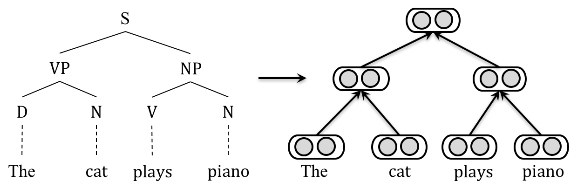


Figure 2: A binarized sentence parse tree (left) and its corresponding RvNN architecture (right).

cades from a source tweet, i.e., the root, to all its receivers, i.e., the decedents, which is similar as (Wu et al., 2015; Ma et al., 2017).

4 RvNN-based Rumor Detection

The core idea of our method is to strengthen the high-level representation of tree nodes by the recursion following the propagation structure over different branches in the tree. For instance, the responsive nodes confirming or supporting a node (e.g., "I agree", "be right", etc) can further reinforce the stance of that node while denial or questioning responses (e.g., "disagree, "really?!) otherwise weaken its stance. Compared to the kernel-based method using propagation tree (Wu et al., 2015; Ma et al., 2017), our method does not need pairwise comparison among large number of subtrees, and can learn much stronger representation of content following the response structure.

In this section, we will describe our extension to the standard RvNN for modeling rumor detection based on the bottom-up and top-down architectures presented in Section 3.

4.1 Standard Recursive Neural Networks

RvNN is a type of tree-structured neural networks. The original version of RvNN utilized binarized sentence parse trees (Socher et al., 2012), in which the representation associated with each node of a parse tree is computed from its direct children. The overall structure of the standard RvNN is illustrated as the right side of Figure 2, corresponding to the input parse tree at the left side.

Leaf nodes are the words in an input sentence, each represented by a low-dimensional word embedding. Non-leaf nodes are sentence constituents, computed by recursion based on the presentations of child nodes. Let p be the feature vector of a parent node whose children are c_1 and c_2, the representation of the parent is computed by $p = f(W \cdot [c_1; c_2] + b)$, where $f(\cdot)$ is the activation function with W and b as parameters. This computation is done recursively over all tree nodes; the learned hidden vectors of the nodes can then be used for various classification tasks.

4.2 Bottom-up RvNN

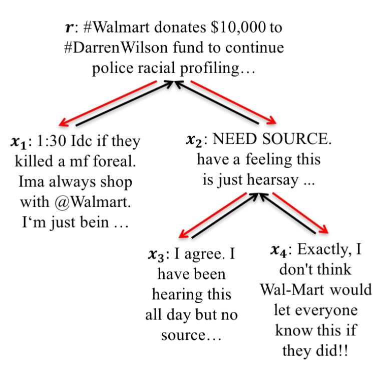
The core idea of bottom-up model is to generate a feature vector for each subtree by recursively visiting every node from the leaves at the bottom to the root at the top. In this way, the subtrees with similar contexts, such as those subtrees having a denial parent and a set of supportive children, will be projected into the proximity in the representation space. And thus such local rumor indicative features are aggregated along different branches into some global representation of the whole tree.

For this purpose, we make a natural extension to the original RvNN. The overall structure of our proposed bottom-up model is illustrated in Figure 3(b), taking a bottom-up tree (see Figure 3(a)) as input. Different from the standard RvNN, the input of each node in the bottom-up model is a post represented as a vector of words in the vocabulary in terms of $tfidf$ values. Here, every node has an input vector, and the number of children of nodes varies significantly[3].

In rumor detection, long short-term memory (LSTM) (Hochreiter and Schmidhuber, 1997) and gated recurrent units (GRU) (Cho et al., 2014) were used to learn textual representation, which adopts memory units to store information over long time steps (Ma et al., 2016). In this paper, we choose to extend GRU as hidden unit to model long-distance interactions over the tree nodes because it is more efficient due to fewer parameters. Let $\mathcal{S}(j)$ denote the set of direct children of the node j. The transition equations of node j in the bottom-up model are formulated as follows:

$$\begin{aligned}
\tilde{x}_j &= x_j E \\
h_{\mathcal{S}} &= \sum_{s \in \mathcal{S}(j)} h_s \\
r_j &= \sigma\left(W_r \tilde{x}_j + U_r h_{\mathcal{S}}\right) \\
z_j &= \sigma\left(W_z \tilde{x}_j + U_z h_{\mathcal{S}}\right) \\
\tilde{h}_j &= tanh\left(W_h \tilde{x}_j + U_h (h_{\mathcal{S}} \odot r_j)\right) \\
h_j &= (1 - z_j) \odot h_{\mathcal{S}} + z_j \odot \tilde{h}_j
\end{aligned} \tag{1}$$

[3]In standard RvNN, since an input instance is the parse tree of a sentence, only leaf nodes have input vector, each node representing a word of the input sentence, and the non-leaf nodes are constituents of the sentence, and thus the number of children of a node is limited.



r: #Walmart donates $10,000 to #DarrenWilson fund to continue police racial profiling…

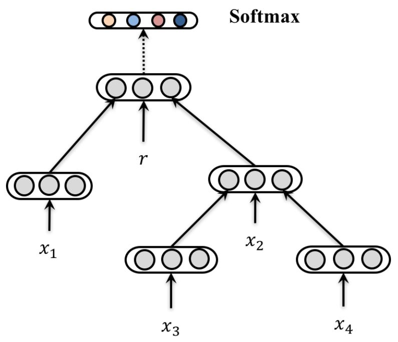
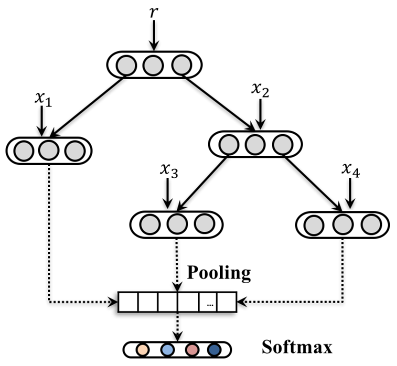
x4: Exactly, I don't think Wal-Mart would let everyone know this if they did!!

(a) Bottom-up/Top-down tree



(b) Bottom-up RvNN model



(c) Top-down RvNN model

Figure 3: A bottom-up/top-down propagation tree and the corresponding RvNN-based models. The black-color and red-color edges differentiate the bottom-up and top-down tree in Figure 3(a).

where x_j is the original input vector of node j, E denotes the parameter matrix for transforming this input post, $\tilde{x}_j$ is the transformed representation of j, $[W_*, U_*]$ are the weight connections inside GRU, and h_j and h_s refer to the hidden state of j and its s-th child. Thus $h_{\mathcal{S}}$ denotes the sum of the hidden state of all the children of j assuming that all children are equally important to j. As with the standard GRU, $\odot$ denotes element-wise multiplication; a reset gate r_j determines how to combine the current input $\tilde{x}_j$ with the memory of children, and an update gate z_j defines how much memory from the children is cascaded into the current node; and $\tilde{h}_j$ denotes the candidate activation of the hidden state of the current node. Different from the standard GRU unit, the gating vectors in our variant of GRU are dependent on the states of many child units, allowing our model to incorporate representations from different children.

After recursive aggregation from bottom to up, the state of root node (i.e., source tweet) can be regard as the representation of the whole tree which is used for supervised classification. So, an output layer is connected to the root node for predicting the class of the tree using a softmax function:

$$\hat{y} = Softmax(Vh_0 + b) \tag{2}$$

where h_0 is the learned hidden vector of root node; V and b are the weights and bias in output layer.

4.3 Top-down RvNN

This model is designed to leverage the structure of top-down tree to capture complex propagation patterns for classifying rumorous claims, which is shown in Figure 3(c). It models how the information flows from source post to the current node. The idea of this top-down approach is to generate a strengthened feature vector for each post considering its propagation path, where rumor-indicative features are aggregated along the propagation history in the path. For example, if current post agree with its parent's stance which denies the source post, the denial stance from the root node down to the current node on this path should be reinforced. Due to different branches of any non-leaf node, the top-down visit to its subtree nodes is also recursive. However, the nature of top-down tree lends this model different from the bottom-up one. The representation of each node is computed by combining its own input and its parent node instead of its children nodes. This process proceeds recursively from the root node to its children until all leaf nodes are reached.

Suppose that the hidden state of a non-leaf node can be passed synchronously to all its child nodes without loss. Then the hidden state h_j of a node j can be computed by combining the hidden state $h_{\mathcal{P}(j)}$ of its parent node $\mathcal{P}(j)$ and its own input vector x_j. Therefore, the transition equations of node j can be formulated as a standard GRU:

$$\begin{aligned}
\tilde{x}_j &= x_j E \\
r_j &= \sigma\left(W_r \tilde{x}_j + U_r h_{\mathcal{P}(j)}\right) \\
z_j &= \sigma\left(W_z \tilde{x}_j + U_z h_{\mathcal{P}(j)}\right) \\
\tilde{h}_j &= tanh\left(W_h \tilde{x}_j + U_h (h_{\mathcal{P}(j)} \odot r_j)\right) \\
h_j &= (1 - z_j) \odot h_{\mathcal{P}(j)} + z_j \odot \tilde{h}_j
\end{aligned} \tag{3}$$

Through the top-down recursion, the learned representations are eventually embedded into the hidden vector of all the leaf nodes. Since the number of leaf nodes varies, the resulting vectors cannot be directly fed into a fixed-size neural layer for output. Therefore, we add a max-pooling layer to take the maximum value of each dimension of the vectors over all the leaf nodes. This can also help capture the most appealing indicative features from all the propagation paths.

Based on the pooling result, we finally use a softmax function in the output layer to predict the label of the tree:

$$\hat{y} = Softmax(Vh_\infty + b) \tag{4}$$

where h_∞ is the pooling vector over all leaf nodes, V and b are parameters in the output layer.

Although both of the two RvNN models aim to capture the structural properties by recursively visiting all nodes, we can conjecture that the top-down model would be better. The hypothesis is that in the bottom-up case the final output relies on the representation of single root, and its information loss can be larger than the top-down one since in the top-down case the representations embedded into all leaf nodes along different propagation paths can be incorporated via pooling holistically.

4.4 Model Training

The model is trained to minimize the squared error between the probability distributions of the predictions and the ground truth:

$$L(y, \hat{y}) = \sum_{n=1}^{N} \sum_{c=1}^{C} (y_c - \hat{y}_c)^2 + \lambda ||\theta||_2^2 \tag{5}$$

where y_c is the ground truth and $\hat{y}_c$ is the prediction probability of a class, N is the number of training claims, C is the number of classes, $||.||_2$ is the L_2 regularization term over all model parameters θ, and λ is the trade-off coefficient.

During training, all the model parameters are updated using efficient back-propagation through structure (Goller and Kuchler, 1996; Socher et al., 2013), and the optimization is gradient-based following the Ada-grad update rule (Duchi et al., 2011) to speed up the convergence. We empirically initialize the model parameters with uniform distribution and set the vocabulary size as 5,000, the size of embedding and hidden units as 100. We iterate over all the training examples in each epoch and continue until the loss value converges or the maximum epoch number is met.

5 Experiments and Results

5.1 Datasets

For experimental evaluation, we use two publicly available Twitter datasets released by Ma et al. (2017), namely Twitter15 and Twitter16[4], which respectively contains 1,381 and 1,181 propagation trees (see (Ma et al., 2017) for detailed statistics). In each dataset, a group of wide spread source tweets along with their propagation threads, i.e., replies and retweets, are provided in the form of tree structure. Each tree is annotated with one of the four class labels, i.e., non-rumor, false rumor, true rumor and unverified rumor. We remove the retweets from the trees since they do not provide any extra information or evidence content-wise. We build two versions for each tree, one for the bottom-up tree and the other for the top-down tree, by flipping the edges' direction.

5.2 Experimental Setup

We make comprehensive comparisons between our models and some state-of-the-art baselines on rumor classification and early detection tasks.

- DTR: Zhao et al. (2015) proposed a Decision-Tree-based Ranking model to identify trending rumors by searching for inquiry phrases.

- DTC: The information credibility model using a Decision-Tree Classifier (Castillo et al., 2011) based on manually engineering various statistical features of the tweets.

- RFC: The Random Forest Classier using 3 fitting parameters as temporal properties and a set of handcrafted features on user, linguistic and structural properties (Kwon et al., 2013).

- SVM-TS: A linear SVM classifier that uses time-series to model the variation of handcrafted social context features (Ma et al., 2015).

- SVM-BOW: A naive baseline we built by representing text content using bag-of-words and using linear SVM for rumor classification.

- SVM-TK and **SVM-HK**: SVM classifier uses a Tree Kernel (Ma et al., 2017) and that uses a Hybrid Kernel (Wu et al., 2015), respectively, both of which model propagation structures with kernels.

- GRU-RNN: A detection model based on recurrent neural networks (Ma et al., 2016) with GRU units for learning rumor representations by modeling sequential structure of relevant posts.

- **BU-RvNN** and **TD-RvNN**: Our bottom-up and top-down RvNN models, respectively.

We implement **DTC** and **RFC** using Weka[5], SVM-based models using LibSVM[6] and all neural-network-based models with Theano[7]. We conduct 5-fold cross-validation on the datasets and use accuracy over all the four categories and F1 measure on each class to evaluate the performance of models.

5.3 Rumor Classification Performance

As shown in Table 1, our proposed models basically yield much better performance than other methods on both datasets via the modeling of interaction structures of posts in the propagation.

It is observed that the performance of the 4 baselines in the first group based on handcrafted features is obviously poor, varying between 0.409 and 0.585 in accuracy, indicating that they fail to generalize due to the lack of capacity capturing helpful features. Among these baselines, SVM-TS and RFC perform relatively better because they use additional temporal traits, but they are still clearly worse than the models not relying on feature engineering. DTR uses a set of regular expressions indicative of stances. However, only 19.6% and 22.2% tweets in the two datasets contain strings covered by these regular expressions, rendering unsatisfactory result.

Among the two kernel methods that are based on comparing propagation structures, we observe that SVM-TK is much more effective than SVM-HK. There are two reasons: 1) SVM-HK was originally proposed and experimented on Sina Weibo (Wu et al., 2015), which may not be generalize well on Twitter. 2) SVM-HK loosely couples two separate kernels: a RBF kernel based on handcrafted features, plus a random walk-based kernel which relies on a set of pre-defined keywords for jumping over the nodes probabilistically. This under utilizes the propagation information due to such oversimplified treatment of tree structure. In contrast, SVM-TK is an integrated kernel and can fully utilize the structure by comparing the trees based on both textual and structural similarities.

It appears that using bag-of-words is already a decent model evidenced as the fairly good performance of SVM-BOW which is even better than SVM-HK. This is because the features of SVM-HK are handcrafted for binary classification (i.e., non-rumor vs rumor), ignoring the importance of indicative words or units that benefit finer-grained classification which can be captured more effectively by SVM-BOW.

The sequential neural model GRU-RNN performs slightly worse than SVM-TK, but much worse than our recursive models. This is because it is a special case of the recursive model where each non-leaf node has only one child. It has to rely on a linear chain as input, which missed out valuable structural information. However, it does learn high-level features from the post content via hidden units of the neural model while SVM-TK cannot which can only evaluates similarities based on the overlapping words among subtrees. Our recursive models are inherently tree-structured and take advantages of representation learning following the propagation structure, thus beats SVM-TK.

In the two recursive models, TD-RvNN outperforms BU-RvNN, which indicates that the bottom-up model may suffer from larger information loss than the top-down one. This verifies the hypothesis we made in Section 4.3 that the pooling layer

in the top-down model can effectively select important features embedded into the leaf nodes.

For only the non-rumor class, it seems that our method does not perform so well as some feature-engineering baselines. This can be explained by the fact that these baselines are trained with additional features such as user information (e.g., profile, verification status, etc) which may contain clues for differentiating non-rumors from rumors. Also, the responses to non-rumors are usually much more diverse with little informative indication, making identification of non-rumors more difficult based on content even with the structure.

5.4 Early Rumor Detection Performance

Detecting rumors at early state of propagation is important so that interventions can be made in a timely manner. We compared different methods in term of different time delays measured by either tweet count received or time elapsed since the source tweet is posted. The performance is evaluated by the accuracy obtained when we incrementally add test data up to the check point given the targeted time delay or tweets volume.

Figure 4 shows that the performance of our recursive models climbs more rapidly and starts to supersede the other models at the early stage. Although all the methods are getting to their best performance in the end, TD-RvNN and BU-RvNN only need around 8 hours or about 90 tweets to achieve the comparable performance of the best baseline model, i.e., SVM-TK, which needs about 36 hours or around 300 posts, indicating superior early detection performance of our method.

Figure 5 shows a sample tree at the early stage of propagation that has been correctly classified as a false rumor by both recursive models. We can see that this false rumor demonstrates typical patterns in subtrees and propagation paths indicative of the falsehood, where a set of responses supporting the parent posts that deny or question the source post are captured by our bottom-up model. Similarly, some patterns of propagation from the root to leaf nodes like "support$\rightarrow$deny$\rightarrow$support" are also seized by our top-down model. In comparison, sequential models may be confused because the supportive key terms such as "be right", "yeah", "exactly!" dominate the responses, and the SVM-TK may miss similar subtrees by just comparing the surface words.

6 Conclusions and Future Work

We propose a bottom-up and a top-down tree-structured model based on recursive neural networks for rumor detection on Twitter. The inherent nature of recursive models allows them using propagation tree to guide the learning of representations from tweets content, such as embedding various indicative signals hidden in the structure, for better identifying rumors. Results on two public Twitter datasets show that our method improves rumor detection performance in very large margins as compared to state-of-the-art baselines.

In our future work, we plan to integrate other types of information such as user properties into the structured neural models to further enhance representation learning and detect rumor spreaders at the same time. We also plan to use unsupervised models for the task by exploiting structural information.

Abstract

Everyday billions of multimodal posts containing both images and text are shared in social media sites such as Snapchat, Twitter or Instagram. This combination of image and text in a single message allows for more creative and expressive forms of communication, and has become increasingly common in such sites. This new paradigm brings new challenges for natural language understanding, as the textual component tends to be shorter, more informal, and often is only understood if combined with the visual context. In this paper, we explore the task of name tagging in multimodal social media posts. We start by creating two new multimodal datasets: one based on Twitter posts[1] and the other based on Snapchat captions (exclusively submitted to public and crowd-sourced stories). We then propose a novel model based on Visual Attention that not only provides deeper visual understanding on the decisions of the model, but also significantly outperforms other state-of-the-art baseline methods for this task. [2]

1 Introduction

Social platforms, like Snapchat, Twitter, Instagram and Pinterest, have become part of our lives and play an important role in making communication easier and accessible. Once text-centric, social media platforms are becoming increasingly multimodal, with users combining images, videos, audios, and texts for better expressiveness. As social media posts become more multimodal, the natural language understanding of the textual components of these messages becomes increasingly challenging. In fact, it is often the case that the textual component can only be understood in combination with the visual context of the message.

In this context, here we study the task of Name Tagging for social media containing both image and textual contents. Name tagging is a key task for language understanding, and provides input to several other tasks such as Question Answering, Summarization, Searching and Recommendation. Despite its importance, most of the research in name tagging has focused on news articles and longer text documents, and not as much in multimodal social media data (Baldwin et al., 2015).

However, multimodality is not the only challenge to perform name tagging on such data. The textual components of these messages are often very short, which limits context around names. Moreover, there linguistic variations, slangs, typos and colloquial language are extremely common, such as using 'looooove' for 'love', 'LosAngeles' for 'Los Angeles', and '#Chicago #Bull' for 'Chicago Bulls'. These characteristics of social media data clearly illustrate the higher difficulty of this task, if compared to traditional newswire name tagging.

In this work, we modify and extend the current state-of-the-art model (Lample et al., 2016; Ma and Hovy, 2016) in name tagging to incorporate the visual information of social media posts using an Attention mechanism. Although the usually short textual components of social media posts provide limited contextual information, the accompanying images often provide rich information that can be useful for name tagging. For ex-

Modern Baseball played an intimate surprise set at Shea
The Veterans Committee "***Modern Baseball***" Hall of Fame ballot is out

Figure 1: Examples of *Modern Baseball* associated with different images.

ample, as shown in Figure 1, both captions include the phrase *'Modern Baseball'*. It is not easy to tell if each *Modern Baseball* refers to a name or not from the textual evidence only. However using the associated images as reference, we can easily infer that *Modern Baseball* in the first sentence should be the name of a band because of the implicit features from the objects like instruments and stage, and the *Modern Baseball* in the second sentence refers to the sport of baseball because of the pitcher in the image.

In this paper, given an image-sentence pair as input, we explore a new approach to leverage visual context for name tagging in text. First, we propose an attention-based model to extract visual features from the regions in the image that are most related to the text. It can ignore irrelevant visual information. Secondly, we propose to use a gate to combine textual features extracted by a Bidirectional Long Short Term Memory (BLSTM) and extracted visual features, before feed them into a Conditional Random Fields(CRF) layer for tag predication. The proposed gate architecture plays the role to modulate word-level multimodal features.

We evaluate our model on two labeled datasets collected from Snapchat and Twitter respectively. Our experimental results show that the proposed model outperforms state-for-the-art name tagger in multimodal social media.

The main contributions of this work are as follows:

- We create two new datasets for name tagging in multimedia data, one using Twitter and the other using crowd-sourced Snapchat posts. These new datasets effectively constitute new benchmarks for the task.

- We propose a visual attention model specifically for name tagging in multimodal social media data. The proposed end-to-end model only uses image-sentence pairs as input without any human designed features, and a Visual Attention component that helps understand the decision making of the model.

2 Model

Figure 2 shows the overall architecture of our model. We describe three main components of our model in this section: BLSTM-CRF sequence labeling model (Section 2.1), Visual Attention Model (Section 2.3) and Modulation Gate (Section 2.4).

Given a pair of sentence and image as input, the Visual Attention Model extracts regional visual features from the image and computes the weighted sum of the regional visual features as the visual context vector, based on their relatedness with the sentence. The BLSTM-CRF sequence labeling model predicts the label for each word in the sentence based on both the visual context vector and the textual information of the words. The modulation gate controls the combination of the visual context vector and the word representations for each word before the CRF layer.

2.1 BLSTM-CRF Sequence Labeling

We model name tagging as a sequence labeling problem. Given a sequence of words: $S = \{s_1, s_2, ..., s_n\}$, we aim to predict a sequence of labels: $L = \{l_1, l_2, ..., l_n\}$, where $l_i \in \mathfrak{L}$ and $\mathfrak{L}$ is a pre-defined label set.

Bidirectional LSTM. Long Short-term Memory Networks (LSTMs) (Hochreiter and Schmidhuber, 1997) are variants of Recurrent Neural Networks (RNNs) designed to capture long-range dependencies of input. The equations of a LSTM cell are as follows:

$$\begin{gathered}
i_t = \sigma(W_{xi}x_t + W_{hi}h_{t-1} + b_i) \\
f_t = \sigma(W_{xf}x_t + W_{hf}h_{t-1} + b_f) \\
\tilde{c}_t = tanh(W_{xc}x_t + W_{hc}h_{t-1} + b_c) \\
c_t = f_t \odot c_{t-1} + i_t \odot \tilde{c}_t \\
o_t = \sigma(W_{xo}x_t + W_{ho}h_{t-1} + b_o) \\
h_t = o_t \odot tanh(c_t)
\end{gathered}$$

where x_t, c_t and h_t are the input, memory and hidden state at time t respectively. W_{xi}, W_{hi}, W_{xf}, W_{hf}, W_{xc}, W_{hc}, W_{xo}, and W_{ho} are weight matrices. $\odot$ is the element-wise product function and σ is the element-wise sigmoid function.

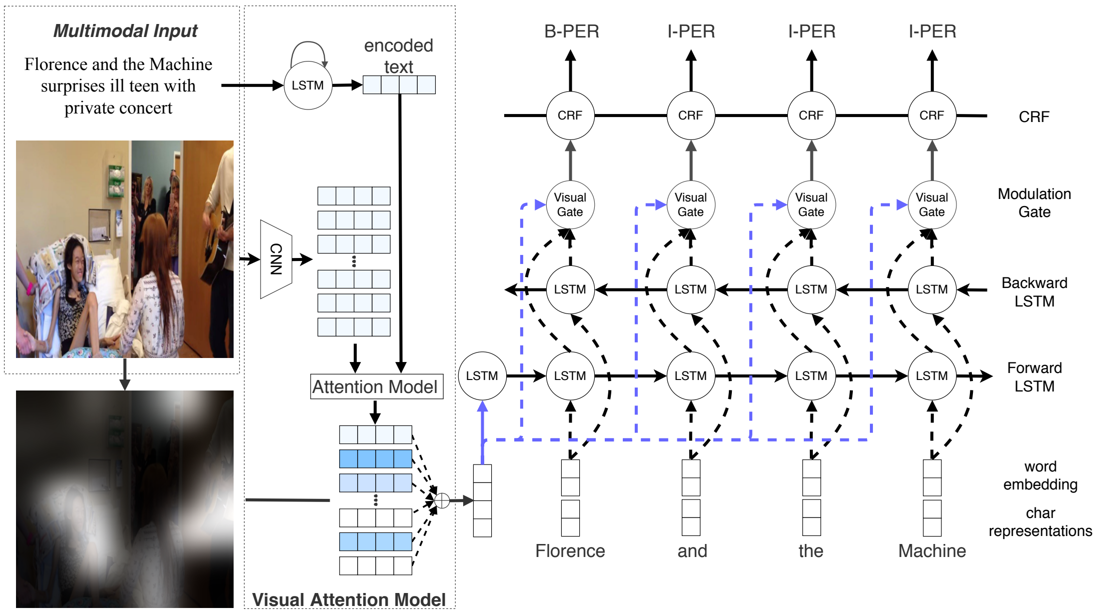

Figure 2: Overall Architecture of the Visual Attention Name Tagging Model.

Name Tagging benefits from both of the past (left) and the future (right) contexts, thus we implement the Bidirectional LSTM (Graves et al., 2013; Dyer et al., 2015) by concatenating the left and right context representations, $h_t = [\overrightarrow{h_t}, \overleftarrow{h_t}]$, for each word.

Character-level Representation. Following (Lample et al., 2016), we generate the character-level representation for each word using another BLSTM. It receives character embeddings as input and generates representations combining implicit prefix, suffix and spelling information. The final word representation x_i is the concatenation of word embedding e_i and character-level representation c_i.

$$c_i = BLSTM_{char}(s_i) \quad s_i \in S$$
$$x_i = [e_i, c_i]$$

Conditional random fields (CRFs). For name tagging, it is important to consider the constraints of the labels in neighborhood (e.g., I-LOC must follow B-LOC). CRFs (Lafferty et al., 2001) are effective to learn those constraints and jointly predict the best chain of labels. We follow the implementation of CRFs in (Ma and Hovy, 2016).

2.2 Visual Feature Representation

We use Convolutional Neural Networks (CNNs) (LeCun et al., 1989) to obtain the representations of images. Particularly, we use Residual Net (ResNet) (He et al., 2016), which

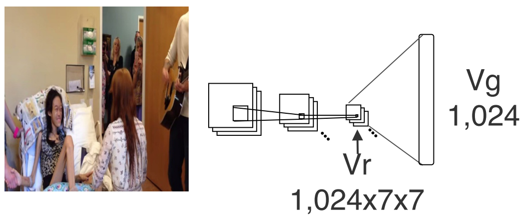

Figure 3: CNN for visual features extraction.

achieves state-of-the-art on ImageNet (Russakovsky et al., 2015) detection, ImageNet localization, COCO (Lin et al., 2014) detection, and COCO segmentation tasks. Given an input pair (S, I), where S represents the word sequence and I represents the image rescaled to 224x224 pixels, we use ResNet to extract visual features for regional areas as well as for the whole image (Fig 3):

$$V_g = ResNet_g(I)$$
$$V_r = ResNet_r(I)$$

where the global visual vector V_g, which represents the whole image, is the output before the last fully connected layer[3]. The dimension of V_g is 1,024. V_r are the visual representations for regional areas and they are extracted from the last convolutional layer of ResNet, and the dimension is 1,024x7x7 as shown in Figure 3. 7x7 is the number of regions in the image and 1,024 is the

[3]the last fully connect layer outputs the probabilities over 1,000 classes of objects.

dimension of the feature vector. Thus each feature vector of V_r corresponds to a 32x32 pixel region of the rescaled input image.

2.3 Visual Attention Model

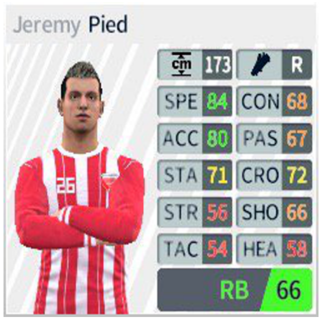

Figure 4: Example of partially related image and sentence. (‘*I have just bought Jeremy Pied.*’)

The global visual representation is a reasonable representation of the whole input image, but not the best. Sometimes only parts of the image are related to the associated sentence. For example, the visual features from the right part of the image in Figure 4 cannot contribute to inferring the information in the associated sentence ‘*I have just bought Jeremy Pied.*’ In this work we utilize visual attention mechanism to combat the problem, which has been proven effective for vision-language related tasks such as Image Captioning (Xu et al., 2015) and Visual Question Answering (Yang et al., 2016b; Lu et al., 2016), by enforcing the model to focus on the regions in images that are mostly related to context textual information while ignoring irrelevant regions. Also the visualization of attention can also help us to understand the decision making of the model. Attention mechanism is mapping a query and a set of key-value pairs to an output. The output is a weighted sum of the values and the assigned weight for each value is computed by a function of the query and corresponding key. We encode the sentence into a query vector using an LSTM, and use regional visual representations V_r as both keys and values.

Text Query Vector. We use an LSTM to encode the sentence into a query vector, in which the inputs of the LSTM are the concatenations of word embeddings and character-level word representations. Different from the LSTM model used for sequence labeling in Section 2.1, the LSTM here aims to get the semantic information of the sentence and it is unidirectional:

$$Q = LSTM_{query}(S) \quad (1)$$

Attention Implementation. There are many implementations of visual attention mechanism such as Multi-layer Perceptron (Bahdanau et al., 2014), Bilinear (Luong et al., 2015), dot product (Luong et al., 2015), Scaled Dot Product (Vaswani et al., 2017), and linear projection after summation (Yang et al., 2016b). Based on our experimental results, dot product implementations usually result in more concentrated attentions and linear projection after summation results in more dispersed attentions. In the context of name tagging, we choose the implementation of linear projection after summation because it is beneficial for the model to utilize as many related visual features as possible, and concentrated attentions may make the model bias. For implementation, we first project the text query vector Q and regional visual features V_r into the same dimensions:

$$P_t = tanh(W_t Q)$$
$$P_v = tanh(W_v V_r)$$

then we sum up the projected query vector with each projected regional visual vector respectively:

$$A = P_t \oplus P_v$$

the weights of the regional visual vectors:

$$E = softmax(W_a A + b_a)$$

where W_a is weights matrix. The weighted sum of the regional visual features is:

$$v_c = \sum \alpha_i v_i \quad \alpha_i \in E, v_i \in V_r$$

We use v_c as the visual context vector to initialize the BLSTM sequence labeling model in Section 2.1. We compare the performances of the models using global visual vector V_g and attention based visual context vector V_c for initialization in Section 4.

2.4 Visual Modulation Gate

The BLSTM-CRF sequence labeling model benefits from using the visual context vector to initialize the LSTM cell. However, the better way to utilize visual features for sequence labeling is to incorporate the features at word level individually. However visual features contribute quite differently when they are used to infer the tags of different words. For example, we can easily find matched visual patterns from associated images for verbs such as '*sing*', '*run*', and '*play*'. Words/Phrases such as names of basketball players, artists, and buildings are often well-aligned with objects in images. However it is difficult to align function words such as '*the*', '*of*' and '*well*' with visual features. Fortunately, most of the challenging cases in name tagging involve nouns and verbs, the disambiguation of which can benefit more from visual features.

We propose to use a visual modulation gate, similar to (Miyamoto and Cho, 2016; Yang et al., 2016a), to dynamically control the combination of visual features and word representation generated by BLSTM at word-level, before feed them into the CRF layer for tag prediction. The equations for the implementation of modulation gate are as follows:

$$\beta_v = \sigma(W_v h_i + U_v v_c + b_v)$$
$$\beta_w = \sigma(W_w h_i + U_w v_c + b_w)$$
$$m = tanh(W_m h_i + U_m v_c + b_m)$$
$$w_m = \beta_w \cdot h_i + \beta_v \cdot m$$

where h_i is the word representation generated by BLSTM, v_c is the computed visual context vector, W_v, W_w, W_m, U_v, U_w and U_m are weight matrices, σ is the element-wise sigmoid function, and w_m is the modulated word representations fed into the CRF layer in Section 2.1. We conduct experiments to evaluate the impact of modulation gate in Section 4.

3 Datasets

We evaluate our model on two multimodal datasets, which are collected from Twitter and Snapchat respectively. Table 1 summarizes the data statistics. Both datasets contain four types of named entities: `Location`, `Person`, `Organization` and `Miscellaneous`. Each data instance contains a pair of sentence and image, and the names in sentences are manually tagged by three expert labelers.

Twitter name tagging. The Twitter name tagging dataset contains pairs of tweets and their associated images extracted from May 2016, January 2017 and June 2017. We use sports and social event related key words, such as *concert, festival, soccer, basketball*, as queries. We don't take into consideration messages without images for this experiment. If a tweet has more than one image associated to it, we randomly select one of the images.

Snap name tagging. The Snap name tagging dataset consists of caption and image pairs exclusively extracted from snaps submitted to public and live stories. They were collected between May and July of 2017. The data contains captions submitted to multiple community curated stories like the Electric Daisy Carnival (EDC) music festival and the Golden State Warrior's NBA parade.

Both Twitter and Snapchat are social media with plenty of multimodal posts, but they have obvious differences with sentence length and image styles. In Twitter, text plays a more important role, and the sentences in the Twitter dataset are much longer than those in the Snap dataset (16.0 tokens vs 8.1 tokens). The image is often more related to the content of the text and added with the purpose of illustrating or giving more context. On the other hand, as users of Snapchat use cameras to communicate, the roles of text and image are switched. Captions are often added to complement what is being portrayed by the snap. On our experiment section we will show that our proposed model outperforms baseline on both datasets.

We believe the Twitter dataset can be an important step towards more research in multimodal name tagging and we plan to provide it as a benchmark upon request.

4 Experiment

4.1 Training

Tokenization. To tokenize the sentences, we use the same rules as (Owoputi et al., 2013), except we separate the hashtag '#' with the words after.

Labeling Schema. We use the standard BIO schema (Sang and Veenstra, 1999), because we see little difference when we switch to BIOES schema (Ratinov and Roth, 2009).

Word embeddings. We use the 100-dimensional GloVe[4] (Pennington et al., 2014) embeddings trained on 2 billions tweets to initialize the lookup table and do fine-tuning during training.

Character embeddings. As in (Lample et al., 2016), we randomly initialize the character embeddings with uniform samples. Based on experimental results, the size of the character embeddings affects little, and we set it as 50.

[4]https://nlp.stanford.edu/projects/glove/

		Training	**Development**	**Testing**
Snapchat	Sentences	4,817	1,032	1,033
	Tokens	39,035	8,334	8,110
Twitter	Sentences	4,290	1,432	1,459
	Tokens	68,655	22,872	23,051

Table 1: Sizes of the datasets in numbers of sentence and token.

Pretrained CNNs. We use the pretrained ResNet-152 (He et al., 2016) from Pytorch.

Early Stopping. We use early stopping (Caruana et al., 2001; Graves et al., 2013) with a patience of 15 to prevent the model from over-fitting.

Fine Tuning. The models are optimized with fine-tuning on both the word-embeddings and the pre-trained ResNet.

Optimization. The models achieve the best performance by using mini-batch stochastic gradient descent (SGD) with batch size 20 and momentum 0.9 on both datasets. We set an initial learning rate of $\eta_0 = 0.03$ with decay rate of $\rho = 0.01$. We use a gradient clipping of 5.0 to reduce the effects of gradient exploding.

Hyper-parameters. We summarize the hyper-parameters in Table 2.

Hyper-parameter	**Value**
LSTM hidden state size	300
Char LSTM hidden state size	50
visual vector size	100
dropout rate	0.5

Table 2: Hyper-parameters of the networks.

4.2 Results

Table 3 shows the performance of the baseline, which is BLSTM-CRF with sentences as input only, and our proposed models on both datasets.

BLSTM-CRF + Global Image Vector: use global image vector to initialize the BLSTM-CRF.

BLSTM-CRF + Visual attention: use attention based visual context vector to initialize the BLSTM-CRF.

BLSTM-CRF + Visual attention + Gate: modulate word representations with visual vector.

Our final model **BLSTM-CRF + VISUAL ATTENTION + GATE**, which has visual attention component and modulation gate, obtains the best F1 scores on both datasets. Visual features successfully play a role of validating entity types. For example, when there is a person in the image, it is more likely to include a person name in the associated sentence, but when there is a soccer field in the image, it is more likely to include a sports team name.

All the models get better scores on Twitter dataset than on Snap dataset, because the average length of the sentences in Snap dataset (8.1 tokens) is much smaller than that of Twitter dataset (16.0 tokens), which means there is much less contextual information in Snap dataset.

Also comparing the gains from visual features on different datasets, we find that the model benefits more from visual features on Twitter dataset, considering the much higher baseline scores on Twitter dataset. Based on our observation, users of Snapchat often post selfies with captions, which means some of the images are not strongly related to their associated captions. In contrast, users of Twitter prefer to post images to illustrate texts

4.3 Attention Visualization

Figure 5 shows some good examples of the attention visualization and their corresponding name tagging results. The model can successfully focus on appropriate regions when the images are well aligned with the associated sentences. Based on our observation, the multimodal contexts in posts related to sports, concerts or festival are usually better aligned with each other, therefore the visual features easily contribute to these cases. For example, the ball and shoot action in example (a) in Figure 5 indicates that the context should be related to basketball, thus the '*Warriors*' should be the name of a sports team. A singing person with a microphone in example (b) indicates that the name of an artist or a band ('*Radiohead*') may appear in the sentence.

The second and the third rows in Figure 5 show some more challenging cases whose tagging results benefit from visual features. In example (d), the model pays attention to the big Apple logo, thus tags the '*Apple*' in the sentence as an Organization name. In example (e) and (i), a small

Model	Snap Captions			Twitter		
	Precision	Recall	F1	Precision	Recall	F1
BLSTM-CRF	57.71	**58.65**	58.18	78.88	77.47	78.17
BLSTM-CRF + Global Image Vector	61.49	57.84	59.61	79.75	77.32	78.51
BLSTM-CRF + Visual attention	65.53	57.03	60.98	80.81	77.36	79.05
BLSTM-CRF + Visual attention + Gate	**66.67**	57.84	**61.94**	**81.62**	**79.90**	**80.75**

Table 3: Results of our models on noisy social media data.

group of people indicates that it is likely to include names of bands (‘*Florence and the Machine*’ and ‘*BTS*’). And a crowd can indicate an organization (‘*Warriorette*’ in example (i)). A jersey shirt on the table indicates a sports team. (‘*Leicester*’ in example (h) can refer to both a city and a soccer club based in it.)

4.4 Error Analysis

Figure 6 shows some failed examples that are categorized into three types: (1) bad alignments between visual and textual information; (2) blur images; (3) wrong attention made by the model.

Name tagging greatly benefits from visual features when the sentences are well aligned with the associated image as we show in Section 4.3. But it is not always the case in social media. The example (a) in Figure 6 shows a failed example resulted from poor alignment between sentences and images. In this image, there are two bins standing in front of a wall, but the sentence talks about basketball players. The unrelated visual information makes the model tag ‘*Cleveland*’ as a Location, however it refers to the basketball team ‘*Cleveland Cavaliers*’.

The image in example (b) is blur, so the extracted visual information extracted actually introduces noise instead of additional information. The

Figure 6: Examples of Failed Visual Attention.

image in example (c) is about a baseball pitcher, but our model pays attention to the top right corner of the image. The visual context feature computed by our model is not related to the sentence, and results in missed tagging of '*SBU*', which is an organization name.

5 Related Work

In this section, we summarize relevant background on previous work on name tagging and visual attention.

Name Tagging. In recent years, (Chiu and Nichols, 2015; Lample et al., 2016; Ma and Hovy, 2016) proposed several neural network architectures for named tagging that outperform traditional explicit features based methods (Chieu and Ng, 2002; Florian et al., 2003; Ando and Zhang, 2005; Ratinov and Roth, 2009; Lin and Wu, 2009; Passos et al., 2014; Luo et al., 2015). They all use Bidirectional LSTM (BLSTM) to extract features from a sequence of words. For character-level representations, (Lample et al., 2016) proposed to use another BLSTM to capture prefix and suffix information of words, and (Chiu and Nichols, 2015; Ma and Hovy, 2016) used CNN to extract position-independent character features. On top of BLSTM, (Chiu and Nichols, 2015) used a softmax layer to predict the label for each word, and (Lample et al., 2016; Ma and Hovy, 2016) used a CRF layer for joint prediction. Compared with traditional approaches, neural networks based approaches do not require hand-crafted features and achieved state-of-the-art performance on name tagging (Ma and Hovy, 2016). However, these methods were mainly developed for newswire and paid little attention to social media. For name tagging in social media, (Ritter et al., 2011) leveraged a large amount of unlabeled data and many dictionaries into a pipeline model. (Limsopatham and Collier, 2016) adapted the BLSTM-CRF model with additional word shape information, and (Aguilar et al., 2017) utilized an effective multi-task approach. Among these methods, our model is most similar to (Lample et al., 2016), but we designed a new visual attention component and a modulation control gate.

Visual Attention. Since the attention mechanism was proposed by (Bahdanau et al., 2014), it has been widely adopted to language and vision related tasks, such as Image Captioning and Visual Question Answering (VQA), by retrieving the visual features most related to text context (Zhu et al., 2016; Anderson et al., 2017; Xu and Saenko, 2016; Chen et al., 2015). (Xu et al., 2015) proposed to predict a word based on the visual patch that is most related to the last predicted word for image captioning. (Yang et al., 2016b; Lu et al., 2016) applied attention mechanism for VQA, to find the regions in images that are most related to the questions. (Yu et al., 2016) applied the visual attention mechanism on video captioning. Our attention implementation approach in this work is similar to those used for VQA. The model finds the regions in images that are most related to the accompanying sentences, and then feed the visual features into an BLSTM-CRF sequence labeling model. The differences are: (1) we add visual context feature at each step of sequence labeling; and (2) we propose to use a gate to control the combination of the visual information and textual information based on their relatedness. 2

6 Conclusions and Future Work

We propose a gated Visual Attention for name tagging in multimodal social media. We construct two multimodal datasets from Twitter and Snapchat. Experiments show an absolute 3%-4% F-score gain. We hope this work will encourage more research on multimodal social media in the future and we plan on making our benchmark available upon request.

Name Tagging for more fine-grained types (e.g.

soccer team, basketball team, politician, artist) can benefit more from visual features. For example, an image including a pitcher indicates that the '*Giants*' in context should refer to the baseball team '*San Francisco Giants*'. We plan to expand our model to tasks such as fine-grained Name Tagging or Entity Liking in the future.

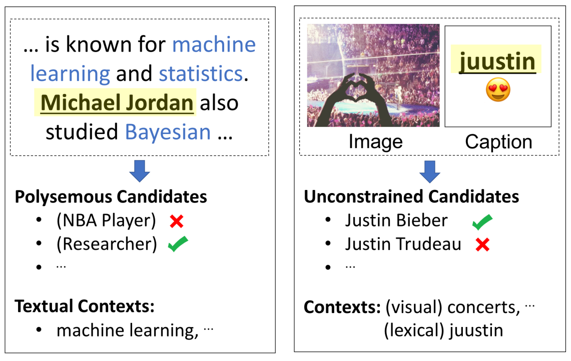
Abstract

We introduce the new Multimodal Named Entity Disambiguation (MNED) task for multimodal social media posts such as Snapchat or Instagram captions, which are composed of short captions with accompanying images. Social media posts bring significant challenges for disambiguation tasks because 1) ambiguity not only comes from polysemous entities, but also from inconsistent or incomplete notations, 2) very limited context is provided with surrounding words, and 3) there are many emerging entities often unseen during training. To this end, we build a new dataset called *SnapCaptionsKB*, a collection of Snapchat image captions submitted to public and crowd-sourced stories, with named entity mentions fully annotated and linked to entities in an external knowledge base. We then build a deep zeroshot multimodal network for MNED that 1) extracts contexts from both text and image, and 2) predicts correct entity in the knowledge graph embeddings space, allowing for zeroshot disambiguation of entities unseen in training set as well. The proposed model significantly outperforms the state-of-the-art text-only NED models, showing efficacy and potentials of the MNED task.



(a) Traditional NED (b) Multimodal NED

Figure 1: Examples of (a) a traditional NED task, focused on disambiguating polysemous entities based on surrounding textual contexts, and (b) the proposed Multimodal NED task for short media posts, which leverages both visual and textual contexts to disambiguate an entity. Note that mentions are often lexically inconsistent or incomplete, and thus a fixed candidates generation method (based on exact mention-entity statistics) is not viable.

1 Introduction

Online communications are increasingly becoming fast-paced and frequent, and hidden in these abundant user-generated social media posts are insights for understanding users and their preferences. However, these social media posts often come in unstructured text or images, making massive-scale opinion mining extremely challenging. Named entity disambiguation (NED), the task of linking ambiguous entities from free-form text *mention* to specific *entities* in a pre-defined knowledge base (KB), is thus a critical step for extracting structured information which leads to its application for recommendations, advertisement, personalized assistance, etc.

While many previous approaches on NED been successful for well-formed text in disambiguating polysemous entities via context resolution, several additional challenges remain for disambiguating entities from extremely short and coarse text found in social media posts (*e.g.* "*juustin* 😍" as opposed to "*I love Justin Bieber/Justin Trudeau/etc.*"). In many of these cases it is simply impossible to disambiguate entities from text alone, due to enormous number of surface forms arising from incomplete and inconsistent notations. In addition, social media posts often include mentions of newly emerging entities unseen in training sets, making traditional context-based entity linking often not viable.

However, as popular social media platforms are increasingly incorporating a mix of text and images (*e.g.* Snapchat, Instargram, Pinterest, etc.), we can advance the disambiguation task to incorporate additional visual context for understanding posts. For example, the mention of 'juuustin' is completely ambiguous in its textual form, but an accompanying snap image of a concert scene may help disambiguate or re-rank among several lexical candidates (*e.g.* Justin Bieber (a pop singer) versus Justin Trudeau (a politician) in Figure 1).

To this end, we introduce a new task called Multimodal Named Entity Disambiguation (MNED) that handles unique challenges for social media posts composed of extremely short text and images, aimed at disambiguationg entities by leveraging both textual and visual contexts.

We then propose a novel zeroshot MNED model, which obtains visual context vectors from images with a CNN (LeCun et al., 1989), and combines with textual context extracted from a bidirectional LSTM (Dyer et al., 2015) (Section 2.2). In addition, we obtain embeddings representation of 1M entities from a knowledge graph, and train the MNED network to predict label embeddings of entities in the same space as corresponding knowledge graph embeddings (Section 2.4). This approach effectively allows for zeroshot prediction of unseen entities, which is critical for scarce-label scenario due to extensive human annotation efforts required. Lastly, we develop a lexical embeddings model that determines lexical similarity between a mention and potential entities, to aid in prediction of a correct entity (Section 2.3). Section 2.5 details the model combining the components above.

Note that our method takes different perspectives from the previous work on NED (He et al., 2013; Yamada et al., 2016; Eshel et al., 2017) in the following important ways. First, while most of the previous methods generate fixed "candidates" for disambiguation given a mention from mention-entity pair statistics (thus disambiguation is limited for entities with exact surface form matches), we do not fixate candidate generation, due to intractable variety of surface forms for each named entity and unforeseen mentions of emerging entities. Instead, we have a lexical model incorporated into the discriminative score function that serves as soft normalization of various surface forms. Second, we extract auxiliary visual contexts for detected entities from user-generated images accompanied with textual posts, which is crucial because captions in our dataset are substantially shorter than text documents in most other NED datasets. To the best of our knowledge, our work is the first in using visual contexts for the named entity disambiguation task. See Section 4 for the detailed literature review.

Our contributions are as follows: for the new MNED task we introduce, we propose a deep zeroshot multimodal network with (1) a CNN-LSTM hybrid module that extracts contexts from both image and text, (2) a zeroshot learning layer which via embeddings projection allows for entity linking with 1M knowledge graph entities even for entities unseen from captions in training set, and (3) a lexical language model called *Deep Levenshtein* to compute lexical similarities between mentions and entities, relaxing the need for fixed candidates generation. We show that the proposed approaches successfully disambiguate incomplete mentions as well as polysemous entities, outperforming the state-of-the-art models on our newly crawled *SnapCaptionsKB* dataset, composed of 12K image-caption pairs with named entities annotated and linked with an external KB.

2 Proposed Methods

Figure 2 illustrates the proposed model, which maps each multimodal social media post data to one of the corresopnding entities in the KB. Given a multimodal input that contains a mention of an ambiguous entity, we first extract textual and visual features contexts with RCNNs and Bi-LSTMs, respectively (Section 2.2). We also obtain lexical character-level representation of a mention to compare with lexical representation of KB entities, using a proposed model called *Deep Levenshtein* (Section 2.3). We then get high-dimensional label embeddings of KB entities constructed from a knowledge graph, where similar entities are mapped as neighbors in the same space (Section 2.4). Finally, we aggregate all the contextual information extracted from surrounding text, image, and lexical notation of a mention, and predict the best matching KB entity based on knowledge graph label representation and lexical notation of KB entity candidates (Section 2.5).

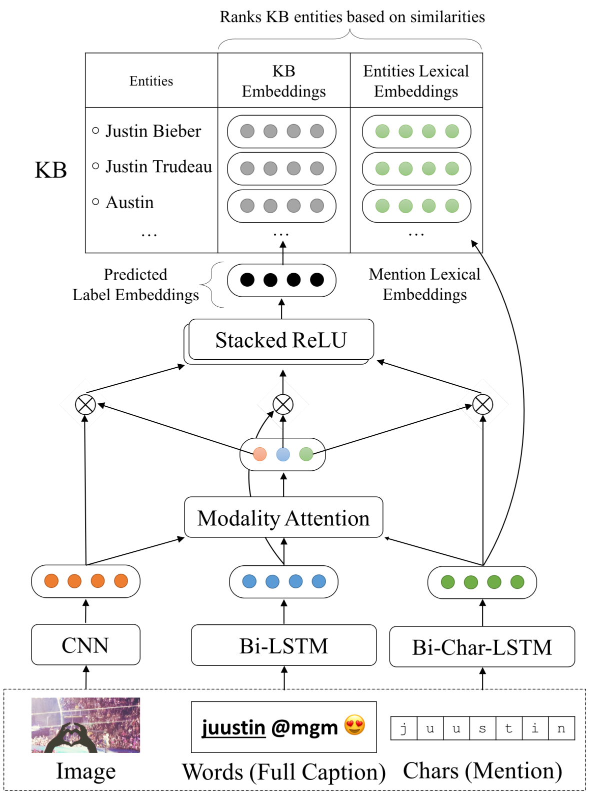


Figure 2: The main architecture of our Multimodal NED network. We extract contextual information from an image, surrounding words, and lexical embeddings of a mention. The modality attention module determines weights for modalities, the weighted projections of which produce label embeddings in the same space as knowledge-base (KB) entity embeddings. We predict a final candidate by ranking based on similarities with KB entity knowledge graph embeddings as well as with lexical embeddings.

2.1 Notations

Let $\mathbf{X} = \{\mathbf{x}^{(i)}\}_{i=1}^{N}$ a set of N input social media posts samples for disambiguation, with corresponding ground truth named entities $\mathbf{Y} = \{\mathbf{y}^{(i)}\}_{i=1}^{N}$ for $\mathbf{y} \in \mathbf{Y}_{\text{KB}}$, where $\mathbf{Y}_{\text{KB}}$ is a set of entities in KB. Each input sample is composed of three modalities: $\mathbf{x} = \{\mathbf{x}_w; \mathbf{x}_v; \mathbf{x}_c\}$, where $\mathbf{x}_w = \{\mathbf{x}_{w,t}\}_{t=1}^{L_w}$ is a sequence of words with length L_w surrounding a mention in a post, $\mathbf{x}_v$ is an image associated with a post (Section 2.2), and $\mathbf{x}_c = \{\mathbf{x}_{c,t}\}_{t=1}^{L_c}$ is a sequence of characters comprising a mention (Section 2.3), respectively. We denote high-dimensinal feature extractor functions for each modality as: $\mathbf{w}(\mathbf{x}_w)$, $\mathbf{c}(\mathbf{x}_c)$, $\mathbf{v}(\mathbf{x}_v)$. We represent each output label in two modalities: $\mathbf{y} = \{\mathbf{y}_{KB}; \mathbf{y}_c\}$, where $\mathbf{y}_{\text{KB}}$ is a knowledge base label embeddings representation (Section 2.4), and and $\mathbf{y}_c$ is a character embeddings representation of KB entities (Section 2.3: Deep Levenshtein).

We formulate our zeroshot multimodal NED task as follows:

$$\mathbf{y} = \underset{\mathbf{y}' \in \mathbf{Y}_{\text{KB}}}{\text{argmax}} \ \text{sim}\big(\mathbf{f}_{\mathbf{x}\to\mathbf{y}}(\mathbf{x}), \mathbf{y}'\big)$$

where $\mathbf{f}_{\mathbf{x}\to\mathbf{y}}$ is a function with learnable parameters that project multimodal input samples ($\mathbf{x}$) into the same space as label representations ($\mathbf{y}$), and $\text{sim}(\cdot)$ produces a similarity score between prediction and ground truth KB entities.

2.2 Textual and Visual Contexts Features

Textual features: we represent textual context of surrounding words of a mention with a Bi-LSTM language model (Dyer et al., 2015) with distributed word semantics embeddings. We use the following implementation for the LSTM.

$$\begin{aligned}
\mathbf{i}_t &= \sigma(\mathbf{W}_{xi}\mathbf{h}_{t-1} + \mathbf{W}_{ci}\mathbf{c}_{t-1}) \\
\mathbf{c}_t &= (1 - \mathbf{i}_t) \odot \mathbf{c}_{t-1} \\
&\quad + \mathbf{i}_t \odot \tanh(\mathbf{W}_{xc}\mathbf{x}_{w,t} + \mathbf{W}_{hc}\mathbf{h}_{t-1}) \\
\mathbf{o}_t &= \sigma(\mathbf{W}_{xo}\mathbf{x}_{w,t} + \mathbf{W}_{ho}\mathbf{h}_{t-1} + \mathbf{W}_{co}\mathbf{c}_t) \\
\mathbf{h}_t &= \mathbf{o}_t \odot \tanh(\mathbf{c}_t) \\
\mathbf{w}(\mathbf{x}_w) &= [\overrightarrow{\mathbf{h}_{L_w}}; \overleftarrow{\mathbf{h}_{L_w}}] \qquad (1)
\end{aligned}$$

where $\mathbf{h}_t$ is an LSTM hidden layer output at decoding step t, and $\mathbf{w}(\mathbf{x}_w)$ is an output textual representation of bi-directional LSTM concatenating left and right context at the last decoding step $t = L_w$. Biase terms for gates are omitted for simplicity of formulation.

For the Bi-LSTM sentence encoder, we use pretrained word embeddings obtained from an unsupervised language model aimed at learning co-occurrence statistics of words from a large external corpus. Word embeddings are thus represented as distributional semantics of words. In our experiments, we use pre-trained embeddings from Stanford GloVE model (Pennington et al., 2014).

Visaul features: we take the final activation of a modified version of the recurrent convolutional network model called Inception (GoogLeNet) (Szegedy et al., 2015) trained on the ImageNet dataset (Russakovsky et al., 2015) to classify multiple objects in the scene. The final layer representation ($\mathbf{v}(\mathbf{x}_v)$) thus encodes discriminative information describing what objects are shown in an image, providing cues for disambiguation.

2.3 Lexical Embeddings: Deep Levenshtein

While traditional NED tasks assume perfect lexical match between mentions and their corresponding entities, in our task it is important to account for various surface forms of mentions (nicknames, mis-spellings, inconsistent notations, etc.) corresponding to each entity. Towards this goal, we train a separate deep neural network to compute approximate Levenshtein distance which we call Deep Levenshtein (Figure 3), composed of a shared bi-directional character LSTM, shared character embedding matrix, fully connected layers, and a dot product merge operation layer. The optimization is as follows:

$$\min_{\mathbf{c}} \left\| \frac{1}{2}\left(\frac{\mathbf{c}(\mathbf{x}_c)\cdot\mathbf{c}(\mathbf{x'}_c)^\top}{\|\mathbf{c}(\mathbf{x}_c)\|\|\mathbf{c}(\mathbf{x'}_c)\|} + 1 \right) - \mathrm{sim}(\mathbf{x}_c, \mathbf{x'}_c) \right\|^2 \quad (2)$$

$$\text{where } \mathbf{c}(\mathbf{x}_c) = [\overrightarrow{\mathbf{h}_{c,L_c}}; \overleftarrow{\mathbf{h}_{c,L_c}}]$$

where $\mathbf{c}(\cdot)$ is a bi-directional LSTM output vector for a character sequence defined similar as in Eq.1, $\mathrm{sim}(\cdot)$ is an output of the Deep Levenshtein network, producing a normalized similarity score with a range [0,1] based on Levenshtein edit distance, and $(\mathbf{x}_c, \mathbf{x'}_c)$ is any pair of two strings. We generate millions of these pairs as training data by artificially corrupting seed strings by varying degrees (addition, deletion, replacement).

Once trained, it can produce a purely lexical embedding of a string without semantic allusion (via $\mathbf{c}(\cdot)$), and predict lexical similarity between two strings based on their distance in the embedding space. On an intuitive level, this component effectively bypasses normalization steps, and instead incorporates lexical similarities between input mentions and output KB entities into the overall optimization of the disambiguation network.

We use by-product $\mathbf{c}(\cdot)$ network to extract lexical embedings of mentions and KB entities, and freeze $\mathbf{c}$ in training of the disambiguation network. We observe that this approach significantly outperforms alternative ways to obtain character embeddings (*e.g.* having a character Bi-LSTM as a part of the disambiguation network training, which unnecessarily learns semantic allusions that are prone to errors when notations are inconsistent.)

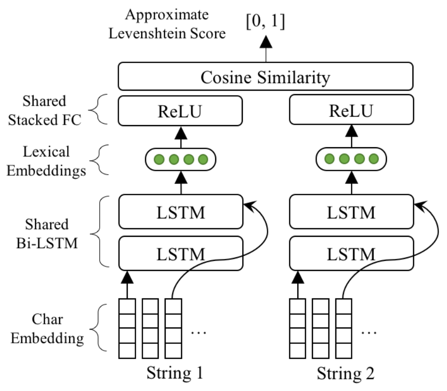

Figure 3: Deep Levenshtein, which predicts approximate Levenshtein scores between two strings. As a byproduct of this model, the shared Bi-LSTM can produce lexical embeddings purely based on lexical property of character sequences.

2.4 Label Embeddings from Knowledge Graph

Due to the overwhelming variety of (newly trending) entities mentioned over social media posts, at test phases we frequently encounter new named entities that are unseen in the training data. In order to address this issue, we propose a zeroshot learning approach (Frome et al., 2013) by inducing embeddings obtained from knowledge graphs on KB entities. Knowledge graph label embeddings are learned from known relations among entities within a graph (*e.g.* 'IS-A', 'LOCATED-AT', etc.), the resulting embeddings of which can group similar entities closer in the same space (*e.g.* 'pop stars' are in a small cluster, 'people' and 'organizations' clusters are far apart, etc.) (Bordes et al., 2013; Wang et al., 2014; Nickel et al., 2016). Once high-level mapping from contextual information to label embeddings is learned, the knowledge-graph based zeroshot approach can improve the entity linking performance given ambiguous entities unseen in training data. In brief formulation, the model for obtaining embeddings from a knowledge graph (composed of subject-relation-object (s, r, o) triplets) is as follows:

$$P(\mathbb{I}_r(s,o) = 1|\mathbf{e}, \mathbf{e}_r, \theta) = \mathrm{score}_\theta\big(\mathbf{e}(s), \mathbf{e}_r(r), \mathbf{e}(o)\big) \quad (3)$$

where $\mathbb{I}_r$ is an indicator function of a known relation r for two entities $(s$,$o)$ (1: valid relation, 0: unknown relation), $\mathbf{e}$ is a function that extracts embeddings for entities, $\mathbf{e}_r$ extracts embeddings for relations, and $\mathrm{score}_\theta(\cdot)$ is a deep neural network that produces a likelihood of a valid triplet.

In our experiments, we use the 1M subset of the Freebase knowledge graph (Bast et al., 2014) to obtain label embeddings with the Holographic KB implementation by (Nickel et al., 2016).

2.5 Deep Zeroshot MNED Network (DZMNED)

Using the contextual information extracted from surrounding text and an accompanying image (Section 2.2) and lexical embeddings of a mention (Section 2.3), we build a Deep Zeroshot MNED network (DZMNED) which predicts a corresponding KB entity based on its knowledge graph embeddings (Section 2.4) and lexical similarity (Section 2.3) with the following objective:

$$\min_{\mathbf{W}} \mathcal{L}_{\text{KB}}(\mathbf{x}, \mathbf{y}_{\text{KB}}; \mathbf{W_w}, \mathbf{W_v}, \mathbf{W_f}) + \mathcal{L}_c(\mathbf{x}_c, \mathbf{y}_c; \mathbf{W_c})$$

where

$$\mathcal{L}_{\text{KB}}(\cdot) = \frac{1}{N}\sum_{i=1}^{N}\sum_{\tilde{\mathbf{y}} \neq \mathbf{y}_{\text{KB}}^{(i)}} \max[0, \tilde{\mathbf{y}} \cdot \mathbf{y}_{\text{KB}}^{(i)} - \mathbf{f}(\overline{\mathbf{x}}^{(i)}) \cdot (\mathbf{y}_{\text{KB}}^{(i)} - \tilde{\mathbf{y}})^\top]$$

$$\mathcal{L}_c(\cdot) = \frac{1}{N}\sum_{i=1}^{N}\sum_{\tilde{\mathbf{y}} \neq \mathbf{y}_c^{(i)}} \max[0, \tilde{\mathbf{y}} \cdot \mathbf{y}_c^{(i)} - \mathbf{c}(\mathbf{x}_c^{(i)}) \cdot (\mathbf{y}_c^{(i)} - \tilde{\mathbf{y}})^\top]$$

$\mathcal{R}(\mathbf{W})$: regularization

where $\mathcal{L}_{\text{KB}}(\cdot)$ is the supervised hinge rank loss for knowledge graph embeddings prediction, $\mathcal{L}_c(\cdot)$ is the loss for lexical mapping between mentions and KB entities, $\overline{\mathbf{x}}$ is a weighted average of three modalities $\mathbf{x} = \{\mathbf{x}_w; \mathbf{x}_v; \mathbf{x}_c\}$ via the modality attention module. $\mathbf{f}(\cdot)$ is a transformation function with stacked layers that projects weighted input to the KB embeddings space, $\tilde{\mathbf{y}}$ refers to the embeddings of negative samples randomly sampled from KB entities except the ground truth label of the instance, $\mathbf{W} = \{\mathbf{W_f}, \mathbf{W_c}, \mathbf{W_w}, \mathbf{W_v}\}$ are the learnable parameters for $\mathbf{f}$, $\mathbf{c}$, $\mathbf{w}$, and $\mathbf{v}$ respectively, and $\mathcal{R}(\mathbf{W})$ is a weight decay regularization term.

Similarly to (Moon et al., 2018), we formulate the **modality attention** module for our MNED network as follows, which selectively attenuates or amplifies modalities:

$$[\mathbf{a}_w; \mathbf{a}_c; \mathbf{a}_v] = \sigma\big(\mathbf{W}_m \cdot [\mathbf{x}w; \mathbf{x}c; \mathbf{x}_v] + \mathbf{b}_m\big) \quad (4)$$

$$\alpha_m = \frac{\exp(\mathbf{a}_m)}{\sum_{m' \in \{w,c,v\}} \exp(\mathbf{a}_{m'})} \quad \forall m \in \{w, c, v\}$$

$$\overline{\mathbf{x}} = \sum_{m \in \{w,c,v\}} \alpha_m \mathbf{x}_m \quad (5)$$

where $\alpha = [\alpha_w; \alpha_c; \alpha_v] \in \mathbb{R}^3$ is an attention vector, and $\overline{\mathbf{x}}$ is a final context vector that maximizes information gain.

Intuitively, the model is trained to produce a higher dot product similarity between the projected embeddings with its correct label than with an incorrect negative label in both the knowledge graph label embeddings and the lexical embeddings spaces, where the margin is defined as the similarity between a ground truth sample and a negative sample.

At test time, the following label-producing nearest neighbor (1-NN) classifier is used for the target task (we cache all the label embeddings to avoid repetitive projections):

$$\text{1-NN}(\mathbf{x}) = \underset{(\mathbf{y}_{\text{KB}}, \mathbf{y}_c) \in \mathbf{Y}_{\text{KB}}}{\text{argmax}} \ \mathbf{f}(\overline{\mathbf{x}}) \cdot \mathbf{y}_{\text{KB}}{}^\top + \mathbf{g}(\mathbf{x}_c) \cdot \mathbf{y_c}{}^\top \quad (6)$$

In summary, the model produces (1) projection of input modalities (mention, surrounding text, image) into the knowledge graph embeddings space, and (2) lexical embeddings representation of mention, which then calculates a combined score of contextual (knowledge graph) and string similarities with each entity in $\mathbf{Y}_{\text{KB}}$.

3 Empirical Evaluation

Task: Given a caption and an accompanying image (if available), the goal is to disambiguate and link a target mention in a caption to a corresponding entity from the knowledge base (1M subset of the Freebase knowledge graph (Bast et al., 2014)).

3.1 Datasets

Our **SnapCaptionsKB** dataset is composed of 12K user-generated image and textual caption pairs where named entities in captions and their links to KB entities are manually labeled by expert human annotators. These captions are collected exclusively from snaps submitted to public and crowd-sourced stories (aka *Live Stories* or *Our Stories*). Examples of such stories are “New York Story” or “Thanksgiving Story”, which are aggregated collections of snaps for various public venues, events, etc. Our data do not contain raw images, and we only provide textual captions and obfuscated visual descriptor features extracted from the pre-trained InceptionNet. We split the dataset randomly into train (70%), validation (15%), and test sets (15%). The captions data have average length of 29.5 characters (5.57 words) with vocabulary size 16,553, where 6,803 are considered unknown tokens from Stanford GloVE embeddings (Pennington et al., 2014).

Named entities annotated in the dataset include many of new and emerging entities found in various surface forms. To the best of our knowledge, our *SnapCaptionsKB* is the only dataset that contains image-caption pairs with human-annotated named entities and their links to KB entities.

3.2 Baselines

We report performance of the following state-of-the-art NED models as baselines, with several candidate generation methods and variations of our proposed approach to examine contributions of each component (W: word, C: char, V: visual).

Candidates generation: Note that our zeroshot approach allows for entity disambiguation without a fixed candidates generation process. In fact, we observe that the conventional method for fixed candidates generation harms the performance for noisy social media posts with many emerging entities. This is because the difficulty of entity linking at test time rises not only from multiple entities (e) linking to a single mention (m), but also from each entity found in multiple surface forms of mentions (often unseen at train time). To show the efficacy of our approach that does not require candidates generation, we compare with the following candidates generation methods:

- $m \rightarrow e$ hash list: This method retrieves KB entity (e) candidates per mention (m) based on exact (m, e) pair occurrence statistics from a training corpora. This is the most predominantly used candidates generation method (He et al., 2013; Yamada et al., 2016; Eshel et al., 2017). Note that this approach is especially vulnerable at test time to noisy mentions or emerging entities with no or a few matching candidate entities from training set.

- k-NN: We also consider using lexical neighbors of mentions from KB entities as candidates. This approach can be seen as soft normalization to relax the issue of having to match a variety of surface forms of a mention to KB entities. We use our Deep Levenshtein (Section 2.3) to compute lexical embeddings of KB entities and mentions, and retrieves Euclidean neighbors (and their polysemous entities) as candidates.

NED models: We choose as baselines the following state-of-the-art NED models for noisy text, as well as several configurations of our proposed approach to examine contributions of each component (W: word, C: char, V: visual).

- sDA-NED (W only) (He et al., 2013): uses a deep neural network with stacked denoising autoencoders (sDA) to encode bag-of-words representation of textual contexts and to directly compare mentions and entities.

- ARNN (W only) (Eshel et al., 2017): uses an Attention RNN model that computes similarity between word and entity embeddings to disambiguate among fixed candidates.

- Deep Zeroshot (W only): uses the deep zeroshot architecture similar to Figure 2, but uses word contexts (caption) only.

- (**proposed**) DZMNED + Deep Levenshtein + InceptionNet with modality attention (W+C+V): is the proposed approach as described in Figure 2.

- (**proposed**) DZMNED + Deep Levenshtein + InceptionNet w/o modality attention (W+C+V): concatenates all the modality vectors instead.

- (**proposed**) DZMNED + Deep Levenshtein (W+C): only uses textual context.

- (**proposed**) DZMNED + Deep Levenshtein w/o modality attention (W+C): does not use the modality attention module, and instead concatenates word and lexical embeddings.

3.3 Results

Parameters: We tune the parameters of each model with the following search space (bold indicate the choice for our final model): character embeddings dimension: {25, 50, **100**, 150, 200, 300}, word embeddings size: {25, 50, **100**, 150, 200, 300}, knowledge graph embeddings size: {**100**, 200, 300}, LSTM hidden states: {50, **100**, 150, 200, 300}, and $\overline{x}$ dimension: {25, 50, **100**, 150, 200, 300}. We optimize the parameters with Adagrad (Duchi et al., 2011) with batch size 10, learning rate 0.01, epsilon 10^{-8}, and decay 0.1.

Main Results: Table 1 shows the Top-1, 3, 5, 10, and 50 candidates retrieval accuracy results on the *Snap Captions* dataset. We see that the proposed approach significantly outperforms the baselines which use fixed candidates generation

Modalities	Model	Candidates Generation	Accuracy (%)				
			Top-1	Top-3	Top-5	Top-10	Top-50
W	ARNN (Eshel et al., 2017)	$m{\rightarrow}e$ list	51.2	60.4	66.5	66.9	66.9
W	ARNN	5-NN (lexical)	35.2	43.3	45.0	-	-
W	ARNN	10-NN (lexical)	31.9	40.1	44.5	50.7	-
W	sDA-NED (He et al., 2013)	$m{\rightarrow}e$ list	48.7	57.3	66.3	66.9	66.9
W	Zeroshot	N/A	43.6	63.8	67.1	70.5	77.2
W + C	DZMNED	N/A	67.0	72.7	74.8	76.8	85.0
W + C	DZMNED + Modality Attention	N/A	67.8	73.5	74.8	76.2	84.6
W + C + V	DZMNED	N/A	67.2	74.6	77.7	80.5	**88.1**
W + C + V	DZMNED + Modality Attention	N/A	**68.1**	**75.5**	**78.2**	**80.9**	87.9

Table 1: NED performance on the *SnapCaptionsKB* dataset at Top-1, 3, 5, 10, 50 accuracies. The classification is over 1M entities. Candidates generation methods: N/A, or over a fixed number of candidates generated with methods: $m{\rightarrow}e$ hash list and kNN (lexical neighbors).

KB Embeddings	Top-1	Top-5	Top-10
Trained with 1M entities	**68.1**	**78.2**	**80.9**
Trained with 10K entities	60.3	72.5	75.9
Random embeddings	41.4	45.8	48.0

Table 2: MNED performance (Top-1, 5, 10 accuracies) on SnapCaptionsKB with varying qualities of KB embeddings. Model: DZMNED (W+C+V)

method. Note that $m \rightarrow e$ hash list-based methods, which retrieve as candidates the KB entities that appear in the training set of captions only, has upper performance limit at 66.9%, showing the limitance of fixed candidates generation method for unseen entities in social media posts. k-NN methods which retrieve lexical neighbors of mention (in an attempt to perform soft normalization on mentions) also do not perform well. Our proposed zeroshot approaches, however, do not fixate candidate generation, and instead compares combined contextual and lexical similarities among all 1M KB entities, achieving higher upper performance limit (Top-50 retrieval accuracy reaches 88.1%). This result indicates that the proposed zeroshot model is capable of predicting for unseen entities as well. The lexical sub-model can also be interpreted as functioning as soft neural mapping of mention to potential candidates, rather than heuristic matching to fixed candidates.

In addition, when visual context is available (W+C+V), the performance generally improves over the textual models (W+C), showing that visual information can provide additional contexts for disambiguation. The modality attention module also adds performance gain by re-weighting the modalities based on their informativeness.

Error Analysis: Table 3 shows example cases where incorporation of visual contexts affects disambiguation of mentions in textual captions. For example, polysemous entities such as 'Jordan' in the caption "*Taking the new Jordan for a walk*" or 'CID' as in "*LETS GO CID*" are hard to disambiguate due to the limited textual contexts provided, while visual information (*e.g.* visual tags 'footwear' for Jordan, 'DJ' for CID) provides similarities to each mention's distributional semantics from other training examples. Mentions unseen at train time ('STEPHHHH', 'murica') often resort to lexical neighbors by (W+C), whereas visual contexts can help disambiguate better. A few cases where visual contexts are not helpful include visual tags that are not related to mentions, or do not complement already ambiguous contexts.

Sensitivity to KB Embeddings Quality: The proposed approach relies its prediction on entity matching in the KB embeddings space, and hence the quality of KB embeddings is crucial for successful disambiguation. To characterize this aspect, we provide Table 2 which shows MNED performance with varying quality of embeddings as follows: KB embeddings learned from 1M knowledge graph entities (same as in the main experiments), from 10K subset of entities (less triplets to train with in Eq.3, hence lower quality), and random embeddings (poorest) - while all the other parameters are kept the same. It can be seen that the performance notably drops with lower quality of KB embeddings. When KB embeddings are replaced by random embeddings, the network effectively prevents the contextual zeroshot matching to KB entities and relies only on lexical similarities, achieving the poorest performance.

	Caption (target)	Visual Tags	GT	Top-1 Prediction	
				(W+C+V)	(W+C)
+	*"YA BOI STEPHHHH"*	sports equip, ball, parade, ...	Stephen Curry	(=GT)	Stephenville
	"Taking the new Jordan for a walk"	footwear, shoe, sock, ...	Air Jordan	(=GT)	Michael Jordan
	"out for murica's bday 😎"	parade, flag, people, ...	U.S.A.	(=GT)	Murcia (Spain)
	"Come on now, Dre"	club, DJ, night, ...	Dr. Dre	(=GT)	Dre Kirkpatrick
	"LETS GO CID"	drum, DJ, drummer, ...	CID (DJ)	(=GT)	CID (ORG)
-	*"kick back hmu for addy."*	weather, fog, tile, ...	Adderall	GoDaddy	(=GT)
	"@Sox to see 3️⃣4️⃣ get retired!⚾🍺"	sunglasses, stadium, ...	Red Sox	White Sox	White Sox

Table 3: Error analysis: **when do images help NED**? Ground-truth (GT) and predictions of our model with vision input (W+C+V) and the one without (W+C) for the underlined mention are shown. For interpretability, visual tags (label output of InceptionNet) are presented instead of actual feature vectors.

4 Related Work

NED task: Most of the previous NED models leverage local textual information (He et al., 2013; Eshel et al., 2017) and/or document-wise global contexts (Hoffart et al., 2011; Chisholm and Hachey, 2015; Pershina et al., 2015; Globerson et al., 2016), in addition to other auxiliary contexts or priors for disambiguating a mention. Note that most of the NED datasets (*e.g.* TAC KBP (Ji et al., 2010), ACE (Bentivogli et al., 2010), CoNLL-YAGO (Hoffart et al., 2011), etc.) are extracted from standardized documents with web links such as Wikipedia (with relatively ample textual contexts), and that named entitiy disambiguation specifically for short and noisy social media posts are rarely discussed. Note also that most of the previous literature assume the availability of "candidates" or web links for disambiguation via mention-entity pair counts from training set, which is vulnerable to inconsistent surface forms of entities predominant in social media posts.

Our model improves upon the state-of-the-art NED models in three very critical ways: (1) incorporation of visual contexts, (2) addition of the zeroshot learning layer, which allows for disambiguation of unseen entities during training, and (3) addition of the lexical model that computes lexical similarity entities to correctly recognize inconsistent surface forms of entities.

Multimodal learning studies learning of a joint model that leverages contextual information from multiple modalities in parallel. Some of the relevant multimodal learning task to our MNED system include the multimodal named entity recognition task (Moon et al., 2018), which leverages both text and image to classify each token in a sentence to named entity or not. In their work, they employ an entity LSTM that takes as input each modality, and a softmax layer that outputs an entity label at each decoding step. Contrast to their work, our MNED addresses unique challenges characterized by zeroshot ranking of 1M knowledge-base entities (vs. categorical entity types prediction), incorporation of an external knowledge graph, lexical embeddings, etc. Another is the multimodal machine translation task (Elliott et al., 2015; Specia et al., 2016), which takes as input text in source language as well as an accompanying image to output a translated text in target language. These models usually employ a sequence-to-sequence architecture (*e.g.* target language decoder takes as input both encoded source language and images) often with traditional attention modules widely used in other image captioning systems (Xu et al., 2015; Sukhbaatar et al., 2015). To the best of our knowledge, our approach is the first multimodal learning work at incorporating visual contexts for the NED task.

5 Conclusions

We introduce a new task called Multimodal Named Entity Disambiguation (MNED), which is applied on short user-generated social media posts that are composed of text and accompanying images. Our proposed MNED model improves upon the state-of-the-art models by 1) extracting visual contexts complementary to textual contexts, 2) by leveraging lexical embeddings into entity matching which accounts for various surface forms of entities, removing the need for fixed candidates generation process, and 3) by performing entity matching in the distributed knowledge graph embeddings space, allowing for matching of unseen mentions and entities by context resolutions.

Abstract

Social media user geolocation is vital to many applications such as event detection. In this paper, we propose GCN, a multiview geolocation model based on Graph Convolutional Networks, that uses both text and network context. We compare GCN to the state-of-the-art, and to two baselines we propose, and show that our model achieves or is competitive with the state-of-the-art over three benchmark geolocation datasets when sufficient supervision is available. We also evaluate GCN under a minimal supervision scenario, and show it outperforms baselines. We find that highway network gates are essential for controlling the amount of useful neighbourhood expansion in GCN.

1 Introduction

User geolocation, the task of identifying the "home" location of a user, is an integral component of many applications ranging from public health monitoring (Paul and Dredze, 2011; Chon et al., 2015; Yepes et al., 2015) and regional studies of sentiment, to real-time emergency awareness systems (De Longueville et al., 2009; Sakaki et al., 2010), which use social media as an implicit information resource about people.

Social media services such as Twitter rely on IP addresses, WiFi footprints, and GPS data to geolocate users. Third-party service providers don't have easy access to such information, and have to rely on public sources of geolocation information such as the profile location field, which is noisy and difficult to map to a location (Hecht et al., 2011), or geotagged tweets, which are publicly available for only 1% of tweets (Cheng et al., 2010; Morstatter et al., 2013). The scarcity of publicly available location information motivates predictive user geolocation from information such as tweet text and social interaction data.

Most previous work on user geolocation takes the form of either supervised text-based approaches (Wing and Baldridge, 2011; Han et al., 2012) relying on the geographical variation of language use, or graph-based semi-supervised label propagation relying on location homophily in user–user interactions (Davis Jr et al., 2011; Jurgens, 2013).

Both text and network views are critical in geolocating users. Some users post a lot of local content, but their social network is lacking or is not representative of their location; for them, text is the dominant view for geolocation. Other users have many local social interactions, and mostly use social media to read other people's comments, and for interacting with friends. Single-view learning would fail to accurately geolocate these users if the more information-rich view is not present. There has been some work that uses both the text and network views, but it either completely ignores unlabelled data (Li et al., 2012a; Miura et al., 2017), or just uses unlabelled data in the network view (Rahimi et al., 2015b; Do et al., 2017). Given that the 1% of geotagged tweets is often used for supervision, it is crucial for geolocation models to be able to leverage unlabelled data, and to perform well under a minimal supervision scenario.

In this paper, we propose GCN, an end-to-end user geolocation model based on Graph Convolutional Networks (Kipf and Welling, 2017) that jointly learns from text and network information to classify a user timeline into a location. Our contributions are: (1) we evaluate our model under a minimal supervision scenario which is close to real world applications and show that GCN outperforms two strong baselines; (2) given sufficient supervision, we show that GCN is competitive, although the much simpler MLP-TXT+NET outperforms state-of-the-art models; and (3) we show that highway gates play a significant role in controlling the amount of useful neighbourhood smoothing in `GCN`.[1]

2 Model

We propose a transductive multiview geolocation model, `GCN`, using Graph Convolutional Networks ("GCN": Kipf and Welling (2017)). We also introduce two multiview baselines: `MLP-TXT+NET` based on concatenation of text and network, and `DCCA` based on Deep Canonical Correlation Analysis (Andrew et al., 2013).

2.1 Multivew Geolocation

Let $X \in \mathbb{R}^{|U| \times |V|}$ be the text view, consisting of the bag of words for each user in U using vocabulary V, and $A \in \mathbb{1}^{|U| \times |U|}$ be the network view, encoding user–user interactions. We partition $U = U_S \cup U_H$ into a supervised and heldout (unlabelled) set, U_S and U_H, respectively. The goal is to infer the location of unlabelled samples Y_U, given the location of labelled samples Y_S, where each location is encoded as a one-hot classification label, $y_i \in \mathbb{1}^c$ with c being the number of target regions.

2.2 `GCN`

GCN defines a neural network model $f(X, A)$ with each layer:

$$\begin{aligned} \hat{A} &= \tilde{D}^{-\frac{1}{2}}(A + \lambda I)\tilde{D}^{-\frac{1}{2}} \\ H^{(l+1)} &= \sigma\Big(\hat{A}H^{(l)}W^{(l)} + b\Big) , \end{aligned} \quad (1)$$

where $\tilde{D}$ is the degree matrix of $A + \lambda I$; hyperparameter λ controls the weight of a node against its neighbourhood, which is set to 1 in the original model (Kipf and Welling, 2017); $H^0 = X$ and the $d_{\text{in}} \times d_{\text{out}}$ matrix $W^{(l)}$ and $d_{\text{out}} \times 1$ matrix b are trainable layer parameters; and σ is an arbitrary nonlinearity. The first layer takes an average of each sample and its immediate neighbours (labelled and unlabelled) using weights in $\hat{A}$, and performs a linear transformation using W and b followed by a nonlinear activation function (σ). In other words, for user u_i, the output of layer l is computed by:

$$\vec{h}_i^{l+1} = \sigma\Big(\sum\nolimits_{j \in \text{nhood}(i)} \hat{A}_{ij}\vec{h}_j^l W^l + b^l\Big) , \quad (2)$$

[1]Code and data available at `https://github.com/afshinrahimi/geographconv`

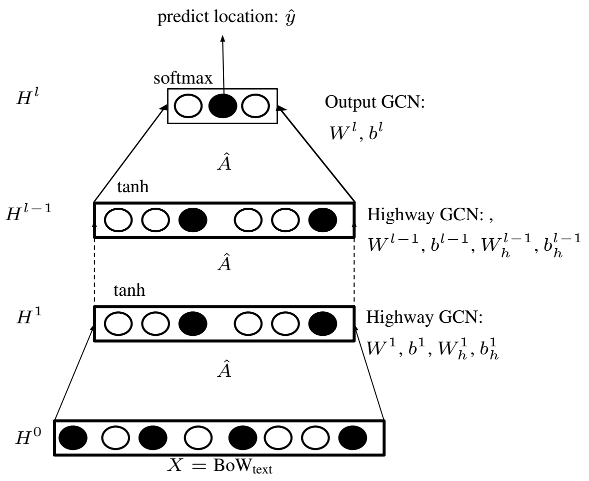

Figure 1: The architecture of `GCN` geolocation model with layer-wise highway gates (W_h^i, b_h^i). `GCN` is applied to a BoW model of user content over the @-mention graph to predict user location.

where W^l and b^l are learnable layer parameters, and $\text{nhood}(i)$ indicates the neighbours of user u_i. Each extra layer in GCN extends the neighbourhood over which a sample is smoothed. For example a GCN with 3 layers smooths each sample with its neighbours up to 3 hops away, which is beneficial if location homophily extends to a neighbourhood of this size.

2.2.1 Highway GCN

Expanding the neighbourhood for label propagation by adding multiple GCN layers can improve geolocation by accessing information from friends that are multiple hops away, but it might also lead to propagation of noisy information to users from an exponentially increasing number of expanded neighbourhood members. To control the required balance of how much neighbourhood information should be passed to a node, we use layer-wise gates similar to highway networks. In highway networks (Srivastava et al., 2015), the output of a layer is summed with its input with gating weights $T(\vec{h}^l)$:

$$\begin{aligned} T(\vec{h}^l) &= \sigma\Big(W_t^l \vec{h}^l + b_t^l\Big) \\ \vec{h}^{l+1} &= \vec{h}^{l+1} \circ T(\vec{h}^l) + \vec{h}^l \circ (1 - T(\vec{h}^l)) , \end{aligned} \quad (3)$$

where $\vec{h}^l$ is the incoming input to layer $l + 1$, (W_t^l, b_t^l) are gating weights and bias variables, $\circ$ is elementwise multiplication, and σ is the Sigmoid function.

2.3 DCCA

Given two views X and $\hat{A}$ (from Equation 1) of data samples, CCA (Hotelling, 1936), and its deep version (DCCA) (Andrew et al., 2013) learn functions $f_1(X)$ and $f_2(\hat{A})$ such that the correlation between the output of the two functions is maximised:

$$\rho = \text{corr}(f_1(X), f_2(\hat{A}))\,. \qquad (4)$$

The resulting representations of $f_1(X)$ and $f_2(\hat{A})$ are the compressed representations of the two views where the uncorrelated noise between them is reduced. The new representations ideally represent user communities for the network view, and the language model of that community for the text view, and their concatenation is a multiview representation of data, which can be used as input for other tasks.

In DCCA, the two views are first projected to a lower dimensionality using a separate multilayer perceptron for each view (the f_1 and f_2 functions of Equation 4), the output of which is used to estimate the CCA cost:

$$\begin{aligned} \text{maximise:} \quad & \text{tr}(W_1^T \Sigma_{12} W_2) \\ \text{subject to:} \quad & W_1^T \Sigma_{11} W_1 = W_2^T \Sigma_{22} W_2 = I \end{aligned} \qquad (5)$$

where Σ_{11} and Σ_{22} are the covariances of the two outputs, and Σ_{12} is the cross-covariance. The weights W_1 and W_2 are the linear projections of the MLP outputs, which are used in estimating the CCA cost. The optimisation problem is solved by SVD, and the error is backpropagated to train the parameters of the two MLPs and the final linear projections. After training, the two networks are used to predict new projections for unseen data. The two projections of unseen data — the outputs of the two networks — are then concatenated to form a multiview sample representation, as shown in Figure 2.

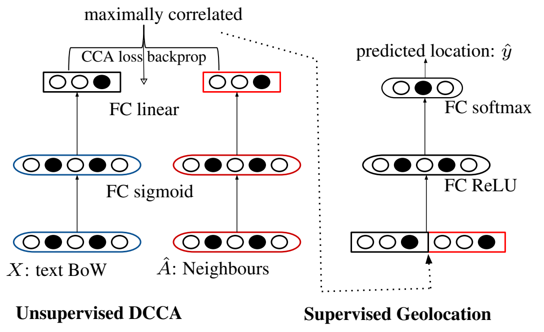

Figure 2: The DCCA model architecture: First the two text and network views X and $\hat{A}$ are fed into two neural networks (left), which are unsupervisedly trained to maximise the correlation of their outputs; next the outputs of the networks are concatenated, and fed as input to another neural network (right), which is trained supervisedly to predict locations.

3 Experiments

3.1 Data

We use three existing Twitter user geolocation datasets: (1) GeoText (Eisenstein et al., 2010), (2) Twitter-US (Roller et al., 2012), and (3) Twitter-World (Han et al., 2012). These datasets have been used widely for training and evaluation of geolocation models. They are all pre-partitioned into training, development and test sets. Each user is represented by the concatenation of their tweets, and labelled with the latitude/longitude of the first collected geotagged tweet in the case of GeoText and Twitter-US, and the centre of the closest city in the case of Twitter-World. GeoText and Twitter-US cover the continental US, and Twitter-World covers the whole world, with 9k, 449k and 1.3m users, respectively. The labels are the discretised geographical coordinates of the training points using a k-d tree following Roller et al. (2012), with the number of labels equal to 129, 256, and 930 for GeoText, Twitter-US, and Twitter-World, respectively.

3.2 Constructing the Views

We build matrix $\hat{A}$ as in Equation 1 using the collapsed @-mention graph between users, where two users are connected ($A_{ij} = 1$) if one mentions the other, or they co-mention another user. The text view is a BoW model of user content with binary term frequency, inverse document frequency, and l_2 normalisation of samples.

3.3 Model Selection

For GCN, we use highway layers to control the amount of neighbourhood information passed to a node. We use 3 layers in GCN with size 300, 600, 900 for GeoText, Twitter-US and Twitter-World respectively. Note that the final softmax layer is also graph convolutional, which sets the radius of the averaging neighbourhood to 4. The

k-d tree bucket size hyperparameter which controls the maximum number of users in each cluster is set to 50, 2400, and 2400 for the respective datasets, based on tuning over the validation set. The architecture of GCN−LP is similar, with the difference that the text view is set to zero. In DCCA, for the unsupervised networks we use a single sigmoid hidden layer with size 1000 and a linear output layer with size 500 for the three datasets. The loss function is CCA loss, which maximises the output correlations. The supervised multilayer perceptron has one hidden layer with size 300, 600, 1000 for GEOTEXT, TWITTER-US, and TWITTER-WORLD, respectively, which we set by tuning over the development sets. We evaluate the models using Median error, Mean error, and Acc@161, accuracy of predicting a user within 161km or 100 miles from the known location.

3.4 Baselines

We also compare DCCA and GCN with two baselines:

GCN−LP is based on GCN, but for input, instead of text-based features , we use one-hot encoding of a user's neighbours, which are then convolved with their k-hop neighbours using the GCN. This approach is similar to label propagation in smoothing the label distribution of a user with that of its neighbours, but uses graph convolutional networks which have extra layer parameters, and also a gating mechanism to control the smoothing neighbourhood radius. Note that for unlabelled samples, the predicted labels are used for input after training accuracy reaches 0.2.

MLP−TXT+NET is a simple transductive supervised model based on a single layer multilayer perceptron where the input to the network is the concatenation of the text view X, the user content's bag-of-words and $\hat{A}$ (Equation 1), which represents the network view as a vector input. For the hidden layer we use a ReLU nonlinearity, and sizes 300, 600, and 600 for GEOTEXT, TWITTER-US, and TWITTER-WORLD, respectively.

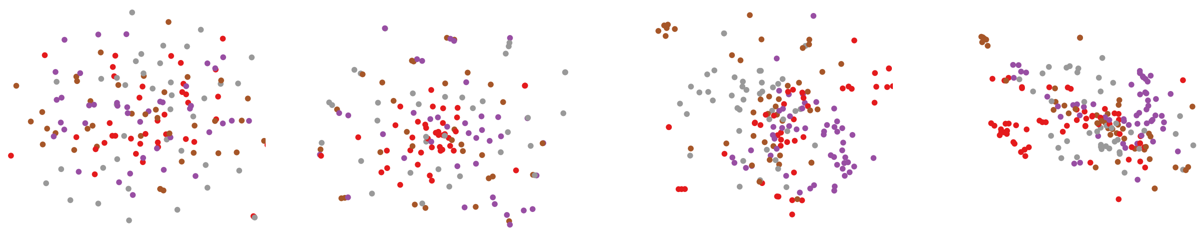
4 Results and Analysis

4.1 Representation

Deep CCA and GCN are able to provide an unsupervised data representation in different ways. Deep CCA takes the two text-based and network-based views, and finds deep non-linear transformations that result in maximum correlation between the two views (Andrew et al., 2013). The representations can be visualised using t-SNE, where we hope that samples with the same label are clustered together. GCN, on the other hand, uses graph convolution. The representations of 50 samples from each of 4 randomly chosen labels of GEOTEXT are shown in Figure 3. As shown, Deep CCA seems to slightly improve the representations from pure concatenation of the two views. GCN, on the other hand, substantially improves the representations. Further application of GCN results in more samples clumping together, which might be desirable when there is strong homophily.

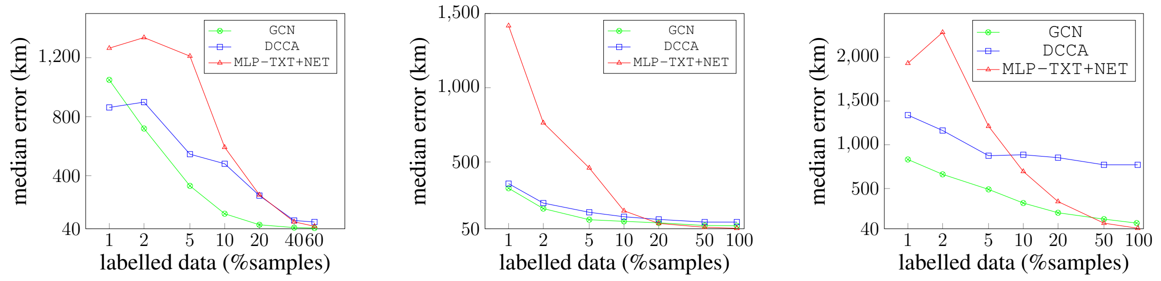
4.2 Labelled Data Size

To achieve good performance in supervised tasks, often large amounts of labelled data are required, which is a big challenge for Twitter geolocation, where only a small fraction of the data is geotagged (about 1%). The scarcity of supervision indicates the importance of semi-supervised learning where unlabelled (e.g. non-geotagged) tweets are used for training. The three models we propose (MLP−TXT+NET, DCCA, and GCN) are all transductive semi-supervised models that use unlabelled data, however, they are different in terms of how much labelled data they require to achieve acceptable performance. Given that in a real-world scenario, only a small fraction of data is geotagged, we conduct an experiment to analyse the effect of labelled samples on the performance of the three geolocation models. We provided the three models with different fractions of samples that are labelled (in terms of % of dataset samples) while using the remainder as unlabelled data, and analysed their Median error performance over the development set of GEOTEXT, TWITTER-US, and TWITTER-WORLD. Note that the text and network view, and the development set, remain fixed for all the experiments. As shown in Figure 4, when the fraction of labelled samples is less than 10% of all the samples, GCN and DCCA outperform MLP−TXT+NET, as a result of having fewer parameters, and therefore, lower supervision requirement to optimise them. When enough training data is available (e.g. more than 20% of all the samples), GCN and MLP−TXT+NET clearly outperform DCCA, possibly as a result of directly modelling the



(a) MLP−TXT+NET (b) DCCA (c) 1 GCN $\hat{A} \cdot X$ (d) 2 GCN $\hat{A} \cdot \hat{A} \cdot X$

Figure 3: Comparing t-SNE visualisations of 50 training samples from each of 4 randomly chosen regions of GEOTEXT using various data representations: (a) concatenation of $\hat{A}$ (Equation 1); (b) concatenation of DCCA transformation of text-based and network-based views X and $\hat{A}$; (c) applying graph convolution $\hat{A} \cdot X$; and (d) applying graph convolution twice $\hat{A} \cdot \hat{A} \cdot X$



(a) GEOTEXT (b) TWITTER-US (c) TWITTER-WORLD

Figure 4: The effect of the amount of labelled data available as a fraction of all samples for GEOTEXT, TWITTER-US, and TWITTER-WORLD on the development performance of GCN, DCCA, and MLP−TXT+NET models in terms of Median error. The dataset sizes are 9k, 440k, and 1.4m for the three datasets, respectively.

interactions between network and text views. When all the training samples of the two larger datasets (95% and 98% for TWITTER-US and TWITTER-WORLD, respectively) are available to the models, MLP−TXT+NET outperforms GCN. Note that the number of parameters increases from DCCA to GCN and to MLP−TXT+NET. In 1% for GEOTEXT, DCCA outperforms GCN as a result of having fewer parameters and just a few labelled samples, insufficient to train the parameters of GCN.

4.3 Highway Gates

Adding more layers to GCN expands the graph neighbourhood within which the user features are averaged, and so might introduce noise, and consequently decrease accuracy as shown in Figure 5 when no gates are used. We see that by adding highway network gates, the performance of GCN slightly improves until three layers are added, but then by adding more layers the performance doesn't change that much as gates are allowing the layer inputs to pass through the network without much change. The performance peaks at 4 layers which is compatible with the distribution of shortest path lengths shown in Figure 6.

4.4 Performance

The performance of the three proposed models (MLP−TXT+NET, DCCA and GCN) is shown in Table 1. The models are also compared with supervised text-based methods (Wing and Baldridge, 2014; Cha et al., 2015; Rahimi et al., 2017b), a network-based method (Rahimi et al., 2015a) and GCN−LP, and also joint text and network models (Rahimi et al., 2017b; Do et al., 2017; Miura et al., 2017). MLP−TXT+NET and GCN outperform all the text- or network-only models, and also the hybrid model of Rahimi et al. (2017b), indicating that joint modelling of text and network features is important. MLP−TXT+NET is competitive with Do et al. (2017), outperforming it on larger datasets, and underperforming on GEO-

Table 1: Geolocation results over the three Twitter datasets for the proposed models: joint text+network MLP-TXT+NET, DCCA, and GCN and network-based GCN-LP. The models are compared with text-only and network-only methods. The performance of the three joint models is also reported for minimal supervision scenario where only 1% of the total samples are labelled. "—" signifies that no results were reported for the given metric or dataset. Note that Do et al. (2017) use timezone, and Miura et al. (2017) use the description and location fields in addition to text and network.

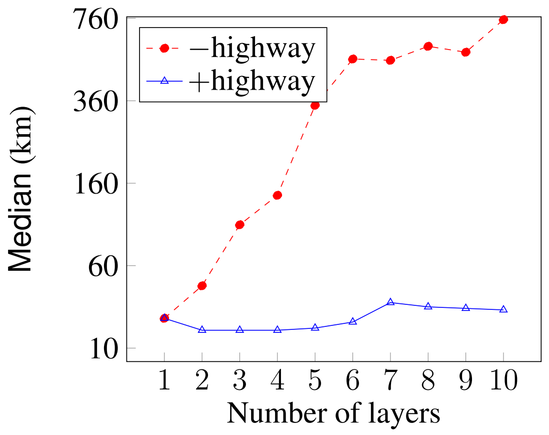

Figure 5: The effect of adding more GCN layers (neighbourhood expansion) to GCN in terms of median error over the development set of GEOTEXT with and without the highway gates, and averaged over 5 runs.

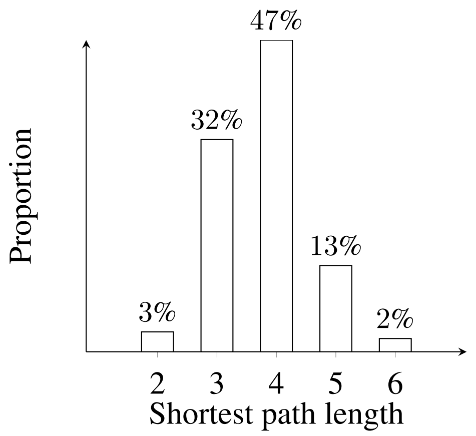

Figure 6: The distribution of shortest path lengths between all the nodes of the largest connected component of GEOTEXT's graph that constitute more than 1% of total.

TEXT. However, it's difficult to make a fair comparison as they use timezone data in their feature set. MLP-TXT+NET outperforms GCN over TWITTER-US and TWITTER-WORLD, which are very large, and have large amounts of labelled data. In a scenario with little supervision (1% of the total samples are labelled) DCCA and GCN clearly outperform MLP-TXT+NET, as they have fewer parameters. Except for Acc@161 over GEOTEXT where the number of labelled samples in the minimal supervision scenario is very low, GCN outperforms DCCA by a large margin, indicating that for a medium dataset where only 1% of samples are labelled (as happens in random samples of Twitter) GCN is superior to MLP-TXT+NET and DCCA, consistent with Section 4.2. Both MLP-TXT+NET and GCN achieve state of the art results compared to network-only, text-only, and hybrid models. The network-based GCN-LP model, which does label propagation using Graph Convolutional Networks, outperforms Rahimi et al. (2015a), which is based on location propagation using Modified Adsorption (Talukdar and Crammer, 2009), possibly because the label propagation in GCN is parametrised.

4.5 Error Analysis

Although the performance of MLP-TXT+NET is better than GCN and DCCA when a large amount of labelled data is available (Table 1), under a scenario where little labelled data is available (1% of data), DCCA and GCN outperform MLP-TXT+NET, mainly because the number of parameters in MLP-TXT+NET grows with the number of samples, and is much larger than GCN and DCCA. GCN outperforms DCCA and MLP-TXT+NET using 1% of data, however, the distribution of errors in the development set of TWITTER-US indicates higher error for smaller states such as Rhode Island (RI), Iowa (IA), North Dakota (ND), and Idaho (ID), which is simply because the number of labelled samples in those states is insufficient.

Although we evaluate geolocation models with Median, Mean, and Acc@161, it doesn't mean that the distribution of errors is uniform over all locations. Big cities often attract more local online discussions, making the geolocation of users in those areas simpler. For example users in LA are more likely to talk about LA-related issues such as their sport teams, Hollywood or local events than users in the state of Rhode Island (RI), which lacks large sport teams or major events. It is also possible that people in less densely populated areas are further apart from each other, and therefore, as a result of discretisation fall in different clusters. The non-uniformity in local discussions results in lower geolocation performance in less densely populated areas like Midwest U.S., and higher performance in densely populated areas such as NYC and LA as shown in Figure 7. The geographical distribution of error for GCN, DCCA and MLP-TXT+NET under the minimal supervision scenario is shown in the supplementary material.

To get a better picture of misclassification between states, we built a confusion matrix based on known state and predicted state for development users of TWITTER-US using GCN using only 1% of labelled data. There is a tendency for users to be wrongly predicted to be in CA, NY, TX, and surprisingly OH. Particularly users from states such as TX, AZ, CO, and NV, which are located close to CA, are wrongly predicted to be in CA, and users from NJ, PA, and MA are misclassified as being in NY. The same goes for OH and TX where users from neighbouring smaller states are misclassified to be there. Users from CA and NY are also misclassified between the two states, which might be the result of business and entertainment connections that exist between NYC and LA/SF. Interestingly, there are a number of misclassifications to FL for users from CA, NY, and TX, which might be the effect of users vacationing or retiring to FL. The full confusion matrix between the U.S. states is provided in the supplementary material.

4.6 Local Terms

In Table 2, local terms of a few regions detected by GCN under minimal supervision are shown. The terms that were present in the labelled data are excluded to show how graph convolutions over the social graph have extended the vocabulary. For example, in case of Seattle, *#goseahawks* is an important term not present in the 1% labelled data but present in the unlabelled data. The convolution over the social graph is able to utilise such terms that don't exist in the labelled data.

5 Related Work

Previous work on user geolocation can be broadly divided into text-based, network-based and multi-view approaches.

Text-based geolocation uses the geographical bias in language use to infer the location of users. There are three main text-based approaches to geolocation: (1) gazetteer-based models which map geographical references in text to location, but ignore non-geographical references and vernacular uses of language (Rauch et al., 2003; Amitay et al., 2004; Lieberman et al., 2010); (2) geographical topic models that learn region-specific topics, but don't scale to the magnitude of social media (Eisenstein et al., 2010; Hong et al., 2012; Ahmed et al., 2013); and (3) supervised models which are often framed as text classification (Serdyukov et al., 2009; Wing and Baldridge, 2011; Roller et al., 2012; Han et al., 2014) or text regression (Iso et al., 2017; Rahimi et al., 2017a). Supervised models scale well and can achieve good performance with sufficient supervision, which is not available in a real world scenario.

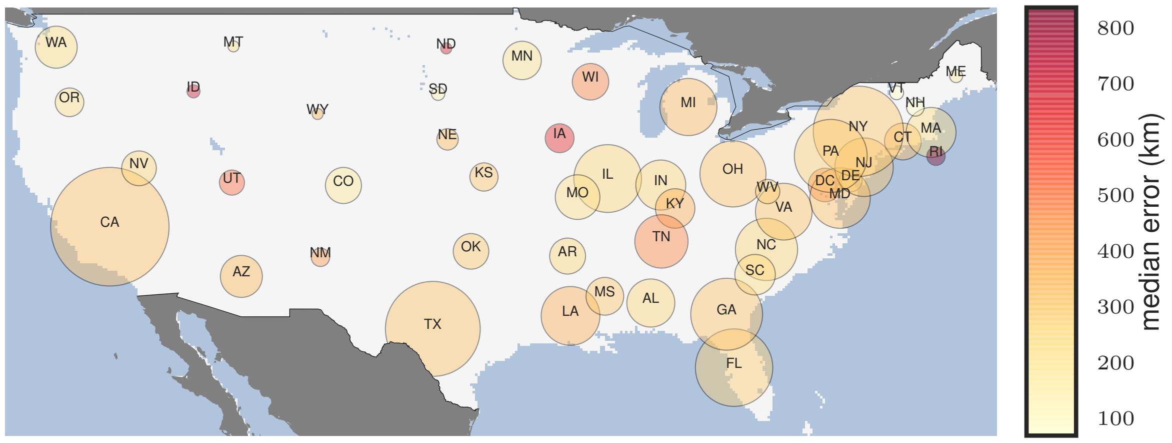

Figure 7: The geographical distribution of Median error of GCN using 1% of labelled data in each state over the development set of TWITTER-US. The colour indicates error and the size indicates the number of development users within the state.

Seattle, WA	Austin, TX	Jacksonville, FL	Columbus, OH	Charlotte, NC	Phoenix, AZ	New Orleans, LA	Baltimore, MD

Table 2: Top terms for selected regions detected by GCN using only 1% of TWITTER-US for supervision. We present the terms that were present only in unlabelled data. The terms include city names, hashtags, food names and internet abbreviations.

Network-based methods leverage the *location homophily* assumption: nearby users are more likely to befriend and interact with each other. There are four main network-based geolocation approaches: distance-based, supervised classification, graph-based label propagation, and node embedding methods. Distance-based methods model the probability of friendship given the distance (Backstrom et al., 2010; McGee et al., 2013; Gu et al., 2012; Kong et al., 2014), supervised models use neighbourhood features to classify a user into a location (Rout et al., 2013; Malmi et al., 2015), and graph-based label-propagation models propagate the location information through the user–user graph to estimate unknown labels (Davis Jr et al., 2011; Jurgens, 2013; Compton et al., 2014). Node embedding methods build heterogeneous graphs between user–user, user–location and location–location, and learn an embedding space to minimise the distance of connected nodes, and maximise the distance of disconnected nodes. The embeddings are then used in supervised models for geolocation (Wang et al., 2017). Network-based models fail to geolocate disconnected users: Jurgens et al. (2015) couldn't geolocation 37% of users as a result of disconnectedness.

Previous work on hybrid text and network methods can be broadly categorised into three main approaches: (1) incorporating text-based information such as toponyms or locations predicted from a text-based model as auxiliary nodes into the user–user graph, which is then used in network-based models (Li et al., 2012a,b; Rahimi et al., 2015b,a); (2) ensembling separately trained text- and network-based models (Gu et al., 2012; Ren et al., 2012; Jayasinghe et al., 2016; Ribeiro and Pappa, 2017); and (3) jointly learning geolocation from several information sources such as text and network information (Miura et al., 2017; Do et al., 2017), which can capture the complementary information in text and network views, and also model the interactions between the two. None of the previous multiview approaches — with the exception of Li et al. (2012a) and Li et al. (2012b) that only use toponyms — effectively uses unlabelled data in the text view, and use only the unlabelled information of the network view via the user–user graph.

There are three main shortcomings in the previous work on user geolocation that we address in this paper: (1) with the exception of few recent works (Miura et al., 2017; Do et al., 2017), previous models don't jointly exploit both text and network information, and therefore the interaction between text and network views is not modelled; (2) the unlabelled data in both text and network views is not effectively exploited, which is crucial given the small amounts of available supervision; and (3) previous models are rarely evaluated under a minimal supervision scenario, a scenario which reflects real world conditions.

6 Conclusion

We proposed `GCN`, `DCCA` and `MLP-TXT+NET`, three multiview, transductive, semi-supervised geolocation models, which use text and network information to infer user location in a joint setting. We showed that joint modelling of text and network information outperforms network-only, text-only, and hybrid geolocation models as a result of modelling the interaction between text and network information. We also showed that `GCN` and `DCCA` are able to perform well under a minimal supervision scenario similar to real world applications by effectively using unlabelled data. We ignored the context in which users interact with each other, and assumed all the connections to hold location homophily. In future work, we are interested in modelling the extent to which a social interaction is caused by geographical proximity (e.g. using user–user gates).

Abstract

Document modeling is essential to a variety of natural language understanding tasks. We propose to use external information to improve document modeling for problems that can be framed as sentence extraction. We develop a framework composed of a hierarchical document encoder and an attention-based extractor with attention over external information. We evaluate our model on extractive document summarization (where the external information is image captions and the title of the document) and answer selection (where the external information is a question). We show that our model consistently outperforms strong baselines, in terms of both informativeness and fluency (for CNN document summarization) and achieves state-of-the-art results for answer selection on WikiQA and NewsQA.[1]

1 Introduction

Recurrent neural networks have become one of the most widely used models in natural language processing (NLP). A number of variants of RNNs such as Long Short-Term Memory networks (LSTM; Hochreiter and Schmidhuber, 1997) and Gated Recurrent Unit networks (GRU; Cho et al., 2014) have been designed to model text capturing long-term dependencies in problems such as language modeling. However, document modeling, a key to many natural language understanding tasks, is still an open challenge. Recently, some neural network architectures were proposed to capture large context for modeling text (Mikolov and Zweig, 2012; Ghosh et al., 2016; Ji et al., 2015; Wang and Cho, 2016). Lin et al. (2015) and Yang et al. (2016) proposed a hierarchical RNN network for document-level modeling as well as sentence-level modeling, at the cost of increased computational complexity. Tran et al. (2016) further proposed a contextual language model that considers information at inter-document level.

It is challenging to rely only on the document for its understanding, and as such it is not surprising that these models struggle on problems such as document summarization (Cheng and Lapata, 2016; Chen et al., 2016; Nallapati et al., 2017; See et al., 2017; Tan and Wan, 2017) and machine reading comprehension (Trischler et al., 2016; Miller et al., 2016; Weissenborn et al., 2017; Hu et al., 2017; Wang et al., 2017). In this paper, we formalize the use of external information to further guide document modeling for end goals.

We present a simple yet effective document modeling framework for sentence extraction that allows machine reading with "external attention." Our model includes a neural hierarchical document encoder (or a machine reader) and a hierarchical attention-based sentence extractor. Our hierarchical document encoder resembles the architectures proposed by Cheng and Lapata (2016) and Narayan et al. (2018) in that it derives the document meaning representation from its sentences and their constituent words. Our novel sentence extractor combines this document meaning representation with an attention mechanism (Bahdanau et al., 2015) over the external information to label sentences from the input document. Our model explicitly biases the extractor with external cues and

[*]The first three authors made equal contributions to this paper. The work was done when the second author was visiting Edinburgh.

[1]Our TensorFlow code and datasets are publicly available at https://github.com/shashiongithub/Document-Models-with-Ext-Information.

implicitly biases the encoder through training.

We demonstrate the effectiveness of our model on two problems that can be naturally framed as sentence extraction with external information. These two problems, extractive document summarization and answer selection for machine reading comprehension, both require local and global contextual reasoning about a given document. Extractive document summarization systems aim at creating a summary by identifying (and subsequently concatenating) the most important sentences in a document, whereas answer selection systems select the candidate sentence in a document most likely to contain the answer to a query. For document summarization, we exploit the title and image captions which often appear with documents (specifically newswire articles) as external information. For answer selection, we use word overlap features, such as the inverse sentence frequency (ISF, Trischler et al., 2016) and the inverse document frequency (IDF) together with the query, all formulated as external cues.

Our main contributions are three-fold: First, our model ensures that sentence extraction is done in a larger (rich) context, i.e., the full document is read first before we start labeling its sentences for extraction, and each sentence labeling is done by implicitly estimating its local and global relevance to the document and by directly attending to some external information for importance cues.

Second, while external information has been shown to be useful for summarization systems using traditional hand-crafted features (Edmundson, 1969; Kupiec et al., 1995; Mani, 2001), our model is the first to exploit such information in deep learning-based summarization. We evaluate our models automatically (in terms of ROUGE scores) on the CNN news highlights dataset (Hermann et al., 2015). Experimental results show that our summarizer, informed with title and image captions, consistently outperforms summarizers that do not use this information. We also conduct a human evaluation to judge which type of summary participants prefer. Our results overwhelmingly show that human subjects find our summaries more informative and complete.

Lastly, with the machine reading capabilities of our model, we confirm that a full document needs to be "read" to produce high quality extracts allowing a rich contextual reasoning, in contrast to previous answer selection approaches that often measure a score between each sentence in the document and the question and return the sentence with highest score in an isolated manner (Yin et al., 2016; dos Santos et al., 2016; Wang et al., 2016). Our model with ISF and IDF scores as external features achieves competitive results for answer selection. Our ensemble model combining scores from our model and word overlap scores using a logistic regression layer achieves state-of-the-art results on the popular question answering datasets WikiQA (Yang et al., 2015) and NewsQA (Trischler et al., 2016), and it obtains comparable results to the state of the art for SQuAD (Rajpurkar et al., 2016). We also evaluate our approach on the MSMarco dataset (Nguyen et al., 2016) and elaborate on the behavior of our machine reader in a scenario where each candidate answer sentence is contextually independent of each other.

2 Document Modeling For Sentence Extraction

Given a document D consisting of a sequence of n sentences $(s_1, s_2, ..., s_n)$, we aim at labeling each sentence s_i in D with a label $y_i \in \{0, 1\}$ where $y_i = 1$ indicates that s_i is extraction-worthy and 0 otherwise. Our architecture resembles those previously proposed in the literature (Cheng and Lapata, 2016; Nallapati et al., 2017). The main components include a sentence encoder, a document encoder, and a novel sentence extractor (see Figure 1) that we describe in more detail below. The novel characteristics of our model are that each sentence is labeled by implicitly estimating its (local and global) relevance to the document and by directly attending to some external information for importance cues.

Sentence Encoder A core component of our model is a convolutional sentence encoder (Kim, 2014; Kim et al., 2016) which encodes sentences into continuous representations. We use temporal narrow convolution by applying a kernel filter K of width h to a window of h words in sentence s to produce a new feature. This filter is applied to each possible window of words in s to produce a feature map $f \in R^{k-h+1}$ where k is the sentence length. We then apply max-pooling over time over the feature map f and take the maximum value as the feature corresponding to this particular filter K. We use multiple kernels of various sizes and each kernel multiple times to construct the representation of a sentence. In Figure 1, kernels of size 2 (red) and 4 (blue) are applied three times each. The max-pooling over time operation yields two feature lists f^{K_2} and $f^{K_4} \in R^3$. The final sentence embeddings have six dimensions.

Document Encoder The document encoder composes a sequence of sentences to obtain a document representation. We use a recurrent neural network with LSTM cells to avoid the vanishing gradient problem when training long sequences (Hochreiter and Schmidhuber, 1997). Given a document D consisting of a sequence of sentences $(s_1, s_2, \ldots, s_n)$, we follow common practice and feed the sentences in reverse order (Sutskever et al., 2014; Li et al., 2015; Filippova et al., 2015).

Sentence Extractor Our sentence extractor sequentially labels each sentence in a document with 1 or 0 by implicitly estimating its relevance in the document and by directly attending to the external information for importance cues. It is implemented with another RNN with LSTM cells with an attention mechanism (Bahdanau et al., 2015) and a softmax layer. Our attention mechanism differs from the standard practice of attending intermediate states of the input (encoder). Instead, our extractor attends to a sequence of p pieces of external information $E : (e_1, e_2, ..., e_p)$ relevant for the task (e.g., e_i is a title or an image caption for summarization) for cues. At time t_i, it reads sentence s_i and makes a binary prediction, conditioned on the document representation (obtained from the document encoder), the previously labeled sentences and the external information. This way, our labeler is able to identify locally and globally important sentences within the document which correlate well with the external information.

Given sentence s_t at time step t, it returns a probability distribution over labels as:

$$p(y_t|s_t, D, E) = \text{softmax}(g(h_t, h'_t)) \quad (1)$$
$$g(h_t, h'_t) = U_o(V_h h_t + W'_h h'_t) \quad (2)$$
$$h_t = \text{LSTM}(s_t, h_{t-1})$$
$$h'_t = \sum_{i=1}^{p} \alpha_{(t,i)} e_i,$$
$$\text{where } \alpha_{(t,i)} = \frac{\exp(h_t e_i)}{\sum_j \exp(h_t e_j)}$$

where $g(\cdot)$ is a single-layer neural network with parameters U_o, V_h and W'_h. h_t is an intermediate RNN state at time step t. The dynamic context vector h'_t is essentially the weighted sum of the external information $(e_1, e_2, \ldots, e_p)$. Figure 1 summarizes our model.

Convolutional Sentence encoder

Figure 1: Hierarchical encoder-decoder model for sentence extraction with external attention. $s_1, \ldots, s_5$ are sentences in the document and, e_1, e_2 and e_3 represent external information. For the extractive summarization task, e_is are external information such as title and image captions. For the answers selection task, e_is are the query and word overlap features.

3 Sentence Extraction Applications

We validate our model on two sentence extraction problems: extractive document summarization and answer selection for machine reading comprehension. Both these tasks require local and global contextual reasoning about a given document. As such, they test the ability of our model to facilitate document modeling using external information.

Extractive Summarization An extractive summarizer aims to produce a summary $\mathcal{S}$ by selecting m sentences from D (where $m < n$). In this setting, our sentence extractor sequentially predicts label $y_i \in \{0, 1\}$ (where 1 means that s_i should be included in the summary) by assigning score $p(y_i|s_i, D, E, \theta)$ quantifying the relevance of s_i to the summary. We assemble a summary $\mathcal{S}$ by selecting m sentences with top $p(y_i = 1|s_i, D, E, \theta)$ scores.

We formulate external information E as the sequence of the title and the image captions associated with the document. We use the convolutional sentence encoder to get their sentence-level representations.

Answer Selection Given a question q and a document D , the goal of the task is to select one candidate sentence $s_i \in D$ in which the answer exists. In this setting, our sentence extractor sequentially predicts label $y_i \in \{0, 1\}$ (where 1 means that s_i contains the answer) and assign score $p(y_i|s_i, D, E, \theta)$ quantifying s_i's relevance to the query. We return as answer the sentence s_i with the highest $p(y_i = 1|s_i, D, E, \theta)$ score.

We treat the question q as external information and use the convolutional sentence encoder to get its sentence-level representation. This simplifies Eq. (1) and (2) as follow:

$$
\begin{aligned}
p(y_t|s_t, D, q) &= \text{softmax}(g(h_t, q)) \\
g(h_t, q) &= U_o(V_h h_t + W_q q),
\end{aligned} \tag{3}
$$

where V_h and W_q are network parameters. We exploit the simplicity of our model to further assimilate external features relevant for answer selection: the inverse sentence frequency (ISF, (Trischler et al., 2016)), the inverse document frequency (IDF) and a modified version of the ISF score which we call *local ISF*. Trischler et al. (2016) have shown that a simple ISF baseline (i.e., a sentence with the highest ISF score as an answer) correlates well with the answers. The ISF score α_{s_i} for the sentence s_i is computed as $\alpha_{s_i} = \sum_{w \in s_i \cap q} \text{IDF}(w)$, where IDF is the inverse document frequency score of word w, defined as: $\text{IDF}(w) = \log \frac{N}{N_w}$, where N is the total number of sentences in the training set and N_w is the number of sentences in which w appears. Note that, $s_i \cap q$ refers to the set of words that appear both in s_i and in q. Local ISF is calculated in the same manner as the ISF score, only with setting the total number of sentences (N) to the number of sentences in the article that is being analyzed.

More formally, this modifies Eq. (3) as follows:

$$
p(y_t|s_t, D, q) = \text{softmax}(g(h_t, q, \alpha_t, \beta_t, \gamma_t)) \tag{4}
$$

where α_t, β_t and γ_t are the ISF, IDF and local ISF scores (real values) of sentence s_t respectively . The function g is calculated as follows:

$$
\begin{aligned}
g(h_t, q, \alpha_t, \beta_t, \gamma_t) = &U_o\,\big(V_h h_t + \\
&W_q q + W_{\text{isf}}(\alpha_t \cdot \mathbb{1}) + \\
&W_{\text{idf}}(\beta_t \cdot \mathbb{1}) + W_{\text{lisf}}(\gamma_t \cdot \mathbb{1})\big)\,,
\end{aligned}
$$

where W_{isf}, W_{idf} and W_{lisf} are new parameters added to the network and $\mathbb{1}$ is a vector of 1s of size equal to the sentence embedding size. In Figure 1, these external feature vectors are represented as 6-dimensional gray vectors accompanied with dashed arrows.

4 Experiments and Results

This section presents our experimental setup and results assessing our model in both the extractive summarization and answer selection setups. In the rest of the paper, we refer to our model as XNET for its ability to exploit e**X**ternal information to improve document representation.

4.1 Extractive Document Summarization

Summarization Dataset We evaluated our models on the CNN news highlights dataset (Hermann et al., 2015).[2] We used the standard splits of Hermann et al. (2015) for training, validation, and testing (90,266/1,220/1,093 documents). We followed previous studies (Cheng and Lapata, 2016; Nallapati et al., 2016, 2017; See et al., 2017; Tan and Wan, 2017) in assuming that the

[2]Hermann et al. (2015) have also released the DailyMail dataset, but we do not report our results on this dataset. We found that the script written by Hermann et al. to crawl DailyMail articles mistakenly extracts image captions as part of the main body of the document. As image captions often do not have sentence boundaries, they blend with the sentences of the document unnoticeably. This leads to the production of erroneous summaries.

"story highlights" associated with each article are gold-standard abstractive summaries. We trained our network on a named-entity-anonymized version of news articles. However, we generated deanonymized summaries and evaluated them against gold summaries to facilitate human evaluation and to make human evaluation comparable to automatic evaluation.

To train our model, we need documents annotated with sentence extraction information, i.e., each sentence in a document is labeled with 1 (summary-worthy) or 0 (not summary-worthy). We followed Nallapati et al. (2017) and automatically extracted ground truth labels such that all positively labeled sentences from an article collectively give the highest ROUGE (Lin and Hovy, 2003) score with respect to the gold summary.

We used a modified script of Hermann et al. (2015) to extract titles and image captions, and we associated them with the corresponding articles. All articles get associated with their titles. The availability of image captions varies from 0 to 414 per article, with an average of 3 image captions. There are 40% CNN articles with at least one image caption.

All sentences, including titles and image captions, were padded with zeros to a sentence length of 100. All input documents were padded with zeros to a maximum document length of 126. For each document, we consider a maximum of 10 image captions. We experimented with various numbers (1, 3, 5, 10 and 20) of image captions on the validation set and found that our model performed best with 10 image captions. We refer the reader to the supplementary material for more implementation details to replicate our results.

Comparison Systems We compared the output of our model against the standard baseline of simply selecting the first three sentences from each document as the summary. We refer to this baseline as LEAD in the rest of the paper.

We also compared our system against the sentence extraction system of Cheng and Lapata (2016). We refer to this system as POINTERNET as the neural attention architecture in Cheng and Lapata (2016) resembles the one of Pointer Networks (Vinyals et al., 2015).[3] It does not exploit any external information.[4] Cheng and Lapata (2016) report only on the DailyMail dataset. We used their code (`https://github.com/cheng6076/NeuralSum`) to produce results on the CNN dataset.[5]

MODELS	R1	R2	R3	R4	RL	Avg.
LEAD	49.2	18.9	9.8	6.0	43.8	25.5
POINTERNET	53.3	19.7	10.4	6.4	47.2	27.4
XNET+TITLE	55.0	21.6	11.7	7.5	48.9	28.9
XNET+CAPTION	55.3	21.3	11.4	7.2	49.0	28.8
XNET+FS	54.8	21.1	11.3	7.2	48.6	28.6
Combination Models (XNET+)						
TITLE+CAPTION	**55.4**	**21.8**	**11.8**	**7.5**	**49.2**	**29.2**
TITLE+FS	55.1	21.6	11.6	7.4	48.9	28.9
CAPTION+FS	55.3	21.5	11.5	7.3	49.0	28.9
TITLE+CAPTION+FS	55.4	21.5	11.6	7.4	49.1	29.0

Table 1: Ablation results on the validation set. We report R1, R2, R3, R4, RL and their average (Avg.). The first block of the table presents LEAD and POINTERNET which do not use any external information. LEAD is the baseline system selecting first three sentences. POINTERNET is the sentence extraction system of Cheng and Lapata. XNET is our model. The second and third blocks of the table present different variants of XNET. We experimented with three types of external information: title (TITLE), image captions (CAPTION) and the first sentence (FS) of the document. The bottom block of the table presents models with more than one type of external information. The best performing model (highlighted in boldface) is used on the test set.

Automatic Evaluation To automatically assess the quality of our summaries, we used ROUGE (Lin and Hovy, 2003), a recall-oriented metric, to compare our model-generated summaries to manually-written highlights.[6] Previous work has reported ROUGE-1 (R1) and ROUGE-2 (R2) scores to access informativeness, and ROUGE-L (RL) to access fluency. In addition to R1, R2 and RL, we also report ROUGE-3 (R3) and ROUGE-4 (R4) capturing higher order n-grams overlap to assess informativeness and fluency simultaneously.

[3]The architecture of POINTERNET is closely related to our model without external information.

[4]Adding external information to POINTERNET is an interesting direction of research but we do not pursue it here. It requires decoding with multiple types of attentions and this is not the focus of this paper.

[5]We are unable to compare our results to the extractive system of Nallapati et al. (2017) because they report their results on the DailyMail dataset and their code is not available. The abstractive systems of Chen et al. (2016) and Tan and Wan (2017) report their results on the CNN dataset, however, their results are not comparable to ours as they report on the full-length F_1 variants of ROUGE to evaluate their abstractive summaries. We report ROUGE recall scores which is more appropriate to evaluate our extractive summaries.

[6]We used `pyrouge`, a Python package, to compute all our ROUGE scores with parameters "-a -c 95 -m -n 4 -w 1.2."

We report our results on both full length (three sentences with the top scores as the summary) and fixed length (first 75 bytes and 275 bytes as the summary) summaries. For full length summaries, our decision of selecting three sentences is guided by the fact that there are 3.11 sentences on average in the gold highlights of the training set. We conduct our ablation study on the validation set with full length ROUGE scores, but we report both fixed and full length ROUGE scores for the test set.

We experimented with two types of external information: title (TITLE) and image captions (CAPTION). In addition, we experimented with the first sentence (FS) of the document as external information. Note that the latter is not external information, it is a sentence in the document. However, we wanted to explore the idea that the first sentence of the document plays a crucial part in generating summaries (Rush et al., 2015; Nallapati et al., 2016). XNET with FS acts as a baseline for XNET with title and image captions.

We report the performance of several variants of XNET on the validation set in Table 1. We also compare them against the LEAD baseline and POINTERNET. These two systems do not use any additional information. Interestingly, all the variants of XNET significantly outperform LEAD and POINTERNET. When the title (TITLE), image captions (CAPTION) and the first sentence (FS) are used separately as additional information, XNET performs best with TITLE as its external information. Our result demonstrates the importance of the title of the document in extractive summarization (Edmundson, 1969; Kupiec et al., 1995; Mani, 2001). The performance with TITLE and CAPTION is better than that with FS. We also tried possible combinations of TITLE, CAPTION and FS. All XNET models are superior to the ones without any external information. XNET performs best when TITLE and CAPTION are jointly used as external information (55.4%, 21.8%, 11.8%, 7.5%, and 49.2% for R1, R2, R3, R4, and RL respectively). It is better than the the LEAD baseline by 3.7 points on average and than POINTERNET by 1.8 points on average, indicating that external information is useful to identify the gist of the document. We use this model for testing purposes.

Our final results on the test set are shown in Table 2. It turns out that for smaller summaries (75 bytes) LEAD and POINTERNET are superior to XNET. This result could be because LEAD (always) and POINTERNET (often) include the first sentence in their summaries, whereas, XNET is better capable at selecting sentences from various document positions. This is not captured by smaller summaries of 75 bytes, but it becomes more evident with longer summaries (275 bytes and full length) where XNET performs best across all ROUGE scores. We note that POINTERNET outperforms LEAD for 75-byte summaries, then its performance drops behind LEAD for 275-byte summaries, but then it outperforms LEAD for full length summaries on the metrics R1, R2 and RL. It shows that POINTERNET with its attention over sentences in the document is capable of exploring more than first few sentences in the document, but it is still behind XNET which is better at identifying salient sentences in the document. XNET performs significantly better than POINTERNET by 0.8 points for 275-byte summaries and by 1.9 points for full length summaries, on average for all ROUGE scores.

MODELS	R1	R2	R3	R4	RL
Fixed length: 75b					
LEAD	20.1	7.1	**3.5**	2.1	14.6
POINTERNET	**20.3**	**7.2**	**3.5**	**2.2**	**14.8**
XNET	20.2	7.1	3.4	2.0	14.6
Fixed length: 275b					
LEAD	39.1	14.5	7.6	4.7	34.6
POINTERNET	38.6	13.9	7.3	4.4	34.3
XNET	**39.7**	**14.7**	**7.9**	**5.0**	**35.2**
Full length summaries					
LEAD	49.3	19.5	10.7	6.9	43.8
POINTERNET	51.7	19.7	10.6	6.6	45.7
XNET	**54.2**	**21.6**	**12.0**	**7.9**	**48.1**

Table 2: Final results on the test set. POINTERNET is the sentence extraction system of Cheng and Lapata. XNET is our best model from Table 1. Best ROUGE score in each block and each column is highlighted in boldface.

Models	1st	2nd	3rd	4th
LEAD	0.15	0.17	**0.47**	0.21
POINTERNET	0.16	0.05	0.31	**0.48**
XNET	0.28	**0.53**	0.15	0.04
HUMAN	**0.41**	0.25	0.07	0.27

Table 3: Human evaluations: Ranking of various systems. Rank 1st is best and rank 4th, worst. Numbers show the percentage of times a system gets ranked at a certain position.

Human Evaluation We complement our automatic evaluation results with human evaluation. We randomly selected 20 articles from the test set.

Annotators were presented with a news article and summaries from four different systems. These include the LEAD baseline, POINTERNET, XNET and the human authored highlights. We followed the guidelines in Cheng and Lapata (2016), and asked our participants to rank the summaries from best (1st) to worst (4th) in order of informativeness (does the summary capture important information in the article?) and fluency (is the summary written in well-formed English?). We did not allow any ties and we only sampled articles with non-identical summaries. We assigned this task to five annotators who were proficient English speakers. Each annotator was presented with all 20 articles. The order of summaries to rank was randomized per article. An example of summaries our subjects ranked is provided in the supplementary material.

The results of our human evaluation study are shown in Table 3. As one might imagine, HUMAN gets ranked 1st most of the time (41%). However, it is closely followed by XNET which ranked 1st 28% of the time. In comparison, POINTERNET and LEAD were mostly ranked at 3rd and 4th places. We also carried out pairwise comparisons between all models in Table 3 for their statistical significance using a one-way ANOVA with post-hoc Tukey HSD tests with ($p < 0.01$). It showed that XNET is significantly better than LEAD and POINTERNET, and it does not differ significantly from HUMAN. On the other hand, POINTERNET does not differ significantly from LEAD and it differs significantly from both XNET and HUMAN. The human evaluation results corroborates our empirical results in Table 1 and Table 2: XNET is better than LEAD and POINTERNET in producing informative and fluent summaries.

4.2 Answer Selection

Question Answering Datasets We run experiments on four datasets collected for open domain question-answering tasks: WikiQA (Yang et al., 2015), SQuAD (Rajpurkar et al., 2016), NewsQA (Trischler et al., 2016), and MSMarco (Nguyen et al., 2016).

NewsQA was especially designed to present lexical and syntactic divergence between questions and answers. It contains 119,633 questions posed by crowdworkers on 12,744 CNN articles previously collected by Hermann et al. (2015). In a similar manner, SQuAD associates 100,000+ question with a Wikipedia article's first paragraph, for 500+ previously chosen articles. WikiQA was collected by mining web-searching query logs and then associating them with the summary section of the Wikipedia article presumed to be related to the topic of the query. A similar collection procedure was followed to create MSMarco with the difference that each candidate answer is a whole paragraph from a different browsed website associated with the query.

We follow the widely used setup of leaving out unanswered questions (Trischler et al., 2016; Yang et al., 2015) and adapt the format of each dataset to our task of answer sentence selection by labeling a candidate sentence with 1 if any answer span is contained in that sentence. In the case of MSMarco, each candidate paragraph comes associated with a label, hence we treat each one as a single long sentence. Since SQuAD keeps the official test dataset hidden and MSMarco does not provide labels for its released test set, we report results on their official validation sets. For validation, we set apart 10% of each official training set.

Our dataset splits consist of 92,525, 5,165 and 5,124 samples for NewsQA; 79,032, 8,567, and 10,570 for SQuAD; 873, 122, and 237 for WikiQA; and 79,704, 9,706, and 9,650 for MSMarco, for training, validation, and testing respectively.

Comparison Systems We compared the output of our model against the ISF (Trischler et al., 2016) and LOCALISF baselines. Given an article, the sentence with the highest ISF score is selected as an answer for the ISF baseline and the sentence with the highest local ISF score for the LOCALISF baseline. We also compare our model against a neural network (PAIRCNN) that encodes (question, candidate) in an isolated manner as in previous work (Yin et al., 2016; dos Santos et al., 2016; Wang et al., 2016). The architecture uses the sentence encoder explained in earlier sections to learn the question and candidate representations. The distribution over labels is given by $p(y_t|q) = p(y_t|s_t, q) = \text{softmax}(g(s_t, q))$ where $g(s_t, q) = \text{ReLU}(W_{sq} \cdot [s_t; q] + b_{sq})$. In addition, we also compare our model against AP-CNN (dos Santos et al., 2016), ABCNN (Yin et al., 2016), L.D.C (Wang and Jiang, 2017), KV-MemNN (Miller et al., 2016), and COMPAGGR, a state-of-the-art system by Wang et al. (2017).

We experiment with several variants of our model. XNET is the vanilla version of our sen-

Table 4: Results (in percentage) for answer selection comparing our approaches (bottom part) to baselines (top): AP-CNN (dos Santos et al., 2016), ABCNN (Yin et al., 2016), L.D.C (Wang and Jiang, 2017), KV-MemNN (Miller et al., 2016), and COMPAGGR, a state-of-the-art system by Wang et al. (2017). (WGT) WRD CNT stands for the (weighted) word count baseline. See text for more details.

tence extractor conditioned only on the query q as external information (Eq. (3)). XNET+ is an extension of XNET which uses ISF, IDF and local ISF scores in addition to the query q as external information (Eqn. (4)). We also experimented with a baseline XNETTOPK where we choose the top k sentences with highest ISF score, and then among them choose the one with the highest probability according to XNET. In our experiments, we set $k = 5$. In the end, we experimented with an ensemble network LRXNET which combines the XNET score, the COMPAGGR score and other word-overlap-based scores (tweaked and optimized for each dataset separately) for each sentence using a logistic regression classifier. It uses ISF and LocalISF scores for NewsQA, IDF and ISF scores for SQuAD, sentence length, IDF and ISF scores for WikiQA, and word overlap and ISF score for MSMarco. We refer the reader to the supplementary material for more implementation and optimization details to replicate our results.

Evaluation Metrics We consider metrics that evaluate systems that return a ranked list of candidate answers: mean average precision (MAP), mean reciprocal rank (MRR), and accuracy (ACC).

Results Table 4 gives the results for the test sets of NewsQA and WikiQA, and the original validation sets of SQuAD and MSMarco. Our first observation is that XNET outperforms PAIRCNN, supporting our claim that it is beneficial to read the whole document in order to make decisions, instead of only observing each candidate in isolation.

Secondly, we can observe that ISF is indeed a strong baseline that outperforms XNET. This means that just "reading" the document using a vanilla version of XNET is not sufficient, and help is required through a coarse filtering. Indeed, we observe that XNET+ outperforms all baselines except for COMPAGGR. Our ensemble model LRXNET can ultimately surpass COMPAGGR on majority of the datasets.

This consistent behavior validates the machine reading capabilities and the improved document representation with external features of our model for answer selection. Specifically, the combination of document reading and word overlap features is required to be done in a soft manner, using a classification technique. Using it as a hard constraint, with XNETTOPK, does not achieve the best result. We believe that often the ISF score is a better indicator of answer presence in the vicinity of certain candidate instead of in the candidate itself. As such, XNET+ is capable of using this feature in datasets with richer context.

It is worth noting that the improvement gained by LRXNET over the state-of-the-art follows a pattern. For the SQuAD dataset, the results are comparable (less than 1%). However, the improvement for WikiQA reaches ~3% and then the gap shrinks again for NewsQA, with an improvement of ~1%. This could be explained by the fact that each sample of the SQuAD is a paragraph, compared to an article summary for WikiQA, and to an entire article for NewsQA. Hence, we further strengthen our hypothesis that a richer context is needed to achieve better results, in this case expressed as document length, but as the length of the context increases the limitation of sequential models to learn from long rich sequences arises.[7]

Interestingly, our model lags behind COMPAGGR on the MSMarco dataset. It turns out this is due to contextual independence between candidates in the MSMarco dataset, i.e., each candidate is a stand-alone paragraph in this dataset, in contrast to contextually dependent candidate sentences from a document in the NewsQA, SQuAD and WikiQA datasets. As a result, our models (XNET+ and LRXNET) with document reading abilities perform poorly. This can be observed by the fact that XNET and PAIRCNN obtain comparable results. COMPAGGR performs better because comparing each candidate independently is a better strategy.

5 Conclusion

We describe an approach to model documents while incorporating external information that informs the representations learned for the sentences in the document. We implement our approach through an attention mechanism of a neural network architecture for modeling documents.

Our experiments with extractive document summarization and answer selection tasks validates our model in two ways: first, we demonstrate that external information is important to guide document modeling for natural language understanding tasks. Our model uses image captions and the title of the document for document summarization, and the query with word overlap features for answer selection and outperforms its counterparts that do not use this information. Second, our external attention mechanism successfully guides the learning of the document representation for the relevant end goal. For answer selection, we show that inserting the query with word overlap features using our external attention mechanism outperforms state-of-the-art systems that naturally also have access to this information.

Acknowledgments

We thank Jianpeng Cheng for providing us with the CNN dataset and the implementation of PointerNet. We also thank the members of the Edinburgh NLP group for participating in our human evaluation experiments. This work greatly benefitted from discussions with Jianpeng Cheng, Annie Louis, Pedro Balage, Alfonso Mendes, Sebastião Miranda, and members of the Edinburgh NLP group. Abstract

Most real-world document collections involve various types of metadata, such as author, source, and date, and yet the most commonly-used approaches to modeling text corpora ignore this information. While specialized models have been developed for particular applications, few are widely used in practice, as customization typically requires derivation of a custom inference algorithm. In this paper, we build on recent advances in variational inference methods and propose a general neural framework, based on topic models, to enable flexible incorporation of metadata and allow for rapid exploration of alternative models. Our approach achieves strong performance, with a manageable tradeoff between perplexity, coherence, and sparsity. Finally, we demonstrate the potential of our framework through an exploration of a corpus of articles about US immigration.

1 Introduction

Topic models comprise a family of methods for uncovering latent structure in text corpora, and are widely used tools in the digital humanities, political science, and other related fields (Boyd-Graber et al., 2017). Latent Dirichlet allocation (LDA; Blei et al., 2003) is often used when there is no prior knowledge about a corpus. In the real world, however, most documents have non-textual attributes such as author (Rosen-Zvi et al., 2004), timestamp (Blei and Lafferty, 2006), rating (McAuliffe and Blei, 2008), or ideology (Eisenstein et al., 2011; Nguyen et al., 2015b), which we refer to as **metadata**.

Many customizations of LDA have been developed to incorporate document metadata. Two models of note are **supervised LDA** (SLDA; McAuliffe and Blei, 2008), which jointly models words and labels (e.g., ratings) as being generated from a latent representation, and **sparse additive generative** models (SAGE; Eisenstein et al., 2011), which assumes that observed covariates (e.g., author ideology) have a sparse effect on the relative probabilities of words given topics. The structural topic model (STM; Roberts et al., 2014), which adds correlations between topics to SAGE, is also widely used, but like SAGE it is limited in the types of metadata it can efficiently make use of, and how that metadata is used. Note that in this work we will distinguish **labels** (metadata that are generated jointly with words from latent topic representations) from **covariates** (observed metadata that influence the distribution of labels and words).

The ability to create variations of LDA such as those listed above has been limited by the expertise needed to develop custom inference algorithms for each model. As a result, it is rare to see such variations being widely used in practice. In this work, we take advantage of recent advances in variational methods (Kingma and Welling, 2014; Rezende et al., 2014; Miao et al., 2016; Srivastava and Sutton, 2017) to facilitate approximate Bayesian inference *without requiring model-specific derivations*, and propose a general neural framework for topic models with metadata, SCHOLAR.[1]

SCHOLAR combines the abilities of SAGE and SLDA, and allows for easy exploration of the following options for customization:

1. Covariates: as in SAGE and STM, we incorporate explicit deviations for observed covariates, as well as effects for *interactions* with topics.
2. Supervision: as in SLDA, we can use metadata as labels to help infer topics that are relevant in predicting those labels.

[1]**S**parse **C**ontextual **H**idden and **O**bserved **L**anguage Autoencode**R**.

3. Rich encoder network: we use the encoding network of a variational autoencoder (VAE) to incorporate additional prior knowledge in the form of word embeddings, and/or to provide interpretable embeddings of covariates.
4. Sparsity: as in SAGE, a sparsity-inducing prior can be used to encourage more interpretable topics, represented as sparse deviations from a background log-frequency.

We begin with the necessary background and motivation (§2), and then describe our basic framework and its extensions (§3), followed by a series of experiments (§4). In an unsupervised setting, we can customize the model to trade off between perplexity, coherence, and sparsity, with improved coherence through the introduction of word vectors. Alternatively, by incorporating metadata we can either learn topics that are more predictive of labels than SLDA, or learn explicit deviations for particular parts of the metadata. Finally, by combining all parts of our model we can meaningfully incorporate metadata in multiple ways, which we demonstrate through an exploration of a corpus of news articles about US immigration.

In presenting this particular model, we emphasize not only its ability to adapt to the characteristics of the data, but the extent to which the VAE approach to inference provides a powerful framework for latent variable modeling that suggests the possibility of many further extensions. Our implementation is available at `https://github.com/dallascard/scholar`.

2 Background and Motivation

LDA can be understood as a non-negative Bayesian matrix factorization model: the observed document-word frequency matrix, $\mathbf{X} \in \mathbb{Z}^{D \times V}$ (D is the number of documents, V is the vocabulary size) is factored into two low-rank matrices, $\mathbf{\Theta}^{D \times K}$ and $\mathbf{B}^{K \times V}$, where each row of $\mathbf{\Theta}$, $\boldsymbol{\theta}_i \in \Delta^K$ is a latent variable representing a distribution over topics in document i, and each row of $\mathbf{B}$, $\boldsymbol{\beta}_k \in \Delta^V$, represents a single topic, i.e., a distribution over words in the vocabulary.[2] While it is possible to factor the count data into unconstrained matrices, the particular priors assumed by LDA are important for interpretability (Wallach et al., 2009). For example, the neural variational document model (NVDM; Miao et al., 2016) allows $\boldsymbol{\theta}_i \in \mathbb{R}^K$ and achieves normalization by taking the softmax of $\boldsymbol{\theta}_i^\top \mathbf{B}$. However, the experiments in Srivastava and Sutton (2017) found the performance of the NVDM to be slightly worse than LDA in terms of perplexity, and dramatically worse in terms of topic coherence.

The topics discovered by LDA tend to be parsimonious and coherent groupings of words which are readily identifiable to humans as being related to each other (Chang et al., 2009), and the resulting mode of the matrix $\mathbf{\Theta}$ provides a representation of each document which can be treated as a measurement for downstream tasks, such as classification or answering social scientific questions (Wallach, 2016). LDA does not require — and cannot make use of — additional prior knowledge. As such, the topics that are discovered may bear little connection to metadata of a corpus that is of interest to a researcher, such as sentiment, ideology, or time.

In this paper, we take inspiration from two models which have sought to alleviate this problem. The first, supervised LDA (SLDA; McAuliffe and Blei, 2008), assumes that documents have labels y which are generated conditional on the corresponding latent representation, i.e., $y_i \sim p(y \mid \boldsymbol{\theta}_i)$.[3] By incorporating labels into the model, it is forced to learn topics which allow documents to be represented in a way that is useful for the classification task. Such models can be used inductively as text classifiers (Balasubramanyan et al., 2012).

SAGE (Eisenstein et al., 2011), by contrast, is an exponential-family model, where the key innovation was to replace topics with sparse deviations from the background log-frequency of words ($\boldsymbol{d}$), i.e., $p(\text{word} \mid \text{softmax}(\boldsymbol{d} + \boldsymbol{\theta}_i^\top \mathbf{B}))$. SAGE can also incorporate deviations for observed covariates, as well as interactions between topics and covariates, by including additional terms inside the softmax. In principle, this allows for inferring, for example, the effect on an author's ideology on their choice of words, as well as ideological variations on each underlying topic. Unlike the NVDM, SAGE still constrains $\boldsymbol{\theta}_i$ to lie on the simplex, as in LDA.

SLDA and SAGE provide two different ways that users might wish to incorporate prior knowl-

[2] $\mathbb{Z}$ denotes nonnegative integers, and Δ^K denotes the set of K-length nonnegative vectors that sum to one. For a proper probabilistic interpretation, the matrix to be factored is actually the matrix of latent mean parameters of the assumed data generating process, $\mathbf{X}_{ij} \sim \text{Poisson}(\mathbf{\Lambda}_{ij})$. See Cemgil (2009) or Paisley et al. (2014) for details.

[3] Technically, the model conditions on the mean of the per-word latent variables, but we elide this detail in the interest of concision.

edge as a way of guiding the discovery of topics in a corpus: SLDA incorporates labels through a distribution conditional on topics; SAGE includes explicit sparse deviations for each unique value of a covariate, in addition to topics.[4]

Because of the Dirichlet-multinomial conjugacy in the original model, efficient inference algorithms exist for LDA. Each variation of LDA, however, has required the derivation of a custom inference algorithm, which is a time-consuming and error-prone process. In SLDA, for example, each type of distribution we might assume for $p(y \mid \boldsymbol{\theta})$ would require a modification of the inference algorithm. SAGE breaks conjugacy, and as such, the authors adopted L-BFGS for optimizing the variational bound. Moreover, in order to maintain computational efficiency, it assumed that covariates were limited to a single categorical label.

More recently, the variational autoencoder (VAE) was introduced as a way to perform approximate posterior inference on models with otherwise intractable posteriors (Kingma and Welling, 2014; Rezende et al., 2014). This approach has previously been applied to models of text by Miao et al. (2016) and Srivastava and Sutton (2017). We build on their work and show how this framework can be adapted to seamlessly incorporate the ideas of both SAGE and SLDA, while allowing for greater flexibility in the use of metadata. Moreover, by exploiting automatic differentiation, we allow for modification of the model without requiring any change to the inference procedure. The result is not only a highly adaptable family of models with scalable inference and efficient prediction; it also points the way to incorporation of many ideas found in the literature, such as a gradual evolution of topics (Blei and Lafferty, 2006), and hierarchical models (Blei et al., 2010; Nguyen et al., 2013, 2015b).

3 SCHOLAR: A Neural Topic Model with Covariates, Supervision, and Sparsity

We begin by presenting the generative story for our model, and explain how it generalizes both SLDA and SAGE (§3.1). We then provide a general explanation of inference using VAEs and how it applies to our model (§3.2), as well as how to infer document representations and predict labels at test time (§3.3). Finally, we discuss how we can incorporate additional prior knowledge (§3.4).

3.1 Generative Story

Consider a corpus of D documents, where document i is a list of N_i words, $\boldsymbol{w}_i$, with V words in the vocabulary. For each document, we may have observed covariates $\boldsymbol{c}_i$ (e.g., year of publication), and/or one or more labels, $\boldsymbol{y}_i$ (e.g., sentiment).

Our model builds on the generative story of LDA, but optionally incorporates labels and covariates, and replaces the matrix product of $\boldsymbol{\Theta}$ and $\mathbf{B}$ with a more flexible generative network, f_g, followed by a softmax transform. Instead of using a Dirichlet prior as in LDA, we employ a logistic normal prior on $\boldsymbol{\theta}$ as in Srivastava and Sutton (2017) to facilitate inference (§3.2): we draw a latent variable, $\boldsymbol{r}$,[5] from a multivariate normal, and transform it to lie on the simplex using a softmax transform.[6]

The generative story is shown in Figure 1a and described in equations below:

```
For each document $i$ of length $N_i$:
    # Draw a latent representation on the simplex from a logistic normal prior:
    $\boldsymbol{r}_i \sim \mathcal{N}(\boldsymbol{r} \mid \boldsymbol{\mu}_0(\alpha), \text{diag}(\boldsymbol{\sigma}_0^2(\alpha)))$
    $\boldsymbol{\theta}_i = \text{softmax}(\boldsymbol{r}_i)$
    # Generate words, incorporating covariates:
    $\boldsymbol{\eta}_i = f_g(\boldsymbol{\theta}_i, \boldsymbol{c}_i)$
    For each word $j$ in document $i$:
        $w_{ij} \sim p(w \mid \text{softmax}(\boldsymbol{\eta}_i))$
    # Similarly generate labels:
    $\boldsymbol{y}_i \sim p(\boldsymbol{y} \mid f_y(\boldsymbol{\theta}_i, \boldsymbol{c}_i))$,
```

where $p(w \mid \text{softmax}(\boldsymbol{\eta}_i))$ is a multinomial distribution and $p(\boldsymbol{y} \mid f_y(\boldsymbol{\theta}_i, \boldsymbol{c}_i))$ is a distribution appropriate to the data (e.g., multinomial for categorical labels). f_g is a model-specific combination of latent variables and covariates, f_y is a multi-layer neural network, and $\boldsymbol{\mu}_0(\alpha)$ and $\boldsymbol{\sigma}_0^2(\alpha)$ are the mean and diagonal covariance terms of a multivariate normal prior. To approximate a symmetric Dirichlet

[4]A third way of incorporating metadata is the approach used by various "upstream" models, such as Dirichlet-multinomial regression (Mimno and McCallum, 2008), which uses observed metadata to inform the document prior. We hypothesize that this approach could be productively combined with our framework, but we leave this as future work.

[5]$\boldsymbol{r}$ is equivalent to $\boldsymbol{z}$ in the original VAE. To avoid confusion with topic assignment of words in the topic modeling literature, we use $\boldsymbol{r}$ instead of $\boldsymbol{z}$.

[6]Unlike the correlated topic model (CTM; Lafferty and Blei, 2006), which also uses a logistic-normal prior, we fix the parameters of the prior and use a diagonal covariance matrix, rather than trying to infer correlations among topics. However, it would be a straightforward extension of our framework to place a richer prior on the latent document representations, and learn correlations by updating the parameters of this prior after each epoch, analogously to the variational EM approach used for the CTM.

prior with hyperparameter α, these are given by the Laplace approximation (Hennig et al., 2012) to be $\mu_{0,k}(\alpha) = 0$ and $\sigma^2_{0,k} = (K-1)/(\alpha K)$.

If we were to ignore covariates, place a Dirichlet prior on $\mathbf{B}$, and let $\boldsymbol{\eta} = \boldsymbol{\theta}_i^\top \mathbf{B}$, this model is equivalent to SLDA with a logistic normal prior. Similarly, we can recover a model that is like SAGE, but lacks sparsity, if we ignore labels, and let

$$\boldsymbol{\eta}_i = \boldsymbol{d} + \boldsymbol{\theta}_i^\top \mathbf{B} + \boldsymbol{c}_i^\top \mathbf{B}^{cov} + (\boldsymbol{\theta}_i \otimes \boldsymbol{c}_i)^\top \mathbf{B}^{int}, \quad (1)$$

where $\boldsymbol{d}$ is the V-dimensional background term (representing the log of the overall word frequency), $\boldsymbol{\theta}_i \otimes \boldsymbol{c}_i$ is a vector of interactions between topics and covariates, and $\mathbf{B}^{cov}$ and $\mathbf{B}^{int}$ are additional weight (deviation) matrices. The background is included to account for common words with approximately the same frequency across documents, meaning that the $\mathbf{B}^*$ weights now represent both positive and negative deviations from this background. This is the form of f_g which we will use in our experiments.

To recover the full SAGE model, we can place a sparsity-inducing prior on each $\mathbf{B}^*$. As in Eisenstein et al. (2011), we make use of the compound normal-exponential prior for each element of the weight matrices, $\mathbf{B}^*_{m,n}$, with hyperparameter γ,[7]

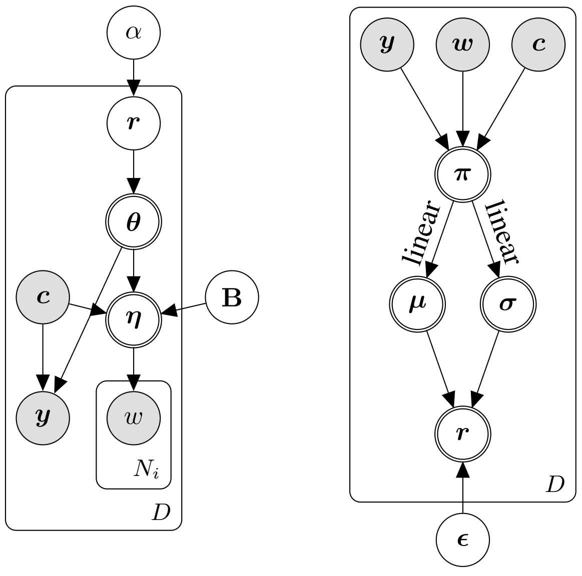
$$\tau_{m,n} \sim \text{Exponential}(\gamma), \quad (2)$$
$$\mathbf{B}^*_{m,n} \sim \mathcal{N}(0, \tau_{m,n}). \quad (3)$$

We can choose to ignore various parts of this model, if, for example, we don't have any labels or observed covariates, or we don't wish to use interactions or sparsity.[8] Other generator networks could also be considered, with additional layers to represent more complex interactions, although this might involve some loss of interpretability.

In the absence of metadata, and without sparsity, our model is equivalent to the ProdLDA model of Srivastava and Sutton (2017) with an explicit background term, and ProdLDA is, in turn, a special case of SAGE, without background log-frequencies, sparsity, covariates, or labels. In the next section we generalize the inference method used for ProdLDA; in our experiments we validate its performance and explore the effects of regularization and word-vector initialization (§3.4). The NVDM (Miao et al., 2016) uses the same approach to inference, but does not not restrict document representations to the simplex.

[7]To avoid having to tune γ, we employ an improper Jeffery's prior, $p(\tau_{m,n}) \propto 1/\tau_{m,n}$, as in SAGE. Although this causes difficulties in posterior inference for the variance terms, τ, in practice, we resort to a variational EM approach, with MAP-estimation for the weights, $\mathbf{B}$, and thus alternate between computing expectations of the τ parameters, and updating all other parameters using some variant of stochastic gradient descent. For this, we only require the expectation of each τ_{mn} for each E-step, which is given by $1/\mathbf{B}^2_{m,n}$. We refer the reader to Eisenstein et al. (2011) for additional details.

[8]We could also ignore latent topics, in which case we would get a naïve Bayes-like model of text with deviations for each covariate $p(\boldsymbol{w}_{ij} \mid \boldsymbol{c}_i) \propto \exp(\boldsymbol{d} + \boldsymbol{c}_i^\top \mathbf{B}^{cov})$.



(a) Generative model (b) Inference model

Figure 1: Figure 1a presents the generative story of our model. Figure 1b illustrates the inference network using the reparametrization trick to perform variational inference on our model. Shaded nodes are observed; double circles indicate deterministic transformations of parent nodes.

3.2 Learning and Inference

As in past work, each document i is assumed to have a latent representation $\boldsymbol{r}_i$, which can be interpreted as its relative membership in each topic (after exponentiating and normalizing). In order to infer an approximate posterior distribution over $\boldsymbol{r}_i$, we adopt the sampling-based VAE framework developed in previous work (Kingma and Welling, 2014; Rezende et al., 2014).

As in conventional variational inference, we assume a variational approximation to the posterior, $q_{\boldsymbol{\Phi}}(\boldsymbol{r}_i \mid \boldsymbol{w}_i, \boldsymbol{c}_i, \boldsymbol{y}_i)$, and seek to minimize the KL divergence between it and the true posterior, $p(\boldsymbol{r}_i \mid \boldsymbol{w}_i, \boldsymbol{c}_i, \boldsymbol{y}_i)$, where $\boldsymbol{\Phi}$ is the set of variational parameters to be defined below. After some manipulations (given in supplementary materials), we obtain the evidence lower bound (ELBO) for a single document,

$$\mathcal{L}(\boldsymbol{w}_i) = \mathbb{E}_{q_{\boldsymbol{\Phi}}(\boldsymbol{r}_i|\boldsymbol{w}_i,\boldsymbol{c}_i,\boldsymbol{y}_i)}\left[\sum_{j=1}^{N_i}\log p(w_{ij} \mid \boldsymbol{r}_i, \boldsymbol{c}_i)\right] + \mathbb{E}_{q_{\boldsymbol{\Phi}}(\boldsymbol{r}_i|\boldsymbol{w}_i,\boldsymbol{c}_i,\boldsymbol{y}_i)}\left[\log p(\boldsymbol{y}_i \mid \boldsymbol{r}_i, \boldsymbol{c}_i)\right] - \mathrm{D}_{\mathrm{KL}}\left[q_{\boldsymbol{\Phi}}(\boldsymbol{r}_i \mid \boldsymbol{w}_i, \boldsymbol{c}_i, \boldsymbol{y}_i) \,||\, p(\boldsymbol{r}_i \mid \alpha)\right]. \tag{4}$$

As in the original VAE, we will encode the parameters of our variational distributions using a shared multi-layer neural network. Because we have assumed a diagonal normal prior on $\boldsymbol{r}$, this will take the form of a network which outputs a mean vector, $\boldsymbol{\mu}_i = f_{\boldsymbol{\mu}}(\boldsymbol{w}_i, \boldsymbol{c}_i, \boldsymbol{y}_i)$ and diagonal of a covariance matrix, $\boldsymbol{\sigma}_i^2 = f_{\boldsymbol{\sigma}}(\boldsymbol{w}_i, \boldsymbol{c}_i, \boldsymbol{y}_i)$, such that $q_{\boldsymbol{\Phi}}(\boldsymbol{r}_i \mid \boldsymbol{w}_i, \boldsymbol{c}_i, \boldsymbol{y}_i) = \mathcal{N}(\boldsymbol{\mu}_i, \boldsymbol{\sigma}_i^2)$. Incorporating labels and covariates to the inference network used by Miao et al. (2016) and Srivastava and Sutton (2017), we use:

$$\boldsymbol{\pi}_i = f_e([\mathbf{W}_x \boldsymbol{x}_i; \mathbf{W}_c \boldsymbol{c}_i; \mathbf{W}_y \boldsymbol{y}_i]), \tag{5}$$
$$\boldsymbol{\mu}_i = \mathbf{W}_\mu \boldsymbol{\pi}_i + \boldsymbol{b}_\mu, \tag{6}$$
$$\log \boldsymbol{\sigma}_i^2 = \mathbf{W}_\sigma \boldsymbol{\pi}_i + \boldsymbol{b}_\sigma, \tag{7}$$

where $\boldsymbol{x}_i$ is a V-dimensional vector representing the counts of words in $\boldsymbol{w}_i$, and f_e is a multilayer perceptron. The full set of encoder parameters, $\boldsymbol{\Phi}$, thus includes the parameters of f_e and all weight matrices and bias vectors in Equations 5–7 (see Figure 1b).

This approach means that the expectations in Equation 4 are intractable, but we can approximate them using sampling. In order to maintain differentiability with respect to $\boldsymbol{\Phi}$, even after sampling, we make use of the reparameterization trick (Kingma and Welling, 2014),[9] which allows us to reparameterize samples from $q_{\boldsymbol{\Phi}}(\boldsymbol{r} \mid \boldsymbol{w}_i, \boldsymbol{c}_i, \boldsymbol{y}_i)$ in terms of samples from an independent source of noise, i.e.,

$$\boldsymbol{\epsilon}^{(s)} \sim \mathcal{N}(0, \mathbf{I}),$$
$$\boldsymbol{r}_i^{(s)} = g_{\boldsymbol{\Phi}}(\boldsymbol{w}_i, \boldsymbol{c}_i, \boldsymbol{y}_i, \boldsymbol{\epsilon}^{(s)}) = \boldsymbol{\mu}_i + \boldsymbol{\sigma}_i \cdot \boldsymbol{\epsilon}^{(s)}.$$

We thus replace the bound in Equation 4 with a Monte Carlo approximation using a single sample[10] of $\boldsymbol{\epsilon}$ (and thereby of $\boldsymbol{r}$):

$$\mathcal{L}(\boldsymbol{w}_i) \approx \sum_{j=1}^{N_i}\log p(w_{ij} \mid \boldsymbol{r}_i^{(s)}, \boldsymbol{c}_i) + \log p(\boldsymbol{y}_i \mid \boldsymbol{r}_i^{(s)}, \boldsymbol{c}_i) - \mathrm{D}_{\mathrm{KL}}\left[q_{\boldsymbol{\Phi}}(\boldsymbol{r}_i \mid \boldsymbol{w}_i, \boldsymbol{c}_i, \boldsymbol{y}_i) \,||\, p(\boldsymbol{r}_i \mid \alpha)\right]. \tag{8}$$

We can now optimize this sampling-based approximation of the variational bound with respect to $\boldsymbol{\Phi}$, $\mathbf{B}^*$, and all parameters of f_g and f_y using stochastic gradient descent. Moreover, because of this stochastic approach to inference, we are *not* restricted to covariates with a small number of unique values, which was a limitation of SAGE. Finally, the KL divergence term in Equation 8 can be computed in closed form (see supplementary materials).

3.3 Prediction on Held-out Data

In addition to inferring latent topics, our model can both infer latent representations for new documents and predict their labels, the latter of which was the motivation for SLDA. In traditional variational inference, inference at test time requires fixing global parameters (topics), and optimizing the per-document variational parameters for the test set. With the VAE framework, by contrast, the encoder network (Equations 5–7) can be used to directly estimate the posterior distribution for each test document, using only a forward pass (no iterative optimization or sampling).

If not using labels, we can use this approach directly, passing the word counts of new documents through the encoder to get a posterior $q_{\boldsymbol{\Phi}}(\boldsymbol{r}_i \mid \boldsymbol{w}_i, \boldsymbol{c}_i)$. When we also include labels to be predicted, we can first train a fully-observed model, as above, then fix the decoder, and retrain the encoder without labels. In practice, however, if we train the encoder network using one-hot encodings of document labels, it is sufficient to provide a vector of all zeros for the labels of test documents; this is what we adopt for our experiments (§4.2), and we still obtain good predictive performance.

The label network, f_y, is a flexible component which can be used to predict a wide range of outcomes, from categorical labels (such as star ratings; McAuliffe and Blei, 2008) to real-valued outputs (such as number of citations or box-office returns;

[9] The Dirichlet distribution cannot be directly reparameterized in this way, which is why we use the logistic normal prior on $\boldsymbol{\theta}$ to approximate the Dirichlet prior used in LDA.

[10] Alternatively, one can average over multiple samples.

Yogatama et al., 2011). For categorical labels, predictions are given by

$$\hat{y}_i = \underset{y \in \mathcal{Y}}{\text{argmax}}\; p(y \mid \boldsymbol{r}_i, \boldsymbol{c}_i). \tag{9}$$

Alternatively, when dealing with a small set of categorical labels, it is also possible to treat them as observed categorical covariates during training. At test time, we can then consider all possible one-hot vectors, $\boldsymbol{e}$, in place of $\boldsymbol{c}_i$, and predict the label that maximizes the probability of the words, i.e.,

$$\hat{y}_i = \underset{y \in \mathcal{Y}}{\text{argmax}} \sum_{j=1}^{N_i} \log p(w_{ij} \mid \boldsymbol{r}_i, \boldsymbol{e}_y). \tag{10}$$

This approach works well in practice (as we show in §4.2), but does not scale to large numbers of labels, or other types of prediction problems, such as multi-class classification or regression.

The choice to include metadata as covariates, labels, or both, depends on the data. The key point is that we can incorporate metadata in two very different ways, depending on what we want from the model. Labels guide the model to infer topics that are relevant to those labels, whereas covariates induce explicit deviations, leaving the latent variables to account for the rest of the content.

3.4 Additional Prior Information

A final advantage of the VAE framework is that the encoder network provides a way to incorporate additional prior information in the form of word vectors. Although we can learn all parameters starting from a random initialization, it is also possible to initialize and fix the initial embeddings of words in the model, $\mathbf{W}_x$, in Equation 5. This leverages word similarities derived from large amounts of unlabeled data, and may promote greater coherence in inferred topics. The same could also be done for some covariates; for example, we could embed the source of a news article based on its place on the ideological spectrum. Conversely, if we choose to learn these parameters, the learned values ($\mathbf{W}_y$ and $\mathbf{W}_c$) may provide meaningful embeddings of these metadata (see section §4.3).

Other variants on topic models have also proposed incorporating word vectors, both as a parallel part of the generative process (Nguyen et al., 2015a), and as an alternative parameterization of topic distributions (Das et al., 2015), but inference is not scalable in either of these models. Because of the generality of the VAE framework, we could also modify the generative story so that word embeddings are emitted (rather than tokens); we leave this for future work.

4 Experiments and Results

To evaluate and demonstrate the potential of this model, we present a series of experiments below. We first test SCHOLAR without observed metadata, and explore the effects of using regularization and/or word vector initialization, compared to LDA, SAGE, and NVDM (§4.1). We then evaluate our model in terms of predictive performance, in comparison to SLDA and an l_2-regularized logistic regression baseline (§4.2). Finally, we demonstrate the ability to incorporate covariates and/or labels in an exploratory data analysis (§4.3).

The scores we report are generalization to held-out data, measured in terms of perplexity; coherence, measured in terms of non-negative point-wise mutual information (NPMI; Chang et al., 2009; Newman et al., 2010), and classification accuracy on test data. For coherence we evaluate NPMI using the top 10 words of each topic, both internally (using test data), and externally, using a decade of articles from the English Gigaword dataset (Graff and Cieri, 2003). Since our model employs variational methods, the reported perplexity is an upper bound based on the ELBO.

As datasets we use the familiar 20 newsgroups, the IMDB corpus of 50,000 movie reviews (Maas et al., 2011), and the UIUC Yahoo answers dataset with 150,000 documents in 15 categories (Chang et al., 2008). For further exploration, we also make use of a corpus of approximately 4,000 time-stamped news articles about US immigration, each annotated with pro- or anti-immigration tone (Card et al., 2015). We use the original author-provided implementations of SAGE[11] and SLDA,[12] while for LDA we use Mallet.[13]. Our implementation of SCHOLAR is in TensorFlow, but we have also provided a preliminary PyTorch implementation of the core of our model.[14] For additional details about datasets and implementation, please refer to the supplementary material.

It is challenging to fairly evaluate the relative computational efficiency of our approach compared to past work (due to the stochastic nature of our ap-

[11]github.com/jacobeisenstein/SAGE

[14]github.com/dallascard/scholar

proach to inference, choices about hyperparameters such as tolerance, and because of differences in implementation). Nevertheless, in practice, the performance of our approach is highly appealing. For all experiments in this paper, our implementation was much faster than SLDA or SAGE (implemented in C and Matlab, respectively), and competitive with Mallet.

4.1 Unsupervised Evaluation

Although the emphasis of this work is on incorporating observed labels and/or covariates, we briefly report on experiments in the unsupervised setting. Recall that, without metadata, SCHOLAR equates to ProdLDA, but with an explicit background term.[15] We therefore use the same experimental setup as Srivastava and Sutton (2017) (learning rate, momentum, batch size, and number of epochs) and find the same general patterns as they reported (see Table 1 and supplementary material): our model returns more coherent topics than LDA, but at the cost of worse perplexity. SAGE, by contrast, attains very high levels of sparsity, but at the cost of worse perplexity and coherence than LDA. As expected, the NVDM produces relatively low perplexity, but very poor coherence, due to its lack of constraints on $\boldsymbol{\theta}$.

Further experimentation revealed that the VAE framework involves a tradeoff among the scores; running for more epochs tends to result in better perplexity on held-out data, but at the cost of worse coherence. Adding regularization to encourage sparse topics has a similar effect as in SAGE, leading to worse perplexity and coherence, but it does create sparse topics. Interestingly, initializing the encoder with pretrained word2vec embeddings, and *not* updating them returned a model with the best internal coherence of any model we considered for IMDB and Yahoo answers, and the second-best for 20 newsgroups.

The background term in our model does not have much effect on perplexity, but plays an important role in producing coherent topics; as in SAGE, the background can account for common words, so they are mostly absent among the most heavily weighted words in the topics. For instance, words like *film* and *movie* in the IMDB corpus are relatively unimportant in the topics learned by our model, but would be much more heavily weighted without the background term, as they are in topics learned by LDA.

Model	Ppl. ↓	NPMI (int.) ↑	NPMI (ext.) ↑	Sparsity ↑
LDA	**1508**	0.13	0.14	0
SAGE	1767	0.12	0.12	**0.79**
NVDM	1748	0.06	0.04	0
SCHOLAR − B.G.	1889	0.09	0.13	0
SCHOLAR	1905	0.14	0.13	0
SCHOLAR + W.V.	1991	**0.18**	**0.17**	0
SCHOLAR + REG.	2185	0.10	0.12	0.58

Table 1: Performance of our various models in an unsupervised setting (i.e., without labels or covariates) on the IMDB dataset using a 5,000-word vocabulary and 50 topics. The supplementary materials contain additional results for 20 newsgroups and Yahoo answers.

4.2 Text Classification

We next consider the utility of our model in the context of categorical labels, and consider them alternately as observed covariates and as labels generated conditional on the latent representation. We use the same setup as above, but tune number of training epochs for our model using a random 20% of training data as a development set, and similarly tune regularization for logistic regression.

Table 2 summarizes the accuracy of various models on three datasets, revealing that our model offers competitive performance, both as a joint model of words and labels (Eq. 9), and a model which conditions on covariates (Eq. 10). Although SCHOLAR is comparable to the logistic regression baseline, our purpose here is not to attain state-of-the-art performance on text classification. Rather, the high accuracies we obtain demonstrate that we are learning low-dimensional representations of documents that are relevant to the label of interest, outperforming SLDA, and have the same attractive properties as topic models. Further, any neural network that is successful for text classification could be incorporated into f_y and trained end-to-end along with topic discovery.

4.3 Exploratory Study

We demonstrate how our model might be used to explore an annotated corpus of articles about immigration, and adapt to different assumptions about the data. We only use a small number of topics in this part ($K = 8$) for compact presentation.

[15]Note, however, that a batchnorm layer in ProdLDA may play a similar role to a background term, and there are small differences in implementation; please see supplementary material for more discussion of this.

	20news	IMDB	Yahoo
Vocabulary size	2000	5000	5000
Number of topics	50	50	250
SLDA	0.60	0.64	0.65
SCHOLAR (labels)	0.67	0.86	0.73
SCHOLAR (covariates)	**0.71**	**0.87**	0.72
Logistic regression	0.70	**0.87**	**0.76**

Table 2: Accuracy of various models on three datasets with categorical labels.

Tone as a label. We first consider using the annotations as a *label*, and train a joint model to infer topics relevant to the tone of the article (pro- or anti-immigration). Figure 2 shows a set of topics learned in this way, along with the predicted probability of an article being pro-immigration conditioned on the given topic. All topics are coherent, and the predicted probabilities have strong face validity, e.g., “arrested charged charges agents operation” is least associated with pro-immigration.

Tone as a covariate. Next we consider using tone as a *covariate*, and build a model using both tone and tone-topic interactions. Table 3 shows a set of topics learned from the immigration data, along with the most highly-weighted words in the corresponding tone-topic interaction terms. As can be seen, these interaction terms tend to capture different frames (e.g., “criminal” vs. “detainees”, and “illegals” vs. “newcomers”, etc).

Combined model with temporal metadata. Finally, we incorporate both the tone annotations and the year of publication of each article, treating the former as a label and the latter as a covariate. In this model, we also include an embedding matrix, $\mathbf{W}_c$, to project the one-hot *year* vectors down to a two-dimensional continuous space, with a learned deviation for each dimension. We omit the topics in the interest of space, but Figure 3 shows the learned embedding for each year, along with the top terms of the corresponding deviations. As can be seen, the model learns that adjacent years tend to produce similar deviations, *even though we have not explicitly encoded this information*. The left-right dimension roughly tracks a temporal trend with positive deviations shifting from the years of *Clinton* and *INS* on the left, to *Obama* and *ICE* on the right.[16] Meanwhile, the events of 9/11 dominate the vertical direction, with the words *sept*,

[16]The Immigration and Naturalization Service (INS) was transformed into Immigration and Customs Enforcement (ICE) and other agencies in 2003.

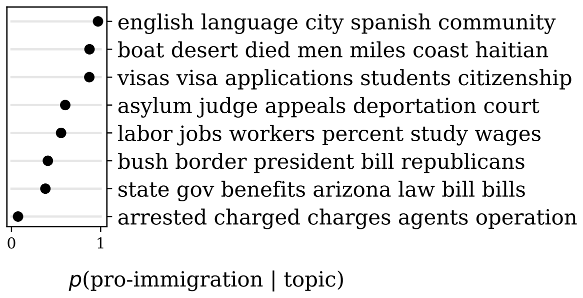

Figure 2: Topics inferred by a joint model of words and tone, and the corresponding probability of pro-immigration tone for each topic. A topic is represented by the top words sorted by word probability throughout the paper.

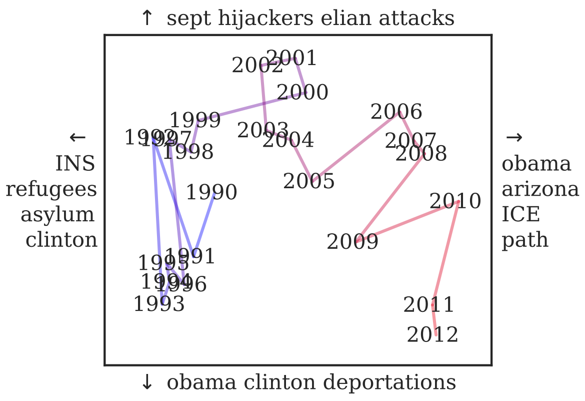

Figure 3: Learned embeddings of year-of-publication (treated as a covariate) from combined model of news articles about immigration.

hijackers, and *attacks* increasing in probability as we move up in the space. If we wanted to look at each year individually, we could drop the embedding of years, and learn a sparse set of topic-year interactions, similar to tone in Table 3.

5 Additional Related Work

The literature on topic models is vast; in addition to papers cited throughout, other efforts to incorporate metadata into topic models include Dirichlet-multinomial regression (DMR; Mimno and McCallum, 2008), Labeled LDA (Ramage et al., 2009), and MedLDA (Zhu et al., 2009). A recent paper also extended DMR by using deep neural networks to embed metadata into a richer document prior (Benton and Dredze, 2018).

A separate line of work has pursued parameterizing unsupervised models of documents using neural networks (Hinton and Salakhutdinov,

Base topics (each row is a topic)	Anti-immigration interactions	Pro-immigration interactions

2009; Larochelle and Lauly, 2012), including non-Bayesian approaches (Cao et al., 2015). More recently, Lau et al. (2017) proposed a neural language model that incorporated topics, and He et al. (2017) developed a scalable alternative to the correlated topic model by simultaneously learning topic embeddings.

Others have attempted to extend the reparameterization trick to the Dirichlet and Gamma distributions, either through transformations (Kucukelbir et al., 2016) or a generalization of reparameterization (Ruiz et al., 2016). Black-box and VAE-style inference have been implemented in at least two general purpose tools designed to allow rapid exploration and evaluation of models (Kucukelbir et al., 2015; Tran et al., 2016).

6 Conclusion

We have presented a neural framework for generalized topic models to enable flexible incorporation of metadata with a variety of options. We take advantage of stochastic variational inference to develop a general algorithm for our framework such that variations do not require any model-specific algorithm derivations. Our model demonstrates the tradeoff between perplexity, coherence, and sparsity, and outperforms SLDA in predicting document labels. Furthermore, the flexibility of our model enables intriguing exploration of a text corpus on US immigration. We believe that our model and code will facilitate rapid exploration of document collections with metadata.

Abstract

Semantic hashing has become a powerful paradigm for fast similarity search in many information retrieval systems. While fairly successful, previous techniques generally require two-stage training, and the binary constraints are handled *ad-hoc*. In this paper, we present an *end-to-end* Neural Architecture for Semantic Hashing (NASH), where the binary hashing codes are treated as *Bernoulli* latent variables. A neural variational inference framework is proposed for training, where gradients are directly backpropagated through the discrete latent variable to optimize the hash function. We also draw connections between proposed method and *rate-distortion theory*, which provides a theoretical foundation for the effectiveness of the proposed framework. Experimental results on three public datasets demonstrate that our method significantly outperforms several state-of-the-art models on both *unsupervised* and *supervised* scenarios.

1 Introduction

The problem of *similarity search*, also called *nearest-neighbor search*, consists of finding documents from a large collection of documents, or *corpus*, which are most similar to a query document of interest. Fast and accurate similarity search is at the core of many information retrieval applications, such as plagiarism analysis (Stein et al., 2007), collaborative filtering (Koren, 2008), content-based multimedia retrieval (Lew et al., 2006) and caching (Pandey et al., 2009). Semantic hashing is an effective approach for fast similarity search (Salakhutdinov and Hinton, 2009; Zhang et al., 2010; Wang et al., 2014). By representing every document in the corpus as a similarity-preserving discrete (binary) *hashing code*, the similarity between two documents can be evaluated by simply calculating pairwise Hamming distances between hashing codes, *i.e.*, the number of bits that are different between two codes. Given that today, an ordinary PC is able to execute millions of Hamming distance computations in just a few milliseconds (Zhang et al., 2010), this semantic hashing strategy is very computationally attractive.

While considerable research has been devoted to text (semantic) hashing, existing approaches typically require two-stage training procedures. These methods can be generally divided into two categories: (i) binary codes for documents are first learned in an unsupervised manner, then l binary classifiers are trained via supervised learning to predict the l-bit hashing code (Zhang et al., 2010; Xu et al., 2015); (ii) continuous text representations are first inferred, which are binarized as a second (separate) step during testing (Wang et al., 2013; Chaidaroon and Fang, 2017). Because the model parameters are not learned in an end-to-end manner, these two-stage training strategies may result in suboptimal local optima. This happens because different modules within the model are optimized separately, preventing the sharing of information between them. Further, in existing methods, binary constraints are typically handled *ad-hoc* by truncation, *i.e.*, the hashing codes are obtained via direct binarization from continuous representations after training. As a result, the information contained in the continuous representations is lost during the (separate) binarization process. Moreover, training different modules (mapping and classifier/binarization) separately often requires additional hyperparameter tuning for each training stage, which can be laborious and time-consuming.

[*] Equal contribution.

In this paper, we propose a simple and generic neural architecture for text hashing that learns binary latent codes for documents in an *end-to-end* manner. Inspired by recent advances in neural variational inference (NVI) for text processing (Miao et al., 2016; Yang et al., 2017; Shen et al., 2017b), we approach semantic hashing from a generative model perspective, where binary (hashing) codes are represented as either *deterministic* or *stochastic* Bernoulli latent variables. The inference (encoder) and generative (decoder) networks are optimized jointly by maximizing a variational lower bound to the marginal distribution of input documents (corpus). By leveraging a simple and effective method to estimate the gradients with respect to discrete (binary) variables, the loss term from the generative (decoder) network can be directly backpropagated into the inference (encoder) network to optimize the hash function.

Motivated by the *rate-distortion theory* (Berger, 1971; Theis et al., 2017), we propose to inject data-dependent noise into the latent codes during the decoding stage, which adaptively accounts for the tradeoff between minimizing *rate* (number of bits used, or effective code length) and *distortion* (reconstruction error) during training. The connection between the proposed method and *rate-distortion theory* is further elucidated, providing a theoretical foundation for the effectiveness of our framework.

Summarizing, the contributions of this paper are: (*i*) to the best of our knowledge, we present the first semantic hashing architecture that can be trained in an *end-to-end* manner; (*ii*) we propose a *neural variational inference* framework to learn compact (regularized) binary codes for documents, achieving promising results on both *unsupervised* and *supervised* text hashing; (*iii*) the connection between our method and *rate-distortion theory* is established, from which we demonstrate the advantage of injecting *data-dependent noise* into the latent variable during training.

2 Related Work

Models with discrete random variables have attracted much attention in the deep learning community (Jang et al., 2016; Maddison et al., 2016; van den Oord et al., 2017; Li et al., 2017; Shu and Nakayama, 2017). Some of these structures are more natural choices for language or speech data, which are inherently discrete. More specifically,

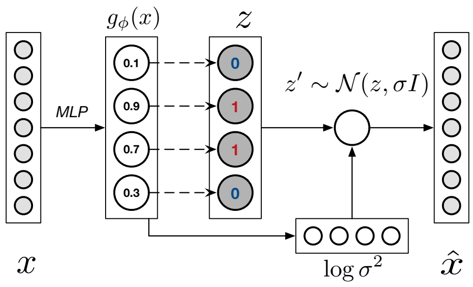

Figure 1: NASH for *end-to-end* semantic hashing. The inference network maps $x \to z$ using an MLP and the generative network recovers x as $z \to \hat{x}$.

van den Oord et al. (2017) combined VAEs with vector quantization to learn discrete latent representation, and demonstrated the utility of these learned representations on images, videos, and speech data. Li et al. (2017) leveraged both pairwise label and classification information to learn discrete hash codes, which exhibit state-of-the-art performance on image retrieval tasks.

For natural language processing (NLP), although significant research has been made to learn *continuous* deep representations for words or documents (Mikolov et al., 2013; Kiros et al., 2015; Shen et al., 2018), *discrete* neural representations have been mainly explored in learning word embeddings (Shu and Nakayama, 2017; Chen et al., 2017). In these recent works, words are represented as a vector of discrete numbers, which are very efficient storage-wise, while showing comparable performance on several NLP tasks, relative to continuous word embeddings. However, discrete representations that are learned in an *end-to-end* manner at the *sentence* or *document* level have been rarely explored. Also there is a lack of strict evaluation regarding their effectiveness. Our work focuses on learning discrete (binary) representations for text documents. Further, we employ semantic hashing (fast similarity search) as a mechanism to evaluate the quality of learned binary latent codes.

3 The Proposed Method

3.1 Hashing under the NVI Framework

Inspired by the recent success of variational autoencoders for various NLP problems (Miao et al., 2016; Bowman et al., 2015; Yang et al., 2017; Miao et al., 2017; Shen et al., 2017b; Wang et al., 2018), we approach the training of discrete (binary) latent variables from a generative perspective. Let x and z denote the input document and its corresponding binary hash code, respectively. Most of the previous text hashing methods focus on modeling the encoding distribution $p(z|x)$, or *hash function*, so the local/global pairwise similarity structure of documents in the original space is preserved in latent space (Zhang et al., 2010; Wang et al., 2013; Xu et al., 2015; Wang et al., 2014). However, the generative (decoding) process of reconstructing x from binary latent code z, *i.e.*, modeling distribution $p(x|z)$, has been rarely considered. Intuitively, latent codes learned from a model that accounts for the generative term should naturally encapsulate key semantic information from x because the generation/reconstruction objective is a function of $p(x|z)$. In this regard, the generative term provides a natural training objective for semantic hashing.

We define a generative model that simultaneously accounts for both the encoding distribution, $p(z|x)$, and decoding distribution, $p(x|z)$, by defining approximations $q_\phi(z|x)$ and $q_\theta(x|z)$, via inference and generative networks, $g_\phi(x)$ and $g_\theta(z)$, parameterized by ϕ and θ, respectively. Specifically, $x \in \mathcal{Z}_+^{|V|}$ is the bag-of-words (count) representation for the input document, where $|V|$ is the vocabulary size. Notably, we can also employ other count weighting schemes as input features x, *e.g.*, the term frequency-inverse document frequency (TFIDF) (Manning et al., 2008). For the encoding distribution, a latent variable z is first inferred from the input text x, by constructing an inference network $g_\phi(x)$ to approximate the true posterior distribution $p(z|x)$ as $q_\phi(z|x)$. Subsequently, the decoder network $g_\theta(z)$ maps z back into input space to reconstruct the original sequence x as $\hat{x}$, approximating $p(x|z)$ as $q_\theta(x|z)$ (as shown in Figure 1). This *cyclic* strategy, $x \to z \to \hat{x} \approx x$, provides the latent variable z with a better ability to generalize (Miao et al., 2016).

To tailor the NVI framework for semantic hashing, we cast z as a binary latent variable and assume a multivariate Bernoulli prior on z: $p(z) \sim \text{Bernoulli}(\gamma) = \prod_{i=1}^{l} \gamma_i^{z_i}(1-\gamma_i)^{1-z_i}$, where $\gamma_i \in [0,1]$ is component i of vector γ. Thus, the encoding (approximate posterior) distribution $q_\phi(z|x)$ is restricted to take the form $q_\phi(z|x) = \text{Bernoulli}(h)$, where $h = \sigma(g_\phi(x))$, $\sigma(\cdot)$ is the sigmoid function, and $g_\phi(\cdot)$ is the (nonlinear) inference network specified as a multilayer perceptron (MLP). As illustrated in Figure 1, we can obtain samples from the Bernoulli posterior either *deterministically* or *stochastically*. Suppose z is a l-bit hash code, for the *deterministic* binarization, we have, for $i = 1, 2, ..., l$:

$$z_i = \mathbf{1}_{\sigma(g_\phi^i(x))>0.5} = \frac{\text{sign}(\sigma(g_\phi^i(x) - 0.5) + 1}{2}, \tag{1}$$

where z is the binarized variable, and z_i and $g_\phi^i(x)$ denote the i-th dimension of z and $g_\phi(x)$, respectively. The standard Bernoulli sampling in (1) can be understood as setting a hard threshold at 0.5 for each representation dimension, therefore, the binary latent code is generated deterministically. Another strategy to obtain the discrete variable is to binarize h in a *stochastic* manner:

$$z_i = \mathbf{1}_{\sigma(g_\phi^i(x))>\mu_i} = \frac{\text{sign}(\sigma(g_\phi^i(x)) - \mu_i) + 1}{2}, \tag{2}$$

where $\mu_i \sim \text{Uniform}(0,1)$. Because of this sampling process, we do not have to assume a predefined threshold value like in (1).

3.2 Training with Binary Latent Variables

To estimate the parameters of the encoder and decoder networks, we would ideally maximize the marginal distribution $p(x) = \int p(z)p(x|z)dz$. However, computing this marginal is intractable in most cases of interest. Instead, we maximize a variational lower bound. This approach is typically employed in the VAE framework (Kingma and Welling, 2013):

$$\begin{aligned}\mathcal{L}_{\text{vae}} &= \mathbb{E}_{q_\phi(z|x)}\left[\log \frac{q_\theta(x|z)p(z)}{q_\phi(z|x)}\right], \qquad (3)\\ &= \mathbb{E}_{q_\phi(z|x)}[\log q_\theta(x|z)] - D_{KL}(q_\phi(z|x)||p(z)),\end{aligned}$$

where the Kullback-Leibler (KL) divergence $D_{KL}(q_\phi(z|x)||p(z))$ encourages the approximate posterior distribution $q_\phi(z|x)$ to be close to the multivariate Bernoulli prior $p(z)$. In this case, $D_{KL}(q_\phi(z|x)|p(z))$ can be written in closed-form as a function of $g_\phi(x)$:

$$\begin{aligned}D_{KL} &= g_\phi(x)\log\frac{g_\phi(x)}{\gamma}\\ &\quad + (1-g_\phi(x))\log\frac{1-g_\phi(x)}{1-\gamma}. \qquad (4)\end{aligned}$$

Note that the gradient for the KL divergence term above can be evaluated easily.

For the first term in (3), we should in principle estimate the influence of μ_i in (2) on $q_\theta(x|z)$ by averaging over the entire (uniform) noise distribution. However, a closed-form distribution does not exist since it is not possible to enumerate all possible configurations of z, especially when the latent dimension is large. Moreover, discrete latent variables are inherently incompatible with backpropagation, since the derivative of the sign function is zero for almost all input values. As a result, the exact gradients of L_{vae} wrt the inputs before binarization would be essentially all zero.

To estimate the gradients for binary latent variables, we utilize the straight-through (ST) estimator, which was first introduced by Hinton (2012). So motivated, the strategy here is to simply backpropagate through the hard threshold by approximating the gradient $\partial z/\partial\phi$ as 1. Thus, we have:

$$\begin{aligned}
&\frac{d\mathbb{E}_{q_\phi(z|x)}[\log q_\theta(x|z)]}{\partial\phi} \\
&= \frac{d\mathbb{E}_{q_\phi(z|x)}[\log q_\theta(x|z)]}{dz}\frac{dz}{d\sigma(g_\phi^i(x))}\frac{d\sigma(g_\phi^i(x))}{d\phi} \\
&\approx \frac{d\mathbb{E}_{q_\phi(z|x)}[\log q_\theta(x|z)]}{dz}\frac{d\sigma(g_\phi^i(x))}{d\phi} \qquad (5)
\end{aligned}$$

Although this is clearly a biased estimator, it has been shown to be a fast and efficient method relative to other gradient estimators for discrete variables, especially for the Bernoulli case (Bengio et al., 2013; Hubara et al., 2016; Theis et al., 2017). With the ST gradient estimator, the first loss term in (3) can be backpropagated into the encoder network to fine-tune the hash function $g_\phi(x)$.

For the approximate generator $q_\theta(x|z)$ in (3), let x_i denote the one-hot representation of ith word within a document. Note that $x = \sum_i x_i$ is thus the bag-of-words representation for document x. To reconstruct the input x from z, we utilize a *softmax* decoding function written as:

$$q(x_i = w|z) = \frac{\exp(z^T E x_w + b_w)}{\sum_{j=1}^{|V|}\exp(z^T E x_j + b_j)}, \qquad (6)$$

where $q(x_i = w|z)$ is the probability that x_i is word $w \in V$, $q_\theta(x|z) = \prod_i q(x_i = w|z)$ and $\theta = \{E, b_1, \dots, b_{|V|}\}$. Note that $E \in \mathbb{R}^{d\times|V|}$ can be interpreted as a word embedding matrix to be learned, and $\{b_i\}_{i=1}^{|V|}$ denote bias terms. Intuitively, the objective in (6) encourages the discrete vector z to be close to the embeddings for every word that appear in the input document x. As shown in Section 5.3.1, meaningful semantic structures can be learned and manifested in the word embedding matrix E.

3.3 Injecting Data-dependent Noise to z

To reconstruct text data x from sampled binary representation z, a deterministic decoder is typically utilized (Miao et al., 2016; Chaidaroon and Fang, 2017). Inspired by the success of employing stochastic decoders in image hashing applications (Dai et al., 2017; Theis et al., 2017), in our experiments, we found that injecting random Gaussian noise into z makes the decoder a more favorable regularizer for the binary codes, which in practice leads to stronger retrieval performance. Below, we invoke the *rate-distortion theory* to perform some further analysis, which leads to interesting findings.

Learning binary latent codes z to represent a continuous distribution $p(x)$ is a classical information theory concept known as *lossy source coding*. From this perspective, semantic hashing, which compresses an input document into compact binary codes, can be casted as a conventional *rate-distortion tradeoff* problem (Theis et al., 2017; Ballé et al., 2016):

$$\min \underbrace{-\log_2 R(z)}_{\text{Rate}} + \beta \cdot \underbrace{D(x,\hat{x})}_{\text{Distortion}}, \qquad (7)$$

where *rate* and *distortion* denote the effective code length, *i.e.*, the number of bits used, and the distortion introduced by the encoding/decoding sequence, respectively. Further, $\hat{x}$ is the reconstructed input and β is a hyperparameter that controls the tradeoff between the two terms.

Considering the case where we have a Bernoulli *prior* on z as $p(z) \sim \text{Bernoulli}(\gamma)$, and x conditionally drawn from a Gaussian distribution $p(x|z) \sim \mathcal{N}(Ez, \sigma^2 I)$. Here, $E = \{e_i\}_{i=1}^{|V|}$, where $e_i \in \mathbb{R}^d$ can be interpreted as a *codebook* with $|V|$ *codewords*. In our case, E corresponds to the *word embedding matrix* as in (6).

For the case of stochastic latent variable z, the objective function in (3) can be written in a form similar to the *rate-distortion* tradeoff:

$$\min \mathbb{E}_{q_\phi(z|x)}\left[\underbrace{-\log q_\phi(z|x)}_{\text{Rate}} + \underbrace{\frac{1}{2\sigma^2}}_{\beta}\underbrace{||x - Ez||_2^2}_{\text{Distortion}} + C\right], \qquad (8)$$

where C is a constant that encapsulates the prior distribution $p(z)$ and the Gaussian distribution normalization term. Notably, the trade-off hyper-parameter $\beta = \sigma^{-2}/2$ is closely related to the variance of the distribution $p(x|z)$. In other words, by controlling the variance σ, the model can adaptively explore different trade-offs between the *rate* and *distortion* objectives. However, the optimal trade-offs for distinct samples may be different.

Inspired by the observations above, we propose to inject data-dependent noise into latent variable z, rather than to setting the variance term σ^2 to a fixed value (Dai et al., 2017; Theis et al., 2017). Specifically, $\log \sigma^2$ is obtained via a one-layer MLP transformation from $g_\phi(x)$. Afterwards, we sample z' from $\mathcal{N}(z, \sigma^2 I)$, which then replace z in (6) to infer the probability of generating individual words (as shown in Figure 1). As a result, the variances are different for every input document x, and thus the model is provided with additional flexibility to explore various trade-offs between *rate* and *distortion* for different training observations. Although our decoder is not a strictly Gaussian distribution, as in (6), we found empirically that injecting data-dependent noise into z yields strong retrieval results, see Section 5.1.

3.4 Supervised Hashing

The proposed Neural Architecture for Semantic Hashing (NASH) can be extended to supervised hashing, where a mapping from latent variable z to labels y is learned, here parametrized by a two-layer MLP followed by a fully-connected softmax layer. To allow the model to explore and balance between maximizing the variational lower bound in (3) and minimizing the discriminative loss, the following joint training objective is employed:

$$\mathcal{L} = -\mathcal{L}_{\text{vae}}(\theta, \phi; x) + \alpha \mathcal{L}_{\text{dis}}(\eta; z, y). \qquad (9)$$

where η refers to parameters of the MLP classifier and α controls the relative weight between the variational lower bound ($\mathcal{L}_{\text{vae}}$) and discriminative loss ($\mathcal{L}_{\text{dis}}$), defined as the cross-entropy loss. The parameters $\{\theta, \phi, \eta\}$ are learned end-to-end *via* Monte Carlo estimation.

4 Experimental Setup

4.1 Datasets

We use the following three standard publicly available datasets for training and evaluation: (i) *Reuters21578*, containing 10,788 news documents, which have been classified into 90 different categories. (ii) *20Newsgroups*, a collection of 18,828 newsgroup documents, which are categorized into 20 different topics. (iii) TMC (stands for SIAM text mining competition), containing air traffic reports provided by NASA. TMC consists 21,519 training documents divided into 22 different categories. To make direct comparison with prior works, we employed the TFIDF features on these datasets supplied by (Chaidaroon and Fang, 2017), where the vocabulary sizes for the three datasets are set to 10,000, 7,164 and 20,000, respectively.

4.2 Training Details

For the inference networks, we employ a feed-forward neural network with 2 hidden layers (both with 500 units) using the ReLU non-linearity activation function, which transform the input documents, *i.e.*, TFIDF features in our experiments, into a continuous representation. Empirically, we found that stochastic binarization as in (2) shows stronger performance than deterministic binarization, and thus use the former in our experiments. However, we further conduct a systematic ablation study in Section 5.2 to compare the two binarization strategies.

Our model is trained using Adam (Kingma and Ba, 2014), with a learning rate of 1×10^{-3} for all parameters. We decay the learning rate by a factor of 0.96 for every 10,000 iterations. Dropout (Srivastava et al., 2014) is employed on the output of encoder networks, with the rate selected from $\{0.7, 0.8, 0.9\}$ on the validation set. To facilitate comparisons with previous methods, we set the dimension of z, *i.e.*, the number of bits within the hashing code) as 8, 16, 32, 64, or 128.

4.3 Baselines

We evaluate the effectiveness of our framework on both unsupervised and supervised semantic hashing tasks. We consider the following *unsupervised* baselines for comparisons: Locality Sensitive Hashing (LSH) (Datar et al., 2004), Stack Restricted Boltzmann Machines (S-RBM) (Salakhutdinov and Hinton, 2009), Spectral Hashing (SpH) (Weiss et al., 2009), Self-taught Hashing (STH) (Zhang et al., 2010) and Variational Deep Semantic Hashing (VDSH) (Chaidaroon and Fang, 2017).

Method	8 bits	16 bits	32 bits	64 bits	128 bits
LSH	0.2802	0.3215	0.3862	0.4667	0.5194
S-RBM	0.5113	0.5740	0.6154	0.6177	0.6452
SpH	0.6080	0.6340	0.6513	0.6290	0.6045
STH	0.6616	0.7351	0.7554	0.7350	0.6986
VDSH	0.6859	0.7165	0.7753	0.7456	0.7318
NASH	0.7113	0.7624	0.7993	0.7812	0.7559
NASH-N	0.7352	0.7904	0.8297	0.8086	0.7867
NASH-DN	**0.7470**	**0.8013**	**0.8418**	**0.8297**	**0.7924**

Table 1: Precision of the top 100 retrieved documents on *Reuters* dataset (*Unsupervised hashing*).

For supervised semantic hashing, we also compare NASH against a number of baselines: Supervised Hashing with Kernels (KSH) (Liu et al., 2012), Semantic Hashing using Tags and Topic Modeling (SHTTM) (Wang et al., 2013) and Supervised VDSH (Chaidaroon and Fang, 2017). It is worth noting that unlike all these baselines, our NASH model is trained end-to-end in one-step.

4.4 Evaluation Metrics

To evaluate the hashing codes for similarity search, we consider each document in the testing set as a query document. Similar documents to the query in the corresponding training set need to be retrieved based on the Hamming distance of their hashing codes, *i.e.* number of different bits. To facilitate comparison with prior work (Wang et al., 2013; Chaidaroon and Fang, 2017), the performance is measured with precision. Specifically, during testing, for a query document, we first retrieve the 100 nearest/closest documents according to the Hamming distances of the corresponding hash codes (i.e., the number of different bits). We then examine the percentage of documents among these 100 retrieved ones that belong to the same label (topic) with the query document (we consider documents having the same label as relevant pairs). The ratio of the number of relevant documents to the number of retrieved documents (fixed value of 100) is calculated as the precision score. The precision scores are further averaged over all test (query) documents.

5 Experimental Results

We experimented with four variants for our NASH model: (*i*) NASH: with deterministic decoder; (*ii*) NASH-N: with *fixed* random noise injected to decoder; (*iii*) NASH-DN: with *data-dependent* noise injected to decoder; (*iv*) NASH-DN-S: NASH-DN with supervised information during training.

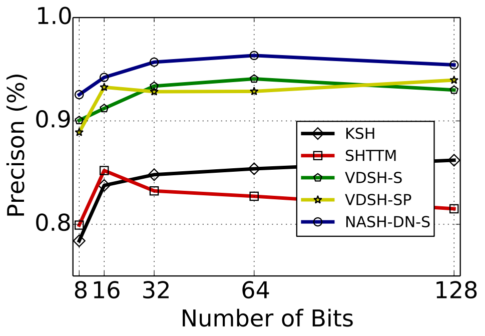

Figure 2: Precision of the top 100 retrieved documents on *Reuters* dataset (*Supervised hashing*), compared with other supervised baselines.

5.1 Semantic Hashing Evaluation

Table 1 presents the results of all models on Reuters dataset. Regarding unsupervised semantic hashing, all the NASH variants consistently outperform the baseline methods by a substantial margin, indicating that our model makes the most effective use of unlabeled data and manage to assign similar hashing codes, *i.e.*, with small Hamming distance to each other, to documents that belong to the same label. It can be also observed that the injection of noise into the decoder networks has improved the robustness of learned binary representations, resulting in better retrieval performance. More importantly, by making the variances of noise adaptive to the specific input, our NASH-DN achieves even better results, compared with NASH-N, highlighting the importance of exploring/learning the trade-off between rate and distortion objectives by the data itself. We observe the same trend and superiority of our NASH-DN models on the other two benchmarks, as shown in Tables 3 and 4.

Another observation is that the retrieval results tend to drop a bit when we set the length of hashing codes to be 64 or larger, which also happens for some baseline models. This phenomenon has been reported previously in Wang et al. (2012); Liu et al. (2012); Wang et al. (2013); Chaidaroon and Fang (2017), and the reasons could be twofold: (i) for longer codes, the number of data points that are assigned to a certain binary code decreases exponentially. As a result, many queries may fail to return any neighbor documents (Wang et al., 2012); (ii) considering the size of training data, it is likely that the model may overfit with long hash codes (Chaidaroon and Fang, 2017). However, even with longer hashing codes,

our NASH models perform stronger than the baselines in most cases (except for the 20Newsgroups dataset), suggesting that NASH can effectively allocate documents to informative/meaningful hashing codes even with limited training data.

We also evaluate the effectiveness of NASH in a *supervised* scenario on the Reuters dataset, where the label or topic information is utilized during training. As shown in Figure 2, our NASH-DN-S model consistently outperforms several supervised semantic hashing baselines, with various choices of hashing bits. Notably, our model exhibits higher Top-100 retrieval precision than VDSH-S and VDSH-SP, proposed by Chaidaroon and Fang (2017). This may be attributed to the fact that in VDSH models, the continuous embeddings are not optimized with their future binarization in mind, and thus could hurt the relevance of learned binary codes. On the contrary, our model is optimized in an end-to-end manner, where the gradients are directly backpropagated to the inference network (through the binary/discrete latent variable), and thus gives rise to a more robust hash function.

5.2 Ablation study

5.2.1 The effect of stochastic sampling

As described in Section 3, the binary latent variables z in NASH can be either deterministically (via (1)) or stochastically (via (2)) sampled. We compare these two types of binarization functions in the case of unsupervised hashing. As illustrated in Figure 3, stochastic sampling shows stronger retrieval results on all three datasets, indicating that endowing the sampling process of latent variables with more stochasticity improves the learned representations.

5.2.2 The effect of encoder/decoder networks

Under the variational framework introduced here, the encoder network, *i.e.*, hash function, and decoder network are jointly optimized to abstract semantic features from documents. An interesting question concerns what types of network should be leveraged for each part of our NASH model. In this regard, we further investigate the effect of

Category	Title/Subject	8-bit code	16-bit code
Baseball	*Dave Kingman for the hall of fame*	1 1 1 0 1 0 0 1	0 0 1 0 1 1 0 1 0 0 0 0 0 1 1 0

	Subliminal message flashing on TV	1 0 1 1 0 1 0 0	0 0 1 0 0 1 1 0 0 0 1 0 1 0 0 1

Table 5: Examples of learned compact hashing codes on *20Newsgroups* dataset.

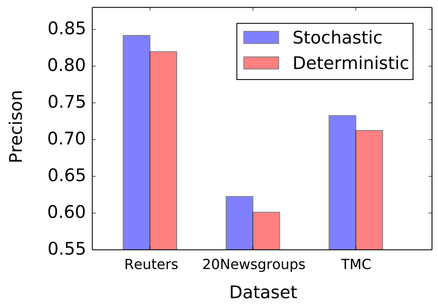

Figure 3: The precisions of the top 100 retrieved documents for NASH-DN with *stochastic* or *deterministic* binary latent variables.

using an encoder or decoder with different non-linearity, ranging from a linear transformation to two-layer MLPs. We employ a base model with an encoder of two-layer MLPs and a linear decoder (the setup described in Section 3), and the ablation study results are shown in Table 6.

Network	Encoder	Decoder
linear	0.5844	0.6225
one-layer MLP	0.6187	0.3559
two-layer MLP	0.6225	0.1047

Table 6: Ablation study with different encoder/decoder networks.

It is observed that for the encoder networks, increasing the non-linearity by stacking MLP layers leads to better empirical results. In other words, endowing the hash function with more modeling capacity is advantageous to retrieval tasks. However, when we employ a non-linear network for the decoder, the retrieval precision drops dramatically. It is worth noting that the only difference between linear transformation and one-layer MLP is whether a non-linear activation function is employed or not.

This observation may be attributed the fact that the decoder networks can be considered as a similarity measure between latent variable z and the word embeddings E_k for every word, and the probabilities for words that present in the document is maximized to ensure that z is informative. As a result, if we allow the decoder to be too expressive (*e.g.*, a one-layer MLP), it is likely that we will end up with a very flexible similarity measure but relatively less meaningful binary representations. This finding is consistent with several image hashing methods, such as SGH (Dai et al., 2017) or binary autoencoder (Carreira-Perpinán and Raziperchikolaei, 2015), where a linear decoder is typically adopted to obtain promising retrieval results. However, our experiments may not speak for other choices of encoder-decoder architectures, *e.g.*, LSTM-based sequence-to-sequence models (Sutskever et al., 2014) or DCNN-based autoencoder (Zhang et al., 2017).

5.3 Qualitative Analysis

5.3.1 Analysis of Semantic Information

To understand what information has been learned in our NASH model, we examine the matrix $E \in \mathbb{R}^{d \times l}$ in (6). Similar to (Miao et al., 2016; Larochelle and Lauly, 2012), we select the 5 nearest words according to the word vectors learned from NASH and compare with the corresponding results from NVDM.

As shown in Table 2, although our NASH model contains a binary latent variable, rather than a continuous one as in NVDM, it also effectively group semantically-similar words together in the learned vector space. This further demonstrates that the proposed generative framework manages to bypass the binary/discrete constraint and is able to abstract useful semantic information from documents.

5.3.2 Case Study

In Table 5, we show some examples of the learned binary hashing codes on *20Newsgroups* dataset. We observe that for both 8-bit and 16-bit cases, NASH typically compresses documents with shared topics into very similar binary codes. On the contrary, the hashing codes for documents with different topics exhibit much larger Hamming distance. As a result, relevant documents can be efficiently retrieved by simply computing their Hamming distances.

6 Conclusions

This paper presents a first step towards *end-to-end* semantic hashing, where the binary/discrete constraints are carefully handled with an effective gradient estimator. A neural variational framework is introduced to train our model. Motivated by the connections between the proposed method and *rate-distortion theory*, we inject data-dependent noise into the Bernoulli latent variable at the training stage. The effectiveness of our framework is demonstrated with extensive experiments.

Abstract

We present a new large-scale corpus of Question-Answer driven Semantic Role Labeling (QA-SRL) annotations, and the first high-quality QA-SRL parser. Our corpus, QA-SRL Bank 2.0, consists of over 250,000 question-answer pairs for over 64,000 sentences across 3 domains and was gathered with a new crowd-sourcing scheme that we show has high precision and good recall at modest cost. We also present neural models for two QA-SRL subtasks: detecting argument spans for a predicate and generating questions to label the semantic relationship. The best models achieve question accuracy of 82.6% and span-level accuracy of 77.6% (under human evaluation) on the full pipelined QA-SRL prediction task. They can also, as we show, be used to gather additional annotations at low cost.

1 Introduction

Learning semantic parsers to predict the predicate-argument structures of a sentence is a long standing, open challenge (Palmer et al., 2005; Baker et al., 1998). Such systems are typically trained from datasets that are difficult to gather,[1] but recent research has explored training non-experts to provide this style of semantic supervision (Abend and Rappoport, 2013; Basile et al., 2012; Reisinger et al., 2015; He et al., 2015). In this paper, we show for the first time that it is possible to go even further by crowdsourcing a large scale dataset that can be used to train high quality parsers at modest cost.

In 1950 Alan M. Turing ***published*** "Computing machinery and intelligence" in Mind, in which he ***proposed*** that machines could be ***tested*** for intelligence ***using*** questions and answers.

Predicate		**Question**	**Answer**
published	1	Who published something?	Alan M. Turing
	2	What was published?	"Computing Machinery and Intelligence"
	3	When was something published?	In 1950
proposed	4	Who proposed something?	Alan M. Turing
	5	What did someone propose?	that machines could be tested for intelligent using questions and answers
	6	When did someone propose something?	In 1950
tested	7	What can be tested?	machines
	8	What can something be tested for?	intelligence
	9	How can something be tested?	using questions and answers
using	10	What was being used?	questions and answers
	11	Why was something being used?	tested for intelligence

Figure 1: An annotated sentence from our dataset. Question 6 was not produced by crowd workers in the initial collection, but was produced by our parser as part of Data Expansion (see Section 5.)

We adopt the Question-Answer-driven Semantic Role Labeling (QA-SRL) (He et al., 2015) annotation scheme. QA-SRL is appealing because it is intuitive to non-experts, has been shown to closely match the structure of traditional predicate-argument structure annotation schemes (He et al., 2015), and has been used for end tasks such as Open IE (Stanovsky and Dagan, 2016). In QA-SRL, each predicate-argument relationship is labeled with a question-answer pair (see Figure 1). He et al. (2015) showed that high precision QA-SRL annotations can be gathered with limited training but that high recall is challenging to achieve; it is relatively easy to gather answerable questions, but difficult to ensure that every possible question is labeled for every verb. For this reason, they hired and trained hourly annotators and only labeled a relatively small dataset (3000 sentences).

Our first contribution is a new, scalable approach for crowdsourcing QA-SRL. We introduce a streamlined web interface (including an auto-suggest mechanism and automatic quality control to boost recall) and use a validation stage to en-

* Much of this work was done while these authors were at the Allen Institute for Artificial Intelligence.

[1]The PropBank (Bonial et al., 2010) and FrameNet (Ruppenhofer et al., 2016) annotation guides are 89 and 119 pages, respectively.

sure high precision (i.e. all the questions must be answerable). With this approach, we produce QA-SRL Bank 2.0, a dataset with 133,479 verbs from 64,018 sentences across 3 domains, totaling 265,140 question-answer pairs, in just 9 days. Our analysis shows that the data has high precision with good recall, although it does not cover every possible question. Figure 1 shows example annotations.

Using this data, our second contribution is a comparison of several new models for learning a QA-SRL parser. We follow a pipeline approach where the parser does (1) unlabeled *span detection* to determine the arguments of a given verb, and (2) *question generation* to label the relationship between the predicate and each detected span. Our best model uses a span-based representation similar to that introduced by Lee et al. (2016) and a custom LSTM to decode questions from a learned span encoding. Our model does not require syntactic information and can be trained directly from the crowdsourced span labels.

Experiments demonstrate that the model does well on our new data, achieving up to 82.2% span-detection F1 and 47.2% exact-match question accuracy relative to the human annotations. We also demonstrate the utility of learning to predict easily interpretable QA-SRL structures, using a simple data bootstrapping approach to expand our dataset further. By tuning our model to favor recall, we over-generate questions which can be validated using our annotation pipeline, allowing for greater recall without requiring costly redundant annotations in the question writing step. Performing this procedure on the training and development sets grows them by 20% and leads to improvements when retraining our models. Our final parser is highly accurate, achieving 82.6% question accuracy and 77.6% span-level precision in an human evaluation. Our data, code, and trained models will be made publicly available.[2]

2 Data Annotation

A QA-SRL annotation consists of a set of question-answer pairs for each verbal predicate in a sentence, where each answer is a set of contiguous spans from the sentence. QA-SRL questions are defined by a 7-slot template shown in Table 1. We introduce a crowdsourcing pipeline to collect annotations rapidly, cheaply, and at large scale.

What did not

What did someone

What did something

What didn't

Figure 2: Interface for the generation step. Autocomplete shows completions of the current QA-SRL slot, and auto-suggest shows fully-formed questions (highlighted green) based on the previous questions.

Pipeline Our crowdsourcing pipeline consists of a *generation* and *validation* step. In the generation step, a sentence with one of its verbs marked is shown to a single worker, who must write QA-SRL questions for the verb and highlight their answers in the sentence. The questions are passed to the validation step, where n workers answer each question or mark it as *invalid*. In each step, no two answers to distinct questions may overlap with each other, to prevent redundancy.

Instructions Workers are instructed that a *valid* question-answer pair must satisfy three criteria: 1) the question is grammatical, 2) the question-answer pair is asking about the time, place, participants, etc., of the target verb, and 3) all correct answers to each question are given.

Autocomplete We provide an autocomplete drop-down to streamline question writing. Autocomplete is implemented as a Non-deterministic Finite Automaton (NFA) whose states correspond to the 7 QA-SRL slots paired with a partial representation of the question's syntax. We use the NFA to make the menu more compact by disallowing obviously ungrammatical combinations (e.g., *What did been appeared?*), and the syntactic representation to auto-suggest complete questions about arguments that have not yet been covered (see Figure 2). The auto-suggest feature significantly reduces the number of keystrokes required to enter new questions after the first one, speeding up the annotation process and making it easier for annotators to provide higher recall.

Wh	Aux	Subj	Verb	Obj	Prep	Misc
Who			blamed	someone		
What	did	someone	blame	something	on	
Who			refused		to	do something
When	did	someone	refuse		to	do something
Who	might		put	something		somewhere
Where	might	someone	put	something		

Table 1: Example QA-SRL questions, decomposed into their slot-based representation. See He et al. (2015) for the full details. All slots draw from a small, deterministic set of options, including verb tense ($present$, $pastparticiple$, etc.) Here we have replaced the verb-tense slot with its conjugated form.

	Wikipedia	Wikinews	Science
Sentences	15,000	14,682	46,715
Verbs	32,758	34,026	66,653
Questions	75,867	80,081	143,388
Valid Qs	67,146	70,555	127,455

Table 2: Statistics for the dataset with questions written by workers across three domains.

Payment and quality control Generation pays 5c for the first QA pair (required), plus 5c, 6c, etc. for each successive QA pair (optional), to boost recall. The validation step pays 8c per verb, plus a 2c bonus per question beyond four. Generation workers must write at least 2 questions per verb and have 85% of their questions counted valid, and validators must maintain 85% answer span agreement with others, or they are disqualified from further work. A validator's answer is considered to agree with others if their answer span overlaps with answer spans provided by a majority of workers.

Preprocessing We use the Stanford CoreNLP tools (Manning et al., 2014) for sentence segmentation, tokenizing, and POS-tagging. We identify verbs by POS tag, with heuristics to filter out auxiliary verbs while retaining non-auxiliary uses of "have" and "do." We identify conjugated forms of each verb for the QA-SRL templates by finding them in Wiktionary.[3]

Dataset We gathered annotations for 133,479 verb mentions in 64,018 sentences (1.27M tokens) across 3 domains: Wikipedia, Wikinews, and science textbook text from the Textbook Question Answering (TQA) dataset (Kembhavi et al., 2017). We partitioned the source documents into train, dev, and test, sampled paragraph-wise from each document with an 80/10/10 split by sentence.

Annotation in our pipeline with $n = 2$ validators took 9 days on Amazon Mechanical Turk.[4] 1,165 unique workers participated, annotating a total of 299,308 questions. Of these, 265,140 (or 89%) were considered valid by both validators, for an average of 1.99 valid questions per verb and 4.14 valid questions per sentence. See Table 2 for a breakdown of dataset statistics by domain. The total cost was $43,647.33, for an average of 32.7c per verb mention, 14.6c per question, or 16.5c per valid question. For comparison, He et al. (2015) interviewed and hired contractors to annotate data at much smaller scale for a cost of about 50c per verb. Our annotation scheme is cheaper, far more scalable, and provides more (though noisier) supervision for answer spans.

To allow for more careful evaluation, we validated 5,205 sentences at a higher density (up to 1,000 for each domain in dev and test), re-running the generated questions through validation with $n = 3$ for a total of 6 answer annotations for each question.

Quality Judgments of question validity had moderate agreement. About 89.5% of validator judgments rated a question as valid, and the agreement rate between judgments of the same question on whether the question is invalid is 90.9%. This gives a Fleiss's Kappa of 0.51. In the higher-density re-run, validators were primed to be more critical: 76.5% of judgments considered a question valid, and agreement was at 83.7%, giving a Fleiss's Kappa of 0.55.

Despite being more critical in the denser annotation round, questions marked valid in the original dataset were marked valid by the new annotators in 86% of cases, showing our data's relatively high precision. The high precision of our annotation pipeline is also backed up by our small-scale manual evaluation (see Coverage below).

Answer spans for each question also exhibit

[3]www.wiktionary.org

[4]www.mturk.com

	P	R	F
He et al. (2015)	97.5	86.6	91.7
This work	95.7	72.4	82.4
This work (unfiltered)	94.9	85.4	89.9

Table 3: Precision and recall of our annotation pipeline on a merged and validated subset of 100 verbs. The unfiltered number represents relaxing the restriction that none of 2 validators marked the question as invalid.

good agreement. On the original dataset, each answer span has a 74.8% chance to exactly match one provided by another annotator (up to two), and on the densely annotated subset, each answer span has an 83.1% chance to exactly match one provided by another annotator (up to five).

Coverage Accurately measuring recall for QA-SRL annotations is an open challenge. For example, question 6 in Figure 1 reveals an inferred temporal relation that would not be annotated as part of traditional SRL. Exhaustively enumerating the full set of such questions is difficult, even for experts.

However, we can compare to the original QA-SRL dataset (He et al., 2015), where Wikipedia sentences were annotated with 2.43 questions per verb. Our data has lower—but loosely comparable—recall, with 2.05 questions per verb in Wikipedia.

In order to further analyze the quality of our annotations relative to (He et al., 2015), we reannotate a 100-verb subset of their data both manually (aiming for exhaustivity) and with our crowdsourcing pipeline. We merge the three sets of annotations, manually remove bad questions (and their answers), and calculate the precision and recall of the crowdsourced annotations and those of He et al. (2015) against this pooled, filtered dataset (using the span detection metrics described in Section 4). Results, shown in Table 3, show that our pipeline produces comparable precision with only a modest decrease in recall. Interestingly, re-adding the questions rejected in the validation step greatly increases recall with only a small decrease in precision, showing that validators sometimes rejected questions considered valid by the authors. However, we use the filtered dataset for our experiments, and in Section 5, we show how another crowdsourcing step can further improve recall.

3 Models

Given a sentence $\boldsymbol{X} = x_0, \dots, x_n$, the goal of a QA-SRL parser is to produce a set of tuples $(v_i, \boldsymbol{Q_i}, \mathcal{S}_i)$, where $v \in \{0, \dots, n\}$ is the index of a verbal predicate, $\boldsymbol{Q}_i$ is a question, and $\mathcal{S}_i \in \{(i,j) \mid i,j \in [0,n], j \geq i\}$ is a set of spans which are valid answers. Our proposed parsers construct these tuples in a three-step pipeline:

1. *Verbal predicates* are identified using the same POS-tags and heuristics as in data collection (see Section 2).
2. *Unlabeled span detection* selects a set $\mathcal{S}_v$ of spans as arguments for a given verb v.
3. *Question generation* predicts a question for each span in $\mathcal{S}_v$. Spans are then grouped by question, giving each question a set of answers.

We describe two models for unlabeled span detection in section 3.1, followed by question generation in section 3.2. All models are built on an LSTM encoding of the sentence. Like He et al. (2017), we start with an input $\boldsymbol{X}_v = \{\boldsymbol{x}_0 \dots \boldsymbol{x}_n\}$, where the representation $\boldsymbol{x}_i$ at each time step is a concatenation of the token w_i's embedding and an embedded binary feature $(i = v)$ which indicates whether w_i is the predicate under consideration. We then compute the output representation $\boldsymbol{H}_v = \text{BiLSTM}(\boldsymbol{X}_v)$ using a stacked alternating LSTM (Zhou and Xu, 2015) with highway connections (Srivastava et al., 2015) and recurrent dropout (Gal and Ghahramani, 2016). Since the span detection and question generation models both use an LSTM encoding, this component could in principle be shared between them. However, in preliminary experiments we found that sharing hurt performance, so for the remainder of this work each model is trained independently.

3.1 Span Detection

Given an encoded sentence $\boldsymbol{H}_v$, the goal of span detection is to select the spans $\mathcal{S}_v$ that correspond to arguments of the given predicate. We explore two models: a sequence-tagging model with BIO encoding, and a span-based model which assigns a probability to every possible span.

3.1.1 BIO Sequence Model

Our BIO model predicts a set of spans via a sequence $\boldsymbol{y}$ where each $y_i \in \{\boldsymbol{B}, \boldsymbol{I}, \boldsymbol{O}\}$, representing a token at the beginning, interior, or outside of any span, respectively. Similar to He et al.

(2017), we make independent predictions for each token at training time, and use Viterbi decoding to enforce hard BIO-constraints[5] at test time. The resulting sequences are in one-to-one correspondence with sets $\mathcal{S}_v$ of spans which are pairwise non-overlapping. The locally-normalized BIO-tag distributions are computed from the BiLSTM outputs $\boldsymbol{H}_v = \{\boldsymbol{h}_{v0}, \ldots, \boldsymbol{h}_{vn}\}$:

$$p(y_t \mid \boldsymbol{x}) \propto exp(\boldsymbol{w}_{\text{tag}}^{\intercal}\text{MLP}(\boldsymbol{h}_{vt}) + \boldsymbol{b}_{\text{tag}}) \quad (1)$$

3.1.2 Span-based Model

Our span-based model makes independent binary decisions for all $O(n^2)$ spans in the sentence. Following Lee et al. (2016), the representation of a span (i, j) is the concatenation of the BiLSTM output at each endpoint:

$$\boldsymbol{s}_{vij} = [\boldsymbol{h}_{vi}, \boldsymbol{h}_{vj}]. \quad (2)$$

The probability that the span is an argument of predicate v is computed by the sigmoid function:

$$p(y_{ij} \mid \boldsymbol{X}_v) = \sigma(\boldsymbol{w}_{\text{span}}^{\intercal}\text{MLP}(\boldsymbol{s}_{vij}) + \boldsymbol{b}_{\text{span}}) \quad (3)$$

At training time, we minimize the binary cross entropy summed over all n^2 possible spans, counting a span as a positive example if it appears as an answer to any question.

At test time, we choose a threshold τ and select every span that the model assigns probability greater than τ, allowing us to trade off precision and recall.

3.2 Question Generation

We introduce two question generation models. Given a span representation $\boldsymbol{s}_{vij}$ defined in subsubsection 3.1.2, our models generate questions by picking a word for each question slot (see Section 2). Each model calculates a joint distribution $p(\boldsymbol{y} \mid \boldsymbol{X}_v, \boldsymbol{s}_{vij})$ over values $\boldsymbol{y} = (y_1, \ldots, y_7)$ for the question slots given a span $\boldsymbol{s}_{vij}$, and is trained to minimize the negative log-likelihood of gold slot values.

3.2.1 Local Model

The local model predicts the words for each slot independently:

$$p(y_k \mid \boldsymbol{X}_v, \boldsymbol{s}_{vij}) \propto \exp(\boldsymbol{w}_k^{\intercal}\text{MLP}(\boldsymbol{s}_{vij}) + \boldsymbol{b}_k). \quad (4)$$

[5]E.g., an I-tag should only follow a B-tag.

3.2.2 Sequence Model

The sequence model uses the machinery of an RNN to share information between slots. At each slot k, we apply a multiple layers of LSTM cells:

$$\boldsymbol{h}_{l,k}, \boldsymbol{c}_{l,k} = \text{LSTMCELL}_{l,k}(\boldsymbol{h}_{l-1,k}, \boldsymbol{h}_{l,k-1}, \boldsymbol{c}_{l,k-1}) \quad (5)$$

where the initial input at each slot is a concatenation of the span representation and the embedding of the previous word of the question: $\boldsymbol{h}_{0,k} = [\boldsymbol{s}_{vij}; \boldsymbol{y}_{k-1}]$. Since each question slot predicts from a different set of words, we found it beneficial to use separate weights for the LSTM cells at each slot k. During training, we feed in the gold token at the previous slot, while at test time, we use the predicted token. The output distribution at slot k is computed via the final layers' output vector $\boldsymbol{h}_{Lk}$:

$$p(y_k \mid \boldsymbol{X}_v, \boldsymbol{s}_{vij}) \propto \exp(\boldsymbol{w}_k^{\intercal}\text{MLP}(\boldsymbol{h}_{Lk}) + \boldsymbol{b}_k) \quad (6)$$

4 Initial Results

Automatic evaluation for QA-SRL parsing presents multiple challenges. In this section, we introduce automatic metrics that can help us compare models. In Section 6, we will report human evaluation results for our final system.

4.1 Span Detection

Metrics We evaluate span detection using a modified notion of precision and recall. We count predicted spans as correct if they match any of the labeled spans in the dataset. Since each predicted span could potentially be a match to multiple questions (due to overlapping annotations) we map each predicted span to one matching question in the way that maximizes measured recall using maximum bipartite matching. We use both exact match and intersection-over-union (IOU) greater than 0.5 as matching criteria.

Results Table 4 shows span detection results on the development set. We report results for the span-based models at two threshold values τ: $\tau = 0.5$, and $\tau = \tau^*$ maximizing F1. The span-based model significantly improves over the BIO model in both precision and recall, although the difference is less pronounced under IOU matching.

4.2 Question Generation

Metrics Like all generation tasks, evaluation metrics for question generation must contend with

Exact Match			
	P	R	F
BIO	69.0	75.9	72.2
Span ($\tau = 0.5$)	81.7	80.9	81.3
Span ($\tau = \tau*$)	80.0	84.7	82.2
IOU $\geq$ 0.5			
	P	R	F
BIO	80.4	86.0	83.1
Span ($\tau = 0.5$)	87.5	84.2	85.8
Span ($\tau = \tau*$)	83.8	93.0	88.1

Table 4: Results for Span Detection on the dense development dataset. Span detection results are given with the cutoff threshold τ at 0.5, and at the value which maximizes F-score. The top chart lists precision, recall and F-score with exact span match, while the bottom reports matches where the intersection over union (IOU) is ≥ 0.5.

	EM	PM	SA
Local	44.2	62.0	83.2
Seq.	47.2	62.3	82.9

Table 5: Question Generation results on the dense development set. **EM** - Exact Match accuracy, **PM** - Partial Match Accuracy, **SA** - Slot-level accuracy

the fact that there are in general multiple possible valid questions for a given predicate-argument pair. For instance, the question "Who did someone blame something on?" may be rephrased as "Who was blamed for something?" However, due to the constrained space of possible questions defined by QA-SRL's slot format, accuracy-based metrics can still be informative. In particular, we report the rate at which the predicted question exactly matches the gold question, as well as a relaxed match where we only count the question word (WH), subject (SBJ), object (OBJ) and Miscellaneous (Misc) slots (see Table 1). Finally, we report average slot-level accuracy.

Results Table 5 shows the results for question generation on the development set. The sequential model's exact match accuracy is significantly higher, while word-level accuracy is roughly comparable, reflecting the fact that the local model learns the slot-level posteriors.

4.3 Joint results

Table 6 shows precision and recall for joint span detection and question generation, using exact match for both. This metric is exceedingly hard, but it shows that almost 40% of predictions are exactly correct in both span and question. In Section 6, we use human evaluation to get a more accurate assessment of our model's accuracy.

	P	R	F
Span + Local	37.8	43.7	40.6
Span + Seq. ($\tau = 0.5$)	39.6	45.8	42.4

Table 6: Joint span detection and question generation results on the dense development set, using exact-match for both spans and questions.

5 Data Expansion

Since our trained parser can produce full QA-SRL annotations, its predictions can be validated by the same process as in our original annotation pipeline, allowing us to focus annotation efforts towards filling potential data gaps.

By detecting spans at a low probability cutoff, we over-generate QA pairs for already-annotated sentences. Then, we filter out QA pairs whose answers overlap with answer spans in the existing annotations, or whose questions match existing questions. What remains are candidate QA pairs which fill gaps in the original annotation. We pass these questions to the validation step of our crowdsourcing pipeline with $n = 3$ validators, resulting in new labels.

We run this process on the training and development partitions of our dataset. For the development set, we use the trained model described in the previous section. For the training set, we use a relaxed version of jackknifing, training 5 models over 5 different folds. We generate 92,080 questions at a threshold of $\tau = 0.2$. Since in this case many sentences have only one question, we restructure the pay to a 2c base rate with a 2c bonus per question after the first (still paying no less than 2c per question).

Data statistics 46,017 (50%) of questions run through the expansion step were considered valid by all three annotators. In total, after filtering, the expansion step increased the number of valid questions in the train and dev partitions by 20%. However, for evaluation, since our recall metric identifies a single question for each answer span (via bipartite matching), we filter out likely question paraphrases by removing questions in the ex-

panded development set whose answer spans have two overlaps with the answer spans of one question in the original annotations. After this filtering, the expanded development set we use for evaluation has 11.5% more questions than the original development set.

The total cost including MTurk fees was $8,210.66, for a cost of 8.9c per question, or 17.8c per valid question. While the cost per valid question was comparable to the initial annotation, we gathered many more negative examples (which may serve useful in future work), and this method allowed us to focus on questions that were missed in the first round and improve the exhaustiveness of the annotation (whereas it is not obvious how to make fully crowdsourced annotation more exhaustive at a comparable cost per question).

Retrained model We retrained our final model on the training set extended with the new valid questions, yielding modest improvements on both span detection and question generation in the development set (see Table 7). The span detection numbers are higher than on the original dataset, because the expanded development data captures true positives produced by the original model (and the resulting increase in precision can be traded off for recall as well).

6 Final Evaluation

We use the crowdsourced validation step to do a final human evaluation of our models. We test 3 parsers: the span-based span detection model paired with each of the local and sequential question generation models trained on the initial dataset, and our final model (span-based span detection and sequential question generation) trained with the expanded data.

Methodology On the 5,205 sentence densely annotated subset of dev and test, we generate QA-SRL labels with all of the models using a span detection threshold of $\tau = 0.2$ and combine the questions with the existing data. We filter out questions that fail the autocomplete grammaticality check (counting them invalid) and pass the data into the validation step, annotating each question to a total of 6 validator judgments. We then compute question and span accuracy as follows: A question is considered correct if 5 out of 6 annotators consider it valid, and a span is considered correct if its generated question is correct and the span is among those selected for the question by validators. We rank all questions and spans by the threshold at which they are generated, which allows us to compute accuracy at different levels of recall.

Results Figure 3 shows the results. As expected, the sequence-based question generation models are much more accurate than the local model; this is largely because the local model generated many questions that failed the grammaticality check. Furthermore, training with our expanded data results in more questions and spans generated at the same threshold. If we choose a threshold value which gives a similar number of questions per sentence as were labeled in the original data annotation (2 questions / verb), question and span accuracy are 82.64% and 77.61%, respectively.

Table 8 shows the output of our best system on 3 randomly selected sentences from our development set (one from each domain). The model was overall highly accurate—only one question and 3 spans are considered incorrect, and each mistake is nearly correct,[6] even when the sentence contains a negation.

[6]The incorrect question "When did someone appear?" would be correct if the Prep and Misc slots were corrected to read "When did someone appear to do something?"

Figure 3: Human evaluation accuracy for questions and spans, as each model's span detection threshold is varied. Questions are considered correct if 5 out of 6 annotators consider it valid. Spans are considered correct if their question was valid, and the span was among those labeled by human annotators for that question. The vertical line indicates a threshold value where the number of questions per sentence matches that of the original labeled data (2 questions / verb).

7 Related Work

Resources and formalisms for semantics often require expert annotation and underlying syntax (Palmer et al., 2005; Baker et al., 1998; Banarescu et al., 2013). Some more recent semantic resources require less annotator training, or can be crowdsourced (Abend and Rappoport, 2013; Reisinger et al., 2015; Basile et al., 2012; Michael et al., 2018). In particular, the original QA-SRL (He et al., 2015) dataset is annotated by freelancers, while we developed streamlined crowdsourcing approaches for more scalable annotation.

Crowdsourcing has also been used for indirectly annotating syntax (He et al., 2016; Duan et al., 2016), and to complement expert annotation of SRL (Wang et al., 2018). Our crowdsourcing approach draws heavily on that of Michael et al. (2018), with automatic two-stage validation for the collected question-answer pairs.

More recently, models have been developed for these newer semantic resources, such as UCCA (Teichert et al., 2017) and Semantic Proto-Roles (White et al., 2017). Our work is the first high-quality parser for QA-SRL, which has several unique modeling challenges, such as its highly structured nature and the noise in crowdsourcing.

Several recent works have explored neural models for SRL tasks (Collobert and Weston, 2007; FitzGerald et al., 2015; Swayamdipta et al., 2017; Yang and Mitchell, 2017), many of which employ a BIO encoding (Zhou and Xu, 2015; He et al., 2017). Recently, span-based models have proven to be useful for question answering (Lee et al., 2016) and coreference resolution (Lee et al., 2017), and PropBank SRL (He et al., 2018).

8 Conclusion

In this paper, we demonstrated that QA-SRL can be scaled to large datasets, enabling a new methodology for labeling and producing predicate-argument structures at a large scale. We presented a new, scalable approach for crowdsourcing QA-SRL, which allowed us to collect QA-SRL Bank 2.0, a new dataset covering over 250,000 question-answer pairs from over 64,000 sentences, in just 9 days. We demonstrated the utility of this data by training the first parser which is able to produce high-quality QA-SRL structures. Finally, we demonstrated that the validation stage of our crowdsourcing pipeline, in combination with our parser tuned for recall, can be used to add new annotations to the dataset, increasing recall.

Abstract

Semantic role labeling (SRL) is dedicated to recognizing the predicate-argument structure of a sentence. Previous studies have shown syntactic information has a remarkable contribution to SRL performance. However, such perception was challenged by a few recent neural SRL models which give impressive performance without a syntactic backbone. This paper intends to quantify the importance of syntactic information to dependency SRL in deep learning framework. We propose an enhanced argument labeling model companying with an extended k-order argument pruning algorithm for effectively exploiting syntactic information. Our model achieves state-of-the-art results on the CoNLL-2008, 2009 benchmarks for both English and Chinese, showing the quantitative significance of syntax to neural SRL together with a thorough empirical survey over existing models.

1 Introduction

Semantic role labeling (SRL), namely semantic parsing, is a shallow semantic parsing task, which aims to recognize the predicate-argument structure of each predicate in a sentence, such as *who* did *what* to *whom*, *where* and *when*, etc. Specifically, we seek to identify arguments and label their semantic roles given a predicate. SRL is an important method to obtain semantic information beneficial to a wide range of natural language processing (NLP) tasks, including machine translation (Shi et al., 2016), question answering (Berant et al., 2013; Yih et al., 2016) and discourse relation sense classification (Mihaylov and Frank, 2016).

There are two formulizations for semantic predicate-argument structures, one is based on constituents (i.e., phrase or span), the other is based on dependencies. The latter proposed by the CoNLL-2008 shared task (Surdeanu et al., 2008) is also called semantic dependency parsing, which annotates the heads of arguments rather than phrasal arguments. Generally, SRL is decomposed into multi-step classification subtasks in pipeline systems, consisting of predicate identification and disambiguation, argument identification and classification.

In prior work of SRL, considerable attention has been paid to feature engineering that struggles to capture sufficient discriminative information, while neural network models are capable of extracting features automatically. In particular, syntactic information, including syntactic tree feature, has been show extremely beneficial to SRL since a larger scale of empirical verification of Punyakanok et al. (2008). However, all the work had to take the risk of erroneous syntactic input, leading to an unsatisfactory performance.

To alleviate the above issues, Marcheggiani et al. (2017) propose a simple but effective model for dependency SRL without syntactic input. It seems that neural SRL does not have to rely on syntactic features, contradicting with the belief that syntax is a necessary prerequisite for SRL as early as Gildea and Palmer (2002). This dramatic contradiction motivates us to make a thorough exploration on syntactic contribution to SRL.

This paper will focus on semantic dependency parsing and formulate SRL as one or two se-

quence tagging tasks with predicate-specific encoding. With the help of the proposed k-order argument pruning algorithm over syntactic tree, our model obtains state-of-the-art scores on the CoNLL benchmarks for both English and Chinese.

In order to quantitatively evaluate the contribution of syntax to SRL, we adopt the ratio between labeled F_1 score for semantic dependencies (Sem-F_1) and the labeled attachment score (LAS) for syntactic dependencies introduced by CoNLL-2008 Shared Task[1] as evaluation metric. Considering that various syntactic parsers contribute different syntactic inputs with various range of quality levels, the ratio provides a fairer comparison between syntactically-driven SRL systems, which will be surveyed by our empirical study.

2 Model

To fully disclose the predicate-argument structure, typical SRL systems have to step by step perform four subtasks. Since the predicates in CoNLL-2009 (Hajič et al., 2009) corpus have been pre-identified, we need to tackle three other subtasks, which are formulized into two-step pipeline in this work, predicate disambiguation and argument labeling. Namely, we do the work of argument identification and classification in one model.

Argument structure for each known predicate will be disclosed by our argument labeler over a sequence including possible arguments (candidates). There are two ways to determine the sequence, one is to simply input the entire sentence as a syntax-agnostic SRL system does, the other is to select words according to syntactic parse tree around the predicate as most previous SRL systems did. The latter strategy usually works through a syntactic tree based argument pruning algorithm. We will use the proposed k-order argument pruning algorithm (Section 2.1) to get a sequence $w = (w_1, \dots, w_n)$ for each predicate. Then, we represent each word $w_i \in w$ as x_i (Section 2.2). Eventually, we obtain contextual features with sequence encoder (Section 2.3). The overall role labeling model is depicted in Figure 1.

2.1 Argument Pruning

As pointed out by Punyakanok et al. (2008), syntactic information is most relevant in identifying

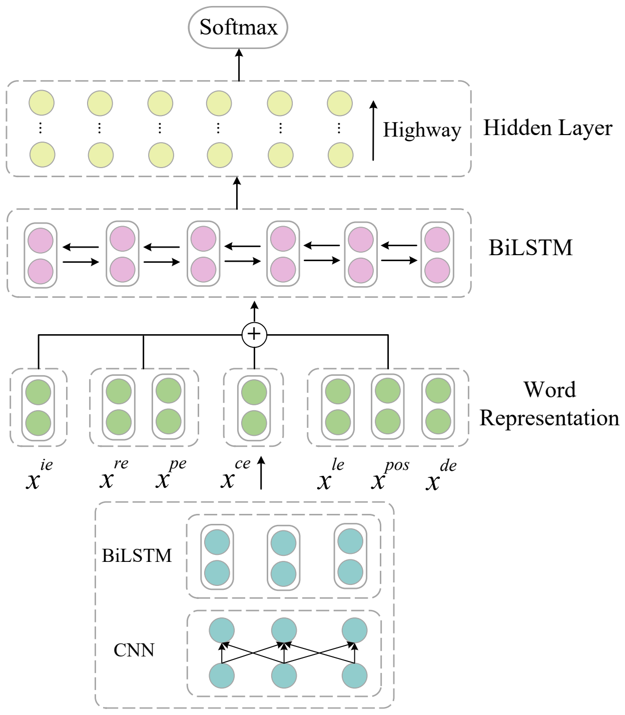

Figure 1: The Argument Labeling Model

the arguments, and the most crucial contribution of full parsing is in the pruning stage. In this paper, we propose a k-order argument pruning algorithm inspired by Zhao et al. (2009b). First of all, for node n and its descendant n_d in a syntactic dependency tree, we define the *order* to be the *distance* between the two nodes, denoted as $\mathcal{D}(n, n_d)$. Then we define k-order descendants of given node satisfying $\mathcal{D}(n, n_d) = k$, and k-order traversal that visits each node from the given node to its descendant nodes within k-th order. Note that the definition of k-order traversal is somewhat different from tree traversal in terminology.

A brief description of the proposed k-order pruning algorithm is given as follow. Initially, we set a given predicate as the current node in a syntactic dependency tree. Then, collect all its argument candidates by the strategy of k-order traversal. Afterwards, reset the current node to its syntactic head and repeat the previous step till the root of the tree. Finally, collect the root and stop. The k-order argument algorithm is presented in Algorithm 1 in detail. An example of a syntactic dependency tree for sentence *She began to trade the art for money* is shown in Figure 2.

The main reasons for applying the extended k-order argument pruning algorithm are two-fold.

[1]CoNLL-2008 is an English-only task, while CoNLL-2009 extends to a multilingual one. Their main difference is that predicates have been beforehand indicated for the latter.

Algorithm 1 k-order argument pruning algorithm

Input: A predicate p, the root node r given a syntactic dependency tree T, the order k

Output: The set of argument candidates S

```
1: initialization set $p$ as current node $c$, $c = p$
2: for each descendant $n_i$ of $c$ in $T$ do
3:     if $\mathcal{D}(c, n_i) \leq k$ and $n_i \notin S$ then
4:         $S = S + n_i$
5:     end if
6: end for
7: find the syntactic head $c_h$ of $c$, and let $c = c_h$
8: if $c = r$ then
9:     $S = S + r$
10: else
11:     goto step 2
12: end if
13: return argument candidates set $S$
```

First, previous standard pruning algorithm may hurt the argument coverage too much, even though indeed arguments usually tend to surround their predicate in a close distance. As a sequence tagging model has been applied, it can effectively handle the imbalanced distribution between arguments and non-arguments, which is hardly tackled by early argument classification models that commonly adopt the standard pruning algorithm. Second, the extended pruning algorithm provides a better trade-off between computational cost and performance by carefully tuning k.

2.2 Word Representation

We produce a predicate-specific word representation x_i for each word w_i, where i stands for the word position in an input sequence, following Marcheggiani et al. (2017). However, we differ by (1) leveraging a predicate-specific indicator embedding, (2) using deeper refined representation, including character and dependency relation embeddings, and (3) applying recent advances in RNNs, such as highway connections (Srivastava et al., 2015).

In this work, word representation x_i is the concatenation of four types of features: predicate-specific feature, character-level, word-level and linguistic features. Unlike previous work, we leverage a predicate-specific indicator embedding x_i^{ie} rather than directly using a binary flag either 0 or 1. At character level, we exploit convolutional neural network (CNN) with bidirectional LSTM (BiLSTM) to learn character embedding

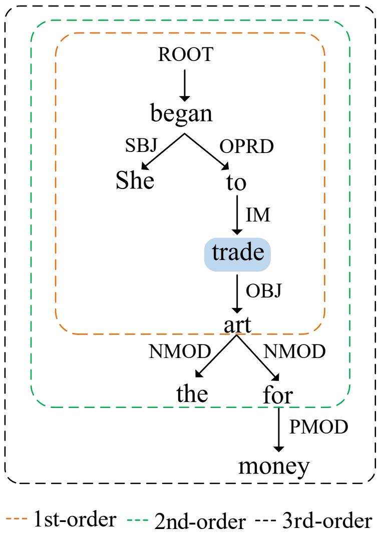

Figure 2: An example of *first*-order, *second*-order and *third*-order argument pruning. Shadow part indicates the given predicate.

x_i^{ce}. As shown in Figure 1, the representation calculated by the CNN is fed as input to BiLSTM. At word level, we use a randomly initialized word embedding x_i^{re} and a pre-trained word embedding x_i^{pe}. For linguistic features, we employ a randomly initialized lemma embedding x_i^{le} and a randomly initialized POS tag embedding x_i^{pos}. In order to incorporate more syntactic information, we adopt an additional feature, the dependency relation to syntactic head. Likewise, it is a randomly initialized embedding x_i^{de}. The resulting word representation is concatenated as $x_i = [x_i^{ie}, x_i^{ce}, x_i^{re}, x_i^{pe}, x_i^{le}, x_i^{pos}, x_i^{de}]$.

2.3 Sequence Encoder

As Long short-term memory (LSTM) networks (Hochreiter and Schmidhuber, 1997) have shown significant representational effectiveness to NLP tasks, we thus use BiLSTM as the sentence encoder. Given an input sequence $x = (x_1, \ldots, x_n)$, BiLSTM processes the sequence in both forward and backward direction to obtain two separated hidden states, $\overrightarrow{h}_i$ which handles data from x_1 to x_i and $\overleftarrow{h}_i$ which tackles data from x_n to x_i for each word representation. Finally, we get a contextual representation $h_i = [\overrightarrow{h}_i, \overleftarrow{h}_i]$ by concatenating the states of BiLSTM networks.

To get the final predicted semantic roles, we exploit a multi-layer perceptron (MLP) with highway connections on the top of BiLSTM networks, which takes as input the hidden representation h_i

Hyperparameter	values
d^{ie} (indicator embedding)	16
d^{pe} (pre-trained embedding)	100
d^{ce} (character embedding)	300
d^{re} (word embedding)	100
d^{le} (lemma embedding)	100
d^{pos} (POS tag embedding)	32
d^{de} (dependency label embedding)	64
LSTM hidden sizes	512
BiLSTM layers	4
Hidden layers	10
Learning rate	0.001
Word dropout	0.1

Table 1: Hyperparameter values.

of all time steps. The MLP network consists of 10 layers with highway connections and we employ *ReLU* activations for the hidden layers. Finally, we use a softmax layer over the outputs to maximize the likelihood of labels.

2.4 Predicate Disambiguation

Although predicates have been identified given a sentence, predicate disambiguation is an indispensable task, which aims to determine the predicate-argument structure for an identified predicate in a particular context. Here, we also use the identical model (BiLSTM composed with MLP) for predicate disambiguation, in which the only difference is that we remove the syntactic dependency relation feature in corresponding word representation (Section 2.2). Exactly, given a predicate p, the resulting word representation is $p_i = [p_i^{ie}, p_i^{ce}, p_i^{re}, p_i^{pe}, p_i^{le}, p_i^{pos}]$.

3 Experiments

Our model[2] is evaluated on the CoNLL-2009 shared task both for English and Chinese datasets, following the standard training, development and test splits. The hyperparameters in our model were selected based on the development set, and are summarized in Table 1. Note that the parameters of predicate model are the same as these in argument model. All real vectors are randomly initialized, and the pre-trained word embeddings for English are GloVe vectors (Pennington et al., 2014). For Chinese, we exploit Wikipedia documents to train Word2Vec embeddings (Mikolov et al., 2013). During training procedures, we use the categorical cross-entropy as objective, with Adam optimizer (Kingma and Ba, 2015). We train models for a maximum of 20 epochs and obtain the nearly best model based on development results. For argument labeling, we preprocess corpus with k-order argument pruning algorithm. In addition, we use four CNN layers with single-layer BiLSTM to induce character representations derived from sentences. For English[3], to further enhance the representation, we adopt CNN-BiLSTM character embedding structure from AllenNLP toolkit (Peters et al., 2018).

[2]The code is available at `https://github.com/bcmi220/srl_syn_pruning`.

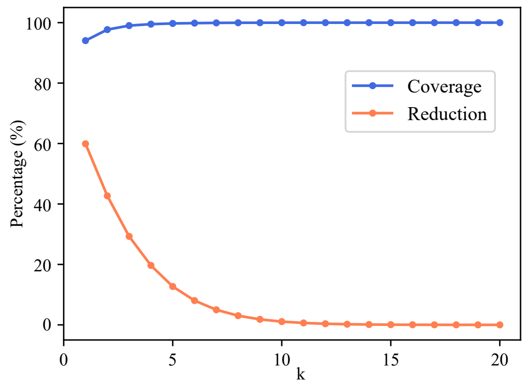

Figure 3: Changing curves of coverage and reduction with different k value on English training set. The coverage rate is the proportion of true arguments in pruning output, while the reduction is the one of pruned argument candidates in total tokens.

3.1 Preprocessing

During the pruning of argument candidates, we use the officially predicted syntactic parses provided by CoNLL-2009 shared-task organizers on both English and Chinese. Figure 3 shows changing curves of coverage and reduction following k on the English train set. According to our statistics, the number of non-arguments is ten times more than that of arguments, where the data distribution is fairly unbalanced. However, a proper pruning strategy could alleviate this problem. Accordingly, the first-order pruning reduces more than 50% candidates at the cost of missing 5.5% true ones on average, and the second-order prunes about 40% candidates with nearly 2.0% loss. The coverage of third-order has achieved 99% and it reduces approximately 1/3 corpus size.

It is worth noting that as k is larger than 19,

[3]For Chinese, we do not use character embedding.

there will come full coverage on all argument candidates for English training set, which let our high order pruning algorithm degrade into a syntax-agnostic setting. In this work, we use the tenth-order pruning for pursuing the best performance.

3.2 Results

Our system performance is measured with the official script from CoNLL-2009 benchmarks, combining the output of our predicate disambiguation with our semantic role labeling. Our predicate disambiguation model achieves the accuracy of 95.01% and 95.58%[4] on development and test sets, respectively. We compare our model performance with the state-of-the-art models for dependency SRL.[5] Noteworthily, our model is local and single without reranking, which neither includes global inference nor combines multiple models. The experimental results on the English in-domain (WSJ) and out-of-domain (Brown) test sets are shown in Tables 2 and 3, respectively.

For English, our syntax-aware model outperforms previously published best single model, scoring 89.5% F_1 with 1.5% absolute improvement on the in-domain (WSJ) test data. Compared with ensemble models, our single model even provides better performance (+0.4% F_1) than the system (Marcheggiani and Titov, 2017), and significantly surpasses all the rest models. In the syntax-agnostic setting (without pruning and dependency relation embedding), we also reach the new state-of-the-art, achieving a performance gain of 1% F_1.

System (syntax-aware)	P	R	F_1

Table 4: Results on the Chinese test set.

On the out-of-domain (Brown) test set, we achieve the new best results of 79.3% (syntax-aware) and 78.8% (syntax-agnostic) in F_1 scores. Moreover, our syntax-aware model performs better than the syntax-agnostic one.

Table 4 presents the results on Chinese test set. Even though we use the same parameters as for English, our model also outperforms the best reported results by 0.3% (syntax-aware) and 0.6% (syntax-agnostic) in F_1 scores.

[4]Note that we give a slightly better predicate model than Roth and Lapata (2016), with 94.77% and 95.47% accuracy on development and test sets, respectively.

[5]Here, we do not compare against span-based SRL models, which annotate roles for entire argument spans instead of semantic dependencies.

System(without predicate sense)	P	R	F_1

3.3 Analysis

To evaluate the contributions of key factors in our method, a series of ablation studies are performed on the English development set.

In order to demonstrate the effectiveness of our k-order pruning algorithm, we report the SRL performance excluding predicate senses in evaluation, eliminating the performance gain from predicate disambiguation. Table 5 shows the results from our syntax-aware model with lower order argument pruning. Compared to the best previous model, our system still yields an increment in recall by more than 1%, leading to improvements in F_1 score. It demonstrates that refining syntactic parser tree based candidate pruning does help in argument recognition.

Table 6 presents the performance of our syntax-agnostic SRL system with a basic configuration, which removes components, including indicator and character embeddings. Note that the first row is the results of BiLSTM (removing MLP from basic model), whose encoding is the same as Marcheggiani et al. (2017). Experiments show that both enhanced representations improve over our basic model, and our adopted labeling model is superior to the simple BiLSTM.

Figure 4 shows F_1 scores in different k-order pruning together with our syntax-agnostic model. It also indicates that the least first-order pruning fails to give satisfactory performance, the best performing setting coming from a moderate setting of $k = 10$, and the largest k shows that our argu-

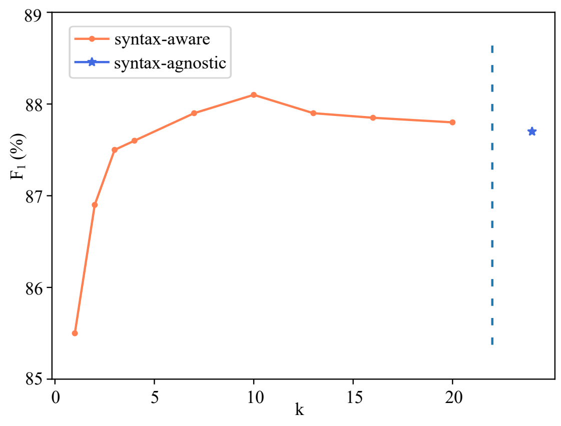

Figure 4: F_1 scores by k-order pruning and the syntax-agnostic result on English development set.

ment pruning falls back to syntax-agnostic type. Meanwhile, from the best k setting to the lower order pruning, we receive a much faster performance drop, compared to the higher order pruning until the complete syntax-agnostic case. The proposed k-order pruning algorithm always works even it reaches the syntax-agnostic setting, which empirically explains why the current syntax-aware and syntax-agnostic SRL models hold little performance difference, as maximum k-order pruning actually removes few words just like syntax-agnostic model.

3.4 End-to-end SRL

In this work, we consider additional model that integrates predicate disambiguation and argument labeling into one sequence labeling model. In order to implement an end-to-end model, we introduce a virtual root (VR) for predicate disambiguation similar to Zhao et al. (2013) who handled the entire SRL task as word pair classification. Concretely, we add a predicate sense feature to the input sequence by concatenating a VR. The word representation of VR is randomly initialized during training. In Figure 5, we give an example sequence with the labels for the given sentence.

We also report results of our end-to-end model on CoNLL-2009 test set with syntax-aware and syntax-agnostic settings. As shown in Table 7, our end-to-end model yields slightly weaker performance compared with our pipeline. A reasonable account for performance degradation is that the training data has completely different genre distributions over predicate senses and argument roles, which may be somewhat confusing for integrative model to make classification decisions.

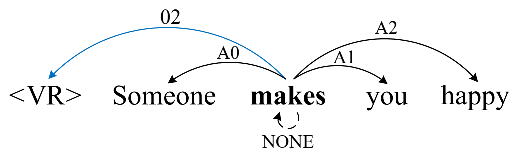

Figure 5: An example sequence with labels of end-to-end model (*makes* is the given predicate).

Our system	P	R	F_1
syntax-aware (end-to-end)	89.3	88.7	89.0
syntax-aware (pipeline)	89.7	89.3	89.5
syntax-agnostic (end-to-end)	88.9	87.9	88.4
syntax-agnostic (pipeline)	89.5	87.9	88.7

Table 7: Comparison of results on CoNLL-2009 data between our end-to-end and pipeline models.

3.5 CoNLL-2008 SRL Setting

For a full SRL task, the predicate identification subtask is also indispensable, which has been included in CoNLL-2008 shared task. We thus evaluate our model in terms of data and setting of the CoNLL-2008 benchmark (WSJ).

To identify predicates, we train the BiLSTM-MLP sequence labeling model with same parameters in Section 2.4 to tackle the predicate identification and disambiguation subtasks in one shot, and the only difference is that we remove the predicate-specific indicator feature. The F_1 score of our predicate labeling model is 90.53% on in-domain (WSJ) data. Compared with the best reported results, we observe absolute improvements in semantic F_1 of 0.8% (in Table 8). Note that as predicate identification is introduced, our same model shows about 6% performance loss for either syntax-agnostic or syntax-aware case, which indicates that predicate identification should be carefully handled, as it is very needed in a complete practical SRL system.

4 Syntactic Contribution

Syntactic information plays an informative role in semantic role labeling. However, few studies were done to quantitatively evaluate the syntactic contribution to SRL. Furthermore, we observe that most of the above compared neural SRL systems took the syntactic parser of (Björkelund et al., 2010) as syntactic inputs instead of the one from CoNLL-2009 shared task, which adopted a much weaker syntactic parser. Especially (Marcheggiani and Titov, 2017), adopted an external syntactic parser with even higher parsing accuracy. Contrarily, our SRL model is based on the automatically predicted parse with moderate performance provided by CoNLL-2009 shared task, but outperforms their models.

System	LAS	Sem-F_1
Johansson and Nugues (2008)	90.13	81.75
Zhao and Kit (2008)	87.52	77.67
Zhao et al. (2009b)	88.39	82.1 (80.53)
	89.28	82.5 (80.94)
Zhao et al. (2013)	88.39	82.5 (80.91)
	89.28	82.4 (80.88)
Ours (syntax-agnostic)	–	82.9
Ours (syntax-aware)	86.0	83.3

Table 8: Results on the CoNLL-2008 in-domain (WSJ) test set. The results in parenthesis are on WSJ + Brown test set.

This section thus attempts to explore how much syntax contributes to dependency-based SRL in deep learning framework and how to effectively evaluate relative performance of syntax-based SRL. To this end, we conduct experiments for empirical analysis with different syntactic inputs.

Syntactic Input In order to obtain different syntactic inputs, we design a faulty syntactic tree generator (refer to STG hereafter), which is able to produce random errors in the output parse tree like a true parser does. To simplify implementation, we construct a new syntactic tree based on the gold standard parse tree. Given an input error probability distribution estimated from a true parser output, our algorithm presented in Algorithm 2 stochastically modifies the syntactic heads of nodes on the premise of a valid tree.

Evaluation Measure For SRL task, the primary evaluation measure is the semantic labeled F_1 score. However, the score is influenced by the quality of syntactic input to some extent, leading to unfaithfully reflecting the competence of syntax-based SRL system. Namely, this is not the outcome of a true and fair quantitative comparison for these types of SRL models. To normalize the semantic score relative to syntactic parse, we take into account additional evaluation measure to estimate the actual overall performance of SRL. Here, we use the ratio between labeled F_1 score for semantic dependencies (Sem-F_1) and the labeled attachment score (LAS) for syntactic dependencies

System	LAS (%)	P (%)	R (%)	Sem-F_1 (%)	Sem-F_1/LAS (%)
Zhao et al. (2009c) [SRL-only]	86.0	–	–	85.4	99.3
Zhao et al. (2009a) [Joint]	89.2	–	–	86.2	96.6
Björkelund et al. (2010)	89.8	87.1	84.5	85.8	95.6
Lei et al. (2015)	90.4	–	–	86.6	95.8
Roth and Lapata (2016)	89.8	88.1	85.3	86.7	96.5
Marcheggiani and Titov (2017)	90.3*	89.1	86.8	**88.0**	97.5
Ours + CoNLL-2009 predicted	86.0	89.7	89.3	89.5	104.0
Ours + Auto syntax	90.0	90.5	89.3	**89.9**	99.9
Ours + Gold syntax	100	91.0	89.7	90.3	90.3

Table 9: Results on English test set, in terms of labeled attachment score for syntactic dependencies (LAS), semantic precision (P), semantic recall (R), semantic labeled F_1 score (Sem-F_1), the ratio Sem-F_1/LAS. A superscript * indicates LAS results from our personal communication with the authors.

Algorithm 2 Faulty Syntactic Tree Generator

```
Input: A gold standard syntactic tree $GT$, the specific error probability $p$
Output: The new generative syntactic tree $NT$
 1: $N$ denotes the number of nodes in $GT$
 2: for each node $n \in GT$ do
 3:     $r$ = random(0, 1), a random number
 4:     if $r < p$ then
 5:         $h$ = random(0, $N$), a random integer
 6:         find the syntactic head $n_h$ of $n$ in $GT$
 7:         modify $n_h = h$, and get a new tree $NT$
 8:         if $NT$ is a valid tree then
 9:             break
10:         else
11:             goto step 5
12:         end if
13:     end if
14: end for
15: return the new generative tree $NT$
```

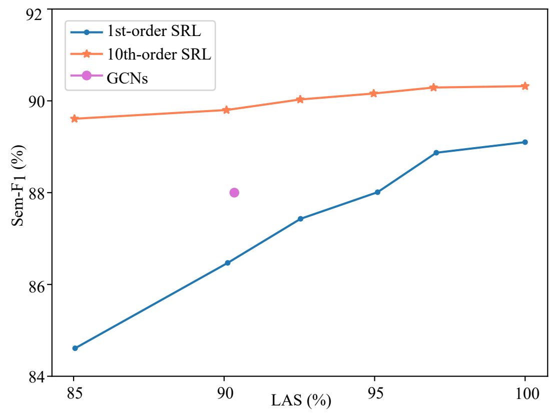

Figure 6: The Sem-F_1 scores of our models with different quality of syntactic inputs vs. GCNs (Marcheggiani and Titov, 2017) on test set.

proposed by Surdeanu et al. (2008) as evaluation metric.[6] The benefits of this measure are twofold: quantitatively evaluating syntactic contribution to SRL and impartially estimating the true performance of SRL, independent of the performance of the input syntactic parser.

Table 9 reports the performance of existing models[7] in term of Sem-F_1/LAS ratio on CoNLL-2009 English test set. Interestingly, even though our system has significantly lower scores than others by 3.8% LAS in syntactic components, we obtain the highest results both on Sem-F_1 and the Sem-F_1/LAS ratio, respectively. These results show that our SRL component is relatively much stronger. Moreover, the ratio comparison in Table 9 also shows that since the CoNLL-2009 shared task, most SRL works actually benefit from the enhanced syntactic component rather than the improved SRL component itself. All post-CoNLL SRL systems, either traditional or neural types, did not exceed the top systems of CoNLL-2009 shared task, (Zhao et al., 2009c) (SRL-only track using the provided predicated syntax) and (Zhao et al., 2009a) (Joint track using self-developed parser). We believe that this work for the first time reports both higher Sem-F_1 and higher Sem-F_1/LAS ratio since CoNLL-2009 shared task.

We also perform our first and tenth order pruning models with different erroneous syntactic inputs generated from STG and evaluate their per-

[6]The idea of ratio score in Surdeanu et al. (2008) actually was from author of this paper, Hai Zhao, which has been indicated in the acknowledgement part of Surdeanu et al. (2008).

[7]Note that several SRL systems without providing syntactic information are not listed in the table.

formance using the Sem-F_1/LAS ratio. Figure 6 shows Sem-F_1 scores at different quality of syntactic parse inputs on the English test set whose LAS varies from 85% to 100%. Compared to previous state-of-the-arts (Marcheggiani and Titov, 2017). Our tenth-order pruning model gives quite stable SRL performance no matter the syntactic input quality varies in a broad range, while our first-order pruning model yields overall lower results (1-5% F_1 drop), owing to missing too many true arguments. These results show that high-quality syntactic parses may indeed enhance dependency SRL. Furthermore, it indicates that our model with an accurate enough syntactic input as Marcheggiani and Titov (2017), namely, 90% LAS, will give a Sem-F_1 exceeding 90% for the first time in the research timeline of semantic role labeling.

5 Related Work

Semantic role labeling was pioneered by Gildea and Jurafsky (2002). Most traditional SRL models rely heavily on feature templates (Pradhan et al., 2005; Zhao et al., 2009b; Björkelund et al., 2009). Among them, Pradhan et al. (2005) combined features derived from different syntactic parses based on SVM classifier, while Zhao et al. (2009b) presented an integrative approach for dependency SRL by greedy feature selection algorithm. Later, Collobert et al. (2011) proposed a convolutional neural network model of inducing word embeddings substituting for hand-crafted features, which was a breakthrough for SRL task.

With the impressive success of deep neural networks in various NLP tasks (Zhang et al., 2016; Qin et al., 2017; Cai et al., 2017), a series of neural SRL systems have been proposed. Foland and Martin (2015) presented a dependency semantic role labeler using convolutional and time-domain neural networks, while FitzGerald et al. (2015) exploited neural network to jointly embed arguments and semantic roles, akin to the work (Lei et al., 2015), which induced a compact feature representation applying tensor-based approach. Recently, researchers consider multiple ways to effectively integrate syntax into SRL learning. Roth and Lapata (2016) introduced dependency path embedding to model syntactic information and exhibited a notable success. Marcheggiani and Titov (2017) leveraged the graph convolutional network to incorporate syntax into neural models. Differently, Marcheggiani et al. (2017) proposed a syntax-agnostic model using effective word representation for dependency SRL, which for the first time achieves comparable performance as state-of-the-art syntax-aware SRL models.

However, most neural SRL works seldom pay much attention to the impact of input syntactic parse over the resulting SRL performance. This work is thus more than proposing a high performance SRL model through reviewing the highlights of previous models, and presenting an effective syntactic tree based argument pruning. Our work is also closely related to (Punyakanok et al., 2008; He et al., 2017). Under the traditional methods, Punyakanok et al. (2008) investigated the significance of syntax to SRL system and shown syntactic information most crucial in the pruning stage. He et al. (2017) presented extensive error analysis with deep learning model for span SRL, including discussion of how constituent syntactic parser could be used to improve SRL performance.

6 Conclusion and Future Work

This paper presents a simple and effective neural model for dependency-based SRL, incorporating syntactic information with the proposed extended k-order pruning algorithm. With a large enough setting of k, our pruning algorithm will result in a syntax-agnostic setting for the argument labeling model, which smoothly unifies syntax-aware and syntax-agnostic SRL in a consistent way. Experimental results show that with the help of deep enhanced representation, our model outperforms the previous state-of-the-art models in both syntax-aware and syntax-agnostic situations.

In addition, we consider the Sem-F1/LAS ratio as a mean of evaluating syntactic contribution to SRL, and true performance of SRL independent of the quality of syntactic parser. Though we again confirm the importance of syntax to SRL with empirical experiments, we are aware that since (Pradhan et al., 2005), the gap between syntax-aware and syntax-agnostic SRL has been greatly reduced, from as high as 10% to only 1-2% performance loss in this work. However, maybe we will never reach a satisfying conclusion, as whenever one proposes a syntax-agnostic SRL system which can outperform all syntax-aware ones at then, always there comes argument that you have never fully explored creative new method to effectively exploit the syntax input.

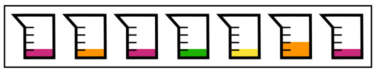
Abstract

We propose a learning approach for mapping context-dependent sequential instructions to actions. We address the problem of discourse and state dependencies with an attention-based model that considers both the history of the interaction and the state of the world. To train from start and goal states without access to demonstrations, we propose SESTRA, a learning algorithm that takes advantage of single-step reward observations and immediate expected reward maximization. We evaluate on the SCONE domains, and show absolute accuracy improvements of 9.8%-25.3% across the domains over approaches that use high-level logical representations.



throw out first beaker
`POP 1, STOP`
pour sixth beaker into last one
`POP 6, POP 6, PUSH 7 O, PUSH 7 O, STOP`
it turns brown
`POP 7, POP 7, POP 7, PUSH 7 B, PUSH 7 B, PUSH 7 B, STOP`
pour purple beaker into yellow one
`POP 3, PUSH 5 P, STOP`
throw out two units of brown one
`POP 7, POP 7, STOP`

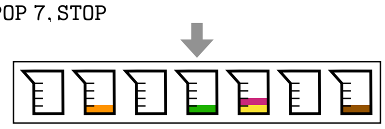


Figure 1: Example from the SCONE (Long et al., 2016) ALCHEMY domain, including a start state (top), sequence of instructions, and a goal state (bottom). Each instruction is annotated with a sequence of actions from the set of actions we define for ALCHEMY.

1 Introduction

An agent executing a sequence of instructions must address multiple challenges, including grounding the language to its observed environment, reasoning about discourse dependencies, and generating actions to complete high-level goals. For example, consider the environment and instructions in Figure 1, in which a user describes moving chemicals between beakers and mixing chemicals together. To execute the second instruction, the agent needs to resolve *sixth beaker* and *last one* to objects in the environment. The third instruction requires resolving *it* to the rightmost beaker mentioned in the second instruction, and reasoning about the set of actions required to mix the colors in the beaker to brown. In this paper, we describe a model and learning approach to map sequences of instructions to actions. Our model considers previous utterances and the world state to select actions, learns to combine simple actions to achieve complex goals, and can be trained using goal states without access to demonstrations.

The majority of work on executing sequences of instructions focuses on mapping instructions to high-level formal representations, which are then evaluated to generate actions (e.g., Chen and Mooney, 2011; Long et al., 2016). For example, the third instruction in Figure 1 will be mapped to mix(prev_arg1), indicating that the mix action should be applied to first argument of the previous action (Long et al., 2016; Guu et al., 2017). In contrast, we focus on directly generating the sequence of actions. This requires resolving references without explicitly modeling them, and learning the sequences of actions required to complete high-level actions; for example, that mixing requires removing everything in the beaker and replacing with the same number of brown items.

A key challenge in executing sequences of instructions is considering contextual cues from both the history of the interaction and the state of the world. Instructions often refer to previously mentioned objects (e.g., *it* in Figure 1) or actions (e.g., *do it again*). The world state provides the set of objects the instruction may refer to, and implicitly determines the available actions. For example, liquid can not be removed from an empty beaker. Both types of contexts continuously change during an interaction. As new instructions are given, the instruction history expands, and as the agent acts the world state changes. We propose an attention-based model that takes as input the current instruction, previous instructions, the initial world state, and the current state. At each step, the model computes attention encodings of the different inputs, and predicts the next action to execute.

We train the model given instructions paired with start and goal states without access to the correct sequence of actions. During training, the agent learns from rewards received through exploring the environment with the learned policy by mapping instructions to sequences of actions. In practice, the agent learns to execute instructions gradually, slowly correctly predicting prefixes of the correct sequences of increasing length as learning progress. A key challenge is learning to correctly select actions that are only required later in execution sequences. Early during learning, these actions receive negative updates, and the agent learns to assign them low probabilities. This results in an exploration problem in later stages, where actions that are only required later are not sampled during exploration. For example, in the ALCHEMY domain shown in Figure 1, the agent behavior early during execution of instructions can be accomplished by only using `POP` actions. As a result, the agent quickly learns a strong bias against `PUSH` actions, which in practice prevents the policy from exploring them again. We address this with a learning algorithm that observes the reward for all possible actions for each visited state, and maximizes the immediate expected reward.

We evaluate our approach on SCONE (Long et al., 2016), which includes three domains, and is used to study recovering predicate logic meaning representations for sequential instructions. We study the problem of generating a sequence of low-level actions, and re-define the set of actions for each domain. For example, we treat the beakers in the ALCHEMY domain as stacks and use only `POP` and `PUSH` actions. Our approach robustly learns to execute sequential instructions with up to 89.1% task-completion accuracy for single instruction, and 62.7% for complete sequences. Our code is available at `https://github.com/clic-lab/scone`.

2 Technical Overview

Task and Notation Let $\mathcal{S}$ be the set of all possible world states, $\mathcal{X}$ be the set of all natural language instructions, and $\mathcal{A}$ be the set of all actions. An instruction $\bar{x} \in \mathcal{X}$ of length $|\bar{x}|$ is a sequence of tokens $\langle x_1, ... x_{|\bar{x}|}\rangle$. Executing an action modifies the world state following a transition function $T : \mathcal{S} \times \mathcal{A} \to \mathcal{S}$. For example, the ALCHEMY domain includes seven beakers that contain colored liquids. The world state defines the content of each beaker. We treat each beaker as a stack. The actions are `POP N` and `PUSH N C`, where $1 \leq \texttt{N} \leq 7$ is the beaker number and `C` is one of six colors. There are a total of 50 actions, including the `STOP` action. Section 6 describes the domains in detail.

Given a start state s_1 and a sequence of instructions $\langle \bar{x}_1, \ldots, \bar{x}_n\rangle$, our goal is to generate the sequence of actions specified by the instructions starting from s_1. We treat the execution of a sequence of instructions as executing each instruction in turn. The execution $\bar{e}$ of an instruction $\bar{x}_i$ starting at a state s_1 and given the history of the instruction sequence $\langle \bar{x}_1, \ldots, \bar{x}_{i-1}\rangle$ is a sequence of state-action pairs $\bar{e} = \langle (s_1, a_1), ..., (s_m, a_m)\rangle$, where $a_k \in \mathcal{A}$, $s_{k+1} = T(s_k, a_k)$. The final action a_m is the special action `STOP`, which indicates the execution has terminated. The final state is then s_m, as $T(s_k, \texttt{STOP}) = s_k$. Executing a sequence of instructions in order generates a sequence $\langle \bar{e}_1, ..., \bar{e}_n\rangle$, where $\bar{e}_i$ is the execution of instruction $\bar{x}_i$. When referring to states and actions in an indexed execution $\bar{e}_i$, the k-th state and action are $s_{i,k}$ and $a_{i,k}$. We execute instructions one after the other: $\bar{e}_1$ starts at the interaction initial state s_1 and $s_{i+1,1} = s_{i,|\bar{e}_i|}$, where $s_{i+1,1}$ is the start state of $\bar{e}_{i+1}$ and $s_{i,|\bar{e}_i|}$ is the final state of $\bar{e}_i$.

Model We model the agent with a neural network policy (Section 4). At step k of executing the i-th instruction, the model input is the current instruction $\bar{x}_i$, the previous instructions $\langle \bar{x}_1, \ldots, \bar{x}_{i-1}\rangle$, the world state s_1 at the beginning of executing $\bar{x}_i$, and the current state s_k. The model predicts the next action a_k to execute. If $a_k = \texttt{STOP}$, we switch to the next instruction, or if at the end of the instruction sequence, terminate. Otherwise, we update the state to $s_{k+1} = T(s_k, a_k)$. The model uses attention to process the different inputs and a recurrent neural network (RNN) decoder to generate actions (Bahdanau et al., 2015).

Learning We assume access to a set of N instruction sequences, where each instruction in each sequence is paired with its start and goal states. During training, we create an example for each instruction. Formally, the training set is $\{(\bar{x}_i^{(j)}, s_{i,1}^{(j)}, \langle \bar{x}_1^{(j)}, \ldots, \bar{x}_{i-1}^{(j)} \rangle, g_i^{(j)})\}_{j=1,i=1}^{N,n^{(j)}}$, where $\bar{x}_i^{(j)}$ is an instruction, $s_{i,1}^{(j)}$ is a start state, $\langle \bar{x}_1^{(j)}, \ldots, \bar{x}_{i-1}^{(j)} \rangle$ is the instruction history, $g_i^{(j)}$ is the goal state, and $n^{(j)}$ is the length of the j-th instruction sequence. This training data contains no evidence about the actions and intermediate states required to execute each instruction.[1] We use a learning method that maximizes the expected immediate reward for a given state (Section 5). The reward accounts for task-completion and distance to the goal via potential-based reward shaping.

Evaluation We evaluate exact task completion for sequences of instructions on a test set $\{(s_1^{(j)}, \langle \bar{x}_1^{(j)}, \ldots, \bar{x}_{n_j}^{(j)} \rangle, g^{(j)})\}_{j=1}^{N}$, where $g^{(j)}$ is the oracle goal state of executing instructions $\bar{x}_1^{(j)}, \ldots, \bar{x}_{n_j}^{(j)}$ in order starting from $s_1^{(j)}$. We also evaluate single-instruction task completion using per-instruction annotated start and goal states.

3 Related Work

Executing instructions has been studied using the SAIL corpus (MacMahon et al., 2006) with focus on navigation using high-level logical representations (Chen and Mooney, 2011; Chen, 2012; Artzi and Zettlemoyer, 2013; Artzi et al., 2014) and low-level actions (Mei et al., 2016). While SAIL includes sequences of instructions, the data demonstrates limited discourse phenomena, and instructions are often processed in isolation. Approaches that consider as input the entire sequence focused on segmentation (Andreas and Klein, 2015). Recently, other navigation tasks were proposed with focus on single instructions (Anderson et al., 2018; Janner et al., 2018). We focus on sequences of environment manipulation instructions and modeling contextual cues from both the changing environment and instruction history. Manipulation using single-sentence instructions has been studied using the Blocks domain (Bisk et al., 2016, 2018; Misra et al., 2017; Tan and Bansal, 2018). Our work is related to the work of Branavan et al. (2009) and Vogel and Jurafsky (2010). While both study executing sequences of instructions, similar to SAIL, the data includes limited discourse dependencies. In addition, both learn with rewards computed from surface-form similarity between text in the environment and the instruction. We do not rely on such similarities, but instead use a state distance metric.

Language understanding in interactive scenarios that include multiple turns has been studied with focus on dialogue for querying database systems using the ATIS corpus (Hemphill et al., 1990; Dahl et al., 1994). Tür et al. (2010) surveys work on ATIS. Miller et al. (1996), Zettlemoyer and Collins (2009), and Suhr et al. (2018) modeled context dependence in ATIS for generating formal representations. In contrast, we focus on environments that change during execution and directly generating environment actions, a scenario that is more related to robotic agents than database query.

The SCONE corpus (Long et al., 2016) was designed to reflect a broad set of discourse context-dependence phenomena. It was studied extensively using logical meaning representations (Long et al., 2016; Guu et al., 2017; Fried et al., 2018). In contrast, we are interested in directly generating actions that modify the environment. This requires generating lower-level actions and learning procedures that are otherwise hardcoded in the logic (e.g., mixing action in Figure 1). Except for Fried et al. (2018), previous work on SCONE assumes access only to the initial and final states during training. This form of supervision does not require operating the agent manually to acquire the correct sequence of actions, a difficult task in robotic agents with complex control. Goal state supervision has been studied for instructional language (e.g., Branavan et al., 2009; Artzi and Zettlemoyer, 2013; Bisk et al., 2016), and more extensively in question answering when learning with answer annotations only (e.g., Clarke et al., 2010; Liang et al., 2011; Kwiatkowski et al., 2013; Berant et al., 2013; Berant and Liang, 2014, 2015; Liang et al., 2017).

4 Model

We map sequences of instructions $\langle \bar{x}_1, \ldots, \bar{x}_n \rangle$ to actions by executing the instructions in or-

[1]This training set is a subset of the data used in previous work (Section 6, Guu et al., 2015), in which training uses all instruction sequences of length 1 and 2.

Figure 2: Illustration of the model architecture while generating the third action a_3 in the third utterance $\bar{x}_3$ from Figure 1. Context vectors computed using attention are highlighted in blue. The model takes as input vector encodings from the current and previous instructions $\bar{x}_1$, $\bar{x}_2$, and $\bar{x}_3$, the initial state s_1, the current state s_3, and the previous action a_2. Instruction encodings are computed with a bidirectional RNN. We attend over the previous and current instructions and the initial and current states. We use an MLP to select the next action.

der. The model generates an execution $\bar{e} = \langle (s_1, a_1), \ldots, (s_{m_i}, a_{m_i}) \rangle$ for each instruction $\bar{x}_i$. The agent context, the information available to the agent at step k, is $\tilde{s}_k = (\bar{x}_i, \langle \bar{x}_1, \ldots, \bar{x}_{i-1} \rangle, s_k, \bar{e}[: k])$, where $\bar{e}[: k]$ is the execution up until but not including step k. In contrast to the world state, the agent context also includes instructions and the execution so far. The agent policy $\pi_\theta(\tilde{s}_k, a)$ is modeled as a probabilistic neural network parametrized by θ, where $\tilde{s}_k$ is the agent context at step k and a is an action. To generate executions, we generate one action at a time, execute the action, and observe the new world state. In step k of executing the i-th instruction, the network inputs are the current utterance $\bar{x}_i$, the previous instructions $\langle \bar{x}_1, \ldots, \bar{x}_{i-1} \rangle$, the initial state s_1 at beginning of executing $\bar{x}_i$, and the current state s_k. When executing a sequence of instructions, the initial state s_1 is either the state at the beginning of executing the sequence or the final state of the execution of the previous instruction. Figure 2 illustrates our architecture.

We generate continuous vector representations for all inputs. Each input is represented as a set of vectors that are then processed with an attention function to generate a single vector representation (Luong et al., 2015). We assume access to a domain-specific encoding function ENC(s) that, given a state s, generates a set of vectors S representing the objects in the state. For example, in the ALCHEMY domain, a vector is generated for each beaker using an RNN. Section 6 describes the different domains and their encoding functions.

We use a single bidirectional RNN with a long short-term memory (LSTM; Hochreiter and Schmidhuber, 1997) recurrence to encode the instructions. All instructions $\bar{x}_1$,…,$\bar{x}_i$ are encoded with a single RNN by concatenating them to $\bar{x}'$. We use two delimiter tokens: one separates previous instructions, and the other separates the previous instructions from the current one. The forward LSTM RNN hidden states are computed as:[2]

$$\overrightarrow{\mathbf{h}_{j+1}} = \overrightarrow{\text{LSTM}^E}\left(\phi^I(x'_{j+1}); \overrightarrow{\mathbf{h}_j}\right) \quad ,$$

where ϕ^I is a learned word embedding function and $\overrightarrow{\text{LSTM}^E}$ is the forward LSTM recurrence function. We use a similar computation to compute the backward hidden states $\overleftarrow{\mathbf{h}_j}$. For each token x'_j in $\bar{x}'$, a vector representation $\mathbf{h}'_j = \left[\overrightarrow{\mathbf{h}_j}; \overleftarrow{\mathbf{h}_j}\right]$ is computed. We then create two sets of vectors, one for all the vectors of the current instruction and one for the previous instructions:

$$\begin{aligned} X^c &= \{\mathbf{h}'_j\}_{j=J}^{J+|\bar{x}_i|} \\ X^p &= \{\mathbf{h}'_j\}_{j=0}^{j<J} \end{aligned}$$

where J is the index in $\bar{x}'$ where the current instruction $\bar{x}_i$ begins. Separating the vectors to two sets will allows computing separate attention on the current instruction and previous ones.

To compute each input representation during decoding, we use a bi-linear attention function (Luong et al., 2015). Given a set of vectors H, a query vector $\mathbf{h}^q$, and a weight matrix $\mathbf{W}$, the attention function ATTEND($H, \mathbf{h}^q, \mathbf{W}$) computes a context vector $\mathbf{z}$:

$$\begin{aligned} \alpha_i &\propto \exp(\mathbf{h}_i^\intercal \mathbf{W} \mathbf{h}^q) : i = 0, \ldots, |H| \\ \mathbf{z} &= \sum_{i=1}^{|H|} \alpha_i \mathbf{h}_i \ . \end{aligned}$$

[2]To simplify the notation, we omit the memory cell (often denoted as $\mathbf{c}_j$) from all LSTM descriptions. We use only the hidden state $\mathbf{h}_j$ to compute the intended representations (e.g., for the input text tokens). All LSTMs in this paper use zero vectors as initial hidden state $\mathbf{h}_0$ and initial cell memory $\mathbf{c}_0$.

We use a decoder to generate actions. At each time step k, we compute an input representation using the attention function, update the decoder state, and compute the next action to execute. Attention is first computed over the vectors of the current instruction, which is then used to attend over the other inputs. We compute the context vectors $\mathbf{z}_k^c$ and $\mathbf{z}_k^p$ for the current instruction and previous instructions:

$$\begin{aligned}\mathbf{z}_k^c &= \text{ATTEND}(X^c, \mathbf{h}_{k-1}^d, \mathbf{W}^c)\\ \mathbf{z}_k^p &= \text{ATTEND}(X^p, [\mathbf{h}_{k-1}^d, \mathbf{z}_k^c], \mathbf{W}^p)\ ,\end{aligned}$$

where $\mathbf{h}_{k-1}^d$ is the decoder hidden state for step $k-1$, and X^c and X^p are the sets of vector representations for the current instruction and previous instructions. Two attention heads are used over both the initial and current states. This allows the model to attend to more than one location in a state at once, for example when transferring items from one beaker to another in ALCHEMY. The current state is computed by the transition function $s_k = T(s_{k-1}, a_{k-1})$, where s_{k-1} and a_{k-1} are the state and action at step $k-1$. The context vectors for the initial state s_1 and the current state s_k are:

$$\begin{aligned}\mathbf{z}_{1,k}^s &= [\text{ATTEND}(\text{ENC}(s_1), [\mathbf{h}_{k-1}^d, \mathbf{z}_k^c], \mathbf{W}^{s_b,1});\\ &\quad\ \text{ATTEND}(\text{ENC}(s_1), [\mathbf{h}_{k-1}^d, \mathbf{z}_k^c], \mathbf{W}^{s_b,2})]\\ \mathbf{z}_{k,k}^s &= [\text{ATTEND}(\text{ENC}(s_k), [\mathbf{h}_{k-1}^d, \mathbf{z}_k^c], \mathbf{W}^{s_c,1});\\ &\quad\ \text{ATTEND}(\text{ENC}(s_k), [\mathbf{h}_{k-1}^d, \mathbf{z}_k^c], \mathbf{W}^{s_c,2})]\ ,\end{aligned}$$

where all $\mathbf{W}^{*,*}$ are learned weight matrices.

We concatenate all computed context vectors with an embedding of the previous action a_{k-1} to create the input for the decoder:

$$\begin{aligned}\mathbf{h}_k &= \tanh([\mathbf{z}_k^c; \mathbf{z}_k^p; \mathbf{z}_{1,k}^s; \mathbf{z}_{k,k}^s; \phi^O(a_{k-1})]\mathbf{W}^d + \mathbf{b}^d)\\ \mathbf{h}_k^d &= \text{LSTM}^D\left(\mathbf{h}_k; \mathbf{h}_{k-1}^d\right)\ ,\end{aligned}$$

where ϕ^O is a learned action embedding function and LSTM^D is the LSTM decoder recurrence.

Given the decoder state $\mathbf{h}_k^d$, the next action a_k is predicted with a multi-layer perceptron (MLP). The actions in our domains decompose to an action type and at most two arguments.[3] For example, the action `PUSH 1 B` in ALCHEMY has the type `PUSH` and two arguments: a beaker number and a color. Section 6 describes the actions of each domain. The probability of an action is:

$$\begin{aligned}\mathbf{h}_k^a &= \tanh(\mathbf{h}_k^d \mathbf{W}^a)\\ s_{k,a_T} &= \mathbf{h}_k^a \mathbf{b}_{a_T}\\ s_{k,a_1} &= \mathbf{h}_k^a \mathbf{b}_{a_1}\\ s_{k,a_2} &= \mathbf{h}_k^a \mathbf{b}_{a_2}\\ p(a_k = a_T(a_1, a_2) \mid \tilde{s}_k; \theta) &\propto\\ &\exp(s_{k,a_T} + s_{k,a_1} + s_{k,a_2})\ ,\end{aligned}$$

where a_T, a_1, and a_2 are an action type, first argument, and second argument. If the predicted action is `STOP`, the execution is complete. Otherwise, we execute the action a_k to generate the next state s_{k+1}, and update the agent context $\tilde{s}_k$ to $\tilde{s}_{k+1}$ by appending the pair (s_k, a_k) to the execution $\bar{e}$ and replacing the current state with s_{k+1}.

The model parameters θ include: the embedding functions ϕ^I and ϕ^O; the recurrence parameters for $\overrightarrow{\text{LSTM}^E}$, $\overleftarrow{\text{LSTM}^E}$, and LSTM^D; $\mathbf{W}^C$, $\mathbf{W}^P$, $\mathbf{W}^{s_b,1}$, $\mathbf{W}^{s_b,2}$, $\mathbf{W}^{s_c,1}$, $\mathbf{W}^{s_c,2}$, $\mathbf{W}^d$, $\mathbf{W}^a$, and $\mathbf{b}^d$; and the domain dependent parameters, including the parameters of the encoding function ENC and the action type, first argument, and second argument weights $\mathbf{b}_{a_T}$, $\mathbf{b}_{a_1}$, and $\mathbf{b}_{a_2}$.

5 Learning

We estimate the policy parameters θ using an exploration-based learning algorithm that maximizes the immediate expected reward. Broadly speaking, during learning, we observe the agent behavior given the current policy, and for each visited state compute the expected immediate reward by observing rewards for all actions. We assume access to a set of training examples $\{(\bar{x}_i^{(j)}, s_{i,1}^{(j)}, \langle \bar{x}_1^{(j)}, \ldots, \bar{x}_{i-1}^{(j)} \rangle, g_i^{(j)})\}_{j=1,i=1}^{N,n^{(j)}}$, where each instruction $\bar{x}_i^{(j)}$ is paired with a start state $s_{i,1}^{(j)}$, the previous instructions in the sequence $\langle \bar{x}_1^{(j)}, \ldots, \bar{x}_{i-1}^{(j)} \rangle$, and a goal state $g_i^{(j)}$.

Reward The reward $R_i^{(j)} : \mathcal{S} \times \mathcal{S} \times \mathcal{A} \to \mathbb{R}$ is defined for each example j and instruction i:

$$R_i^{(j)}(s, a, s') = P_i^{(j)}(s, a, s') + \phi_i^{(j)}(s') - \phi_i^{(j)}(s)\ ,$$

where s is a source state, a is an action, and s' is a target state.[4] $P_i^{(j)}(s, a, s')$ is a problem reward and $\phi_i^{(j)}(s') - \phi_i^{(j)}(s)$ is a shaping term. The problem reward $P_i^{(j)}(s, a, s')$ is positive for stopping at the goal $g_i^{(j)}$ and negative for stopping in an incorrect

[3]We use a `NULL` argument for unused arguments.

[4]While the reward function is defined for any state-action-state tuple, in practice, it is used during learning with tuples that follow the system dynamics, $s' = T(s, a)$.

16:      for $a \in \mathcal{A}$ do
17:        $s' \leftarrow T(s_{k'}, a)$
18:        » Compute gradient for action $a$.
19:        $\Delta \leftarrow \Delta + R_i^{(j)}(s_{k'}, a, s') \nabla_\theta \pi_\theta(\tilde{s}_{k'}, a)$
20:    $\theta \leftarrow \theta + \mu \text{RMSPROP}\left(\frac{\Delta}{k}\right)$
21: return $\theta$
```

state or taking an invalid action:

$$P_i^{(j)}(s,a,s') = \begin{cases} 1.0 & a = \texttt{STOP} \wedge s' = g_i^{(j)} \\ -1.0 & a = \texttt{STOP} \wedge s' \neq g_i^{(j)} \\ -1.0 - \delta & s = s' \\ -\delta & \text{otherwise} \end{cases},$$

where δ is a verbosity penalty. The case $s = s'$ indicates that a was invalid in state s, as in this domain, all valid actions except STOP modify the state. We use a potential-based shaping term $\phi_i^{(j)}(s') - \phi_i^{(j)}(s)$ (Ng et al., 1999), where $\phi_i^{(j)}(s) = -||s - g_i^{(j)}||$ computes the edit distance between the state s and the goal, measured over the objects in each state. The shaping term densifies the reward, providing a meaningful signal for learning in nonterminal states.

Objective We maximize the immediate expected reward over all actions and use entropy regularization. The gradient is approximated by sampling an execution $\bar{e} = \langle (s_1, a_1), \ldots, (s_k, a_k) \rangle$ using our current policy:

$$\nabla_\theta \mathcal{J} = \frac{1}{k} \sum_{k'=1}^{k} \Bigg(\sum_{a \in \mathcal{A}} R(s_k, a, T(s_k, a)) \nabla_\theta \pi(\tilde{s}_k, a) + \lambda \nabla_\theta H(\pi(\tilde{s}_k, \cdot)) \Bigg),$$

where $H(\pi(\tilde{s}_k, \cdot)$ is the entropy term.

Algorithm Algorithm 1 shows the Single-step Reward Observation (SESTRA) learning algorithm. We iterate over the training data T times (line 1). For each example j and turn i, we first perform a rollout by sampling an execution $\bar{e}$ from π_θ with at most M actions (lines 5-11). If the rollout reaches the horizon without predicting STOP, we set the problem reward $P_i^{(j)}$ to -1.0 for the last step. Given the sampled states visited, we compute the entropy (line 15) and observe the immediate reward for all actions (line 19) for each step. Entropy and rewards are used to accumulate the gradient, which is applied to the parameters using RMSPROP (Dauphin et al., 2015) (line 20).

Discussion Observing the rewards for all actions for each visited state addresses an on-policy learning exploration problem. Actions that consistently receive negative reward early during learning will be visited with very low probability later on, and in practice, often not explored at all. Because the network is randomly initialized, these early negative rewards are translated into strong general biases that are not grounded well in the observed context. Our algorithm exposes the agent to such actions later on when they receive positive rewards even though the agent does not explore them during rollout. For example, in ALCHEMY, POP actions are sufficient to complete the first steps of good executions. As a result, early during learning, the agent learns a strong bias against PUSH actions. In practice, the agent then will not explore PUSH actions again. In our algorithm, as the agent learns to roll out the correct POP prefix, it is then exposed to the reward for the first PUSH even though it likely sampled another POP. It then unlearns its bias towards predicting POP.

Our learning algorithm can be viewed as a cost-sensitive variant of the oracle in DAGGER (Ross et al., 2011), where it provides the rewards for all actions instead of an oracle action. It is also related to Locally Optimal Learning to Search (LOLS; Chang et al., 2015) with two key distinctions: (a) instead of using different roll-in and roll-out policies, we use the model policy; and (b) we branch at each step, instead of once, but do not rollout

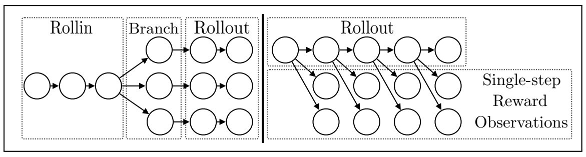

Figure 3: Illustration of LOLS (left; Chang et al., 2015) and our learning algorithm (SESTRA, right). LOLS branches a single time, and samples complete rollout for each branch to obtain the trajectory loss. SESTRA uses a complete on-policy rollout and single-step branching for all actions in each sample state.

Table 2: Counts of discourse phenomena in SCONE from 30 randomly selected development interactions for each domain. We count occurrences of coreference between instructions (e.g., *he leaves* in SCENE) and ellipsis (e.g., *then, drain 2 units* in ALCHEMY), when the last explicit mention of the referent was 1, 2, 3, or 4 turns in the past. We also report the average number of multi-turn references per interaction (Refs/Ex).

from branched actions since we only optimize the immediate reward. Figure 3 illustrates the comparison. Our summation over immediate rewards for all actions is related the summation of estimated Q-values for all actions in the Mean Actor-Critic algorithm (Asadi et al., 2017). Finally, our approach is related to Misra et al. (2017), who also maximize the immediate reward, but do not observe rewards for all actions for each state.

6 SCONE Domains and Data

SCONE has three domains: ALCHEMY, SCENE, and TANGRAMS. Each interaction contains five instructions. Table 1 shows data statistics. Table 2 shows discourse reference analysis. State encodings are detailed in the Supplementary Material.

ALCHEMY Each environment in ALCHEMY contains seven numbered beakers, each containing up to four colored chemicals in order. Figure 1 shows an example. Instructions describe pouring chemicals between and out of beakers, and mixing beakers. We treat all beakers as stacks. There are two action types: `PUSH` and `POP`. `POP` takes a beaker index, and removes the top color. `PUSH` takes a beaker index and a color, and adds the color at the top of the beaker. To encode a state, we encode each beaker with an RNN, and concatenate the last output with the beaker index embedding. The set of vectors is the state embedding.

SCENE Each environment in SCENE contains ten positions, each containing at most one person defined by a shirt color and an optional hat color. Instructions describe adding or removing people, moving a person to another position, and moving a person's hat to another person. There are four action types: `ADD_PERSON`, `ADD_HAT`, `REMOVE_PERSON`, and `REMOVE_HAT`. `ADD_PERSON` and `ADD_HAT` take a position to place the person or hat and the color of the person's shirt or hat. `REMOVE_PERSON` and `REMOVE_HAT` take the position to remove a person or hat from. To encode a state, we use a bidirectional RNN over the ordered positions. The input for each position is a concatenation of the color embeddings for the person and hat. The set of RNN hidden states is the state embedding.

TANGRAMS Each environment in TANGRAMS is a list containing at most five unique objects. Instructions describe removing or inserting an object into a position in the list, or swapping the positions of two items. There are two action types: `INSERT` and `REMOVE`. `INSERT` takes the position to insert an object, and the object identifier. `REMOVE` takes an object position. We embed each object by concatenating embeddings for its type and position. The resulting set is the state embedding.

7 Experimental Setup

Evaluation Following Long et al. (2016), we evaluate task completion accuracy using exact match between the final state and the annotated goal state. We report accuracy for complete interactions (5utts), the first three utterances of each interaction (3utts), and single instructions (Inst). For single instructions, execution starts from the annotated start state of the instruction.

Systems We report performance of ablations and two baseline systems: POLICYGRADIENT: policy gradient with cumulative episodic reward without a baseline, and CONTEXTUALBANDIT: the contextual bandit approach of Misra et al. (2017). Both systems use the reward with the

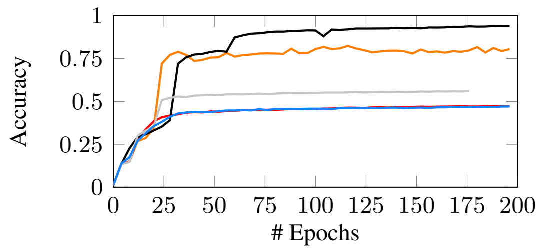

Figure 4: Instruction-level training accuracy per epoch when training five models on SCENE, demonstrating the effect of randomization in the learning method. Three of five experiments fail to learn effective models. The red and blue learning trajectories are overlapping.

shaping term and our model. We also report supervised learning results (SUPERVISED) by heuristically generating correct executions and computing maximum-likelihood estimate using context-action demonstration pairs. Only the supervised approach uses the heuristically generated labels. Although the results are not comparable, we also report the performance of previous approaches to SCONE. All three approaches generate logical representations based on lambda calculus. In contrast to our approach, this requires an ontology of hand built symbols and rules to evaluate the logical forms. Fried et al. (2018) uses supervised learning with annotated logical forms.

Training Details For test results, we run each experiment five times and report results for the model with best validation interaction accuracy. For ablations, we do the same with three experiments. We use a batch size of 20. We stop training using a validation set sampled from the training data. We hold the validation set constant for each domain for all experiments. We use patience over the average reward, and select the best model using interaction-level (5utts) validation accuracy. We tune λ, δ, and M on the development set. The selected values and other implementation details are described in the Supplementary Material.

8 Results

Table 3 shows test results. Our approach significantly outperforms POLICYGRADIENT and CONTEXTUALBANDIT, both of which suffer due to biases learned early during learning, hindering later exploration. This problem does not appear in TANGRAMS, where no action type is dominant at the beginning of executions, and all methods perform well. POLICYGRADIENT completely fails to learn ALCHEMY and SCENE due to observing only negative total rewards early during learning. Using a baseline, for example with an actor-critic method, will potentially close the gap to CONTEXTUALBANDIT. However, it is unlikely to address the on-policy exploration problem.

Table 4 shows development results, including model ablation studies. Removing previous instructions (– previous instructions) or both states (– current and initial state) reduces performance across all domains. Removing only the initial state (– initial state) or the current state (– current state) shows mixed results across the domains. Providing access to both initial and current states increases performance for ALCHEMY, but reduces performance on the other domains. We hypothesize that this is due to the increase in the number of parameters outweighing what is relatively marginal information for these domains. In our development and test results we use a single architecture across the three domains, the full approach, which has the highest interactive-level accuracy when averaged across the three domains (62.7 5utts). We also report mean and standard deviation for our approach over five trials. We observe exceptionally high variance in performance on SCENE, where some experiments fail to learn and training performance remains exceptionally low (Figure 4). This highlights the sensitivity of the model to the random effects of initialization, dropout, and ordering of training examples.

We analyze the instruction-level errors made by our best models when the agent is provided the correct initial state for the instruction. We study fifty examples in each domain to identify the type of failures. Table 5 shows the counts of major error categories. We consider multiple reference resolution errors. State reference errors indicate a failure to resolve a reference to the world state. For example, in ALCHEMY, the phrase *leftmost red beaker* specifies a beaker in the environment. If the model picked the correct action, but the wrong beaker, we count it as a state reference. We distinguish between multi-turn reference errors that should be feasible, and these that that are impossible to solve without access to states before executing previous utterances, which are not provided to our model. For example, in TANGRAMS, the instruction *put it back in the same place* refers to a previously-removed item. Because the agent only has access to the world state after following this instruction, it does not observe what kind of item was previously removed, and cannot identify the item to add. We

Class	ALC	SCE	TAN
State reference	23	13	7
Multi-turn reference	12	5	13
Impossible multi-turn reference	2	5	13
Ambiguous or incorrect label	2	19	12

Table 5: Common error counts in the three domains.

also find a significant number of errors due to ambiguous or incorrect instructions. For example, the SCENE instruction *person in green appears on the right end* is ambiguous. In the annotated goal, it is interpreted as referring to a person already in the environment, who moves to the 10th position. However, it can also be interpreted as a new person in green appearing in the 10th position.

We also study performance with respect to multi-turn coreference by observing whether the model was able to identify the correct referent for each occurrence included in the analysis in Table 2. The models were able to correctly resolve 92.3%, 88.7%, and 76.0% of references in ALCHEMY, SCENE, and TANGRAMS respectively.

Finally, we include attention visualization for examples from the three domains in the Supplementary Material.

9 Discussion

We propose a model to reason about context-dependent instructional language that display strong dependencies both on the history of the interaction and the state of the world. Future modeling work may include using intermediate world states from previous turns in the interaction, which is required for some of the most complex references in the data. We propose to train our model using SESTRA, a learning algorithm that takes advantage of single-step reward observations to overcome learned biases in on-policy learning. Our learning approach requires additional reward observations in comparison to conventional reinforcement learning. However, it is particularly suitable to recovering from biases acquired early during learning, for example due to biased action spaces, which is likely to lead to incorrect blame assignment in neural network policies. When the domain and model are less susceptible to such biases, the benefit of the additional reward observations is less pronounced. One possible direction for future work is to use an estimator to predict rewards for all actions, rather than observing them.

Abstract

The success of many natural language processing (NLP) tasks is bound by the number and quality of annotated data, but there is often a shortage of such training data. In this paper, we ask the question: "Can we combine a neural network (NN) with regular expressions (RE) to improve supervised learning for NLP?". In answer, we develop novel methods to exploit the rich expressiveness of REs at different levels within a NN, showing that the combination significantly enhances the learning effectiveness when a small number of training examples are available. We evaluate our approach by applying it to spoken language understanding for intent detection and slot filling. Experimental results show that our approach is highly effective in exploiting the available training data, giving a clear boost to the RE-unaware NN.

1 Introduction

Regular expressions (REs) are widely used in various natural language processing (NLP) tasks like pattern matching, sentence classification, sequence labeling, etc. (Chang and Manning, 2014). As a technique based on human-crafted rules, it is concise, interpretable, tunable, and does not rely on much training data to generate. As such, it is commonly used in industry, especially when the available training examples are limited – a problem known as few-shot learning (GC et al., 2015).

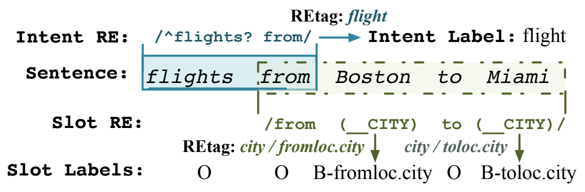
While powerful, REs have a poor generalization ability because all synonyms and variations in a RE must be explicitly specified. As a result, REs are often ensembled with data-driven methods, such as neural network (NN) based techniques, where a set of carefully-written REs are used to handle certain cases with high precision, leaving the rest for data-driven methods.

We believe the use of REs can go beyond simple pattern matching. In addition to being a separate classifier to be ensembled, a RE also encodes a developer's knowledge for the problem domain. The knowledge could be, for example, the informative words (***clue words***) within a RE's surface form. We argue that such information can be utilized by data-driven methods to achieve better prediction results, especially in few-shot learning.

This work investigates the use of REs to improve NNs – a learning framework that is widely used in many NLP tasks (Goldberg, 2017). The combination of REs and a NN allows us to exploit the conciseness and effectiveness of REs and the strong generalization ability of NNs. This also provides us an opportunity to learn from various kinds of REs, since NNs are known to be good at tolerating noises (Xie et al., 2016).

This paper presents novel approaches to combine REs with a NN at different levels. At the input layer, we propose to use the evaluation outcome of REs as the input features of a NN (Sec.3.2). At the network module level, we show how to exploit the knowledge encoded in REs to guide the attention mechanism of a NN (Sec. 3.3). At the output layer, we combine the evaluation outcome of a RE with the NN output in a learnable manner (Sec. 3.4).

We evaluate our approach by applying it to two spoken language understanding (SLU) tasks, namely *intent detection* and *slot filling*, which respectively correspond to two fundamental NLP tasks: sentence classification and sequence labeling. To demonstrate the usefulness of REs in real-world scenarios where the available number of annotated data can vary, we explore both the few-shot learning setting and the one with full training data. Experimental results show that our approach is highly effective in utilizing the available



REtag: flight
Intent RE:
/^flights? from/
Intent Label: flight
Sentence:
flights from Boston to Miami
Slot RE:
/from (__CITY) to (__CITY)/
REtag: city / fromloc.city
city / toloc.city
Slot Labels:
O O B-fromloc.city O B-toloc.city

Figure 1: A sentence from the ATIS dataset. REs can be used to detect the intent and label slots.

annotated data, yielding significantly better learning performance over the RE-unaware method.

Our contributions are as follows. (1) We present the first work to systematically investigate methods for combining REs with NNs. (2) The proposed methods are shown to clearly improve the NN performance in both the few-shot learning and the full annotation settings. (3) We provide a set of guidance on how to combine REs with NNs and RE annotation.

2 Background

2.1 Typesetting

In this paper, we use italic for emphasis like *intent detection*, the Courier typeface for abbreviations like RE, bold italic for the first appearance of a concept like ***clue words***, Courier surrounded by / for regular expressions like /list(the)? __AIRLINE/, and underlined italic for words of sentences in our dataset like *Boston*.

2.2 Problem Definition

Our work targets two SLU tasks: *intent detection* and *slot filling*. The former is a sentence classification task where we learn a function to map an input sentence of n words, $\mathbf{x} = [x_1, ..., x_n]$, to a corresponding ***intent label***, c. The latter is a sequence labeling task for which we learn a function to take in an input query sentence of n words, $\mathbf{x} = [x_1, ..., x_n]$, to produce a corresponding labeling sequence, $\mathbf{y} = [y_1, ..., y_n]$, where y_i is the ***slot label*** of the corresponding word, x_i.

Take the sentence in Fig. 1 as an example. A successful intent detector would suggest the intent of the sentence as *flight*, i.e., querying about flight-related information. A slot filler, on the other hand, should identify the slots *fromloc.city* and *toloc.city* by labeling *Boston* and *Miami*, respectively, using the begin-inside-outside (BIO) scheme.

2.3 The Use of Regular Expressions

In this work, a RE defines a mapping from a text *pattern* to several ***REtags*** which are the same as or related to the ***target labels*** (i.e., intent and slot labels). A search function takes in a RE, applies it to all sentences, and returns any texts that match the pattern. We then assign the REtag (s) (that are associated with the matching RE) to either the matched sentence (for intent detection) or some matched phrases (for slot filling).

Specifically, our REtags for intent detection are the same as the intent labels. For example, in Fig. 1, we get a REtag of *flight* that is the same as the intent label *flight*.

For slot filling, we use two different sets of REs. Given the group functionality of RE, we can assign REtags to our interested ***RE groups*** (i.e., the expressions defined inside parentheses). The translation from REtags to slot labels depends on how the corresponding REs are used. (1) When REs are used at the network module level (Sec. 3.3), the corresponding REtags are the same as the target slot labels. For instance, the slot RE in Fig. 1 will assign *fromloc.city* to the first RE group and *toloc.city* to the second one. Here, __CITY is a list of city names, which can be replaced with a RE string like /Boston|Miami|LA|.../. (2) If REs are used in the input (Sec. 3.2) and the output layers (Sec. 3.4) of a NN, the corresponding REtag would be different from the target slot labels. In this context, the two RE groups in Fig. 1 would be simply tagged as *city* to capture the commonality of three related target slot labels: *fromloc.city*, *toloc.city*, *stoploc.city*. Note that we could use the target slot labels as REtags for all the settings. The purpose of abstracting REtags to a simplified version of the target slot labels here is to show that REs can still be useful when their evaluation outcome does not exactly match our learning objective. Further, as shown in Sec. 4.2, using simplified REtags can also make the development of REs easier in our tasks.

Intuitively, complicated REs can lead to better performance but require more efforts to generate. Generally, there are two aspects affecting RE complexity most: the number of RE groups[1] and *or* clauses (i.e., expressions separated by the disjunction operator |) in a RE group. Having a larger number of RE groups often leads to better

[1] When discussing complexity, we consider each semantically independent consecutive word sequence as a RE group (excluding clauses, such as \w+, that can match any word). For instance, the RE: /how long(\w+){1,2}? (it take|flight)/ has two RE groups: (how long) and (it take|flight).

precision but lower coverage on pattern matching, while a larger number of *or* clauses usually gives a higher coverage but slightly lower precision.

3 Our Approach

As depicted in Fig. 2, we propose to combine `NNs` and `REs` from three different angles.

3.1 Base Models

We use the Bi-directional LSTM (`BLSTM`) as our base `NN` model because it is effective in both intent detection and slot filling (Liu and Lane, 2016).

Intent Detection. As shown in Fig. 2, the `BLSTM` takes as input the word embeddings $[\mathbf{x}_1, ..., \mathbf{x}_n]$ of a n-word sentence, and produces a vector $\mathbf{h}_i$ for each word i. A self-attention layer then takes in the vectors produced by the `BLSTM` to compute the sentence embedding $\mathbf{s}$:

$$\mathbf{s} = \sum_i \alpha_i \mathbf{h}_i, \quad \alpha_i = \frac{\exp(\mathbf{h}_i^\intercal \mathbf{W}\mathbf{c})}{\sum_i \exp(\mathbf{h}_i^\intercal \mathbf{W}\mathbf{c})} \tag{1}$$

where α_i is the attention for word i, $\mathbf{c}$ is a randomly initialized trainable vector used to select informative words for classification, and $\mathbf{W}$ is a weight matrix. Finally, $\mathbf{s}$ is fed to a softmax classifier for intent classification.

Slot Filling. The model for slot filling is straightforward – the slot label prediction is generated by a softmax classier which takes in the `BLSTM`'s output $\mathbf{h}_i$ and produces the slot label of word i. Note that attention aggregation in Fig. 2 is only employed by the network module level method presented in Sec. 3.3.

3.2 Using REs at the Input Level

At the input level, we use the evaluation outcomes of `REs` as features which are fed to `NN` models.

Intent Detection. Our `REtag` for intent detection is the same as our target intent label. Because real-world `REs` are unlikely to be perfect, one sentence may be matched by more than one `RE`. This may result in several `REtags` that are conflict with each other. For instance, the sentence *list the Delta airlines flights to Miami* can match a `RE`: `/list( the)? __AIRLINE/` that outputs tag *airline*, and another `RE`: `/list( \w+){0,3} flights?/` that outputs tag *flight*.

To resolve the conflicting situations illustrated above, we average the randomly initialized trainable tag embeddings to form an aggregated embedding as the `NN` input. There are two ways to use the aggregated embedding. We can append the aggregated embedding to either the embedding of every input word, or the input of the softmax classifier (see ① in Fig. 2(a)). To determine which strategy works best, we perform a pilot study. We found that the first method causes the tag embedding to be copied many times; consequently, the `NN` tends to heavily rely on the `REtags`, and the resulting performance is similar to the one given by using `REs` alone in few-shot settings. Thus, we adopt the second approach.

Slot Filling. Since the evaluation outcomes of slot `REs` are word-level tags, we can simply embed and average the `REtags` into a vector $\mathbf{f}_i$ for each word, and append it to the corresponding word embedding $\mathbf{w}_i$ (as shown in ① in Fig. 2(b)). Note that we also extend the slot `REtags` into the `BIO` format, e.g., the `REtags` of phrase *New York* are *B-city* and *I-city* if its original tag is *city*.

3.3 Using REs at the Network Module Level

At the network module level, we explore ways to utilize the clue words in the surface form of a `RE` (bold blue arrows and words in ② of Fig. 2) to guide the attention module in `NNs`.

Intent Detection. Taking the sentence in Fig. 1 for example, the `RE`: `/^flights? from/` that leads to intent *flight* means that *flights from* are the key words to decide the intent *flight*. Therefore, the attention module in `NNs` should leverage these two words to get the correct prediction. To this end, we extend the base intent model by making two changes to incorporate the guidance from `REs`.

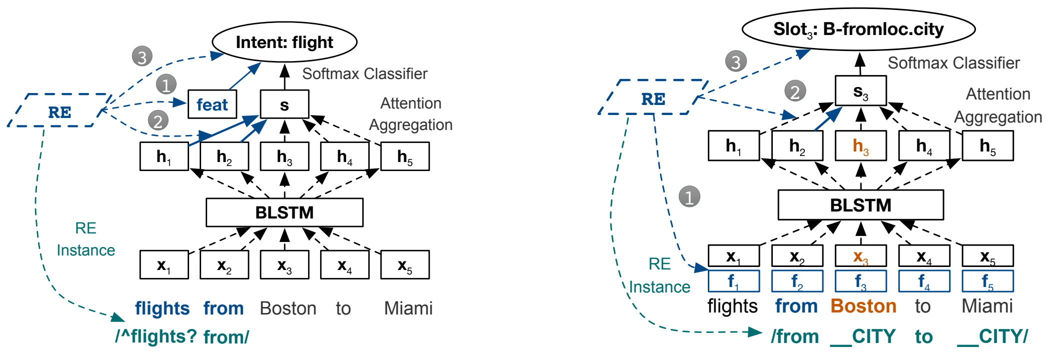
First, since each intent has its own clue words, using a single sentence embedding for all intent labels would make the attention less focused. Therefore, we let each intent label k use different attention $\mathbf{a}_k$, which is then used to generate the sentence embedding $\mathbf{s}_k$ for that intent:

$$\mathbf{s}_k = \sum_i \alpha_{ki} \mathbf{h}_i, \quad \alpha_{ki} = \frac{\exp(\mathbf{h}_i^\intercal \mathbf{W}_a \mathbf{c}_k)}{\sum_i \exp(\mathbf{h}_i^\intercal \mathbf{W}_a \mathbf{c}_k)} \tag{2}$$

where $\mathbf{c}_k$ is a trainable vector for intent k which is used to compute attention $\mathbf{a}_k$, $\mathbf{h}_i$ is the `BLSTM` output for word i, and $\mathbf{W}_a$ is a weight matrix.

The probability p_k that the input sentence expresses intent k is computed by:

$$p_k = \frac{\exp(logit_k)}{\sum_k \exp(logit_k)}, \qquad logit_k = \mathbf{w}_k \mathbf{s}_k + b_k \tag{3}$$



(a) Intent Detection (b) Slot Filling (predicting slot label for *Boston*)

Figure 2: Overview of our methods. ①, ②, ③ refers to the methods in Sec. 3.2, 3.3, 3.4 respectively.

where $\mathbf{w}_k$, $logit_k$, b_k are weight vector, logit, and bias for intent k, respectively.

Second, apart from indicating a sentence for intent k (***positive REs***), a RE can also indicate that a sentence does not express intent k (***negative REs***). We thus use a new set of attention (***negative attentions***, in contrast to ***positive attentions***), to compute another set of logits for each intent with Eqs. 2 and 3. We denote the logits computed by positive attentions as $logit_{pk}$, and those by negative attentions as $logit_{nk}$, the final logit for intent k can then be calculated as:

$$logit_k = logit_{pk} - logit_{nk} \tag{4}$$

To use REs to guide attention, we add an attention loss to the final loss:

$$loss_{att} = \sum_k \sum_i t_{ki} \log(\alpha_{ki}) \tag{5}$$

where t_{ki} is set to 0 when none of the matched REs (that leads to intent k) marks word i as a clue word – otherwise t_{ki} is set to $1/l_k$, where l_k is the number of clue words for intent k (if no matched RE leads to intent k, then $t_{k*} = 0$). We use Eq. 5 to compute the positive attention loss, $loss_{att\_p}$, for positive REs and negative attention loss, $loss_{att\_n}$, for negative ones. The final loss is computed as:

$$loss = loss_c + \beta_p loss_{att\_p} + \beta_n loss_{att\_n} \tag{6}$$

where $loss_c$ is the original classification loss, β_p and β_n are weights for the two attention losses.

Slot Filling. The ***two-side attention*** (positive and negative attention) mechanism introduced for intent prediction is unsuitable for slot filling. Because for slot filling, we need to compute attention for each word, which demands more computational and memory resources than doing that for intent detection[2].

Because of the aforementioned reason, we use a simplified version of the two-side attention, where all the slot labels share the same set of positive and negative attention. Specifically, to predict the slot label of word i, we use the following equations, which are similar to Eq. 1, to generate a sentence embedding $\mathbf{s}_{pi}$ with regard to word i from positive attention:

$$\mathbf{s}_{pi} = \sum_j \alpha_{pij}\mathbf{h}_j, \quad \alpha_{pij} = \frac{\exp(\mathbf{h}_j^\intercal \mathbf{W}_{sp}\mathbf{h}_i)}{\sum_j \exp(\mathbf{h}_j^\intercal \mathbf{W}_{sp}\mathbf{h}_i)} \tag{7}$$

where $\mathbf{h}_i$ and $\mathbf{h}_j$ are the BLSTM outputs for word i and j respectively, $\mathbf{W}_{sp}$ is a weight matrix, and α_{pij} is the positive attention value for word j with respect to word i. Further, by replacing $\mathbf{W}_{sp}$ with $\mathbf{W}_{sn}$, we use Eq. 7 again to compute negative attention and generate the corresponding sentence embedding $\mathbf{s}_{ni}$.

Finally, the prediction $\mathbf{p}_i$ for word i can be calculated as:

$$\begin{aligned}\mathbf{p}_i = \text{softmax}((&\mathbf{W}_p[\mathbf{s}_{pi};\mathbf{h}_i] + \mathbf{b}_p) \\ &-(\mathbf{W}_n[\mathbf{s}_{ni};\mathbf{h}_i] + \mathbf{b}_n))\end{aligned} \tag{8}$$

where $\mathbf{W}_p$, $\mathbf{W}_n$, $\mathbf{b}_p$, $\mathbf{b}_n$ are weight matrices and bias vectors for positive and negative attention, respectively. Here we append the BLSTM output $\mathbf{h}_i$ to $\mathbf{s}_{pi}$ and $\mathbf{s}_{ni}$ because the word i itself also plays a crucial part in identifying its slot label.

3.4 Using REs at the Output Level

At the output level, REs are used to amend the output of NNs. At this level, we take the same

[2]Since we need to assign a label to each word, if we still compute attention for each slot label, we will have to compute $2 \times L \times n^2$ attention values for one sentence. Here, L is the number of tags and n is the sentence length. The BIO tagging format will further double the number of tags.

approach used for intent detection and slot filling (see ③ in Fig. 2).

As mentioned in Sec. 2.3, the slot `RE`s used in the output level only produce a simplified version of target slot labels, for which we can further annotate their corresponding target slot labels. For instance, a `RE` that outputs *city* can lead to three slot labels: *fromloc.city*, *toloc.city*, *stoploc.city*.

Let z_k be a 0-1 indicator of whether there is at least one matched `RE` that leads to target label k (intent or slot label), the final logits of label k for a sentence (or a specific word for slot filling) is:

$$logit_k = logit'_k + w_k z_k \tag{9}$$

where $logit'_k$ is the logit produced by the original `NN`, and w_k is a trainable weight indicating the overall confidence for `RE`s that lead to target label k. Here we do not assign a trainable weight for each `RE` because it is often that only a few sentences match a `RE`.

We modify the logit instead of the final probability because a logit is an unconstrained real value, which matches the property of $w_k z_k$ better than probability. Actually, when performing model ensemble, ensembling with logits is often empirically better than with the final probability[3]. This is also the reason why we choose to operate on logits in Sec. 3.3.

4 Evaluation Methodology

Our experiments aim to answer three questions: **Q1:** Does the use of `RE`s enhance the learning quality when the number of annotated instances is small? **Q2:** Does the use of `RE`s still help when using the full training data? **Q3:** How can we choose from different combination methods?

4.1 Datasets

We use the ATIS dataset (Hemphill et al., 1990) to evaluate our approach. This dataset is widely used in `SLU` research. It includes queries of flights, meal, etc. We follow the setup of Liu and Lane (2016) by using 4,978 queries for training and 893 for testing, with 18 intent labels and 127 slot labels. We also split words like *Miami's* into *Miami 's* during the tokenization phase to reduce the number of words that do not have a pre-trained word embedding. This strategy is useful for few-shot learning.

[3] An example can be found in the ensemble version that Juan et al. (2016) used in the Avazu Kaggle competition.

To answer **Q1** , we also exploit the ***full few-shot learning setting***. Specifically, for intent detection, we randomly select 5, 10, 20 training instances for each intent to form the few-shot training set; and for slot filling, we also explore 5, 10, 20 shots settings. However, since a sentence typically contains multiple slots, the number of mentions of frequent slot labels may inevitably exceeds the target shot count. To better approximate the target shot count, we select sentences for each slot label in ascending order of label frequencies. That is k_1-shot dataset will contain k_2-shot dataset if $k_1 > k_2$. All settings use the original test set.

Since most existing few-shot learning methods require either many few-shot classes or some classes with enough data for training, we also explore the ***partial few-shot learning setting*** for intent detection to provide a fair comparison for existing few-shot learning methods. Specifically, we let the 3 most frequent intents have 300 training instances, and the rest remains untouched. This is also a common scenario in real world, where we often have several frequent classes and many classes with limited data. As for slot filling, however, since the number of mentions of frequent slot labels already exceeds the target shot count, the original slot filling few-shot dataset can be directly used to train existing few-shot learning methods. Therefore, we do not distinguish full and partial few-shot learning for slot filling.

4.2 Preparing REs

We use the syntax of `RE`s in Perl in this work. Our `RE`s are written by a paid annotator who is familiar with the domain. It took the annotator in total less than 10 hours to develop all the `RE`s, while a domain expert can accomplish the task faster. We use the 20-shot training data to develop the `RE`s, but word lists like cities are obtained from the full training set. The development of `RE`s is considered completed when the `RE`s can cover most of the cases in the 20-shot training data with resonable precision. After that, the `RE`s are fixed throughout the experiments.

The majority of the time for writing the `RE`s is proportional to the number of `RE` groups. It took about 1.5 hours to write the 54 intent `RE`s with on average 2.2 groups per `RE`. It is straightforward to write the slot `RE`s for the input and output level methods, for which it took around 1 hour to write the 60 `RE`s with 1.7 groups on average. By contrast, writing slot REs to guide attention requires more efforts as the annotator needs to carefully select clue words and annotate the full slot label. As a result, it took about 5.5 hours to generate 115 REs with on average 3.3 groups. The performance of the REs can be found in the last line of Table 1.

In practice, a positive RE for intent (or slot) k can often be treated as negative REs for other intents (or slots). As such, we use the positive REs for intent (or slot) k as the negative REs for other intents (or slots) in our experiments.

4.3 Experimental Setup

Hyper-parameters. Our hyper-parameters for the BLSTM are similar to the ones used by Liu and Lane (2016). Specifically, we use batch size 16, dropout probability 0.5, and BLSTM cell size 100. The attention loss weight is 16 (both positive and negative) for full few-shot learning settings and 1 for other settings. We use the 100d GloVe word vectors (Pennington et al., 2014) pre-trained on Wikipedia and Gigaword (Parker et al., 2011), and the Adam optimizer (Kingma and Ba, 2014) with learning rate 0.001.

Evaluation Metrics. We report accuracy and macro-F1 for intent detection, and micro/macro-F1 for slot filling. Micro/macro-F1 are the harmonic mean of micro/macro precision and recall. Macro-precision/recall are calculated by averaging precision/recall of each label, and micro-precision/recall are averaged over each prediction.

Competitors and Naming Conventions. Here, a bold Courier typeface like **BLSTM** denotes the notations of the models that we will compare in Sec. 5.

Specifically, we compare our methods with the baseline **BLSTM** model (Sec. 3.1). Since our attention loss method (Sec. 3.3) uses two-side attention, we include the raw two-side attention model without attention loss (**+two**) for comparison as well. Besides, we also evaluate the RE output (**REO**), which uses the REtags as prediction directly, to show the quality of the REs that we will use in the experiments.[4]

As for our methods for combinging REs with NN, **+feat** refers to using REtag as input features (Sec. 3.2), **+posi** and **+neg** refer to using positive and negative attention loss respectively, **+both** refers to using both postive and negative attention losses (Sec. 3.3), and **+logit** means using REtag to modify NN output (Sec. 3.4).

Moverover, since the REs can also be formatted as first-order-logic (FOL) rules, we also compare our methods with the teacher-student framework proposed by Hu et al. (2016a), which is a general framework for distilling knowledge from FOL rules into NN (**+hu16**). Besides, since we consider few-short learning, we also include the memory module proposed by Kaiser et al. (2017), which performs well in various few-shot datasets (**+mem**)[5]. Finally, the state-of-art model on the ATIS dataset is also included (**L&L16**), which jointly models the intent detection and slot filling in a single network (Liu and Lane, 2016).

5 Experimental Results

5.1 Full Few-Shot Learning

To answer **Q1** , we first explore the full few-shot learning scenario.

Intent Detection. As shown in Table 1, except for 5-shot, all approaches improve the baseline BLSTM. Our network-module-level methods give the best performance because our attention module directly receives signals from the clue words in REs that contain more meaningful information than the REtag itself used by other methods. We also observe that since negative REs are derived from positive REs with some noises, posi performs better than neg when the amount of available data is limited. However, neg is slightly better in 20-shot, possibly because negative REs significantly outnumbers the positive ones. Besides, two alone works better than the BLSTM when there are sufficient data, confirming the advantage of our two-side attention architecture.

As for other proposed methods, the output level method (logit) works generally better than the input level method (feat), except for the 5-shot case. We believe this is due to the fewer number of RE related parameters and the shorter distance that the gradient needs to travel from the loss to these parameters – both make logit easier to train. However, since logit directly modifies the output, the final prediction is more sensitive to the insufficiently trained weights in logit, leading to the inferior results in the 5-shot setting.

[4] For slot filling, we evaluate the REs that use the target slot labels as REtags.

[5] We tune C and π_0 of hu16, and choose (0.1, 0.3) for intent, and (1, 0.3) for slot. We tune memory-size and k of mem, and choose (1024, 64) for intent, and (2048, 64) for slot.

Model Type	Model Name	Intent 5-shot	Intent 10-shot	Intent 20-shot	Slot 5-shot	Slot 10-shot	Slot 20-shot
		Macro-F1 / Accuracy			Macro-F1 / Accuracy		
Base Model	BLSTM	45.28 / 60.02	60.62 / 64.61	63.60 / 80.52	60.78 / 83.91	74.28 / 90.19	80.57 / 93.08
Input Level	+feat	49.40 / 63.72	64.34 / 73.46	65.16 / 83.20	**66.84 / 88.96**	79.67 / **93.64**	84.95 / 95.00
Output Level	+logit	46.01 / 58.68	63.51 / 77.83	69.22 / **89.25**	63.68 / 86.18	76.12 / 91.64	83.71 / 94.43

	+two+both	**54.86 / 75.36**	**71.23 / 85.44**	**75.58** / 88.80	59.47 / 83.35	73.55 / 89.54	79.02 / 92.22
Few-Shot Model	+mem	-	-	-	61.25 / 83.45	77.83 / 90.57	82.98 / 93.49
	+mem+feat	-	-	-	65.08 / 88.07	**80.64** / 93.47	**85.45 / 95.39**
RE Output	REO	70.31 / 68.98			42.33 / 70.79		

Table 1: Results on Full Few-Shot Learning Settings. For slot filling, we do not distinguish full and partial few-shot learning settings (see Sec. 4.1).

To compare with existing methods of combining NN and rules, we also implement the teacher-student network (Hu et al., 2016a). This method lets the NN learn from the posterior label distribution produced by FOL rules in a teacher-student framework, but requires considerable amounts of data. Therefore, although both hu16 and logit operate at the output level, logit still performs better than hu16 in these few-shot settings, since logit is easier to train.

It can also be seen that starting from 10-shot, two+both significantly outperforms pure REO. This suggests that by using our attention loss to connect the distributional representation of the NN and the clue words of REs, we can generalize RE patterns within a NN architecture by using a small amount of annotated data.

Slot Filling. Different from intent detection, as shown in Table 1, our attention loss does not work for slot filling. The reason is that the slot label of a ***target word*** (the word for which we are trying to predict a slot label) is decided mainly by the semantic meaning of the word itself, together with 0-3 phrases in the context to provide supplementary information. However, our attention mechanism can only help in recognizing clue words in the context, which is less important than the word itself and have already been captured by the BLSTM, to some extent. Therefore, the attention loss and the attention related parameters are more of a burden than a benefit. As is shown in Fig. 1, the model recognizes *Boston* as *fromloc.city* mainly because *Boston* itself is a city, and its context word *from* may have already been captured by the BLSTM and our attention mechanism does not help much. By examining the attention values of +two trained on the full dataset, we find that instead of marking informative context words, the attention tends to concentrate on the target word itself. This observation further reinforces our hypothesis on the attention loss.

On the other hand, since the REtags provide extra information, such as type, about words in the sentence, logit and feat generally work better. However, different from intent detection, feat only outperforms logit by a margin. This is because feat can use the REtags of all words to generate better context representations through the NN, while logit can only utilize the REtag of the target word before the final output layer. As a result, feat actually gathers more information from REs and can make better use of them than logit. Again, hu16 is still outperformed by logit, possibly due to the insufficient data support in this few-shot scenario. We also see that even the BLSTM outperforms REO in 5-shot, indicating while it is hard to write high-quality RE patterns, using REs to boost NNs is still feasible.

Summary. The amount of extra information that a NN can utilize from the combined REs significantly affects the resulting performance. Thus, the attention loss methods work best for intent detection and feat works best for slot filling. We also see that the improvements from REs decreases as having more training data. This is not surprising because the implicit knowledge embedded in the REs are likely to have already been captured by a sufficient large annotated dataset and in this scenario using the REs will bring in fewer benefits.

5.2 Partial Few-Shot Learning

To better understand the relationship between our approach and existing few-shot learning methods, we also implement the memory network method

Model	5-shot	10-shot	20-shot
	Macro-F1 / Accuracy		
BLSTM	64.73 / 91.71	78.55 / 96.53	82.05 / 97.20
+hu16	65.22 / 91.94	84.49 / 96.75	84.80 / 97.42
+two	65.59 / 91.04	77.92 / 95.52	81.01 / 96.86
+two+both	66.62 / 92.05	85.75 / 96.98	**87.97 / 97.76**
+mem	67.54 / 91.83	82.16 / 96.75	84.69 / 97.42
+mem+posi	**70.46 / 93.06**	**86.03 / 97.09**	86.69 / 97.65

Table 2: Intent Detection Results on Partial Few-Shot Learning Setting.

Model	Intent	Slot
	Macro-F1/Accuracy	Macro-F1/Micro-F1
BLSTM	92.50 / 98.77	85.01 / 95.47
+feat	91.86 / 97.65	86.7 / 95.55
+logit	92.48 / 98.77	86.94 / 95.42
+hu16	93.09 / 98.77	85.74 / 95.33
+two	93.64 / 98.88	84.45 / 95.05
+two+both	**96.20 / 98.99**	85.44 / 95.27
+mem	93.42 / 98.77	85.72 / 95.37
+mem+posi/feat	94.36 / **98.99**	**87.82 / 95.90**
L&L16	- / 98.43	- / 95.98

Table 3: Results on Full Dataset. The left side of '/' applies for intent, and the right side for slot.

(Kaiser et al., 2017) which achieves good results in various few-shot datasets. We adapt their open-source code, and add their memory module (mem) to our BLSTM model.

Since the memory module requires to be trained on either many few-shot classes or several classes with extra data, we expand our full few-shot dataset for intent detection, so that the top 3 intent labels have 300 sentences (partial few-shot).

As shown in Table 2, mem works better than BLSTM, and our attention loss can be further combined with the memory module (mem+posi), with even better performance. hu16 also works here, but worse than two+both. Note that, the memory module requires the input sentence to have only one embedding, thus we only use one set of positive attention for combination.

As for slot filling, since we already have extra data for frequent tags in the original few-shot data (see Sec. 4.1), we use them directly to run the memory module. As shown in the bottom of Table 1, mem also improves the base BLSTM, and gains further boost when it is combined with feat[6].

5.3 Full Dataset

To answer **Q2**, we also evaluate our methods on the full dataset. As seen in Table 3, for intent detection, while two+both still works, feat and logit no longer give improvements. This shows

[6]For compactness, we only combine the best method in each task with mem, but others can also be combined.

Model	Intent		Slot	
	Macro-F1 / Accuracy		Macro-F1 / Micro-F1	
	Complex	Simple	Complex	Simple
BLSTM	63.60 / 80.52		80.57 / 93.08	
+feat	65.16/**83.20**	**66.51**/80.40	**84.95/95.00**	83.88/94.71
+logit	**69.22/89.25**	65.09/83.09	**83.71/94.43**	83.22/93.94
+both	**75.58/88.80**	74.51/87.46	-	-

Table 4: Results on 20-Shot Data with Simple REs. +both refers to +two +both for short.

that since both REtag and annotated data provide intent labels for the input sentence, the value of the extra noisy tag from RE become limited as we have more annotated data. However, as there is no guidance on attention in the annotations, the clue words from REs are still useful. Further, since feat concatenates REtags at the input level, the powerful NN makes it more likely to overfit than logit, therefore feat performs even worse when compared to the BLSTM.

As for slot filling, introducing feat and logit can still bring further improvements. This shows that the word type information contained in the REtags is still hard to be fully learned even when we have more annotated data. Moreover, different from few-shot settings, two+both has a better macro-F1 score than the BLSTM for this task, suggesting that better attention is still useful when the base model is properly trained.

Again, hu16 outperforms the BLSTM in both tasks, showing that although the REtags are noisy, their teacher-student network can still distill useful information. However, hu16 is a general framework to combine FOL rules, which is more indirect in transferring knowledge from rules to NN than our methods. Therefore, it is still inferior to attention loss in intent detection and feat in slot filling, which are designed to combine REs.

Further, mem generally works in this setting, and can receive further improvement by combining our fusion methods. We can also see that two+both works clearly better than the state-of-art method (L&L16) in intent detection, which jointly models the two tasks. And mem+feat is comparative to L&L16 in slot filling.

5.4 Impact of the RE Complexity

We now discuss how the RE complexity affects the performance of the combination. We choose to control the RE complexity by modifying the number of groups. Specifically, we reduce the number of groups for existing REs to decrease RE complexity. To mimic the process of writing simple

REs from scratch, we try our best to keep the key RE groups. For intent detection, all the REs are reduced to at most 2 groups. As for slot filling, we also reduce the REs to at most 2 groups, and for some simples case, we further reduce them into word-list patterns, e.g., (__CITY).

As shown in Table 4, the simple REs already deliver clear improvements to the base NN models, which shows the effectiveness of our methods, and indicates that simple REs are quite cost-efficient since these simple REs only contain 1-2 RE groups and thus very easy to produce. We can also see that using complex REs generally leads to better results compared to using simple REs. This indicates that when considering using REs to improve a NN model, we can start with simple REs, and gradually increase the RE complexity to improve the performance over time[7].

6 Related Work

Our work builds upon the following techniques, while qualitatively differing from each

NN with Rules. On the initialization side, Li et al. (2017) uses important n-grams to initialize the convolution filters. On the input side, Wang et al. (2017a) uses knowledge base rules to find relevant concepts for short texts to augment input. On the output side, Hu et al. (2016a; 2016b) and Guo et al. (2017) use FOL rules to rectify the output probability of NN, and then let NN learn from the rectified distribution in a teacher-student framework. Xiao et al. (2017), on the other hand, modifies the decoding score of NN by multiplying a weight derived from rules. On the loss function side, people modify the loss function to model the relationship between premise and conclusion (Demeester et al., 2016), and fit both human-annotated and rule-annotated labels (Alashkar et al., 2017). Since fusing in initialization or in loss function often require special properties of the task, these approaches are not applicable to our problem. Our work thus offers new ways to exploit RE rules at different levels of a NN.

NNs and REs. As for NNs and REs, previous work has tried to use RE to speed up the decoding phase of a NN (Strauß et al., 2016) and generating REs from natural language specifications of the RE (Locascio et al., 2016). By contrast, our work aims to use REs to improve the prediction ability of a NN.

Few-Shot Learning. Prior work either considers few-shot learning in a metric learning framework (Koch et al., 2015; Vinyals et al., 2016), or stores instances in a memory (Santoro et al., 2016; Kaiser et al., 2017) to match similar instances in the future. Wang et al. (2017b) further uses the semantic meaning of the class name itself to provide extra information for few-shot learning. Unlike these previous studies, we seek to use the human-generated REs to provide additional information.

Natural Language Understanding. Recurrent neural networks are proven to be effective in both intent detection (Ravuri and Stoicke, 2015) and slot filling (Mesnil et al., 2015). Researchers also find ways to jointly model the two tasks (Liu and Lane, 2016; Zhang and Wang, 2016). However, no work so far has combined REs and NNs to improve intent detection and slot filling.

7 Conclusions

In this paper, we investigate different ways to combine NNs and REs for solving typical SLU tasks. Our experiments demonstrate that the combination clearly improves the NN performance in both the few-shot learning and the full dataset settings. We show that by exploiting the implicit knowledge encoded within REs, one can significantly improve the learning performance. Specifically, we observe that using REs to guide the attention module works best for intent detection, and using REtags as features is an effective approach for slot filling. We provide interesting insights on how REs of various forms can be employed to improve NNs, showing that while simple REs are very cost-effective, complex REs generally yield better results.

Token-level and sequence-level loss smoothing for RNN language models

Abstract

Despite the effectiveness of recurrent neural network language models, their maximum likelihood estimation suffers from two limitations. It treats all sentences that do not match the ground truth as equally poor, ignoring the structure of the output space. Second, it suffers from "exposure bias": during training tokens are predicted given ground-truth sequences, while at test time prediction is conditioned on generated output sequences. To overcome these limitations we build upon the recent reward augmented maximum likelihood approach *i.e.* sequence-level smoothing that encourages the model to predict sentences close to the ground truth according to a given performance metric. We extend this approach to token-level loss smoothing, and propose improvements to the sequence-level smoothing approach. Our experiments on two different tasks, image captioning and machine translation, show that token-level and sequence-level loss smoothing are complementary, and significantly improve results.

1 Introduction

Recurrent neural networks (RNNs) have recently proven to be very effective sequence modeling tools, and are now state of the art for tasks such as machine translation (Cho et al., 2014; Sutskever et al., 2014; Bahdanau et al., 2015), image captioning (Kiros et al., 2014; Vinyals et al., 2015; Anderson et al., 2017) and automatic speech recognition (Chorowski et al., 2015; Chiu et al., 2017).

The basic principle of RNNs is to iteratively compute a vectorial sequence representation, by applying at each time-step the same trainable function to compute the new network state from the previous state and the last symbol in the sequence. These models are typically trained by maximizing the likelihood of the target sentence given an encoded source (text, image, speech).

Maximum likelihood estimation (MLE), however, has two main limitations. First, the training signal only differentiates the ground-truth target output from all other outputs. It treats all other output sequences as equally incorrect, regardless of their semantic proximity from the ground-truth target. While such a "zero-one" loss is probably acceptable for coarse grained classification of images, *e.g.* across a limited number of basic object categories (Everingham et al., 2010) it becomes problematic as the output space becomes larger and some of its elements become semantically similar to each other. This is in particular the case for tasks that involve natural language generation (captioning, translation, speech recognition) where the number of possible outputs is practically unbounded. For natural language generation tasks, evaluation measures typically do take into account structural similarity, *e.g.* based on n-grams, but such structural information is not reflected in the MLE criterion. The second limitation of MLE is that training is based on predicting the next token given the input and preceding *ground-truth* output tokens, while at test time the model predicts conditioned on the input and the so-far *generated* output sequence. Given the exponentially large output space of natural language sentences, it is not obvious that the learned RNNs generalize well beyond the relatively sparse distribution of ground-truth sequences used during MLE optimization. This phenomenon is known as "exposure bias" (Ranzato et al., 2016; Bengio et al., 2015).

MLE minimizes the KL divergence between a target Dirac distribution on the ground-truth sentence(s) and the model's distribution. In this paper, we build upon the "loss smoothing" approach by Norouzi et al. (2016), which smooths the Dirac target distribution over similar sentences, increasing the support of the training data in the output space. We make the following main contributions:

- We propose a token-level loss smoothing approach, using word-embeddings, to achieve smoothing among semantically similar terms, and we introduce a special procedure to promote rare tokens.
- For sequence-level smoothing, we propose to use restricted token replacement vocabularies, and a "lazy evaluation" method that significantly speeds up training.
- We experimentally validate our approach on the MSCOCO image captioning task and the WMT'14 English to French machine translation task, showing that on both tasks combining token-level and sequence-level loss smoothing improves results significantly over maximum likelihood baselines.

In the remainder of the paper, we review the existing methods to improve RNN training in Section 2. Then, we present our token-level and sequence-level approaches in Section 3. Experimental evaluation results based on image captioning and machine translation tasks are laid out in Section 4.

2 Related work

Previous work aiming to improve the generalization performance of RNNs can be roughly divided into three categories: those based on regularization, data augmentation, and alternatives to maximum likelihood estimation.

Regularization techniques are used to increase the smoothness of the function learned by the network, *e.g.* by imposing an ℓ_2 penalty on the network weights, also known as "weight decay". More recent approaches mask network activations during training, as in dropout (Srivastava et al., 2014) and its variants adapted to recurrent models (Pham et al., 2014; Krueger et al., 2017). Instead of masking, batch-normalization (Ioffe and Szegedy, 2015) rescales the network activations to avoid saturating the network's non-linearities. Instead of regularizing the network parameters or activations, it is also possible to directly regularize based on the entropy of the output distribution (Pereyra et al., 2017).

Data augmentation techniques improve the robustness of the learned models by applying transformations that might be encountered at test time to the training data. In computer vision, this is common practice, and implemented by, *e.g.*, scaling, cropping, and rotating training images (LeCun et al., 1998; Krizhevsky et al., 2012; Paulin et al., 2014). In natural language processing, examples of data augmentation include input noising by randomly dropping some input tokens (Iyyer et al., 2015; Bowman et al., 2015; Kumar et al., 2016), and randomly replacing words with substitutes sampled from the model (Bengio et al., 2015). Xie et al. (2017) introduced data augmentation schemes for RNN language models that leverage n-gram statistics in order to mimic Kneser-Ney smoothing of n-grams models. In the context of machine translation, Fadaee et al. (2017) modify sentences by replacing words with rare ones when this is plausible according to a pre-trained language model, and substitutes its equivalent in the target sentence using automatic word alignments. This approach, however, relies on the availability of additional monolingual data for language model training.

The *de facto* standard way to train RNN language models is maximum likelihood estimation (MLE) (Cho et al., 2014; Sutskever et al., 2014; Bahdanau et al., 2015). The sequential factorization of the sequence likelihood generates an additive structure in the loss, with one term corresponding to the prediction of each output token given the input and the preceding ground-truth output tokens. In order to directly optimize for sequence-level structured loss functions, such as measures based on n-grams like BLEU or CIDER, Ranzato et al. (2016) use reinforcement learning techniques that optimize the expectation of a sequence-level reward. In order to avoid early convergence to poor local optima, they pre-train the model using MLE.

Leblond et al. (2018) build on the learning to search approach to structured prediction (Daumé III et al., 2009; Chang et al., 2015) and adapts it to RNN training. The model generates candidate sequences at each time-step using all possible tokens, and scores these at sequence-level to derive a training signal for each time step. This leads to an approach that is structurally close to MLE, but computationally expensive. Norouzi et al. (2016) introduce a reward augmented maximum likelihood (RAML) approach, that incorporates a notion of sequence-level reward without facing the difficulties of reinforcement learning. They define a target distribution over output sentences using a soft-max over the reward over all possible outputs. Then, they minimize the KL divergence between the target distribution and the model's output distribution. Training with a general reward distribution is similar to MLE training, except that we use multiple sentences sampled from the target distribution instead of only the ground-truth sentences.

In our work, we build upon the work of Norouzi et al. (2016) by proposing improvements to sequence-level smoothing, and extending it to token-level smoothing. Our token-level smoothing approach is related to the label smoothing approach of Szegedy et al. (2016) for image classification. Instead of maximizing the probability of the correct class, they train the model to predict the correct class with a large probability and all other classes with a small uniform probability. This regularizes the model by preventing overconfident predictions. In natural language generation with large vocabularies, preventing such "narrow" over-confident distributions is imperative, since for many tokens there are nearly interchangeable alternatives.

3 Loss smoothing for RNN training

We briefly recall standard recurrent neural network training, before presenting sequence-level and token-level loss smoothing below.

3.1 Maximum likelihood RNN training

We are interested in modeling the conditional probability of a sequence $y = (y_1, \dots, y_T)$ given a conditioning observation x,

$$p_\theta(y|x) = \prod_{t=1}^{T} p_\theta(y_t|x, y_{<t}), \tag{1}$$

where $y_{<t} = (y_1, \dots, y_{t-1})$, the model parameters are given by θ, and x is a source sentence or an image in the contexts of machine translation and image captioning, respectively.

In a recurrent neural network, the sequence y is predicted based on a sequence of states h_t,

$$p_\theta(y_t|x, y_{<t}) = p_\theta(y_t|h_t), \tag{2}$$

where the RNN state is computed recursively as

$$h_t = \begin{cases} f_\theta(h_{t-1}, y_{t-1}, x) & \text{for } t \in \{1, ..T\}, \\ g_\theta(x) & \text{for } t = 0. \end{cases} \tag{3}$$

The input is encoded by g_θ and used to initialize the state sequence, and f_θ is a non-linear function that updates the state given the previous state h_{t-1}, the last output token y_{t-1}, and possibly the input x. The state update function can take different forms, the ones including gating mechanisms such as LSTMs (Hochreiter and Schmidhuber, 1997) and GRUs (Chung et al., 2014) are particularly effective to model long sequences.

In standard teacher-forced training, the hidden states will be computed by forwarding the ground truth sequence y^* *i.e.* in Eq. (3), the RNN has access to the true previous token y^*_{t-1}. In this case we will note the hidden states h^*_t.

Given a ground-truth target sequence y^*, maximum likelihood estimation (MLE) of the network parameters θ amounts to minimizing the loss

$$\ell_{\text{MLE}}(y^*, x) = -\ln p_\theta(y^*|x) \tag{4}$$

$$= -\sum_{t=1}^{T} \ln p_\theta(y^*_t|h^*_t). \tag{5}$$

The loss can equivalently be expressed as the KL-divergence between a Dirac centered on the target output (with $\delta_a(x) = 1$ at $x = a$ and 0 otherwise) and the model distribution, either at the sequence-level or at the token-level:

$$\ell_{\text{MLE}}(y^*, x) = D_{\text{KL}}\big(\delta_{y^*}||p_\theta(y|x)\big) \tag{6}$$

$$= \sum_{t=1}^{T} D_{\text{KL}}\big(\delta_{y^*_t}||p_\theta(y_t|h^*_t)\big). \tag{7}$$

Loss smoothing approaches considered in this paper consist in replacing the Dirac on the ground-truth sequence with distributions with larger support. These distributions can be designed in such a manner that they reflect which deviations from ground-truth predictions are preferred over others.

3.2 Sequence-level loss smoothing

The reward augmented maximum likelihood approach of Norouzi et al. (2016) consists in replacing the sequence-level Dirac δ_{y^*} in Eq. (6) with a distribution

$$r(y|y^*) \propto \exp r(y, y^*)/\tau, \tag{8}$$

where $r(y, y^*)$ is a "reward" function that measures the quality of sequence y w.r.t. y^*, *e.g.* metrics used for evaluation of natural language processing tasks can be used, such as BLEU (Papineni et al., 2002) or CIDEr (Vedantam et al., 2015). The temperature parameter τ controls the concentration of the distribution around y^*. When $m > 1$ ground-truth sequences are paired with the same input x, the reward function can be adapted to fit this setting and be defined as $r(y, \{y^{*(1)}, \dots, y^{*(m)}\})$. The sequence-level smoothed loss function is then given by

$$\begin{aligned}\ell_{\text{Seq}}(y^*, x) &= D_{\text{KL}}\big(r(y|y^*)||p_\theta(y|x)\big)\\ &= H(r(y|y^*)) - \mathbb{E}_r[\ln p_\theta(y|x)]\,, \quad (9)\end{aligned}$$

where the entropy term $H(r(y|y^*))$ does not depend on the model parameters θ.

In general, expectation in Eq. (9) is intractable due to the exponentially large output space, and replaced with a Monte-Carlo approximation:

$$\mathbb{E}_r[-\ln p_\theta(y|x)] \approx -\sum_{l=1}^{L} \ln p_\theta(y^l|x). \qquad (10)$$

Stratified sampling. Norouzi et al. (2016) show that when using the Hamming or edit distance as a reward, we can sample directly from $r(y|y^*)$ using a stratified sampling approach. In this case sampling proceeds in three stages. (i) Sample a distance d from $\{0, \dots, T\}$ from a prior distribution on d. (ii) Uniformly select d positions in the sequence to be modified. (iii) Sample the d substitutions uniformly from the token vocabulary.

Details on the construction of the prior distribution on d for a reward based on the Hamming distance can be found in Appendix A.

Importance sampling. For a reward based on BLEU or CIDEr , we cannot directly sample from $r(y|y^*)$ since the normalizing constant, or "partition function", of the distribution is intractable to compute. In this case we can resort to importance sampling. We first sample L sequences y^l from a tractable proposal distribution $q(y|y^*)$. We then compute the importance weights

$$\omega_l \approx \frac{r(y^l|y^*)/q(y^l|y^*)}{\sum_{k=1}^{L} r(y^k|y^*)/q(y^k|y^*)}, \qquad (11)$$

where $r(y^k|y^*)$ is the un-normalized reward distribution in Eq. (8). We finally approximate the expectation by reweighing the samples in the Monte Carlo approximation as

$$\mathbb{E}_r[-\ln p_\theta(y|x)] \approx -\sum_{l=1}^{L} \omega_l \ln p_\theta(y^l|x). \qquad (12)$$

In our experiments we use a proposal distribution based on the Hamming distance, which allows for tractable stratified sampling, and generates sentences that do not stray away from the ground truth.

We propose two modifications to the sequence-level loss smoothing of Norouzi et al. (2016): sampling to a restricted vocabulary (described in the following paragraph) and lazy sequence-level smoothing (described in section 3.4).

Restricted vocabulary sampling. In the stratified sampling method for Hamming and edit distance rewards, instead of drawing from the large vocabulary $\mathcal{V}$, containing typically in the order of 10^4 words or more, we can restrict ourselves to a smaller subset $\mathcal{V}_{sub}$ more adapted to our task. We considered three different possibilities for $\mathcal{V}_{sub}$.

$\mathcal{V}$: the full vocabulary from which we sample uniformly (default), or draw from our token-level smoothing distribution defined below in Eq. (13).

$\mathcal{V}_{refs}$: uniformly sample from the set of tokens that appear in the ground-truth sentence(s) associated with the current input.

$\mathcal{V}_{batch}$: uniformly sample from the tokens that appear in the ground-truth sentences across all inputs that appear in a given training mini-batch.

Uniformly sampling from $\mathcal{V}_{batch}$ has the effect of boosting the frequencies of words that appear in many reference sentences, and thus approximates to some extent sampling substitutions from the uni-gram statistics of the training set.

3.3 Token-level loss smoothing

While the sequence-level smoothing can be directly based on performance measures of interest such as BLEU or CIDEr, the support of the smoothed distribution is limited to the number of samples drawn during training. We propose smoothing the token-level Diracs $\delta_{y_t^*}$ in Eq. (7) to increase its support to similar tokens. Since we apply smoothing to each of the tokens independently, this approach implicitly increases the support to an exponential number of sequences, unlike the sequence-level smoothing approach. This comes at the price, however, of a naive token-level independence assumption in the smoothing.

We define the smoothed token-level distribution, similar as the sequence-level one, as a softmax over a token-level "reward" function,

$$r(y_t|y_t^*) \propto \exp r(y_t, y_t^*)/\tau, \qquad (13)$$

where τ is again a temperature parameter. As a token-level reward $r(y_t, y_t^*)$ we use the cosine similarity between y_t and y_t^* in a semantic word-embedding space. In our experiments we use GloVe (Pennington et al., 2014); preliminary experiments with word2vec (Mikolov et al., 2013) yielded somewhat worse results.

Promoting rare tokens. We can further improve the token-level smoothing by promoting rare tokens. To do so, we penalize frequent tokens when smoothing over the vocabulary, by subtracting $\beta\,\mathrm{freq}(y_t)$ from the reward, where $\mathrm{freq}(\cdot)$ denotes the term frequency and β is a non-negative weight. This modification encourages frequent tokens into considering the rare ones. We experimentally found that it is also beneficial for rare tokens to boost frequent ones, as they tend to have mostly rare tokens as neighbors in the word-embedding space. With this in mind, we define a new token-level reward as:

$$r^{\mathrm{freq}}(y_t, y_t^*) = r(y_t, y_t^*) - \beta \min\left(\frac{\mathrm{freq}(y_t)}{\mathrm{freq}(y_t^*)}, \frac{\mathrm{freq}(y_t^*)}{\mathrm{freq}(y_t)}\right), \quad (14)$$

where the penalty term is strongest if both tokens have similar frequencies.

3.4 Combining losses

In both loss smoothing methods presented above, the temperature parameter τ controls the concentration of the distribution. As τ gets smaller the distribution peaks around the ground-truth, while for large τ the uniform distribution is approached. We can, however, not separately control the spread of the distribution and the mass reserved for the ground-truth output. We therefore introduce a second parameter $\alpha \in [0, 1]$ to interpolate between the Dirac on the ground-truth and the smooth distribution. Using $\bar{\alpha} = 1 - \alpha$, the sequence-level and token-level loss functions are then defined as

$$\begin{aligned}\ell^{\alpha}_{\mathrm{Seq}}(y^*, x) &= \alpha \ell_{\mathrm{Seq}}(y^*, x) + \bar{\alpha}\ell_{\mathrm{MLE}}(y^*, x) \quad (15)\\ &= \alpha \mathbb{E}_r[\ell_{\mathrm{MLE}}(y, x)] + \bar{\alpha}\ell_{\mathrm{MLE}}(y^*, x)\\ \ell^{\alpha}_{\mathrm{Tok}}(y^*, x) &= \alpha \ell_{\mathrm{Tok}}(y^*, x) + \bar{\alpha}\ell_{\mathrm{MLE}}(y^*, x) \quad (16)\end{aligned}$$

To benefit from both sequence-level and token-level loss smoothing, we also combine them by applying token-level smoothing to the different sequences sampled for the sequence-level smoothing. We introduce two mixing parameters α_1 and α_2. The first controls to what extent sequence-level smoothing is used, while the second controls to what extent token-level smoothing is used. The combined loss is defined as

$$\begin{aligned}\ell^{\alpha_1,\alpha_2}_{\mathrm{Seq,\,Tok}}(y^*, x, r) &= \alpha_1 \mathbb{E}_r[\ell_{\mathrm{Tok}}(y, x)] + \bar{\alpha}_1 \ell_{\mathrm{Tok}}(y^*, x)\\ &= \alpha_1 \mathbb{E}_r[\alpha_2 \ell_{\mathrm{Tok}}(y, x) + \bar{\alpha}_2 \ell_{\mathrm{MLE}}(y, x)]\\ &\quad + \bar{\alpha}_1(\alpha_2 \ell_{\mathrm{Tok}}(y^*, x) + \bar{\alpha}_2 \ell_{\mathrm{MLE}}(y^*, x)). \quad (17)\end{aligned}$$

In our experiments, we use held out validation data to set mixing and temperature parameters.

Algorithm 1 Sequence-level smoothing algorithm

```
Input: $x, y^*$
Output: $\ell^{\alpha}_{\mathrm{seq}}(x, y^*)$
  Encode $x$ to initialize the RNN
  Forward $y^*$ in the RNN to compute the hidden states $h_t^*$
  Compute the MLE loss $\ell_{\mathrm{MLE}}(y^*, x)$
  for $l \in \{1, \ldots, L\}$ do
      Sample $y^l \sim r(|y^*)$
      if Lazy then
          Compute $\ell(y^l, x) = -\sum_t \log p_\theta(y_t^l | h_t^*)$
      else
          Forward $y^l$ in the RNN to get its hidden states $h_t^l$
          Compute $\ell(y^l, x) = \ell_{\mathrm{MLE}}(y^l, x)$
      end if
  end for
  $\ell^{\alpha}_{\mathrm{Seq}}(x, y^*) = \bar{\alpha}\ell_{\mathrm{MLE}}(y^*, x) + \frac{\alpha}{L}\sum_l \ell(y^l, x)$
```

Lazy sequence smoothing. Although sequence-level smoothing is computationally efficient compared to reinforcement learning approaches (Ranzato et al., 2016; Rennie et al., 2017), it is slower compared to MLE. In particular, we need to forward each of the samples y^l through the RNN in teacher-forcing mode so as to compute its hidden states h_t^l, which are used to compute the sequence MLE loss as

$$\ell_{\mathrm{MLE}}(y^l, x) = -\sum_{t=1}^{T} \ln p_\theta(y_t^l | h_t^l). \quad (18)$$

To speed up training, and since we already forward the ground truth sequence in the RNN to evaluate the MLE part of $\ell^{\alpha}_{\mathrm{Seq}}(y^*, x)$, we propose to use the same hidden states h_t^* to compute both the MLE and the sequence-level smoothed loss. In this case:

$$\ell_{\mathrm{lazy}}(y^l, x) = -\sum_{t=1}^{T} \ln p_\theta(y_t^l | h_t^*) \quad (19)$$

In this manner, we only have a single instead of $L + 1$ forwards-passes in the RNN. We provide the pseudo-code for training in Algorithm 1.

Table 1: MS-COCO 's test set evaluation measures.

4 Experimental evaluation

In this section, we compare sequence prediction models trained with maximum likelihood (MLE) with our token and sequence-level loss smoothing on two different tasks: image captioning and machine translation.

4.1 Image captioning

4.1.1 Experimental setup.

We use the MS-COCO datatset (Lin et al., 2014), which consists of 82k training images each annotated with five captions. We use the standard splits of Karpathy and Li (2015), with 5k images for validation, and 5k for test. The test set results are generated via beam search (beam size 3) and are evaluated with the MS-COCO captioning evaluation tool. We report CIDEr and BLEU scores on this internal test set. We also report results obtained on the official MS-COCO server that additionally measures METEOR (Denkowski and Lavie, 2014) and ROUGE-L (Lin, 2004). We experiment with both non-attentive LSTMs (Vinyals et al., 2015) and the ResNet baseline of the state-of-the-art top-down attention (Anderson et al., 2017).

The MS-COCO vocabulary consists of 9,800 words that occur at least 5 times in the training set. Additional details and hyperparameters can be found in Appendix B.1.

4.1.2 Results and discussion

Restricted vocabulary sampling In this section, we evaluate the impact of the vocabulary subset from which we sample the modified sentences for sequence-level smoothing. We experiment with two rewards: CIDEr , which scores w.r.t. all five available reference sentences, and Hamming distance reward taking only a single reference into account. For each reward we train our (Seq) models with each of the three subsets detailed previously in Section 3.2, Restricted vocabulary sampling.

From the results in Table 1 we note that for the inattentive models, sampling from $\mathcal{V}_{refs}$ or $\mathcal{V}_{batch}$ has a better performance than sampling from the full vocabulary on all metrics. In fact, using these subsets introduces a useful bias to the model and improves performance. This improvement is most notable using the CIDEr reward that scores candidate sequences w.r.t. to multiple references, which stabilizes the scoring of the candidates.

With an attentive decoder, no matter the reward, re-sampling sentences with words from $\mathcal{V}_{ref}$ rather than the full vocabulary $\mathcal{V}$ is better for both reward functions, and all metrics. Additional experimental results, presented in Appendix B.2, obtained with a BLEU-4 reward, in its single and

multiple references variants, further corroborate this conclusion.

Lazy training. From the results of Table 1, we see that lazy sequence-level smoothing is competitive with exact non-lazy sequence-level smoothing, while requiring roughly equivalent training time as MLE. We provide detailed timing results in Appendix B.3.

Overall For reference, we include in Table 1 baseline results obtained using MLE, and our implementation of MLE with entropy regularization (MLE+γH) (Pereyra et al., 2017), as well as the RAML approach of Norouzi et al. (2016) which corresponds to sequence-level smoothing based on the Hamming reward and sampling replacements from the full vocabulary (Seq, Hamming, $\mathcal{V}$)

We observe that entropy smoothing is not able to improve performance much over MLE for the model without attention, and even deteriorates for the attention model. We improve upon RAML by choosing an adequate subset of vocabulary for substitutions.

We also report the performances of token-level smoothing, where the promotion of rare tokens boosted the scores in both attentive and non-attentive models.

For sequence-level smoothing, choosing a task-relevant reward with importance sampling yielded better results than plain Hamming distance.

Moreover, we used the two smoothing schemes (Tok-Seq) and achieved the best results with CIDEr as a reward for sequence-level smoothing combined with a token-level smoothing that promotes rare tokens improving CIDEr from 93.59 (MLE) to 99.92 for the model without attention, and improving from 101.63 to 103.81 with attention.

Qualitative results. In Figure 1 we showcase captions obtained with MLE and our three variants of smoothing *i.e.* token-level (Tok), sequence-level (Seq) and the combination (Tok-Seq). We note that the sequence-level smoothing tend to generate lengthy captions overall, which is maintained in the combination. On the other hand, the token-level smoothing allows for a better recognition of objects in the image that stems from the robust training of the classifier *e.g.* the 'cement block' in the top right image or the carrots in the bottom right. More examples are available in Appendix B.4

Comparison to the state of the art. We compare our model to state-of-the-art systems on the MS-COCO evaluation server in Table 2. We submitted a single model (Tok-Seq, CIDEr , $\mathcal{V}_{refs}$) as well as an ensemble of five models with different initializations trained on the training set plus 35k images from the dev set (a total of 117k images) to the MS-COCO server. The three best results on the server (Rennie et al., 2017; Yao et al., 2017; Anderson et al., 2017) are trained in two stages where they first train using MLE, before switching to policy gradient methods based on CIDEr. Anderson et al. (2017) reported an increase of 5.8% of CIDEr on the test split after the CIDEr optimization. Moreover, Yao et al. (2017) uses additional information about image regions to train the attributes classifiers, while Anderson et al. (2017) pre-trains its bottom-up attention model on the Visual Genome dataset (Krishna et al., 2017). Lu et al. (2017); Yao et al. (2017) use the same CNN encoder as ours (ResNet-152), (Vinyals et al., 2015; Yang et al., 2016) use Inception-v3 (Szegedy et al., 2016) for image encoding and Rennie et al. (2017); Anderson et al.

(2017) use Resnet-101, both of which have similar performances to ResNet-152 on ImageNet classification (Canziani et al., 2016).

4.2 Machine translation

4.2.1 Experimental setup.

For this task we validate the effectiveness of our approaches on two different datasets. The first is WMT'14 English to French, in its filtered version, with 12M sentence pairs obtained after dynamically selecting a "clean" subset of 348M words out of the original "noisy" 850M words (Bahdanau et al., 2015; Cho et al., 2014; Sutskever et al., 2014). The second benchmark is IWSLT'14 German to English consisting of around 150k pairs for training. In all our experiments we use the attentive model of (Bahdanau et al., 2015) The hyperparameters of each of these models as well as any additional pre-processing can be found in Appendix C.1

To assess the translation quality we report the BLEU-4 metric.

4.2.2 Results and analysis

Loss	Reward	$\mathcal{V}_{sub}$	**WMT'14**	**IWSLT'14**
MLE			30.03	27.55
tok	Glove sim		30.16	27.69
tok	Glove sim r^{freq}		30.19	27.83
Seq	Hamming	$\mathcal{V}$	30.85	27.98
Seq	Hamming	$\mathcal{V}_{batch}$	31.18	28.54
Seq	BLEU-4	$\mathcal{V}_{batch}$	31.29	28.56
Tok-Seq	Hamming	$\mathcal{V}_{batch}$	31.36	28.70
Tok-Seq	BLEU-4	$\mathcal{V}_{batch}$	31.39	28.74

Table 3: Tokenized BLEU score on WMT'14 En-Fr evaluated on the news-test-2014 set. And Tokenzied, case-insensitive BLEU on IWSLT'14 De-En.

We present our results in Table 3. On both benchmarks, we improve on both MLE and RAML approach of Norouzi et al. (2016) (Seq, Hamming, $\mathcal{V}$): using the smaller batch-vocabulary for replacement improves results, and using importance sampling based on BLEU-4 further boosts results. In this case, unlike in the captioning experiment, token-level smoothing brings smaller improvements. The combination of both smoothing approaches gives best results, similar to what was observed for image captioning, improving the MLE BLEU-4 from 30.03 to 31.39 on WMT'14 and from 27.55 to 28.74 on IWSLT'14. The outputs of our best model are compared to the MLE in some examples showcased in Appendix C.

5 Conclusion

We investigated the use of loss smoothing approaches to improve over maximum likelihood estimation of RNN language models. We generalized the sequence-level smoothing RAML approach of Norouzi et al. (2016) to the token-level by smoothing the ground-truth target across semantically similar tokens. For the sequence-level, which is computationally expensive, we introduced an efficient "lazy" evaluation scheme, and introduced an improved re-sampling strategy. Experimental evaluation on image captioning and machine translation demonstrates the complementarity of sequence-level and token-level loss smoothing, improving over both the maximum likelihood and RAML.

Abstract

Numeracy is the ability to understand and work with numbers. It is a necessary skill for composing and understanding documents in clinical, scientific, and other technical domains. In this paper, we explore different strategies for modelling numerals with language models, such as memorisation and digit-by-digit composition, and propose a novel neural architecture that uses a continuous probability density function to model numerals from an open vocabulary. Our evaluation on clinical and scientific datasets shows that using hierarchical models to distinguish numerals from words improves a perplexity metric on the subset of numerals by 2 and 4 orders of magnitude, respectively, over non-hierarchical models. A combination of strategies can further improve perplexity. Our continuous probability density function model reduces mean absolute percentage errors by 18% and 54% in comparison to the second best strategy for each dataset, respectively.

1 Introduction

Language models (LMs) are statistical models that assign a probability over sequences of words. Language models can often help with other tasks, such as speech recognition (Mikolov et al., 2010; Prabhavalkar et al., 2017), machine translation (Luong et al., 2015; Gülçehre et al., 2017), text summarisation (Filippova et al., 2015; Gambhir and Gupta, 2017), question answering (Wang et al., 2017), semantic error detection (Rei and Yannakoudakis, 2017; Spithourakis et al., 2016a), and fact checking (Rashkin et al., 2017).

Numeracy and literacy refer to the ability to comprehend, use, and attach meaning to numbers and words, respectively. Language models exhibit literacy by being able to assign higher probabilities to sentences that are both grammatical and realistic, as in this example:

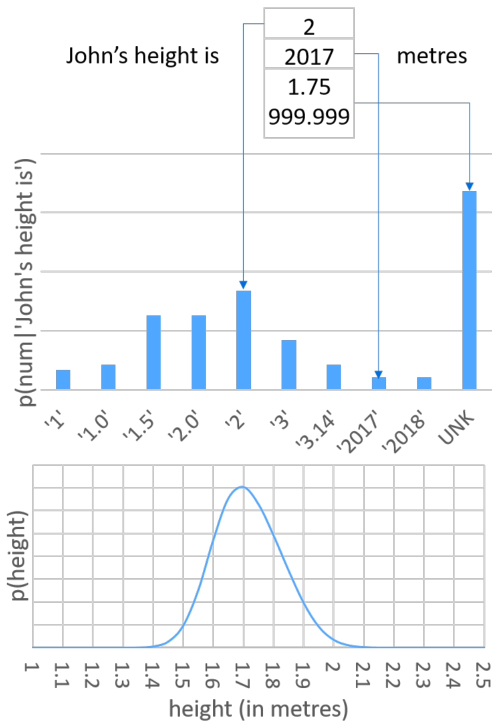

Figure 1: Modelling numerals with a categorical distribution over a fixed vocabulary maps all out-of-vocabulary numerals to the same type, e.g. UNK, and does not reflect the smoothness of the underlying continuous distribution of certain attributes.

'I eat an apple' (grammatical and realistic)
'An apple eats me' (unrealistic)
'I eats an apple' (ungrammatical)

Likewise, a numerate language model should be able to rank numerical claims based on plausibility:

'John's height is 1.75 metres' (realistic)
'John's height is 999.999 metres' (unrealistic)

Existing approaches to language modelling treat numerals similarly to other words, typically using categorical distributions over a fixed vocabulary.

However, this maps all unseen numerals to the same unknown type and ignores the smoothness of continuous attributes, as shown in Figure 1. In that respect, existing work on language modelling does not explicitly evaluate or optimise for numeracy. Numerals are often neglected and low-resourced, e.g. they are often masked (Mitchell and Lapata, 2009), and there are only $15{,}164$ (3.79%) numerals among GloVe's $400{,}000$ embeddings pretrained on 6 billion tokens (Pennington et al., 2014). Yet, numbers appear ubiquitously, from children's magazines (Joram et al., 1995) to clinical reports (Bigeard et al., 2015), and grant objectivity to sciences (Porter, 1996).

Previous work finds that numerals have higher out-of-vocabulary rates than other words and proposes solutions for representing unseen numerals as inputs to language models, e.g. using numerical magnitudes as features (Spithourakis et al., 2016b,a). Such work identifies that the perplexity of language models on the subset of numerals can be very high, but does not directly address the issue. This paper focuses on evaluating and improving the ability of language models to predict numerals. The main contributions of this paper are as follows:

1. We explore different strategies for modelling numerals, such as memorisation and digit-by-digit composition, and propose a novel neural architecture based on continuous probability density functions.

2. We propose the use of evaluations that adjust for the high out-of-vocabulary rate of numerals and account for their numerical value (magnitude).

3. We evaluate on a clinical and a scientific corpus and provide a qualitative analysis of learnt representations and model predictions. We find that modelling numerals separately from other words can drastically improve the perplexity of LMs, that different strategies for modelling numerals are suitable for different textual contexts, and that continuous probability density functions can improve the LM's prediction accuracy for numbers.

2 Language Models

Let $s_1,s_2,...,s_L$ denote a document, where s_t is the token at position t. A language model estimates the probability of the next token given previous tokens, i.e. $p(s_t|s_1,...,s_{t-1})$. Neural LMs estimate this probability by feeding embeddings, i.e. vectors that represent each token, into a Recurrent Neural Network (RNN) (Mikolov et al., 2010).

Token Embeddings Tokens are most commonly represented by a D-dimensional dense vector that is unique for each word from a vocabulary $\mathcal{V}$ of known words. This vocabulary includes special symbols (e.g. 'UNK') to handle out-of-vocabulary tokens, such as unseen words or numerals. Let w_s be the one-hot representation of token s, i.e. a sparse binary vector with a single element set to 1 for that token's index in the vocabulary, and $E \in \mathbb{R}^{D\times|\mathcal{V}|}$ be the token embeddings matrix. The token embedding for s is the vector $e_s^{\text{token}} = Ew_s$.

Character-Based Embeddings A representation for a token can be build from its constituent characters (Luong and Manning, 2016; Santos and Zadrozny, 2014). Such a representation takes into account the internal structure of tokens. Let $d_1,d_2,...,d_N$ be the characters of token s. A character-based embedding for s is the final hidden state of a D-dimensional character-level RNN: $e_s^{\text{chars}} = \text{RNN}(d_0,d_1,...d_L)$.

Recurrent and Output Layer The computation of the conditional probability of the next token involves recursively feeding the embedding of the current token e_{s_t} and the previous hidden state h_{t-1} into a D-dimensional token-level RNN to obtain the current hidden state h_t. The output probability is estimated using the softmax function, i.e.

$$\begin{aligned} p(s_t|h_t) &= \text{softmax}(\psi(s_t)) = \tfrac{1}{Z}e^{\psi(s_t)} \\ Z &= \sum_{s'\in\mathcal{V}} e^{\psi(s')}, \end{aligned} \tag{1}$$

where $\psi(.)$ is a score function.

Training and Evaluation Neural LMs are typically trained to minimise the cross entropy on the training corpus:

$$\mathcal{H}_{train} = -\frac{1}{N}\sum_{s_t \in train} \log p(s_t|s_{<t}) \tag{2}$$

A common performance metric for LMs is per token perplexity (Eq. 3), evaluated on a test corpus. It can also be interpreted as the branching factor: the size of an equally weighted distribution with equivalent uncertainty, i.e. how many sides you need on a fair die to get the same uncertainty as the model distribution.

$$PP_{test} = \exp(\mathcal{H}_{test}) \tag{3}$$

3 Strategies for Modelling Numerals

In this section we describe models with different strategies for generating numerals and propose the use of number-specific evaluation metrics that adjust for the high out-of-vocabulary rate of numerals and account for numerical values. We draw inspiration from theories of numerical cognition. The triple code theory (Dehaene et al., 2003) postulates that humans process quantities through two exact systems (verbal and visual) and one approximate number system that semantically represents a number on a mental number line. Tzelgov et al. (2015) identify two classes of numbers: i) primitives, which are holistically retrieved from long-term memory; and ii) non-primitives, which are generated online. An in-depth review of numerical and mathematical cognition can be found in Kadosh and Dowker (2015) and Campbell (2005).

3.1 Softmax Model and Variants

This class of models assumes that numerals come from a finite vocabulary that can be memorised and retrieved later. The *softmax* model treats all tokens (words and numerals) alike and directly uses Equation 1 with score function:

$$\psi(s_t) = h_t^T e_{s_t}^{\text{token}} = h_t^T E_{\text{out}} w_{s_t}, \tag{4}$$

where $E_{out} \in \mathbb{R}^{D \times |\mathcal{V}|}$ is an output embeddings matrix. The summation in Equation 1 is over the complete target vocabulary, which requires mapping any out-of-vocabulary tokens to special symbols, e.g. 'UNK$_{\text{word}}$' and 'UNK$_{\text{numeral}}$'.

Softmax with Digit-Based Embeddings The *softmax+rnn* variant considers the internal syntax of a numeral's digits by adjusting the score function:

$$\begin{aligned}\psi(s_t) &= h_t^T e_{s_t}^{\text{token}} + h_t^T e_{s_t}^{\text{chars}} \\ &= h_t^T E_{\text{out}} w_{s_t} + h_t^T E_{\text{out}}^{\text{RNN}} w_{s_t},\end{aligned} \tag{5}$$

where the columns of $E_{\text{out}}^{\text{RNN}}$ are composed of character-based embeddings for in-vocabulary numerals and token embeddings for the remaining vocabulary. The character set comprises digits (0-9), the decimal point, and an end-of-sequence character. The model still requires normalisation over the whole vocabulary, and the special unknown tokens are still needed.

Hierarchical Softmax A hierarchical softmax (Morin and Bengio, 2005a) can help us decouple the modelling of numerals from that of words. The probability of the next token s_t is decomposed to that of its class c_t and the probability of the exact token from within the class:

$$\begin{aligned}p(s_t|h_t) &= \sum_{c_t \in C} p(c_t|h_t) p(s_t|c_t, h_t) \\ p(c_t|h_t) &= \sigma\left(h_t^T b\right)\end{aligned} \tag{6}$$

where the valid token classes are $C = \{\text{word, numeral}\}$, σ is the sigmoid function and b is a D-dimensional vector. Each of the two branches of $p(s_t|c_t, h_t)$ can now be modelled by independently normalised distributions. The hierarchical variants (*h-softmax* and *h-softmax+rnn*) use two independent softmax distributions for words and numerals. The two branches share no parameters, and thus words and numerals will be embedded into separate spaces.

The hierarchical approach allows us to use any well normalised distribution to model each of its branches. In the next subsections, we examine different strategies for modelling the branch of numerals, i.e. $p(s_t|c_t = \text{numeral}, h_t)$. For simplicity, we will abbreviate this to $p(s)$.

3.2 Digit-RNN Model

Let $d_1, d_2 ... d_N$ be the digits of numeral s. A digit-by-digit composition strategy estimates the probability of the numeral from the probabilities of its digits:

$$p(s) = p(d_1) p(d_2|d_1) ... p(d_N|d_{<N}) \tag{7}$$

The *d-RNN* model feeds the hidden state h_t of the token-level RNN into a character-level RNN (Graves, 2013; Sutskever et al., 2011) to estimate this probability. This strategy can accommodate an open vocabulary, i.e. it eliminates the need for an UNK$_{\text{numeral}}$ symbol, as the probability is normalised one digit at a time over the much smaller vocabulary of digits (digits 0-9, decimal separator, and end-of-sequence).

3.3 Mixture of Gaussians Model

Inspired by the approximate number system and the mental number line (Dehaene et al., 2003), our proposed *MoG* model computes the probability of numerals from a probability density function (pdf) over real numbers, using a mixture of Gaussians for the underlying pdf:

$$\begin{aligned}q(v) &= \sum_{k=1}^{K} \pi_k \mathcal{N}_k(v; \mu_k, \sigma_k^2) \\ \pi_k &= \text{softmax}\left(B^T h_t\right),\end{aligned} \tag{8}$$

where K is the number of components, π_k are mixture weights that depend on hidden state h_t of the token-level RNN, $\mathcal{N}_k$ is the pdf of the normal distribution with mean $\mu_k \in \mathbb{R}$ and variance $\sigma_k^2 \in \mathbb{R}$, and $B \in \mathbb{R}^{D \times K}$ is a matrix.

The difficulty with this approach is that for any continuous random variable, the probability that it equals a specific value is always zero. To resolve this,

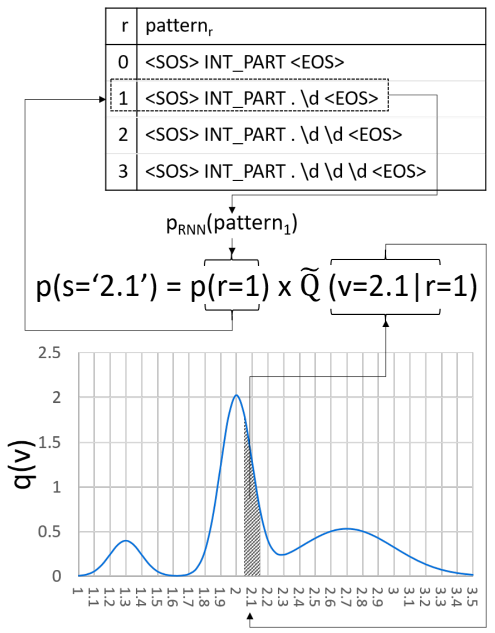

Figure 2: Mixture of Gaussians model. The probability of a numeral is decomposed into the probability of its decimal precision and the probability that an underlying number will produce the numeral when rounded at the given precision.

we consider a probability mass function (pmf) that discretely approximates the pdf:

$$\widetilde{Q}(v|r) = \int_{v-\epsilon_r}^{v+\epsilon_r} q(u)du = F(v+\epsilon_r) - F(v-\epsilon_r), \quad (9)$$

where $F(.)$ is the cumulative density function of $q(.)$, and $\epsilon_r = 0.5 \times 10^{-r}$ is the number's precision. The level of discretisation r, i.e. how many decimal digits to keep, is a random variable in $\mathbb{N}$ with distribution $p(r)$. The mixed joint density is:

$$p(s) = p(v,r) = p(r)\widetilde{Q}(v|r) \quad (10)$$

Figure 2 summarises this strategy, where we model the level of discretisation by converting the numeral into a pattern and use a RNN to estimate the probability of that pattern sequence:

$$p(r) = p(\text{SOS INT\_PART . } \overbrace{\text{\\d ... \\d}}^{r \text{ decimal digits}} \text{ EOS}) \quad (11)$$

3.4 Combination of Strategies

Different mechanisms might be better for predicting numerals in different contexts. We propose a *combination* model that can select among different strategies for modelling numerals:

$$p(s) = \sum_{\forall m \in M} \alpha_m p(s|m)$$
$$\alpha_m = \text{softmax}(A^T h_t), \quad (12)$$

where M={h-softmax, d-RNN, MoG}, and $A \in \mathbb{R}^{D \times |M|}$. Since both d-RNN and MoG are open-vocabulary models, the unknown numeral token can now be removed from the vocabulary of h-softmax.

3.5 Evaluating the Numeracy of LMs

Numeracy skills are centred around the understanding of numbers and numerals. A number is a mathematical object with a specific magnitude, whereas a numeral is its symbolic representation, usually in the positional decimal Hindu–Arabic numeral system (McCloskey and Macaruso, 1995). In humans, the link between numerals and their numerical values boosts numerical skills (Griffin et al., 1995).

Perplexity Evaluation Test perplexity evaluated only on numerals will be informative of the symbolic component of numeracy. However, model comparisons based on naive evaluation using Equation 3 might be problematic: perplexity is sensitive to out-of-vocabulary (OOV) rate, which might differ among models, e.g. it is zero for open-vocabulary models. As an extreme example, in a document where all words are out of vocabulary, the best perplexity is achieved by a trivial model that predicts everything as unknown.

Ueberla (1994) proposed Adjusted Perplexity (APP; Eq. 14), also known as unknown-penalised perplexity (Ahn et al., 2016), to cancel the effect of the out-of-vocabulary rate on perplexity. The APP is the perplexity of an adjusted model that uniformly redistributes the probability of each out-of-vocabulary class over all different types in that class:

$$p'(s) = \begin{cases} p(s)\frac{1}{|OOV_c|} & \text{if } s \in OOV_c \\ p(s) & \text{otherwise} \end{cases} \quad (13)$$

where OOV_c is an out-of-vocabulary class (e.g. words and numerals), and $|OOV_c|$ is the cardinality of each OOV set. Equivalently, adjusted perplexity can be calculated as:

$$APP_{test} = \exp\left(\mathcal{H}_{test} + \sum_c \mathcal{H}^c_{\text{adjust}}\right)$$
$$\mathcal{H}^c_{\text{adjust}} = -\sum_t \frac{|s_t \in OOV_c|}{N} \log \frac{1}{|OOV_c|} \quad (14)$$

where N is the total number of tokens in the test set and $|s \in OOV_c|$ is the count of tokens from the test set belonging in each OOV set.

Evaluation on the Number Line While perplexity looks at symbolic performance on numerals, this evaluation focuses on numbers and particularly on their numerical value, which is their most prominent semantic content (Dehaene et al., 2003; Dehaene and Cohen, 1995).

Let v_t be the numerical value of token s_t from the test corpus. Also, let $\hat{v}_t$ be the value of the most probable numeral under the model $s_t = \text{argmax}\,(p(s_t|h_t, c_t{=}\text{num}))$. Any evaluation metric from the regression literature can be used to measure the models performance. To evaluate on the number line, we can use any evaluation metric from the regression literature. In reverse order of tolerance to extreme errors, some of the most popular are Root Mean Squared Error (RMSE), Mean Absolute Error (MAE), and Median Absolute Error (MdAE):

$$\begin{aligned} e_i &= v_i - \hat{v}_i \\ RMSE &= \sqrt{\frac{1}{N}\sum_{i=1}^{N} e_i^2} \\ MAE &= \frac{1}{N}\sum_{i=1}^{N} |e_i| \\ MdAE &= \text{median}\{|e_i|\} \end{aligned} \tag{15}$$

The above are sensitive to the scale of the data. If the data contains values from different scales, percentage metrics are often preferred, such as the Mean/Median Absolute Percentage Error (MAPE/MdAPE):

$$\begin{aligned} pe_i &= \frac{v_i - \hat{v}_i}{v_i} \\ MAPE &= \frac{1}{N}\sum_{i=1}^{N} |pe_i| \\ MdAPE &= \text{median}\{|pe_i|\} \end{aligned} \tag{16}$$

4 Data

To evaluate our models, we created two datasets with documents from the clinical and scientific domains, where numbers abound (Bigeard et al., 2015; Porter, 1996). Furthermore, to ensure that the numbers will be informative of some attribute, we only selected texts that reference tables.

Clinical Data Our *clinical* dataset comprises clinical records from the London Chest Hospital. The records where accompanied by tables with 20 numeric attributes (age, heart volumes, etc.) that they partially describe, as well as include numbers not found in the tables. Numeric tokens constitute only a small proportion of each sentence (4.3%), but account for a large part of the unique tokens vocabulary (>40%) and suffer high OOV rates.

Scientific Data Our *scientific* dataset comprises paragraphs from Cornell's ARXIV [1] repository of scientific articles, with more than half a million converted papers in 37 scientific sub-fields. We used the preprocessed ARXMLIV (Stamerjohanns et al., 2010; Stamerjohanns and Kohlhase, 2008) [2] version, where papers have been converted from LATEX into a custom XML format using the LATEXML [3] tool. We then kept all paragraphs with at least one reference to a table and a number.

max	$\sim 10^{7}$	$\sim 10^{5}$	$\sim 10^{7}$	$\sim 10^{26}$	$\sim 10^{11}$	$\sim 10^{11}$

Table 1: Statistical description of the clinical and scientific datasets: Number of instances (i.e. paragraphs), maximum and average lengths, proportions of words and numerals, descriptive statistics of numbers.

For both datasets, we lowercase tokens and normalise numerals by omitting the thousands separator ("2,000" becomes "2000") and leading zeros ("007" becomes "7"). Special mathematical symbols are tokenised separately, e.g. negation ("-1" as "-", "1"), fractions ("3/4" as "3", "/", "4"), etc. For this reason, all numbers were non-negative. Table 1 shows descriptive statistics for both datasets.

5 Experimental Results and Discussion

We set the vocabularies to the 1,000 and 5,000 most frequent token types for the clinical and scientific datasets, respectively. We use gated token-character embeddings (Miyamoto and Cho, 2016) for the input of numerals and token embeddings for the input and output of words, since the scope of our paper is numeracy. We set the models' hidden dimensions to $D = 50$ and initialise all token embeddings to pretrained GloVe (Pennington et al., 2014). All our

Table 3: Test set regression evaluation for the clinical and scientific data. Mean absolute percentage error (MAPE) is scale independent and allows for comparison across data, whereas root mean square and mean absolute errors (RMSE, MAE) are scale dependent. Medians (MdAE, MdAPE) are informative of the distribution of errors.

RNNs are LSTMs (Hochreiter and Schmidhuber, 1997) with the biases of LSTM forget gate were initialised to 1.0 (Józefowicz et al., 2015). We train using mini-batch gradient decent with the Adam optimiser (Kingma and Ba, 2014) and regularise with early stopping and 0.1 dropout rate (Srivastava, 2013) in the input and output of the token-based RNN.

For the mixture of Gaussians, we select the mean and variances to summarise the data at different granularities by fitting 7 separate mixture of Gaussian models on all numbers, each with twice as many components as the previous, for a total of $2^{7+1} - 1 = 256$ components. These models are initialised at percentile points from the data and trained with the expectation-minimisation algorithm. The means and variances are then fixed and not updated when we train the language model.

5.1 Quantitative Results

Perplexities Table 2 shows perplexities evaluated on the subsets of words, numerals and all tokens of the test data. Overall, all models performed better on the clinical than on the scientific data. On words, all models achieve similar perplexities in each dataset.

On numerals, softmax variants perform much better than other models in PP, which is an artefact of the high OOV-rate of numerals. APP is significantly worse, especially for non-hierarchical variants, which perform about 2 and 4 orders of magnitude worse than hierarchical ones.

For open-vocabulary models, i.e. d-RNN, MoG, and combination, PP is equivalent to APP. On numerals, d-RNN performed better than softmax variants in both datasets. The MoG model performed twice as well as softmax variants on the clinical dataset, but had the third worse performance in the scientific dataset. The combination model had the best overall APP results for both datasets.

Evaluations on the Number Line To factor out model specific decoding processes for finding the best next numeral, we use our models to rank a set of candidate numerals: we compose the union of in-vocabulary numbers and 100 percentile points from the training set, and we convert numbers into numerals by considering all formats up to n decimal points. We select n to represent 90% of numerals seen at training, which yields $n=3$ and $n=4$ for the clinical and scientific data, respectively.

Table 3 shows evaluation results, where we also include two naive baselines of constant predictions: with the mean and median of the training data. For both datasets, RMSE and MAE were too sensitive to extreme errors to allow drawing safe conclusions, particularly for the scientific dataset, where both metrics were in the order of 10^9. MdAE can be of some use, as 50% of the errors are absolutely smaller than that.

Along percentage metrics, MoG achieved the best MAPE in both datasets (18% and 54% better that the second best) and was the only model to perform better than the median baseline for the clinical data. However, it had the worst MdAPE, which means that MoG mainly reduced larger percentage errors. The d-RNN model came third and second in the clinical and scientific datasets, respectively. In the latter it achieved the best MdAPE, i.e. it was effective at reducing errors for 50% of the numbers. The combination model did not perform better than its constituents. This is possibly because MoG is the only strategy that takes into account the numerical magnitudes of the numerals.

5.2 Learnt Representations

Softmax versus Hierarchical Softmax Figure 3 visualises the cosine similarities of the output token embeddings of numerals for the softmax and h-softmax models. Simple softmax enforced high similarities among all numerals and the unknown numeral token, so as to make them more dissimilar to words, since the model embeds both in the same space. This is not the case for h-softmax that uses two different spaces: similarities are concentrated along the diagonal and fan out as the magnitude grows, with the exception of numbers with special meaning, e.g. years and percentile points.

Digit embeddings Figure 4 shows the cosine similarities between the digits of the d-RNN output mode. We observe that each primitive digit is mostly similar to its previous and next digit. Similar behaviour was found for all digit embeddings of all models.

5.3 Predictions from the Models

Next Numeral Figure 5 shows the probabilities of different numerals under each model for two examples from the clinical development set. Numerals are grouped by number of decimal points. The h-softmax model's probabilities are spiked, d-RNNs are saw-tooth like and MoG's are smooth, with the occasional spike, whenever a narrow component allows for it. Probabilities rapidly decrease for more decimal digits, which is reminiscent of the theoretical expectation that the probability of en exact value for a continuous variable is zero.

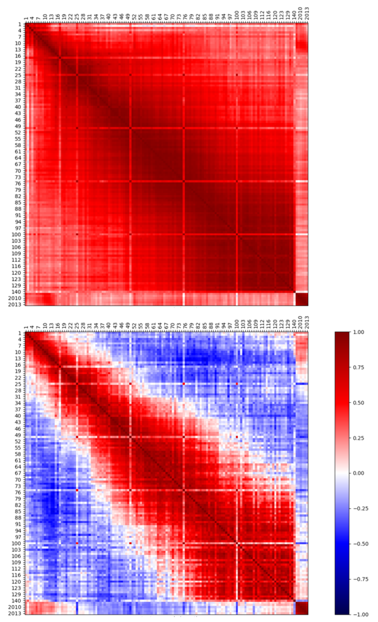

Figure 3: Numeral embeddings for the softmax (top) and h-softmax (bottom) models on the clinical data. Numerals are sorted by value.

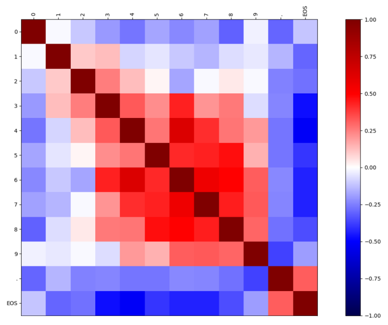

Figure 4: Cosine similarities for d-RNN's output digit embeddings trained on the scientific data.

Selection of Strategy in Combination Model Table 4 shows development set examples with high selection probabilities for each strategy of the combination model, along with numerals with the highest average selection per mode. The h-softmax model is responsible for mostly integers with special functions,

	Clinical	Scientific

e.g. years, typical drug dosages, percentile points, etc. In the clinical data, d-RNN picks up two-digit integers (mostly dimensions) and MoG is activated for continuous attributes, which are mostly out of vocabulary. In the scientific data, d-RNN and MoG

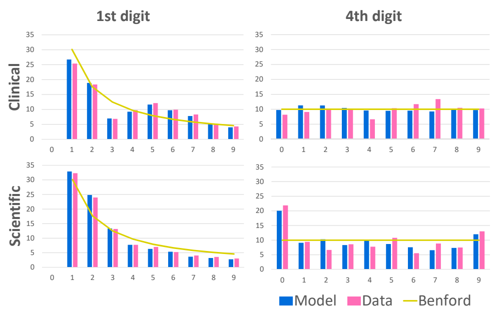

Figure 6: Distributions of significant digits from d-RNN model, data, and theoretical expectation (Benford's law).

showed affinity to different indices from catalogues of astronomical objects: d-RNN mainly to NGC (Dreyer, 1888) and MoG to various other indices, such as GL (Gliese, 1988) and HIP (Perryman et al., 1997). In this case, MoG was wrongly selected for numerals with a labelling function, which also highlights a limitation of evaluating on the number line, when a numeral is not used to represent its magnitude.

Significant Digits Figure 5 shows the distributions of the most significant digits under the d-RNN model and from data counts. The theoretical estimate has been overlayed, according to Benford's law (Benford, 1938), also called the first-digit law, which applies to many real-life numerals. The law predicts that the first digit is 1 with higher probability (about 30%) than 9 ($< 5\%$) and weakens towards uniformity at higher digits. Model probabilities closely follow estimates from the data. Violations from Benford's law can be due to rounding (Beer, 2009) and can be used as evidence for fraud detection (Lu et al., 2006).

6 Related Work

Numerical quantities have been recognised as important for textual entailment (Lev et al., 2004; Dagan et al., 2013). Roy et al. (2015) proposed a quantity entailment sub-task that focused on whether a given quantity can be inferred from a given text and, if so, what its value should be. A common framework for acquiring common sense about numerical attributes of objects has been to collect a corpus of numerical values in pre-specified templates and then model attributes as a normal distribution (Aramaki et al., 2007; Davidov and Rappoport, 2010; Iftene and Moruz, 2010; Narisawa et al., 2013; de Marneffe et al., 2010). Our model embeds these approaches into a LM that has a sense for numbers.

Other tasks that deal with numerals are numerical information extraction and solving mathematical problems. Numerical relations have at least one argument that is a number and the aim of the task is to extract all such relations from a corpus, which can range from identifying a few numerical attributes (Nguyen and Moschitti, 2011; Intxaurrondo et al., 2015) to generic numerical relation extraction (Hoffmann et al., 2010; Madaan et al., 2016). Our model does not extract values, but rather produces an probabilistic estimate.

Much work has been done in solving arithmetic (Mitra and Baral, 2016; Hosseini et al., 2014; Roy and Roth, 2016), geometric (Seo et al., 2015), and algebraic problems (Zhou et al., 2015; Koncel-Kedziorski et al., 2015; Upadhyay et al., 2016; Upadhyay and Chang, 2016; Shi et al., 2015; Kushman et al., 2014) expressed in natural language. Such models often use mathematical background knowledge, such as linear system solvers. The output of our model is not based on such algorithmic operations, but could be extended to do so in future work.

In language modelling, generating rare or unknown words has been a challenge, similar to our unknown numeral problem. Gulcehre et al. (2016) and Gu et al. (2016) adopted pointer networks (Vinyals et al., 2015) to copy unknown words from the source in translation and summarisation tasks. Merity et al. (2016) and Lebret et al. (2016) have models that copy from context sentences and from Wikipedia's infoboxes, respectively. Ahn et al. (2016) proposed a LM that retrieves unknown words from facts in a knowledge graph. They draw attention to the inappropriateness of perplexity when OOV-rates are high and instead propose an adjusted perplexity metric that is equivalent to APP. Other methods aim at speeding up LMs to allow for larger vocabularies (Chen et al., 2015), such as hierarchical softmax (Morin and Bengio, 2005b), target sampling (Jean et al., 2014), etc., but still suffer from the unknown word problem. Finally, the problem is resolved when predicting one character at a time, as done by the character-level RNN (Graves, 2013; Sutskever et al., 2011) used in our d-RNN model.

7 Conclusion

In this paper, we investigated several strategies for LMs to model numerals and proposed a novel open-vocabulary generative model based on a continuous probability density function. We provided the first thorough evaluation of LMs on numerals on two corpora, taking into account their high out-of-vocabulary rate and numerical value (magnitude). We found that modelling numerals separately from other words through a hierarchical softmax can substantially improve the perplexity of LMs, that different strategies are suitable for different contexts, and that a combination of these strategies can help improve the perplexity further. Finally, we found that using a continuous probability density function can improve prediction accuracy of LMs for numbers by substantially reducing the mean absolute percentage metric.

Our approaches in modelling and evaluation can be used in future work in tasks such as approximate information extraction, knowledge base completion, numerical fact checking, numerical question answering, and fraud detection. Our code and data are available at: `https://github.com/uclmr/numerate-language-models`.

Abstract

With the recent success of Recurrent Neural Networks (RNNs) in Machine Translation (MT), attention mechanisms have become increasingly popular. The purpose of this paper is two-fold; firstly, we propose a novel attention model on Tree Long Short-Term Memory Networks (Tree-LSTMs), a tree-structured generalization of standard LSTM. Secondly, we study the interaction between attention and syntactic structures, by experimenting with three LSTM variants: bidirectional-LSTMs, Constituency Tree-LSTMs, and Dependency Tree-LSTMs. Our models are evaluated on two semantic relatedness tasks: semantic relatedness scoring for sentence pairs (SemEval 2012, Task 6 and SemEval 2014, Task 1) and paraphrase detection for question pairs (Quora, 2017).[1]

1 Introduction

Recurrent Neural Networks (RNNs), in particular Long Short-Term Memory Networks (LSTMs) (Hochreiter and Schmidhuber, 1997), have demonstrated remarkable accomplishments in Natural Language Processing (NLP) in recent years. Several tasks such as information extraction, question answering, and machine translation have benefited from them. However, in their vanilla forms, these networks are constrained by the sequential order of tokens in a sentence. To mitigate this limitation, structural (*dependency* or *constituency*) information in a sentence was exploited and witnessed partial success in various tasks (Goller and Kuchler, 1996; Yamada and Knight, 2001; Quirk et al., 2005; Socher et al., 2011; Tai et al., 2015).

On the other hand, alignment techniques (Brown et al., 1993) and attention mechanisms (Bahdanau et al., 2014) act as a catalyst to augment the performance of classical Statistical Machine Translation (SMT) and Neural Machine Translation (NMT) models, respectively. In short, both approaches focus on sub-strings of source sentence which are significant for predicting target words while translating. Currently, the combination of linear RNNs/LSTMs and attention mechanisms has become a *de facto* standard architecture for many NLP tasks.

At the intersection of sentence encoding and attention models, some interesting questions emerge: Can attention mechanisms be employed on tree structures, such as Tree-LSTMs (Tai et al., 2015)? If yes, what are the possible tree-based attention models? Do different tree structures (in particular constituency vs. dependency) have different behaviors in such models? With these questions in mind, we present our investigation and findings in the context of semantic relatedness tasks.

2 Background

2.1 Long Short-Term Memory Networks (LSTMs)

Concisely, an LSTM network (Hochreiter and Schmidhuber, 1997) (Figure 1) includes a *memory cell* at each time step which controls the amount of information being penetrated into the cell, neglected, and yielded by the cell. Various LSTM networks (Greff et al., 2017) have been explored till now; we focus on one representative form. To be more precise, we consider a LSTM memory cell involving: an *input gate* i_t, a forget gate f_t, and an output gate o_t at time step t. Apart from

[1]Our code for experiments on the SICK dataset is publicly available at https://github.com/amulyahwr/acl2018

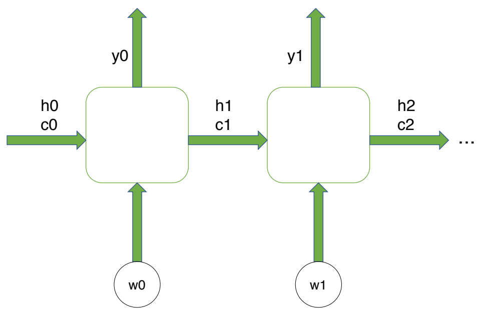

Figure 1: A linear LSTM network. w_t is the word embedding, h_t is the hidden state vector, c_t is the memory cell vector and y_t is the final processed output at time step *t*.

the hidden state h_{t-1} and input embedding w_t of the current word, the recursive function in LSTM also takes the previous time's *memory cell state*, c_{t-1}, into account, which is not the case in simple RNN. The following equations summarize a LSTM memory cell at time step *t*:

$$i_t = \sigma(w_t W^i + h_{t-1} R^i + b^i) \tag{1}$$

$$f_t = \sigma(w_t W^f + h_{t-1} R^f + b^f) \tag{2}$$

$$o_t = \sigma(w_t W^o + h_{t-1} R^o + b^o) \tag{3}$$

$$u_t = \tanh(w_t W^u + h_{t-1} R^u + b^u) \tag{4}$$

$$c_t = i_t \odot u_t + f_t \odot c_{t-1} \tag{5}$$

$$h_t = o_t \odot \tanh(c_t) \tag{6}$$

where:

- $(\boldsymbol{W^i}, \boldsymbol{W^f}, \boldsymbol{W^o}, \boldsymbol{W^u}) \in \mathbb{R}^{\mathrm{D\ x\ d}}$ represent input weight matrices, where $\boldsymbol{d}$ is the dimension of the hidden state vector and $\boldsymbol{D}$ is the dimension of the input word embedding, $\boldsymbol{w_t}$.
- $(\boldsymbol{R^i}, \boldsymbol{R^f}, \boldsymbol{R^o}, \boldsymbol{R^u}) \in \mathbb{R}^{\mathrm{d\ x\ d}}$ represent recurrent weight matrices and $(\boldsymbol{b^i}, \boldsymbol{b^f}, \boldsymbol{b^o}, \boldsymbol{b^u}) \in \mathbb{R}^{\mathrm{d}}$ represent biases.
- $\boldsymbol{c_t} \in \mathbb{R}^{\mathrm{d}}$ is the new memory cell vector at time step *t*.

As can be seen in Eq. 5, the input gate i_t limits the new information, u_t, by employing the element wise multiplication operator $\odot$. Moreover, the forget gate f_t regulates the amount of information from the previous state c_{t-1}. Therefore, the current memory state c_t includes both new and previous time step's information but partially.

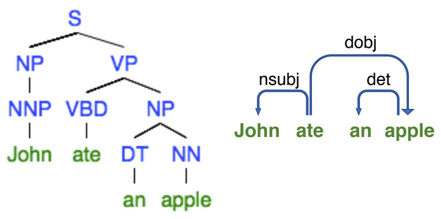

Figure 2: a. **Left**: A constituency tree; b. **Right**: A dependency tree

A natural extension of LSTM network is a *bidirectional* LSTM (bi-LSTM), which lets the sequence pass through the architecture in both directions and aggregate the information at each time step. Again, it strictly preserves the sequential nature of LSTMs.

2.2 Linguistically Motivated Sentence Structures

Most computational linguists have developed a natural inclination towards hierarchical structures of natural language, which follow guidelines collectively referred to as *syntax*. Typically, such structures manifest themselves in *parse trees*. We investigate two popular forms: *Constituency* and *Dependency* trees.

2.2.1 Constituency structure

Briefly, constituency trees (Figure 2:a) indicate a hierarchy of syntactic units and encapsulate phrase grammar rules. Moreover, these trees explicitly demonstrate groups of phrases (e.g., Noun Phrases) in a sentence. Additionally, they discriminate between terminal (lexical) and non-terminal nodes (non-lexical) tokens.

2.2.2 Dependency structure

In short, dependency trees (Figure 2:b) describe the syntactic structure of a sentence in terms of the words (lemmas) and associated grammatical relations among the words. Typically, these dependency relations are explicitly *typed*, which makes the trees valuable for practical applications such as information extraction, paraphrase detection and semantic relatedness.

2.3 Tree Long Short-Term Memory Network (Tree-LSTM)

Child-Sum Tree-LSTM (Tai et al., 2015) is an epitome of structure-based neural network which explicitly capture the structural information in a sentence. Tai et al. demonstrated that information at

Figure 3: A compositional view of parent node in Tree-LSTM network.

a parent node can be consolidated selectively from each of its child node. Architecturally, each gated vector and memory state update of the head node is dependent on the hidden states of its children in the Tree-LSTM. Assuming a good tree structure of a sentence, each node *j* of the structure incorporates the following equations.:

$$\tilde{h_j} = \sum_{k \in C(j)} h_k \tag{7}$$

$$i_j = \sigma(w_j W^i + \tilde{h_j} R^i + b^i) \tag{8}$$

$$f_{jk} = \sigma(w_j W^f + h_k R^f + b^f) \tag{9}$$

$$o_j = \sigma(w_j W^o + \tilde{h_j} R^o + b^o) \tag{10}$$

$$u_j = \tanh(w_j W^u + \tilde{h_j} R^u + b^u) \tag{11}$$

$$c_j = i_j \odot u_j + \sum_{k \in C(j)} f_{jk} \odot c_k \tag{12}$$

$$h_j = o_j \odot \tanh(c_j) \tag{13}$$

where:

- $\boldsymbol{w_j} \in \mathbb{R}^{\mathrm{D}}$ represents word embedding of all nodes in Dependency structure and only terminal nodes in Constituency structure. [2]
- $(\boldsymbol{W^i}, \boldsymbol{W^f}, \boldsymbol{W^o}, \boldsymbol{W^u}) \in \mathbb{R}^{\mathrm{D\ x\ d}}$ represent input weight matrices.
- $(\boldsymbol{R^i}, \boldsymbol{R^f}, \boldsymbol{R^o}, \boldsymbol{R^u}) \in \mathbb{R}^{\mathrm{d\ x\ d}}$ represent recurrent weight matrices, and $(\boldsymbol{b^i}, \boldsymbol{b^f}, \boldsymbol{b^o}, \boldsymbol{b^u}) \in \mathbb{R}^{\mathrm{d}}$ represent biases.

[2] $\boldsymbol{w_j}$ is ignored for non-terminal nodes in a Constituency structure by removing the $\boldsymbol{wW}$ terms in Equations 8-11.

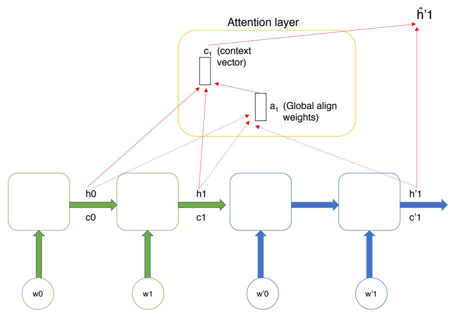

Figure 4: Global attention model

- $\boldsymbol{c_j} \in \mathbb{R}^{\mathrm{d}}$ is the new memory state vector of node *j*.
- $\boldsymbol{C(j)}$ is the set of children of node *j*.
- $\boldsymbol{f_{jk}} \in \mathbb{R}^{\mathrm{d}}$ is the forget gate vector for child *k* of node *j*.

Referring to Equation 12, the new memory cell state, c_j of node *j*, receives new information, u_j, partially. More importantly, it includes the partial information from each of its direct children, set *C(j)*, by employing the corresponding forget gate, f_{jk}.

When the Child-Sum Tree model is deployed on a dependency tree, it is referred to as *Dependency Tree-LSTM*, whereas a constituency-tree-based instantiation is referred to as *Constituency Tree-LSTM*.

2.4 Attention Mechanisms

Alignment models were first introduced in statistical machine translation (SMT) (Brown et al., 1993), which connect sub-strings in the source sentence to sub-strings in the target sentence.

Recently, attention techniques (which are effectively soft alignment models) in neural machine translation (NMT) (Bahdanau et al., 2014) came into prominence, where *attention* scores are calculated by considering words of source sentence while decoding words in target language. Although effective attention mechanisms (Luong et al., 2015) such as Global Attention Model (GAM) (Figure 4) and Local Attention Model (LAM) have been developed, such techniques have not been explored over Tree-LSTMs.

3 Inter-Sentence Attention on Tree-LSTMs

We present two types of tree-based attention models in this section. With trivial adaptation, they can be deployed in the sequence setting (degenerated trees).

3.1 Modified Decomposable Attention (MDA)

Parikh et al. (2016)'s original decomposable inter-sentence attention model only used word embeddings to construct the attention matrix, without any structural encoding of sentences. Essentially, the model incorporated three components:

Attend: Input representations (without sequence or structural encoding) of both sentences, L and R, are soft-aligned.

Compare: A set of vectors is produced by separately comparing each sub-phrase of L to sub-phrases in R. Vector representation of each sub-phrase in L is a non-linear combination of representation of word in sentence L and its aligned sub-phrase in sentence R. The same holds true for the set of vectors for sentence R.

Aggregate: Both sets of sub-phrases vectors are summed up separately to form final sentence representation of sentence L and sentence R.

We decide to augment the original decomposable inter-sentence attention model and generalize it into the tree (and sequence) setting. To be more specific, we consider two input sequences: L = (l_1, $l_2....l_{len_L}$), R = (r_1, $r_2....r_{len_R}$) and their corresponding input representations: $\bar{L}$ = ($\bar{l}_1$, $\bar{l}_2....\bar{l}_{len_L}$), $\bar{R}$ = ($\bar{r}_1$, $\bar{r}_2....\bar{r}_{len_R}$); where len_L and len_R represents number of words in L and R, respectively.

3.1.1 MDA on dependency structure

Let's assume sequences L and R have dependency tree structures D_L and D_R. In this case, len_L and len_R represents number of nodes in D_L and D_R, respectively. ***After*** using a Tree-LSTM to encode tree representations, which results in: $D_L^{'}$ = ($\bar{l}_1^{'}$, $\bar{l}_2^{'}....\bar{l}_{len_L}^{'}$), $D_R^{'}$ = ($\bar{r}_1^{'}$, $\bar{r}_2^{'}....\bar{r}_{len_R}^{'}$), we gather unnormalized attention weights, e_{ij} and normalize them as follows:

$$e_{ij} = \bar{l}_i^{'}(\bar{r}_j^{'})^T \tag{14}$$

$$\beta_i = \sum_{j=1}^{len_R} \frac{exp(e_{ij})}{\sum_{k=1}^{len_R} exp(e_{ik})} * \bar{r}_j^{'} \tag{15}$$

$$\alpha_j = \sum_{i=1}^{len_L} \frac{exp(e_{ij})}{\sum_{k=1}^{len_L} exp(e_{kj})} * \bar{l}_i^{'} \tag{16}$$

From the equations above, we can infer that the attention matrix will have a dimension len_L x len_R. In contrast to the original model, we compute the final representations of the each sentence by concatenating the LSTM-encoded representation of root with the attention-weighted representation of the root [3]:

$$h_L^{''} = G([\bar{l}_{root_L}^{'}; \beta_{root_L}]) \tag{17}$$

$$h_R^{''} = G([\bar{r}_{root_R}^{'}; \alpha_{root_R}]) \tag{18}$$

where G is a feed-forward neural network. $h_L^{''}$ and $h_R^{''}$ are final vector representations of input sequences L and R, respectively.

3.1.2 MDA on constituency structure

Let's assume sequences L and R have constituency tree structures C_L and C_R. Moreover, assume C_L and C_R have total number of nodes as N_L ($> len_L$) and N_R ($> len_R$), respectively. As in 3.1.1, the attention mechanism is employed **after** encoding the trees C_L and C_R. While encoding trees, terminal and non-terminal nodes are handled in the same way as in the original Tree-LSTM model (see 2.3).

It should be noted that we collect hidden states of all the nodes (N_L and N_R) individually in C_L and C_R during the encoding process. Hence, hidden states matrix will have dimension N_L x *d* for tree C_L whereas for tree C_R, it will have dimension N_R x *d*; where *d* is dimension of each hidden state. Therefore, attention matrix will have a dimension N_L x N_R. Finally, we employ Equations 14-18 to compute the final representations of sequences L and R.

3.2 Progressive Attention (PA)

In this section, we propose a novel attention mechanism on Tree-LSTM, inspired by (Quirk et al., 2005) and (Yamada and Knight, 2001).

3.2.1 PA on dependency structure

Let's assume a dependency tree structure of sentence L = (l_1, $l_2....l_{len_L}$) is available as D_L; where len_L represents number of nodes in D_L. Similarly, tree D_R corresponds to the sentence R = (r_1, $r_2....r_{len_R}$); where len_R represents number of nodes in D_R.

In PA, the objective is to produce the final vector representation of tree D_R conditional on the hidden state vectors of *all* nodes of D_L. Similar to

[3]In the sequence setting, we compute the corresponding representations for the *last* word in the sentence.

the encoding process in NMT, we encode R by *attending* each node of D_R to all nodes in D_L. Let's name this process *Phase1*. Next, *Phase2* is performed where L is encoded in the similar way to get the final vector representation of D_L.

Referring to Figure 5 and assuming Phase1 is being executed, a hidden state matrix, H_L, is obtained by concatenating the hidden state vector of every node in tree D_L, where the number of nodes in D_L = 3. Next, tree D_R is processed by calculating the hidden state vector at every node. Assume that the current node being processed is n_{R2} of D_R, which has a hidden state vector, h_{R2}. Before further processing, normalized weights are calculated based on h_{R2} and H_L. Formally,

$$H_{pj} = stack[h_{pj}] \tag{19}$$

$$con_{pj} = concat[H_{pj}, H_q] \tag{20}$$

$$a_{pj} = softmax(tanh(con_{pj}W_c + b) * W_a) \tag{21}$$

where:

- $\boldsymbol{p}, \boldsymbol{q} \in \{\boldsymbol{L}, \boldsymbol{R}\}$ and $\boldsymbol{q} \neq \boldsymbol{p}$
- $\boldsymbol{H_q} \in \mathbb{R}^{\boldsymbol{x} \text{ x d}}$ represents a matrix obtained by concatenating hidden state vectors of nodes in tree $\boldsymbol{D_q}$; $\boldsymbol{x}$ is $\boldsymbol{len_q}$ of sentence $\boldsymbol{q}$.
- $\boldsymbol{H_{pj}} \in \mathbb{R}^{\boldsymbol{x} \text{ x d}}$ represents a matrix obtained by stacking hidden state, $\boldsymbol{h_{pj}}$, vertically $\boldsymbol{x}$ times.
- $\boldsymbol{con_{pj}} \in \mathbb{R}^{\boldsymbol{x} \text{ x 2d}}$ represents the concatenated matrix.
- $\boldsymbol{a_{pj}} \in \mathbb{R}^{\boldsymbol{x}}$ represents the normalized attention weights at node *j* of tree $\boldsymbol{D_p}$; where $\boldsymbol{D_p}$ is the dependency structure of sentence $\boldsymbol{p}$.
- $\boldsymbol{W_c} \in \mathbb{R}^{\text{2d x d}}$ and $\boldsymbol{W_a} \in \mathbb{R}^{\text{d}}$ represent learned weight matrices.

The normalized attention weights in above equations provide an opportunity to align the subtree at the current node, n_{R2}, in D_R to sub-trees available at all nodes in D_L. Next, a gated mechanism is employed to compute the final vector representation at node n_{R2}.

Formally,

$$h'_{pj} = \sum_{0}^{(x-1)} ((1 - a_{pj}) * H_q + (a_{pj}) * H_{pj}) \tag{22}$$

where:

- $\boldsymbol{h'_{pj}} \in \mathbb{R}^{\text{d}}$ represents the final vector representation of node *j* in tree $\boldsymbol{D_p}$
- $\sum_{\boldsymbol{0}}^{\boldsymbol{(x-1)}}$ represents column-wise sum

Assuming the final vector representation of tree D_R is h'_R, the exact same steps are followed for Phase2 with the exception that the entire process is now conditional on tree D_R. As a result, the final vector representation of tree D_L, h'_L, is computed.

Lastly, the following equations are applied to vectors h'_L and h'_R, before calculating the *angle* and *distance* similarity (see Section 4).

$$h''_L = tanh(h'_L + h_L) \tag{23}$$

$$h''_R = tanh(h'_R + h_R) \tag{24}$$

where:

- $\boldsymbol{h_L} \in \mathbb{R}^{\text{d}}$ represents the vector representation of tree $\boldsymbol{D_L}$ without attention.
- $\boldsymbol{h_R} \in \mathbb{R}^{\text{d}}$ represents the vector representation of tree $\boldsymbol{D_R}$ without attention.

3.2.2 PA on constituency structure

Let C_L and C_R represent constituency trees of L and R, respectively; where C_L and C_R have total number of nodes N_L ($> len_L$) and N_R ($> len_R$). Additionally, let's assume that trees C_L and C_R have the same configuration of nodes as in Section 3.1.2, and the encoding of *terminal* and *non-terminal* nodes follow the same process as in Section 3.1.2. Assuming we have already encoded all N_L nodes of tree C_L using Tree-LSTM, we will have the hidden state matrix, H_L, with dimension N_L x d. Next, while encoding any node of C_R, we consider H_L which results in an attention vector having shape N_L. Using Equations 19-22 [4], we retrieve the final hidden state of the current node. Finally, we compute the representation of sentence R based on attention to sentence L. We perform Phase2 with the same process, except that we now condition on sentence R.

In summary, the *progressive attention* mechanism refers to all nodes in the other tree ***while*** encoding a node in the current tree, instead of waiting till the end of the structural encoding to establish cross-sentence attention, as was done in the *decomposable attention* model.

[4]At this point, we will consider $\boldsymbol{C_q}$ and $\boldsymbol{C_p}$ instead of $\boldsymbol{D_q}$ and $\boldsymbol{D_p}$, respectively, in Equations 19-22. Additionally, $\boldsymbol{x}$ will be equal to total number of nodes in the constituency tree.

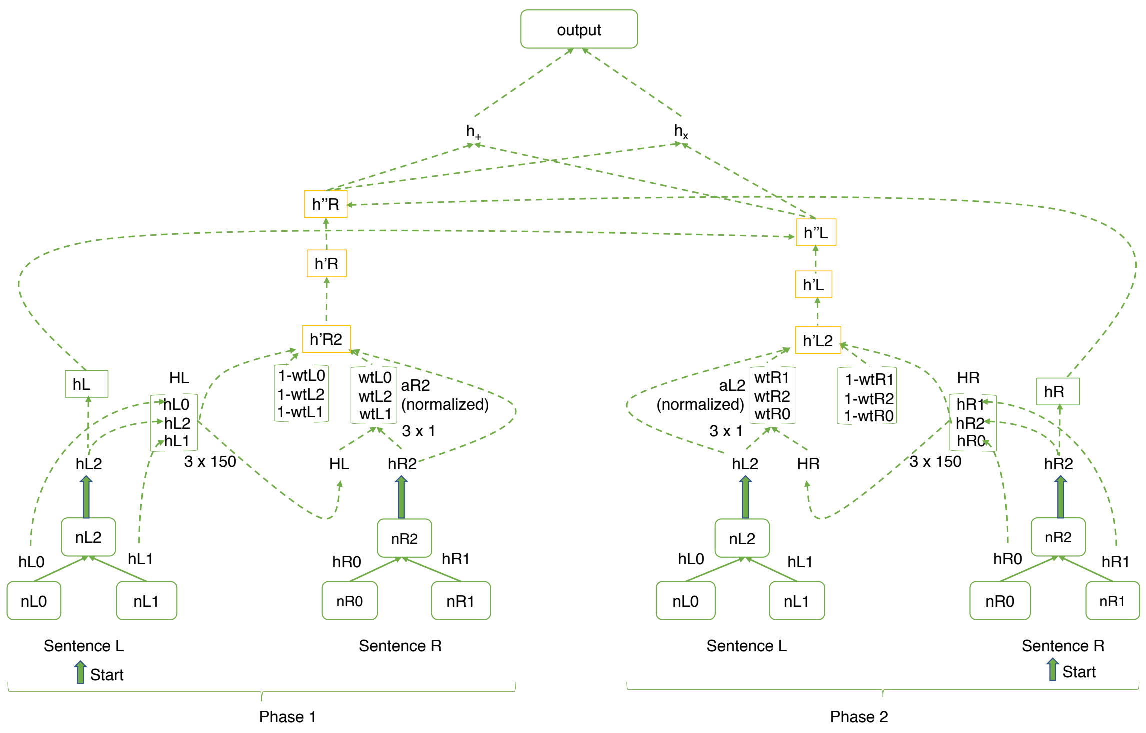

Figure 5: Progressive Attn-Tree-LSTM model

4 Evaluation Tasks

We evaluate our models on two tasks: (1) semantic relatedness scoring for sentence pairs (SemEval 2012, Task 6 and SemEval 2014, Task 1) and (2) paraphrase detection for question pairs (Quora, 2017).

4.1 Semantic Relatedness for Sentence Pairs

In SemEval 2012, Task 6 and SemEval 2014, Task 1, every sentence pair has a real-valued score that depicts the extent to which the two sentences are semantically related to each other. Higher score implies higher semantic similarity between the two sentences. Vector representations h''_L and h''_R are produced by using our *Modified Decomp-Attn* or *Progressive-Attn* models. Next, a similarity score, $\hat{y}$ between h''_L and h''_R is computed using the same neural network (see below), for the sake of fair comparison between our models and the original *Tree-LSTM* (Tai et al., 2015).

$$h_x = h''_L \odot h''_R \tag{25}$$

$$h_+ = |h''_L - h''_R| \tag{26}$$

$$h_s = \sigma(h_x W^x + h_+ W^+ + b^h) \tag{27}$$

$$\hat{p_\theta} = softmax(h_s W^p + b^p) \tag{28}$$

$$\hat{y} = r^T \hat{p_\theta} \tag{29}$$

where:

- $r^T = [1, 2..S]$
- $h_x \in \mathbb{R}^d$ measures the sign similarity between h''_L and h''_R
- $h_+ \in \mathbb{R}^d$ measures the absolute distance between h''_L and h''_R

Following (Tai et al., 2015), we convert the regression problem into a soft classification. We also use the same sparse distribution, p, which was defined in the original Tree-LSTM to transform the gold rating for a sentence pair, such that $y = r^T p$ and $\hat{y} = r^T \hat{p_\theta} \approx y$. The loss function is the KL-divergence between p and $\hat{p}$:

$$J(\theta) = \frac{\sum_{k=1}^{m} KL(p^k || \hat{p}_\theta^k)}{m} + \frac{\lambda ||\theta||_2^2}{2} \tag{30}$$

- m is the number of sentence pairs in the dataset.
- λ represents the regularization penalty.

4.2 Paraphrase Detection for Question Pairs

In this task, each question pair is labeled as either paraphrase or not, hence the task is binary classification. We use Eqs. 25 - 28 to compute the predicted distribution $\hat{p}_\theta$. The predicted label, $\hat{y}$, will be:

$$\hat{y} = \arg\max_y \hat{p}_\theta \tag{31}$$

The loss function is the negative log-likelihood:

$$J(\theta) = -\frac{\sum_{k=1}^{m} y^k \log \hat{y}^k}{m} + \frac{\lambda ||\theta||_2^2}{2} \tag{32}$$

5 Experiments

5.1 Semantic Relatedness for Sentence Pairs

We utilized two different datasets:

- The Sentences Involving Compositional Knowledge (SICK) dataset (Marelli et al. (2014)), which contains a total of 9,927 sentence pairs. Specifically, the dataset has a split of 4500/500/4927 among training, dev, and test. Each sentence pair has a score $S \in [1,5]$, which represents an average of 10 different human judgments collected by crowd-sourcing techniques.

- The MSRpar dataset (Agirre et al., 2012), which consists of 1,500 sentence pairs. In this dataset, each pair is annotated with a score $S \in [0,5]$ and has a split of 750/750 between training and test.

We used the Stanford Parsers (Chen and Manning, 2014; Bauer) to produce dependency and constituency parses of sentences. Moreover, we initialized the word embeddings with 300-dimensional Glove vectors (Pennington et al., 2014); the word embeddings were held fixed during training. We experimented with different optimizers, among which AdaGrad performed the best. We incorporated a learning rate of 0.025 and regularization penalty of 10^{-4} without dropout.

5.2 Paraphrase Detection for Question Pairs

For this task, we utilized the Quora dataset (Iyer; Kaggle, 2017). Given a pair of questions, the objective is to identify whether they are semantic duplicates. It is a binary classification problem where a duplicate question pair is labeled as 1 otherwise as 0. The training set contains about 400,000 labeled question pairs, whereas the test set consists of 2.3 million unlabeled question pairs. Moreover, the training dataset has only 37% positive samples; average length of a question is 10 words. Due to hardware and time constraints, we extracted 50,000 pairs from the original training while maintaining the same positive/negative ratio. A stratified 80/20 split was performed on this subset to produce the training/test set. Finally, 5% of the training set was used as a validation set in our experiments.

We used an identical training configuration as for the semantic relatedness task since the essence of both the tasks is practically the same. We also performed pre-processing to clean the data and then parsed the sentences using Stanford Parsers.

6 Results

6.1 Semantic Relatedness for Sentence Pairs

Table 1 summarizes our results. According to (Marelli et al., 2014), we compute three evaluation metrics: Pearson's *r*, Spearman's ρ and Mean Squared Error (MSE). We compare our attention models against the original Tree-LSTM (Tai et al., 2015), instantiated on both constituency trees and dependency trees. We also compare earlier baselines with our models, and the best results are in bold. Since Tree-LSTM is a generalization of Linear LSTM, we also implemented our attention models on Linear *Bidirectional* LSTM (BiLSTM). All results are average of 5 runs. It is witnessed that the *Progressive-Attn* mechanism combined with *Constituency Tree-LSTM* is overall the strongest contender, but PA failed to yield any performance gain on Dependency Tree-LSTM in either dataset.

6.2 Paraphrase Detection for Question Pairs

Table 2 summarizes our results where best results are highlighted in bold within each category. It should be noted that Quora is a new dataset and we have done our analysis on only 50,000 samples. Therefore, to the best of our knowledge, there is no published baseline result yet. For this task, we considered four standard evaluation metrics: Accuracy, F1-score, Precision and Recall. The *Progressive-Attn + Constituency Tree-LSTM* model still exhibits the best performance by a small margin, but the *Progressive-Attn* mechanism works surprisingly well on the linear bi-LSTM.

6.3 Effect of the Progressive Attention Model

Table 3 illustrates how various models operate on two sentence pairs from SICK test dataset. As we can infer from the table, the first pair demonstrates an instance of the active-passive voice phenomenon. In this case, the linear LSTM and vanilla Tree-LSTMs really struggle to perform.

Table 1: Results on test dataset for SICK and MSRpar semantic relatedness task. Mean scores are presented based on 5 runs (standard deviation in parenthesis). Categories of results: (1) Previous models (2) Dependency structure (3) Constituency structure (4) Linear structure

Dataset	Model	Pearson's *r*	Spearman's ρ	MSE

Constituency Tree-LSTM	0.7881 (0.0042)	0.7065 (0.0034)	0.7192 (0.0216)	0.6846 (0.0380)
Decomp-Attn (Constituency)	0.7776 (0.0004)	0.6942 (0.0050)	0.7055 (0.0069)	0.6836 (0.0164)
Progressive-Attn (Constituency)	**0.7956 (0.0020)**	**0.7192 (0.0024)**	**0.7300 (0.0079)**	**0.7089 (0.0104)**
Linear Bi-LSTM	0.7859 (0.0024)	0.7097 (0.0047)	0.7112 (0.0129)	0.7089 (0.0219)
Decomp-Attn (Linear)	0.7861 (0.0034)	0.7074 (0.0109)	0.7151 (0.0135)	0.7010 (0.0315)
Progressive-Attn (Linear)	**0.7949 (0.0031)**	**0.7182 (0.0162)**	**0.7298 (0.0115)**	**0.7092 (0.0469)**

However, when our progressive attention mechanism is integrated into syntactic structures (dependency or constituency), we witness a boost in the semantic relatedness score. Such desirable behavior is consistently observed in multiple active-passive voice pairs. The second pair points to a possible issue in data annotation. Despite the presence of strong negation, the gold-standard score is 4 out of 5 (indicating high relatedness). Interestingly, the *Progressive-Attn + Dependency Tree-LSTM* model favors the negation facet and outputs a low relatedness score.

7 Discussion

In this section, let's revisit our research questions in light of the experimental results.

First, can attention mechanisms be built for Tree-LSTMs? Does it work? The answer is yes. Our novel progressive-attention Tree-LSTM model, when instantiated on constituency trees,

Table 3: Effect of the progressive attention model

ID	Test Pair	Gold	BiLSTM		Const. Tree		Dep. Tree	
			(no attn)	(PA)	(no attn)	(PA)	(no attn)	(PA)
1	S1: The badger is burrowing a hole. S2: A hole is being burrowed by the badger.	4.9	2.60	3.02	3.52	4.34	3.41	4.63
2	S1: There is no man screaming. S2: A man is screaming.	4	3.44	3.20	3.65	3.50	3.51	2.15

significantly outperforms its counterpart without attention. The same model can also be deployed on sequences (degenerated trees) and achieve quite impressive results.

Second, the performance gap between the two attention models is quite striking, in the sense that the progressive model completely dominate its decomposable counterpart. The difference between the two models is the *pacing* of attention, i.e., when to refer to nodes in the other tree while encoding a node in the current tree. The progressive attention model garners it's empirical superiority by *attending while encoding*, instead of waiting till the end of the structural encoding to establish cross-sentence attention. In retrospect, this may justify why the original decomposable attention model in (Parikh et al., 2016) achieved competitive results without any LSTM-type encoding. Effectively, they implemented a naive version of our progressive attention model.

Third, do structures matter/help? The overall trend in our results is quite clear: the tree-based models exhibit convincing empirical strength; linguistically motivated structures are valuable. Admittedly though, on the relatively large Quora dataset, we observe some diminishing returns of incorporating structural information. It is not counter-intuitive that the sheer size of data can possibly allow structural patterns to emerge, hence lessen the need to explicitly model syntactic structures in neural architectures.

Last but not least, in trying to assess the impact of attention mechanisms (in particular the progressive attention model), we notice that the extra mileage gained on different structural encodings is different. Specifically, performance lift on Linear Bi-LSTM > performance lift on Constituency Tree-LSTM, and PA struggles to see performance lift on dependency Tree-LSTM. Interestingly enough, this observation is echoed by an earlier study (Gildea, 2004), which showed that tree-based alignment models work better on constituency trees than on dependency trees.

In summary, our results and findings lead to several intriguing questions and conjectures, which call for investigation beyond the scope of our study:

- Is it reasonable to conceptualize attention mechanisms as an implicit form of structure, which complements the representation power of explicit syntactic structures?

- If yes, does there exist some trade-off between the modeling efforts invested into syntactic and attention structures respectively, which seemingly reveals itself in our empirical results?

- The marginal impact of attention on dependency Tree-LSTMs suggests some form of saturation effect. Does that indicate a closer affinity between dependency structures (relative to constituency structures) and compositional semantics (Liang et al., 2013)?

- If yes, *why* is dependency structure a better stepping stone for compositional semantics? Is it due to the strongly lexicalized nature of the grammar? Or is it because the dependency relations (grammatical functions) embody more semantic information?

8 Conclusion

In conclusion, we proposed a novel *progressive attention* model on syntactic structures, and demonstrated its superior performance in semantic relatedness tasks. Our work also provides empirical ingredients for potentially profound questions and debates on syntactic structures in linguistics.

What you can cram into a single $&!#* vector: Probing sentence embeddings for linguistic properties

Abstract

Although much effort has recently been devoted to training high-quality sentence embeddings, we still have a poor understanding of what they are capturing. "Downstream" tasks, often based on sentence classification, are commonly used to evaluate the quality of sentence representations. The complexity of the tasks makes it however difficult to infer what kind of information is present in the representations. We introduce here 10 probing tasks designed to capture simple linguistic features of sentences, and we use them to study embeddings generated by three different encoders trained in eight distinct ways, uncovering intriguing properties of both encoders and training methods.

1 Introduction

Despite Ray Mooney's quip that you cannot cram the meaning of a whole %&!$# sentence into a single $&!#* vector, sentence embedding methods have achieved impressive results in tasks ranging from machine translation (Sutskever et al., 2014; Cho et al., 2014) to entailment detection (Williams et al., 2018), spurring the quest for "universal embeddings" trained once and used in a variety of applications (e.g., Kiros et al., 2015; Conneau et al., 2017; Subramanian et al., 2018). Positive results on concrete problems suggest that embeddings capture important linguistic properties of sentences. However, real-life "downstream" tasks require complex forms of inference, making it difficult to pinpoint the information a model is relying upon. Impressive as it might be that a system can tell that the sentence "A movie that doesn't aim too high, but it doesn't need to" (Pang and Lee, 2004) expresses a subjective viewpoint, it is hard to tell *how* the system (or even a human) comes to this conclusion. Complex tasks can also carry hidden biases that models might lock onto (Jabri et al., 2016). For example, Lai and Hockenmaier (2014) show that the simple heuristic of checking for explicit negation words leads to good accuracy in the SICK sentence entailment task.

Model introspection techniques have been applied to sentence encoders in order to gain a better understanding of which properties of the input sentences their embeddings retain (see Section 5). However, these techniques often depend on the specifics of an encoder architecture, and consequently cannot be used to compare different methods. Shi et al. (2016) and Adi et al. (2017) introduced a more general approach, relying on the notion of what we will call *probing tasks*. A probing task is a classification problem that focuses on simple linguistic properties of sentences. For example, one such task might require to categorize sentences by the tense of their main verb. Given an encoder (e.g., an LSTM) pre-trained on a certain task (e.g., machine translation), we use the sentence embeddings it produces to train the tense classifier (without further embedding tuning). If the classifier succeeds, it means that the pre-trained encoder is storing readable tense information into the embeddings it creates. Note that: (i) The probing task asks a simple question, minimizing interpretability problems. (ii) Because of their simplicity, it is easier to control for biases in probing tasks than in downstream tasks. (iii) The probing task methodology is agnostic with respect to the encoder architecture, as long as it produces a vector representation of sentences.

We greatly extend earlier work on probing tasks as follows. First, we introduce a larger set of probing tasks (10 in total), organized by the type of linguistic properties they probe. Second, we systematize the probing task methodology, controlling for a number of possible nuisance factors, and framing all tasks so that they only require single sentence representations as input, for maximum generality and to ease result interpretation. Third, we use our probing tasks to explore a wide range of state-of-the-art encoding architectures and training methods, and further relate probing and downstream task performance. Finally, we are publicly releasing our probing data sets and tools, hoping they will become a standard way to study the linguistic properties of sentence embeddings.[1]

2 Probing tasks

In constructing our probing benchmarks, we adopted the following criteria. First, for generality and interpretability, the task classification problem should only require single sentence embeddings as input (as opposed to, e.g., sentence and word embeddings, or multiple sentence representations). Second, it should be possible to construct large training sets in order to train parameter-rich multi-layer classifiers, in case the relevant properties are non-linearly encoded in the sentence vectors. Third, nuisance variables such as lexical cues or sentence length should be controlled for. Finally, and most importantly, we want tasks that address an interesting set of linguistic properties. We thus strove to come up with a set of tasks that, while respecting the previous constraints, probe a wide range of phenomena, from superficial properties of sentences such as which words they contain to their hierarchical structure to subtle facets of semantic acceptability. We think the current task set is reasonably representative of different linguistic domains, but we are not claiming that it is exhaustive. We expect future work to extend it.

The sentences for all our tasks are extracted from the Toronto Book Corpus (Zhu et al., 2015), more specifically from the random pre-processed portion made available by Paperno et al. (2016). We only sample sentences in the 5-to-28 word range. We parse them with the Stanford Parser (2017-06-09 version), using the pre-trained PCFG model (Klein and Manning, 2003), and we rely on the part-of-speech, constituency and dependency parsing information provided by this tool where needed. For each task, we construct training sets containing 100k sentences, and 10k-sentence validation and test sets. All sets are balanced, having an equal number of instances of each target class.

Surface information These tasks test the extent to which sentence embeddings are preserving surface properties of the sentences they encode. One can solve the surface tasks by simply looking at tokens in the input sentences: no linguistic knowledge is called for. The first task is to predict the *length* of sentences in terms of number of words (**SentLen**). Following Adi et al. (2017), we group sentences into 6 equal-width bins by length, and treat SentLen as a 6-way classification task. The *word content* (**WC**) task tests whether it is possible to recover information about the original words in the sentence from its embedding. We picked 1000 mid-frequency words from the source corpus vocabulary (the words with ranks between 2k and 3k when sorted by frequency), and sampled equal numbers of sentences that contain one and only one of these words. The task is to tell which of the 1k words a sentence contains (1k-way classification). This setup allows us to probe a sentence embedding for word content without requiring an auxiliary word embedding (as in the setup of Adi and colleagues).

Syntactic information The next batch of tasks test whether sentence embeddings are sensitive to syntactic properties of the sentences they encode. The *bigram shift* (**BShift**) task tests whether an encoder is sensitive to legal word orders. In this binary classification problem, models must distinguish intact sentences sampled from the corpus from sentences where we inverted two random adjacent words ("What *you are* doing out there?").

The *tree depth* (**TreeDepth**) task checks whether an encoder infers the hierarchical structure of sentences, and in particular whether it can group sentences by the depth of the longest path from root to any leaf. Since tree depth is naturally correlated with sentence length, we de-correlate these variables through a structured sampling procedure. In the resulting data set, tree depth values range from 5 to 12, and the task is to categorize sentences into the class corresponding to their depth (8 classes). As an example, the following is a long (22 tokens) but shallow (max depth: 5) sentence: "[$_1$ [$_2$ But right now, for the time being, my past, my fears, and my thoughts [$_3$ were [$_4$ my [$_5$business]]].]]" (the outermost brackets correspond to the ROOT and S nodes in the parse).

[1]https://github.com/facebookresearch/SentEval/tree/master/data/probing

In the top constituent task (**TopConst**), sentences must be classified in terms of the sequence of top constituents immediately below the sentence (S) node. An encoder that successfully addresses this challenge is not only capturing latent syntactic structures, but clustering them by constituent types. TopConst was introduced by Shi et al. (2016). Following them, we frame it as a 20-way classification problem: 19 classes for the most frequent top constructions, and one for all other constructions. As an example, "[Then] [very dark gray letters on a black screen] [appeared] [.]" has top constituent sequence: "ADVP NP VP .".

Note that, while we would not expect an untrained human subject to be explicitly aware of tree depth or top constituency, similar information must be implicitly computed to correctly parse sentences, and there is suggestive evidence that the brain tracks something akin to tree depth during sentence processing (Nelson et al., 2017).

Semantic information These tasks also rely on syntactic structure, but they further require some understanding of what a sentence denotes. The **Tense** task asks for the tense of the main-clause verb (VBP/VBZ forms are labeled as present, VBD as past). No target form occurs across the train/dev/test split, so that classifiers cannot rely on specific words (it is not clear that Shi and colleagues, who introduced this task, controlled for this factor). The *subject number* (**SubjNum**) task focuses on the number of the subject of the main clause (number in English is more often explicitly marked on nouns than verbs). Again, there is no target overlap across partitions. Similarly, *object number* (**ObjNum**) tests for the number of the direct object of the main clause (again, avoiding lexical overlap). To solve the previous tasks correctly, an encoder must not only capture tense and number, but also extract structural information (about the main clause and its arguments). We grouped Tense, SubjNum and ObjNum with the semantic tasks, since, at least for models that treat words as unanalyzed input units (without access to morphology), they must rely on what a sentence denotes (e.g., whether the described event took place in the past), rather than on structural/syntactic information. We recognize, however, that the boundary between syntactic and semantic tasks is somewhat arbitrary.

In the *semantic odd man out* (**SOMO**) task, we modified sentences by replacing a random noun or verb o with another noun or verb r. To make the task more challenging, the bigrams formed by the replacement with the previous and following words in the sentence have frequencies that are comparable (on a log-scale) with those of the original bigrams. That is, if the original sentence contains bigrams $w_{n-1}o$ and ow_{n+1}, the corresponding bigrams $w_{n-1}r$ and rw_{n+1} in the modified sentence will have comparable corpus frequencies. No sentence is included in both original and modified format, and no replacement is repeated across train/dev/test sets. The task of the classifier is to tell whether a sentence has been modified or not. An example modified sentence is: " No one could see this Hayes and I wanted to know if it was real or a *spoonful* (orig.: *ploy*)." Note that judging plausibility of a syntactically well-formed sentence of this sort will often require grasping rather subtle semantic factors, ranging from selectional preference to topical coherence.

The coordination inversion (**CoordInv**) benchmark contains sentences made of two coordinate clauses. In half of the sentences, we inverted the order of the clauses. The task is to tell whether a sentence is intact or modified. Sentences are balanced in terms of clause length, and no sentence appears in both original and inverted versions. As an example, original "They might be only memories, but I can still feel each one" becomes: "I can still feel each one, but they might be only memories." Often, addressing CoordInv requires an understanding of broad discourse and pragmatic factors.

Row **Hum. Eval.** of Table 2 reports human-validated "reasonable" upper bounds for all the tasks, estimated in different ways, depending on the tasks. For the surface ones, there is always a straightforward correct answer that a human annotator with enough time and patience could find. The upper bound is thus estimated at 100%. The TreeDepth, TopConst, Tense, SubjNum and ObjNum tasks depend on automated PoS and parsing annotation. In these cases, the upper bound is given by the proportion of sentences correctly annotated by the automated procedure. To estimate this quantity, one linguistically-trained author checked the annotation of 200 randomly sampled test sentences from each task. Finally, the BShift, SOMO and CoordInv manipulations can accidentally generate acceptable sentences. For example, one modified SOMO sentence is: "He pulled out the large round *onion* (orig.: *cork*) and saw the amber balm inside.", that is arguably not more anomalous than the original. For these tasks, we ran Amazon Mechanical Turk experiments in which subjects were asked to judge whether 1k randomly sampled test sentences were acceptable or not. Reported human accuracies are based on majority voting. See Appendix for details.

3 Sentence embedding models

In this section, we present the three sentence encoders that we consider and the seven tasks on which we train them.

3.1 Sentence encoder architectures

A wide variety of neural networks encoding sentences into fixed-size representations exist. We focus here on three that have been shown to perform well on standard NLP tasks.

BiLSTM-last/max For a sequence of T words $\{w_t\}_{t=1,\ldots,T}$, a bidirectional LSTM computes a set of T vectors $\{h_t\}_t$. For $t \in [1, \ldots, T]$, h_t is the concatenation of a forward LSTM and a backward LSTM that read the sentences in two opposite directions. We experiment with two ways of combining the varying number of $(h_1, \ldots, h_T)$ to form a fixed-size vector, either by selecting the last hidden state of h_T or by selecting the maximum value over each dimension of the hidden units. The choice of these models are motivated by their demonstrated efficiency in seq2seq (Sutskever et al., 2014) and universal sentence representation learning (Conneau et al., 2017), respectively.[2]

Gated ConvNet We also consider the non-recurrent convolutional equivalent of LSTMs, based on stacked gated temporal convolutions. Gated convolutional networks were shown to perform well as neural machine translation encoders (Gehring et al., 2017) and language modeling decoders (Dauphin et al., 2017). The encoder is composed of an input word embedding table that is augmented with positional encodings (Sukhbaatar et al., 2015), followed by a stack of temporal convolutions with small kernel size. The output of each convolutional layer is filtered by a gating mechanism, similar to the one of LSTMs. Finally, max-pooling along the temporal dimension is performed on the output feature maps of the last convolution (Collobert and Weston, 2008).

[2]We also experimented with a unidirectional LSTM, with consistently poorer results.

3.2 Training tasks

Seq2seq systems have shown strong results in machine translation (Zhou et al., 2016). They consist of an *encoder* that encodes a source sentence into a fixed-size representation, and a *decoder* which acts as a conditional language model and that generates the target sentence. We train **Neural Machine Translation** systems on three language pairs using about 2M sentences from the Europarl corpora (Koehn, 2005). We pick **English-French**, which involves two similar languages, **English-German**, involving larger syntactic differences, and **English-Finnish**, a distant pair. We also train with an **AutoEncoder** objective (Socher et al., 2011) on Europarl source English sentences. Following Vinyals et al. (2015), we train a seq2seq architecture to generate linearized grammatical parse trees (see Table 1) from source sentences (**Seq2Tree**). We use the Stanford parser to generate trees for Europarl source English sentences. We train **SkipThought** vectors (Kiros et al., 2015) by predicting the next sentence given the current one (Tang et al., 2017), on 30M sentences from the Toronto Book Corpus, excluding those in the probing sets. Finally, following Conneau et al. (2017), we train sentence encoders on **Natural Language Inference** using the concatenation of the SNLI (Bowman et al., 2015) and MultiNLI (Bowman et al., 2015) data sets (about 1M sentence pairs). In this task, a sentence encoder is trained to encode two sentences, which are fed to a classifier and whose role is to distinguish whether the sentences are contradictory, neutral or entailed. Finally, as in Conneau et al. (2017), we also include **Untrained** encoders with random weights, which act as random projections of pre-trained word embeddings.

3.3 Training details

BiLSTM encoders use 2 layers of 512 hidden units ($\sim$4M parameters), Gated ConvNet has 8 convolutional layers of 512 hidden units, kernel size 3 ($\sim$12M parameters). We use pre-trained fastText word embeddings of size 300 (Mikolov et al., 2018) without fine-tuning, to isolate the impact of encoder architectures and to handle words outside the training sets. Training task performance and further details are in Appendix.

Table 1: **Source and target examples for seq2seq training tasks.**

4 Probing task experiments

Baselines Baseline and human-bound performance are reported in the top block of Table 2. **Length** is a linear classifier with sentence length as sole feature. **NB-uni-tfidf** is a Naive Bayes classifier using words' tfidf scores as features, **NB-bi-tfidf** its extension to bigrams. Finally, **BoV-fastText** derives sentence representations by averaging the fastText embeddings of the words they contain (same embeddings used as input to the encoders).[3]

Except, trivially, for Length on SentLen and the NB baselines on WC, there is a healthy gap between top baseline performance and human upper bounds. NB-uni-tfidf evaluates to what extent our tasks can be addressed solely based on knowledge about the distribution of words in the training sentences. Words are of course to some extent informative for most tasks, leading to relatively high performance in Tense, SubjNum and ObjNum. Recall that the words containing the probed features are disjoint between train and test partitions, so we are not observing a confound here, but rather the effect of the redundancies one expects in natural language data. For example, for Tense, since sentences often contain more than one verb in the same tense, NB-uni-tfidf can exploit non-target verbs as cues: the NB features most associated to the past class are verbs in the past tense (e.g "sensed", "lied", "announced"), and similarly for present (e.g "uses", "chuckles", "frowns"). Using bigram features (NB-bi-tfidf) brings in general little or no improvement with respect to the unigram baseline, except, trivially, for the BShift task, where NB-bi-tfidf can easily detect unlikely bigrams. NB-bi-tfidf has below-random performance on SOMO, confirming that the semantic intruder is not given away by superficial bigram cues.

[3]Similar results are obtained summing embeddings, and using GloVe embeddings (Pennington et al., 2014).

Our first striking result is the good overall performance of Bag-of-Vectors, confirming early insights that aggregated word embeddings capture surprising amounts of sentence information (Pham et al., 2015; Arora et al., 2017; Adi et al., 2017). BoV's good WC and SentLen performance was already established by Adi et al. (2017). Not surprisingly, word-order-unaware BoV performs randomly in BShift and in the more sophisticated semantic tasks SOMO and CoordInv. More interestingly, BoV is very good at the Tense, SubjNum, ObjNum, and TopConst tasks (much better than the word-based baselines), and well above chance in TreeDepth. The good performance on Tense, SubjNum and ObjNum has a straightforward explanation we have already hinted at above. Many sentences are naturally "redundant", in the sense that most tensed verbs in a sentence are in the same tense, and similarly for number in nouns. In 95.2% Tense, 75.9% SubjNum and 78.7% ObjNum test sentences, the target tense/number feature is also the majority one for the whole sentence. Word embeddings capture features such as number and tense (Mikolov et al., 2013), so aggregated word embeddings will naturally track these features' majority values in a sentence. BoV's TopConst and TreeDepth performance is more surprising. Accuracy is well above NB, showing that BoV is exploiting cues beyond specific words strongly associated to the target classes. We conjecture that more abstract word features captured

Table 2: **Probing task accuracies.** Classification performed by a MLP with sigmoid nonlinearity, taking pre-learned sentence embeddings as input (see Appendix for details and logistic regression results).

by the embeddings (such as the part of speech of a word) might signal different syntactic structures. For example, sentences in the "WHNP SQ ." top constituent class (e.g., "*How* long before you leave us again?") must contain a wh word, and will often feature an auxiliary or modal verb. BoV can rely on this information to noisily predict the correct class.

Encoding architectures Comfortingly, proper encoding architectures clearly outperform BoV. An interesting observation in Table 2 is that different encoder architectures trained with the same objective, and achieving similar performance on the training task,[4] can lead to linguistically different embeddings, as indicated by the probing tasks. Coherently with the findings of Conneau et al. (2017) for the downstream tasks, this suggests that the prior imposed by the encoder architecture strongly preconditions the nature of the embeddings. Complementing recent evidence that convolutional architectures are on a par with recurrent ones in seq2seq tasks (Gehring et al., 2017), we find that Gated ConvNet's overall probing task performance is comparable to that of the best LSTM architecture (although, as shown in Appendix, the LSTM has a slight edge on downstream tasks). We also replicate the finding of Conneau et al. (2017) that BiLSTM-max outperforms BiLSTM-last both in the downstream tasks (see Appendix) and in the probing tasks (Table 2). Interestingly, the latter only outperforms the former in SentLen, a task that captures a superficial aspect of sentences (how many words they contain), that could get in the way of inducing more useful linguistic knowledge.

[4]See Appendix for details on training task performance.

Training tasks We focus next on how different training tasks affect BiLSTM-max, but the patterns are generally representative across architectures. NMT training leads to encoders that are more linguistically aware than those trained on the NLI data set, despite the fact that we confirm the finding of Conneau and colleagues that NLI is best for downstream tasks (Appendix). Perhaps, NMT captures richer linguistic features useful for the probing tasks, whereas shallower or more *ad-hoc* features might help more in our current downstream tasks. Suggestively, the one task where NLI clearly outperforms NMT is WC. Thus, NLI training is better at preserving shallower word features that might be more useful in downstream tasks (cf. Figure 2 and discussion there).

Unsupervised training (SkipThought and AutoEncoder) is not on a par with supervised tasks, but still effective. AutoEncoder training leads, unsurprisingly, to a model excelling at SentLen, but it attains low performance in the WC prediction task. This curious result might indicate that the latter information is stored in the embeddings in a complex way, not easily readable by our MLP. At the other end, Seq2Tree is trained to predict annotation from the same parser we used to create some of the probing tasks. Thus, its high performance on TopConst, Tense, SubjNum, ObjNum and TreeDepth is probably an artifact. Indeed, for most of these tasks, Seq2Tree performance is above the human bound, that is, Seq2Tree learned to mimic the parser errors in our benchmarks. For the more challenging SOMO and CoordInv tasks, that only indirectly rely on tagging/parsing information, Seq2Tree is comparable to NMT, that does not use explicit syntactic information.

Perhaps most interestingly, BiLSTM-max already achieves very good performance without any training (Untrained row in Table 2). Untrained BiLSTM-max also performs quite well in the downstream tasks (Appendix). This architecture must encode priors that are intrinsically good for sentence representations. Untrained BiLSTM-max exploits the input fastText embeddings, and multiplying the latter by a random recurrent matrix provides a form of positional encoding. However, good performance in a task such as SOMO, where BoV fails and positional information alone should not help (the intruder is randomly distributed across the sentence), suggests that other architectural biases are at work. Intriguingly, a preliminary comparison of untrained BiLSTM-max and human subjects on the SOMO sentences evaluated by both reveals that, whereas humans have a bias towards finding sentences acceptable (62% sentences are rated as untampered with, vs. 48% ground-truth proportion), the model has a strong bias in the opposite direction (it rates 83% of the sentences as modified). A cursory look at contrasting errors confirms, unsurprisingly, that those made by humans are perfectly justified, while model errors are opaque. For example, the sentence "I didn't come here to *reunite* (orig. *undermine*) you" seems perfectly acceptable in its modified form, and indeed subjects judged it as such, whereas untrained BiLSTM-max "correctly" rated it as a modified item. Conversely, it is difficult to see any clear reason for the latter tendency to rate perfectly acceptable originals as modified. We leave a more thorough investigation to further work. See similar observations on the effectiveness of untrained ConvNets in vision by Ulyanov et al. (2017).

Probing task comparison A good encoder, such as NMT-trained BiLSTM-max, shows generally good performance across probing tasks. At one extreme, performance is not particularly high on the surface tasks, which might be an indirect sign of the encoder extracting "deeper" linguistic properties. At the other end, performance is still far from the human bounds on TreeDepth, BShift, SOMO and CoordInv. The last 3 tasks ask if a sentence is syntactically or semantically anomalous. This is a daunting job for an encoder that has not been explicitly trained on acceptability, and it is interesting that the best models are, at least to a certain extent, able to produce reasonable anomaly judgments. The asymmetry between the difficult TreeDepth and easier TopConst is also interesting. Intuitively, TreeDepth requires more nuanced syntactic information (down to the deepest leaf of the tree) than TopConst, that only requires identifying broad chunks.

Figure 1 reports how probing task accuracy changes in function of encoder training epochs. The figure shows that NMT probing performance is largely independent of target language, with strikingly similar development patterns across French, German and Finnish. Note in particular the similar probing accuracy curves in French and Finnish, while the corresponding BLEU scores (in lavender) are consistently higher in the former lan-

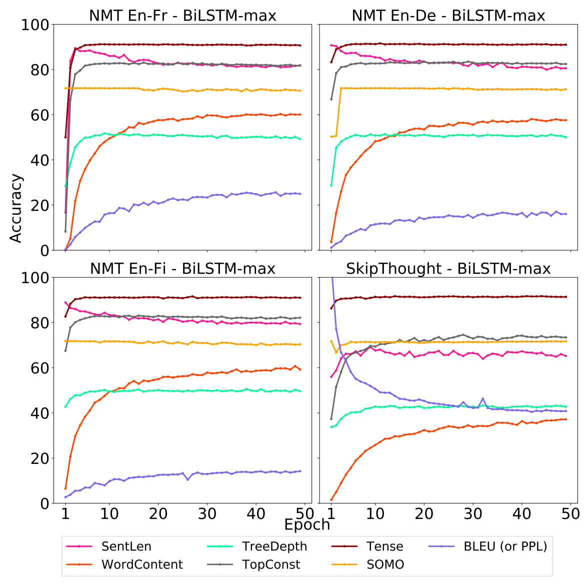

Figure 1: **Probing task scores after each training epoch, for NMT and SkipThought.** We also report training score evolution: BLEU for NMT; perplexity (PPL) for SkipThought.

guage. For both NMT and SkipThought, WC performance keeps increasing with epochs. For the other tasks, we observe instead an early flattening of the NMT probing curves, while BLEU performance keeps increasing. Most strikingly, SentLen performance is actually *decreasing*, suggesting again that, as a model captures deeper linguistic properties, it will tend to forget about this superficial feature. Finally, for the challenging SOMO task, the curves are mostly flat, suggesting that what BiLSTM-max is able to capture about this task is already encoded in its architecture, and further training doesn't help much.

Probing vs. downstream tasks Figure 2 reports correlation between performance on our probing tasks and the downstream tasks available in the SentEval[5] suite, which consists of classification (MR, CR, SUBJ, MPQA, SST2, SST5, TREC), natural language inference (SICK-E), semantic relatedness (SICK-R, STSB), paraphrase detection (MRPC) and semantic textual similarity (STS 2012 to 2017) tasks. Strikingly, WC is significantly positively correlated with all downstream tasks. This suggests that, at least for current models, the latter do not require extracting particularly abstract knowledge from the data. Just relying on the *words* contained in the input sentences can get you a long way. Conversely, there is a significant negative correlation between SentLen and most downstream tasks. The number of words in a sentence is not informative about its linguistic contents. The more models abstract away from such information, the more likely it is they will use their capacity to capture more interesting features, as the decrease of the SentLen curve along training (see Figure 1) also suggests. CoordInv and, especially, SOMO, the tasks requiring the most sophisticated semantic knowledge, are those that positively correlate with the largest number of downstream tasks after WC. We observe intriguing asymmetries: SOMO correlates with the SICK-E sentence entailment test, but not with SICK-R, which is about modeling sentence relatedness intuitions. Indeed, logical entailment requires deeper semantic analysis than modeling similarity judgments. TopConst and the number tasks negatively correlate with various similarity and sentiment data sets (SST, STS, SICK-R). This might expose biases in these tasks: SICK-R, for example, deliberately contains sentence pairs with opposite voice, that will have different constituent structure but equal meaning (Marelli et al., 2014). It might also mirrors genuine factors affecting similarity judgments (e.g., two sentences differing only in object number are very similar). Remarkably, TREC question type classification is the downstream task correlating with most probing tasks. Question classification is certainly an outlier among our downstream tasks, but we must leave a full understanding of this behaviour to future work (this is exactly the sort of analysis our probing tasks should stimulate).

5 Related work

Adi et al. (2017) introduced SentLen, WC and a word order test, focusing on a bag-of-vectors baseline, an autoencoder and skip-thought (all trained on the same data used for the probing tasks). We recast their tasks so that they only require a sentence embedding as input (two of their tasks also require word embeddings, polluting sentence-level evaluation), we extend the evaluation to more tasks, encoders and training objectives, and we relate performance on the probing tasks with that on downstream tasks. Shi et al. (2016) also use 3 probing tasks, including Tense and TopConst. It is not clear that they controlled for the same factors we considered (in particular, lexical overlap and

[5] https://github.com/facebookresearch/SentEval

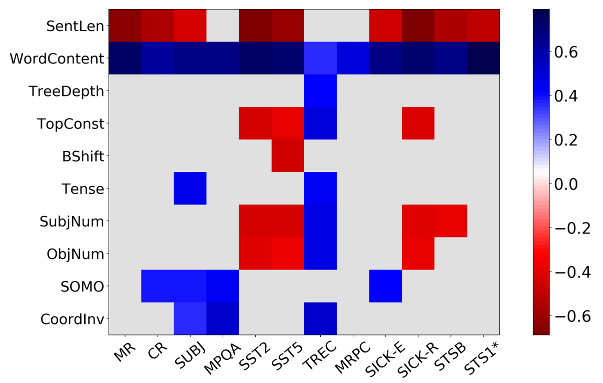

Figure 2: **Spearman correlation matrix between probing and downstream tasks.** Correlations based on all sentence embeddings we investigated (more than 40). Cells in gray denote task pairs that are not significantly correlated (after correcting for multiple comparisons).

sentence length), and they use much smaller training sets, limiting classifier-based evaluation to logistic regression. Moreover, they test a smaller set of models, focusing on machine translation.

Belinkov et al. (2017a), Belinkov et al. (2017b) and Dalvi et al. (2017) are also interested in understanding the type of linguistic knowledge encoded in sentence and word embeddings, but their focus is on word-level morphosyntax and lexical semantics, and specifically on NMT encoders and decoders. Sennrich (2017) also focuses on NMT systems, and proposes a contrastive test to assess how they handle various linguistic phenomena. Other work explores the linguistic behaviour of recurrent networks and related models by using visualization, input/hidden representation deletion techniques or by looking at the word-by-word behaviour of the network (e.g., Nagamine et al., 2015; Hupkes et al., 2017; Li et al., 2016; Linzen et al., 2016; Kàdàr et al., 2017; Li et al., 2017). These methods, complementary to ours, are not agnostic to encoder architecture, and cannot be used for general-purpose cross-model evaluation.

Finally, Conneau et al. (2017) propose a large-scale, multi-task evaluation of sentence embeddings, focusing entirely on downstream tasks.

6 Conclusion

We introduced a set of tasks probing the linguistic knowledge of sentence embedding methods. Their purpose is not to encourage the development of *ad-hoc* models that attain top performance on them, but to help exploring what information is captured by different pre-trained encoders.

We performed an extensive linguistic evaluation of modern sentence encoders. Our results suggest that the encoders are capturing a wide range of properties, well above those captured by a set of strong baselines. We further uncovered interesting patterns of correlation between the probing tasks and more complex "downstream" tasks, and presented a set of intriguing findings about the linguistic properties of various embedding methods. For example, we found that Bag-of-Vectors is surprisingly good at capturing sentence-level properties, thanks to redundancies in natural linguistic input. We showed that different encoder architectures trained with the same objective with similar performance can result in different embeddings, pointing out the importance of the architecture prior for sentence embeddings. In particular, we found that BiLSTM-max embeddings are already capturing interesting linguistic knowledge before training, and that, after training, they detect semantic acceptability without having been exposed to anomalous sentences before. We hope that our publicly available probing task set will become a standard benchmarking tool of the linguistic properties of new encoders, and that it will stir research towards a better understanding of what they learn.

In future work, we would like to extend the probing tasks to other languages (which should be relatively easy, given that they are automatically generated), investigate how multi-task training affects probing task performance and leverage our probing tasks to find more linguistically-aware universal encoders.

Abstract

Distant supervision has become the standard method for relation extraction. However, even though it is an efficient method, it does not come at no cost—The resulted distantly-supervised training samples are often very noisy. To combat the noise, most of the recent state-of-the-art approaches focus on selecting one-best sentence or calculating soft attention weights over the set of the sentences of one specific entity pair. However, these methods are suboptimal, and the **false positive** problem is still a key stumbling bottleneck for the performance. We argue that those incorrectly-labeled candidate sentences must be treated with a hard decision, rather than being dealt with soft attention weights. To do this, our paper describes a radical solution—We explore a deep reinforcement learning strategy to generate the false-positive indicator, where we automatically recognize false positives for each relation type without any supervised information. Unlike the removal operation in the previous studies, we redistribute them into the negative examples. The experimental results show that the proposed strategy significantly improves the performance of distant supervision comparing to state-of-the-art systems.

1 Introduction

Relation extraction is a core task in information extraction and natural language understanding. The goal of relation extraction is to predict relations for entities in a sentence (Zelenko et al., 2003; Bunescu and Mooney, 2005; GuoDong et al., 2005). For example, given a sentence *"**Barack Obama** is married to **Michelle Obama**."*, a relation classifier aims at predicting the relation of *"**spouse**"*. In downstream applications, relation extraction is the key module for constructing knowledge graphs, and it is a vital component of many natural language processing applications such as structured search, sentiment analysis, question answering, and summarization.

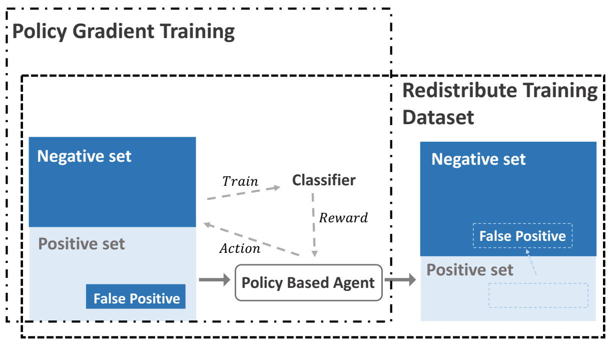

Figure 1: Our deep reinforcement learning framework aims at dynamically recognizing false positive samples, and moving them from the positive set to the negative set during distant supervision.

A major issue encountered in the early development of relation extraction algorithms is the data sparsity issue—It is extremely expensive, and almost impossible for human annotators to go through a large corpus of millions of sentences to provide a large amount of labeled training instances. Therefore, distant supervision relation extraction (Mintz et al., 2009; Hoffmann et al., 2011; Surdeanu et al., 2012) becomes popular, because it uses entity pairs from knowledge bases to select a set of noisy instances from unlabeled data. In recent years, neural network approaches (Zeng et al., 2014, 2015) have been proposed to train the relation extractor under these noisy conditions. To suppress the noisy(Roth et al., 2013), recent studies (Lin et al., 2016) have proposed the use of attention mechanisms to place soft weights on a set of noisy sentences, and select samples. However, we argue that only selecting one example or based on soft attention weights are not the optimal strategy: To improve the robustness, we need a systematic solution to make use of more instances, while removing false positives and placing them in the right place.

In this paper, we investigate the possibility of using dynamic selection strategies for robust distant supervision. More specifically, we design a deep reinforcement learning agent, whose goal is to learn to choose whether to remove or remain the distantly supervised candidate instance based on the performance change of the relation classifier. Intuitively, our agent would like to remove false positives, and reconstruct a cleaned set of distantly supervised instances to maximize the reward based on the classification accuracy. Our proposed method is classifier-independent, and it can be applied to any existing distant supervision model. Empirically, we show that our method has brought consistent performance gains in various deep neural network based models, achieving strong performances on the widely used New York Times dataset (Riedel et al., 2010). Our contributions are three-fold:

- We propose a novel deep reinforcement learning framework for robust distant supervision relation extraction.
- Our method is model-independent, meaning that it could be applied to any state-of-the-art relation extractors.
- We show that our method can boost the performances of recently proposed neural relation extractors.

In Section 2, we will discuss related works on distant supervision relation extraction. Next, we will describe our robust distant supervision framework in Section 3. In Section 4, empirical evaluation results are shown. And finally, we conclude in Section 5.

2 Related Work

Mintz et al. (2009) is the first study that combines dependency path and feature aggregation for distant supervision. However, this approach would introduce a lot of false positives, as the same entity pair might have multiple relations. To alleviate this issue, Hoffmann et al. (2011) address this issue, and propose a model to jointly learn with multiple relations. Surdeanu et al. (2012) further propose a multi-instance multi-label learning framework to improve the performance. Note that these early approaches do not explicitly remove noisy instances, but rather hope that the model would be able to suppress the noise.

Recently, with the advance of neural network techniques, deep learning methods (Zeng et al., 2014, 2015) are introduced, and the hope is to model noisy distant supervision process in the hidden layers. However, their approach only selects one most plausible instance per entity pair, inevitably missing out a lot of valuable training instances. Recently, Lin et al. (2016) propose an attention mechanism to select plausible instances from a set of noisy instances. However, we believe that soft attention weight assignment might not be the optimal solution, since the false positives should be completely removed and placed in the negative set. Ji et al. (2017) combine the external knowledge to rich the representation of entity pair, in which way to improve the accuracy of attention weights. Even though these above-mentioned methods can select high-quality instances, they ignore the false positive case: all the sentences of one entity pair belongs to the false positives. In this work, we take a radical approach to solve this problem—We will make use of the distantly labeled resources as much as possible, while learning a independent false-positive indicator to remove false positives, and place them in the right place. After our ACL submission, we notice that a contemporaneous study Feng et al. (2018) also adopts reinforcement learning to learn an instance selector, but their reward is calculated from the prediction probabilities. In contrast, while in our method, the reward is intuitively reflected by the performance change of the relation classifier. Our approach is also complement to most of the approaches above, and can be directly applied on top of any existing relation extraction classifiers.

3 Reinforcement Learning for Distant Supervision

We introduce a performance-driven, policy-based reinforcement learning method to heuristically recognize false positive samples. Comparing to a prior study that has underutilized the distantly-supervised samples (Lin et al., 2016), we consider an RL agent for robust distant supervision relation extraction. We first describe the definitions of our RL method, including the policy-based agent, external environment, and pre-training strategy. Next, we describe the retraining strategy for our RL agent. The goal of our agent is to determine whether to **retain** or **remove** a distantly-supervised sentence, based on the performance change of relation classifier. Finally, we describe the noisy-suppression method, where we teach our policy-based agent to make a redistribution for a cleaner distant supervision training dataset.

Distant supervision relation extraction is to predict the relation type of entity pair under the automatically-generated training set. However, the issue is that these distantly-supervised sentences that mention this entity pair may not express the desired relation type. Therefore, what our RL agent should do is to determine whether the distantly-supervised sentence is a true positive instance for this relation type. For reinforcement learning, external environment and RL agent are two necessary components, and a robust agent is trained from the dynamic interaction between these two parts (Arulkumaran et al., 2017). First, the prerequisite of reinforcement learning is that the external environment should be modeled as a Markov decision process (MDP). However, the traditional setting of relation extraction cannot satisfy this condition: the input sentences are independent of each other. In other words, we cannot merely use the information of the sentence being processed as the state. Thus, we add the information from the early states into the representation of the current state, in which way to model our task as a MDP problem (Fang et al., 2017). The other component, RL agent, is parameterized with a policy network $\pi_\theta(s, a) = p(a|s; \theta)$. The probability distribution of actions $\mathcal{A} = \{a_{remove}, a_{remain}\}$ is calculated by policy network based on state vectors. What needs to be noted is that, Deep Q Network (DQN) (Mnih et al., 2013) is also a widely-used RL method; however, it is not suitable for our case, even if our action space is small. First, we cannot compute the immediate reward for every operation; In contrast, the accurate reward can only be obtained after finishing processing the whole training dataset. Second, the stochastic policy of the policy network is capable of preventing the agent from getting stuck in an intermediate state. The following subsections detailedly introduce the definitions of the fundamental components in the proposed RL method.

States In order to satisfy the condition of MDP, the state s includes the information from the current sentence and the sentences that have been removed in early states. The semantic and syntactic information of sentence is represented by a continuous real-valued vector. According to some state-of-the-art supervised relation extraction approaches (Zeng et al., 2014; Nguyen and Grishman, 2015), we utilize both word embedding and position embedding to convert sentence into vector. With this sentence vector, the current state is the concatenation of the current sentence vector and the average vector of the removed sentences in early states. We give relatively larger weight for the vector of the current sentence, in which way to magnify the dominating influence of the current sentence information for the decision of action.

Actions At each step, our agent is required to determine whether the instance is false positive for target relation type. Each relation type has a agent[1]. There are two actions for each agent: whether to remove or retain the current instance from the training set. With the initial distantly-supervised dataset that is blended with incorrectly-labeled instances, we hope that our agent is capable of using the policy network to filter noisy instances; Under this cleaned dataset, distant supervision is then expected to achieve better performance.

Rewards As previously mentioned, the intuition of our model is that, when the incorrectly-labeled instances are filtered, the better performance of relation classifier will achieve. Therefore, we use the change of performance as the result-driven reward for a series of actions decided by the agent. Compared to accuracy, we adopt the F_1 score as the evaluation criterion, since accuracy might not be an indicative metric in a multi-class classification setting where the data distribution could be imbalanced. Thus, the reward can be formulated as the

[1]We also tried the strategy that just builds a single agent for all relation types: a binary classifier(TP/FP) or a multi-class classifier(rela1/rela2/.../FP). But, it has the limitation in the performance. We found that our one-agent-for-one-relation strategy obtained better performance than the single agent strategy.

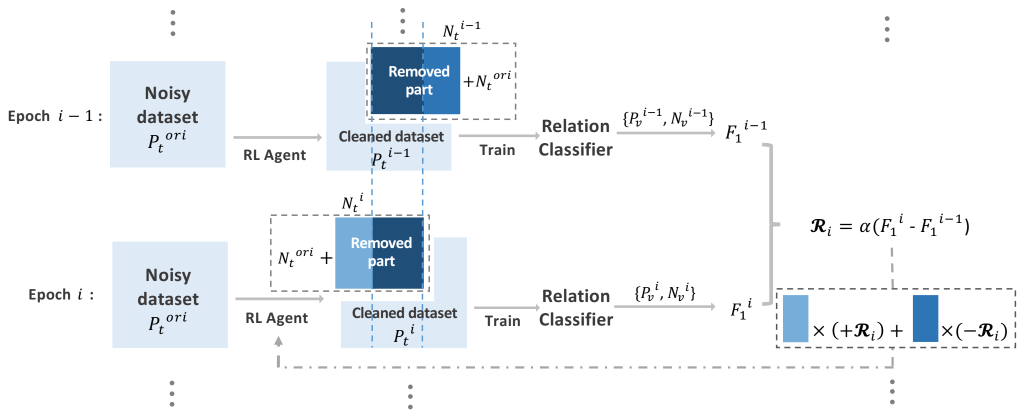

Figure 2: The proposed policy-based reinforcement learning framework. The agent tries to remove the wrong-labeled sentences from the distantly-supervised positive dataset P^{ori}. In order to calculate the reward, P^{ori} is split into the training part P_t^{ori} and the validation part P_v^{ori}; their corresponding negative part are represented as N_t^{ori} and N_v^{ori}. In each epoch i, the agent performs a series of actions to recognize the false positive samples from P_t^{ori} and treat them as negative samples. Then, a new relation classifier is trained under the new dataset $\{P_t^i, N_t^i\}$. With this relation classifier, F_1 score is calculated from the new validation set $\{P_v^i, N_v^i\}$, where P_v^i is also filtered by the current agent. After that, the current reward is measured as the difference of F_1 between the adjacent epochs.

difference between the adjacent epochs:

$$R_i = \alpha(F_1^i - F_1^{i-1}) \tag{1}$$

As this equation shows, in step i, our agent is given a positive reward only if F_1 gets improved; otherwise, the agent will receive a negative reward. Under this setting, the value of reward is proportional to the difference of F_1, and α is used to convert this difference into a rational numeric range. Naturally, the value of the reward is in a continuous space, which is more reasonable than a binary reward (-1 and 1), because this setting can reflect the number of wrong-labeled instance that the agent has removed. In order to avoid the randomness of F_1, we use the average F_1 of last five epochs to calculate the reward.

Policy Network For each input sentence, our policy network is to determine whether it expresses the target relation type and then make removal action if it is irrelevant to the target relation type. Thus, it is analogous to a binary relation classifier. CNN is commonly used to construct relation classification system (Santos et al., 2015; Xu et al., 2015; Shen and Huang, 2016), so we adopt a simple CNN with window size c_w and kernel size c_k, to model policy network $\pi(s;\theta)$. The reason why we do not choice the variants of CNN (Zeng et al., 2015; Lin et al., 2016) that are well-designed for distant supervision is that these two models belong to bag-level models (dealing with a bag of sentences simultaneously) and deal with the multi-classification problem; We just need a model to do binary sentence-level classification. Naturally, the simpler network is adopted.

3.1 Training Policy-based Agent

Unlike the goal of distant supervision relation extraction, our agent is to determine whether an annotated sentence expresses the target relation type rather than predict the relationship of entity pair, so sentences are treated independently despite belonging to the same entity pair. In distant supervision training dataset, one relation type contains several thousands or ten thousands sentences; moreover, reward R can only be calculated after processing the whole positive set of this relation type. If we randomly initialize the parameters of policy network and train this network by trial and errors, it will waste a lot of time and be inclined to poor convergence properties. In order to overcome this problem, we adopt a supervised learning procedure to pre-train our policy network, in which way to provide a general learning direction for our policy-based agent.

3.1.1 Pre-training Strategy

The pre-training strategy, inspired from *AlphaGo* (Silver et al., 2016), is a common strategy in RL related works to accelerate the training of RL agents. Normally, they utilize a small part of the annotated dataset to train policy networks before reinforcement learning. For example, *AlphaGo* uses the collected experts moves to do a supervised learning for *Go* RL agent. However, in distant supervision relation extraction task, there is not any supervised information that can be used unless let linguistic experts to do some manual annotations for part of the entity pairs. However, this is expensive, and it is not the original intention of distant supervision. Under this circumstance, we propose a compromised solution. With well-aligned corpus, the true positive samples should have evident advantage in quantity compared with false positive samples in the distantly-supervised dataset. So, for a specific relation type, we directly treat the distantly-supervised positive set as the positive set, and randomly extract part of distantly-supervised negative set as the negative set. In order to better consider prior information during this pre-training procedure, the amount of negative samples is 10 times of the number of positive samples. It is because, when learning with massive negative samples, the agent is more likely to develop toward a better direction. Cross-entropy cost function is used to train this binary classifier, where the negative label corresponds to the removing action, and the positive label corresponds to the retaining action.

$$\begin{aligned} J(\theta) = \sum_i & y_i \log[\pi(a = y_i|s_i;\theta)] \\ & + (1 - y_i)\log[1 - \pi(a = y_i|s_i;\theta)] \end{aligned} \tag{2}$$

Due to the noisy nature of the distantly-labeled instances, if we let this pre-training process overfit this noisy dataset, the predicted probabilities of most samples tend to be close to 0 or 1, which is difficult to be corrected and unnecessarily increases the training cost of reinforcement learning. So, we stop this training process when the accuracy reaches $85\% \sim 90\%$. Theoretically, our approach can be explained as increasing the entropy of the policy gradient agent, and preventing the entropy of the policy being too low, which means that the lack of exploration may be a concern.

3.1.2 Retraining Agent with Rewards

As shown in Figure 2, in order to discover incorrectly-labeled instances without any supervised information, we introduce a policy-based RL method. What our agent tries to deal with is the noisy samples from the distantly-supervised positive dataset; Here we call it as the *DS positive dataset*. We split it into the training positive set P_t^{ori} and the validation positive set P_v^{ori}; naturally, both of these two set are noisy. Correspondingly, the training negative set N_t^{ori} and the validation negative set N_v^{ori} are constructed by randomly selected from the DS negative dataset. In every epoch, the agent removes a noisy sample set Ψ_i from P_t^{ori} according to the stochastic policy $\pi(a|s)$, and we obtain a new positive set $P_t = P_t^{ori} - \Psi_i$. Because Ψ_i is recognized as the wrong-labeled samples, we redistribute it into the negative set $N_t = N_t^{ori} + \Psi_i$. Under this setting, the scale of training set is constant for each epoch. Now we utilize the cleaned data $\{P_t, N_t\}$ to train a relation classifier. The desirable situation is that RL agent has the capacity to increase the performance of relation classifier through relocating incorrectly-labeled false positive instances. Therefore, we use the validation set $\{P_v^{ori}, N_v^{ori}\}$ to measure the performance of the current agent. First, this validation set is filtered and redistributed by the current agent as $\{P_v, N_v\}$; the F_1 score of the current relation classifier is calculated from it. Finally, the difference of F_1 scores between the current and previous epoch is used to calculate reward. Next, we will introduce several strategies to train a more robust RL agent.

Removing the fixed number of sentences in each epoch In every epoch, we let the RL agent to remove a fixed number of sentences or less (when the number of the removed sentences in one epoch does not reach this fixed number during training), in which way to prevent the case that the agent tries to remove more false positive instances by removing more instances. Under the restriction of fixed number, if the agent decides to remove the current state, it means the chance of removing other states decrease. Therefore, in order to obtain a better reward, the agent should try to remove a instance set that includes more negative instances.

Loss function The quality of the RL agent is reflected by the quality of the removed part. After the pre-training process, the agent just possesses

Algorithm 1 Retraining agent with rewards for relation k. For a clearer expression, k is omitted in the following algorithm.

```
Require: Positive set $\{P_t^{ori}, P_v^{ori}\}$, Negative set $\{N_t^{ori}, N_v^{ori}\}$, the fixed number of removal $\gamma_t, \gamma_v$
 1: Load parameters $\theta$ from pre-trained policy network
 2: Initialize $s^*$ as the all-zero vector with the same dimension of $s_j$
 3: for epoch $i = 1 \to N$ do
 4:     for $s_j \in P_t^{ori}$ do
 5:         $\widetilde{s_j} = concatenation(s_j, s^*)$
 6:         Randomly sample $a_j \sim \pi(a|\widetilde{s_j};\theta)$; compute $p_j = \pi(a = 0|\widetilde{s_j};\theta)$
 7:         if $a_j == 0$ then
 8:             Save tuple $t_j = (\widetilde{s_j}, p_j)$ in $T$ and recompute the average vector of removed sentences $s^*$
 9:         end if
10:     end for
11:     Rank $T$ based on $p_j$ from high to low, obtain $T_{rank}$
12:     for $t_i$ in $T_{rank}[:\gamma_t]$ do
13:         Add $t_i[0]$ into $\Psi_i$
14:     end for
15:     $P_t^i = P_t^{ori} - \Psi_i, N_t^i = N_t^{ori} + \Psi_i$, and generate the new validation set $\{P_v^i, N_v^i\}$ with current agent
16:     Train the relation classifier based on $\{P_t^i, N_t^i\}$
17:     Calculate $F_1^i$ on the new validation set $\{P_v^i, N_v^i\}$, and Save $F_1^i$, $\Psi_i$
18:     $\mathcal{R} = \alpha(F_1^i - F_1^{i-1})$
19:     $\Omega_{i-1} = \Psi_{i-1} - \Psi_i \cap \Psi_{i-1}$; $\Omega_i = \Psi_i - \Psi_i \cap \Psi_{i-1}$
20:
21:     Updata $\theta$: $g \propto \triangledown_\theta \sum^{\Omega_i} \log \pi(a|s;\theta)\mathcal{R} + \triangledown_\theta \sum^{\Omega_{i-1}} \log \pi(a|s;\theta)(-\mathcal{R})$

the ability to distinguish the obvious false positive instances, which means the discrimination of the indistinguishable wrong-labeled instances are still ambiguous. Particularly, this indistinguishable part is the criterion to reflect the quality of the agent. Therefore, regardless of these easy-distinguished instances, the different parts of the removed parts in different epochs are the determinant of the change of F_1 scores. Therefore, we definite two sets:

$$\Omega_{i-1} = \Psi_{i-1} - (\Psi_i \cap \Psi_{i-1}) \quad (3)$$

$$\Omega_i = \Psi_i - (\Psi_i \cap \Psi_{i-1}) \quad (4)$$

where Ψ_i is the removed part of epoch i. Ω_{i-1} and Ω_i are represented with the different colors in Figure 2. If F_1 score increases in the epoch i, it means the actions of the epoch i is more reasonable than that in the epoch $i-1$. In other words, Ω_i is more negative than Ω_{i-1}. Thus, we assign the positive reward to Ω_i and the negative reward to Ω_{i-1}, and vice versa. In summary, the ultimate loss function is formulated as follow:

$$\begin{aligned} J(\theta) = &\sum^{\Omega_i} \log \pi(a|s;\theta)R \\ &+ \sum^{\Omega_{i-1}} \log \pi(a|s;\theta)(-R) \end{aligned} \quad (5)$$

3.2 Redistributing Training Dataset with Policy-based Agents

Through the above reinforcement learning procedure, for each relation type, we obtain a agent as the false-positive indicator. These agents possess the capability of recognizing incorrectly-labeled instances of the corresponding relation types. We adopt these agents as classifiers to recognize false positive samples in the noisy distantly-supervised training dataset. For one entity pair, if all the sentence aligned from corpus are classified as false positive, then this entity pair is redistributed into the negative set.

4 Experiments

We adopt a policy-based RL method to generate a series of relation indicators and use them to redistribute training dataset by moving false positive samples to negative sample set. Therefore, our experiments are intended to demonstrate that our RL agents possess this capability.

4.1 Datast and Evaluation Metrics

We evaluate the proposed method on a commonly-used dataset[2], which is first presented in Riedel et al. (2010). This dataset is generated by aligning entity pairs from Freebase with New York Times corpus(NYT). Entity mentions of NYT corpus are recognized by the Stanford named entity recognizer (Finkel et al., 2005). The sentences from the years 2005-2006 are used as the training corpus and sentences from 2007 are used as the testing corpus. There are 52 actual relations and a special relation NA which indicates there is no relation between the head and tail entities. The sentences of NA are from the entity pairs that exist in the same sentence of the actual relations but do not appear in the Freebase.

Similar to the previous works, we adopt the held-out evaluation to evaluate our model, which can provide an approximate measure of the classification ability without costly human evaluation. Similar to the generation of the training set, the entity pairs in test set are also selected from Freebase, which will be predicted under the sentences discovered from the NYT corpus.

4.2 Experimental Settings

4.2.1 Policy-based Agent

The action space of our RL agent just includes two actions. Therefore, the agent can be modeled as a binary classifier. We adopt a single-window CNN as this policy network. The detailed hyperparameter settings are presented in Table 1. As for word embeddings, we directly use the word embedding file released by Lin et al. (2016)[3], which just keeps the words that appear more than 100 times in NYT. Moreover, we have the same dimension setting of the position embedding, and the maximum length of relative distance is -30 and 30 ("-" and "+" represent the left and right side of the entities). The learning rate of reinforcement learning is $2e^{-5}$. For each relation type, the fixed number γ_t, γ_v are according to the pre-trained agent. When one relation type has too many distant-supervised positive sentences (for example, /location/location/contains has 75768 sentences), we sample a subset of size 7,500 sentences to train the agent. For the average vector of the removed sentences, in the pre-training process and the first state of the retraining process, it is set as all-zero vector.

Hyperparameter	**Value**

10	/peo/dec/p	82.2	83.0	**84.6**

Table 2: Comparison of F_1 scores among three cases: the relation classifier is trained with the original dataset, the redistributed dataset generated by the pre-trained agent, and the redistributed dataset generated by our RL agent respectively. The name of relation types are abbreviated: $/peo/per/pob$ represents $/people/person/place\_of\_birth$

4.2.2 Relation Classifier for Calculating Reward

In order to evaluate a series of actions by agent, we use a simple CNN model, because the simple network is more sensitive to the quality of the training set. The proportion between P_t^{ori} and P_v^{ori} is 2:1, and they are all derived from the training set of Riedel dataset; the corresponding negative sample sets N_t^{ori} and N_v^{ori} are randomly selected from the Riedel negative dataset, whose size is twice that of their corresponding positive sets.

4.3 The Effectiveness of Reinforcement Learning

In Table 2, we list the F_1 scores before and after adopting the proposed RL method. Even though there are 52 actual relation types in Riedel dataset, only 10 relation types have more than 1000 pos-

itive instances[4]. Because of the randomness of deep neural network on the small-scale dataset, we just train policy-based agents for these 10 relation types. First, compared with *O*riginal case, most of the *Pretrain* agents yield obvious improvements: It not only demonstrates the rationality of our pretraining strategy, but also verifies our hypothesis that most of the positive samples in Riedel dataset are true positive. More significantly, after retraining with the proposed policy-based RL method, the F_1 scores achieve further improvement, even for the case the *Pretrain* agents perform bad. These comparable results illustrate that the proposed policy-based RL method is capable of making agents develop towards a good direction.

[4]The supervised relation classification task Semeval-2010 Task 8 (Hendrickx et al., 2009) annotates nearly 1,000 instances for each relation type.

Model	**-**	**+RL**	**p-value**
CNN+ONE	0.177	**0.190**	1.24e-4

4.4 Impact of False Positive Samples

Zeng et al. (2015) and Lin et al. (2016) are both the robust models to solve wrong labeling problem of distant supervision relation extraction. Zeng et al. (2015) combine at-least-one multi-instance learning with deep neural network to extract only one active sentence to predict the relation between entity pair; Lin et al. (2016) combine all sentences of one entity pair and assign soft attention weights to them, in which way to generate a compositive relation representation for this entity pair. However, the false positive phenomenon also includes the case that all the sentences of one entity pair are wrong, which is because the corpus is not completely aligned with the knowledge base. This phenomenon is also common between Riedel dataset and Freebase through our manual inspection. Obviously, there is nothing the above two methods can do in this case.

The proposed RL method is to tackle this problem. We adopt our RL agents to redistribute Riedel dataset by moving false positive samples into the negative sample set. Then we use Zeng et al. (2015) and Lin et al. (2016) to predict relations on this cleaned dataset, and compare the performance with that on the original Riedel dataset. As shown in Figure 3 and Figure 4, under the assistant of our RL agent, the same model can achieve obvious improvement with more reasonable training dataset. In order to give the more intuitive comparison, we calculate the AUC value of each PR curve, which reflects the area size under these curves. These comparable results also indicate the effectiveness of our policy-based RL method. Moreover, as can be seen from the result of t-test evaluation, all the p-values are less than 5e-02, so the improvements are significant.

4.5 Case Study

Figure 5 indicates that, for different relations, the scale of the detected false positive samples is not

Relation	**/people/person/place_of_birth**
FP	1. GHETTO SUPERSTAR (THE MAN THAT I AM) – Ranging from **Pittsburgh** to Broadway, **Billy Porter** performs his musical memoir.
FP	1. "They are trying to create a united front at home in the face of the pressures **Syria** is facing," said **Sami Moubayed**, a political analyst and writer here. 2. "Iran injected **Syria** with a lot of confidence: stand up, show defiance," said **Sami Moubayed**, a political analyst and writer in Damascus.
Relation	**/people/deceased_person/place_of_death**
FP	1. Some **New York city** mayors – **William O'Dwyer**, Vincent R. Impellitteri and Abraham Beame – were born abroad. 2. Plenty of local officials have, too, including two **New York city** mayors, James J. Walker, in 1932, and **William O'Dwyer**, in 1950.

Table 4: Some examples of the false positive samples detected by our policy-based agent. Each row denotes the annotated sentences of one entity pair.

proportional to the original scale, which is in accordance with the actual accident situation. At the same time, we analyze the correlation between the false positive phenomenon and the number of sentences of entity pairs : With this the number ranging from 1 to 5, the corresponding percentages are [55.9%, 32.0%, 3.7%, 4.4%, 0.7%]. This distribution is consistent with our assumption. Because Freebase is, to some extent, not completely aligned with the NYT corpus, entity pairs with fewer sentences are more likely to be false positive, which is the major factor hindering the performance of the previous systems. In Table 4, we present some false positive examples selected by our agents. Taking entity pair (*Sami Moubayed*, *Syria*) as an example, it is obvious that there is not any valuable information reflecting relation */people/person/place_of_birth*. Both of these sentences talks about the situation analysis of *Syria* from the political analyst *Sami Moubayed*. We also found that, for some entity pairs, even though there are multiple sentences, all of them are identical. This phenomenon also increases the probability of the appearance of false positive samples.

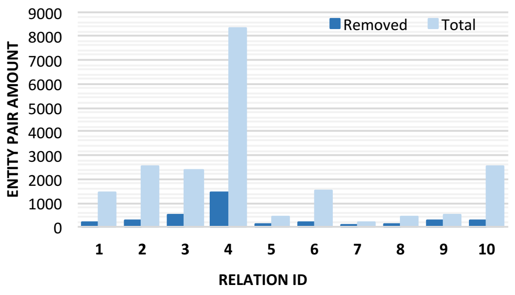

Figure 5: This figure presents the scale of the removed part for each relation type, where the horizontal axis corresponds to the IDs in Table 2.

5 Conclusion

In this work, we propose a deep reinforcement learning framework for robust distant supervision. The intuition is that, in contrast to prior works that utilize only one instance per entity pair and use soft attention weights to select plausible distantly supervised examples, we describe a policy-based framework to systematically learn to relocate the false positive samples, and better utilize the unlabeled data. More specifically, our goal is to teach the reinforcement agent to optimize the selection/redistribution strategy that maximizes the reward of boosting the performance of relation classification. An important aspect of our work is that our framework does not depend on a specific form of the relation classifier, meaning that it is a plug-and-play technique that could be potentially applied to any relation extraction pipeline. In experiments, we show that our framework boosts the performance of distant supervision relation extraction of various strong deep learning baselines on the widely used New York Times - Freebase dataset.

Abstract

Embedding models for entities and relations are extremely useful for recovering missing facts in a knowledge base. Intuitively, a relation can be modeled by a matrix mapping entity vectors. However, relations reside on low dimension sub-manifolds in the parameter space of arbitrary matrices – for one reason, composition of two relations M_1, M_2 may match a third M_3 (e.g. composition of relations currency_of_country and country_of_film usually matches currency_of_film_budget), which imposes compositional constraints to be satisfied by the parameters (i.e. $M_1 \cdot M_2 \approx M_3$). In this paper we investigate a dimension reduction technique by training relations jointly with an autoencoder, which is expected to better capture compositional constraints. We achieve state-of-the-art on Knowledge Base Completion tasks with strongly improved Mean Rank, and show that joint training with an autoencoder leads to interpretable sparse codings of relations, helps discovering compositional constraints and benefits from compositional training. Our source code is released at github.com/tianran/glimvec.

1 Introduction

Broad-coverage knowledge bases (KBs) such as Freebase (Bollacker et al., 2008) and DBPedia (Auer et al., 2007) store a large amount of facts in the form of ⟨head entity, relation, tail entity⟩ triples (e.g. ⟨*The Matrix*, country_of_film, *Australia*⟩), which could support a wide range of reasoning and question answering applications. The Knowledge Base Completion (KBC) task aims

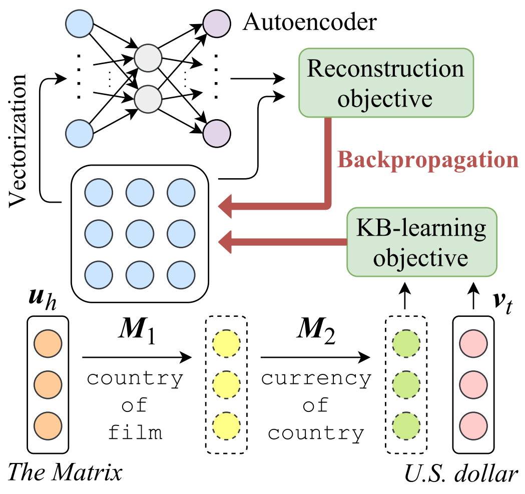

Figure 1: In joint training, relation parameters (e.g. M_1) receive updates from both a *KB-learning objective*, trying to predict entities in the KB; and a *reconstruction objective* from an autoencoder, trying to recover relations from low dimension codings.

to predict the missing part of an incomplete triple, such as ⟨*Finding Nemo*, country_of_film, ?⟩, by reasoning from known facts stored in the KB.

As a most common approach (Wang et al., 2017), modeling entities and relations to operate in a low dimension vector space helps KBC, for three conceivable reasons. First, when dimension is low, entities modeled as vectors are forced to share parameters, so "similar" entities which participate in many relations in common get close to each other (e.g. *Australia* close to *US*). This could imply that an entity (e.g. *US*) "type matches" a relation such as country_of_film. Second, relations may share parameters as well, which could transfer facts from one relation to other similar relations, for example from ⟨x, award_winner, y⟩ to ⟨x, award_nominated, y⟩. Third, spatial positions might be used to implement *composition* of relations, as relations can be regarded as mappings from head to tail entities, and the composition of two maps can match a third (e.g. the composition of `currency_of_country` and `country_of_film` matches the relation `currency_of_film_budget`), which could be captured by modeling composition in a space.

However, modeling relations as mappings naturally requires more parameters – a general linear map between d-dimension vectors is represented by a matrix of d^2 parameters – which are less likely to be shared, impeding transfers of facts between similar relations. Thus, it is desired to reduce dimensionality of relations; furthermore, the existence of a composition of two relations (assumed to be modeled by matrices $\boldsymbol{M}_1, \boldsymbol{M}_2$) matching a third ($\boldsymbol{M}_3$) also justifies dimension reduction, because it implies a *compositional constraint* $\boldsymbol{M}_1 \cdot \boldsymbol{M}_2 \approx \boldsymbol{M}_3$ that can be satisfied only by a lower dimension sub-manifold in the parameter space[1].

Previous approaches reduce dimensionality of relations by imposing pre-designed hard constraints on the parameter space, such as constraining that relations are translations (Bordes et al., 2013) or diagonal matrices (Yang et al., 2015), or assuming they are linear combinations of a small number of prototypes (Xie et al., 2017). However, pre-designed hard constraints do not seem to cope well with compositional constraints, because it is difficult to know *a priori* which two relations compose to which third relation, hence difficult to choose a pre-design; and compositional constraints are not always exact (e.g. the composition of `currency_of_country` and `headquarter_location` usually matches `business_operation_currency` but not always), so hard constraints are less suited.

In this paper, we investigate an alternative approach by training relation parameters jointly with an autoencoder (Figure 1). During training, the autoencoder tries to reconstruct relations from low dimension codings, with the reconstruction objective back-propagating to relation parameters as well. We show this novel technique promotes parameter sharing between different relations, and drives them toward low dimension manifolds (Sec.6.2). Besides, we expect the technique to cope better with compositional constraints, because it discovers low dimension manifolds posteriorly from data, and it does not impose any explicit hard constraints.

[1]It is noteworthy that similar compositional constraints apply to most modeling schemes of relations, not just matrices.

Yet, joint training with an autoencoder is not simple; one has to keep a subtle balance between gradients of the reconstruction and KB-learning objectives throughout the training process. We are not aware of any theoretical principles directly addressing this problem; but we found some important settings after extensive pre-experiments (Sec.4). We evaluate our system using standard KBC datasets, achieving state-of-the-art on several of them (Sec.6.1), with strongly improved Mean Rank. We discuss detailed settings that lead to the performance (Sec.4.1), and we show that joint training with an autoencoder indeed helps discovering compositional constraints (Sec.6.2) and benefits from compositional training (Sec.6.3).

2 Base Model

A knowledge base (KB) is a set $\mathcal{T}$ of triples of the form $\langle h, r, t\rangle$, where $h, t \in \mathcal{E}$ are entities and $r \in \mathcal{R}$ is a relation (e.g. $\langle$*The Matrix*, `country_of_film`, *Australia*$\rangle$). A relation r has its inverse $r^{-1} \in \mathcal{R}$ so that for every $\langle h, r, t\rangle \in \mathcal{T}$, we regard $\langle t, r^{-1}, h\rangle$ as also in the KB. Under this assumption and given $\mathcal{T}$ as training data, we consider the Knowledge Base Completion (KBC) task that predicts candidates for a missing tail entity in an incomplete $\langle h, r, ?\rangle$ triple.

Most approaches tackle this problem by training a *score function* measuring the plausibility of triples being facts. The model we implement in this work represents entities h, t as d-dimension vectors $\boldsymbol{u}_h, \boldsymbol{v}_t$ respectively, and relation r as a $d \times d$ matrix $\boldsymbol{M}_r$. If $\boldsymbol{u}_h, \boldsymbol{v}_t$ are one-hot vectors with dimension $d = |\mathcal{E}|$ corresponding to each entity, one can take $\boldsymbol{M}_r$ as the adjacency matrix of entities joined by relation r, so the set of tail entities filling into $\langle h, r, ?\rangle$ is calculated by $\boldsymbol{u}_h^\top \boldsymbol{M}_r$ (with each nonzero entry corresponds to an answer). Thus, we have $\boldsymbol{u}_h^\top \boldsymbol{M}_r \boldsymbol{v}_t > 0$ if and only if $\langle h, r, t\rangle \in \mathcal{T}$. This motivates us to use $\boldsymbol{u}_h^\top \boldsymbol{M}_r \boldsymbol{v}_t$ as a natural parameter to model plausibility of $\langle h, r, t\rangle$, even in a low dimension space with $d \ll |\mathcal{E}|$. Thus, we define the score function as

$$s(h, r, t) := \exp(\boldsymbol{u}_h^\top \boldsymbol{M}_r \boldsymbol{v}_t) \qquad (1)$$

for the basic model. This is similar to the bilinear model of Nickel et al. (2011), except that we distinguish $\boldsymbol{u}_h$ (the vector for head entities) from $\boldsymbol{v}_t$ (the vector for tail entities). It has also been proposed in Tian et al. (2016), but for modeling dependency trees rather than KBs.

More generally, we consider *composition* of relations $r_1/\ldots/r_l$ to model *path*s in a KB (Guu et al., 2015), as defined by $r_1, \ldots, r_l$ participating in a sequence of facts such that the head entity of each fact coincides with the tail of its previous. For example, a sequence of two facts ⟨*The Matrix*, `country_of_film`, *Australia*⟩ and ⟨*Australia*, `currency_of_country`, *Australian Dollar*⟩ form a path of composition `country_of_film/currency_of_country`, because the head of the second fact (i.e. *Australia*) coincides with the tail of the first. Using the previous $d = |\mathcal{E}|$ analogue, one can verify that composition of relations is represented by multiplication of adjacency matrices, so we accordingly define

$$s(h, r_1/\ldots/r_l, t) := \exp(\boldsymbol{u}_h^\top \boldsymbol{M}_{r_1} \cdots \boldsymbol{M}_{r_l} \boldsymbol{v}_t)$$

to measure the plausibility of a path. It is explored in Guu et al. (2015) to learn a score function not only for single facts but also for paths. This *compositional training* scheme is shown to bring valuable information about the structure of the KB and may help KBC. In this work, we conduct experiments both with and without compositional training.

In order to learn parameters $\boldsymbol{u}_h, \boldsymbol{v}_t, \boldsymbol{M}_r$ of the score function, we follow Tian et al. (2016) using a Noise Contrastive Estimation (NCE) (Gutmann and Hyvärinen, 2012) objective. For each path (or triple) $\langle h, r_1/\ldots, t\rangle$ taken from the KB, we generate negative samples by replacing the tail entity t with some random noise t^*. Then, we maximize

$$\mathcal{L}_1 := \sum_{\text{path}} \ln \frac{s(h, r_1/\ldots, t)}{k + s(h, r_1/\ldots, t)} + \sum_{\text{noise}} \ln \frac{k}{k + s(h, r_1/\ldots, t^*)}$$

as our *KB-learning objective*. Here, k is the number of noises generated for each path. When the score function is regarded as probability, $\mathcal{L}_1$ represents the log-likelihood of "$\langle h, r_1/\ldots, t\rangle$ being actual path and $\langle h, r_1/\ldots, t^*\rangle$ being noise". Maximizing $\mathcal{L}_1$ increases the scores of actual paths and decreases the scores of noises.

3 Joint Training with an Autoencoder

Autoencoders learn efficient codings of high-dimensional data while trying to reconstruct the original data from the coding. By joint training relation matrices with an autoencoder, we also expect it to help reducing the dimensionality of the original data (i.e. relation matrices).

Formally, we define a *vectorization* $\boldsymbol{m}_r$ for each relation matrix $\boldsymbol{M}_r$, and use it as input to the autoencoder. $\boldsymbol{m}_r$ is defined as a reshape of $\boldsymbol{M}_r$ flattened into a d^2-dimension vector, and normalized such that $\|\boldsymbol{m}_r\| = \sqrt{d}$. We define

$$\boldsymbol{c}_r := \mathrm{ReLU}(\boldsymbol{A}\boldsymbol{m}_r) \qquad (2)$$

as the coding. Here $\boldsymbol{A}$ is a $c \times d^2$ matrix with $c \ll d^2$, and ReLU is the Rectified Linear Unit function (Nair and Hinton, 2010). We reconstruct the input from $\boldsymbol{c}_r$ by multiplying a $d^2 \times c$ matrix $\boldsymbol{B}$. We want $\boldsymbol{B}\boldsymbol{c}_r$ to be more similar to $\boldsymbol{m}_r$ than other relations. For this purpose, we define a similarity

$$g(r_1, r_2) := \exp(\frac{1}{\sqrt{dc}} \boldsymbol{m}_{r_1}^\top \boldsymbol{B}\boldsymbol{c}_{r_2}), \qquad (3)$$

which measures the length of $\boldsymbol{B}\boldsymbol{c}_{r_2}$ projected to the direction of $\boldsymbol{m}_{r_1}$. In order to learn the parameters $\boldsymbol{A}, \boldsymbol{B}$, we adopt the Noise Contrastive Estimation scheme as in Sec.2, generate random noises r^* for each relation r and maximize

$$\mathcal{L}_2 := \sum_{r \in \mathcal{R}} \ln \frac{g(r, r)}{k + g(r, r)} + \sum_{r^* \sim \mathcal{R}} \ln \frac{k}{k + g(r, r^*)}$$

as our *reconstruction objective*. Maximizing $\mathcal{L}_2$ increases $\boldsymbol{m}_r$'s similarity with $\boldsymbol{B}\boldsymbol{c}_r$, and decreases it with $\boldsymbol{B}\boldsymbol{c}_{r^*}$.

During joint training, both $\mathcal{L}_1$ and $\mathcal{L}_2$ are simultaneously maximized, and the gradient $\nabla\mathcal{L}_2$ propagates to relation matrices as well. Since $\nabla\mathcal{L}_2$ depends on $\boldsymbol{A}$ and $\boldsymbol{B}$, and $\boldsymbol{A}, \boldsymbol{B}$ interact with all relations, they promote indirect parameter sharing between different relation matrices. In Sec.6.2, we further show that joint training drives relations toward a low dimension manifold.

4 Optimization Tricks

Joint training with an autoencoder is not simple. Relation matrices receive updates from both $\nabla\mathcal{L}_1$ and $\nabla\mathcal{L}_2$, but if they update $\nabla\mathcal{L}_1$ too much, the autoencoder has no effect; conversely, if they update $\nabla\mathcal{L}_2$ too often, all relation matrices crush into one cluster. Furthermore, an autoencoder should learn from genuine patterns of relation matrices that emerge from fitting the KB, but not the reverse – in which the autoencoder imposes arbitrary patterns to relation matrices according to random initialization. Therefore, it is not surprising that a naive optimization of $\mathcal{L}_1 + \mathcal{L}_2$ does not work.

After extensive pre-experiments, we have found some crucial settings for successful training. The most important "magic" is the scaling factor $\frac{1}{\sqrt{dc}}$ in definition of the similarity function (3), perhaps being combined with other settings as we discuss below. We have tried different factors 1, $\frac{1}{\sqrt{d}}$, $\frac{1}{\sqrt{c}}$ and $\frac{1}{dc}$ instead, with various combinations of d and c; but the autoencoder failed to learn meaningful codings in other settings. When the scaling factor is too small (e.g. $\frac{1}{dc}$), all relations get almost the same coding; conversely if the factor is too large (e.g. 1), all codings get very close to 0.

The next important rule is to keep a balance between the updates coming from $\nabla\mathcal{L}_1$ and $\nabla\mathcal{L}_2$. We use Stochastic Gradient Descent (SGD) for optimization, and the common practice (Bottou, 2012) is to set the learning rate as

$$\alpha(\tau) := \frac{\eta}{1 + \eta\lambda\tau}. \tag{4}$$

Here, η, λ are hyper-parameters and τ is a counter of processed data points. In this work, in order to control the updates in detail to keep a balance, we modify (4) to use a a step counter τ_r for each relation r, counting "number of updates" instead of data points[2]. That is, whenever $\boldsymbol{M}_r$ gets a nonzero update from a gradient calculation, τ_r increases by 1. Furthermore, we use different hyper-parameters for different "types of updates", namely η_1, λ_1 for updates coming from $\nabla\mathcal{L}_1$, and η_2, λ_2 for updates coming from $\nabla\mathcal{L}_2$. Thus, let Δ_1 be the partial gradient of $\nabla\mathcal{L}_1$, and Δ_2 the partial gradient of $\nabla\mathcal{L}_2$, we update $\boldsymbol{M}_r$ by $\alpha_1(\tau_r)\Delta_1 + \alpha_2(\tau_r)\Delta_2$ at each step, where

$$\alpha_1(\tau_r) := \frac{\eta_1}{1 + \eta_1\lambda_1\tau_r}, \quad \alpha_2(\tau_r) := \frac{\eta_2}{1 + \eta_2\lambda_2\tau_r}.$$

The rule for setting η_1, λ_1 and η_2, λ_2 is that, η_2 should be much smaller than η_1, because η_1, η_2 control the magnitude of learning rates at the early stage of training, with the autoencoder still largely random and Δ_2 not making much sense; on the other hand, one has to choose λ_1 and λ_2 such that $\|\Delta_1\|/\lambda_1$ and $\|\Delta_2\|/\lambda_2$ are at the same scale, because the learning rates approach $1/(\lambda_1\tau_r)$ and $1/(\lambda_2\tau_r)$ respectively, as the training proceeds. In this way, the autoencoder will not impose random patterns to relation matrices according to its initialization at the early stage, and a balance is kept between $\alpha_1(\tau_r)\Delta_1$ and $\alpha_2(\tau_r)\Delta_2$ later.

But how to estimate $\|\Delta_1\|$ and $\|\Delta_2\|$? It seems that we can approximately calculate their scales from initialization. In this work, we use i.i.d. Gaussians of variance $1/d$ to initialize parameters, so the initial Euclidean norms are $\|\boldsymbol{u}_h\| \approx 1$, $\|\boldsymbol{v}_t\| \approx 1$, $\|\boldsymbol{M}_r\| \approx \sqrt{d}$, and $\|\boldsymbol{BAm}_r\| \approx \sqrt{dc}$. Thus, by calculating $\nabla\mathcal{L}_1$ and $\nabla\mathcal{L}_2$ using (1) and (3), we have approximately

$$\|\Delta_1\| \approx \|\boldsymbol{u}_h\boldsymbol{v}_t^\top\| \approx 1, \quad \text{and}$$
$$\|\Delta_2\| \approx \|\frac{1}{\sqrt{dc}}\boldsymbol{Bc}_r\| \approx \frac{1}{\sqrt{dc}}\|\boldsymbol{BAm}_r\| \approx 1.$$

It suggests that, because of the scaling factor $\frac{1}{\sqrt{dc}}$ in (3), we have $\|\Delta_1\|$ and $\|\Delta_2\|$ at the same scale, so we can set $\lambda_1 = \lambda_2$. This might not be a mere coincidence.

4.1 Training the Base Model

Besides the tricks for joint training, we also found settings that significantly improve the base model on KBC, as briefly discussed below. In Sec.6.3, we will show performance gains by these settings using the FB15k-237 validation set.

Normalization It is better to normalize relation matrices to $\|\boldsymbol{M}_r\| = \sqrt{d}$ during training. This might reduce fluctuations in entity vector updates.

Regularizer It is better to minimize $\|\boldsymbol{M}_r^\top\boldsymbol{M}_r - \frac{1}{d}\operatorname{tr}(\boldsymbol{M}_r^\top\boldsymbol{M}_r)I\|$ during training. This regularizer drives $\boldsymbol{M}_r$ toward an orthogonal matrix (Tian et al., 2016) and might reduce fluctuations in entity vector updates. As a result, all relation matrices trained in this work are very close to orthogonal.

Initialization Instead of pure Gaussian, it is better to initialize matrices as $(I + G)/2$, where G is random. The identity matrix I helps passing information from head to tail (Tian et al., 2016).

Negative Sampling Instead of a unigram distribution, it is better to use a *uniform* distribution for generating noises. This is somehow counter-intuitive compared to training word embeddings.

5 Related Works

KBs have a wide range of applications (Berant et al., 2013; Hixon et al., 2015; Nickel et al., 2016a) and KBC has inspired a huge amount of research (Bordes et al., 2013; Riedel et al., 2013; Socher et al., 2013; Wang et al., 2014b,a; Xiao et al., 2016; Nguyen et al., 2016; Toutanova et al., 2016; Das et al., 2017; Hayashi and Shimbo, 2017).

[2]Similarly, we set separate step counters for all head and tail entities, and the autoencoder as well.

Among the previous works, TransE (Bordes et al., 2013) is the classic method which represents a relation as a translation of the entity vector space, and is partially inspired by Mikolov et al. (2013)'s vector arithmetic method of solving word analogy tasks. Although competitive in KBC, it is speculated that this method is well-suited for 1-to-1 relations but might be too simple to represent N-to-N relations accurately(Wang et al., 2017). Thus, extensions such as TransR (Lin et al., 2015b) and STransE (Nguyen et al., 2016) are proposed to map entities into a relation-specific vector space before translation. The ITransF model (Xie et al., 2017) further enhances this approach by imposing a hard constraint that the relation-specific maps should be linear combinations of a small number of prototypical matrices. Our work inherits the same motivation with ITransF in terms of promoting parameter-sharing among relations.

On the other hand, the base model used in this work originates from RESCAL (Nickel et al., 2011), in which relations are naturally represented as analogue to the adjacency matrices (Sec.2). Further developments include HolE (Nickel et al., 2016b) and ConvE (Dettmers et al., 2018) which improve this approach in terms of parameter-efficiency, by introducing low dimension factorizations of the matrices. We inherit the basic model of RESCAL but draw additional training techniques from Tian et al. (2016), and show that the base model already can achieve near state-of-the-art performance (Sec.6.1,6.3). This sends a message similar to Kadlec et al. (2017), saying that training tricks might be as important as model designs.

Nevertheless, we emphasize the novelty of this work in that the previous models mostly achieve dimension reduction by imposing some pre-designed hard constraints (Bordes et al., 2013; Yang et al., 2015; Trouillon et al., 2016; Nickel et al., 2016b; Xie et al., 2017; Dettmers et al., 2018), whereas the constraints themselves are not learned from data; in contrast, our approach by jointly training an autoencoder does not impose any explicit hard constraints, so it leads to more flexible modeling.

Moreover, we additionally focus on leveraging composition in KBC. Although this idea has been frequently explored before (Guu et al., 2015; Neelakantan et al., 2015; Lin et al., 2015a), our discussion about the concept of compositional constraints and its connection to dimension reduction has not been addressed similarly in previous research. In experiments, we will show (Sec.6.2,6.3) that joint training with an autoencoder indeed helps finding compositional constraints and benefits from compositional training.

Autoencoders have been used solo for learning distributed representations of syntactic trees (Socher et al., 2011), words and images (Silberer and Lapata, 2014), or semantic roles (Titov and Khoddam, 2015). It is also used for pretraining other deep neural networks (Erhan et al., 2010). However, when combined with other models, the learning of autoencoders, or more generally *sparse codings* (Rubinstein et al., 2010), is usually conveyed in an alternating manner, fixing one part of the model while optimizing the other, such as in Xie et al. (2017). To our knowledge, joint training with an autoencoder is not widely used previously for reducing dimensionality.

Jointly training an autoencoder is not simple because it takes non-stationary inputs. In this work, we modified SGD so that it shares traits with some modern optimization algorithms such as Adagrad (Duchi et al., 2011), in that they both set different learning rates for different parameters. While Adagrad sets them adaptively by keeping track of gradients for all parameters, our modification of SGD is more efficient and allows us to grasp a rough intuition about which parameter gets how much update. We believe our techniques and findings in joint training with an autoencoder could be helpful to reducing dimensionality and improving interpretability in other neural network architectures as well.

6 Experiments

We evaluate on standard KBC datasets, including WN18 and FB15k (Bordes et al., 2013), WN18RR (Dettmers et al., 2018) and FB15k-237 (Toutanova and Chen, 2015). The statistical information of these datasets are shown in Table 1.

WN18 collects word relations from WordNet (Miller, 1995), and FB15k is taken from Freebase (Bollacker et al., 2008); both have filtered out low frequency entities. However, it is reported in Toutanova and Chen (2015) that both WN18 and FB15k have information leaks because the inverses of some test triples appear in the training set. FB15k-237 and WN18RR fix this problem by deleting such triples from training and test data. In this work, we do evaluate on WN18 and FB15k, but our models are mainly tuned on FB15k-237.

Dataset	$\|\mathcal{E}\|$	$\|\mathcal{R}\|$	#Train	#Valid	#Test
WN18	40,943	18	141,442	5,000	5,000
FB15k	14,951	1,345	483,142	50,000	59,071
WN18RR	40,943	11	86,835	3,034	3,134
FB15k-237	14,541	237	272,115	17,535	20,466

Table 1: Statistical information of the KBC datasets. $|\mathcal{E}|$ and $|\mathcal{R}|$ denote the number of entities and relation types, respectively; #Train, #Valid, and #Test are the numbers of triples in the training, validation, and test sets, respectively.

For all datasets, we set the dimension $d = 256$ and $c = 16$, the SGD hyper-parameters $\eta_1 = 1/64$, $\eta_2 = 2^{-14}$ and $\lambda_1 = \lambda_2 = 2^{-14}$. The training batch size is 32 and the triples in each batch share the same head entity. We compare the base model (BASE) to our joint training with an autoencoder model (JOINT), and the base model with compositional training (BASE+COMP) to our joint model with compositional training (JOINT+COMP). When compositional training is enabled (BASE+COMP, JOINT+COMP), we use random walk to sample paths of length $1 + X$, where X is drawn from a Poisson distribution of mean $\lambda = 1.0$.

For any incomplete triple $\langle h, r, ?\rangle$ in KBC test, we calculate a score $s(h, r, e)$ from (1), for every entity $e \in \mathcal{E}$ such that $\langle h, r, e\rangle$ *does not appear in any of the training, validation, or test sets* (Bordes et al., 2013). Then, the calculated scores together with $s(h, r, t)$ for the gold triple is converted to ranks, and the rank of the gold entity t is used for evaluation. Evaluation metrics include Mean Rank (MR), Mean Reciprocal Rank (MRR), and Hits at 10 (H10). Lower MR, higher MRR, and higher H10 indicate better performance.

We consult MR and MRR on validation sets to determine training epochs; we stop training when both MR and MRR have stopped improving.

6.1 KBC Results

The results are shown in Table 2. We found that joint training with an autoencoder mostly improves performance, and the improvement becomes more clear when compositional training is enabled (i.e., JOINT $\geq$ BASE and JOINT+COMP $>$ BASE+COMP). This is convincing because generally, joint training contributes with its regularizing effects, and drastic improvements are less expected[3]. When compositional training is enabled, the system usually achieves better MR, though not always improves in other measures. The performance gains are more obvious on the WN18RR and FB15k-237 datasets, possibly because WN18 and FB15k contain a lot of easy instances that can be solved by a simple rule (Dettmers et al., 2018).

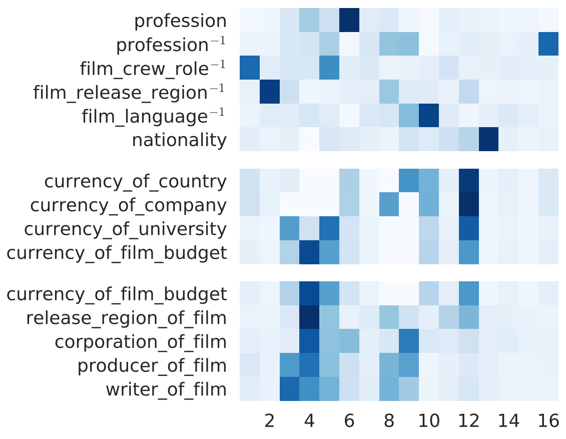

Figure 2: Examples of relation codings learned from FB15k-237. Each row shows a 16 dimension vector encoding a relation. Vectors are normalized such that their entries sum to 1.

Furthermore, the numbers demonstrated by our joint and base models are among the strongest in the literature. We have conducted re-experiments of several representative algorithms, and also compare with state-of-the-art published results. For re-experiments, we use Lin et al. (2015b)'s implementation[4] of TransE (Bordes et al., 2013) and TransR, which represent relations as vector translations; and Nickel et al. (2016b)'s implementation[5] of RESCAL (Nickel et al., 2011) and HolE, where RESCAL is most similar to the BASE model and HolE is a more parameter-efficient variant. We experimented with the default settings, and found that our models outperform most of them.

Among the published results, STransE (Nguyen et al., 2016) and ITransF (Xie et al., 2017) are more complicated versions of TransR, achieving the previous highest MR on WN18 but are outperformed by our JOINT+COMP model. ITransF is most similar to our JOINT model in that they both learn sparse codings for relations. On WN18RR and FB15k-237, Dettmers et al. (2018)'s report of ComplEx

[3]The source code and trained models are publicly released at `https://github.com/tianran/glimvec`, where we also show the mean performance and deviations of multiple random initializations, to give a more complete picture.

The first and second sectors compare our joint to the base models with and without compositional training, respectively; the third sector shows our re-experiments and the fourth shows previous published results. Bold numbers are the best in each sector, and (*) indicates the best of all.

(Trouillon et al., 2016) and ConvE were previously the best results. Our models mostly outperform them. Other results include Kadlec et al. (2017)'s simple but strong baseline and several recent models (Schlichtkrull et al., 2017; Shi and Weninger, 2017; Shen et al., 2017) which achieve best results on FB15k or WN18 in some measure. Our models have comparable results.

6.2 Intuition and Insight

What does the autoencoder look like? How does joint training affect relation matrices? We address these questions by analyses showing that **(i)** the autoencoder learns sparse and interpretable codings of relations, **(ii)** the joint training drives relation matrices toward a low dimension manifold, and **(iii)** it helps discovering compositional constraints.

Sparse Coding and Interpretability

Due to the ReLU function in (2), our autoencoder learns sparse coding, with most relations having large code values at only two or three dimensions. This sparsity makes it easy to find patterns in the model that to some extent explain the semantics of relations. Figure 2 shows some examples.

In the first group of Figure 2, we show a small number of relations that are almost always assigned a near one-hot coding, regardless of initialization. These are high frequency relations joining two large categories (e.g. film and language), which probably constitute the skeleton of a KB.

In the second group, we found the 12th dimension strongly correlates with `currency`; and in the third group, we found the 4th dimension strongly correlates with `film`. As for the relation `currency_of_film_budget`, it has large code values at both dimensions. This kind of relation clustering also seems independent of initialization. Intuitively, it shows that the autoencoder may discover similarities between relations and promote indirect parameter sharing among them. Yet, as the autoencoder only reconstructs *approximations* of relation matrices but never constrain them to be exactly equal to the original, relation matrices with very similar codings may still differ considerably. For example, `producer_of_film` and `writer_of_film` have codings of cosine similarity 0.973, but their relation matrices only have[6] a cosine similarity 0.338.

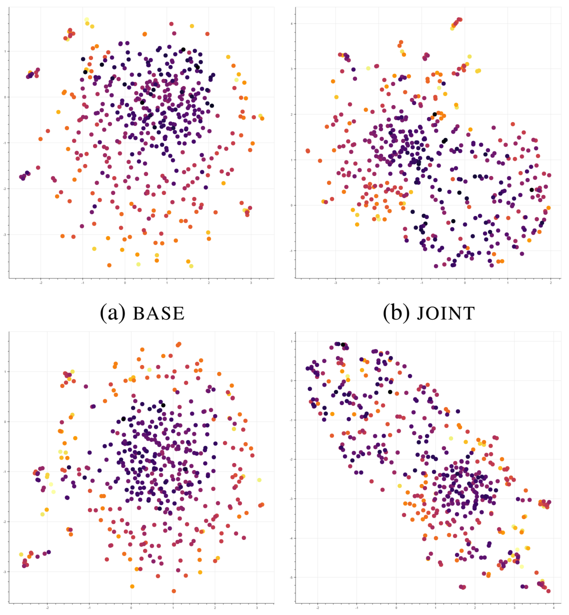
Low dimension manifold

In order to visualize the relation matrices learned by our joint and base models, we use UMAP[7] (McInnes and Healy, 2018) to embed M_r into a 2D plane[8]. We use relation matrices trained on

[6]Cosine similarity 0.338 is still high for matrices, due to the high dimensionality of their parameter space.

[7]`https://github.com/lmcinnes/umap`

[8]UMAP is a recently proposed manifold learning algorithm based on the fuzzy topological structure. We also tried



(a) BASE (b) JOINT (c) BASE+COMP (d) JOINT+COMP

Figure 3: By UMAP, relation matrices are embedded into a 2D plane. Colors show frequencies of relations; and lighter color means more frequent.

FB15k-237, and compare models trained by the same number of epochs. The results are shown in Figure 3.

We can see that Figure 3a and Figure 3c are mostly similar, with high frequency relations scattered randomly around a low frequency cluster, suggesting that they come from various directions of a high dimension space, with frequent relations probably being pulled further by the training updates. On the other hand, in Figure 3b and Figure 3d we found less frequent relations being clustered with frequent ones, and multiple traces of low dimension structures. It suggests that joint training with an autoencoder indeed drives relations toward a low dimension manifold. In addition, Figure 3d shows different structures against Figure 3b, which we conjecture could be related to compositional constraints discovered by compositional training.

Compositional constraints

In order to directly evaluate a model's ability to find compositional constraints, we extracted from FB15k-237 a list of $(r_1/r_2, r_3)$ pairs such that r_1/r_2 matches r_3. Formally, the list is constructed as below. For any relation r, we define a *content set* $C(r)$ as the set of (h, t) pairs such that $\langle h, r, t\rangle$ is a fact in the KB. Similarly, we define $C(r_1/r_2)$

t-SNE (van der Maaten and Hinton, 2008) but found UMAP more insightful.

Model	MR	MRR
JOINT+COMP	**130±27**	**.0481±.0090**
BASE+COMP	150±3	.0280±.0010
RANDOMM2	181±19	.0356±.0100

Table 3: Performance at discovering compositional constraints extracted from FB15k-237

as the set of (h, t) pairs such that $\langle h, r_1/r_2, t\rangle$ is a path. We regard $(r_1/r_2, r_3)$ as a compositional constraint if their content sets are similar; that is, if $|C(r_1/r_2) \cap C(r_3)| \geq 50$ and the Jaccard similarity between $C(r_1/r_2)$ and $C(r_3)$ is ≥ 0.4. Then, after filtering out degenerated cases such as $r_1 = r_3$ or $r_2 = r_1^{-1}$, we obtained a list of 154 compositional constraints, e.g. (`currency_of_country/country_of_film`, `currency_of_film_budget`).

For each compositional constraint $(r_1/r_2, r_3)$ in the list, we take the matrices $\boldsymbol{M}_1$, $\boldsymbol{M}_2$ and $\boldsymbol{M}_3$ corresponding to r_1, r_2 and r_3 respectively, and rank $\boldsymbol{M}_3$ according to its cosine similarity with $\boldsymbol{M}_1\boldsymbol{M}_2$, among all relation matrices. Then, we calculate MR and MRR for evaluation. We compare the JOINT+COMP model to BASE+COMP, as well as a randomized baseline where M_2 is selected randomly from the relation matrices in JOINT+COMP instead (RANDOMM2). The results are shown in Table 3. We have evaluated 5 different random initializations for each model, trained by the same number of epochs, and we report the mean and standard deviation. We verify that JOINT+COMP performs better than BASE+COMP, indicating that joint training with an autoencoder indeed helps discovering compositional constraints. Furthermore, the random baseline RANDOMM2 tests a hypothesis that joint training might be just clustering M_3 and M_1 here, to the extent that M_3 and M_1 are so close that even a random M_2 can give the correct answer; but as it turns out, JOINT+COMP largely outperforms RANDOMM2, excluding this possibility. Thus, joint training performs better not simply because it clusters relation matrices; it learns compositions indeed.

6.3 Losses and Gains

In the KBC task, where are the losses and what are the gains of different settings? With additional evaluations, we show **(i)** some crucial settings for the base model, and **(ii)** joint training with an autoencoder benefits more from compositional training.

Settings	MR	MRR	H10
BASE	**214**	**.338**	**52.5**
no normalization	309	.326	49.9
no regularizer	400	.328	51.3
pure Gaussian	221	.336	52.1
unigram distribution	215	.324	50.6

Table 4: Ablation of the four settings of the base model as described in Sec.4.1

Crucial settings for the base model

It is noteworthy that our base model already achieves strong results. This is due to several detailed but crucial settings as we discussed in Sec.4.1; Table 4 shows their gains on the FB15k-237 validation data. The most dramatic improvement comes from the regularizer that drives matrices to orthogonal.

Gains with compositional training

One can force a model to focus more on (longer) compositions of relations, by sampling longer paths in compositional training. Since joint training with an autoencoder helps discovering compositional constraints, we expect it to be more helpful when the sampled paths are longer. In this work, path lengths are sampled from a Poisson distribution, we thus vary the mean λ of the Poisson to control the strength of compositional training. The results on FB15k-237 are shown in Table 5.

We can see that, as λ gets larger, MR improves much but MRR slightly drops. It suggests that in FB15k-237, composition of relations might mainly help finding more appropriate candidates for a missing entity, rather than pinpointing a correct one. Yet, joint training improves base models even more as the paths get longer, especially in MR. It further supports our conjecture that joint training with an autoencoder may strongly interact with compositional training.

7 Conclusion

We have investigated a dimension reduction technique which trains a KB embedding model jointly with an autoencoder. We have developed new training techniques and achieved state-of-the-art results on several KBC tasks with strong improvements in Mean Rank. Furthermore, we have shown that the autoencoder learns low dimension sparse codings that can be easily explained; the joint training technique drives high-dimensional data toward low dimension manifolds; and the reduction of dimensionality may interact strongly with composition, help discovering compositional constraints and benefit from compositional training. We believe these findings provide insightful understandings of KB embedding models and might be applied to other neural networks beyond the KBC task.

Model	λ	Valid			Test		
		MR	MRR	H10	MR	MRR	H10

A Out-of-vocabulary Entities in KBC

Occasionally, a KBC test set may contain entities that never appear in the training data. Such out-of-vocabulary (OOV) entities pose a challenge to KBC systems; while some systems address this issue by explicitly learn an OOV entity vector (Dettmers et al., 2018), our approach is described below. For an incomplete triple $\langle h, r, ?\rangle$ in the test, if h is OOV, we replace it with the most frequent entity that has ever appeared as a head of relation r in the training data. If the gold tail entity is OOV, we use the zero vector for computing the score and the rank of the gold entity.

Usually, OOV entities are rare and negligible in evaluation; except for the WN18RR test data which contains about 6.7% triples with OOV entities. Here, we also report adjusted scores on WN18RR in the setting that all triples with OOV entities are removed from the test. The results are shown in Table 6.

Abstract

Most previous supervised event extraction methods have relied on features derived from manual annotations, and thus cannot be applied to new event types without extra annotation effort. We take a fresh look at event extraction and model it as a generic grounding problem: mapping each event mention to a specific type in a target event ontology. We design a transferable architecture of structural and compositional neural networks to jointly represent and map event mentions and types into a shared semantic space. Based on this new framework, we can select, for each event mention, the event type which is semantically closest in this space as its type. By leveraging manual annotations available for a small set of existing event types, our framework can be applied to new unseen event types without additional manual annotations. When tested on 23 unseen event types, this zero-shot framework, without manual annotations, achieves performance comparable to a supervised model trained from 3,000 sentences annotated with 500 event mentions.[1]

1 Introduction

The goal of event extraction is to identify event triggers and their arguments in unstructured text data, and then to assign an event type to each trigger and a semantic role to each argument. An example is shown in Figure 1. Traditional supervised methods have typically modeled this task of event extraction as a classification problem, by assigning event triggers to event types from a pre-defined fixed set. These methods rely heavily on manual annotations and features specific to each event type, and thus are not easily adapted to new event types without extra annotation effort. Handling new event types may even entail starting over, without being able to re-use annotations from previous event types.

To make event extraction effective as new real-world scenarios emerge, we take a look at this task from the perspective of zero-shot learning, ZSL (Frome et al., 2013; Norouzi et al., 2013; Socher et al., 2013a). ZSL, as a type of transfer learning, makes use of separate, pre-existing classifiers to build a semantic, cross-concept space that maps between their respective classes. The resulting shared semantic space then allows for building a novel "zero-shot" classifier, i,e,, requiring no (zero) additional training examples, to handle *unseen* cases. We observe that each event mention has a structure consisting of a candidate trigger and arguments, with corresponding predefined name labels for the event type and argument roles. We propose to enrich the semantic representations of each event mention and event type with rich structures, and determine the type based on the semantic similarity between an event mention and each event type defined in a target ontology. Let's consider two example sentences:

E1. The Government of <u>*China*</u> has ruled Tibet since 1951 after **dispatching** <u>*troops*</u> to the <u>*Himalayan*</u> region in <u>*1950*</u>.

E2. Iranian state television stated that the **conflict** between the <u>*Iranian police*</u> and the drug <u>*smugglers*</u> took place near the town of <u>*mirjaveh*</u>.

In E1, as also diagrammed in Figure 1, **dis-**

Figure 1: Event Mention Example: **dispatching** is the trigger of a *Transport-Person* event with four arguments: the solid lines show the event annotations for the sentence while the dotted lines show the Abstract Meaning Representation parsing output.

patching is the trigger for the event mention of type *Transport_Person* and in E2, **conflict** is the trigger for the event mention of type *Attack*. We make use of Abstract Meaning Representations (AMR) (Banarescu et al., 2013) to identify the candidate arguments and construct event mention structures as shown in Figure 2 (top). Figure 2 (bottom) also shows event type structures defined in the Automatic Content Extraction (ACE) guideline.[2] We can see that a trigger and its event type name usually have some shared meaning. Furthermore, their structures also tend to be similar: a *Transport_Person* event typically involves a *Person* as its *patient* role, while an *Attack* event involves a *Person* or *Location* as an *Attacker*. This observation matches the theory by Pustejovsky (1991): "the semantics of an event structure can be generalized and mapped to event mention structures in a systematic and predictable way".

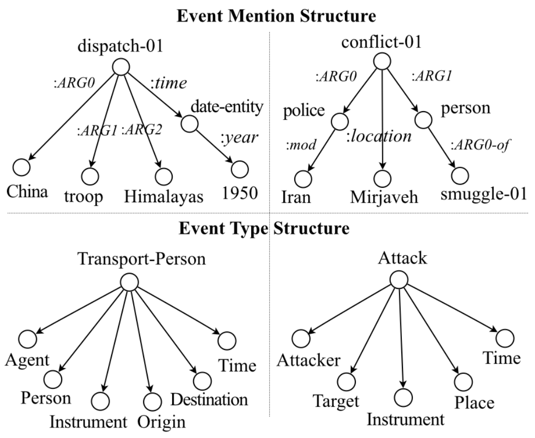

Figure 2: Examples of Event Mention Structures and Type Structures from ACE.

Inspired by this theory, for the first time, we model event extraction as a generic grounding problem, by mapping each mention to its semantically closest event type. Given an event ontology, where each event type structure is well-defined, we will refer to the event types for which we have annotated event mentions as *seen* types, while those without annotations as *unseen* types. Our goal is to learn a generic mapping function independent of event types, which can be trained from annotations for a limited number of seen event types and then used for any new unseen event types. We design a transferable neural architecture, which jointly learns and maps the structural representations of event mentions and types into a shared semantic space, by minimizing the distance between each event mention and its corresponding type. For event mentions with *unseen* types, their structures will be projected into the same semantic space using the same framework and assigned types with top-ranked similarity values.

To summarize, to apply our new zero-shot transfer learning framework to any new unseen event types, we only need (1) a structured definition of the unseen event type (its type name along with role names for its arguments, from the event ontology); and (2) some annotations for one or a few seen event types. Without requiring any additional manual annotations for the new unseen types, our ZSL framework achieves performance comparable to supervised methods trained from a substantial amount of training data for the same types.

2 Approach Overview

Briefly here, we overview the phases involved in building our framework's shared semantic space that, in turn, is the basis for the ZSL framework. Given a sentence s, we start by identifying candidate triggers and arguments based on AMR parsing (Wang et al., 2015b). For the example shown in Figure 1, we identify *dispatching* as a trigger, and its candidate arguments: *China*, *troops*, *Himalayan* and *1950*. The details will be described in Section 3.

[2]https://en.wikipedia.org/wiki/Automatic_content_extraction

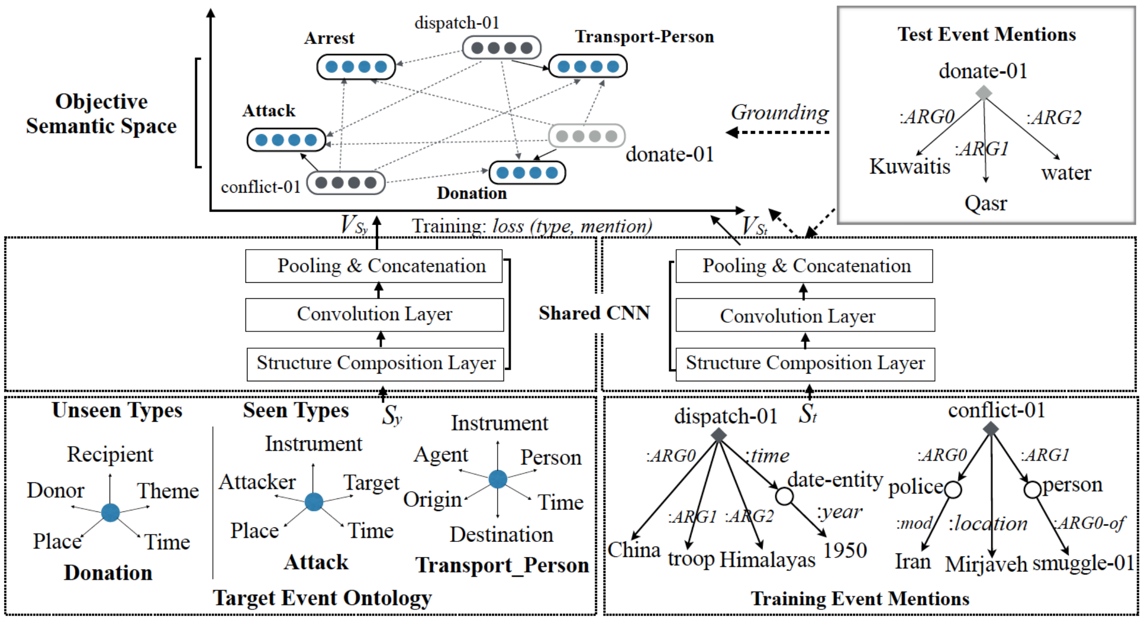

Figure 3: Architecture Overview. The blue circles denote event types and event type representations. The dark grey diamonds and circles denote triggers and trigger representations from training set. The light grey diamonds and circles denote triggers and trigger representations from testing set.

After this identification phase, we use our new neural architecture, as depicted in Figure 3, to classify triggers into event types. (The classification of arguments into roles follows the same pipeline.) For each trigger t, e.g., *dispatch-01*, we determine its type by comparing its semantic representation with that of any event type in the event ontology. In order to incorporate the contexts into the semantic representation of t, we build a structure S_t using AMR as shown in Figure 3. Each structure is composed of a set of tuples, e.g, ⟨*dispatch-01*, *:ARG0*, *China*⟩. We use a matrix to represent each AMR relation, composing its semantics with two concepts for each tuple (in Section 4), and feed all tuple representations into a CNN to generate a dense vector representation V_{S_t} for the event mention structure (in Section 5.1).

Given a target event ontology, for each type y, e.g., *Transport_Person*, we construct a type structure S_y consisting of its predefined roles, and use a tensor to denote the implicit relation between any type and argument role. We compose the semantics of type and argument role with the tensor for each tuple, e.g., ⟨*Transport_Person*, *Destination*⟩ (in Section 4). Then we generate the event type structure representation V_{S_y} using the same CNN (in Section 5.1). By minimizing the semantic distance between *dispatch-01* and *Transport_Person* using their dense vectors, V_{S_t} and V_{S_y} respectively, we jointly map the representations of event mention and event types into a shared semantic space, where each mention is closest to its annotated type.

After training that completes the construction of the semantic space, the compositional functions and CNNs are then used to project any new event mention (e.g., *donate-01*) into the semantic space and find its closest event type (e.g., *Donation*) (in Section 5.3). In the next sections we will elaborate each step in great detail.

3 Trigger and Argument Identification

Similar to Huang et al. (2016), we identify candidate triggers and arguments based on AMR Parsing (Wang et al., 2015b) and apply the same word sense disambiguation (WSD) tool (Zhong and Ng, 2010) to disambiguate word senses and link each sense to OntoNotes, as shown in Figure 1.

Given a sentence, we consider all noun and verb concepts that can be mapped to OntoNotes senses by WSD as candidate event triggers. In addition, the concepts that can be matched with verbs or nominal lexical units in FrameNet (Baker et al., 1998) are also considered as candidate triggers. For each candidate trigger, we consider any concepts that are involved in a subset of AMR relations as candidate arguments [3]. We manually select this subset of AMR relations that are useful for capturing generic relations between event triggers and arguments, as shown in Table 1.

Categories	Relations
Core roles	ARG0, ARG1, ARG2, ARG3, ARG4
Non-core roles	mod, location, instrument, poss, manner, topic, medium, prep-X
Temporal	year, duration, decade, weekday, time
Spatial	destination, path, location

Table 1: Event-Related AMR Relations.

4 Trigger and Type Structure Composition

As Figure 3 shows, for each candidate trigger t, we construct its event mention structure S_t based on its candidate arguments and AMR parsing. For each type y in the target event ontology, we construct a structure S_y by including its pre-defined roles and using its type as the root.

Each S_t or S_y is composed of a collection of tuples. For each event mention structure, a tuple consists of two AMR concepts and an AMR relation. For each event type structure, a tuple consists of a type name and an argument role name. Next we will describe how to compose semantic representations for event mention and event type respectively based on these structures.

Event Mention Structure For each tuple $u = \langle w_1, \lambda, w_2 \rangle$ in an event mention structure, we use a matrix to represent each AMR relation λ, and compose the semantics of λ between two concepts w_1 and w_2 as:

$$V_u = [V'_{w_1}; V'_{w_2}] = f([V_{w_1}; V_{w_2}] \cdot M_\lambda)$$

where V_{w_1}, $V_{w_2} \in \mathbb{R}^d$ are the vector representations of words w_1 and w_2. d is the dimension size of each word vector. $[\,;\,]$ denotes the concatenation of two vectors. $M_\lambda \in \mathbb{R}^{2d \times 2d}$ is the matrix representation for AMR relation λ. V_u is the composition representation of tuple u, which consists of two updated vector representations V'_{w_1}, V'_{w_2} for w_1 and w_2 by incorporating the semantics of λ.

Event Type Structure For each tuple $u' = \langle y, r \rangle$ in an event type structure, where y denotes the event type and r denotes an argument role, following Socher et al. (2013b), we assume an implicit relation exists between any pair of type and argument, and use a single and powerful tensor to represent the implicit relation:

$$V_{u'} = [V'_y; V'_r] = f([V_y; V_r]^T \cdot U^{[1:2d]} \cdot [V_y; V_r])$$

where V_y and V_r are vector representations for y and r. $U^{[1:2d]} \in \mathbb{R}^{2d \times 2d \times 2d}$ is a 3-order tensor. V'_u is the composition representation of tuple u', which consists of two updated vector representations V'_y, V'_r for y and r by incorporating the semantics of their implicit relation $U^{[1:2d]}$.

5 Trigger and Argument Classification

5.1 Trigger Classification for Seen Types

Both event mention and event type structures are relatively simple and can be represented with a set of tuples. CNNs have been demonstrated effective at capturing sentence level information by aggregating compositional n-gram representations. In order to generate structure-level representations, we use CNN to learn to aggregate all edge and tuple representations.

Input layer is a sequence of tuples, where the order of tuples is from top to bottom in the structure. Each tuple is represented by a $d \times 2$ dimensional vector, thus each mention structure and each type structure are represented as a feature map of dimensionality $d \times 2h^*$ and $d \times 2p^*$ respectively, where h^* and p^* are the maximal number of tuples for event mention and type structures. We use zero-padding to the right to make the volume of all input structures consistent.

Convolution layer Take S_t with h^* tuples: $u_1, u_2, ..., u_{h^*}$ as an example. The input matrix of S_t is a feature map of dimensionality $d \times 2h^*$. We make c_i as the concatenated embeddings of n continuous columns from the feature map, where n is the filter width and $0 < i < 2h^* + n$. A convolution operation involves a filter $W \in \mathbb{R}^{nd}$, which is applied to each sliding window c_i:

$$c'_i = \tanh(W \cdot c_i + b)$$

where c'_i is the new feature representation, and $b \in \mathbb{R}^d$ is a biased vector. We set filter width as 2 and stride as 2 to make the convolution function operate on each tuple with two input columns.

[3]On the whole ACE2005 corpus, using the AMR parser (Wang et al., 2015b), the coverage for trigger identification is 89.4% and the coverage for argument candidate identification is 66.0%.

Max-Pooling: All tuple representations $c_i^{'}$ are used to generate the representation of the input sequence by max-pooling.

Learning: For each event mention t, we name the correct type as *positive* and all the other types in the target event ontology as *negative*. To train the composition functions and CNN, we first consider the following hinge ranking loss:

$$L_1(t, y) = \sum_{j \in Y,\, j \neq y} \max\{0, m - C_{t,y} + C_{t,j}\}$$

$$C_{t,y} = \cos([V_t; V_{S_t}], [V_y; V_{S_y}])$$

where y is the positive event type for t. Y is the type set of the target event ontology. $[V_t; V_{S_t}]$ denotes the concatenation of representations of t and S_t. j is a negative event type for t from Y. m is a margin. $C_{t,y}$ denotes the cosine similarity between t and y.

The hinge loss is commonly used in zero-shot visual object classification task. However, it tends to overfit the seen types in our experiments. While clever data augmentation can help alleviate overfitting, we design two strategies: (1) we add "negative" event mentions into the training process. Here a "negative" event mention means that the mention has no positive event type among all seen types, namely it belongs to *Other*. (2) we design a new loss function as follows:

$$L_1^d(t, y) = \begin{cases} \max\limits_{j \in Y, j \neq y} \max\{0, m - C_{t,y} + C_{t,j}\}, & y \neq Other \\ \max\limits_{j \in Y^{'}, j \neq y^{'}} \max\{0, m - C_{t,y^{'}} + C_{t,j}\}, & y = Other \end{cases}$$

where Y is the type set of the event ontology. $Y^{'}$ is the seen type set. y is the annotated type. $y^{'}$ is the type which ranks the highest among all event types for event mention t, while t belongs to *Other*.

By minimizing L_1^d, we can learn the optimized model which can compose structure representations and map both event mention and types into a shared semantic space, where the positive type ranks the highest for each mention.

5.2 Argument Classification for Seen Types

For each mention, we map each candidate argument to a specific role based on the semantic similarity of the argument path. Take E1 as an example. *China* is matched to *Agent* based on the semantic similarity between *dispatch-01→ :ARG0→ China* and *Transport-Person→Agent*.

Given a trigger t and a candidate argument a, we first extract a path $S_a = (u_1, u_2, ..., u_p)$, which connects t and a and consists of p tuples. Each predefined role r is also represented as a structure by incorporating the event type, $S_r = \langle y, r \rangle$. We apply the same framework to take the sequence of tuples contained in S_a and S_r into a weight-sharing CNN to rank all possible roles for a.

$$L_2^d(a, r) = \begin{cases} \max\limits_{j \in R_y, j \neq r} \max\{0, m - C_{a,r} + C_{a,j}\} & r \neq Other \\ \max\limits_{j \in R_{Y^{'}}, j \neq r^{'}} \max\{0, m - C_{a,r^{'}} + C_{a,j}\} & r | y = Other \end{cases}$$

where R_y and $R_{Y^{'}}$ are the set of argument roles which are predefined for trigger type y and all seen types $Y^{'}$. r is the annotated role and $r^{'}$ is the argument role which ranks the highest for a when a or y is annotated as *Other*.

In our experiments, we sample various size of "negative" training data for trigger and argument labeling respectively. In the following section, we describe how the negative training instances are generated.

5.3 Zero-Shot Classification for Unseen Types

During test, given a new event mention $t^{'}$, we compute its mention structure representation for $S_{t^{'}}$ and all event type structure representations for $S_Y = \{S_{y_1}, S_{y_2}, ..., S_{y_n}\}$ using the same parameters trained from seen types. Then we rank all event types based on their similarity scores with mention $t^{'}$. The top ranked prediction for $t^{'}$ from the event type set, denoted as $\widehat{y}(t^{'}, 1)$, is given by:

$$\widehat{y}(t^{'}, 1) = \arg\max_{y \in Y} \cos([V_{t^{'}}; V_{S_{t^{'}}}], [V_y; V_{S_y}])$$

Moreover, $\widehat{y}(t^{'}, k)$ denotes the k^{th} most probable event type predicted for $t^{'}$. We will investigate the event extraction performance based on the top-k predicted event types.

After determining the type $y^{'}$ for mention $t^{'}$, for each candidate argument, we adopt the same ranking function to find the most appropriate role from the role set defined for $y^{'}$.

6 Experiments

6.1 Hyper-Parameters

We used the English Wikipedia dump to learn trigger sense and argument embeddings based on the Continuous Skip-gram model (Mikolov et al., 2013). Table 2 shows the hyper-parameters we used to train models.

Parameter Name	Value
Word Sense Embedding Size	200
Initial Learning Rate	0.1
# of Filters in Convolution Layer	500
Maximal # of Tuples for Mention Structure	10
Maximal # of Tuples for Argument Path	5
Maximal # of Tuples for Event Type Structure	5
Maximal # of Tuples for Argument Role Path	1

Table 2: Hyper-parameters.

6.2 ACE Event Classification

Setting	N	Seen Types for Training/Dev
A	1	Attack
B	3	Attack, Transport, Die
C	5	Attack, Transport, Die, Meet, Arrest-Jail
D	10	Attack, Transport, Die, Meet, Sentence, Arrest-Jail, Transfer-Money, Elect, Transfer-Ownership, End-Position

Table 3: Seen Types in Each Experiment Setting.

We first used the ACE event schema [4] as our target event ontology and assumed the boundaries of triggers and arguments as given. Of the 33 ACE event types, we selected the top-N most popular event types from ACE05 data as "seen" types, and used 90% event annotations of these for training and 10% for development. We set N as 1, 3, 5, 10 respectively. We tested the zero-shot classification performance on the annotations for the remaining 23 unseen types. Table 3 shows the types that we selected for training in each experiment setting.

The negative event mentions and arguments that belong to *Other* were sampled from the output of the system developed by Huang et al. (2016) based on ACE05 training sentences, which groups all candidate triggers and arguments into clusters based on semantic representations and assigns a type/role name to each cluster. We sampled the negative event mentions from the clusters (e.g., *Build*, *Threaten*) which do not map to ACE event types. We sampled the negative arguments from the arguments of negative event mentions. Table 4 shows the statistics of the training, development and testing data sets.

To show the effectiveness of structural similarity in our approach, we designed a baseline, WSD-Embedding, which directly maps event mentions and arguments to their candidate types and roles using our pre-trained word sense embeddings. Table 5 makes the contrast clear: structural similarity (our approach) is much more effective than lexical similarity (baseline) for both trigger and argument classification. Also, as the number of seen types in training increases, the performance of the transfer model improves.

We further evaluated the performance of our transfer approach on similar and distinct unseen types. The 33 subtypes defined in ACE fall within 8 coarse-grained main types, such as *Life* and *Justice*. Each subtype belongs to one main type. Subtypes that belong to the same main type tend to have similar structures. For example, *Trial-Hearing* and *Charge-Indict* have the same set of argument roles. For training our transfer model, we selected 4 subtypes of *Justice*: **Arrest-Jail**, **Convict**, **Charge-Indict**, **Execute**. For testing, we selected 3 other subtypes of *Justice*: *Sentence, Appeal, Release-Parole*. Additionally, we selected one subtype from each of the other seven main types for comparison. Table 6 shows that, when testing on a new unseen type, the more similar it is to the seen types, the better performance is achieved.

6.3 ACE Event Identification & Classification

The ACE2005 corpus includes the richest event annotations currently available for 33 types. However, in real-world scenarios, there may be thousands of event types of interest. To enrich the target event ontology and assess our transferable neural architecture on a large number of unseen types, when trained on limited annotations of seen types, we manually constructed a new event ontology which combined 33 ACE event types and argument roles, and 1,161 frames from FrameNet, except for the most generic frames such as *Entity* and *Locale*. Some ACE event types were easily aligned to frames, e.g., *Die* aligned to *Death*. Some frames were instead more accurately treated as inheritors of ACE types, such as *Suicide-Attack*, which inherits from *Attack*. We manually mapped the selected frames to ACE types.

We then compared our approach with the following state-of-the-art *supervised* methods:

- LSTM: A long short-term memory neural network (Hochreiter and Schmidhuber, 1997) based on distributed semantic features, similar

Table 6: Performance on Various Types Using Justice Subtypes for Training

to (Feng et al., 2016).

- Joint: A structured perceptron model based on symbolic semantic features (Li et al., 2013).

For our approach, we followed the experiment setting *D* in the previous section, using the same training and development data sets for the 10 seen types, but targeted all 1,194 event types in our new event ontology, instead of just the 33 ACE event types. For evaluation, we sampled 150 sentences from the remaining ACE05 data, including 129 annotated event mentions for the 23 unseen types. For both LSTM and Joint approaches, we used the entire ACE05 annotated data for 33 ACE event types for training except for the held-out 150 evaluation sentences.

We first identified the candidate triggers and arguments, then mapped each of these to the target event ontology. We evaluated our model on their extracting of event mentions which were classified into 23 testing ACE types. Table 7 shows the performance.

To further demonstrate the effectiveness of zero-shot learning in our framework and its impact in saving human annotation effort, we used the supervised LSTM approach for comparison. The training data of LSTM contained 3,464 sentences with 905 annotated event mentions for the 23 unseen event types. We divided these event annotations into 10 subsets and successively added one subset at a time (10% of annotations) into the training data of LSTM. Figure 4 shows the LSTM learning curve. By contrast, without any annotated mentions on the 23 unseen test event types in its training set, our transfer learning approach achieved performance comparable to that of the LSTM, which was trained on 3,000 sentences[5] with 500 annotated event mentions.

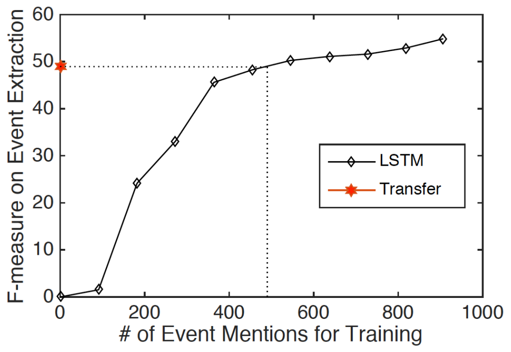

Figure 4: Comparison between Our Approach and Supervised LSTM model on 23 Unseen Event Types.

[5]The 3,000 sentences included all the sentences which even have not any event annotations.

Method	Trigger Identification			Trigger Identification + Classification			Arg Identification			Arg Identification + Classification		
	P	R	F	P	R	F	P	R	F	P	R	F
Supervised LSTM	94.7	41.8	58.0	89.4	39.5	54.8	47.8	22.6	30.6	28.9	13.7	18.6
Supervised Joint	55.8	67.4	61.1	50.6	61.2	55.4	36.4	28.1	31.7	33.3	25.7	29.0

Table 7: Event Trigger and Argument Extraction Performance (%) on Unseen ACE Types.

6.4 Impact of AMR

Recall that we used AMR parsing output to identify triggers and arguments in constructing event structures. To assess the impact of the AMR parser (Wang et al., 2015a) on event extraction, we chose a subset of the ERE (Entity, Relation, Event) corpus (Song et al., 2015) which has ground-truth AMR annotations. This subset contains 304 documents with 1,022 annotated event mentions of 40 types. We selected the top-6 most popular event types (*Arrest-Jail, Execute, Die, Meet, Sentence, Charge-Indict*) with manual annotations of 548 event mentions as seen types. We sampled 500 negative event mentions from distinct types of clusters generated from the system (Huang et al., 2016) based on ERE training sentences. We combined the annotated events for seen types and the negative event mentions, and used 90% for training and 10% for development. For evaluation, we selected 200 sentences from the remaining ERE subset, which contains 128 *Attack* event mentions and 40 *Convict* event mentions. Table 8 shows the event extraction performances based on ground-truth AMR and system AMR respectively.

We also compared AMR analyses with Semantic Role Labeling (SRL) output (Palmer et al., 2010) by keeping only the core roles (e.g., *:ARG0, :ARG1*) from AMR annotations. As Table 8 shows, comparing the full AMR (top row) to this SRL proxy (middle row), the fine-grained AMR semantic relations such as *:location*, *:instrument* appear to be more informative for inferring event argument role labeling.

Method	Trigger Labeling			Argument Labeling		
	P	R	F_1	P	R	F_1
Perfect AMR	79.1	47.1	59.1	25.4	21.4	23.2
Perfect AMR with Core Roles only (SRL)	77.1	47.0	58.4	19.7	16.9	18.2
System AMR	85.7	32.0	46.7	22.6	15.8	18.6

Table 8: Impact of AMR and Semantic Roles on Trigger and Argument Extraction (%).

7 Related Work

Most previous event extraction methods have been based on supervised learning, using either symbolic features (Ji and Grishman, 2008; Miwa et al., 2009; Liao and Grishman, 2010; Liu et al., 2010; Hong et al., 2011; McClosky et al., 2011; Riedel and McCallum, 2011; Li et al., 2013; Liu et al., 2016) or distributional features (Chen et al., 2015; Nguyen and Grishman, 2015; Feng et al., 2016; Nguyen et al., 2016) derived from a large amount of training data, and treating event types and argument role labels as symbols. These approaches can achieve high quality for known event types, but cannot be applied to new types without additional annotation effort. In contrast, we provide a new angle on event extraction, modeling it as a generic grounding task by taking advantage of rich semantics of event types.

Some other IE paradigms such as Open IE (Etzioni et al., 2005; Banko et al., 2007, 2008; Etzioni et al., 2011; Ritter et al., 2012), Preemptive IE (Shinyama and Sekine, 2006), On-demand IE (Sekine, 2006), Liberal IE (Huang et al., 2016, 2017), and semantic frame-based event discovery (Kim et al., 2013) can discover many events without pre-defined event schema. These paradigms however rely on information redundancy, and so they are not effective when the input data only consists of a few sentences. Our work can discover events from any size of input corpus and can also be complementary with these paradigms.

Our event extraction paradigm is similar to the task of entity linking (Ji and Grishman, 2011) in semantic mapping. However, entity linking aims to map entity mentions to the same concept, while our framework maps each event mention to a specific category. In addition, Bronstein et al. (2015) and Peng et al. (2016) employ an event-independent similarity-based function for event trigger detection, which follows few-shot learning setting and requires some trigger examples as seeds. Lu and Roth (2012) design a structure preference modeling framework, which can automatically predict argument roles without any annotated data, but it relies on manually constructed patterns.

Zero-Shot learning has been widely applied in visual object classification (Frome et al., 2013; Norouzi et al., 2013; Socher et al., 2013a; Chen et al., 2017; Li et al., 2017; Xian et al., 2017; Changpinyo et al., 2017), fine-grained name tagging (Ma et al., 2016; Qu et al., 2016), relation extraction (Verga et al., 2016; Levy et al., 2017), semantic parsing (Bapna et al., 2017) and domain adaptation (Romera-Paredes and Torr, 2015; Kodirov et al., 2015; Peng et al., 2017). In contrast to these tasks, for our case, the number of seen types in event extraction with manual annotations is quite limited. The most popular event schemas, such as ACE, define 33 event types while most visual object training sets contain more than 1,000 types. Therefore, methods proposed for zero-shot visual-object classification cannot be directly applied to event extraction due to overfitting. In this work, we designed a new loss function by creating "negative" training instances to avoid overfitting.

8 Conclusions and Future Work

In this work, we take a fresh look at the event extraction task and model it as a generic grounding problem. We propose a transferable neural architecture, which leverages existing human-constructed event schemas and manual annotations for a small set of seen types, and transfers the knowledge from the existing types to the extraction of unseen types, to improve the scalability of event extraction as well as to save human effort. To the best of our knowledge, this work is the first time that zero-shot learning has been applied to event extraction. Without any annotation, our approach can achieve performance comparable to state-of-the-art supervised models trained on a large amount of labeled data. In the future, we will extend this framework to other Information Extraction problems.

Recursive Neural Structural Correspondence Network for Cross-domain Aspect and Opinion Co-Extraction

Wenya Wang[†‡] **and Sinno Jialin Pan**[†]

{wa0001ya, sinnopan}@ntu.edu.sg

Abstract

Fine-grained opinion analysis aims to extract aspect and opinion terms from each sentence for opinion summarization. Supervised learning methods have proven to be effective for this task. However, in many domains, the lack of labeled data hinders the learning of a precise extraction model. In this case, unsupervised domain adaptation methods are desired to transfer knowledge from the source domain to any unlabeled target domain. In this paper, we develop a novel recursive neural network that could reduce domain shift effectively in word level through syntactic relations. We treat these relations as invariant "pivot information" across domains to build structural correspondences and generate an auxiliary task to predict the relation between any two adjacent words in the dependency tree. In the end, we demonstrate state-of-the-art results on three benchmark datasets.

1 Introduction

The problem of fine-grained opinion analysis involves extraction of opinion targets (or aspect terms) and opinion expressions (or opinion terms) from each review sentence. For example, in the sentence: "*They offer good appetizers*", the aspect and opinion terms are *appetizers* and *good* correspondingly. Many supervised deep models have been proposed for this problem (Liu et al., 2015; Yin et al., 2016; Wang et al., 2017), and obtained promising results. However, these methods fail to adapt well across domains, because the aspect terms from two different domains are usually disjoint, e.g., *laptop* v.s. *restaurant*, leading to large domain shift in the feature vector space. Though unsupervised methods (Hu and Liu, 2004; Qiu et al., 2011) can deal with data with few labels, their performance is unsatisfactory compared with supervised ones.

There have been a number of domain adaptation methods for coarse-grained sentiment classification problems across domains, where an overall sentiment polarity of a sentence or document is being predicted. Nevertheless, very few approaches exist for cross-domain fine-grained opinion analysis due to the difficulties in fine-grained adaptation, which is more challenging than coarse-grained problems. Li et al. (2012) proposed a bootstrap method based on the TrAdaBoost algorithm (Dai et al., 2007) to iteratively expand opinion and aspect lexicons in the target domain by exploiting source-domain labeled data and cross-domain common relations between aspect terms and opinion terms. However, their model requires a seed opinion lexicon in the target domain and pre-mined syntactic patterns as a bridge. Ding et al. (2017) proposed to use rules to generate auxiliary supervision on top of a recurrent neural network to learn domain-invariant hidden representation for each word. The performance highly depends on the quality of the manually defined rules and the prior knowledge of a sentiment lexicon. In addition, the recurrent structure fails to capture the syntactic interactions among words intrinsically for opinion extraction. The requirement for rules makes the above methods non-flexible.

In this paper, we propose a novel cross-domain Recursive Neural Network (RNN)[1] for aspect and opinion terms co-extraction across domains. Our motivations are twofold: 1) The dependency relations capture the interactions among different words. These relations are especially important for identifying aspect terms and opinion terms (Qiu et al., 2011; Wang et al., 2016), which are also domain-invariant within the same language. Therefore, they can be used as "pivot" information to

[1]Here, we use RNN to denote recursive neural networks, rather than recurrent neural networks.

bridge the gap between different domains. 2) Inspired by the idea of *structural learning* (Ando and Zhang, 2005), the success of target task depends on the ability of finding good predictive structures learned from other related tasks, e.g., structural correspondence learning (SCL) (Blitzer et al., 2006) for coarse-grained cross-domain sentiment classification. Here, we aim to generate an auxiliary task on dependency relation classification. Different from previous approaches, our auxiliary task and the target extraction task are of heterogeneous label spaces. We aim to integrate this auxiliary task with distributed relation representation learning into a recursive neural network.

Specifically, we generate a dependency tree for each sentence from the dependency parser and construct a unified RNN that integrates an auxiliary task into the computation of each node. The auxiliary task is to classify the dependency relation for each direct edge in the dependency tree by learning a relation feature vector. To reduce label noise brought by inaccurate parsing trees, we further propose to incorporate an autoencoder into the auxiliary task to group the relations into different clusters. Finally, to model the sequential context interaction, we develop a joint architecture that combines RNN with a sequential labeling model for aspect and opinion terms extraction. Extensive experiments are conducted to demonstrate the advantage of our proposed model.

2 Related Work

Existing works for single-domain aspect/opinion terms extraction include unsupervised methods based on association rule mining (Hu and Liu, 2004), syntactic rule propagation (Qiu et al., 2011) or topic modeling (Titov and McDonald, 2008; Lu et al., 2009; Zhang et al., 2010), as well as supervised methods based on extensive feature engineering with graphical models (Jin and Ho, 2009; Li et al., 2010) or deep learning (Liu et al., 2015; Zhang et al., 2015; Wang et al., 2017; Yin et al., 2016). Among exiting deep models, improved results are obtained using dependency relations (Yin et al., 2016; Wang et al., 2016), which indicates the significance of syntactic word interactions for target term extraction. In cross-domain setting, there are very few works for aspect/opinion terms extraction including a pipelined approach (Li et al., 2012) and a recurrent neural network (Ding et al., 2017). Both of the methods require manual construction of common and pivot syntactic patterns or rules, which are indicative of aspect or opinion words.

There have been a number of domain adaptation approaches proposed for coarse-grained sentiment classification. Among existing methods, one active line focuses on projecting original feature spaces of two domains into the same low-dimensional space to reduce domain shift using pivot features as a bridge (Blitzer et al., 2007; Pan et al., 2010; Bollegala et al., 2015; Yu and Jiang, 2016). Another line learns domain-invariant features via autoencoders (Glorot et al., 2011; Chen et al., 2012; Zhou et al., 2016). Our work is more related to the first line by utilizing pivot information to transfer knowledge across domains, but we integrate the idea into a unified deep structure that can fully utilize syntactic structure for domain adaptation in fine-grained sentiment analysis.

3 Problem Definition & Motivation

Our task is to extract opinion and aspect terms within each review sentence. We denote a sentence by a sequence of tokens $\mathbf{x} = (w_1, w_2, ..., w_n)$. The output is a sequence of token-level labels $\mathbf{y} = (y_1, y_2, ..., y_n)$, with $y_i \in \{\text{BA}, \text{IA}, \text{BO}, \text{IO}, \text{N}\}$ that represents beginning of an aspect (BA), inside of an aspect (IA), beginning of an opinion (BO), inside of an opinion (IO) or none of the above (N). A subsequence of labels started with "BA" and followed by "IA" indicates a multi-word aspect term. In unsupervised domain adaptation, we are given a set of labeled review sentences from a source domain $\mathcal{D}_S = \{(\mathbf{x}_{S_i}, \mathbf{y}_{S_i})\}_{i=1}^{n_S}$, and a set of unlabeled sentences from a target domain $\mathcal{D}_T = \{\mathbf{x}_{T_j}\}_{j=1}^{n_T}$. Our goal is to predict token-level labels on $\mathcal{D}_T$.

Existing works for cross-domain aspect and/or opinion terms extraction require hand-coded rules and a sentiment lexicon in order to transfer knowledge across domains. For example in Figure 1, given a review sentence "*They offer good appetizers*" in the source domain and "*The laptop has a nice screen*" in the target domain. If *nice* has been extracted as a common sentiment word, and "OPINION-amod-ASPECT" has been identified as a common syntactic pattern from the source domain, *screen* could be deduced as an aspect term using the identified syntactic pattern (Li et al., 2012). Similarly, Ding et al. (2017) used a set of predefined rules based on syntactic relations and a sentiment lexicon to generate auxiliary labels to learn high-level feature representations through a

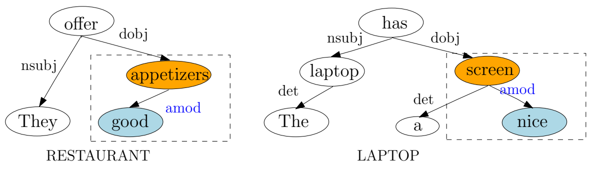

Figure 1: An example of two reviews with similar syntactic patterns.

recurrent neural network.

On one hand, these previous attempts have verified that syntactic information between words, which can be used as a bridge between domains, is crucial for domain adaptation. On the other hand, dependency-tree-based RNN (Socher et al., 2010) has proven to be effective to learn high-level feature representation of each word by encoding syntactic relations between aspect terms and opinion terms (Wang et al., 2016). With the above findings, we propose a novel RNN named **R**ecursive **N**eural **S**tructural **C**orrespondence **N**etwork (RNSCN) to learn high-level representation for each word across different domains. Our model is built upon dependency trees generated from a dependency parser. Different from previous approaches, we do not require any hand-coded rules or pre-selected pivot features to construct correspondences, but rather focus on the automatically generated dependency relations as the pivots. The model associates each direct edge in the tree with a relation feature vector, which is used to predict the corresponding dependency relation as an auxiliary task.

Note that the relation vector is the key in the model: it associates with the two interacting words and is used to construct structural correspondences between two different domains. Hence, the auxiliary task guides the learning of relation vectors, which in turn affects their correspondingly interactive words. Specifically in Figure 1, the relation vector for "amod" is computed from the features of its child and parent words, and also used to produce the hidden representation of its parent. For this relation path in both sentences, the auxiliary task enforces close proximity for these two relation vectors. This pushes the hidden representations for their parent nodes *appetizers* and *screen* closer to each other, provided that *good* and *nice* have similar representations. In a word, the auxiliary task bridges the gap between two different domains by drawing the words with similar syntactic properties closer to each other.

However, the relation vectors may be sensitive to the accuracy of the dependency parser. It might harm the learning process when some noise exists for certain relations, especially for informal texts. This problem of noisy labels has been addressed using perceptual consistency (Reed et al., 2015). Inspired by the taxonomy of dependency relations (de Marneffe and Manning, 2008), relations with similar functionalities could be grouped together, e.g., *dobj*, *iobj* and *pobj* all indicate objects. We propose to use an auto-encoder to automatically group these relations in an unsupervised manner. The reconstruction loss serves as the consistency objective that reduces label noise by aligning relation features with their intrinsic relation group.

4 Proposed Methodology

Our model consists of two components. The first component is a Recursive Neural Structural Correspondence Network (RNSCN), and the second component is a sequence labeling classifier. In this paper, we focus on Gated Recurrent Unit (GRU) as an implementation for the sequence labeling classifier. We choose GRU because it is able to deal with long-term dependencies compared to a simple Recurrent neural network and requires less parameters making it easier to train than LSTM. The resultant deep learning model is denoted by RNSCN-GRU. We also implement Conditional Random Field as the sequence labeling classifier, and denote the model by RNSCN-CRF accordingly.

The overall architecture of RNSCN-GRU without auto-encoder on relation denoising is shown in Figure 2. The left and right are two example sentences from the source and the target domain, respectively. In the first component, RNSCN, an auxiliary task to predict the dependency relation for each direct edge is integrated into a dependency-tree-based RNN. We generate a relation vector for each direct edge from its child node to parent node, and use it to predict the relation and produce the hidden representation for the parent node in the dependency tree. To address the issues of noisy relation labels, we further incorporate an auto-encoder into RNSCN, as will be shown in Figure 3.

While RNSCN mainly focuses on syntactic interactions among the words, the second component, GRU, aims to compute linear-context interactions. GRU takes the hidden representation of each word computed from RNSCN as inputs and further produces final representation of each word by taking linear contexts into consideration. We describe each component in detail in the following sections.

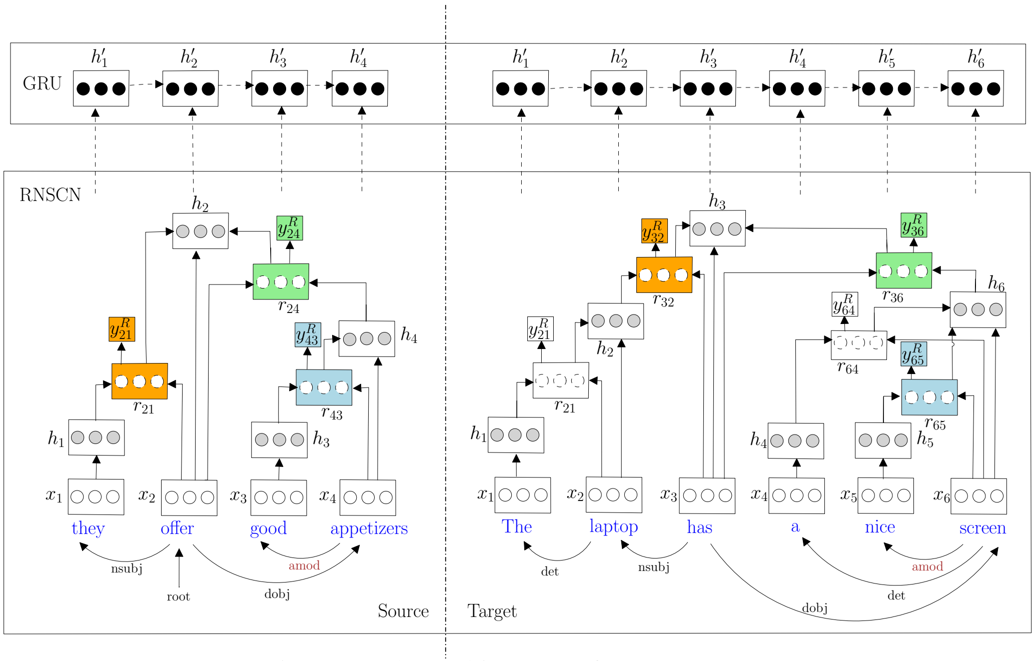

Figure 2: The architecture of RNSCN-GRU.

4.1 Recursive Neural Structural Correspondence Network

RNSCN is built on the dependency tree of each sentence, which is pre-generated from a dependency parser. Specifically, each node in the tree is associated with a word w_n, an input word embedding $\mathbf{x}_n \in \mathbb{R}^d$ and a transformed hidden representation $\mathbf{h}_n \in \mathbb{R}^d$. Each direct edge in the dependency tree associates with a relation feature vector $\mathbf{r}_{nm} \in \mathbb{R}^d$ and a true relation label vector $\mathbf{y}^R_{nm} \in \mathbb{R}^K$, where K is the total number of dependency relations, n and m denote the indices of the parent and child word of the dependency edge, respectively. Based on the dependency tree, the hidden representations are generated in a recursive manner from leaf nodes until reaching the root node. Consider the source-domain sentence shown in Figure 2 as an illustrative example, we first compute hidden representations for leaf nodes *they* and *good*:

$$\mathbf{h}_1 = \tanh(\mathbf{W}_x\mathbf{x}_1 + \mathbf{b}), \quad \mathbf{h}_3 = \tanh(\mathbf{W}_x\mathbf{x}_3 + \mathbf{b}),$$

where $\mathbf{W}_x \in \mathbb{R}^{d\times d}$ transforms word embeddings to hidden space. For non-leaf node *appetizer*, we first generate the relation vector $\mathbf{r}_{43}$ for the dependency edge $\mathbf{x}_4$ (appetizers) $\xrightarrow{\text{amod}}$ $\mathbf{x}_3$ (good) by

$$\mathbf{r}_{43} = \tanh(\mathbf{W}_h\mathbf{h}_3 + \mathbf{W}_x\mathbf{x}_4),$$

where $\mathbf{W}_h \in \mathbb{R}^{d\times d}$ transforms the hidden representation to the relation vector space. We then compute the hidden representation for *appetizer*:

$$\mathbf{h}_4 = \tanh(\mathbf{W}_{\text{amod}}\mathbf{r}_{43} + \mathbf{W}_x\mathbf{x}_4 + \mathbf{b}).$$

Moreover, the relation vector $\mathbf{r}_{43}$ is used for the auxiliary task on relation prediction:

$$\hat{\mathbf{y}}^R_{43} = \text{softmax}(\mathbf{W}_R\mathbf{r}_{43} + \mathbf{b}_R),$$

where $\mathbf{W}_R \in \mathbb{R}^{K\times d}$ is the relation classification matrix. The supervised relation classifier enforces close proximity of similar $\{\mathbf{r}_{nm}\}$'s in the distributed relation vector space. The relation features bridge the gap of word representations in different domains by incorporating them into the forward computations. In general, the hidden representation $\mathbf{h}_n$ for a non-leaf node is produced through

$$\mathbf{h}_n = \tanh\Big(\sum_{m\in\mathcal{M}_n} \mathbf{W}_{R_{nm}}\mathbf{r}_{nm} + \mathbf{W}_x\mathbf{x}_n + \mathbf{b}\Big), \quad (1)$$

where $\mathbf{r}_{nm} = \tanh(\mathbf{W}_h \cdot \mathbf{h}_m + \mathbf{W}_x \cdot \mathbf{x}_n)$, $\mathcal{M}_n$ is the set of child nodes of w_n, and $\mathbf{W}_{R_{nm}}$ is the relation transformation matrix tied with each relation R_{nm}. The predicted label vector $\hat{\mathbf{y}}^R_{nm}$ for $\mathbf{r}_{nm}$ is

$$\hat{\mathbf{y}}^R_{nm} = \text{softmax}(\mathbf{W}_R \cdot \mathbf{r}_{nm} + \mathbf{b}_R). \quad (2)$$

Here we adopt the the cross-entropy loss for relation classification between the predicted label vector $\hat{\mathbf{y}}^R_{nm}$ and the ground-truth $\mathbf{y}^R_{nm}$ to encode relation side information into feature learning:

$$\ell_R = \sum_{k=1}^{K} -\mathbf{y}^R_{nm[k]} \log \hat{\mathbf{y}}^R_{nm[k]}. \quad (3)$$

Through the auxiliary task, similar relations enforce participating words close to each other so that words with similar syntactic functionalities are clustered across domains. On the other hand, the pre-trained word embeddings group semantically-similar words. By taking them as input to RNN, together with the auxiliary task, our model encodes both semantic and syntactic information.

4.2 Reduce Label Noise with Auto-encoders

As discussed in Section 3, it might be hard to learn an accurate relation classifier when each class is a unique relation, because the dependency parser may generate incorrect relations as noisy labels. To address it, we propose to integrate an autoencoder into RNSCN. Suppose there is a set of latent groups of relations: $G = \{1, 2, ..., |G|\}$, where each relation belongs to only one group. For each relation vector, $\mathbf{r}_{nm}$, an autoencoder is performed before feeding it into the auxiliary classifier (2). The goal is to encode the relation vector to a probability distribution of assigning this relation to any group. As can be seen Figure 3, each relation vector $\mathbf{r}_{nm}$ is first passed through the autoencoder as follows,

$$p(G_{nm} = i|\mathbf{r}_{nm}) = \frac{\exp(\mathbf{r}_{nm}^\top \mathbf{W}_{enc}\mathbf{g}_i)}{\sum_{j\in G} \exp(\mathbf{r}_{nm}^\top \mathbf{W}_{enc}\mathbf{g}_j)}, \quad (4)$$

where G_{nm} denotes the inherent relation group for $\mathbf{r}_{nm}$, $\mathbf{g}_i \in \mathbb{R}^d$ represents the feature embedding for group i, and $\mathbf{W}_{enc} \in \mathbb{R}^{d\times d}$ is the encoding matrix that computes bilinear interactions between relation vector $\mathbf{r}_{nm}$ and relation group embedding $\mathbf{g}_i$. Thus, $p(G_{nm} = i|\mathbf{r}_{nm})$ represents the probability of $\mathbf{r}_{nm}$ being mapped to group i. An accumulated relation group embedding is computed as:

$$\mathbf{g}_{nm} = \sum_{i=1}^{|G|} p(G_{nm} = i|\mathbf{r}_{nm})\mathbf{g}_i. \quad (5)$$

For decoding, the decoder takes $\mathbf{g}_{nm}$ as input and tries to reconstruct the relation feature input $\mathbf{r}_{nm}$. Moreover, $\mathbf{g}_{nm}$ is also used as the higher-level feature vector for $\mathbf{r}_{nm}$ for predicting the relation label. Therefore, the objective for the auxiliary task in (3) becomes:

$$\ell_R = \ell_{R_1} + \alpha\ell_{R_2} + \beta\ell_{R_3}, \quad (6)$$

where

$$\ell_{R_1} = \|\mathbf{r}_{nm} - \mathbf{W}_{dec}\mathbf{g}_{nm}\|_2^2, \quad (7)$$

$$\ell_{R_2} = \sum_{k=1}^{K} -\mathbf{y}^R_{nm[k]} \log \hat{\mathbf{y}}^R_{nm[k]}, \quad (8)$$

$$\ell_{R_3} = \left\|\mathbf{I} - \bar{\mathbf{G}}^\top\bar{\mathbf{G}}\right\|_F^2. \quad (9)$$

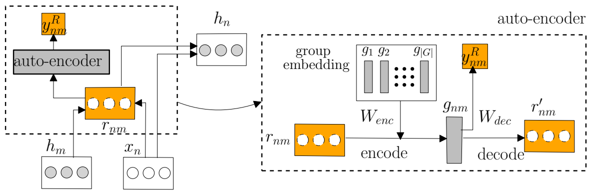

Figure 3: An autoencoder for relation grouping.

Here ℓ_{R_1} is the reconstruction loss with $\mathbf{W}_{dec}$ being the decoding matrix, ℓ_{R_2} follows (3) with $\hat{\mathbf{y}}^R_{nm} = \text{softmax}(\mathbf{W}_R\mathbf{g}_{nm} + \mathbf{b}_R)$ and ℓ_{R_3} is the regularization term on the correlations among latent groups with $\mathbf{I}$ being the identity matrix and $\bar{\mathbf{G}}$ being a normalized group embedding matrix that consists of normalized $\mathbf{g}_i$'s as column vectors. This regularization term enforces orthogonality between $\mathbf{g}_i$ and $\mathbf{g}_j$ for $i \neq j$. α and β are used to control the trade-off among different losses. With the auto-encoder, the auxiliary task of relation classification is conditioned on group assignment. The reconstruction loss further ensures the consistency between relation features and groupings, which is supposed to dominate classification loss when the observed labels are inaccurate. We denote RNSCN with auto-encoder by RNSCN$^+$.

4.3 Joint Models for Sequence Labeling

RNSCN or RNSCN$^+$ focuses on capturing and representing syntactic relations to build a bridge between domains and learn more powerful representations for tokens. However, it ignores the linear-chain correlations among tokens within a sentence, which is important for aspect and opinion terms extraction. Therefore, we propose a joint model, denoted by RNSCN-GRU (RNSCN$^+$-GRU), which integrates a GRU-based recurrent neural network on top of RNSCN (RNSCN$^+$), i.e., the input for GRU is the hidden representations $\mathbf{h}_n$ learned by RNSCN or RNSCN$^+$ for the n-th token in the sentence. For simplicity in presentation, we denote the computation of GRU by using the notation f_{GRU}. To be specific, by taking $\mathbf{h}_n$ as input, the final feature representation $\mathbf{h}'_n$ for each word is obtained through

$$\mathbf{h}'_n = f_{GRU}(\mathbf{h}'_{n-1}, \mathbf{h}_n; \mathbf{\Theta}), \quad (10)$$

where $\mathbf{\Theta}$ is the collection of the GRU parameters. The final token-level prediction is made through

$$\hat{\mathbf{y}}_n = \text{softmax}(\mathbf{W}_l \cdot \mathbf{h}'_n + \mathbf{b}_l), \quad (11)$$

where $\mathbf{W}_l \in \mathbb{R}^{5\times d'}$ transforms a d'-dimensional feature vector to class probabilities (note that we have 5 different classes as defined in Section 3).

The second joint model, namely RNSCN-CRF, combines a linear-chain CRF with RNSCN to learn the discriminative mapping from high-level features to labels. The advantage of CRF is to learn sequential interactions between each pair of adjacent words as well as labels and provide structural outputs. Formally, the joint model aims to output a sequence of labels with maximum conditional probability given its input. Denote by $\mathbf{y}$ a sequence of labels for a sentence and by $\mathbf{H}$ the embedding matrix for each sentence (each column denotes a hidden feature vector of a word in the sentence learned by RNSCN), the inference is computed as:

$$\begin{aligned}\hat{\mathbf{y}} &= \arg\max_{\mathbf{y}} p(\mathbf{y}|\mathbf{H}) \\ &= \arg\max_{\mathbf{y}} \frac{1}{Z(\mathbf{H})}\prod_{c\in C}\exp\langle \mathbf{W}_c, g(\mathbf{H}, \mathbf{y}_c)\rangle \quad (12)\end{aligned}$$

where C indicates the set of different cliques (unary and pairwise cliques in the context of linear-chain). $\mathbf{W}_c$ is tied for each different $\mathbf{y}_c$, which indicates the labels for clique c. The operator $\langle\cdot,\cdot\rangle$ is the element-wise multiplication, and $g(\cdot)$ produces the concatenation of $\{\mathbf{h}_n\}$'s in a context window of each word. The above two models both consider the sequential interaction of the words within each sentence, but the formalization and training are totally different. We will report the results for both joint models in the experiment section.

4.4 Training

Recall that in our cross-domain setting, the labels for terms extraction are only available in the source domain, but the auxiliary relation labels can be automatically produced for both domains via the dependency parser. Besides the source domain labeled data $\mathcal{D}_S = \{(\mathbf{x}_{S_i}, \mathbf{y}_{S_i})\}_{i=1}^{n_S}$, we denote by $\mathcal{D}_R = \{(\mathbf{r}_j, \mathbf{y}_j^R)\}_{j=1}^{n_R}$ the combined source and target domain data with auxiliary relation labels. For training, the total loss consists of token-prediction loss ℓ_S and relation-prediction loss ℓ_R:

$$\mathcal{L} = \sum_{\mathcal{D}_S} \ell_S(\mathbf{y}_{S_i}, \hat{\mathbf{y}}_{S_i}) + \gamma \sum_{\mathcal{D}_R} \ell_R(\mathbf{r}_j, \mathbf{y}_j^R), \quad (13)$$

where γ is the trade-off parameter, ℓ_S is the cross-entropy loss between the predicted extraction label in (11) and the ground-truth, and ℓ_R is defined in (6) for RNSCN$^+$ or (3) for RNSCN. For RNSCN-CRF, the loss becomes the negative log probability of the true label given the corresponding input:

$$\ell_S(\mathbf{y}_{S_i}, \hat{\mathbf{y}}_{S_i}) = -\log(\mathbf{y}_{S_i}|\mathbf{h}_{S_i}). \quad (14)$$

Dataset	Description	# Sentences	Training	Testing
R	Restaurant	5,841	4,381	1,460
L	Laptop	3,845	2,884	961
D	Device	3,836	2,877	959

Table 1: Data statistics with number of sentences.

The parameters for token-level predictions and relation-level predictions are updated jointly such that the information from the auxiliary task could be propagated to the target task to obtain better performance. This idea is in accordance with structural learning proposed by Ando and Zhang (2005), which shows that multiple related tasks are useful for finding the optimal hypothesis space. In our case, the set of multiple tasks includes the target terms extraction task and the auxiliary relation prediction task, which are closely related. The parameters are all shared across domains. The joint model is trained using back-propagation from the top layer of GRU or CRF to RNSCN until reaching to the input word embeddings in the bottom.

5 Experiments

5.1 Data & Experimental Setup

The data is taken from the benchmark customer reviews in three different domains, namely restaurant, laptop and digital devices. The restaurant domain contains a combination of restaurant reviews from SemEval 2014 task 4 subtask 1 (Pontiki et al., 2014) and SemEval 2015 task 12 subtask 1 (Pontiki et al., 2015). The laptop domain consists of laptop reviews from SemEval 2014 task 4 subtask 1. For digital device, we take reviews from (Hu and Liu, 2004) containing sentences from 5 digital devices. The statistics for each domain are shown in Table 1. In our experiments, we randomly split the data in each domain into training set and testing set with the proportion being 3:1. To obtain more rigorous result, we make three random splits for each domain and test the learned model on each split. The number of sentences for training and testing after each split is also shown in Table 1. Each sentence is labeled with aspect terms and opinion terms.

For each cross-domain task, we conduct both inductive and transductive experiments. Specifically, we train our model only on the training sets from both (labeled) source and (unlabeled) target domains. For testing, the inductive results are obtained using the test data from the target domain, and the transductive results are obtained using the (unlabeled) training data from the target domain.

The evaluation metric we used is F1 score. Following the setting from existing work, only exact match could be counted as correct.

For experimental setup, we use Stanford Dependency Parser (Klein and Manning, 2003) to generate dependency trees. There are in total 43 different dependency relations, i.e. 43 classes for the auxiliary task. We set the number of latent relation groups as 20. The input word features for RNSCN are pre-trained word embeddings using word2vec (Mikolov et al., 2013) which is trained on 3M reviews from the Yelp dataset[2] and electronics dataset in Amazon reviews[3] (McAuley et al., 2015). The dimension of word embeddings is 100. Because of the relatively small size of the training data compared with the number of parameters, we firstly pre-train RNSCN for 5 epochs with mini-batch size 30 and rmsprop initialized at 0.01. The joint model of RNSCN$^+$-GRU is then trained with rmsprop initialized at 0.001 and mini-batch size 30. The trade-off parameter α, β and γ are set to be 1, 0.001 and 0.1, respectively. The hidden-layer dimension for GRU is 50, and the context window size is 3 for input feature vectors of GRU. For the joint model of RNSCN-CRF, we implement SGD with a decaying learning rate initialized at 0.02. The context window size is also 3 in this case. Both joint models are trained for 10 epochs.

5.2 Comparison & Results

We compared our proposed model with several baselines and variants of the proposed model:

- **RNCRF**: A joint model of recursive neural network and CRF proposed by (Wang et al., 2016) for single-domain aspect and opinion terms extraction. We make all the parameters shared across domains for target prediction.
- **RNGRU**: A joint model of RNN and GRU. The hidden layer of RNN is taken as input for GRU. We share all the parameters across domains, similar to RNCRF.
- **CrossCRF**: A linear-chain CRF with hand-engineered features that are useful for cross-domain settings (Jakob and Gurevych, 2010), e.g., POS tags, dependency relations.
- **RAP**: The Relational Adaptive bootstraPping method proposed by (Li et al., 2012) that uses TrAdaBoost to expand lexicons.
- **Hier-Joint**: A recent deep model proposed by Ding et al. (2017) that achieves state-of-the-art performance on aspect terms extraction across domains.
- **RNSCN-GRU**: Our proposed joint model integrating auxiliary relation prediction task into RNN that is further combined with GRU.
- **RNSCN-CRF**: The second proposed model similar to RNSCN-GRU, which replace GRU with CRF.
- **RNSCN$^+$-GRU**: Our final joint model with auto-encoders to reduce auxiliary label noise.

Note that we do not implement other recent deep adaptation models for comparison (Chen et al., 2012; Yang and Hospedales, 2015), because Hier-Joint (Ding et al., 2017) has already demonstrated better performances than these models. The overall comparison results with the baselines are shown in Table 2 with average F1 scores and standard deviations over three random splits. Clearly, the results for aspect terms (AS) transfer are much lower than opinion terms (OP) transfer, which indicate that the aspect terms are usually quite different across domains, whereas the opinion terms could be more common and similar. Hence the ability to adapt the aspect extraction from the source domain to the target domain becomes more crucial. On this behalf, our proposed model shows clear advantage over other baselines for this more difficult transfer problem. Specifically, we achieve 6.77%, 5.88%, 10.55% improvement over the best-performing baselines for aspect extraction in R$\rightarrow$L, L$\rightarrow$D and D$\rightarrow$L, respectively. By comparing with RNCRF and RNGRU, we show that the structural correspondence network is indeed effective when integrated into RNN.

To show the effect of the integration of the autoencoder, we conduct experiments over different variants of the proposed model in Table 3. RNSCN-GRU represents the model without autoencoder, which achieves much better F1 scores on most experiments compared with the baselines in Table 2. RNSCN$^+$-GRU outperforms RNSCN-GRU in almost all experiments. This indicates the autoencoder automatically learns data-dependent groupings, which is able to reduce unnecessary label noise. To further verify that the autoencoder indeed reduces label noise when the parser is inaccurate, we generate new noisy parse trees by replacing some relations within each sentence with a random

relation. Specifically, in each source domain, for each relation that connects to any aspect or opinion word, it has 0.5 probability of being replaced by any other relation. In Table 3, We denote the model with noisy relations with (r). Obviously, the performance of RNSCN-GRU without an autoencoder significantly deteriorates when the auxiliary labels are very noisy. On the contrary, RNSCN$^+$-GRU (r) achieves acceptable results compared to RNSCN$^+$-GRU. This proves that the autoencoder makes the model more robust to label noise and helps to adapt the information more accurately to the target data. Note that a large drop for $L \rightarrow R$ in aspect extraction might be caused by a large portion of noisy replacements for this particular data which makes it too hard to train a good classifier. This may not greatly influence opinion extraction, as shown, because the two domains usually share many common opinion terms. However, the significant difference in aspect terms makes the learning more dependent on common relations.

The above comparisons are made using the test data from target domains which are not available during training (i.e., the inductive setting). For more complete comparison, we also conduct experiments in the transductive setting. We pick our best model RNSCN$^+$-GRU, and show the effect of different components. To do that, we first remove the sequential structure on top, resulting in RNSCN$^+$. Moreover, we create another variant by removing opinion term labels to show the effect of the double propogation between aspect terms and opinion terms. The resulting model is named RNSCN$^+$-GRU*. As shown in Table 4, we denote by OUT and IN the inductive and transductive setting, respectively. The results shown are the average F1 scores among three splits[4]. In general, RNSCN$^+$-GRU shows similar performances for both inductive and transductive settings. This indicates the

robustness and the ability to learn well when test data is not presented during training. Without opinion labels, RNSCN$^+$-GRU* still achieves better results than Hier-Joint most of the time. Its lower performance compared to RNSCN$^+$-GRU also indicates that in the cross-domain setting, the dual information between aspects and opinions is beneficial to find appropriate and discriminative relation feature space. Finally, the results for RNSCN$^+$ by removing GRU are lower than the joint model, which proves the importance of combining syntactic tree structure with sequential modeling.

To qualitatively show the effect of the auxiliary task with auto-encoders for clustering syntactically similar words across domains, we provide some case studies on the predicted groups of some words in Table 5. Specifically, for each relation in the dependency tree, we use (4) to obtain the most probable group to assign the word in the child node. The left column shows the predicted group index with the right column showing the corresponding words. Clearly, the words in the same group have similar syntactic functionalities, whereas the word types vary across groups.

In the end, we verify the robustness and capability of the model by conducting sensitivity studies and experiments with varying number of unlabeled target data for training, respectively. Figure 4 shows the sensitivity test for L$\rightarrow$D, which indicates that changing of the trade-off parameter γ or the number of groups $|G|$ does not affect the model's performance greatly, i.e., less than 1% for aspect extraction and 2% for opinion extraction. This proves that our model is robust and stable against small variations. Figure 5 compares the results of RNSCN$^+$-GRU with Hier-Joint when increasing the proportion of unlabeled target training data from 0 to 1. Obviously, our model shows steady improvement with the increasing number of unlabeled target data. This pattern proves our model's capability of learning from target domain for adaptation.

6 Conclusion

We propose a novel dependency-tree-based RNN, namely RNSCN (or RNSCN$^+$), for domain adaptation. The model integrates an auxiliary task into representation learning of nodes in the dependency tree. The adaptation takes place in a common relation feature space, which builds the structural correspondences using syntactic relations among the words in each sentence. We further develop a joint model to combine RNSCN/RNSCN$^+$ with a sequential labeling model for terms extraction.

Abstract

Training a task-completion dialogue agent via reinforcement learning (RL) is costly because it requires many interactions with real users. One common alternative is to use a user simulator. However, a user simulator usually lacks the language complexity of human interlocutors and the biases in its design may tend to degrade the agent. To address these issues, we present Deep Dyna-Q, which to our knowledge is the first deep RL framework that integrates planning for task-completion dialogue policy learning. We incorporate into the dialogue agent a model of the environment, referred to as the *world model*, to mimic real user response and generate simulated experience. During dialogue policy learning, the world model is constantly updated with real user experience to approach real user behavior, and in turn, the dialogue agent is optimized using both real experience and simulated experience. The effectiveness of our approach is demonstrated on a movie-ticket booking task in both simulated and human-in-the-loop settings[1].

1 Introduction

Learning policies for task-completion dialogue is often formulated as a reinforcement learning (RL) problem (Young et al., 2013; Levin et al., 1997). However, applying RL to real-world dialogue systems can be challenging, due to the constraint that an RL learner needs an environment to operate in. In the dialogue setting, this requires a dialogue agent to interact with real users and adjust its policy in an online fashion, as illustrated in Figure 1(a). Unlike simulation-based games such as Atari games (Mnih et al., 2015) and AlphaGo (Silver et al., 2016a, 2017) where RL has made its greatest strides, task-completion dialogue systems may incur significant real-world cost in case of failure. Thus, except for very simple tasks (Singh et al., 2002; Gašić et al., 2010, 2011; Pietquin et al., 2011; Li et al., 2016a; Su et al., 2016b), RL is too expensive to be applied to real users to train dialogue agents from scratch.

One strategy is to convert human-interacting dialogue to a simulation problem (similar to Atari games), by building a user simulator using human conversational data (Schatzmann et al., 2007; Li et al., 2016b). In this way, the dialogue agent can learn its policy by interacting with the simulator instead of real users (Figure 1(b)). The simulator, in theory, does not incur any real-world cost and can provide unlimited simulated experience for reinforcement learning. The dialogue agent trained with such a user simulator can then be deployed to real users and further enhanced by only a small number of human interactions. Most of recent studies in this area have adopted this strategy (Su et al., 2016a; Lipton et al., 2016; Zhao and Eskenazi, 2016; Williams et al., 2017; Dhingra et al., 2017; Li et al., 2017; Liu and Lane, 2017; Peng et al., 2017b; Budzianowski et al., 2017; Peng et al., 2017a).

However, user simulators usually lack the conversational complexity of human interlocutors, and the trained agent is inevitably affected by biases in the design of the simulator. Dhingra et al. (2017) demonstrated a significant discrepancy in a simulator-trained dialogue agent when evaluated with simulators and with real users. Even more challenging is the fact that there is no universally accepted metric to evaluate a user simulator (Pietquin and Hastie, 2013). Thus, it remains

(a) Learning with real users (b) Learning with user simulators (c) Learning with real users via DDQ

Figure 1: Three strategies of learning task-completion dialogue policies via RL.

controversial whether training task-completion dialogue agent via simulated users is a valid approach.

We propose a new strategy of learning dialogue policy by interacting with real users. Compared to previous works (Singh et al., 2002; Li et al., 2016a; Su et al., 2016b; Papangelis, 2012), our dialogue agent learns in a much more efficient way, using only a small number of real user interactions, which amounts to an affordable cost in many nontrivial dialogue tasks.

Our approach is based on the Dyna-Q framework (Sutton, 1990) where planning is integrated into policy learning for task-completion dialogue. Specifically, we incorporate a model of the environment, referred to as the *world model*, into the dialogue agent, which simulates the environment and generates simulated user experience. During the dialogue policy learning, real user experience plays two pivotal roles: first, it can be used to improve the world model and make it behave more like real users, via supervised learning; second, it can also be used to directly improve the dialogue policy via RL. The former is referred to as *world model learning*, and the latter *direct reinforcement learning*. Dialogue policy can be improved either using real experience directly (i.e., direct reinforcement learning) or via the world model indirectly (referred to as *planning* or *indirect reinforcement learning*). The interaction between world model learning, direct reinforcement learning and planning is illustrated in Figure 1(c), following the Dyna-Q framework (Sutton, 1990).

The original papers on Dyna-Q and most its early extensions used tabular methods for both planning and learning (Singh, 1992; Peng and Williams, 1993; Moore and Atkeson, 1993; Kuvayev and Sutton, 1996). This table-lookup representation limits its application to small problems only. Sutton et al. (2012) extends the Dyna architecture to linear function approximation, making it applicable to larger problems. In the dialogue setting, we are dealing with a much larger action-state space. Inspired by Mnih et al. (2015), we propose Deep Dyna-Q (DDQ) by combining Dyna-Q with deep learning approaches to representing the state-action space by neural networks (NN).

By employing the world model for planning, the DDQ method can be viewed as a model-based RL approach, which has drawn growing interest in the research community. However, most model-based RL methods (Tamar et al., 2016; Silver et al., 2016b; Gu et al., 2016; Racanière et al., 2017) are developed for simulation-based, synthetic problems (e.g., games), but not for human-in-the-loop, real-world problems. To these ends, our main contributions in this work are two-fold:

- We present Deep Dyna-Q, which to the best of our knowledge is the first deep RL framework that incorporates planning for task-completion dialogue policy learning.
- We demonstrate that a task-completion dialogue agent can efficiently adapt its policy on the fly, by interacting with real users via RL. This results in a significant improvement in success rate on a nontrivial task.

2 Dialogue Policy Learning via Deep Dyna-Q (DDQ)

Our DDQ dialogue agent is illustrated in Figure 2, consisting of five modules: (1) an LSTM-based natural language understanding (NLU) module (Hakkani-Tür et al., 2016) for identifying user intents and extracting associated slots; (2) a state tracker (Mrkšić et al., 2016) for tracking the dialogue states; (3) a dialogue policy which selects

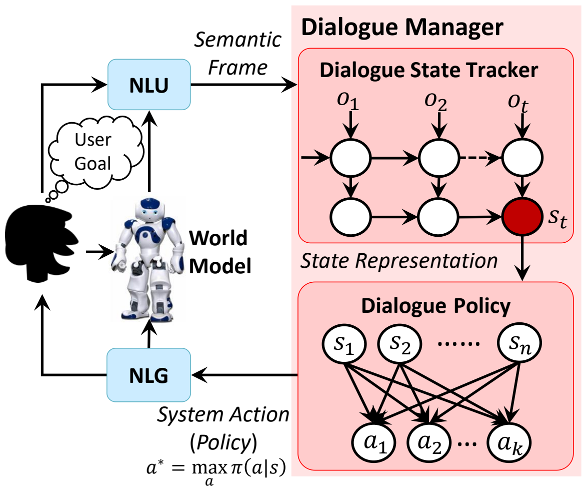

Figure 2: Illustration of the task-completion DDQ dialogue agent.

the next action[2] based on the current state; (4) a model-based natural language generation (NLG) module for converting dialogue actions to natural language response (Wen et al.); and (5) a world model for generating simulated user actions and simulated rewards.

As illustrated in Figure 1(c), starting with an initial dialogue policy and an initial world model (both trained with pre-collected human conversational data), the training of the DDQ agent consists of three processes: (1) *direct reinforcement learning*, where the agent interacts with a real user, collects real experience and improves the dialogue policy; (2) *world model learning*, where the world model is learned and refined using real experience; and (3) *planning*, where the agent improves the dialogue policy using simulated experience.

Although these three processes conceptually can occur simultaneously in the DDQ agent, we implement an iterative training procedure, as shown in Algorithm 1, where we specify the order in which they occur within each iteration. In what follows, we will describe these processes in details.

2.1 Direct Reinforcement Learning

In this process (lines 5-18 in Algorithm 1) we use the DQN method (Mnih et al., 2015) to improve the dialogue policy based on real experience. We consider task-completion dialogue as a Markov Decision Process (MDP), where the agent interacts with a user in a sequence of actions to accomplish a user goal. In each step, the agent observes the dialogue state s, and chooses the action a to execute, using an ϵ-greedy policy that selects a random action with probability ϵ or otherwise follows the greedy policy $a = \text{argmax}_{a'} Q(s, a'; \theta_Q)$. $Q(s, a; \theta_Q)$ which is the approximated value function, implemented as a Multi-Layer Perceptron (MLP) parameterized by θ_Q. The agent then receives reward[3] r, observes next user response a^u, and updates the state to s'. Finally, we store the experience (s, a, r, a^u, s') in the replay buffer D^u. The cycle continues until the dialogue terminates.

We improve the value function $Q(s, a; \theta_Q)$ by adjusting θ_Q to minimize the mean-squared loss function, defined as follows:

$$\begin{aligned}\mathcal{L}(\theta_Q) &= \mathbb{E}_{(s,a,r,s')\sim\mathcal{D}^u}[(y_i - Q(s, a; \theta_Q))^2] \\ y_i &= r + \gamma \max_{a'} Q'(s', a'; \theta_{Q'}) \qquad (1)\end{aligned}$$

where $\gamma \in [0, 1]$ is a discount factor, and $Q'(.)$ is the target value function that is only periodically updated (line 42 in Algorithm 1). By differentiating the loss function with respect to θ_Q, we arrive at the following gradient:

$$\begin{aligned}\nabla_{\theta_Q}\mathcal{L}(\theta_Q) = \mathbb{E}_{(s,a,r,s')\sim\mathcal{D}^u}[(r+ \\ \gamma \max_{a'} Q'(s', a'; \theta_{Q'}) - Q(s, a; \theta_Q)) \qquad (2) \\ \nabla_{\theta_Q} Q(s, a; \theta_Q)]\end{aligned}$$

As shown in lines 16-17 in Algorithm 1, in each iteration, we improve $Q(.)$ using minibatch Deep Q-learning.

2.2 Planning

In the planning process (lines 23-41 in Algorithm 1), the world model is employed to generate simulated experience that can be used to improve dialogue policy. K in line 24 is the number of planning steps that the agent performs per step of direct reinforcement learning. If the world model is able to accurately simulate the environment, a big K can be used to speed up the policy learning. In DDQ, we use two replay buffers, D^u for storing real experience and D^s for simulated experience. Learning and planning are accomplished

[2]In the dialogue scenario, actions are dialogue-acts, consisting of a single act and a (possibly empty) collection of $(slot = value)$ pairs (Schatzmann et al., 2007).

[3]In the dialogue scenario, reward is defined to measure the degree of success of a dialogue. In our experiment, for example, success corresponds to a reward of 80, failure to a reward of -40, and the agent receives a reward of -1 at each turn so as to encourage shorter dialogues.

Algorithm 1 Deep Dyna-Q for Dialogue Policy Learning

```
Require: $N, \epsilon, K, L, C, Z$
Ensure: $Q(s,a;\theta_Q)$, $M(s,a;\theta_M)$
 1: initialize $Q(s,a;\theta_Q)$ and $M(s,a;\theta_M)$ via pre-training on human conversational data
 2: initialize $Q'(s,a;\theta_{Q'})$ with $\theta_{Q'} = \theta_Q$
 3: initialize real experience replay buffer $D^u$ using Reply Buffer Spiking (RBS), and simulated experience replay buffer $D^s$ as empty
 4: for $n$=1:$N$ do
 5:     # Direct Reinforcement Learning starts
 6:     user starts a dialogue with user action $a^u$
 7:     generate an initial dialogue state $s$
 8:     while $s$ is not a terminal state do

by the same DQN algorithm, operating on real experience in D^u for learning and on simulated experience in D^s for planning. Thus, here we only describe the way the simulated experience is generated.

Similar to Schatzmann et al. (2007), at the beginning of each dialogue, we uniformly draw a user goal $G = (C, R)$, where C is a set of constraints and R is a set of requests (line 26 in Algorithm 1). For movie-ticket booking dialogues, constraints are typically the name and the date of the movie, the number of tickets to buy, etc. Requests can contain these slots as well as the location of the theater, its start time, etc. Table 3 presents some sampled user goals and dialogues generated by simulated and real users, respectively. The first user action a^u (line 27) can be either a request or an inform dialogue-act. A request, such as `request(theater; moviename=batman)`, consists of a request slot and multiple ($\geqslant$ 1) constraint slots, uniformly sampled from R and C, respectively. An inform contains constraint slots only. The user action can also be converted to natural language via NLG, e.g., `"which theater will show batman?"`

In each dialogue turn, the world model takes as input the current dialogue state s and the last agent action a (represented as an one-hot vector), and generates user response a^u, reward r, and a binary variable t, which indicates whether the dialogue terminates (line 33). The generation is accomplished using the world model $M(s,a;\theta_M)$, a MLP shown in Figure 3, as follows:

$$\begin{aligned} h &= \tanh(W_h(s,a) + b_h) \\ r &= W_r h + b_r \\ a^u &= \text{softmax}(W_a h + b_a) \\ t &= \text{sigmoid}(W_t h + b_t) \end{aligned}$$

where (s,a) is the concatenation of s and a, and W and b are parameter matrices and vectors, respectively.

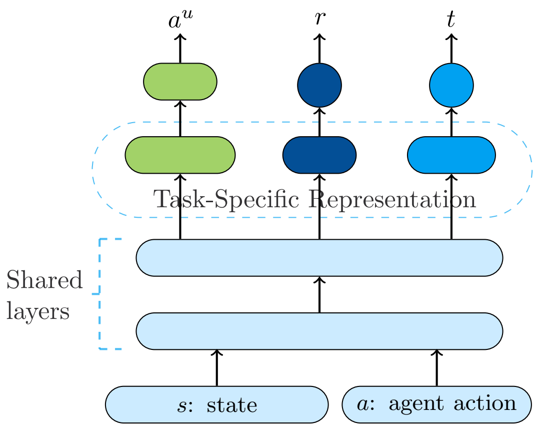

Figure 3: The world model architecture.

2.3 World Model Learning

In this process (lines 19-22 in Algorithm 1), $M(s, a; \theta_M)$ is refined via minibatch SGD using real experience in the replay buffer D^u. As shown in Figure 3, $M(s, a; \theta_M)$ is a multi-task neural network (Liu et al., 2015) that combines two classification tasks of simulating a^u and t, respectively, and one regression task of simulating r. The lower layers are shared across all tasks, while the top layers are task-specific.

3 Experiments and Results

We evaluate the DDQ method on a movie-ticket booking task in both simulation and human-in-the-loop settings.

3.1 Dataset

Raw conversational data in the movie-ticket booking scenario was collected via Amazon Mechanical Turk. The dataset has been manually labeled based on a schema defined by domain experts, as shown in Table 4, which consists of 11 dialogue acts and 16 slots. In total, the dataset contains 280 annotated dialogues, the average length of which is approximately 11 turns.

3.2 Dialogue Agents for Comparison

To benchmark the performance of DDQ, we have developed different versions of task-completion dialogue agents, using variations of Algorithm 1.

- A **DQN** agent is learned by standard DQN, implemented with direct reinforcement learning only (lines 5-18 in Algorithm 1) in each epoch.
- The **DDQ(**K**)** agents are learned by DDQ of Algorithm 1, with an initial world model pre-trained on human conversational data, as described in Section 3.1. K is the number of planning steps. We trained different versions of DDQ(K) with different K's.
- The **DDQ(**K**, rand-init** θ_M**)** agents are learned by the DDQ method with a randomly initialized world model.
- The **DDQ(**K**, fixed** θ_M**)** agents are learned by DDQ with an initial world model pre-trained on human conversational data. But the world model is not updated afterwards. That is, the *world model learning* part in Algorithm 1 (lines 19-22) is removed. The DDQ(K, fixed θ_M) agents are evaluated in the simulation setting only.
- The **DQN(**K**)** agents are learned by DQN, but with K times more real experiences than the DQN agent. DQN(K) is evaluated in the simulation setting only. Its performance can be viewed as the upper bound of its DDQ(K) counterpart, assuming that the world model in DDQ(K) perfectly matches real users.

Implementation Details All the models in these agents ($Q(s, a; \theta_Q)$, $M(s, a; \theta_M)$) are MLPs with `tanh` activations. Each policy network $Q(.)$ has one hidden layer with 80 hidden nodes. As shown in Figure 3, the world model $M(.)$ contains two shared hidden layers and three task-specific hidden layers, with 80 nodes in each. All the agents are trained by Algorithm 1 with the same set of hyper-parameters. ϵ-greedy is always applied for exploration. We set the discount factor γ = 0.95. The buffer sizes of both D^u and D^s are set to 5000. The target value function is updated at the end of each epoch. In each epoch, $Q(.)$ and $M(.)$ are refined using one-step ($Z = 1$) 16-tuple-minibatch update. [4] In planning, the maximum length of a simulated dialogue is 40 ($L = 40$). In addition, to make the dialogue training efficient, we also applied a variant of imitation learning, called Reply Buffer Spiking (RBS) (Lipton et al., 2016). We built a naive but occasionally successful rule-based agent based on human conversational dataset (line 1 in Algorithm 1), and pre-filled the real experience replay buffer D^u with 100 dialogues of experience (line 2) before training for all the variants of agents.

3.3 Simulated User Evaluation

In this setting the dialogue agents are optimized by interacting with user simulators, instead of real users. Thus, the world model is learned to mimic user simulators. Although the simulator-trained agents are sub-optimal when applied to real users due to the discrepancy between simulators and real users, the simulation setting allows us to perform a detailed analysis of DDQ without much cost and to reproduce the experimental results easily.

[4] We found in our experiments that setting $Z > 1$ improves the performance of all agents, but does not change the conclusion of this study: DDQ consistently outperforms DQN by a statistically significant margin. Conceptually, the optimal value of Z used in planning is different from that in direct reinforcement learning, and should vary according to the quality of the world model. The better the world model is, the more aggressive update (thus bigger Z) is being used in planning. We leave it to future work to investigate how to optimize Z for planning in DDQ.

Agent	Epoch = 100			Epoch = 200			Epoch = 300		
	Success	Reward	Turns	Success	Reward	Turns	Success	Reward	Turns
DQN	.4260	-3.84	31.93	.5308	10.78	22.72	.6480	27.66	22.21

DQN(10)	*.7944*	*48.61*	*15.43*	*.8296*	*54.00*	*13.09*	*.8356*	*54.89*	*12.77*

Table 1: Results of different agents at training epoch = {100, 200, 300}. Each number is averaged over 5 runs, each run tested on 2000 dialogues. Excluding DQN(5) and DQN(10) which serve as the upper bounds, any two groups of success rate (except three groups: at epoch 100, DDQ(5, rand-init θ_M) and DDQ(10, fixed θ_M), at epoch 200, DDQ(5, rand-init θ_M) and DDQ(10, rand-init θ_M), at epoch 300, DQN and DDQ(10, fixed θ_M)) evaluated at the same epoch is statistically significant in mean with $p < 0.01$. (Success: success rate)

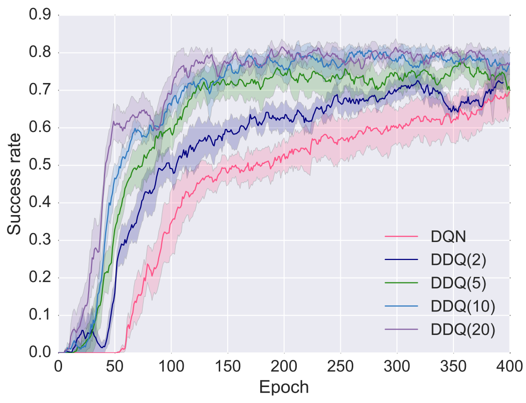

Figure 4: Learning curves of the DDQ(K) agents with $K = 2, 5, 10, 20$. The DQN agent is identical to a DDQ(K) agent with $K = 0$.

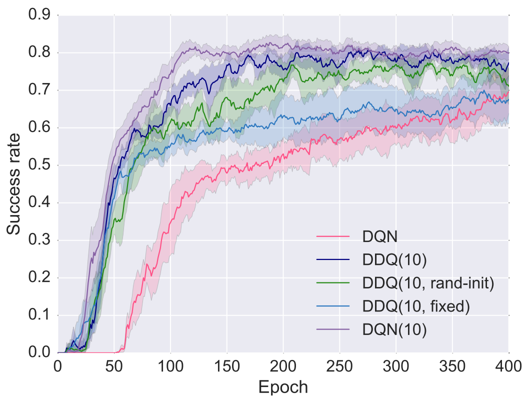

Figure 5: Learning curves of DQN, DDQ(10), DDQ(10, rand-init θ_M), DDQ(10, fixed θ_M), and DQN(10).

User Simulator We adapted a publicly available user simulator (Li et al., 2016b) to the task-completion dialogue setting. During training, the simulator provides the agent with a simulated user response in each dialogue turn and a reward signal at the end of the dialogue. A dialogue is considered successful only when a movie ticket is booked successfully and when the information provided by the agent satisfies all the user's constraints. At the end of each dialogue, the agent receives a positive reward of $2 * L$ for success, or a negative reward of $-L$ for failure, where L is the maximum number of turns in each dialogue, and is set to 40 in our experiments. Furthermore, in each turn, the agent receives a reward of -1, so that shorter dialogues are encouraged. Readers can refer to Appendix B for details on the user simulator.

Results The main simulation results are reported in Table 1 and Figures 4 and 5. For each agent, we report its results in terms of success rate, average reward, and average number of turns (averaged over 5 repetitions of the experiments). Results show that the DDQ agents consistently outperform DQN with a statistically significant margin. Figure 4 shows the learning curves of different DDQ agents trained using different planning steps. Since the training of all RL agents started with RBS using the same rule-based agent, their performance in the first few epochs is very close. After that, performance improved for all values of K, but much more rapidly for larger values. Recall that the DDQ(K) agent with K=0 is identical to the DQN agent, which does no planning but relies on direct reinforcement learning only. Without planning, the DQN agent took about 180 epochs (real dialogues) to reach the success rate of 50%,

Agent	Epoch = 100			Epoch = 150			Epoch = 200		
	Success	Reward	Turns	Success	Reward	Turns	Success	Reward	Turns
DQN	.0000	-58.69	39.38	.4080	-5.730	30.38	.4545	0.350	30.38
DDQ(5)	.4620	00.78	31.33	.5637	15.05	26.17	.6000	19.84	26.32
DDQ(5, rand-init θ_M)	.3600	-11.67	31.74	.5500	13.71	26.58	.5752	16.84	26.37
DDQ(10)	**.5555**	14.69	25.92	**.6416**	25.85	24.28	**.7332**	38.88	20.21
DDQ(10, rand-init θ_M)	.5010	6.27	29.70	.6055	22.11	23.11	.7023	36.90	21.20

Table 2: The performance of different agents at training epoch = $\{100, 150, 200\}$ in the human-in-the-loop experiments. The difference between the results of all agent pairs evaluated at the same epoch is statistically significant ($p < 0.01$). (Success: success rate)

and DDQ(10) took only 50 epochs.

Intuitively, the optimal value of K needs to be determined by seeking the best trade-off between the quality of the world model and the amount of simulated experience that is useful for improving the dialogue agent. This is a non-trivial optimization problem because both the dialogue agent and the world model are updated constantly during training and the optimal K needs to be adjusted accordingly. For example, we find in our experiments that at the early stages of training, it is fine to perform planning aggressively by using large amounts of simulated experience even though they are of low quality, but in the late stages of training where the dialogue agent has been significantly improved, low-quality simulated experience is likely to hurt the performance. Thus, in our implementation of Algorithm 1, we use a heuristic[5] to reduce the value of K in the late stages of training (e.g., after 150 epochs in Figure 4) to mitigate the negative impact of low-qualify simulated experience. We leave it to future work how to optimize the planning step size during DDQ training in a principled way.

Figure 5 shows that the quality of the world model has a significant impact on the agent's performance. The learning curve of DQN(10) indicates the best performance we can expect with a *perfect* world model. With a pre-trained world model, the performance of the DDQ agent improves more rapidly, although eventually, the DDQ and DDQ(rand-init θ_M) agents reach the same success rate after many epochs. The world model learning process is crucial to both the efficiency of dialogue policy learning and the final performance of the agent. For example, in the early stages (before 60 epochs), the performances of DDQ and DDQ(fixed θ_M) remain very close to each other, but DDQ reaches a success rate almost 10% better than DDQ(fixed θ_M) after 400 epochs.

[5]The heuristic is not presented in Algorithm 1. Readers can refer to the released source code for details.

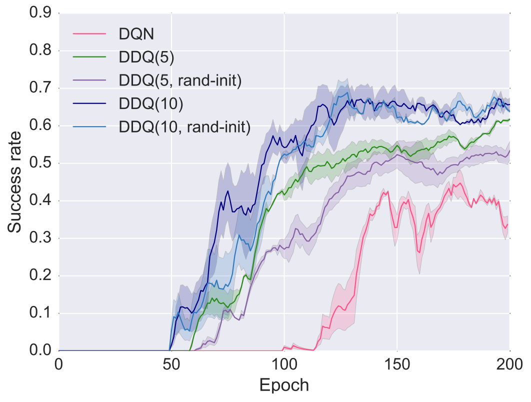

Figure 6: Human-in-the-loop dialogue policy learning curves in four different agents.

3.4 Human-in-the-Loop Evaluation

In this setting, five dialogue agents (i.e., DQN, DDQ(10), DDQ(10, rand-init θ_M), DDQ(5), and DDQ(5, rand-init θ_M)) are trained via RL by interacting with real human users. In each dialogue session, one of the agents was randomly picked to converse with a user. The user was presented with a user goal sampled from the corpus, and was instructed to converse with the agent to complete the task. The user had the choice of abandoning the task and ending the dialogue at any time, if she or he believed that the dialogue was unlikely to succeed or simply because the dialogue dragged on for too many turns. In such cases, the dialogue session is considered failed. At the end of each session, the user was asked to give explicit feedback whether the dialogue succeeded (i.e., whether the movie tickets were booked with all the user constraints satisfied). Each learning curve is trained with two runs, with each run generating 150 dialogues (and $K{*}150$ additional simulated dialogues when planning is applied). In total, we collected 1500 dialogue sessions for training all five agents.

The main results are presented in Table 2 and

Table 3: Two sample dialogue sessions by DQN and DDQ(10) agents trained at epoch 100: Left: simulated user experiments; Right: human-in-the-loop experiments. (*agt*: agent, *usr*: user)

Figure 6, with each agent averaged over two independent runs. The results confirm what we observed in the simulation experiments. The conclusions are summarized as below:

- The DDQ agent significantly outperforms DQN, as demonstrated by the comparison between DDQ(10) and DQN. Table 3 presents four example dialogues produced by two dialogue agents interacting with simulated and human users, respectively. The DQN agent, after being trained with 100 dialogues, still behaved like a naive rule-based agent that requested information bit by bit in a fixed order. When the user did not answer the request explicitly (e.g., `usr: which theater is available?`), the agent failed to respond properly. On the other hand, with planning, the DDQ agent trained with 100 real dialogues is much more robust and can complete 50% of user tasks successfully.
- A larger K leads to more aggressive planning and better results, as shown by DDQ(10) vs. DDQ(5).
- Pre-training world model with human con-

versational data improves the learning efficiency and the agent's performance, as shown by DDQ(5) vs. DDQ(5, rand-init θ_M), and DDQ(10) vs. DDQ(10, rand-init θ_M).

4 Conclusion

We propose a new strategy for a task-completion dialogue agent to learn its policy by interacting with real users. Compared to previous work, our agent learns in a much more efficient way, using only a small number of real user interactions, which amounts to an affordable cost in many nontrivial domains. Our strategy is based on the Deep Dyna-Q (DDQ) framework where planning is integrated into dialogue policy learning. The effectiveness of DDQ is validated by human-in-the-loop experiments, demonstrating that a dialogue agent can efficiently adapt its policy on the fly by interacting with real users via deep RL.

One interesting topic for future research is *exploration in planning*. We need to deal with the challenge of adapting the world model in a changing environment, as exemplified by the domain extension problem (Lipton et al., 2016). As pointed out by Sutton and Barto (1998), the general problem here is a particular manifestation of the conflict between exploration and exploitation. In a planning context, exploration means trying actions that may improve the world model, whereas exploitation means trying to behave in the optimal way given the current model. To this end, we want the agent to explore in the environment, but not so much that the performance would be greatly degraded.

A Dataset Annotation Schema

Table 4 lists all annotated dialogue acts and slots in details.

Annotations	
Intent	request, inform, deny, confirm_question, confirm_answer, greeting, closing, not_sure, multiple_choice, thanks, welcome
Slot	city, closing, date, distanceconstraints, greeting, moviename, numberofpeople, price, starttime, state, taskcomplete, theater, theater_chain, ticket, video_format, zip

Table 4: The data annotation schema

B User Simulator

In the task-completion dialogue setting, the entire conversation is around a user goal implicitly, but the agent knows nothing about the user goal explicitly and its objective is to help the user to accomplish this goal. Generally, the definition of user goal contains two parts:

- *inform_slots* contain a number of slot-value pairs which serve as constraints from the user.
- *request_slots* contain a set of slots that user has no information about the values, but wants to get the values from the agent during the conversation. ticket is a default slot which always appears in the *request_slots* part of user goal.

To make the user goal more realistic, we add some constraints in the user goal: slots are split into two groups. Some of slots must appear in the user goal, we called these elements as *Required slots*. In the movie-booking scenario, it includes moviename, theater, starttime, date, numberofpeople; the rest slots are *Optional slots*, for example, theater_chain, video_format etc.

We generated the user goals from the labeled dataset mentioned in Section 3.1, using two mechanisms. One mechanism is to extract all the slots (known and unknown) from the first user turns (excluding the greeting user turn) in the data, since usually the first turn contains some or all the required information from user. The other mechanism is to extract all the slots (known and unknown) that first appear in all the user turns, and then aggregate them into one user goal. We dump these user goals into a file as the user-goal database. Every time when running a dialogue, we randomly sample one user goal from this user goal database.

Learning to Ask Questions in Open-domain Conversational Systems with Typed Decoders

Abstract

Asking good questions in large-scale, open-domain conversational systems is quite significant yet rather untouched. This task, substantially different from traditional question generation, requires to question not only with various patterns but also on diverse and relevant topics. We observe that a good question is a natural composition of *interrogatives*, *topic words*, and *ordinary words*. Interrogatives lexicalize the pattern of questioning, topic words address the key information for topic transition in dialogue, and ordinary words play syntactical and grammatical roles in making a natural sentence. We devise two typed decoders (*soft typed decoder* and *hard typed decoder*) in which a type distribution over the three types is estimated and used to modulate the final generation distribution. Extensive experiments show that the typed decoders outperform state-of-the-art baselines and can generate more meaningful questions.

1 Introduction

Learning to ask questions (or, question generation) aims to generate a question to a given input. Deciding what to ask and how is an indicator of machine understanding (Mostafazadeh et al., 2016), as demonstrated in machine comprehension (Du et al., 2017; Zhou et al., 2017b; Yuan et al., 2017) and question answering (Tang et al., 2017; Wang et al., 2017). Raising good questions is essential to conversational systems because a good system can well interact with users by asking and responding (Li et al., 2016). Furthermore, asking questions is one of the important proactive behaviors that can drive dialogues to go deeper and further (Yu et al., 2016).

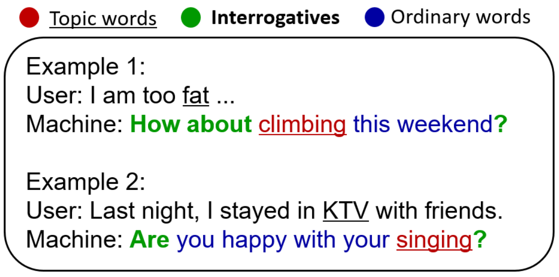
Question generation (QG) in open-domain conversational systems differs substantially from the traditional QG tasks. The ultimate goal of this task is to enhance the *interactiveness and persistence of human-machine interactions*, while for traditional QG tasks, seeking information through a generated question is the major purpose. The response to a generated question will be supplied in the following conversations, which may be novel but not necessarily occur in the input as that in traditional QG (Du et al., 2017; Yuan et al., 2017; Tang et al., 2017; Wang et al., 2017; Mostafazadeh et al., 2016). Thus, the purpose of this task is to spark novel yet related information to drive the interactions to continue.

Due to the different purposes, this task is unique in two aspects: it requires to question not only in various patterns but also about diverse yet relevant topics. **First**, there are various questioning patterns for the same input, such as Yes-no questions and Wh-questions with different interrogatives. Diversified questioning patterns make dialogue interactions richer and more flexible. Instead, traditional QG tasks can be roughly addressed by syntactic transformation (Andrenucci and Sneiders, 2005; Popowich and Winne, 2013), or implicitly modeled by neural models (Du et al., 2017). In such tasks, the information questioned on is pre-specified and usually determines the pattern of questioning. For instance, asking Who-question for a given person, or Where-question for a given location.

Second, this task requires to address much more transitional topics of a given input, which is the nature of conversational systems. For instance, for the input *"I went to dinner with my friends"*, we may question about topics such as *friend, cuisine,*

[*]Authors contributed equally to this work.
[†]Corresponding author: Minlie Huang.

price, place and *taste*. Thus, this task generally requires *scene understanding* to imagine and comprehend a scenario (e.g., *dining at a restaurant*) that can be interpreted by topics related to the input. However, in traditional QG tasks, the core information to be questioned on is pre-specified and rather static, and *paraphrasing* is more required.



● Topic words ● **Interrogatives** ● Ordinary words

Example 1:
User: I am too fat ...
Machine: **How about** climbing this weekend**?**

Example 2:
User: Last night, I stayed in KTV with friends.
Machine: **Are** you happy with your singing**?**

Figure 1: Good questions in conversational systems are a natural composition of interrogatives, topic words, and ordinary words.

Undoubtedly, asking good questions in conversational systems needs to address the above issues (*questioning with diversified patterns, and addressing transitional topics naturally in a generated question*). As shown in Figure 1, a good question is a natural composition of interrogatives, topic words, and ordinary words. Interrogatives indicate the pattern of questioning, topic words address the key information of topic transition, and ordinary words play syntactical and grammatical roles in making a natural sentence.

We thus classify the words in a question into three types: **interrogative**, **topic word**, and **ordinary word** automatically. We then devise two decoders, Soft Typed Decoder (STD) and Hard Typed Decoder (HTD), for question generation in conversational systems[1]. STD deals with word types in a latent and implicit manner, while HTD in a more explicit way. At each decoding position, we firstly estimate a type distribution over word types. STD applies a mixture of type-specific generation distributions where type probabilities are the coefficients. By contrast, HTD reshapes the type distribution by Gumbel-softmax and modulates the generation distribution by type probabilities. Our contributions are as follows:

- To the best of our knowledge, this is the first study on question generation in the setting of conversational systems. We analyze the key differences between this new task and other traditional question generation tasks.
- We devise soft and hard typed decoders to ask good questions by capturing different roles of different word types. Such typed decoders may be applicable to other generation tasks if word semantic types can be identified.

[1]To simplify the task, as a preliminary research, we consider the one-round conversational system.

2 Related Work

Traditional question generation can be seen in task-oriented dialogue system (Curto et al., 2012), sentence transformation (Vanderwende, 2008), machine comprehension (Du et al., 2017; Zhou et al., 2017b; Yuan et al., 2017; Subramanian et al., 2017), question answering (Qin, 2015; Tang et al., 2017; Wang et al., 2017; Song et al., 2017), and visual question answering (Mostafazadeh et al., 2016). In such tasks, the answer is known and is part of the input to the generated question. Meanwhile, the generation tasks are not required to predict additional topics since all the information has been provided in the input. They are applicable in scenarios such as designing questions for reading comprehension (Du et al., 2017; Zhou et al., 2017a; Yuan et al., 2017), and justifying the visual understanding by generating questions to a given image (video) (Mostafazadeh et al., 2016).

In general, traditional QG tasks can be addressed by the heuristic rule-based reordering methods (Andrenucci and Sneiders, 2005; Ali et al., 2010; Heilman and Smith, 2010), slot-filling with question templates (Popowich and Winne, 2013; Chali and Golestanirad, 2016; Labutov et al., 2015), or implicitly modeled by recent neural models(Du et al., 2017; Zhou et al., 2017b; Yuan et al., 2017; Song et al., 2017; Subramanian et al., 2017). These tasks generally do not require to generate a question with various patterns: for a given answer and a supporting text, the question type is usually decided by the input.

Question generation in large-scale, open-domain dialogue systems is relatively unexplored. Li et al. (2016) showed that asking questions in task-oriented dialogues can offer useful feedback to facilitate learning through interactions. Several questioning mechanisms were devised with hand-crafted templates, but unfortunately not applicable to open-domain conversational systems. Similar to our goal, a visual QG task is proposed to generate a question to interact with other people, given an image as input (Mostafazadeh et al., 2016).

3 Methodology

3.1 Overview

The task of question generation in conversational systems can be formalized as follows: given a user post $X = x_1 x_2 \cdots x_m$, the system should generate a natural and meaningful question $Y = y_1 y_2 \cdots y_n$ to interact with the user, formally as

$$Y^* = \underset{Y}{argmax}\, \mathcal{P}(Y|X).$$

As aforementioned, asking good questions in conversational systems requires to question with diversified patterns and address transitional topics naturally in a question. To this end, we classify the words in a sentence into three types: *interrogative, topic word*, and *ordinary word*, as shown in Figure 1. During training, the type of each word in a question is decided automatically[2]. We manually collected about 20 interrogatives. The verbs and nouns in a question are treated as topic words, and all the other words as ordinary words. During test, we resort to PMI (Church and Hanks, 1990) to predict a few topic words for a given post.

On top of an encoder-decoder framework, we propose two decoders to effectively use word types in question generation. The first model is *soft typed decoder (STD)*. It estimates a type distribution over word types and three type-specific generation distributions over the vocabulary, and then obtains a mixture of type-specific distributions for word generation.

The second one is a *hard* form of STD, *hard typed decoder (HTD)*, in which we can control the decoding process more explicitly by approximating the operation of *argmax* with Gumbel-softmax (Jang et al., 2016). In both decoders, the final generation probability of a word is modulated by its word type.

3.2 Encoder-Decoder Framework

Our model is based on the general encoder-decoder framework (Cho et al., 2014; Sutskever et al., 2014). Formally, the model encodes an input sequence $X = x_1 x_2 \cdots x_m$ into a sequence of hidden states $\mathbf{h}_i$, as follows,

$$\mathbf{h}_t = \mathbf{GRU}(\mathbf{h}_{t-1}, \boldsymbol{e}(x_t)),$$

[2]Though there may be errors in word type classification, we found it works well in response generation.

where GRU denotes gated recurrent units (Cho et al., 2014), and $\boldsymbol{e}(x)$ is the word vector of word x. The decoder generates a word sequence by sampling from the probability $\mathcal{P}(y_t|y_{<t}, X)$ ($y_{<t} = y_1 y_2 \cdots y_{t-1}$, the generated subsequence) which can be computed via

$$\mathcal{P}(y_t|y_{<t}, X) = \mathbf{MLP}(\mathbf{s}_t, \boldsymbol{e}(y_{t-1}), \mathbf{c}_t),$$
$$\mathbf{s}_t = \mathbf{GRU}(\mathbf{s}_{t-1}, \boldsymbol{e}(y_{t-1}), \mathbf{c}_t),$$

where $\mathbf{s}_t$ is the state of the decoder at the time step t, and this GRU has different parameters with the one of the encoder. The context vector $\mathbf{c}_t$ is an attentive read of the hidden states of the encoder as $\mathbf{c}_t = \sum_{i=1}^{T} \alpha_{t,i}\mathbf{h}_i$, where the weight $\alpha_{t,i}$ is scored by another $\mathbf{MLP}(\mathbf{s}_{t-1}, \mathbf{h}_i)$ network.

3.3 Soft Typed Decoder (STD)

In a general encoder-decoder model, the decoder tends to generate universal, meaningless questions like "*What's up?*" and "*So what?*". In order to generate more meaningful questions, we propose a soft typed decoder. It assumes that each word has a *latent type* among the set {*interrogative, topic word, ordinary word*}. The soft typed decoder firstly estimates a word type distribution over latent types in the given context, and then computes type-specific generation distributions over the entire vocabulary for different word types. The final probability of generating a word is a mixture of type-specific generation distributions where the coefficients are type probabilities.

The final generation distribution $\mathcal{P}(y_t|y_{<t}, X)$ from which a word can be sampled, is given by

$$\mathcal{P}(y_t|y_{<t}, X) = \sum_{i=1}^{k} \mathcal{P}(y_t|ty_t = c_i, y_{<t}, X) \cdot \mathcal{P}(ty_t = c_i|y_{<t}, X), \quad (1)$$

where ty_t denotes the word type at time step t and c_i is a word type. Apparently, this formulation states that the final generation probability is a mixture of the type-specific generation probabilities $\mathcal{P}(y_t|ty_t = c_i, y_{<t}, X)$, weighted by the probability of the type distribution $\mathcal{P}(ty_t = c_i|y_{<t}, X)$. We name this decoder as *soft typed decoder*. In this model, word type is latent because we do not need to specify the type of a word explicitly. In other words, each word can belong to any of the three types, but with different probabilities given the current context.

The probability distribution over word types $\mathcal{C} = \{c_1, c_2, \cdots, c_k\}$ ($k = 3$ in this paper) (termed

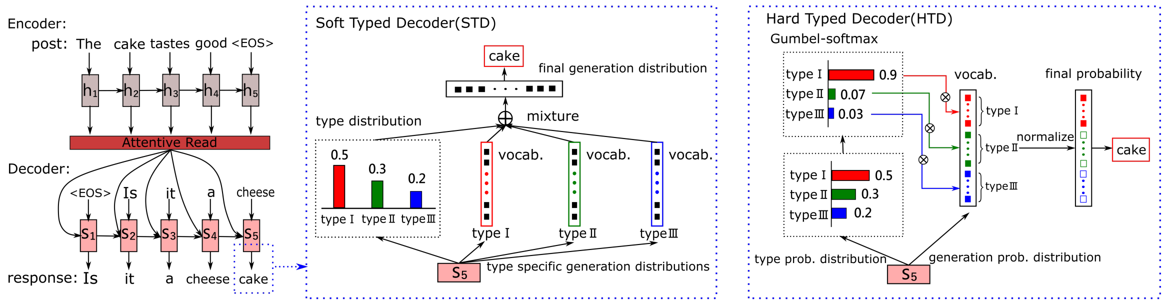


Figure 2: Illustration of STD and HTD. STD applies a mixture of type-specific generation distributions where type probabilities are the coefficients. In HTD, the type probability distribution is reshaped by Gumbel-softmax and then used to modulate the generation distribution. In STD, the generation distribution is over the same vocabulary whereas dynamic vocabularies are applied in HTD.

as *type distribution*) is given by

$$\mathcal{P}(ty_t|y_{<t}, X) = softmax(\mathbf{W}_0\mathbf{s}_t + \mathbf{b}_0), \qquad (2)$$

where s_t is the hidden state of the decoder at time step t, $\mathbf{W}_0 \in R^{k\times d}$, and d is the dimension of the hidden state.

The type-specific generation distribution is given by

$$\mathcal{P}(y_t|ty_t = c_i, y_{<t}, X) = softmax(\mathbf{W}_{c_i}\mathbf{s}_t + \mathbf{b}_{c_i}),$$

where $\mathbf{W}_{c_i} \in R^{|V|\times d}$ and $|V|$ is the size of the entire vocabulary. Note that the type-specific generation distribution is parameterized by $\mathbf{W}_{c_i}$, indicating that the distribution for each word type has its own parameters.

Instead of using a single distribution $\mathcal{P}(y_t|y_{<t}, X)$ as in a general Seq2Seq decoder, our soft typed decoder enriches the model by applying multiple type-specific generation distributions. This enables the model to express more information about the next word to be generated. Also note that the generation distribution is over the same vocabulary, and therefore there is no need to specify word types explicitly.

3.4 Hard Typed Decoder (HTD)

In the soft typed decoder, we assume that each word is a distribution over the word types. In this sense, the type of a word is **implicit**. We do not need to specify the type of each word **explicitly**. In the hard typed decoder, words in the entire vocabulary are dynamically classified into three types for each post, and the decoder first estimates a type distribution at each position and then generates a word with the highest type probability. This process can be formulated as follows:

$$c^* = \arg\max_{c_i} \mathcal{P}(ty_t = c_i|y_{<t}, X), \qquad (3)$$

$$\mathcal{P}(y_t|y_{<t}, X) = \mathcal{P}(y_t|ty_t = c^*, y_{<t}, X). \qquad (4)$$

This is essentially the *hard* form of Eq. 1, which just selects the type with the maximal probability. However, this *argmax* process may cause two problems. First, such a cascaded decision process (firstly selecting the most probable word type and secondly choosing a word from that type) may lead to severe grammatical errors if the first selection is wrong. Second, *argmax* is discrete and non-differentiable, and it breaks the back-propagation path during training.

To make best use of word types in *hard typed decoder*, we address the above issues by applying *Gumbel-Softmax* (Jang et al., 2016) to approximate the operation of *argmax*. There are several steps in the decoder (see Figure 2):

First, the type of each word (*interrogative, topic, or ordinary*) in a question is decided automatically during training, as aforementioned.

Second, the generation probability distribution is estimated as usual,

$$\mathcal{P}(y_t|y_{<t}, X) = softmax(\mathbf{W}_0\mathbf{s}_t + \mathbf{b}_0). \qquad (5)$$

Further, the type probability distribution at each decoding position is estimated as follows,

$$\mathcal{P}(ty_t|y_{<t}, X) = softmax(\mathbf{W}_1\mathbf{s}_t + \mathbf{b}_1). \qquad (6)$$

Third, the generation probability for each word is modulated by its corresponding type probability:

$$\mathcal{P}'(y_t|y_{<t},X) = \mathcal{P}(y_t|y_{<t},X)\cdot\boldsymbol{m}(y_t),$$
$$\boldsymbol{m}(y_t) = \begin{cases} 1 & ,c(y_t) = c^* \\ 0 & ,c(y_t) \neq c^* \end{cases} \tag{7}$$

where $c(y_t)$ looks up the word type of word y_t, and c^* is the type with the highest probability as defined in Eq. 3. This formulation has exactly the effect of *argmax*, where the decoder will only generate words of type with the highest probability.

To make $\mathcal{P}^*(y_t|y_{<t},X)$ a distribution, we normalize these values by a normalization factor Z:

$$Z = \frac{1}{\sum_{y_t\in\mathcal{V}}\mathcal{P}'(y_t|y_{<t},X)}$$

where $\mathcal{V}$ is the decoding vocabulary. Then, the final probability can be denoted by

$$\mathcal{P}^*(y_t|y_{<t},X) = Z\cdot\mathcal{P}'(y_t|y_{<t},X). \tag{8}$$

As mentioned, in order to have an effect of *argmax* but still maintain the differentiability, we resort to *Gumbel-Softmax* (Jang et al., 2016), which is a differentiable surrogate to the *argmax* function. The type probability distribution is then adjusted to the following form:

$$\boldsymbol{m}(y_t) = \mathbf{GS}(\mathcal{P}(ty_t = c(y_t)|y_{<t},X)),$$
$$\mathbf{GS}(\pi_i) = \frac{e^{(log(\pi_i)+g_i)/\tau}}{\sum_{j=1}^{k} e^{(log(\pi_j)+g_j)/\tau}}, \tag{9}$$

where $\pi_1, \pi_2, \cdots, \pi_k$ represents the probabilities of the original categorical distribution, g_j are i.i.d samples drawn from Gumbel(0,1)[3] and τ is a constant that controls the smoothness of the distribution. When $\tau \to 0$, Gumbel-Softmax performs like argmax, while if $\tau \to \infty$, Gumbel-Softmax performs like a uniform distribution. In our experiments, we set τ a constant between 0 and 1, making Gumbel-Softmax smoother than argmax, but sharper than normal softmax.

Note that in HTD, we apply dynamic vocabularies for different responses during training. The words in a response are classified into the three types dynamically. A specific type probability will only affect the words of that type. During test, for each post, topic words are predicted with PMI, interrogatives are picked from a small dictionary, and the rest of words in the vocabulary are treated as ordinary words.

[3]If $u \sim Uniform(0,1)$, then $g = -log(-log(u)) \sim Gumbel(0,1)$.

3.5 Loss Function

We adopt negative data likelihood (equivalent to cross entropy) as the loss function, and additionally, we apply supervision on the mixture weights of word types, formally as follows:

$$\Phi_1 = \sum_t -\log\mathcal{P}(y_t = \tilde{y}_t|y_{<t},X), \tag{10}$$
$$\Phi_2 = \sum_t -\log\mathcal{P}(ty_t = \widetilde{ty}_t|y_{<t},X), \tag{11}$$
$$\Phi = \Phi_1 + \lambda\Phi_2, \tag{12}$$

where $\widetilde{ty}_t$ represents the reference word type and $\tilde{y}_t$ represents the reference word at time t. λ is a factor to balance the two loss terms, and we set λ=0.8 in our experiments.

Note that for HTD, we substitute $\mathcal{P}^*(y_t = w_j|y_{<t},X)$ (as defined by Eq. 8) into Eq. 10.

3.6 Topic Word Prediction

The only difference between training and inference is the means of choosing topic words. During training, we identify the nouns and verbs in a response as topic words; whereas during inference, we adopt PMI (Church and Hanks, 1990) and $Rel(k_i, X)$ to predict a set of topic words k_i for an input post X, as defined below:

$$PMI(w_x, w_y) = log\frac{p(w_x, w_y)}{p_1(w_x) * p_2(w_y)},$$
$$Rel(k_i, X) = \sum_{w_x\in X} e^{PMI(w_x,k_i)},$$

where $p_1(w)/p_2(w)$ represent the probability of word w occurring in a post/response, respectively, and $p(w_x, w_y)$ is the probability of word w_x occurring in a post and w_y in a response.

During inference, we predict at most 20 topic words for an input post. Too few words will affect the grammaticality since the predicted set contains infrequent topic words, while too many words introduce more common topics leading to more general responses.

4 Experiment

4.1 Dataset

To estimate the probabilities in PMI, we collected about 9 million post-response pairs from Weibo. To train our question generation models, we distilled the pairs whereby the responses are in question form with the help of around 20 hand-crafted templates. The templates contain a list of interrogatives and other implicit questioning patterns. Such patterns detect sentences led by words like *what, how many, how about* or sentences ended with a *question mark*. After that, we removed the pairs whose responses are universal questions that can be used to reply many different posts. This is a simple yet effective way to avoid situations where the type probability distribution is dominated by interrogatives and ordinary words.

Ultimately, we obtained the dataset comprising about 491,000 post-response pairs. We randomly selected 5,000 pairs for testing and another 5,000 for validation. The average number of words in post/response is 8.3/9.3 respectively. The dataset contains 66,547 different words, and 18,717 words appear more than 10 times. The dataset is available at: `http://coai.cs.tsinghua.edu.cn/hml/dataset/`.

4.2 Baselines

We compared the proposed decoders with four state-of-the-art baselines.

Seq2Seq: A simple encoder-decoder with attention mechanisms (Luong et al., 2015).

MA: The mechanism-aware (MA) model applies multiple responding mechanisms represented by real-valued vectors (Zhou et al., 2017a). The number of mechanisms is set to 4 and we randomly picked one response from the generated responses for evaluation to avoid selection bias.

TA: The topic-aware (TA) model generates informative responses by incorporating topic words predicted from the input post (Xing et al., 2017).

ERM: Elastic responding machine (ERM) adaptively selects a subset of responding mechanisms using reinforcement learning (Zhou et al., 2018a). The settings are the same as the original paper.

4.3 Experiment Settings

Parameters were set as follows: we set the vocabulary size to $20,000$ and the dimension of word vectors as 100. The word vectors were pre-trained with around 9 million post-response pairs from Weibo and were being updated during the training of the decoders. We applied the 4-layer GRU units (hidden states have 512 dimensions). These settings were also applied to all the baselines. λ in Eq. 12 is 0.8. We set different values of τ in Gumbel-softmax at different stages of training. At the early stage, we set τ to a small value (0.6) to obtain a sharper reformed distribution (more like argmax). After several steps, we set τ to a larger value (0.8) to apply a more smoothing distribution. Our codes are available at: `https://github.com/victorywys/Learning2Ask_TypedDecoder`.

4.4 Automatic Evaluation

We conducted automatic evaluation over the $5,000$ test posts. For each post, we obtained responses from the six models, and there are $30,000$ post-response pairs in total.

4.4.1 Evaluation Metrics

We adopted *perplexity* to quantify how well a model fits the data. Smaller values indicate better performance. To evaluate the diversity of the responses, we employed *distinct-1* and *distinct-2* (Li et al., 2015). These two metrics calculates the proportion of the total number of distinct unigrams or bigrams to the total number of generated tokens in all the generated responses.

Further, we calculated the proportion of the responses containing at least one topic word in the list predicted by PMI. This is to evaluate the ability of addressing topic words in response. We term this metric as *topical response ratio (TRR)*. We predicted 20 topic words with PMI for each post.

4.4.2 Results

Comparative results are presented in Table 1. STD and HTD perform fairly well with lower perplexities, higher distinct-1 and distinct-2 scores, and remarkably better topical response ratio (TRR). Note that MA has the lowest perplexity because the model tends to generate more universal responses.

Model	Perplexity	Distinct-1	Distinct-2	TRR
Seq2Seq	63.71	0.0573	0.0836	6.6%
MA	**54.26**	0.0576	0.0644	4.5%
TA	58.89	0.1292	0.1781	8.7%
ERM	67.62	0.0355	0.0710	4.5%
STD	56.77	0.1325	0.2509	12.1%
HTD	56.10	**0.1875**	**0.3576**	**43.6%**

Table 1: Results of automatic evaluation.

Our decoders have better distinct-1 and distinct-2 scores than baselines do, and HTD performs much better than the strongest baseline TA. Noticeably, the means of using topic information in our models differs substantially from that in TA. Our decoders predict whether a topic word should be decoded at each position, whereas TA takes as

Models	Appropriateness			Richness			Willingness		
	Win (%)	Lose (%)	Tie (%)	Win (%)	Lose (%)	Tie (%)	Win (%)	Lose (%)	Tie (%)
STD vs. Seq2Seq	42.0	38.6	19.4	37.2**	15.2	47.6	45.4*	38.6	16.0
STD vs. MA	39.6*	31.2	29.2	32.6**	16.8	50.6	49.4**	27.0	23.6
STD vs. TA	42.2	40.0	17.8	49.0**	5.4	45.6	47.6*	40.2	12.2
STD vs. ERM	43.4*	34.4	22.2	60.6**	13.2	26.2	43.2*	36.8	20.0
HTD vs. Seq2Seq	50.6**	30.6	18.8	46.0**	10.2	43.8	58.4**	33.2	8.4
HTD vs. MA	54.8**	24.4	20.8	45.0**	17.0	38.0	67.0**	18.0	15.0
HTD vs. TA	52.0**	38.2	9.8	55.0**	5.4	39.6	62.6**	31.0	6.4
HTD vs. ERM	64.8**	23.2	12.0	72.2**	8.4	19.4	56.6**	36.6	6.8
HTD vs. STD	52.0**	33.0	15.0	38.0**	26.2	35.8	61.8**	30.6	7.6

Table 2: Annotation results. Win for "A vs. B" means A is better than B. Significance tests with Z-test were conducted. Values marked with * means *p-value* < 0.05, and ** for *p-value* < 0.01.

input topic word embeddings at all decoding positions.

Our decoders have remarkably better topic response ratios (TRR), indicating that they are more likely to include topic words in generation.

4.5 Manual Evaluation

We resorted to a crowdsourcing service for manual annotation. 500 posts were sampled for manual annotation[4]. We conducted pair-wise comparison between two responses generated by two models for the same post. In total, there are 4,500 pairs to be compared. For each response pair, five judges were hired to give a preference between the two responses, in terms of the following three metrics. Tie was allowed, and system identifiers were masked during annotation.

4.5.1 Evaluation Metrics

Each of the following metrics is evaluated independently on each pair-wise comparison:

Appropriateness: measures whether a question is reasonable in logic and content, and whether it is questioning on the key information. Inappropriate questions are either irrelevant to the post, or have grammatical errors, or universal questions.

Richness: measures whether a response contains topic words that are relevant to a given post.

Willingness to respond: measures whether a user will respond to a generated question. This metric is to justify how likely the generated questions can elicit further interactions. If people are willing to respond, the interactions can go further.

[4]During the sampling process, we removed those posts that are only interpretable with other context or background.

4.5.2 Results

The label of each pair-wise comparison is decided by majority voting from five annotators. Results shown in Table 2 indicate that STD and HTD outperform all the baselines in terms of all the metrics. This demonstrates that our decoders produce more appropriate questions, with richer topics. Particularly, our decoders have substantially better *willingness scores*, indicating that questions generated by our models are more likely to elicit further interactions. Noticeably, HTD outperforms STD significantly, indicating that it is beneficial to specify word types explicitly and apply dynamic vocabularies in generation.

We also observed that STD outperforms Seq2Seq and TA, but the differences are not significant in appropriateness. This is because STD generated about 7% non-question responses which were judged as inappropriate, while Seq2Seq and TA generated universal questions (inappropriate too but beat STD in annotation) to these posts.

4.5.3 Annotation Statistics

The proportion of the pair-wise annotations in which at least three of five annotators assign the same label to a record is 90.57%/93.11%/96.62% for appropriateness/ richness/willingness, respectively. The values show that we have fairly good agreements with majority voting.

4.6 Questioning Pattern Distribution

To analyze whether the model can question with various patterns, we manually annotated the questioning patterns of the responses to 100 sampled posts. The patterns are classified into 11 types including Yes-No, How-, Why-, What-, When-, and Who- questions. We then calculated the KL divergence between the pattern type distribution by a model and that by human (i.e., gold responses).

Results in Table 3 show that the pattern distribution by our model is closer to that in human-written responses, indicating that our decoders can better learn questioning patterns from human language. Further investigation reveals that the baselines tend to generate simple questions like *What?*(什么？) or *Really?*(真的吗), and constantly focus on using one or two question patterns whereas our decoders use more diversified patterns as appeared in the human language.

Model	Seq2Seq	TA	MA	ERM	STD	HTD
KLD	0.431	0.416	0.332	0.276	**0.072**	0.140

Table 3: KL divergence between the questioning pattern distribution by a model and that by human.

4.7 Examples of the Generated Questions

Table 4 presents some generated questions by our decoders, which are more appropriate. On the contrary, Seq2Seq, MA and ERM tend to generate more universal questions. These examples also clearly show that asking questions in open-domain conversational systems requires *scene understanding*, which is verified by this scene example of *singing at karaoke*(在卡拉ok唱歌).

Post:	我们昨天去唱歌了 We went to karaoke yesterday.
Seq2Seq:	**什么时候?** **When?**
MA:	你**怎么**知道我是在问 **How** did you know I am questioning you**?**
TA:	**什么?** **What?**
ERM:	**什么**情况**?** **What** happened **?**
STD:	去**哪里**唱歌**?** **Where** did you sing karaoke**?**
HTD:	你们**几**个人唱歌**?** **How many** people were singing with you**?**

Table 4: Generated question examples. Interrogative words are bolded and topic words underlined.

To further understand how to ask good questions in conversational systems, we presented more generated question examples by human and our typed decoders. The first example (Post-1) in Table 5 shows that a good question can be composed of only interrogatives and ordinary words. This shows the complexity of this task and also the necessity of modeling interrogatives. Post-2 indicates a typical questioning pattern which is ques-

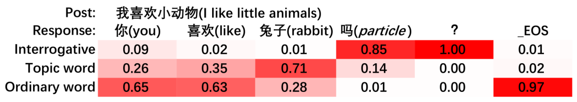
Post-1:	不好不好。哼！讨厌你啦。 No, no. Humph, I hate you!
Human:	我**怎么**了**?** **What** is wrong with me**?**
STD:	我**怎么**了**?** **What** is wrong with me**?**
HTD:	我**怎么**了**?** **What** is wrong with me**?**
Post-2:	刚用了杀虫剂，现在已经有效果了。 I just sprayed the insecticide, and now the effect appears.
Human:	这么快!效果**怎么样?** So quick! **What** is the effect**?**
STD:	效果**如何?** **What** is the effect**?**
HTD:	效果**如何?** **What** is the effect**?**
Post-3:	我在体育中心上班。 I work at the sports center.
Human:	你每天从家过去要**多久?** **How** long does it take you to go there from home**?**
STD:	你是**什么**部门的啊**?** **Which** department are you from**?**
HTD:	那你是体育学院的学生**吗?** **Are** you a student from the College of Physical Education**?**
Post-4:	今天的寿司真好吃。 The sushi today is so delicious!
Human:	我记得你不喜欢吃日式料理的不是**吗?** I remember you didn't like eating Japanese food, **did** you**?**
STD:	你**什么**时候来无锡，我请你。 **When** will you come to Wuxi**?** It is my treat.
HTD:	是**吗?**改天尝尝! Really**?** I will try sometime!

Table 5: Examples for typical questioning patterns. Interrogative words in response are bolded and topic words are underlined.

tioning on a particular topic word (效果-*effect*) of the input. While for Post-3, the questions are asking about transitional topics of the input (上班-*work* → 部门-*department;* 体育中心-*sports center* → 体育学院-*college of Physical Education*), indicating a typical case of **topic transition** in our task (also seen in Post-4, 寿司-sushi →日式料理-Japanese food). This example also demonstrates that for the same input, there are **various questioning patterns**: a How-question asked by human, a Which-question by STD, and a Yes-No question by HTD. As for Post-4, the gold question requires a background that is only shared between the poster and responder, while STD and HTD tend to raise more general questions due to the lack of such shared knowledge.

4.8 Visualization of Type Distribution

To gain more insights into how a word type influence the generation process, we visualized the type probability at each decoding position in HTD. This example (Figure 3) shows that the model can capture word types well at different positions. For instance, at the first and second positions, ordinary words have the highest probabilities for generating 你-*you* and 喜欢-*like*, and at the third position, a topic word 兔子-*rabbit* is predicted while the last two positions are for interrogatives (a particle and a question mark).



Post:	我喜欢小动物(I like little animals)					
Response:	你(you)	喜欢(like)	兔子(rabbit)	吗(*particle*)	?	_EOS
Interrogative	0.09	0.02	0.01	0.85	1.00	0.01
Topic word	0.26	0.35	0.71	0.14	0.00	0.02
Ordinary word	0.65	0.63	0.28	0.01	0.00	0.97

Figure 3: Type distribution examples from HTD. The generated question is "你喜欢兔子吗? *do you like rabbit?*". *_EOS* means end of sentence.

4.9 Error Analysis

We presented error type distribution by manually analyzing 100 bad responses sampled from STD and HTD respectively, where *bad* means the response by our model is worse than that by some baseline during the pair-wise annotation.

There are 4 typical error types: *no topic words (NoT)* in a response (mainly universal questions), *wrong topics (WrT)* where topic words are irrelevant, *type generation error (TGE)* where a wrong word type is predicted (See Eq. 2) and it causes grammatical errors, and *other errors*.

Error Type	NoT	WrT	TGE	Others
STD	34%	34%	29%	3%
HTD	29%	39%	29%	3%

Table 6: Error type distribution.

The error distribution is shown in Table 6. For STD, most of the errors are attributed to no topic or wrong topics, while for HTD, the majority of errors fall into *wrong topics*.

NoT	**Post-1:**	今天好开心啊! I am so happy today!
	STD:	你**怎么**知道**?** **How** do you know **?**
WrT	**Post-2:**	海报非常棒，期待若曦与我们男人的首度合作。 The poster is great and we look forward to our first cooperation with Ruoxi.
	HTD:	你海报**怎么**样啊**?** **How** about your poster **?**
TGE	**Post-3:**	又生病啦?吃点药就好了。 Got sick again? Just take some medicine and you'll be fine soon.
	STD:	我也不知道**怎么**回事。 I don't know **what** happened.
	HTD:	肠胃痛了，上火**吗?** Stomach aching, ulcer **?**

Table 7: Cases for the error types with interrogative words bolded and topic words underlined.

There are typical cases for these error types: (1) Posts such as *"I am so happy today!"* contains no topic words or rare topic words. In this case, our method is unable to predict the topic words so that the models tend to generate universal questions. This happens more frequently in STD because the topic words are not specified explicitly. (2) Posts contains multiple topic words, but the model sometimes focuses on an inappropriate one. For instance, for Post-2 in Table 7, HTD focused on 海报-*poster* but 合作-*cooperation* is a proper one to be focused on. (3) For complex posts, the models failed to predict the correct word type in response. For Post-3, STD generated a declarative sentence and HTD generated a question which, however, is not adequate within the context.

These cases show that controlling the questioning patterns and the informativeness of the content faces with the compatibility issue, which is challenging in language generation. These errors are also partially due to the imperfect ability of topic word prediction by PMI, which is challenging itself in open-domain conversational systems.

5 Conclusion and Future Work

We present two typed decoders to generate questions in open-domain conversational systems. The decoders firstly estimate a type distribution over word types, and then use the type distribution to modulate the final word generation distribution. Through modeling the word types in language generation, the proposed decoders are able to question with various patterns and address novel yet related transitional topics in a generated question. Results show that our models can generate more appropriate questions, with richer topics, thereby more likely to elicit further interactions.

The work can be extended to multi-turn conversation generation by including an additional detector predicting when to ask a question. The detector can be implemented by a classifier or some heuristics. Furthermore, the typed decoders are applicable to the settings where word types can be easily obtained, such as in emotional text generation (Ghosh et al., 2017; Zhou et al., 2018b).

Abstract

Chit-chat models are known to have several problems: they lack specificity, do not display a consistent personality and are often not very captivating. In this work we present the task of making chit-chat more engaging by conditioning on profile information. We collect data and train models to (i) condition on their given profile information; and (ii) information about the person they are talking to, resulting in improved dialogues, as measured by next utterance prediction. Since (ii) is initially unknown, our model is trained to engage its partner with personal topics, and we show the resulting dialogue can be used to predict profile information about the interlocutors.

1 Introduction

Despite much recent success in natural language processing and dialogue research, communication between a human and a machine is still in its infancy. It is only recently that neural models have had sufficient capacity and access to sufficiently large datasets that they appear to generate meaningful responses in a chit-chat setting. Still, conversing with such generic chit-chat models for even a short amount of time quickly exposes their weaknesses (Serban et al., 2016; Vinyals and Le, 2015).

Common issues with chit-chat models include: (i) the lack of a consistent personality (Li et al., 2016a) as they are typically trained over many dialogs each with different speakers, (ii) the lack of an explicit long-term memory as they are typically trained to produce an utterance given only the recent dialogue history (Vinyals and Le, 2015); and (iii) a tendency to produce non-specific answers like "I don't know" (Li et al., 2015). Those three problems combine to produce an unsatisfying overall experience for a human to engage with. We believe some of those problems are due to there being no good publicly available dataset for general chit-chat.

[1]Work done while at Facebook AI Research.

Because of the low quality of current conversational models, and because of the difficulty in evaluating these models, chit-chat is often ignored as an end-application. Instead, the research community has focused on task-oriented communication, such as airline or restaurant booking (Bordes and Weston, 2016), or else single-turn information seeking, i.e. question answering (Rajpurkar et al., 2016). Despite the success of the latter, simpler, domain, it is well-known that a large quantity of human dialogue centers on socialization, personal interests and chit-chat (Dunbar et al., 1997). For example, less than 5% of posts on Twitter are questions, whereas around 80% are about personal emotional state, thoughts or activities, authored by so called "Meformers" (Naaman et al., 2010).

In this work we make a step towards more engaging chit-chat dialogue agents by endowing them with a configurable, but persistent persona, encoded by multiple sentences of textual description, termed a profile. This profile can be stored in a memory-augmented neural network and then used to produce more personal, specific, consistent and engaging responses than a persona-free model, thus alleviating some of the common issues in chit-chat models. Using the same mechanism, any existing information about the persona of the dialogue partner can also be used in the same way. Our models are thus trained to both ask and answer questions about personal topics, and the resulting dialogue can be used to build a model of the persona of the speaking partner.

To support the training of such models, we present the PERSONA-CHAT dataset, a new dialogue dataset consisting of 164,356 utterances between crowdworkers who were randomly paired and each asked to act the part of a given provided persona (randomly assigned, and created by another set of crowdworkers). The paired workers were asked to chat naturally and to get to know each other during the conversation. This produces interesting and engaging conversations that our agents can try to learn to mimic.

Studying the next utterance prediction task during dialogue, we compare a range of models: both generative and ranking models, including Seq2Seq models and Memory Networks (Sukhbaatar et al., 2015) as well as other standard retrieval baselines. We show experimentally that in either the generative or ranking case conditioning the agent with persona information gives improved prediction of the next dialogue utterance. The PERSONA-CHAT dataset is designed to facilitate research into alleviating some of the issues that traditional chit-chat models face, and with the aim of making such models more consistent and engaging, by endowing them with a persona. By comparing against chit-chat models built using the OpenSubtitles and Twitter datasets, human evaluations show that our dataset provides more engaging models, that are simultaneously capable of being fluent and consistent via conditioning on a persistent, recognizable profile.

2 Related Work

Traditional dialogue systems consist of building blocks, such as dialogue state tracking components and response generators, and have typically been applied to tasks with labeled internal dialogue state and precisely defined user intent (i.e., goal-oriented dialogue), see e.g. (Young, 2000). The most successful goal-oriented dialogue systems model conversation as partially observable Markov decision processes (POMDPs) (Young et al., 2013). All those methods typically do not consider the chit-chat setting and are more concerned with achieving functional goals (e.g. booking an airline flight) than displaying a personality. In particular, many of the tasks and datasets available are constrained to narrow domains (Serban et al., 2015).

Non-goal driven dialogue systems go back to Weizenbaum's famous program ELIZA (Weizenbaum, 1966), and hand-coded systems have continued to be used in applications to this day. For example, modern solutions that build an open-ended dialogue system to the Alexa challenge combine hand-coded and machine-learned elements (Serban et al., 2017a). Amongst the simplest of statistical systems that can be used in this domain, that are based on data rather than hand-coding, are information retrieval models (Sordoni et al., 2015), which retrieve and rank responses based on their matching score with the recent dialogue history. We use IR systems as a baseline in this work.

End-to-end neural approaches are a class of models which have seen growing recent interest. A popular class of methods are generative recurrent systems like seq2seq applied to dialogue (Sutskever et al., 2014; Vinyals and Le, 2015; Sordoni et al., 2015; Li et al., 2016b; Serban et al., 2017b). Rooted in language modeling, they are able to produce syntactically coherent novel responses, but their memory-free approach means they lack long-term coherence and a persistent personality, as discussed before. A promising direction, that is still in its infancy, to fix this issue is to use a memory-augmented network instead (Sukhbaatar et al., 2015; Dodge et al., 2015) by providing or learning appropriate memories.

Serban et al. (2015) list available corpora for training dialogue systems. Perhaps the most relevant to learning chit-chat models are ones based on movie scripts such as OpenSubtitles and Cornell Movie-Dialogue Corpus, and dialogue from web platforms such as Reddit and Twitter, all of which have been used for training neural approaches (Vinyals and Le, 2015; Dodge et al., 2015; Li et al., 2016b; Serban et al., 2017b). Naively training on these datasets leads to models with the lack of a consistent personality as they will learn a model averaged over many different speakers. Moreover, the data does little to encourage the model to engage in understanding and maintaining knowledge of the dialogue partner's personality and topic interests.

According to Serban et al. (2015)'s survey, personalization of dialogue systems is "an important task, which so far has not received much attention". In the case of goal-oriented dialogue some work has focused on the agent being aware of the human's profile and adjusting the dialogue accordingly, but without a personality to the agent itself (Lucas et al., 2009; Joshi et al., 2017). For the chit-chat setting, the most relevant work is (Li et al., 2016a). For each user in the Twitter corpus, personas were captured via distributed embeddings (one per speaker) to encapsulate individual characteristics such as background information and speaking style, and they then showed using those vectors improved the output of their seq2seq model for the same speaker. Their work does not focus on attempting to engage the other speaker by getting to know them, as we do here. For that reason, our focus is on explicit profile information, not hard-to-interpret latent variables.

3 The PERSONA-CHAT Dataset

The aim of this work is to facilitate more engaging and more personal chit-chat dialogue. The PERSONA-CHAT dataset is a crowd-sourced dataset, collected via Amazon Mechanical Turk, where each of the pair of speakers condition their dialogue on a given profile, which is provided.

The data collection consists of three stages:

(i) Personas: we crowdsource a set of 1155 possible personas, each consisting of at least 5 profile sentences, setting aside 100 never seen before personas for validation, and 100 for test.

(ii) Revised personas: to avoid modeling that takes advantage of trivial word overlap, we crowdsource additional rewritten sets of the same 1155 personas, with related sentences that are rephrases, generalizations or specializations, rendering the task much more challenging.

(iii) Persona chat: we pair two Turkers and assign them each a random (original) persona from the pool, and ask them to chat. This resulted in a dataset of 164,356 utterances over 10,981 dialogs, 15,705 utterances (968 dialogs) of which are set aside for validation, and 15,119 utterances (1000 dialogs) for test.

The final dataset and its corresponding data collection source code, as well as models trained on the data, are all available open source in ParlAI[2].

In the following, we describe each data collection stage and the resulting tasks in more detail.

3.1 Personas

We asked the crowdsourced workers to create a character (persona) description using 5 sentences, providing them only a single example:

"I am a vegetarian. I like swimming. My father used to work for Ford. My favorite band is Maroon5. I got a new job last month, which is about advertising design."

Our aim was to create profiles that are natural and descriptive, and contain typical topics of human interest that the speaker can bring up in conversation. Because the personas are not the real profiles of the Turkers, the dataset does not contain personal information (and they are told specifically not to use any). We asked the workers to make each sentence short, with a maximum of 15 words per sentence. This is advantageous both for humans and machines: if they are too long, crowdsourced workers are likely to lose interest, and for machines the task could become more difficult.

Some examples of the personas collected are given in Table 1 (left).

3.2 Revised Personas

A difficulty when constructing dialogue datasets, or text datasets in general, is that in order to encourage research progress, the task must be carefully constructed so that is neither too easy nor too difficult for the current technology (Voorhees et al., 1999). One issue with conditioning on textual personas is that there is a danger that humans will, even if asked not to, unwittingly repeat profile information either verbatim or with significant word overlap. This may make any subsequent machine learning tasks less challenging, and the solutions will not generalize to more difficult tasks. This has been a problem in some recent datasets: for example, the dataset curation technique used for the well-known SQuAD dataset suffers from this word overlap problem to a certain extent (Chen et al., 2017).

To alleviate this problem, we presented the original personas we collected to a new set of crowdworkers and asked them to rewrite the sentences so that a new sentence is about *"a related characteristic that the same person may have"*, hence the revisions could be rephrases, generalizations or specializations. For example *"I like basketball"* can be revised as *"I am a big fan of Michael Jordan"* not because they mean the same thing but because the same persona could contain both.

In the revision task, workers are instructed not to trivially rephrase the sentence by copying the original words. However, during the entry stage if a non-stop word is copied we issue a warning,

[2]`https://github.com/facebookresearch/ParlAI/tree/master/projects/personachat`

Original Persona	**Revised Persona**
I love the beach.	To me, there is nothing like a day at the seashore.
My dad has a car dealership	My father sales vehicles for a living.
I just got my nails done	I love to pamper myself on a regular basis.
I am on a diet now	I need to lose weight.
Horses are my favorite animal.	I am into equestrian sports.
I play a lot of fantasy videogames.	RPGs are my favorite genre.
I have a computer science degree.	I also went to school to work with technology.
My mother is a medical doctor	The woman who gave birth to me is a physician.
I am very shy.	I am not a social person.
I like to build model spaceships.	I enjoy working with my hands.

Table 1: Example Personas (left) and their revised versions (right) from the PERSONA-CHAT dataset. The revised versions are designed to be characteristics that the same persona might have, which could be rephrases, generalizations or specializations.

Persona 1	**Persona 2**
I like to ski	I am an artist
My wife does not like me anymore	I have four children
I have went to Mexico 4 times this year	I recently got a cat
I hate Mexican food	I enjoy walking for exercise
I like to eat cheetos	I love watching Game of Thrones

[PERSON 1:] Hi
[PERSON 2:] Hello ! How are you today ?
[PERSON 1:] I am good thank you , how are you.
[PERSON 2:] Great, thanks ! My children and I were just about to watch Game of Thrones.
[PERSON 1:] Nice ! How old are your children?
[PERSON 2:] I have four that range in age from 10 to 21. You?
[PERSON 1:] I do not have children at the moment.
[PERSON 2:] That just means you get to keep all the popcorn for yourself.
[PERSON 1:] And Cheetos at the moment!
[PERSON 2:] Good choice. Do you watch Game of Thrones?
[PERSON 1:] No, I do not have much time for TV.
[PERSON 2:] I usually spend my time painting: but, I love the show.

Table 2: Example dialog from the PERSONA-CHAT dataset. Person 1 is given their own persona (top left) at the beginning of the chat, but does not know the persona of Person 2, and vice-versa. They have to get to know each other during the conversation.

and ask them to rephrase, guaranteeing that the instructions are followed. For example, *"My father worked for Ford."* can be revised to *"My dad worked in the car industry"*, but not *"My dad was employed by Ford."* due to word overlap.

Some examples of the revised personas collected are given in Table 1 (right).

3.3 Persona Chat

After collecting personas, we then collected the dialogues themselves, conditioned on the personas. For each dialogue, we paired two random crowdworkers, and gave them the instruction that they will chit-chat with another worker, while playing the part of a given character. We then provide them with a randomly chosen persona from our pool, different to their partners. The instructions are on purpose quite terse and simply ask them to "chat with the other person naturally and try to get to know each other". In an early study we noticed the crowdworkers tending to talk about themselves (their own persona) too much, so we also added the instructions "both ask questions and answer questions of your chat partner" which seemed to help. We also gave a bonus for high quality dialogs. The dialog is turn-based, with a maximum of 15 words per message. We again gave instructions to not trivially copy the character descriptions into the messages, but also wrote explicit code sending them an error if they tried to do so, using simple string matching. We define a minimum dialogue length which is randomly between 6 and 8 turns each for each dialogue. An example dialogue from the dataset is given in Table 2.

3.4 Evaluation

We focus on the standard dialogue task of predicting the next utterance given the dialogue history, but consider this task both with and without the profile information being given to the learning agent. Our goal is to enable interesting directions for future research, where chatbots can for instance have personalities, or imputed personas could be used to make dialogue more engaging to the user.

We consider this in four possible scenarios: conditioning on no persona, your own persona, their persona, or both. These scenarios can be tried using either the original personas, or the revised ones. We then evaluate the task using three metrics: (i) the log likelihood of the correct sequence, measured via perplexity, (ii) F1 score, and (iii) next utterance classification loss, following Lowe et al. (2015). The latter consists of choosing N random distractor responses from other dialogues (in our setting, N=19) and the model selecting the best response among them, resulting in a score of one if the model chooses the correct response, and zero otherwise (called hits@1 in the experiments).

4 Models

We consider two classes of model for next utterance prediction: ranking models and generative models. Ranking models produce a next utterance by considering any utterance in the training set as a possible candidate reply. Generative models generate novel sentences by conditioning on the dialogue history (and possibly, the persona), and then generating the response word-by-word. Note one can still evaluate the latter as ranking models by computing the probability of generating a given candidate, and ranking candidates by those scores.

4.1 Baseline ranking models

We first consider two baseline models, an IR baseline (Sordoni et al., 2015) and a supervised embedding model, Starspace (Wu et al., 2017)[3]. While there are many IR variants, we adopt the simplest one: find the most similar message in the (training) dataset and output the response from that exchange. Similarity is measured by the tf-idf weighted cosine similarity between the bags of words. Starspace is a recent model that also performs information retrieval but by learning the similarity between the dialog and the next utterance by optimizing the embeddings directly for that task using the margin ranking loss and k-negative sampling. The similarity function $sim(q, c')$ is the cosine similarity of the sum of word embeddings of the query q and candidate c'. Denoting the dictionary of $\mathcal{D}$ word embeddings as W which is a $\mathcal{D} \times d$ matrix, where W_i indexes the i^{th} word (row), yielding its d-dimensional embedding, it embeds the sequences q and c'.

[3]github.com/facebookresearch/StarSpace

In both methods, IR and StarSpace, to incorporate the profile we simply concatenate it to the query vector bag of words.

4.2 Ranking Profile Memory Network

Both the previous models use the profile information by combining it with the dialogue history, which means those models cannot differentiate between the two when deciding on the next utterance. In this model we instead use a memory network with the dialogue history as input, which then performs attention over the profile to find relevant lines from the profile to combine with the input, and then finally predicts the next utterance. We use the same representation and loss as in the Starspace model, so without the profile, the two models are identical. When the profile is available attention is performed by computing the similarity of the input q with the profile sentences p_i, computing the softmax, and taking the weighted sum:

$$q^+ = q + \sum s_i p_i, \qquad s_i = \text{Softmax}(sim(q, p_i))$$

where $\text{Softmax}(z_i) = e^{z_i} / \sum_j e^{z_j}$. One can then rank the candidates c' using $sim(q^+, c')$. One can also perform multiple "hops" of attention over the profile rather than one, as shown here, although that did not bring significant gains in our parameter sweeps.

4.3 Key-Value Profile Memory Network

The key-value (KV) memory network (Miller et al., 2016) was proposed as an improvement to the memory network by performing attention over keys and outputting the values (instead of the same keys as in the original), which can outperform memory networks dependent on the task and definition of the key-value pairs. Here, we apply this model to dialogue, and consider the keys as dialog histories (from the training set), and the values as the next dialogue utterances, i.e., the replies from the speaking partner. This allows the model to have a memory of past dialogues that it can directly use to help influence its prediction for the current conversation. The model we choose is identical to the profile memory network just described in the first hop over profiles, while in the second hop, q^+ is used to attend over the keys and output a weighted sum of values as before, producing q^{++}. This is then used to rank the candidates c' using $sim(q^{++}, c')$ as before. As the set of (key-value) pairs is large this would make training very slow. In our experiments we simply trained the profile memory network and used the same weights from that model and applied this architecture at test time instead. Training the model directly would presumably give better results, however this heuristic already proved beneficial compared to the original network.

4.4 Seq2Seq

The input sequence x is encoded by applying $h_t^e = LSTM_{enc}(x_t \mid h_{t-1}^e)$. We use GloVe (Pennington et al., 2014) for our word embeddings. The final hidden state, h_t^e, is fed into the decoder $LSTM_{dec}$ as the initial state h_0^d. For each time step t, the decoder then produces the probability of a word j occurring in that place via the softmax, i.e.,

$$p(y_{t,j} = 1 \mid y_{t-1}, \dots, y_1) = \frac{\exp(w_j h_t^d)}{\sum_{j'=1}^{K} \exp(w_{j'} h_t^d)}.$$

The model is trained via negative log likelihood. The basic model can be extended to include persona information, in which case we simply prepend it to the input sequence x, i.e., $x = \forall p \in P \mid\mid x$, where $\mid\mid$ denotes concatenation. For the OpenSubtitles and Twitter datasets trained in Section 5.2 we found training a language model (LM), essentially just the decoder part of this model, worked better and we report that instead.

4.5 Generative Profile Memory Network

Finally, we introduce a generative model that encodes each of the profile entries as individual memory representations in a memory network. As before, the dialogue history is encoded via $LSTM_{enc}$, the final state of which is used as the initial hidden state of the decoder. Each entry $p_i = \langle p_{i,1}, \dots, p_{i,n} \rangle \in P$ is then encoded via $f(p_i) = \sum_j^{|p_i|} \alpha_i p_{i,j}$. That is, we weight words by their inverse term frequency: $\alpha_i = 1/(1 + log(1 + \text{tf}))$ where tf is computed from the GloVe index via Zipf's law[4]. Let F be the set of encoded memories. The decoder now attends over the encoded profile entries, i.e., we compute the mask a_t, context c_t and next input $\hat{x}_t$ as:

$$a_t = softmax(FW_a h_t^d),$$
$$c_t = a_t^\intercal F; \quad \hat{x}_t = tanh(W_c[c_{t-1}, x_t]).$$

If the model has no profile information, and hence no memory, it becomes equivalent to the Seq2Seq model.

5 Experiments

We first report results using automated evaluation metrics, and subsequently perform an extrinsic evaluation where crowdsourced workers perform a human evaluation of our models.

5.1 Automated metrics

The main results are reported in Table 3. Overall, the results show the following key points:

Persona Conditioning Most models improve significantly when conditioning prediction on their own persona at least for the original (non-revised) versions, which is an easier task than the revised ones which have no word overlap. For example, the Profile Memory generation model has improved perplexity and hits@1 compared to Seq2Seq, and all the ranking algorithms (IR baseline, Starspace and Profile Memory Networks) obtain improved hits@1.

Ranking vs. Generative. Ranking models are far better than generative models at ranking. This is perhaps obvious as that is the metric they are optimizing, but still the performance difference is quite stark. It may be that the word-based probability which generative models use works well, but is not calibrated well enough to give a sentence-based probability which ranking requires. Human evaluation is also used to compare these methods, which we perform in Sec. 5.2.

Ranking Models. For the ranking models, the IR baseline is outperformed by Starspace due to its learnt similarity metric, which in turn is outperformed by Profile Memory networks due to the attention mechanism over the profiles (as all other parts of the models are the same). Finally KV Profile Memory networks outperform Profile Memory Networks in the no persona case due to the ability to consider neighboring dialogue history and next

Table 4: **Human Evaluation** of various PERSONA-CHAT models, along with a comparison to human performance, and Twitter and OpenSubtitles based models (last 4 rows), standard deviation in parenthesis.

utterance pairs in the training set that are similar to the current dialogue, however when using persona information the performance is similar.

Revised Personas. Revised personas are much harder to use. We do however still see some gain for the Profile Memory networks compared to none (0.354 vs. 0.318 hits@1). We also tried two variants of training: with the original personas in the training set or the revised ones, a comparison of which is shown in Table 6 of the Appendix. *Training* on revised personas helps, both for test examples that are in original form or revised form, likely due to the model be forced to learn more than simple word overlap, forcing the model to generalize more (i.e., learn semantic similarity of differing phrases).

Their Persona. We can also condition a model on the other speaker's persona, or both personas at once, the results of which are in Tables 5 and 6 in the Appendix. Using "Their persona" has less impact on this dataset. We believe this is because most speakers tend to focus on themselves when it comes to their interests. It would be interesting how often this is the case in other datasets. Certainly this is skewed by the particular instructions one could give to the crowdworkers. For example if we gave the instructions "try not to talk about yourself, but about the other's interests' likely these metrics would change.

5.2 Human Evaluation

As automated metrics are notoriously poor for evaluating dialogue (Liu et al., 2016) we also perform human evaluation using crowdsourced workers. The procedure is as follows. We perform almost exactly the same setup as in the dataset collection process itself as in Section 3.3. In that setup, we paired two Turkers and assigned them each a random (original) persona from the collected pool, and asked them to chat. Here, from the Turker's point of view everything looks the same except instead of being paired with a Turker they are paired with one of our models instead (they do not know this). In this setting, for both the Turker and the model, the personas come from the test set pool.

After the dialogue, we then ask the Turker some additional questions in order to evaluate the quality of the model. We ask them to evaluate fluency, engagingness and consistency (scored between 1-5). Finally, we measure the ability to detect the other speaker's profile by displaying two possible profiles, and ask which is more likely to be the profile of the person the Turker just spoke to. More details of these measures are given in the Appendix.

The results are reported in Table 4 for the best performing generative and ranking models, in both the No Persona and Self Persona categories, 100 dialogues each. We also evaluate the scores of human performance by replacing the chatbot with a human (another Turker). This effectively gives us upper bound scores which we can aim for with our models. Finally, and importantly, we compare our models trained on PERSONA-CHAT with chit-chat models trained with the Twitter and OpenSubtitles datasets (2009 and 2018 versions) instead, following Vinyals and Le (2015). Example chats from a few of the models are shown in the Appendix in Tables 7, 8, 9, 10, 11 and 12.

Firstly, we see a difference in fluency, engagingness and consistency between all PERSONA-CHAT models and the models trained on OpenSubtitles and Twitter. PERSONA-CHAT is a resource that is particularly strong at providing training data for the beginning of conversations, when the two speakers do not know each other, focusing on asking and answering questions, in contrast to other resources. We also see suggestions of more subtle differences between the models, although these differences are obscured by the high variance of the human raters' evaluations. For example, in both the generative and ranking model cases, models endowed with a persona can be detected by the human conversation partner, as evidenced by the persona detection accuracies, whilst maintaining fluency and consistency compared to their non-persona driven counterparts.

Finding the balance between fluency, engagement, consistency, and a persistent persona remains a strong challenge for future research.

5.3 Profile Prediction

Two tasks could naturally be considered using PERSONACHAT: (1) next utterance prediction during dialogue, and (2) profile prediction given dialogue history. The main study of this work has been Task 1, where we have shown the use of profile information. Task 2, however, can be used to extract such information. While a full study is beyond the scope of this paper, we conducted some preliminary experiments, the details of which are in Appendix D. They show (i) human speaker's profiles can be predicted from their dialogue with high accuracy (94.3%, similar to human performance in Table 4) or even from the model's dialogue (23% with KV Profile Memory) showing the model is paying attention to the human's interests. Further, the accuracies clearly improve with further dialogue, as shown in Table 14. Combining Task 1 and Task 2 into a full system is an exciting area of future research.

6 Conclusion & Discussion

In this work we have introduced the PERSONA-CHAT dataset, which consists of crowd-sourced dialogues where each participant plays the part of an assigned persona; and each (crowd-sourced) persona has a word-distinct paraphrase. We test various baseline models on this dataset, and show that models that have access to their own personas in addition to the state of the dialogue are scored as more consistent by annotators, although not more engaging. On the other hand, we show that models trained on PERSONA-CHAT (with or without personas) are more engaging than models trained on dialogue from other resources (movies, Twitter).

We believe PERSONA-CHAT will be a useful resource for training components of future dialogue systems. Because we have paired human generated profiles and conversations, the data aids the construction of agents that have consistent personalities and viewpoints. Furthermore, predicting the profiles from a conversation moves chit-chat tasks in the direction of goal-directed dialogue, which has metrics for success. Because we collect paraphrases of the profiles, they cannot be trivially matched; indeed, we believe the original and rephrased profiles are interesting as a semantic similarity dataset in their own right. We hope that the data will aid training agents that can ask questions about users' profiles, remember the answers, and use them naturally in conversation.

Abstract

In this paper, we explore the task of mapping spoken language utterances to one of thousands of natural language understanding domains in intelligent personal digital assistants (IPDAs). This scenario is observed in mainstream IPDAs in industry that allow third parties to develop thousands of new domains to augment built-in first party domains to rapidly increase domain coverage and overall IPDA capabilities. We propose a scalable neural model architecture with a shared encoder, a novel attention mechanism that incorporates personalization information and domain-specific classifiers that solves the problem efficiently. Our architecture is designed to efficiently accommodate incremental domain additions achieving two orders of magnitude speed up compared to full model retraining. We consider the practical constraints of real-time production systems, and design to minimize memory footprint and runtime latency. We demonstrate that incorporating personalization significantly improves domain classification accuracy in a setting with thousands of overlapping domains.

1 Introduction

Intelligent personal digital assistants (IPDAs) are one of the most advanced and successful artificial intelligence applications that have spoken language understanding (SLU). Many IPDAs have recently emerged in industry including Amazon Alexa, Google Assistant, Apple Siri, and Microsoft Cortana (Sarikaya, 2017). IPDAs have traditionally supported only dozens of well-separated domains, each defined in terms of a specific application or functionality such as calendar and local search (Tur and de Mori, 2011; Sarikaya et al., 2016). To rapidly increase domain coverage and extend capabilities, some IPDAs have released Software Development Toolkits (SDKs) to allow third-party developers to quickly build and integrate new domains, which we refer to as *skills* henceforth. Amazon's *Alexa Skills Kit* (Kumar et al., 2017a), Google's *Actions* and Microsoft's *Cortana Skills Kit* are all examples of such SDKs. Alexa Skills Kit is the largest of these services with over 40,000 skills.

For IPDAs, finding the most relevant skill to handle an utterance is an open problem for three reasons. First, the sheer number of skills makes the task difficult. Unlike traditional systems that have on the order of 10-20 built-in domains, large-scale IPDAs can have up to 40,000 skills. Second, the number of skills is rapidly expanding with 100+ new skills added per week. Large-scale IPDAs should be able to accommodate new skills efficiently without compromising performance. Third, unlike traditional built-in domains that are carefully designed to be disjoint by a central team, skills are built independently by different developers and can cover overlapping functionalities. For instance, there are over 50 recipe skills in Alexa that can handle recipe-related utterances.

One simple solution to this problem has been to require the user to explicitly mention a skill name and follow a strict invocation pattern as in *"Ask {Uber} to {get me a ride}."* However, this significantly limits the natural interaction with IPDAs. Users have to remember skill names and invocation patterns, and it places a cognitive burden on users who tend to forget both. Skill discovery is difficult with a pure voice user interface, it is hard for users to know the capabilities of thousands of skills a priori, which may leads to limited user engagement with skills and potentially with IPDAs.

In this paper, we propose a solution that addresses all three practical challenges without requiring skill names or invocation patterns. Our approach is based on a scalable neural model architecture with a shared encoder, a skill attention mechanism and skill-specific classification networks that can efficiently perform large-scale skill classification in IPDAs using a weakly supervised training dataset. We demonstrate that our model achieves a high accuracy on a manually transcribed test set after being trained with weak supervision. Moreover, our architecture is designed to efficiently integrate new skills that appear in-between full model retraining cycles into the model. Besides accuracy, we also keep practical constraints in mind and focus on minimizing memory footprint and runtime latency, while ensuring architecture is scalable to thousands of skills, all of which are important for real-time production systems. Furthermore, we investigate two different ways of incorporating user personalization information into the model, our naive baseline method adds the information as a 1-bit flag in the feature space of the skill-specific networks, the *personalized attention* technique computes a convex combination of skill embeddings for the user's enabled skills and significantly outperforms the naive personalization baseline. We show the effectiveness of our approach with extensive experiments using 1,500 skills from a deployed IPDA system.

2 Related Work

Traditional multi-domain SLU/NLU systems are designed hierarchically, starting with domain classification to classify an incoming utterance into one of many possible domains, followed by further semantic analysis with domain-specific intent classification and slot tagging (Tur and de Mori, 2011). Traditional systems have typically been limited to a small number of domains, designed by specialists to be well-separable. Therefore, domain classification has been considered a less complex task compared to other semantic analysis such as intent and slot predictions. Traditional domain classifiers are built using simple linear models such as Multinomial Logistic Regression or Support Vector Machines in a one-versus-all setting for multi-class prediction. The models typically use word n-gram features and also those based on static lexicon match, and there have been several recent studies applying deep learning techniques (Xu and Sarikaya, 2014).

There is also a line of prior work on enhancing sequential text classification or tagging. Hierarchical character-to-word level LSTM (Hochreiter and Schmidhuber, 1997) architectures similar to our models have been explored for the Named Entity Recognition task by Lample et al. (2016). Character-informed sequence models have also been explored for simple text classification with small sets of classes by Xiao and Cho (2016). Joulin et al. (2016) explored highly scalable text classification using a shared hierarchical encoder, but their hierarchical softmax-based output formulation is unsuitable for incremental model updates. Work on zero-shot domain classifier expansion by Kumar et al. (2017b) struggled to rank incoming domains higher than training domains. The attention-based approach of Kim et al. (2017d) does not require retraining from scratch, but it requires keeping all models stored in memory which is computationally expensive. Multi-Task learning was used in the context of SLU by Tur (2006) and has been further explored using neural networks for phoneme recognition (Seltzer and Droppo, 2013) and semantic parsing (Fan et al., 2017; Bapna et al., 2017). There have been many other pieces of prior work on improving NLU systems with pre-training (Kim et al., 2015b; Celikyilmaz et al., 2016; Kim et al., 2017e), multi-task learning (Zhang and Wang, 2016; Liu and Lane, 2016; Kim et al., 2017b), transfer learning (El-Kahky et al., 2014; Kim et al., 2015a,c; Chen et al., 2016a; Yang et al., 2017), domain adaptation (Kim et al., 2016; Jaech et al., 2016; Liu and Lane, 2017; Kim et al., 2017d,c) and contextual signals (Bhargava et al., 2013; Chen et al., 2016b; Hori et al., 2016; Kim et al., 2017a).

3 Weakly Supervised Training Data Generation

Our model addresses the domain classification task in SLU systems. In traditional IPDA systems, these domains are hand-crafted by experts to be well separable and can easily be annotated by humans because they are small in number. The emergence of self-service SLU results in a large number of potentially mutually overlapping SLU domains. This means that eliciting large volumes of high quality human annotations to train our model

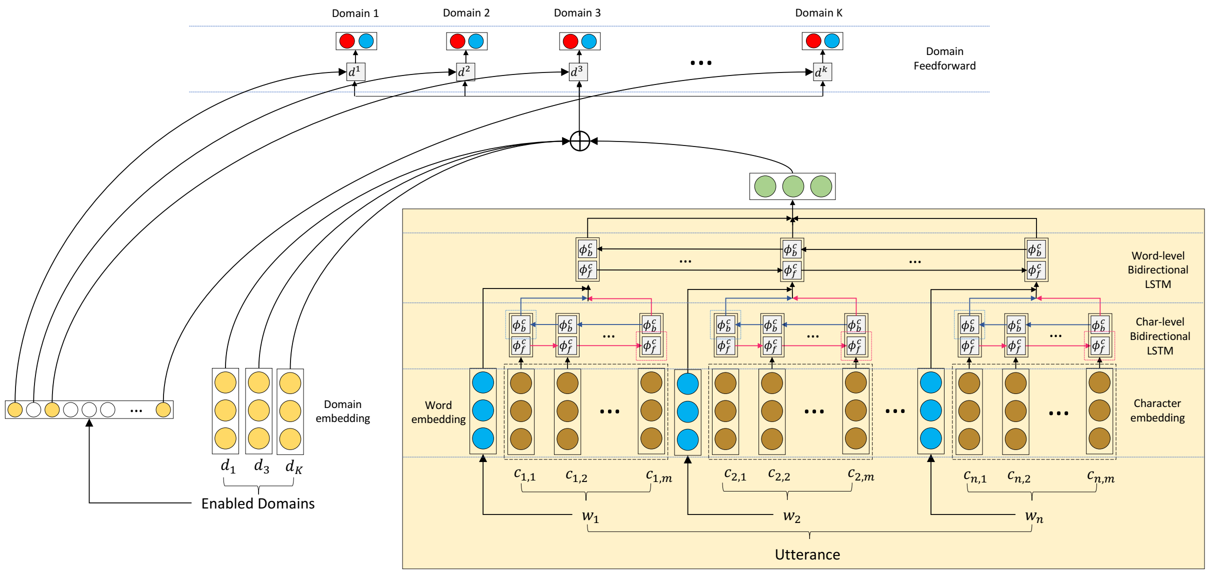

Figure 1: The overall architecture of the personalized dynamic domain classifier.

is no longer feasible, and we cannot assume that domains are designed to be well separable.

Instead we can generate training data by adopting the weak supervision paradigm introduced by (Hoffmann et al., 2011), which proposes using heuristic labeling functions generate large numbers of noisy data samples. Clean data generation with weak supervision is a challenging problem, so we address it by decomposing it into two simpler problems, of candidate generation and noise suppression, however it remains important for our model to be noise robust.

3.1 Data Programming

The key insight of the *Data Programming* approach is that $O(1)$ simple labeling functions can be used to approximate $O(n)$ human annotated data points with much less effort. We adopt the formalism used by (Ratner et al., 2016) to treat each of instance data generation rule as a rich generative model, defined by a labeling function λ and describe different families of labeling functions. Our data programming pipeline is analogous to the noisy channel model proposed for spelling correction by (Kernighan et al., 1990), and consists of a set of candidate generation and noise detection functions.

$$\arg\max_{\mu} P(\mu|s_i) = \arg\max_{\mu} P(s_i|\mu).\, P(\mu)$$

where μ and s_i represent utterances and the ith skill respectively. $P(s_i|\mu)$ the probability of a skill being valid for an utterance is approximated by simple functions that act as candidate data *generators* $\lambda_g \in \Lambda_g$ based on recognitions produced by a family of *query patterns* $\lambda_q \in \Lambda_q$. $P(\mu)$ is represented by a family of simple functions that act as *noise detectors* $\lambda_n \in \Lambda_n$, which mark utterances as likely being noise.

We apply the technique to the query logs of a popular IPDA, which has support for personalized third party domains. Looking at the structure of utterances that match query pattern λ_q, each utterance of form *"Ask $\{$Uber$\}$ to $\{$get me a car$\}$"* can be considered as being parametrized by the underlying latent command μ_z, that is *"Get me a car"*, a target domain corresponding to service s_t, which in this case is *Uber* and the query recognition pattern λ_q, in this case *"Ask $\{s_t\}$ to $\{\mu_z\}$"*. Next we assume that the distribution of latent commands over domains are independent of the query pattern.

$$P(\mu_z, s_t) \approx P(\mu, s_t, \lambda_q)$$

Making this simple distributional approximation allows us to generate a large number of noisy training samples. The family of generator functions $\lambda_g \in \Lambda_g$ is thus defined such that $u_z = \lambda_g^i(\mu, \lambda_q^i)$

3.2 Noise Reduction

The distribution defined above contains a large number of noisy positive samples. Related to $P(\mu)$ in the noisy channel in the spell correction context, we defined a small family of heuristic noise detection functions $\lambda_n \in \Lambda_n$ that discards training data instances that are not likely to be well formed. For instance,

- λ_n^1 requires u to contain a minimum threshold of information by removing those with μ_z that has token length fewer than 3. Utterances shorter than this mostly consist of non-actionable commands.
- λ_n^2 discards all data samples below a certain threshold of occurrences in live traffic, since utterances that are rarely observed are more likely to be ASR errors or unnatural.
- λ_n^3 discards the data samples for a domain if they come from an overly broad pattern with a catch-all behavior.
- λ_n^4 discards utterances that belong to shared intents provided by the SLU SDK.

The end result of this stage is to retain utterances such as 'call me a cab' from 'Ask Uber to call me a cab' but discard 'Boston' from 'Ask Accuweather for Boston'. One can easily imagine extending this framework with other high recall noise detectors, for example, using language models to discard candidates that are unlikely to be spoken sentences.

4 Model Architecture

Our model consists of a *shared encoder* network consisting of an orthography-sensitive hierarchical LSTM encoder that feeds into a set of domain specific classification layers trained to make a binary decision for each output label.

Our main novel contribution is the extension of this architecture with a *personalized attention* mechanism which uses the attention mechanism of (Bahdanau et al., 2014) to attend to memory locations corresponding to the specific domains enabled by a user, and allows the system to learn semantic representations of each domain via *domain embeddings*. As we will show, incorporating personalization features is key to disambiguating between multiple overlapping domains[1], and the personalized attention mechanism outperforms more naive forms of personalization. The personalized attention mechanism first computes an attention weight for each of enabled domains, performs a convex combination to compute a context vector and then concatenates this vector to the encoded utterance before the final domain classification. Figure 1 depicts the model in detail.

Our model can efficiently accommodate new domains not seen during initial training by keeping the shared encoder frozen, bootstrapping a domain embedding based on existing ones, then optimizing a small number of network parameters corresponding to domain-specific classifier, which is orders of magnitude faster and more data efficient than retraining the full classifier.

We make design decisions to ensure that our model has a low memory and latency footprint. We avoid expensive large vocabulary matrix multiplications on both the input and output stages, and instead use a combination of character embeddings and word embeddings in the input stage.[2] The output matrix is lightweight because each domain-specific classifier is a matrix of only 201×2 parameters. The inference task can be trivially parallelized across cores since there's no requirement to compute a partition function across a high-dimensional softmax layer, which is the slowest component of large label multiclass neural networks. Instead, we achieve comparability between the probability scores generated by individual models by using a customized loss formulation.[3]

4.1 Shared Encoder

First we describe our shared hierarchical utterance encoder, which is marked by the almond colored box in Figure 1. Our hierarchical character to word to utterance design is motivated by the need to make the model operate on an open vocabulary in terms of words and to make it robust to small changes in orthography resulting from fluctuations in the upstream ASR system, all while avoiding expensive large matrix multiplications associated with one-hot word encoding in large vocabulary systems.

We denote an LSTM simply as a mapping $\phi : \mathbb{R}^d \times \mathbb{R}^{d'} \rightarrow \mathbb{R}^{d'}$ that takes a d dimensional input vector x and a d' dimensional state vector h to output a new d' dimensional state vector $h' =$

[1]We assume that users can customize their IPDA settings to enable certain domains.

[2]Using a one-hot representation of word vocabulary size 60,000 and hidden dimension 100 would require learning a matrix of size 60000 x 100 - using 100-dim word embeddings requires only a $\mathcal{O}(1)$ lookup followed by a 100 x 100 matrix, thus allowing our model to be significantly smaller and faster despite having what is effectively an open vocabulary

[3]Current inference consumes 50MB memory and the p99 latency is 15ms.

$\phi(x, h)$. Let $\mathcal{C}$ denote the set of characters and $\mathcal{W}$ the set of words in a given utterance. Let $\oplus$ denote the vector concatenation operation. We encode an utterance using BiLSTMs, and the model parameters Θ associated with this BiLSTM layer are

- Char embeddings $e_c \in \mathbb{R}^{25}$ for each $c \in \mathcal{C}$
- Char LSTMs $\phi_f^{\mathcal{C}}, \phi_b^{\mathcal{C}} : \mathbb{R}^{25} \times \mathbb{R}^{25} \rightarrow \mathbb{R}^{25}$
- Word embeddings $e_w \in \mathbb{R}^{50}$ for each $w \in \mathcal{W}$
- Word LSTMs $\phi_f^{\mathcal{W}}, \phi_b^{\mathcal{W}} : \mathbb{R}^{100} \times \mathbb{R}^{50} \rightarrow \mathbb{R}^{50}$

Let $w_1 \ldots w_n \in \mathcal{W}$ denote a word sequence where word w_i has character $w_i(j) \in \mathcal{C}$ at position j. First, the model computes a character-sensitive word representation $v_i \in \mathbb{R}^{100}$ as

$$\begin{aligned} f_j^{\mathcal{C}} &= \phi_f^{\mathcal{C}}\left(e_{w_i(j)}, f_{j-1}^{\mathcal{C}}\right) \qquad \forall j = 1 \ldots |w_i| \\ b_j^{\mathcal{C}} &= \phi_b^{\mathcal{C}}\left(e_{w_i(j)}, b_{j+1}^{\mathcal{C}}\right) \qquad \forall j = |w_i| \ldots 1 \\ v_i &= f_{|w_i|}^{\mathcal{C}} \oplus b_1^{\mathcal{C}} \oplus e_{w_i} \end{aligned}$$

for each $i = 1 \ldots n$.[4] These word representation vectors are encoded by forward and backward LSTMs for word $\phi_f^{\mathcal{W}}, \phi_b^{\mathcal{W}}$ as

$$\begin{aligned} f_i^{\mathcal{W}} &= \phi_f^{\mathcal{W}}\left(v_i, f_{i-1}^{\mathcal{W}}\right) \qquad \forall i = 1 \ldots n \\ b_i^{\mathcal{W}} &= \phi_b^{\mathcal{W}}\left(v_i, b_{i+1}^{\mathcal{W}}\right) \qquad \forall i = n \ldots 1 \end{aligned}$$

and induces a character and context-sensitive word representation $h_i \in \mathbb{R}^{100}$ as

$$h_i = f_i^{\mathcal{W}} \oplus b_i^{\mathcal{W}}$$

for each $i = 1 \ldots n$. For convenience, we write the entire operation as a mapping BiLSTM$_\Theta$:

$$(h_1 \ldots h_n) \leftarrow \text{BiLSTM}_\Theta(w_1 \ldots w_n)$$

$$\bar{h} = \sum_{i=1}^{n} h_i \tag{1}$$

4.2 Domain Classification

Our Multitask domain classification formulation is motivated by a desire to avoid computing the full partition function during test time, which tends to be the slowest component of a multiclass neural network classifer, as has been documented before by (Jozefowicz et al., 2016) and (Mikolov et al., 2013), amongst others.

[4]For simplicity, we assume some random initial state vectors such as $f_0^{\mathcal{C}}$ and $b_{|w_i|+1}^{\mathcal{C}}$ when we describe LSTMs.

However, we also want access to reliable probability estimates instead of raw scores - we accomplish this by constructing a custom loss function. During training, each domain classifier receives in-domain (IND) and out-of-domain (OOD) utterances, and we adapt the one-sided selection mechanism of (Kubat et al., 1997) to prevent OOD utterances from overpowering IND utterances, thus an utterance in a domain $d \in \mathcal{D}$ is considered as an IND utterance in the viewpoint of domain d and OOD for all other domains.

We first use the shared encoder to compute the utterance representation $\bar{h}$ as previously described. Then we define the probability of domain $\tilde{d}$ for the utterance by mapping $\bar{h}$ to a 2-dimensional output vector with a linear transformation for each domain $\tilde{d}$ as

$$z^{\tilde{d}} = \sigma(W^{\tilde{d}} \cdot \bar{h} + b^{\tilde{d}})$$

$$p(\tilde{d}|\bar{h}) \propto \begin{cases} \exp\left([z^{\tilde{d}}]_{IND}\right), & \text{if } \tilde{d} = d \\ \exp\left([z^{\tilde{d}}]_{OOD}\right), & \text{otherwise} \end{cases}$$

where σ is scaled exponential linear unit (SeLU) for normalized activation outputs (Klambauer et al., 2017) and $[z^{\tilde{d}}]_{IND}$ and $[z^{\tilde{d}}]_{OOD}$ denote the values in the IND and OOD position of vector $z^{\tilde{d}}$.

We define the joint domain classification loss $\mathcal{L}^{\mathcal{D}}$ as the summation of positive ($\mathcal{L}^P$) and negative ($\mathcal{L}^N$) class loss functions [5]:

$$\begin{aligned} \mathcal{L}^P\left(\Theta, \Theta^{\tilde{d}}\right) &= -\log p\left(\tilde{d}|\bar{h}\right) \\ \mathcal{L}^N\left(\Theta, \Theta^{\tilde{d}}\right) &= -\frac{1}{k-1}\left(\sum_{\bar{d} \in \mathcal{D}, \bar{d} \neq \tilde{d}} \log p\left(\bar{d}|\bar{h}\right)\right) \\ \mathcal{L}^{\mathcal{D}}\left(\Theta, \Theta^{\tilde{d}}\right) &= L^P\left(\Theta, \Theta^{\tilde{d}}\right) + L^N\left(\Theta, \Theta^{\tilde{d}}\right) \end{aligned}$$

where k is the total number of domains. We divide the second term by $k-1$ so that $\mathcal{L}^P$ and $\mathcal{L}^N$ are balanced in terms of the ratio of the training examples for a domain to those for other domains. While a softmax over the entire domains tends to highlight only the ground-truth domain while suppressing all the rest, the our joint domain classification with a softmax over two classes is designed to produce a more balanced confidence score per domain independent of other domains.

[5]$\Theta^{\tilde{d}}$ denotes the additional parameters in the classification layer for domain $\tilde{d}$.

4.3 Personalized Attention

We explore encoding a user's domain preferences in two ways. Our baseline method is a *1-bit flag* that is appended to the input features of each domain-specific classifier. Our novel *personalized attention* method induces domain embeddings by supervising an attention mechanism to attend to a user's enabled domains with different weights depending on their relevance. The domain embedding matrix in Figure 1 represents the embeddings of a user's enabled domains. We hypothesize that attention enables the network learn richer representations of user preferences and domain co-occurrence features.

Let $e_{\mathcal{D}}(\tilde{d}) \in R^{100}$ and $\bar{h} \in R^{100}$ denote the domain embeddings for domain $\tilde{d}$ and the utterance representation calculated by Eq. (1), respectively. The domain attention weights for a given user u who has a preferred domain list $d^{(u)} = \left(\tilde{d}_1^{(u)}, \ldots, \tilde{d}_k^{(u)}\right)$ are calculated by the dot-product operation,

$$a_i = \bar{h} \cdot e_{\mathcal{D}}\left(\tilde{d}_i^{(u)}\right) \qquad \forall i = 1 \ldots k$$

The final, normalized attention weights $\bar{a}$ are obtained after normalization via a softmax layer,

$$\bar{a}_i = \frac{\exp(a_i)}{\sum_{j=1}^{k} \exp(a_j)} \qquad \forall i = 1 \ldots k$$

The weighted combination of domain embeddings is

$$\bar{S}^{attended} = \sum_{i=1}^{k} \left(\bar{a}_i \cdot e_{\mathcal{D}}\left(\tilde{d}_i^{(u)}\right)\right)$$

Finally the two representations of enabled domains, namely the *attention* model and *1-bit flag* are then concatenated with the utterance representation and used to make per-domain predictions via domain-specific affine transformations:

$$\bar{z}_{att} = \bar{h} \oplus \bar{S}^{attended}$$
$$\bar{z}_{1bit} = \bar{h} \oplus \mathbb{I}(\tilde{d} \in enabled)$$

Here $\mathbb{I}(\bar{d} \in enabled)$ is a 1-bit indicator for whether the domain is enabled by the user or not. $\bar{z}_{att}$ and $\bar{z}_{1bit}$ represent the encoded hidden state of the `Attention` and `1-Bit Flag` configurations of the model from the experiment section. In our experiments we will compare these two ways of encoding personalization information, as well as evaluate a variant that combines the two. In this way we can ascertain whether the two personalization signals are complementary via an ablation study on the full model.

4.4 Domain Bootstrapping

Our model separates the responsibilities for utterance representation and domain classification between the shared encoder and the domain-specific classifiers. That is, the shared encoder needs to be retrained only if it cannot encode an utterance well (e.g., a new domain introduces completely new words) and the existing domain classifiers need to be retrained only when the shared encoder changes. For adding new domains efficiently without full retraining, the only two components in the architecture need to be updated for each new domain $\tilde{d}_{new}$, are the domain embeddings for the new domain and its domain-specific classifier.[6] We keep the weights of the encoder network frozen and use the hidden state vector $\bar{h}$, calculated by Eq. 1, as a feature vector to feed into the downstream classifiers. To initialize the m-dimensional domain embeddings $e_{\tilde{d}_{new}}$, we use the column-wise average of all utterance vectors in the training data $\bar{h}^{avg}$, and project it to the domain embedding space using a matrix $U \in R^{m \times m}$. Thus,

$$e_{\tilde{d}_{new}} = U^{*} \cdot \bar{h}^{avg}$$

The parameters of U^{*} are learned using the column-wise average utterance vectors $\bar{h}_j^{avg}$ and learned domain vectors for all existing domains d_j

$$U^{*} = \arg\min_{U} ||U \cdot \bar{h}_j^{avg} - e_{d_j}|| \quad \forall d_j \in \mathcal{D}$$

This is a write-to-memory operation that creates a new domain representation after attending to all existing domain representations. We then train the parameters of the domain-specific classifier with the new domain's data while keeping the encoder fixed. This mechanism allows us to efficiently support new domains that appear in-between full model deployment cycles without compromising performance on existing domains. A full model refresh would require us to fully retrain with the domains that have appeared in the intermediate period.

[6]We have assumed that the shared encoder covers most of the vocabulary of new domains; otherwise, the entire network may need to be retrained. Based on our observation of live usage data, this assumption is reasonable since the shared encoder after initial training is still shown to cover 95% of the vocabulary of new domains added in the subsequent week.

Table 1: The performance of different variants of our neural model in terms of top-N accuracy. `Binary` trains a separate binary classifier for each skill. `MultiClass` has a shared encoder followed by a softmax. `MultiTask` replaces the softmax with per-skill classifiers. `1-Bit Flag` adds a single bit for personalization to each skill classifier in MultiTask. `Attention` extends MultiTask with personalized attention. The last 3 models are personalized. **Best single encoding.*

5 Experiments

In this section we aim to demonstrate the effectiveness of our model architecture in two settings. First, we will demonstrate that attention based personalization significantly outperforms the baseline approach. Secondly, we will show that our model new domain bootstrapping procedure results in accuracies comparable to full retraining while requiring less than 1% of the orignal training time.

5.1 Experimental Setup

Weak: This is a weakly supervised dataset was generated by preprocessing utterances with strict invocation patterns according to the setup mentioned in Section 3. The dataset consists of 5.34M utterances from 637,975 users across 1,500 different skills. Since we are interested in capturing the temporal effects of the dataset as well as personalization effects, we partitioned the data based both on user and time. Our core training data for the experiments in this paper was drawn from one month of live usage, the validation data came from the next 15 days of usage, and the test data came from the subsequent 15 days. The training, validation and test sets are user-independent, and each user belongs to only one of the three sets to ensure no leakage of information.

MTurk: Since the Weak dataset is generated by weak supervision, we verified the performance of our approach with human generated utterances. A random sample of 12,428 utterances from the test partition of users were presented to 300 human judges, who were asked to produce two natural ways to issue the same command. This dataset is treated as a representative clean held out test set on which we can observe the generalization of our weakly supervised training and validation data to natural language.

New Skills: In order to simulate the scenario in which new skills appear within a week between model updates, we selected 250 new skills which do not overlap with the skills in the Weak dataset. The vocabulary size of 1,500 skills is 200K words, and on average, 5% of the vocabulary for new skills is not covered. We randomly sampled 4,000 unique utterances for each skill using the same weak supervision method, and split them into 3,000 utterances for training and 1,000 for testing.

5.2 Results and Discussion

Generalization from Weakly Supervised to Natural Utterances We first show the progression of model performance as we add more components to show their individual contribution. Secondly, we show that training our models on a weakly supervised dataset can generalize to natural speech by showing their test performance on the human-annotated test data. Finally, we compare two personalization strategies.

The full results are summarized in Table 1, which shows the top-N test results separately for the Weak dataset (weakly supervised) and MTurk dataset (human-annotated). We report top-N accuracy to show the potential for further re-ranking or disambiguation downstream. For top-1 results on the Weak dataset, using a separate binary classifier for each domain (Binary) shows a prediction accuracy at 78.29% and using a softmax layer on top of the shared encoder (MultiClass) shows a comparable accuracy at 78.58%. The performance shows a slight improvement when using the Multitask neural loss structure, but adding personalization signals to the Multitask structure showed a significant boost in performance. We noted the large difference between the 1-bit and attention architecture. At 94.83% accuracy, attention resulted in 35.6% relative error reduction over the 1-bit baseline 91.97% on the Weak validation set and 23.25% relative on the MTurk test set. We hypothesize that this may be because the attention mechanism allows the model to focus on complementary features in case of overlapping domains as well as learning domain co-occurrence statistics, both of which are not possible with the simple 1-bit flag.

When both personalization representations were combined, the performance peaked at 95.19% for the Weak dataset and a more modest

	Time	Accuracy
Binary	34.81	78.13
Expand	30.34	94.03
Refresh	5300.18	94.58

Table 2: Comparison of per-epoch training time (seconds) and top-1 accuracy (%) on an NVIDIA Tesla M40 GPU.

89.65% for the MTurk dataset. The improvement trend is extremely consistent across all top-N results for both of the Weak and MTurk datasets across all experiments. The disambiguation task is complex due to similar and overlapping skills, but the results suggest that incorporating personalization signals equip the models with much better discriminative power. The results also suggest that the two mechanisms for encoding personalization provide a small amount of complementary information since combining them together is better than using them individually. Although the performance on the Weak dataset tends to be more optimistic, the best performance on the human-annotated test data is still close to 90% for top-1 accuracy, which suggests that training our model with the samples derived from the invocation patterns can generalize well to natural utterances.

Rapid Bootstrapping of New Skills We show the results when new domains are added to an IPDA and the model needs to efficiently accommodate them with a limited number of data samples. We show the classification performance on the skills in the New Skills dataset while assuming we have access to the WEAK dataset to pre-train our model for transfer learning. In the `Binary` setting, a domain-specific binary classifier is trained for each domain. `Expand` describes the case in which we incrementally train on top of an existing model. `Refresh` is the setting in which the model is fully retrained from scratch with the new data - which would be ideal in case there were no time constraints.

We record the average training time for each epoch and the performance is measured with top-1 classification accuracy over new skills. The experiment results can be found in Table 2. Adapting a new skill is two orders of magnitude faster (30.34 seconds) than retraining the model (5300.18 seconds) while achieving 94.03% accuracy which is comparable to 94.58% accuracy of full retraining. The first two techniques can also be easily parallelized unlike the `Refresh` configuration.

	Top-1	Top-3	Top-5
Full	6.17	14.30	20.41
Enabled	85.62	96.15	98.06

Table 3: Top-N prediction accuracy (%) on the full skill set (Full) and only enabled skills (Enabled).

Behavior of Attention Mechanism Our expectation is that the model is able to learn to attend the relevant skills during the inference process. To study the behavior of the attention layer, we compute the top-N prediction accuracy based on the most relevant skills defined by the attention weights. In this experiment, we considered the subset of users who had enabled more than 20 domains to exclude trivial cases[7]. The results are shown in Table 3. When the model attends to the entire set of 1500 (*Full*), the top-5 prediction accuracy is 20.41%, which indicates that a large number of skills can process the utterance, and thus it is highly likely to miss the correct one in the top-5 predictions. This ambiguity issue can be significantly improved by users' enabled domain lists as proved by the accuracies (*Enabled*): 85.62% for top-1, 96.15% for top-3, and 98.06% for top-5.[8] Thus the attention mechanism can thus be viewed as an initial soft selection which is then followed by a fine-grained selection at the classification stage.

End-to-End User Evaluation All intermediate metrics on this task are proxies to a human customer's eventual evaluation. In order to assess the user experience, we need to measure its end-to-end performance. For a brief end-to-end system evaluation, 983 utterances from 283 domains were randomly sampled from the test set in the large-scale IPDA setting. 15 human judges (male=12, female=3) rated the system responses, 1 judge per utterance, on a 5-point Likert scale with 1 being *Terrible* and 5 being *Perfect*. The judgment score of 3 or above was taken as *SUCCESS* and 2 or below as *DEFECT*. The end-to-end *SUCCESS* rate,

[7]Thus, the random prediction accuracy on enabled domains is less than 5% and across the Full domain list is 0.066%

[8]Visual inspection of the embeddings confirms that meaningful clusters are learned. We see clusters related to home automation, commerce, cooking, trivia etc, we show some examples in Figure 2, 3 and 4. However there are still other clusters where the the relationships cannot be established as easily. An example of these is show in Figure 5. The personalized attention mechanism is learned using the semantic content as well as personalization signals, so we hypothesize clusters like this may be capturing user tendencies to enable these domains in a correlated manner.

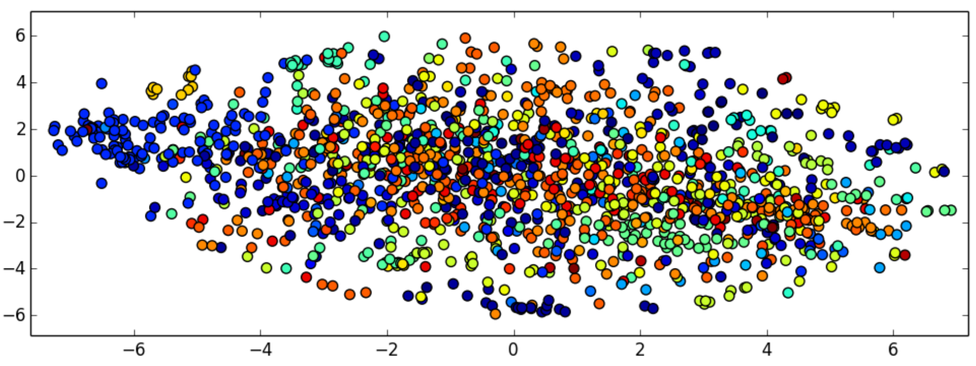

Figure 2: Embeddings of different domain categories visualized in 2D using TSNE (van der Maaten and Hinton, 2008). Different colors represent different categories, for e.g. the large blue cluster on the left is Home Automation.

thus user satisfaction, was shown to be 95.52%. The discrepancy between this score and the score produced on MTurk dataset indicates that even in cases in which the model makes classification mistakes, some of these interpretations remain perceptually meaningful to humans.

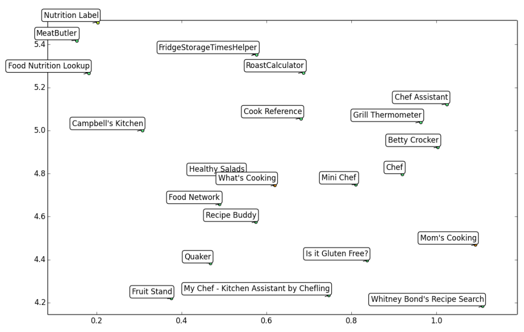

Figure 4: A cluster of domains related to cooking.

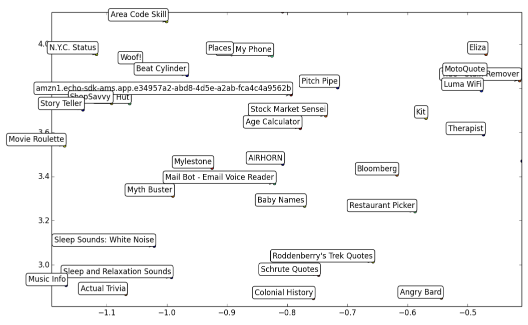

Figure 5: A mixed cluster with several different domain categories represented.

6 Conclusions

We have described a neural model architecture to address large-scale skill classification in an IPDA used by tens of millions of users every day. We have described how personalization features and an attention mechanism can be used for handling ambiguity between domains. We have also shown that the model can be extended efficiently and incrementally for new domains, saving multiple orders of magnitude in terms of training time. The model also addresses practical constraints of having a low memory footprint, low latency and being easily parallelized, all of which are important characteristics for real-time production systems. In future work, we plan to incorporate various types of context (e.g. anaphora, device-specific capabilities) and dialogue history into a large-scale NLU system.

Abstract

Multimodal affective computing, learning to recognize and interpret human affect and subjective information from multiple data sources, is still challenging because: (i) it is hard to extract informative features to represent human affects from heterogeneous inputs; (ii) current fusion strategies only fuse different modalities at abstract levels, ignoring time-dependent interactions between modalities. Addressing such issues, we introduce a hierarchical multimodal architecture with attention and word-level fusion to classify utterance-level sentiment and emotion from text and audio data. Our introduced model outperforms state-of-the-art approaches on published datasets, and we demonstrate that our model's synchronized attention over modalities offers visual interpretability.

1 Introduction

With the recent rapid advancements in social media technology, affective computing is now a popular task in human-computer interaction. Sentiment analysis and emotion recognition, both of which require applying subjective human concepts for detection, can be treated as two affective computing subtasks on different levels (Poria et al., 2017a). A variety of data sources, including voice, facial expression, gesture, and linguistic content have been employed in sentiment analysis and emotion recognition. In this paper, we focus on a multimodal structure to leverage the advantages of each data source. Specifically, given an utterance, we consider the linguistic content and acoustic characteristics together to recognize the opinion or emotion. Our work is important and useful because speech is the most basic and commonly used form of human expression.

A basic challenge in sentiment analysis and emotion recognition is filling the gap between extracted features and the actual affective states (Zhang et al., 2017). The lack of high-level feature associations is a limitation of traditional approaches using low-level handcrafted features as representations (Seppi et al., 2008; Rozgic et al., 2012). Recently, deep learning structures such as CNNs and LSTMs have been used to extract high-level features from text and audio (Eyben et al., 2010a; Poria et al., 2015). However, not all parts of the text and vocal signals contribute equally to the predictions. A specific word may change the entire sentimental state of text; a different vocal delivery may indicate inverse emotions despite having the same linguistic content. Recent approaches introduce attention mechanisms to focus the models on informative words (Yang et al., 2016) and attentive audio frames (Mirsamadi et al., 2017) for each individual modality. However, to our knowledge, there is no common multimodal structure with attention for utterance-level sentiment and emotion classification. To address such issue, we design a deep hierarchical multimodal architecture with an attention mechanism to classify utterance-level sentiments and emotions. It extracts high-level informative textual and acoustic features through individual bidirectional gated recurrent units (GRU) and uses a multi-level attention mechanism to select the informative features in both the text and audio module.

Another challenge is the fusion of cues from heterogeneous data. Most previous works focused on combining multimodal information at a holistic level, such as integrating independent predictions of each modality via algebraic rules (Wöllmer et al., 2013) or fusing the extracted modality-specific features from entire utterances

* Equally Contribution

(Poria et al., 2016). They extract word-level features in a text branch, but process audio at the frame-level or utterance-level. These methods fail to properly learn the time-dependent interactions across modalities and restrict feature integration at timestamps due to the different time scales and formats of features of diverse modalities (Poria et al., 2017a). However, to determine human meaning, it is critical to consider both the linguistic content of the word and how it is uttered. A loud pitch on different words may convey inverse emotions, such as the emphasis on "hell" for anger but indicating happy on "great". Synchronized attentive information across text and audio would then intuitively help recognize the sentiments and emotions. Therefore, we compute a forced alignment between text and audio for each word and propose three fusion approaches (horizontal, vertical, and fine-tuning attention fusion) to integrate both the feature representations and attention at the word-level.

We evaluated our model on four published sentiment and emotion datasets. Experimental results show that the proposed architecture outperforms state-of-the-art approaches. Our methods also allow for attention visualization, which can be used for interpreting the internal attention distribution for both single- and multi-modal systems. The contributions of this paper are: (i) a hierarchical multimodal structure with attention mechanism to learn informative features and high-level associations from both text and audio; (ii) three word-level fusion strategies to combine features and learn correlations in a common time scale across different modalities; (iii) word-level attention visualization to help human interpretation.

The paper is organized as follows: We list related work in section 2. Section 3 describes the proposed structure in detail. We present the experiments in section 4 and provide the result analysis in section 5. We discuss the limitations in section 6 and conclude with section 7.

2 Related Work

Despite the large body of research on audio-visual affective analysis, there is relatively little work on combining text data. Early work combined human transcribed lexical features and low-level hand-crafted acoustic features using feature-level fusion (Forbes-Riley and Litman, 2004; Litman and Forbes-Riley, 2004). Others used SVMs fed bag of words (BoW) and part of speech (POS) features in addition to low-level acoustic features (Seppi et al., 2008; Rozgic et al., 2012; Savran et al., 2012; Rosas et al., 2013; Jin et al., 2015). All of the above extracted low-level features from each modality separately. More recently, deep learning was used to extract higher-level multimodal features. Bidirectional LSTMs were used to learn long-range dependencies from low-level acoustic descriptors and derivations (LLDs) and visual features (Eyben et al., 2010a; Wöllmer et al., 2013). CNNs can extract both textual (Poria et al., 2015) and visual features (Poria et al., 2016) for multiple kernel learning of feature-fusion. Later, hierarchical LSTMs were used (Poria et al., 2017b). A deep neural network was used for feature-level fusion in (Gu et al., 2018) and (Zadeh et al., 2017) introduced a tensor fusion network to further improve the performance. A very recent work using word-level fusion was provided by (Chen et al., 2017). The key differences between this work and the proposed architecture are: (i) we design a fine-tunable hierarchical attention structure to extract word-level features for each individual modality, rather than simply using the initialized textual embedding and extracted LLDs from COVAREP (Degottex et al., 2014); (ii) we propose diverse representation fusion strategies to combine both the word-level representations and attention weights, instead of using only word-level fusion; (iii) our model allows visualizing the attention distribution at both the individual modality and at fusion to help model interpretability.

Our architecture is inspired by the document classification hierarchical attention structure that works at both the sentence and word level (Yang et al., 2016). For audio, an attention-based BLSTM and CNN were applied to discovering emotion from frames (Huang and Narayanan, 2016; Neumann and Vu, 2017). Frame-level weighted-pooling with local attention was shown to outperform frame-wise, final-frame, and frame-level mean-pooling for speech emotion recognition (Mirsamadi et al., 2017).

3 Method

We introduce a multimodal hierarchical attention structure with word-level alignment for sentiment analysis and emotion recognition (Figure 1). The model consists of three major parts: text attention module, audio attention module, and word-level fusion module. We first make a forced alignment between the text and audio during preprocessing. Then, the text attention module and audio attention module extract the features from the corresponding inputs (shown in Algorithm 1). The word-level fusion module fuses the extracted feature vectors and makes the final prediction via a shared representation (shown in Algorithm 2).

3.1 Forced Alignment and Preprocessing

The forced alignment between the audio and text on the word-level prepares the different data for feature extraction. We align the data at the word-level because words are the basic unit in English for human speech comprehension. We used *aeneas*[1] to determine the time interval for each word in the audio file based on the Sakoe-Chiba Band Dynamic Time Warping (DTW) algorithm (Sakoe and Chiba, 1978).

For the text input, we first embedded the words into 300-dimensional vectors by *word2vec* (Mikolov et al., 2013), which gives us the best result compared to GloVe and LexVec. Unknown words were randomly initialized. Given a sentence S with N words, let w_i represent the ith word. We embed the words through the *word2vec* embedding matrix W_e by:

$$T_i = W_e w_i, i \in [1, N] \tag{1}$$

where T_i is the embedded word vector.

For the audio input, we extracted Mel-frequency spectral coefficients (MFSCs) from raw audio signals as acoustic inputs for two reasons. Firstly, MFSCs maintain the locality of the data by preventing new bases of spectral energies resulting from discrete cosine transform in MFCCs extraction (Abdel-Hamid et al., 2014). Secondly, it has more dimensions in the frequency domain that aid learning in deep models (Gu et al., 2017). We used 64 filter banks to extract the MFSCs for each audio frame to form the MFSCs map. To facilitate training, we only used static coefficients. Each word's MFSCs can be represented as a matrix with $64 \times n$ dimensions, where n is the interval for the given word in frames. We zero-pad all intervals to the same length L, the maximum frame numbers of the word in the dataset. We did extract LLD features using OpenSmile (Eyben et al., 2010b) software and combined them with the MFSCs during our training stage. However, we did not find an obvious performance improvement, especially for the sentiment analysis. Considering the training cost of the proposed hierarchical acoustic architecture, we decided the extra features were not worth the tradeoff. The output is a 3D MFSCs map with dimensions $[N, 64, L]$.

[1]https://www.readbeyond.it/aeneas/

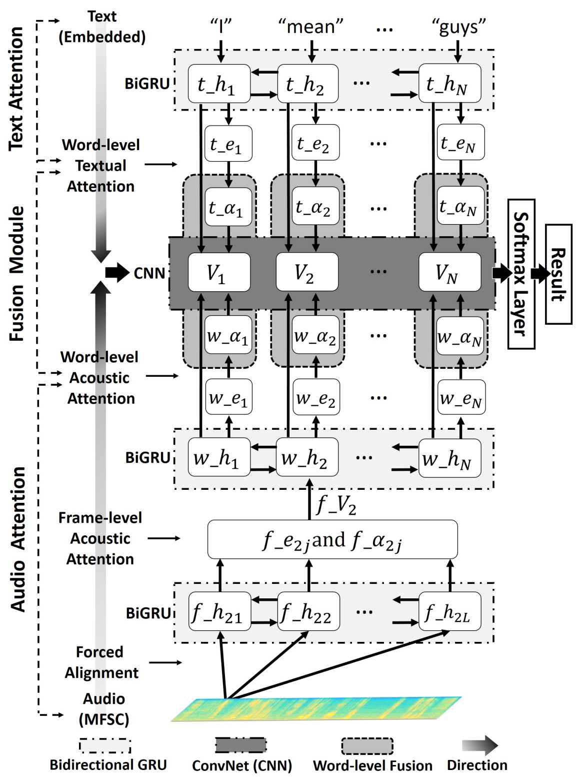

Figure 1: Overall Architecture

3.2 Text Attention Module

To extract features from embedded text input at the word level, we first used bidirectional GRUs, which are able to capture the contextual information between words. It can be represented as:

$$t\_h_i^{\rightarrow}, t\_h_i^{\leftarrow} = bi\_GRU(T_i), i \in [1, N] \tag{2}$$

where bi_GRU is the bidirectional GRU, $t\_h_i^{\rightarrow}$ and $t\_h_i^{\leftarrow}$ denote respectively the forward and backward contextual state of the input text. We combined $t\_h_i^{\rightarrow}$ and $t\_h_i^{\leftarrow}$ as t_h_i to represent the feature vector for the ith word. We choose GRUs instead of LSTMs because our experiments show that LSTMs lead to similar performance (0.07% higher accuracy) with around 25% more trainable parameters.

To create an informative word representation, we adopted a word-level attention strategy that generates a one-dimensional vector denoting the importance for each word in a sequence (Yang et al., 2016). As defined by (Bahdanau et al.,

Algorithm 1 FEATURE EXTRACTION

```

23:        $f\_V_i \leftarrow weightedSum(f\_\alpha_{ij}, f\_h_{ij})$
24:        Word-Level Attention Module
25:        $w\_h_i \leftarrow bi\_GRU(f\_V_i)$
26:        $w\_e_i \leftarrow getEnergies(w\_h_i)$
27:        $w\_\alpha_i \leftarrow getDistribution(w\_e_i)$
28:    end for
29:    return $w\_h_i, w\_\alpha_i$
30: end procedure
```

2014), we compute the textual attentive energies t_e_i and textual attention distribution t_α_i by:

$$t\_e_i = tanh(W_t t\_h_i + b_t), i \in [1, N] \quad (3)$$

$$t\_\alpha_i = \frac{exp(t\_e_i{}^\top v_t)}{\sum_{k=1}^{N} exp(t\_e_k{}^\top v_t)} \quad (4)$$

where W_t and b_t are the trainable parameters and v_t is a randomly-initialized word-level weight vector in the text branch. To learn the word-level interactions across modalities, we directly use the textual attention distribution t_α_i and textual bidirectional contextual state t_h_i as the output to aid word-level fusion, which allows further computations between text and audio branch on both the contextual states and attention distributions.

3.3 Audio Attention Module

We designed a hierarchical attention model with frame-level acoustic attention and word-level attention for acoustic feature extraction.

Frame-level Attention captures the important MFSC frames from the given word to generate the word-level acoustic vector. Similar to the text attention module, we used a bidirectional GRU:

$$f\_h_{ij}^{\rightarrow}, f\_h_{ij}^{\leftarrow} = bi\_GRU(A_{ij}), j \in [1, L] \quad (5)$$

where $f\_h_{ij}^{\rightarrow}$ and $f\_h_{ij}^{\leftarrow}$ denote the forward and backward contextual states of acoustic frames. A_{ij} denotes the MFSCs of the jth frame from the ith word, $i \in [1, N]$. f_h_{ij} represents the hidden state of the jth frame of the ith word, which consists of $f\_h_{ij}^{\rightarrow}$ and $f\_h_{ij}^{\leftarrow}$. We apply the same attention mechanism used for textual attention module to extract the informative frames using equation 3 and 4. As shown in Figure 1, the input of equation 3 is f_h_{ij} and the output is the frame-level acoustic attentive energies f_e_{ij}. We calculate the frame-level attention distribution f_α_{ij} by using f_e_{ij} as the input for equation 4. We form the word-level acoustic vector f_V_i by taking a weighted sum of bidirectional contextual state f_h_{ij} of the frame and the corresponding frame-level attention distribution f_α_{ij} Specifically,

$$f\_V_i = \sum\nolimits_j f\_\alpha_{ij} f\_h_{ij} \quad (6)$$

Word-level Attention aims to capture the word-level acoustic attention distribution w_α_i based on formed word vector f_V_i. We first used equation 2 to generate the word-level acoustic contextual states w_h_i, where the input is f_V_i and $w\_h_i = (w\_h_i^{\rightarrow}, w\_h_i^{\leftarrow})$. Then, we compute the word-level acoustic attentive energies w_e_i via equation 3 as the input for equation 4. The final output is an acoustic attention distribution w_α_i from equation 4 and acoustic bidirectional contextual state w_h_i.

3.4 Word-level Fusion Module

Fusion is critical to leveraging multimodal features for decision-making. Simple feature concatenation without considering the time scales ignores the associations across modalities. We introduce word-level fusion capable of associating the text and audio at each word. We propose three fusion strategies (Figure 2 and Algorithm 2): horizontal fusion, vertical fusion, and fine-tuning attention fusion. These methods allow easy synchronization between modalities, taking advantage of the attentive associations across text and audio, creating a shared high-level representation.

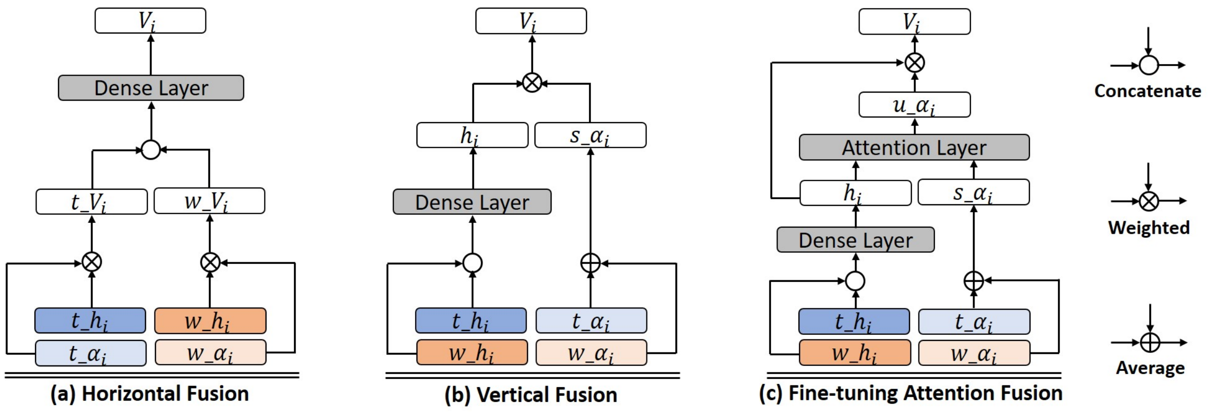

Figure 2: Fusion strategies. t_h_i: word-level textual bidirectional state. t_α_i: word-level textual attention distribution. w_h_i: word-level acoustic bidirectional state. w_α_i: word-level acoustic attention distribution. s_α_i: shared attention distribution. u_α_i: fine-tuning attention distribution. V_i: shared word-level representation.

Algorithm 2 FUSION

```
 1: procedure FUSION BRANCH
 2:     Horizontal Fusion (HF)
 3:     for $i \in [1, N]$ do
 4:         $t\_V_i \leftarrow weighted(t\_\alpha_i, t\_h_i)$
 5:         $w\_V_i \leftarrow weighted(w\_\alpha_i, w\_h_i)$
 6:         $V_i \leftarrow dense([t\_V_i, w\_V_i])$
 7:     end for
 8:     Vertical Fusion (VF)
 9:     for $i \in [1, N]$ do

Horizontal Fusion (HF) provides the shared representation that contains both the textual and acoustic information for a given word (Figure 2 (a)). The HF has two steps: (i) combining the bidirectional contextual states (t_h_i and w_h_i in Figure 1) and attention distributions for each branch (t_α_i and w_α_i in Figure 1) independently to form the word-level textual and acoustic representations. As shown in Figure 2, given the input (t_α_i, t_h_i) and (w_α_i, w_h_i), we first weighed each input branch by:

$$t\_V_i = t\_\alpha_i t\_h_i \tag{7}$$

$$w\_V_i = w\_\alpha_i w\_h_i \tag{8}$$

where t_V_i and w_V_i are word-level representations for text and audio branches, respectively; (ii) concatenating them into a single space and further applying a dense layer to create the shared context vector V_i, and $V_i = (t\_V_i, w\_V_i)$. The HF combines the unimodal contextual states and attention weights; there is no attention interaction between the text modality and audio modality. The shared vectors retain the most significant characteristics from respective branches and encourages the decision making to focus on local informative features.

Vertical Fusion (VF) combines textual attentions and acoustic attentions at the word-level, using a shared attention distribution over both modalities instead of focusing on local informative representations (Figure 2 (b)). The VF is computed in three steps: (i) using a dense layer after the concatenation of the word-level textual (t_h_i) and acoustic (w_h_i) bidirectional contextual states to form the shared contextual state h_i; (ii) averaging the textual (t_α_i) and acoustic (w_α_i) attentions for each word as the shared attention distribution s_α_i; (iii) computing the weight of h_i and s_α_i as final shared context vectors V_i, where $V_i = h_i s\_\alpha_i$. Because the shared attention distribution (s_α_i) is based on averages of unimodal attentions, it is a joint attention of both textual and acoustic attentive information.

Fine-tuning Attention Fusion (FAF) preserves the original unimodal attentions and provides a fine-tuning attention for the final prediction (Figure2 (c)). The averaging of attention weights in vertical fusion potentially limits the representational power. Addressing such issue, we propose a trainable attention layer to tune the shared attention in three steps: (i) computing the shared attention distribution s_α_i and shared bidirectional contextual states h_i separately using the same approach as in vertical fusion; (ii) applying attention fine-tuning:

$$u\_e_i = tanh(W_u h_i + b_u) \tag{9}$$

$$u\_\alpha_i = \frac{exp(u\_e_i{}^\top v_u)}{\sum_{k=1}^{N} exp(u\_e_k{}^\top v_u)} + s\_\alpha_i \tag{10}$$

where W_u, b_u, and v_u are additional trainable parameters. The u_α_i can be understood as the sum of the fine-tuning score and the original shared attention distribution s_α_i; (iii) calculating the weight of u_α_i and h_i to form the final shared context vector V_i.

3.5 Decision Making

The output of the fusion layer V_i is the ith shared word-level vectors. To further make use of the combined features for classification, we applied a CNN structure with one convolutional layer and one max-pooling layer to extract the final representation from shared word-level vectors (Poria et al., 2016; Wang et al., 2016). We set up various widths for the convolutional filters (Kim, 2014) and generated a feature map c_k by:

$$f_i = tanh(W_c V_{i:i+k-1} + b_c) \tag{11}$$

$$c_k = max\{f_1, f_2, ..., f_N\} \tag{12}$$

where k is the width of the convolutional filters, f_i represents the features from window i to $i+k-1$. W_c and b_c are the trainable weights and biases. We get the final representation c by concatenating all the feature maps. A softmax function is used for the final classification.

4 Experiments

4.1 Datasets

We evaluated our model on four published datasets: two multimodal sentiment datasets (MOSI and YouTube) and two multimodal emotion recognition datasets (IEMOCAP and EmotiW).

MOSI dataset is a multimodal sentiment intensity and subjectivity dataset consisting of 93 reviews with 2199 utterance segments (Zadeh et al., 2016). Each segment was labeled by five individual annotators between -3 (strong negative) to +3 (strong positive). We used binary labels based on the sign of the annotations' average.

YouTube dataset is an English multimodal dataset that contains 262 positive, 212 negative, and 133 neutral utterance-level clips provided by (Morency et al., 2011). We only consider the positive and negative labels during our experiments.

IEMOCAP is a multimodal emotion dataset including visual, audio, and text data (Busso et al., 2008). For each sentence, we used the label agreed on by the majority (at least two of the three annotators). In this study, we evaluate both the 4-catgeory (*happy+excited*, *sad*, *anger*, and *neutral*) and 5-catgeory(*happy+excited*, *sad*, *anger*, *neutral*, and *frustration*) emotion classification problems. The final dataset consists of 586 *happy*, 1005 *excited*, 1054 *sad*, 1076 *anger*, 1677 *neutral*, and 1806 *frustration*.

EmotiW[2] is an audio-visual multimodal utterance-level emotion recognition dataset consist of video clips. To keep the consistency with the IEMOCAP dataset, we used four emotion categories as the final dataset including 150 *happy*, 117 *sad*, 133 *anger*, and 144 *neutral*. We used IBM Watson[3] speech to text software to transcribe the audio data into text.

4.2 Baselines

We compared the proposed architecture to published models. Because our model focuses on extracting sentiment and emotions from human speech, we only considered the audio and text branch applied in the previous studies.

4.2.1 Sentiment Analysis Baselines

BL-SVM extracts a bag-of-words as textual features and low-level descriptors as acoustic features. An SVM structure is used to classify the sentiments (Rosas et al., 2013).

LSTM-SVM uses LLDs as acoustic features and bag-of-n-grams (BoNGs) as textual features. The final estimate is based on decision-level fusion of text and audio predictions (Wöllmer et al., 2013).

Table 1: Comparison of models. *WA* = weighted accuracy. *UA* = unweighted accuracy. * denotes that we duplicated the method from cited research with the corresponding dataset in our experiment.

C-MKL$_1$ uses a CNN structure to capture the textual features and fuses them via multiple kernel learning for sentiment analysis (Poria et al., 2015).

TFN uses a tensor fusion network to extract interactions between different modality-specific features (Zadeh et al., 2017).

LSTM(A) introduces a word-level LSTM with temporal attention structure to predict sentiments on MOSI dataset (Chen et al., 2017).

4.2.2 Emotion Recognition Baselines

SVM Trees extracts LLDs and handcrafted bag-of-words as features. The model automatically generates an ensemble of SVM trees for emotion classification (Rozgic et al., 2012).

GSV-eVector generates new acoustic representations from selected LLDs using Gaussian Supervectors and extracts a set of weighed handcrafted textual features as an eVector. A linear kernel SVM is used as the final classifier (Jin et al., 2015).

C-MKL$_2$ extracts textual features using a CNN and uses openSMILE to extract 6373 acoustic features. Multiple kernel learning is used as the final classifier (Poria et al., 2016).

H-DMS uses a hybrid deep multimodal structure to extract both the text and audio emotional features. A deep neural network is used for feature-level fusion (Gu et al., 2018).

4.2.3 Fusion Baselines

Utterance-level Fusion (UL-Fusion) focuses on fusing text and audio features from an entire utterance (Gu et al., 2017). We simply concatenate the textual and acoustic representations into a joint feature representation. A softmax function is used for sentiment and emotion classification.

Decision-level Fusion (DL-Fusion) Inspired by (Wöllmer et al., 2013), we extract textual and acoustic sentence representations individually and infer the results via two softmax classifiers, respectively. As suggested by Wöllmer, we calculate a weighted sum of the text (1.2) result and audio (0.8) result as the final prediction.

4.3 Model Training

We implemented the model in Keras with Tensorflow as the backend. We set 100 as the dimension for each GRU, meaning the bidirectional GRU dimension is 200. For the decision making, we selected 2, 3, 4, and 5 as the filter width and apply 300 filters for each width. We used the rectified linear unit (ReLU) activation function and set 0.5 as the dropout rate. We also applied batch normalization functions between each layer to overcome internal covariate shift (Ioffe and Szegedy, 2015). We first trained the text attention module and audio attention module individually. Then, we tuned the fusion network based on the word-level representation outputs from each fine-tuning module. For all training procedures, we set the learning rate to 0.001 and used Adam optimization and categorical cross-entropy loss. For all datasets, we considered the speakers independent and used an 80-20 training-testing split. We further separated 20% from the training dataset for validation. We trained the model with 5-fold cross validation and used 8 as the mini batch size. We set the same amount of samples from each class to balance the training dataset during each iteration.

5 Result Analysis

5.1 Comparison with Baselines

The experimental results of different datasets show that our proposed architecture achieves state-of-the-art performance in both sentiment analysis and emotion recognition (Table 1). We re-implemented some published methods (Rosas et al., 2013; Wöllmer et al., 2013) on MOSI to get baselines.

For sentiment analysis, the proposed architecture with FAF strategy achieves 76.4% weighted accuracy, which outperforms all the five baselines (Table 1). The result demonstrates that the proposed hierarchical attention architecture and word-level fusion strategies indeed help improve the performance. There are several findings worth mentioning: (i) our model outperforms the baselines without using the low-level handcrafted acoustic features, indicating the sufficiency of MFSCs; (ii) the proposed approach achieves performance comparable to the model using text, audio, and visual data together (Zadeh et al., 2017). This demonstrates that the visual features do not contribute as much during the fusion and prediction on MOSI; (iii) we notice that (Poria et al., 2017b) reports better accuracy (79.3%) on MOSI, but their model uses a set of utterances instead of a single utterance as input.

For emotion recognition, our model with FAF achieves 72.7% accuracy, outperforming all the baselines. The result shows the proposed model brings a significant accuracy gain to emotion recognition, demonstrating the pros of the fine-tuning attention structure. It also shows that word-level attention indeed helps extract emotional features. Compared to C-MKL$_2$ and SVM Trees that require feature selection before fusion and prediction, our model does not need an additional architecture to select features. We further evaluated our models on 5 emotion categories, including frustration. Our model shows 4.2% performance improvement over H-DMS and achieves 0.644 weighted-F1. As H-DMS only achieves 0.594 F1 and also uses low-level handcrafted features, our model is more robust and efficient.

From Table 1, all the three proposed fusion strategies outperform UL-Fusion and DL-Fusion on both MOSI and IEMOCAP. Unlike utterance-level fusion that ignores the time-scale-sensitive associations across modalities, word-level fusion combines the modality-specific features for each word by aligning text and audio, allowing associative learning between the two modalities, similar to what humans do in natural conversation. The result indicates that the proposed methods improve the model performance by around 6% accuracy. We also notice that the structure with FAF outperforms the HF and VF on both MOSI and IEMOCAP dataset, which demonstrates the effectiveness and importance of the FAF strategy.

Modality	MOSI		IEMOCAP	
	WA	F1	WA	F1
T	75.0	0.748	61.8	0.620
A	60.2	0.604	62.5	0.614
T+A	**76.4**	**0.768**	**72.7**	**0.726**

Table 2: Accuracy (%) and F1 score on text only (T), audio only (A), and multi-modality using FAF (T+A).

Approach	MOSI ↓ YouTube		IEMOCAP ↓ EmotiW	
	WA	F1	WA	F1
Ours-HF	62.9	0.627	59.3	0.584
Ours-VF	64.7	0.643	60.8	0.591
Ours-FAF	**66.2**	**0.665**	**61.4**	**0.608**

Table 3: Accuracy (%) and F1 score for generalization testing.

5.2 Modality and Generalization Analysis

From Table 2, we see that textual information dominates the sentiment prediction on MOSI and there is an only 1.4% accuracy improvement from fusing text and audio. However, on IEMOCAP, audio-only outperforms text-only, but as expected, there is a significant performance improvement by combining textual and audio. The difference in modality performance might because of the more significant role vocal delivery plays in emotional expression than in sentimental expression.

We further tested the generalizability of the proposed model. For sentiment generalization testing, we trained the model on MOSI and tested on the YouTube dataset (Table 3), which achieves 66.2% accuracy and 0.665 F1 scores. For emotion recognition generalization testing, we tested the model (trained on IEMOCAP) on EmotiW and achieves 61.4% accuracy. The potential reasons that may influence the generalization are: (i) the biased labeling for different datasets (five annotators of MOSI vs one annotator of Youtube); (ii) incomplete utterance in YouTube dataset (such as "about", "he", etc.); (iii) without enough speech information (EmotiW is a wild audio-visual dataset that focuses on facial expression).

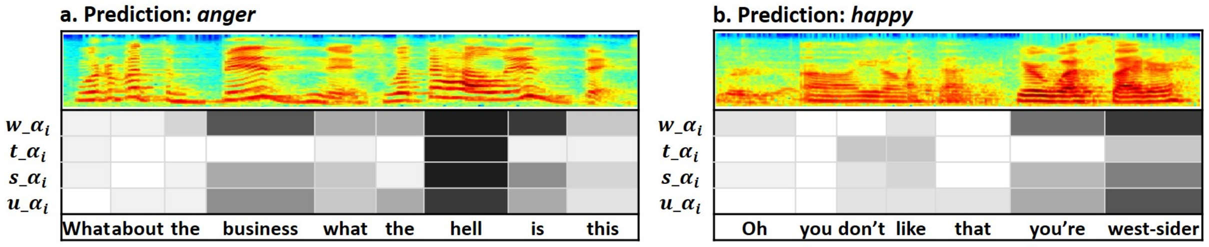

Figure 3: Attention visualization.

5.3 Visualize Attentions

Our model allows us to easily visualize the attention weights of text, audio, and fusion to better understand how the attention mechanism works. We introduce the emotional distribution visualizations for word-level acoustic attention (w_α_i), word-level textual attention (t_α_i), shared attention (s_α_i), and fine-tuning attention based on the FAF structure (u_α_i) for two example sentences (Figure 3). The color gradation represents the importance of the corresponding source data at the word-level.

Based on our visualization, the textual attention distribution (t_α_i) denotes the words that carry the most emotional significance, such as "hell" for *anger* (Figure 3 a). The textual attention shows that "don't", "like", and "west-sider" have similar weights in the *happy* example (Figure 3 b). It is hard to assign this sentence *happy* given only the text attention. However, the acoustic attention focuses on "you're" and "west-sider", removing emphasis from "don't" and "like". The shared attention (s_α_i) and fine-tuning attention (u_α_i) successfully combine both textual and acoustic attentions and assign joint attention to the correct words, which demonstrates that the proposed method can capture emphasis from both modalities at the word-level.

6 Discussion

There are several limitations and potential solutions worth mentioning: (i) the proposed architecture uses both the audio and text data to analyze the sentiments and emotions. However, not all the data sources contain or provide textual information. Many audio-visual emotion clips only have acoustic and visual information. The proposed architecture is more related to spoken language analysis than predicting the sentiments or emotions based on human speech. Automatic speech recognition provides a potential solution for generating the textual information from vocal signals. (ii) The word alignment can be easily applied to human speech. However, it is difficult to align the visual information with text, especially if the text only describes the video or audio. Incorporating visual information into an aligning model like ours would be an interesting research topic. (iii) The limited amount of multimodal sentiment analysis and emotion recognition data is a key issue for current research, especially for deep models that require a large number of samples. Compared large unimodal sentiment analysis and emotion recognition datasets, the MOSI dataset only consists of 2199 sentence-level samples. In our experiments, the EmotiW and MOUD datasets could only be used for generalization analysis due to their small size. Larger and more general datasets are necessary for multimodal sentiment analysis and emotion recognition in the future.

7 Conclusion

In this paper, we proposed a deep multimodal architecture with hierarchical attention for sentiment and emotion classification. Our model aligned the text and audio at the word-level and applied attention distributions on textual word vectors, acoustic frame vectors, and acoustic word vectors. We introduced three fusion strategies with a CNN structure to combine word-level features to classify emotions. Our model outperforms the state-of-the-art methods and provides effective visualization of modality-specific features and fusion feature interpretation.

Abstract

Analyzing human multimodal language is an emerging area of research in NLP. Intrinsically human communication is multimodal (heterogeneous), temporal and asynchronous; it consists of the language (words), visual (expressions), and acoustic (paralinguistic) modalities all in the form of asynchronous coordinated sequences. From a resource perspective, there is a genuine need for large scale datasets that allow for in-depth studies of multimodal language. In this paper we introduce CMU Multimodal Opinion Sentiment and Emotion Intensity (CMU-MOSEI), the largest dataset of sentiment analysis and emotion recognition to date. Using data from CMU-MOSEI and a novel multimodal fusion technique called the Dynamic Fusion Graph (DFG), we conduct experimentation to investigate how modalities interact with each other in human multimodal language. Unlike previously proposed fusion techniques, DFG is highly interpretable and achieves competitive performance compared to the current state of the art.

1 Introduction

Theories of language origin identify the combination of language and nonverbal behaviors (vision and acoustic modality) as the prime form of communication utilized by humans throughout evolution (Müller, 1866). In natural language processing, this form of language is regarded as human multimodal language. Modeling multimodal language has recently become a centric research direction in both NLP and multimodal machine learning (Hazarika et al., 2018; Zadeh et al., 2018a; Poria et al., 2017a; Baltrušaitis et al., 2017; Chen et al., 2017). Studies strive to model the dual dynamics of multimodal language: intra-modal dynamics (dynamics within each modality) and cross-modal dynamics (dynamics across different modalities). However, from a resource perspective, previous multimodal language datasets have severe shortcomings in the following aspects:

Diversity in the training samples: The diversity in training samples is crucial for comprehensive multimodal language studies due to the complexity of the underlying distribution. This complexity is rooted in variability of intra-modal and cross-modal dynamics for language, vision and acoustic modalities (Rajagopalan et al., 2016). Previously proposed datasets for multimodal language are generally small in size due to difficulties associated with data acquisition and costs of annotations.

Variety in the topics: Variety in topics opens the door to generalizable studies across different domains. Models trained on only few topics generalize poorly as language and nonverbal behaviors tend to change based on the impression of the topic on speakers' internal mental state.

Diversity of speakers: Much like writing styles, speaking styles are highly idiosyncratic. Training models on only few speakers can lead to degenerate solutions where models learn the identity of speakers as opposed to a generalizable model of multimodal language (Wang et al., 2016).

Variety in annotations Having multiple labels to predict allows for studying the relations between labels. Another positive aspect of having variety of labels is allowing for multi-task learning which has shown excellent performance in past research.

Our first contribution in this paper is to introduce the largest dataset of multimodal sentiment and emotion recognition called CMU Multimodal Opinion Sentiment and Emotion Intensity (CMU-MOSEI). CMU-MOSEI contains 23,453 annotated video segments from 1,000 distinct speakers and

Proceedings of the 56th Annual Meeting of the Association for Computational Linguistics (Long Papers), pages 2236–2246
Melbourne, Australia, July 15 - 20, 2018. ©2018 Association for Computational Linguistics

250 topics. Each video segment contains manual transcription aligned with audio to phoneme level. All the videos are gathered from online video sharing websites [1]. The dataset is currently a part of the CMU Multimodal Data SDK and is freely available to the scientific community through Github [2].

Our second contribution is an interpretable fusion model called Dynamic Fusion Graph (DFG) to study the nature of cross-modal dynamics in multimodal language. DFG contains built-in efficacies that are directly related to how modalities interact. These efficacies are visualized and studied in detail in our experiments. Aside interpretability, DFG achieves superior performance compared to previously proposed models for multimodal sentiment and emotion recognition on CMU-MOSEI.

2 Background

In this section we compare the CMU-MOSEI dataset to previously proposed datasets for modeling multimodal language. We then describe the baselines and recent models for sentiment analysis and emotion recognition.

2.1 Comparison to other Datasets

We compare CMU-MOSEI to an extensive pool of datasets for sentiment analysis and emotion recognition. The following datasets include a combination of language, visual and acoustic modalities as their input data.

2.1.1 Multimodal Datasets

CMU-MOSI (Zadeh et al., 2016b) is a collection of 2199 opinion video clips each annotated with sentiment in the range [-3,3]. CMU-MOSEI is the next generation of CMU-MOSI. The **ICT-MMMO** (Wöllmer et al., 2013) consists of online social review videos annotated at the video level for sentiment. **YouTube** (Morency et al., 2011) contains videos from the social media web site YouTube that span a wide range of product reviews and opinion videos. **MOUD** (Perez-Rosas et al., 2013) consists of product review videos in Spanish. Each video consists of multiple segments labeled to display positive, negative or neutral sentiment. **IEMOCAP** (Busso et al., 2008) consists of 151 videos of recorded dialogues, with 2 speakers per session for a total of 302 videos across the dataset. Each segment is annotated for the presence of 9 emotions (angry, excited, fear, sad, surprised, frustrated, happy, disappointed and neutral) as well as valence, arousal and dominance.

[1]following creative commons license allows for personal unrestricted use and redistribution of the videos

Table 1: Comparison of the CMU-MOSEI dataset with previous sentiment analysis and emotion recognition datasets. #S denotes the number of annotated data points. #Sp is the number of distinct speakers. Mod indicates the subset of modalities present from $\{(l)anguage, (v)ision, (a)udio\}$. Sent and Emo columns indicate presence of sentiment and emotion labels. TL denotes the total number of video hours.

2.1.2 Language Datasets

Stanford Sentiment Treebank (SST) (Socher et al., 2013) includes fine grained sentiment labels for phrases in the parse trees of sentences collected from movie review data. While SST has larger pool of annotations, we only consider the root level annotations for comparison. **Cornell Movie Review** (Pang et al., 2002) is a collection of 2000 movie-review documents and sentences labeled with respect to their overall sentiment polarity or subjective rating. **Large Movie Review** dataset (Maas et al., 2011) contains text from highly polar movie reviews. **Sanders Tweets Sentiment (STS)** consists of 5513 hand-classified tweets each classified with respect to one of four topics of Microsoft, Apple, Twitter, and Google.

2.1.3 Visual and Acoustic Datasets

The **Vera am Mittag (VAM)** corpus consists of 12 hours of recordings of the German TV talk-show “Vera am Mittag” (Grimm et al., 2008). This audio-visual data is labeled for continuous-valued scale for three emotion primitives: valence, activation and dominance. VAM-Audio and VAM-Faces are subsets that contain on acoustic and visual inputs respectively. **RECOLA** (Ringeval et al., 2013) consists of 9.5 hours of audio, visual, and physiological (electrocardiogram, and electrodermal activity) recordings of online dyadic interactions. **Mimicry** (Bilakhia et al., 2015) consists of audiovisual recordings of human interactions in two situations: while discussing a political topic and while playing a role-playing game. **AFEW** (Dhall et al., 2012, 2015) is a dynamic temporal facial expressions data corpus consisting of close to real world environment extracted from movies.

Detailed comparison of CMU-MOSEI to the datasets in this section is presented in Table 1. CMU-MOSEI has longer total duration as well as larger number of data point in total. Furthermore, CMU-MOSEI has a larger variety in number of speakers and topics. It has all three modalities provided, as well as annotations for both sentiment and emotions.

2.2 Baseline Models

Modeling multimodal language has been the subject of studies in NLP and multimodal machine learning. Notable approaches are listed as follows and indicated with a symbol for reference in the Experiments and Discussion section (Section 5).

# **MFN:** (Memory Fusion Network) (Zadeh et al., 2018a) synchronizes multimodal sequences using a multi-view gated memory that stores intra-view and cross-view interactions through time. ■ **MARN:** (Multi-attention Recurrent Network) (Zadeh et al., 2018b) models intra-modal and multiple cross-modal interactions by assigning multiple attention coefficients. Intra-modal and cross-modal interactions are stored in a hybrid LSTM memory component. $*$ **TFN** (Tensor Fusion Network) (Zadeh et al., 2017) models inter and intra modal interactions by creating a multi-dimensional tensor that captures unimodal, bimodal and trimodal interactions. $\diamond$ **MV-LSTM** (Multi-View LSTM) (Rajagopalan et al., 2016) is a recurrent model that designates regions inside a LSTM to different views of the data. § **EF-LSTM** (Early Fusion LSTM) concatenates the inputs from different modalities at each time-step and uses that as the input to a single LSTM (Hochreiter and Schmidhuber, 1997; Graves et al., 2013; Schuster and Paliwal, 1997). In case of unimodal models EF-LSTM refers to a single LSTM.

We also compare to the following baseline models: † **BC-LSTM** (Poria et al., 2017b), ♣ **C-MKL** (Poria et al., 2016), $\flat$ **DF** (Nojavanasghari et al., 2016), ♡ **SVM** (Cortes and Vapnik, 1995; Zadeh et al., 2016b; Perez-Rosas et al., 2013; Park et al., 2014), $\bullet$ **RF** (Breiman, 2001), **THMM** (Morency et al., 2011), **SAL-CNN** (Wang et al., 2016), **3D-CNN** (Ji et al., 2013). For language only baseline models: $\cup$ **CNN-LSTM** (Zhou et al., 2015), **RNTN** (Socher et al., 2013), $\times$: **DynamicCNN** (Kalchbrenner et al., 2014), $\triangleright$ **DAN** (Iyyer et al., 2015), $\wr$ **DHN** (Srivastava et al., 2015), $\triangleleft$ **RHN** (Zilly et al., 2016). For acoustic only baseline models: **AdieuNet** (Trigeorgis et al., 2016), **SER-LSTM** (Lim et al., 2016).

3 CMU-MOSEI Dataset

Understanding expressed sentiment and emotions are two crucial factors in human multimodal language. We introduce a novel dataset for multimodal sentiment and emotion recognition called CMU Multimodal Opinion Sentiment and Emotion Intensity (CMU-MOSEI). In the following subsections, we first explain the details of the CMU-MOSEI data acquisition, followed by details of annotation and feature extraction.

3.1 Data Acquisition

Social multimedia presents a unique opportunity for acquiring large quantities of data from various speakers and topics. Users of these social multimedia websites often post their opinions in the forms of monologue videos; videos with only one person in front of camera discussing a certain topic of interest. Each video inherently contains three modalities: language in the form of spoken text, visual via perceived gestures and facial expressions, and acoustic through intonations and prosody.

During our automatic data acquisition process, videos from YouTube are analyzed for the presence of one speaker in the frame using face detection to ensure the video is a monologue. We limit the videos to setups where the speaker’s attention is exclusively towards the camera by rejecting videos that have moving cameras (such as camera on bikes or selfies recording while walking). We use a diverse set of 250 frequently used topics in online videos as the seed for acquisition. We restrict the

Figure 1: The diversity of topics of videos in CMU-MOSEI, displayed as a word cloud. Larger words indicate more videos from that topic. The most frequent 3 topics are reviews (16.2%), debate (2.9%) and consulting (1.8%) while the remaining topics are almost uniformly distributed.

number of videos acquired from each channel to a maximum of 10. This resulted in discovering 1,000 identities from YouTube. The definition of a identity is proxy to the number of channels since accurate identification requires quadratic manual annotations, which is infeasible for high number of speakers. Furthermore, we limited the videos to have manual and properly punctuated transcriptions provided by the uploader. The final pool of acquired videos included 5,000 videos which were then manually checked for quality of video, audio and transcript by 14 expert judges over three months. The judges also annotated each video for gender and confirmed that each video is an acceptable monologue. A set of 3228 videos remained after manual quality inspection. We also performed automatic checks on the quality of video and transcript which are discussed in Section 3.3 using facial feature extraction confidence and forced alignment confidence. Furthermore, we balance the gender in the dataset using the data provided by the judges (57% male to 43% female). This constitutes the final set of raw videos in CMU-MOSEI. The topics covered in the final set of videos are shown in Figure 1 as a Venn-style word cloud (Coppersmith and Kelly, 2014) with the size proportional to the number of videos gathered for that topic. The most frequent 3 topics are reviews (16.2%), debate (2.9%) and consulting (1.8%). The remaining topics are almost uniformly distributed [3].

The final set of videos are then tokenized into

[3]more detailed analysis such as exact percentages and number of videos per topic are available in the supplementary material

Total number of sentences	23453
Total number of videos	3228
Total number of distinct speakers	1000
Total number of distinct topics	250
Average number of sentences in a video	7.3
Average length of sentences in seconds	7.28
Total number of words in sentences	447143
Total of unique words in sentences	23026
Total number of words appearing at least 10 times in the dataset	3413
Total number of words appearing at least 20 times in the dataset	1971
Total number of words appearing at least 50 times in the dataset	888

Table 2: Summary of CMU-MOSEI dataset statistics.

sentences using punctuation markers manually provided by transcripts. Due to the high quality of the transcripts, using punctuation markers showed better sentence quality than using the Stanford CoreNLP tokenizer (Manning et al., 2014). This was verified on a set of 20 random videos by two experts. After tokenization, a set of 23,453 sentences were chosen as the final sentences in the dataset. This was achieved by restricting each identity to contribute at least 10 and at most 50 sentences to the dataset. Table 2 shows high-level summary statistics of the CMU-MOSEI dataset.

3.2 Annotation

Annotation of CMU-MOSEI follows closely the annotation of CMU-MOSI (Zadeh et al., 2016a) and Stanford Sentiment Treebank (Socher et al., 2013). Each sentence is annotated for sentiment on a [-3,3] Likert scale of: [-3: highly negative, -2 negative, -1 weakly negative, 0 neutral, +1 weakly positive, +2 positive, +3 highly positive]. Ekman emotions (Ekman et al., 1980) of {happiness, sadness, anger, fear, disgust, surprise} are annotated on a [0,3] Likert scale for presence of emotion x: [0: no evidence of x, 1: weakly x, 2: x, 3: highly x]. The annotation was carried out by 3 crowdsourced judges from Amazon Mechanical Turk platform. To avert implicitly biasing the judges and to capture the raw perception of the crowd, we avoided extreme annotation training and instead provided the judges with a 5 minutes training video on how to use the annotation system. All the annotations have been carried out by only master workers with higher than 98% approval rate to assure high quality annotations [4].

Figure 2 shows the distribution of sentiment and emotions in CMU-MOSEI dataset. The distribution

[4]Extensive statistics of the dataset including the crawling mechanism, the annotation UI, training procedure for the workers, agreement scores are available in submitted supplementary material available on arXiv.

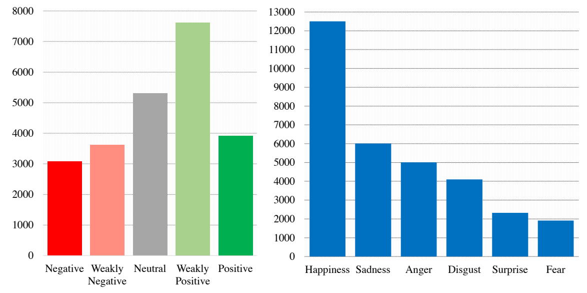

Figure 2: Distribution of sentiment and emotions in the CMU-MOSEI dataset. The distribution shows a natural skew towards more frequently used emotions. However, the least frequent emotion, fear, still has 1,900 data points which is an acceptable number for machine learning studies.

shows a slight shift in favor of positive sentiment which is similar to distribution of CMU-MOSI and SST. We believe that this is an implicit bias in online opinions being slightly shifted towards positive, since this is also present in CMU-MOSI. The emotion histogram shows different prevalence for different emotions. The most common category is happiness with more than 12,000 positive sample points. The least prevalent emotion is fear with almost 1900 positive sample points which is an acceptable number for machine learning studies.

3.3 Extracted Features

Data points in CMU-MOSEI come in video format with one speaker in front of the camera. The extracted features for each modality are as follows (for other benchmarks we extract the same features):

Language: All videos have manual transcription. Glove word embeddings (Pennington et al., 2014) were used to extract word vectors from transcripts. Words and audio are aligned at phoneme level using P2FA forced alignment model (Yuan and Liberman, 2008). Following this, the visual and acoustic modalities are aligned to the words by interpolation. Since the utterance duration of words in English is usually short, this interpolation does not lead to substantial information loss.

Visual: Frames are extracted from the full videos at 30Hz. The bounding box of the face is extracted using the MTCNN face detection algorithm (Zhang et al., 2016). We extract facial action units through Facial Action Coding System (FACS) (Ekman et al., 1980). Extracting these action units allows for accurate tracking and understanding of the facial expressions (Baltrušaitis et al., 2016). We also extract a set of six basic emotions purely from static faces using Emotient FACET (iMotions, 2017). MultiComp OpenFace (Baltrušaitis et al., 2016) is used to extract the set of 68 facial landmarks, 20 facial shape parameters, facial HoG features, head pose, head orientation and eye gaze (Baltrušaitis et al., 2016). Finally, we extract face embeddings from commonly used facial recognition models such as DeepFace (Taigman et al., 2014), FaceNet (Schroff et al., 2015) and SphereFace (Liu et al., 2017).

Acoustic: We use the COVAREP software (Degottex et al., 2014) to extract acoustic features including 12 Mel-frequency cepstral coefficients, pitch, voiced/unvoiced segmenting features (Drugman and Alwan, 2011), glottal source parameters (Drugman et al., 2012; Alku et al., 1997, 2002), peak slope parameters and maxima dispersion quotients (Kane and Gobl, 2013). All extracted features are related to emotions and tone of speech.

4 Multimodal Fusion Study

From the linguistics perspective, understanding the interactions between language, visual and audio modalities in multimodal language is a fundamental research problem. While previous works have been successful with respect to accuracy metrics, they have not created new insights on how the fusion is performed in terms of what modalities are related and how modalities engage in an interaction during fusion. Specifically, to understand the fusion process one must first understand the n-modal dynamics (Zadeh et al., 2017). n-modal dynamics state that there exists different combination of modalities and that all of these combinations must be captured to better understand the multimodal language. In this paper, we define building the n-modal dynamics as a hierarchical process and propose a new fusion model called the Dynamic Fusion Graph (DFG). DFG is easily interpretable through what is called efficacies in graph connections. To utilize this new fusion model in a multimodal language framework, we build upon Memory Fusion Network (MFN) by replacing the original fusion component in the MFN with our DFG. We call this resulting model the Graph Memory Fusion Network (Graph-MFN). Once the model is trained end to end, we analyze the efficacies in the DFG to study the fusion mechanism learned for modalities in multimodal language. In addition to being an interpretable fusion mechanism,

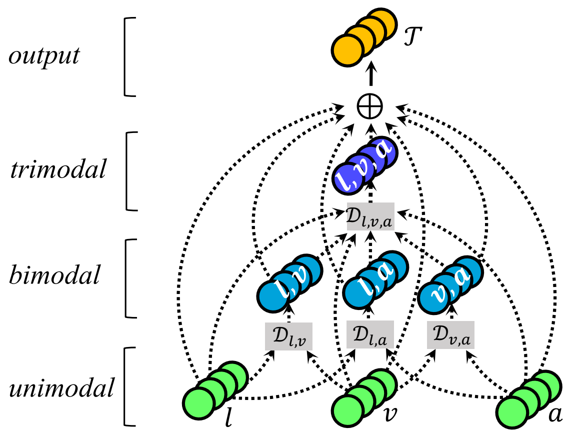

Figure 3: The structure of Dynamic Fusion Graph (DFG) for three modalities of $\{(l)anguage, (v)ision, (a)coustic\}$. Dashed lines in DFG show the dynamic connections between vertices controlled by the efficacies (α).

Graph-MFN also outperforms previously proposed state-of-the-art models for sentiment analysis and emotion recognition on the CMU-MOSEI.

4.1 Dynamic Fusion Graph

In this section we discuss the internal structure of the proposed Dynamic Fusion Graph (DFG) neural model (Figure 3. DFG has the following properties: 1) it explicitly models the n-modal interactions, 2) does so with an efficient number of parameters (as opposed to previous approaches such as Tensor Fusion (Zadeh et al., 2017)) and 3) can dynamically alter its structure and choose the proper fusion graph based on the importance of each n-modal dynamics during inference. We assume the set of modalities to be $M = \{(l)anguage, (v)ision, (a)coustic\}$. The unimodal dynamics are denoted as $\{l\}, \{v\}, \{a\}$, the bimodal dynamics as $\{l, v\}, \{v, a\}, \{l, a\}$ and trimodal dynamics as $\{l, v, a\}$. These dynamics are in the form of latent representations and are each considered as vertices inside a graph $G = (V, E)$ with V the set of vertices and E the set of edges. A directional neural connection is established between two vertices v_i and v_j only if $v_i \subset v_j$. For example, $\{l\} \subset \{l, v\}$ which results in a connection between $< language >$ and $< language, vision >$. This connection is denoted as an edge e_{ij}. $\mathcal{D}_j$ takes as input all v_i that satisfy the neural connection formula above for v_j.

We define an efficacy for each edge e_{ij} denoted as α_{ij}. v_i is multiplied by α_{ij} before being used as input to D_j. Each α is a sigmoid activated probability neuron which indicates how strong or weak the connection is between v_i and v_j. αs are the main source of interpretability in DFG. The vector of all αs is inferred using a deep neural network $\mathcal{D}_\alpha$ which takes as input singleton vertices in V (l, v, and a). We leave it to the supervised training objective to learn parameters of $\mathcal{D}_\alpha$ and make good use of efficacies, thus dynamically controlling the structure of the graph. The singleton vertices are chosen for this purpose since they have no incoming edges thus no efficacy associated with those edges (no efficacy is needed to infer the singleton vertices). The same singleton vertices l, v, and a are the inputs to the DFG. In the next section we discuss how these inputs are given to DFG. All vertices are connected to the output vertex $\mathcal{T}_t$ of the network via edges scaled by their respective efficacy. The overall structure of the vertices, edges and respective efficacies is shown in Figure 3. There are a total of 8 vertices (counting the output vertex), 19 edges and subsequently 19 efficacies.

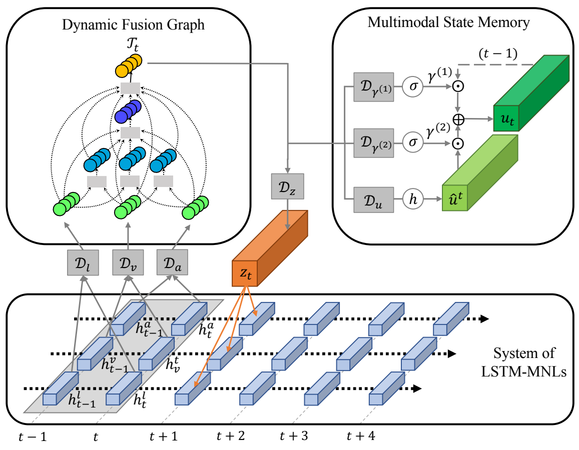

Figure 4: The overview of Graph Memory Fusion Network (Graph-MFN) pipeline. Graph-MFN replaces the fusion block in MFN with a Dynamic Fusion Graph (DFG). For description of variables and memory formulation please refer to the original Memory Fusion Network paper (Zadeh et al., 2018a).

4.2 Graph-MFN

To test the performance of DFG, we use a similar recurrent architecture to Memory Fusion Network (MFN). MFN is a recurrent neural model with three main components 1) System of LSTMs: a set of parallel LSTMs with each LSTM modeling a single modality. 2) Delta-memory Attention Network is the component that performs multimodal fusion

Table 3: Results for sentiment analysis and emotion recognition on the MOSEI dataset (reported results are as of 5/11/2018. please check the CMU Multimodal Data SDK github for current state of the art and new features for CMU-MOSEI and other datasets). SOTA1 and SOTA2 refer to the previous best and second best state-of-the-art models (from Section 2) respectively. Compared to the baselines Graph-MFN achieves superior performance in sentiment analysis and competitive performance in emotion recognition. For all metrics, higher values indicate better performance except for MAE where lower values indicate better performance.

by assigning coefficients to highlight cross-modal dynamics. 3) Multiview Gated Memory is a component that stores the output of multimodal fusion. We replace the Delta-memory Attention Network with DFG and refer to the modified model as Graph Memory Fusion Network (Graph-MFN). Figure 4 shows the overall architecture of the Graph-MFN.

Similar to MFN, Graph-MFN employs a system of LSTMs for modeling individual modalities. c_l, c_v, and c_a represent the memory of LSTMs for language, vision and acoustic modalities respectively. $D_m, m \in \{l, v, a\}$ is a fully connected deep neural network that takes in $h^m_{[t-1,t]}$ the LSTM representation across two consecutive timestamps, which allows the network to track changes in memory dimensions across time. The outputs of D_l, D_v and D_a are the singleton vertices for the DFG. The DFG models cross-modal interactions and encodes the cross-modal representations in its output vertex $\mathcal{T}_t$ for storage in the Multi-view Gated Memory u_t. The Multi-view Gated Memory functions using a network D_u that transforms $\mathcal{T}_t$ into a proposed memory update $\hat{u}_t$. γ_1 and γ_2 are the Multi-view Gated Memory's retain and update gates respectively and are learned using networks D_{γ_1} and D_{γ_2}. Finally, a network D_z transforms $\mathcal{T}_t$ into a multimodal representation z_t to update the system of LSTMs. The output of Graph-MFN in all the experiments is the output of each LSTM h^m_T as well as contents of the Multi-view Gated Memory at time T (last recurrence timestep), u_T. This output is subsequently connected to a classification or regression layer for final prediction (for sentiment and emotion recognition).

5 Experiments and Discussion

In our experiments, we seek to evaluate how modalities interact during multimodal fusion by studying the efficacies of DFG through time.

Table 3 shows the results on CMU-MOSEI. Accuracy is reported as A^x where x is the number of sentiment classes as well as F1 measure. For regression we report MAE and correlation (r). For emotion recognition due to the natural imbalances across various emotions, we use weighted accuracy (Tong et al., 2017) and F1 measure. Graph-MFN shows superior performance in sentiment analysis and competitive performance in emotion recognition. Therefore, DFG is both an effective and interpretable model for multimodal fusion.

To better understand the internal fusion mechanism between modalities, we visualize the behavior of the learned DFG efficacies in Figure 5 for various cases (deep red denotes high efficacy and deep blue denotes low efficacy).

Multimodal Fusion has a Volatile Nature: The first observation is that the structure of the DFG is changing case by case and for each case over time. As a result, the model seems to be selectively prioritizing certain dynamics over the others. For example, in case (I) where all modalities are informative, all efficacies seem to be high, imply-

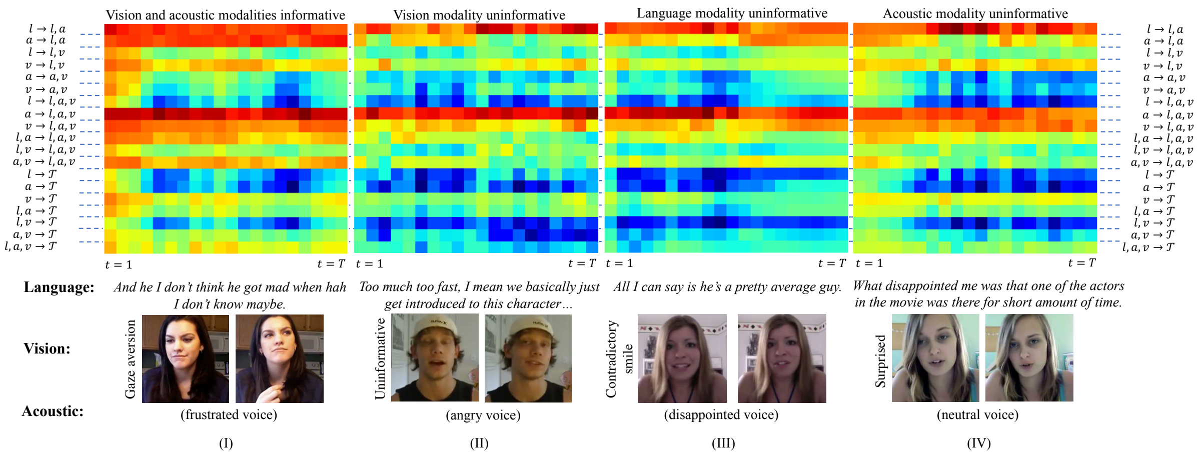

Figure 5: Visualization of DFG efficacies across time. The efficacies (thus the DFG structure) change over time as DFG is exposed to new information. DFG is able choose which n-modal dynamics to rely on. It also learns priors about human communication since certain efficacies (thus edges in DFG) remain unchanged across time and across data points.

ing that the DFG is able to find useful information in unimodal, bimodal and trimodal interactions. However, in cases (II) and (III) where the visual modality is either uninformative or contradictory, the efficacies of $v \to l, v$ and $v \to l, a, v$ and $l, a \to l, a, v$ are reduced since no meaningful interactions involve the visual modality.

Priors in Fusion: Certain efficacies remain unchanged across cases and across time. These are priors from Human Multimodal Language that DFG learns. For example the model always seems to prioritize fusion between language and audio in $(l \to l, a)$, and $(a \to l, a)$. Subsequently, DFG gives low values to efficacies that rely unilaterally on language or audio alone: the $(l \to \tau)$ and $(a \to \tau)$ efficacies seem to be consistently low. On the other hand, the visual modality appears to have a partially isolated behavior. In the presence of informative visual information, the model increases the efficacies of $(v \to \tau)$ although the values of other visual efficacies also increase.

Trace of Multimodal Fusion: We trace the dominant path that every modality undergoes during fusion: 1) *language* tends to first fuse with audio via $(l \to l, a)$ and the language and acoustic modalities together engage in higher level fusions such as $(l, a \to l, a, v)$. Intuitively, this is aligned with the close ties between language and audio through word intonations. 2) The *visual* modality seems to engage in fusion only if it contains meaningful information. In cases (I) and (IV), all the paths involving the visual modality are relatively active while in cases (II) and (III) the paths involving the visual modality have low efficacies. 3) The *acoustic* modality is mostly present in fusion with the language modality. However, unlike language, the acoustic modality also appears to fuse with the visual modality if both modalities are meaningful, such as in case (I).

An interesting observation is that in almost all cases the efficacies of unimodal connections to terminal $\mathcal{T}$ is low, implying that $\mathcal{T}$ prefers to not rely on just one modality. Also, DFG always prefers to perform fusion between language and audio as in most cases both $l \to l, a$ and $a \to l, a$ have high efficacies; intuitively in most natural scenarios language and acoustic modalities are highly aligned. Both of these cases show unchanging behaviors which we believe DFG has learned as natural priors of human communicative signal.

With these observations, we believe that DFG has successfully learned how to manage its internal structure to model human communication.

6 Conclusion

In this paper we presented the largest dataset of multimodal sentiment analysis and emotion recognition called CMU Multimodal Opinion Sentiment and Emotion Intensity (CMU-MOSEI). CMU-MOSEI consists of 23,453 annotated sentences from more than 1000 online speakers and 250 different topics. The dataset expands the horizons of Human Multimodal Language studies in NLP. One such study was presented in this paper where we analyzed the structure of multimodal fusion in sentiment analysis and emotion recognition. This was done using a novel interpretable fusion mechanism called Dynamic Fusion Graph (DFG). In our studies we investigated the behavior of modalities in interacting with each other using built-in efficacies of DFG. Aside analysis of fusion, DFG was trained in the Memory Fusion Network pipeline and showed superior performance in sentiment analysis and competitive performance in emotion recognition.

Abstract

Multimodal research is an emerging field of artificial intelligence, and one of the main research problems in this field is multimodal fusion. The fusion of multimodal data is the process of integrating multiple unimodal representations into one compact multimodal representation. Previous research in this field has exploited the expressiveness of tensors for multimodal representation. However, these methods often suffer from exponential increase in dimensions and in computational complexity introduced by transformation of input into tensor. In this paper, we propose the Low-rank Multimodal Fusion method, which performs multimodal fusion using low-rank tensors to improve efficiency. We evaluate our model on three different tasks: multimodal sentiment analysis, speaker trait analysis, and emotion recognition. Our model achieves competitive results on all these tasks while drastically reducing computational complexity. Additional experiments also show that our model can perform robustly for a wide range of low-rank settings, and is indeed much more efficient in both training and inference compared to other methods that utilize tensor representations.

1 Introduction

Multimodal research has shown great progress in a variety of tasks as an emerging research field of artificial intelligence. Tasks such as speech recognition (Yuhas et al., 1989), emotion recognition, (De Silva et al., 1997), (Chen et al., 1998), (Wöllmer et al., 2013), sentiment analysis, (Morency et al., 2011) as well as speaker trait analysis and media description (Park et al., 2014a) have seen a great boost in performance with developments in multimodal research.

However, a core research challenge yet to be solved in this domain is multimodal fusion. The goal of fusion is to combine multiple modalities to leverage the complementarity of heterogeneous data and provide more robust predictions. In this regard, an important challenge has been on scaling up fusion to multiple modalities while maintaining reasonable model complexity. Some of the recent attempts (Fukui et al., 2016), (Zadeh et al., 2017) at multimodal fusion investigate the use of tensors for multimodal representation and show significant improvement in performance. Unfortunately, they are often constrained by the exponential increase of cost in computation and memory introduced by using tensor representations. This heavily restricts the applicability of these models, especially when we have more than two views of modalities in the dataset.

In this paper, we propose the Low-rank Multimodal Fusion, a method leveraging low-rank weight tensors to make multimodal fusion efficient without compromising on performance. The overall architecture is shown in Figure 1. We evaluated our approach with experiments on three multimodal tasks using public datasets and compare its performance with state-of-the-art models. We also study how different low-rank settings impact the performance of our model and show that our model performs robustly within a wide range of rank settings. Finally, we perform an analysis of the impact of our method on the number of parameters and run-time with comparison to other fusion methods. Through theoretical analysis, we show that our model can scale linearly in the number of modalities, and our experiments also show a corresponding speedup in training when compared with

Figure 1: Overview of our Low-rank Multimodal Fusion model structure: LMF first obtains the unimodal representation z_a, z_v, z_l by passing the unimodal inputs x_a, x_v, x_l into three sub-embedding networks f_v, f_a, f_l respectively. LMF produces the multimodal output representation by performing low-rank multimodal fusion with modality-specific factors. The multimodal representation can be then used for generating prediction tasks.

other tensor-based models.

The main contributions of our paper are as follows:

- We propose the Low-rank Multimodal Fusion method for multimodal fusion that can scale linearly in the number of modalities.
- We show that our model compares to state-of-the-art models in performance on three multimodal tasks evaluated on public datasets.
- We show that our model is computationally efficient and has fewer parameters in comparison to previous tensor-based methods.

2 Related Work

Multimodal fusion enables us to leverage complementary information present in multimodal data, thus discovering the dependency of information on multiple modalities. Previous studies have shown that more effective fusion methods translate to better performance in models, and there's been a wide range of fusion methods.

Early fusion is a technique that uses feature concatenation as the method of fusion of different views. Several works that use this method of fusion (Poria et al., 2016) , (Wang et al., 2016) use input-level feature concatenation and use the concatenated features as input, sometimes even removing the temporal dependency present in the modalities (Morency et al., 2011). The drawback of this class of method is that although it achieves fusion at an early stage, intra-modal interactions are potentially suppressed, thus losing out on the context and temporal dependencies within each modality.

On the other hand, late fusion builds separate models for each modality and then integrates the outputs together using a method such as majority voting or weighted averaging (Wortwein and Scherer, 2017), (Nojavanasghari et al., 2016). Since separate models are built for each modality, inter-modal interactions are usually not modeled effectively.

Given these shortcomings, more recent work focuses on intermediate approaches that model both intra- and inter-modal dynamics. Fukui et al. (2016) proposes to use Compact Bilinear Pooling over the outer product of visual and linguistic representations to exploit the interactions between vision and language for visual question answering. Similar to the idea of exploiting interactions, Zadeh et al. (2017) proposes Tensor Fusion Network, which computes the outer product between unimodal representations from three different modalities to compute a tensor representation. These methods exploit tensor representations to model inter-modality interactions and have shown a great success. However, such methods suffer from exponentially increasing computational complexity, as the outer product over multiple modalities results in extremely high dimensional tensor representations.

For unimodal data, the method of low-rank tensor approximation has been used in a variety of applications to implement more efficient tensor operations. Razenshteyn et al. (2016) proposes a modified weighted version of low-rank approximation, and Koch and Lubich (2010) applies the method towards temporally dependent data to obtain low-rank approximations. As for applications, Lei et al. (2014) proposes a low-rank tensor technique for dependency parsing while Wang and Ahuja (2008) uses the method of low-rank approximation applied directly on multidimensional image data (Datum-as-is representation) to enhance computer vision applications. Hu et al. (2017) proposes a low-rank tensor-based fusion framework to improve the face recognition performance using the fusion of facial attribute information. However, none of these previous work aims to apply low-rank tensor techniques for multimodal fusion.

Our Low-rank Multimodal Fusion method provides a much more efficient method to compute tensor-based multimodal representations with much fewer parameters and computational complexity. The efficiency and performance of our approach are evaluated on different downstream tasks, namely sentiment analysis, speaker-trait recognition and emotion recognition.

3 Low-rank Multimodal Fusion

In this section, we start by formulating the problem of multimodal fusion and introducing fusion methods based on tensor representations. Tensors are powerful in their expressiveness but do not scale well to a large number of modalities. Our proposed model decomposes the weights into low-rank factors, which reduces the number of parameters in the model. This decomposition can be performed efficiently by exploiting the parallel decomposition of low-rank weight tensor and input tensor to compute tensor-based fusion. Our method is able to scale linearly with the number of modalities.

3.1 Multimodal Fusion using Tensor Representations

In this paper, we formulate multimodal fusion as a multilinear function $f : V_1 \times V_2 \times ... \times V_M \rightarrow H$ where $V_1, V_2, ..., V_M$ are the vector spaces of input modalities and H is the output vector space. Given a set of vector representations, $\{z_m\}_{m=1}^{M}$ which are encoding unimodal information of the M different modalities, the goal of multimodal fusion is to integrate the unimodal representations into one compact multimodal representation for downstream tasks.

Tensor representation is one successful approach for multimodal fusion. It first requires a transformation of the input representations into a high-dimensional tensor and then mapping it back to a lower-dimensional output vector space. Previous works have shown that this method is more effective than simple concatenation or pooling in terms of capturing multimodal interactions (Zadeh et al., 2017), (Fukui et al., 2016). Tensors are usually created by taking the outer product over the input modalities. In addition, in order to be able to model the interactions between any subset of modalities using one tensor, Zadeh et al. (2017) proposed a simple extension to append 1s to the unimodal representations before taking the outer product. The input tensor $\mathcal{Z}$ formed by the unimodal representation is computed by:

$$\mathcal{Z} = \bigotimes_{m=1}^{M} z_m, z_m \in \mathbb{R}^{d_m} \tag{1}$$

where $\bigotimes_{m=1}^{M}$ denotes the tensor outer product over a set of vectors indexed by m, and z_m is the input representation with appended 1s.

The input tensor $\mathcal{Z} \in \mathbb{R}^{d_1 \times d_2 \times ... d_M}$ is then passed through a linear layer $g(\cdot)$ to to produce a vector representation:

$$h = g(\mathcal{Z}; \mathcal{W}, b) = \mathcal{W} \cdot \mathcal{Z} + b, \ h, b \in \mathbb{R}^{d_y} \tag{2}$$

where $\mathcal{W}$ is the weight of this layer and b is the bias. With $\mathcal{Z}$ being an order-M tensor (where M is the number of input modalities), the weight $\mathcal{W}$ will naturally be a tensor of order-$(M+1)$ in $\mathbb{R}^{d_1 \times d_2 \times ... \times d_M \times d_h}$. The extra $(M+1)$-th dimension corresponds to the size of the output representation d_h. In the tensor dot product $\mathcal{W} \cdot \mathcal{Z}$, the weight tensor $\mathcal{W}$ can be then viewed as d_h order-M tensors. In other words, the weight $\mathcal{W}$ can be partitioned into $\widetilde{\mathcal{W}}_k \in \mathbb{R}^{d_1 \times ... \times d_M}$, $k = 1, ..., d_h$. Each $\widetilde{\mathcal{W}}_k$ contributes to one dimension in the output vector h, i.e. $h_k = \widetilde{\mathcal{W}}_k \cdot \mathcal{Z}$. This interpretation of tensor fusion is illustrated in Figure 2 for the bi-modal case.

One of the main drawbacks of tensor fusion is that we have to explicitly create the high-dimensional tensor $\mathcal{Z}$. The dimensionality of $\mathcal{Z}$

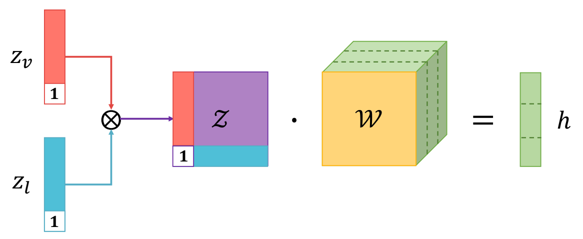

Figure 2: Tensor fusion via tensor outer product

will increase exponentially with the number of modalities as $\prod_{m=1}^{M} d_m$. The number of parameters to learn in the weight tensor $\mathcal{W}$ will also increase exponentially. This not only introduces a lot of computation but also exposes the model to risks of overfitting.

3.2 Low-rank Multimodal Fusion with Modality-Specific Factors

As a solution to the problems of tensor-based fusion, we propose Low-rank Multimodal Fusion (LMF). LMF parameterizes $g(\cdot)$ from Equation 2 with a set of modality-specific low-rank factors that can be used to recover a low-rank weight tensor, in contrast to the full tensor $\mathcal{W}$. Moreover, we show that by decomposing the weight into a set of low-rank factors, we can exploit the fact that the tensor $\mathcal{Z}$ actually decomposes into $\{z_m\}_{m=1}^{M}$, which allows us to directly compute the output h without explicitly tensorizing the unimodal representations. LMF reduces the number of parameters as well as the computation complexity involved in tensorization from being exponential in M to linear.

3.2.1 Low-rank Weight Decomposition

The idea of LMF is to decompose the weight tensor $\mathcal{W}$ into M sets of modality-specific factors. However, since $\mathcal{W}$ itself is an order-$(M+1)$ tensor, commonly used methods for decomposition will result in $M+1$ parts. Hence, we still adopt the view introduced in Section 3.1 that $\mathcal{W}$ is formed by d_h order-M tensors $\widetilde{\mathcal{W}}_k \in \mathbb{R}^{d_1 \times \ldots \times d_M}, k = 1, \ldots, d_h$ stacked together. We can then decompose each $\widetilde{\mathcal{W}}_k$ separately.

For an order-M tensor $\widetilde{\mathcal{W}}_k \in \mathbb{R}^{d_1 \times \ldots \times d_M}$, there always exists an exact decomposition into vectors in the form of:

$$\widetilde{\mathcal{W}}_k = \sum_{i=1}^{R} \bigotimes_{m=1}^{M} w_{m,k}^{(i)}, \quad w_{m,k}^{(i)} \in \mathbb{R}_m^{d} \tag{3}$$

The minimal R that makes the decomposition valid is called the **rank** of the tensor. The vector sets $\{\{w_{m,k}^{(i)}\}_{m=1}^{M}\}_{i=1}^{R}$ are called the rank R decomposition factors of the original tensor.

In LMF, we start with a fixed rank r, and parameterize the model with r decomposition factors $\{\{w_{m,k}^{(i)}\}_{m=1}^{M}\}_{i=1}^{r}, k = 1, \ldots, d_h$ that can be used to reconstruct a low-rank version of these $\widetilde{\mathcal{W}}_k$.

We can regroup and concatenate these vectors into M modality-specific low-rank factors. Let $\mathbf{w}_m^{(i)} = [w_{m,1}^{(i)}, w_{m,2}^{(i)}, \ldots, w_{m,d_h}^{(i)}]$, then for modality m, $\{\mathbf{w}_m^{(i)}\}_{i=1}^{r}$ is its corresponding low-rank factors. And we can recover a low-rank weight tensor by:

$$\mathcal{W} = \sum_{i=1}^{r} \bigotimes_{m=1}^{M} \mathbf{w}_m^{(i)} \tag{4}$$

Hence equation 2 can be computed by

$$h = \left(\sum_{i=1}^{r} \bigotimes_{m=1}^{M} \mathbf{w}_m^{(i)} \right) \cdot \mathcal{Z} \tag{5}$$

Note that for all m, $\mathbf{w}_m^{(i)} \in \mathbb{R}^{d_m \times d_h}$ shares the same size for the second dimension. We define their outer product to be over only the dimensions that are not shared: $\mathbf{w}_m^{(i)} \otimes \mathbf{w}_n^{(i)} \in \mathbb{R}^{d_m \times d_n \times d_h}$. A bimodal example of this procedure is illustrated in Figure 3.

Nevertheless, by introducing the low-rank factors, we now have to compute the reconstruction of $\mathcal{W} = \sum_{i=1}^{r} \bigotimes_{m=1}^{M} \mathbf{w}_m^{(i)}$ for the forward computation. Yet this introduces even more computation.

3.2.2 Efficient Low-rank Fusion Exploiting Parallel Decomposition

In this section, we will introduce an efficient procedure for computing h, exploiting the fact that tensor $\mathcal{Z}$ naturally decomposes into the original input $\{z_m\}_{m=1}^{M}$, which is parallel to the modality-specific low-rank factors. In fact, that is the main reason why we want to decompose the weight tensor into M modality-specific factors.

Using the fact that $\mathcal{Z} = \bigotimes_{m=1}^{M} z_m$, we can simplify equation 5:

$$\begin{aligned} h &= \left(\sum_{i=1}^{r} \bigotimes_{m=1}^{M} \mathbf{w}_m^{(i)} \right) \cdot \mathcal{Z} \\ &= \sum_{i=1}^{r} \left(\bigotimes_{m=1}^{M} \mathbf{w}_m^{(i)} \cdot \mathcal{Z} \right) \\ &= \sum_{i=1}^{r} \left(\bigotimes_{m=1}^{M} \mathbf{w}_m^{(i)} \cdot \bigotimes_{m=1}^{M} z_m \right) \\ &= \bigwedge_{m=1}^{M} \left[\sum_{i=1}^{r} \mathbf{w}_m^{(i)} \cdot z_m \right] \end{aligned} \tag{6}$$

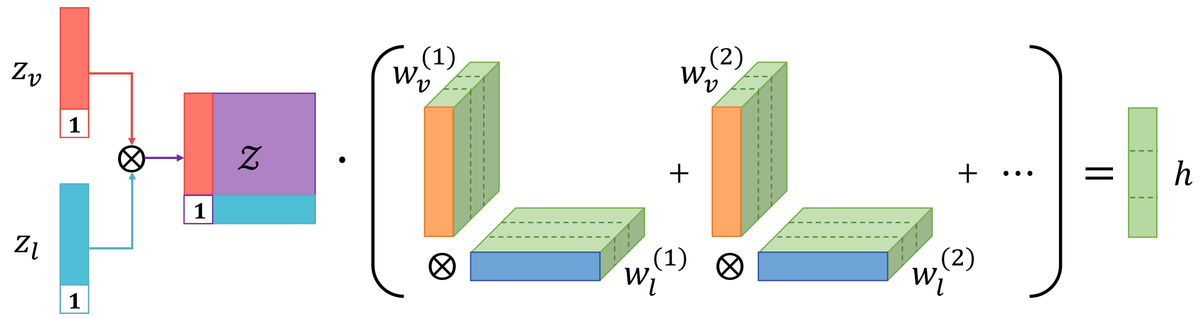

Figure 3: Decomposing weight tensor into low-rank factors (See Section 3.2.1 for details.)

where $\bigwedge_{m=1}^{M}$ denotes the element-wise product over a sequence of tensors: $\bigwedge_{t=1}^{3} x_t = x_1 \circ x_2 \circ x_3$.

An illustration of the trimodal case of equation 6 is shown in Figure 1. We can also derive equation 6 for a bimodal case to clarify what it does:

$$\begin{aligned} h &= \left(\sum_{i=1}^{r} \mathbf{w}_a^{(i)} \otimes \mathbf{w}_v^{(i)} \right) \cdot \mathcal{Z} \\ &= \left(\sum_{i=1}^{r} \mathbf{w}_a^{(i)} \cdot z_a \right) \circ \left(\sum_{i=1}^{r} \mathbf{w}_v^{(i)} \cdot z_v \right) \end{aligned} \tag{7}$$

An important aspect of this simplification is that it exploits the parallel decomposition of both $\mathcal{Z}$ and $\mathcal{W}$, so that we can compute h without actually creating the tensor $\mathcal{Z}$ from the input representations z_m. In addition, different modalities are decoupled in the simplified computation of h, which allows for easy generalization of our approach to an arbitrary number of modalities. Adding a new modality can be simply done by adding another set of modality-specific factors and extend Equation 7. Last but not least, Equation 6 consists of fully differentiable operations, which enables the parameters $\{\mathbf{w}_m^{(i)}\}_{i=1}^{r}\, m = 1, ..., M$ to be learned end-to-end via back-propagation.

Using Equation 6, we can compute h directly from input unimodal representations and their modal-specific decomposition factors, avoiding the weight-lifting of computing the large input tensor $\mathcal{Z}$ and $\mathcal{W}$, as well as the r linear transformation. Instead, the input tensor and subsequent linear projection are computed implicitly together in Equation 6, and this is far more efficient than the original method described in Section 3.1. Indeed, LMF reduces the computation complexity of tensorization and fusion from $O(d_y \prod_{m=1}^{M} d_m)$ to $O(d_y \times r \times \sum_{m=1}^{M} d_m)$.

In practice, we use a slightly different form of Equation 6, where we concatenate the low-rank factors into M order-3 tensors and swap the order in which we do the element-wise product and summation:

$$h = \sum_{i=1}^{r} \left[\bigwedge_{m=1}^{M} \left[\mathbf{w}_m^{(1)}, \mathbf{w}_m^{(2)}, ..., \mathbf{w}_m^{(r)} \right] \cdot \hat{z}_m \right]_{i,:} \tag{8}$$

and now the summation is done along the first dimension of the bracketed matrix. $[\cdot]_{i,:}$ indicates the i-th slice of a matrix. In this way, we can parameterize the model with M order-3 tensors, instead of parameterizing with sets of vectors.

4 Experimental Methodology

We compare LMF with previous state-of-the-art baselines, and we use the Tensor Fusion Networks (TFN) (Zadeh et al., 2017) as a baseline for tensor-based approaches, which has the most similar structure with us except that it explicitly forms the large multi-dimensional tensor for fusion across different modalities.

We design our experiments to better understand the characteristics of LMF. Our goal is to answer the following four research questions:

(1) Impact of Multimodal Low-rank Fusion: Direct comparison between our proposed LMF model and the previous TFN model.

(2) Comparison with the State-of-the-art: We evaluate the performance of LMF and state-of-the-art baselines on three different tasks and datasets.

(3) Complexity Analysis: We study the modal complexity of LMF and compare it with the TFN model.

(4) Rank Settings: We explore performance of LMF with different rank settings.

The results of these experiments are presented in Section 5.

4.1 Datasets

We perform our experiments on the following multimodal datasets, CMU-MOSI (Zadeh et al., 2016a),

Dataset	CMU-MOSI	IEMOCAP	POM
Level	Segment	Segment	Video
# Train	1284	6373	600
# Valid	229	1775	100
# Test	686	1807	203

Table 1: The speaker independent data splits for training, validation, and test sets.

POM (Park et al., 2014b), and IEMOCAP (Busso et al., 2008) for sentiment analysis, speaker traits recognition, and emotion recognition task, where the goal is to identify speakers emotions based on the speakers' verbal and nonverbal behaviors.

CMU-MOSI The CMU-MOSI dataset is a collection of 93 opinion videos from YouTube movie reviews. Each video consists of multiple opinion segments and each segment is annotated with the sentiment in the range [-3,3], where -3 indicates highly negative and 3 indicates highly positive.

POM The POM dataset is composed of 903 movie review videos. Each video is annotated with the following speaker traits: confident, passionate, voice pleasant, dominant, credible, vivid, expertise, entertaining, reserved, trusting, relaxed, outgoing, thorough, nervous, persuasive and humorous.

IEMOCAP The IEMOCAP dataset is a collection of 151 videos of recorded dialogues, with 2 speakers per session for a total of 302 videos across the dataset. Each segment is annotated for the presence of 9 emotions (angry, excited, fear, sad, surprised, frustrated, happy, disappointed and neutral).

To evaluate model generalization, all datasets are split into training, validation, and test sets such that the splits are speaker independent, i.e., no identical speakers from the training set are present in the test sets. Table 1 illustrates the data splits for all datasets in detail.

4.2 Features

Each dataset consists of three modalities, namely language, visual, and acoustic modalities. To reach the same time alignment across modalities, we perform word alignment using P2FA (Yuan and Liberman, 2008) which allows us to align the three modalities at the word granularity. We calculate the visual and acoustic features by taking the average of their feature values over the word time interval (Chen et al., 2017).

Language We use pre-trained 300-dimensional Glove word embeddings (Pennington et al., 2014) to encode a sequence of transcribed words into a sequence of word vectors.

Visual The library Facet[1] is used to extract a set of visual features for each frame (sampled at 30Hz) including 20 facial action units, 68 facial landmarks, head pose, gaze tracking and HOG features (Zhu et al., 2006).

Acoustic We use COVAREP acoustic analysis framework (Degottex et al., 2014) to extract a set of low-level acoustic features, including 12 Mel frequency cepstral coefficients (MFCCs), pitch, voiced/unvoiced segmentation, glottal source, peak slope, and maxima dispersion quotient features.

4.3 Model Architecture

In order to compare our fusion method with previous work, we adopt a simple and straightforward model architecture [2] for extracting unimodal representations. Since we have three modalities for each dataset, we simply designed three unimodal sub-embedding networks, denoted as f_a, f_v, f_l, to extract unimodal representations z_a, z_v, z_l from unimodal input features x_a, x_v, x_l. For acoustic and visual modality, the sub-embedding network is a simple 2-layer feed-forward neural network, and for language modality, we used an LSTM (Hochreiter and Schmidhuber, 1997) to extract representations. The model architecture is illustrated in Figure 1.

4.4 Baseline Models

We compare the performance of LMF to the following baselines and state-of-the-art models in multimodal sentiment analysis, speaker trait recognition, and emotion recognition.

Support Vector Machines Support Vector Machines (SVM) (Cortes and Vapnik, 1995) is a widely used non-neural classifier. This baseline is trained on the concatenated multimodal features for classification or regression task (Pérez-Rosas et al., 2013), (Park et al., 2014a), (Zadeh et al., 2016b).

Deep Fusion The Deep Fusion model (DF) (Nojavanasghari et al., 2016) trains one deep neural model for each modality and then combine the output of each modality network with a joint neural network.

Tensor Fusion Network The Tensor Fusion Network (TFN) (Zadeh et al., 2017) explicitly models view-specific and cross-view dynamics by creating a multi-dimensional tensor that captures uni-

[1]goo.gl/1rh1JN

[2]The source code of our model is available on Github at https://github.com/Justin1904/Low-rank-Multimodal-Fusion

modal, bimodal and trimodal interactions across three modalities.

Memory Fusion Network The Memory Fusion Network (MFN) (Zadeh et al., 2018a) accounts for view-specific and cross-view interactions and continuously models them through time with a special attention mechanism and summarized through time with a Multi-view Gated Memory.

Bidirectional Contextual LSTM The Bidirectional Contextual LSTM (BC-LSTM) (Zadeh et al., 2017), (Fukui et al., 2016) performs context-dependent fusion of multimodal data.

Multi-View LSTM The Multi-View LSTM (MV-LSTM) (Rajagopalan et al., 2016) aims to capture both modality-specific and cross-modality interactions from multiple modalities by partitioning the memory cell and the gates corresponding to multiple modalities.

Multi-attention Recurrent Network The Multi-attention Recurrent Network (MARN) (Zadeh et al., 2018b) explicitly models interactions between modalities through time using a neural component called the Multi-attention Block (MAB) and storing them in the hybrid memory called the Long-short Term Hybrid Memory (LSTHM).

4.5 Evaluation Metrics

Multiple evaluation tasks are performed during our evaluation: multi-class classification and regression. The multi-class classification task is applied to all three multimodal datasets, and the regression task is applied to the CMU-MOSI and the POM dataset. For binary classification and multi-class classification, we report F1 score and accuracy Acc$-k$ where k denotes the number of classes. Specifically, Acc-2 stands for the binary classification. For regression, we report Mean Absolute Error (MAE) and Pearson correlation (Corr). Higher values denote better performance for all metrics except for MAE.

5 Results and Discussion

In this section, we present and discuss the results from the experiments designed to study the research questions introduced in section 4.

5.1 Impact of Low-rank Multimodal Fusion

In this experiment, we compare our model directly with the TFN model since it has the most similar structure to our model, except that TFN explicitly forms the multimodal tensor fusion. The comparison reported in the last two rows of Table 2 demonstrates that our model significantly outperforms TFN across all datasets and metrics. This competitive performance of LMF compared to TFN emphasizes the advantage of Low-rank Multimodal Fusion.

5.2 Comparison with the State-of-the-art

We compare our model with the baselines and state-of-the-art models for sentiment analysis, speaker traits recognition and emotion recognition. Results are shown in Table 2. LMF is able to achieve competitive and consistent results across all datasets.

On the multimodal sentiment regression task, LMF outperforms the previous state-of-the-art model on MAE and Corr. Note the multiclass accuracy is calculated by mapping the range of continuous sentiment values into a set of intervals that are used as discrete classes.

On the multimodal speaker traits Recognition task, we report the average evaluation score over 16 speaker traits and shows that our model achieves the state-of-the-art performance over all three evaluation metrics on the POM dataset.

On the multimodal emotion recognition task, our model achieves better results compared to the state-of-the-art models across all emotions on the F1 score. F1-emotion in the evaluation metrics indicates the F1 score for a certain emotion class.

5.3 Complexity Analysis

Theoretically, the model complexity of our fusion method is $O(d_y \times r \times \sum_{m=1}^{M} d_m)$ compared to $O(d_y \prod_{m=1}^{M} d_m)$ of TFN from Section 3.1. In practice, we calculate the total number of parameters used in each model, where we choose $M = 3$, $d_1 = 32$, $d_2 = 32$, $d_3 = 64$, $r = 4$, $d_y = 1$. Under this hyper-parameter setting, our model contains about 1.1e6 parameters while TFN contains about 12.5e6 parameters, which is nearly 11 times more. Note that, the number of parameters above counts not only the parameters in the multimodal fusion stage but also the parameters in the subnetworks.

Furthermore, we evaluate the computational complexity of LMF by measuring the training and testing speeds between LMF and TFN. Table 3 illustrates the impact of Low-rank Multimodal Fusion on the training and testing speeds compared with TFN model. Here we set rank to be 4 since it can generally achieve fairly competent performance.

Dataset	CMU-MOSI					POM			IEMOCAP			
Metric	MAE	Corr	Acc-2	F1	Acc-7	MAE	Corr	Acc	F1-Happy	F1-Sad	F1-Angry	F1-Neutral

LMF	**0.912**	**0.668**	76.4	75.7	32.8	**0.796**	**0.396**	**42.8**	**85.8**	**85.9**	**89.0**	**71.7**

Table 2: Results for sentiment analysis on CMU-MOSI, emotion recognition on IEMOCAP and personality trait recognition on POM. Best results are highlighted in bold.

Model	Training Speed (IPS)	Testing Speed (IPS)
TFN	340.74	1177.17
LMF	1134.82	2249.90

Table 3: Comparison of the training and testing speeds between TFN and LMF. The second and the third columns indicate the number of data point inferences per second (IPS) during training and testing time respectively. Both models are implemented in the same framework with equivalent running environment.

Based on these results, performing a low-rank multimodal fusion with modality-specific low-rank factors significantly reduces the amount of time needed for training and testing the model. On an NVIDIA Quadro K4200 GPU, LMF trains with an average frequency of 1134.82 IPS (data point inferences per second) while the TFN model trains at an average of 340.74 IPS.

5.4 Rank Settings

To evaluate the impact of different rank settings for our LMF model, we measure the change in performance on the CMU-MOSI dataset while varying the number of rank. The results are presented in Figure 4. We observed that as the rank increases, the training results become more and more unstable and that using a very low rank is enough to achieve fairly competent performance.

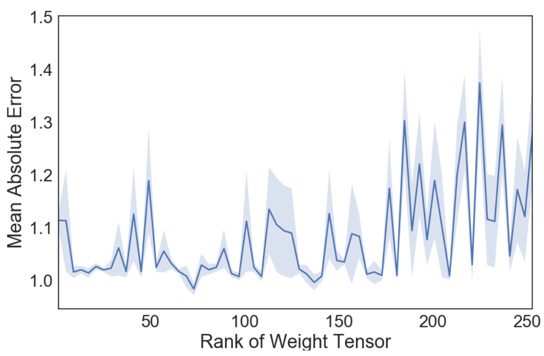

Figure 4: The Impact of different rank settings on Model Performance: As the rank increases, the results become unstable and low rank is enough in terms of the mean absolute error.

6 Conclusion

In this paper, we introduce a Low-rank Multimodal Fusion method that performs multimodal fusion with modality-specific low-rank factors. LMF scales linearly in the number of modalities. LMF achieves competitive results across different multimodal tasks. Furthermore, LMF demonstrates a significant decrease in computational complexity from exponential to linear time. In practice, LMF effectively improves the training and testing efficiency compared to TFN which performs multimodal fusion with tensor representations.

Future work on similar topics could explore the applications of using low-rank tensors for attention models over tensor representations, as they can be even more memory and computationally intensive.

Discourse Coherence: Concurrent Explicit and Implicit Relations

Hannah Rohde[1] **Alexander Johnson**[1] **Nathan Schneider**[2] **Bonnie Webber**[1]

Abstract

Theories of discourse coherence posit relations between discourse segments as a key feature of coherent text. Our prior work suggests that multiple discourse relations can be simultaneously operative between two segments for reasons not predicted by the literature. Here we test how this joint presence can lead participants to endorse seemingly divergent conjunctions (e.g., *but* and *so*) to express the link they see between two segments. These apparent divergences are not symptomatic of participant naïveté or bias, but arise reliably from the concurrent availability of multiple relations between segments – some available through explicit signals and some via inference. We believe that these new results can both inform future progress in theoretical work on discourse coherence and lead to higher levels of performance in discourse parsing.

1 Introduction

A question that remains unresolved in work on discourse coherence is the nature and number of relations that can hold between clauses in a coherent text (Halliday and Hasan, 1976; Stede, 2012).

Our earlier work (Rohde et al., 2015, 2016) showed that, in the presence of explicit discourse adverbials, people also infer additional discourse relations that they take to hold jointly with those associated with the adverbials. For example, in:

(1) It's too far to walk. Instead let's take the bus.

people infer a RESULT relation in the context of the adverbial *instead*, which itself signals that the bus stands in a SUBSTITUTION relation to walking. We showed this using crowdsourced conjunction-insertion experiments (Rohde et al., 2015, 2016), in which participants were asked to insert into the gap between two discourse segments, a *conjunction* that best expressed how they took the segments to be related. Rohde et al. (2017) also asked participants to select any other conjunctions that they took to convey the same sense as their "best" choice. (More details of these experiments are given in Section 3.)

All three studies showed participants selecting conjunctions whose sense differed from that of the explicit discourse adverbial. But Rohde et al. (2015, 2016) also showed participants often selecting conjunctions that signal different coherence relations than those selected by other participants. And Rohde et al. (2017) showed participants often identifying very different conjunctions as conveying the same meaning. For example, in passage (2), with the discourse adverbial *in other words*, one large fraction of participants chose to insert OR, while another large fraction inserted SO. Since the two are neither synonymous nor representative of the same relation, either the participants have come up with different analyses of the passages (Section 2) or something more surprising is at work.

(2) Unfortunately, nearly 75,000 acres of tropical forest are converted or deforested every day ______ in other words an area the size of Central Park disappears every 16 minutes. [SO$\sim$OR]

Rohde et al. (2017) noted other cases where different pairs of conjunctions (e.g., BECAUSE and BUT, BUT and OR, and BECAUSE and OR) appear systematically across participants and across passages for particular adverbials, and speculated on what these odd pairings may reveal, but did not provide any empirical evidence for why this happens. Here we present such evidence from an experiment on three discourse adverbials (*in other words*, *otherwise*, and *instead*).

After describing related work on multiple discourse relations (Section 2) and then our experimental methodology (Section 3), we step through results for these three adverbials. As a final piece of evidence, we manipulate the presence and absence of a fourth adverbial, *after all*, in order to demonstrate that inference of the relation(s) between segments in a passage is not always driven by the presence of such an adverbial.

2 Related Work

This is not the first work on discourse coherence to acknowledge the possibility of multiple relations holding between given discourse segments.

For example, the developers of Rhetorical Structure Theory acknowledged that even experienced RST analysts may interpret a text differently in terms of the relations they take to hold (Mann and Thompson, 1988, p. 265). But while RST allows for multiple **alternative analyses** of a text in terms of discourse relations, in practice, researchers working in the RST framework standardly produce a single analysis of a text, with a single relational labeling, selecting the analysis that is "most plausible in terms of the perceived goals of the writer" (Mann et al., 1989, pp. 34–35). If that single analysis is later mapped into a different structure to support further processing – e.g., a binary branching tree structure – the mapping does not change the chosen relational labeling.

Multiple relations may additionally hold in theories of discourse coherence that posit multiple *levels* of text analysis. For example, following Grosz and Sidner (1986), Moore and Pollack (1992) characterized text as having both an *informational structure* (relating information conveyed by discourse segments) and an *intentional structure* (relating the functions of those segments with respect to what the speaker is trying to accomplish through the text). The kinds of relations at the two levels are different, as can be seen in the following example from (Moore and Pollack, 1992, p. 540):

(3) a. George Bush supports big business.
b. He's sure to veto House Bill 1711.

At the level of intentions, (3a) aims to provide EVIDENCE for the claim in (3b), while at an informational level, (3a) serves as the CAUSE of the situation in (3b). RST would force annotators to choose only the analysis that best reflected the perceived goals of the writer.

Additionally, multiple relations can hold where there are **distinct explicit signals** for distinct discourse relations holding between a pair of segments (Cuenca and Marin, 2009; Fraser, 2013), as in:

(4) It's too far to walk. So instead let's take the bus.

where the conjunction *so* signals a RESULT relation and the adverbial *instead* signals that taking the bus stands in an SUBSTITUTION relation to walking.

Finally, a fourth way in which the previous literature has taken multiple discourse relations to hold is when a single phrase or lexico-syntactic construction **jointly signals** multiple discourse relations as holding over a text – for example, *since* as a subordinating conjunction may, in particular contexts, signal both a TEMPORAL relation and a CAUSAL relation, rather than just one or the other (Miltsakaki et al., 2005).

We are aware of only two resources that allow more than one discourse relation to be annotated between two segments – the Penn Discourse TreeBank (PDTB; Prasad et al., 2008, 2014) and, more recently, the BECauSE Corpus 2.0 (Dunietz et al., 2017). The PDTB allows multiple discourse relations of the third and fourth types noted above. It also allows them to be annotated if there is no explicit connective between a pair of segments but annotators see more than one sense relation as linking them, as in the following variant of (4):

(5) It's too far to walk. Let's take the bus.

Here a RESULT relation can be associated with an implicit token of *so* between the clauses, while a SUBSTITUTION relation can be associated with an implicit token of *instead*. The above are the main cases in which PDTB annotates multiple relations. Relevant to this paper, the PDTB does not annotate implicit conjunction relations where there is already an explicit discourse adverbial. Thus the PDTB would either ignore the implicit RESULT relation for (1) or (incorrectly) annotate *instead* in (1) as conveying both SUBSTITUTION and RESULT.

Moreover, while the PDTB has been used in training many (but not all) discourse parsers (Marcu, 2000; Lin et al., 2014; Feng and Hirst, 2012; Xue et al., 2015, 2016; Ji and Eisenstein, 2014), discourse parsing has for the most part ignored its annotations of multiple concurrent relations between clauses, except in the case of distinct explicit connectives expressing distinct relations. Instead, they have arbitrarily taken just a single relation to hold, even though the relations are simply recorded in an *a priori* canonical order. This practice is problematic because, for example, there may well be a difference in the properties of segments where two relations are jointly seen to hold, versus those segments in which only one or the other holds. This can result in unwanted noise in the data and lower the reliability of whatever is induced.

While our previous studies showed another source of multiple discourse relations holding concurrently between discourse segments, the work reported here explains how, in the context of multiple relations, participants can take very different conjunctions to be conveying the same relation, and what can change participants' selection of a conjunction to mark the relation they infer alongside that conveyed by an explicit discourse adverbial.

3 Methodology

A locally crowdsourced conjunction-insertion task provided a proxy for labelling relations between adjacent discourse segments within a passage.

Our materials consisted of passages containing an explicit discourse adverbial, preceded by a gap, which effectively separated the passage into two segments. The passages consisted of 16 with *in other words*, 16 with *instead*, 16 with *after all*, and 48 with *otherwise*. Participants were asked to read each passage and choose the conjunction(s) that best expressed how the two segments link together. The presentation of conjunction choices varied in order for each participant, but always consisted of AND, BECAUSE, BUT, OR, SO, NONE. While the task admittedly encourages participants to select one (or more) conjunctions, our prior work has shown that participants are very willing to use NONE if no conjunction is appropriate. We therefore take their insertion of a conjunction as their endorsement of the relation signaled by that conjunction. To further control data quality, we included 6 catch trials with an expected correct conjunction like "To be _______ not to be".

Three of the explicit discourse adverbials that we chose are *anaphoric*: *in other words*, *otherwise*, and *instead* (Webber et al., 2000). Unlike conjunctions such as AND, BECAUSE, BUT, OR and SO, they are not constrained by structure as to what they establish discourse relations with. So a conjunction-insertion task can be used to assess links between the segments (see also Scholman and Demberg 2017). Our three anaphoric adverbials share a core meaning of 'otherness' via their lexical semantics and flexibility in the relations they can participate in, making them a fruitful set to compare. The fourth adverbial, *after all*, allows us to test a hypothesis that the inferred connection between clauses is not driven by the adverbial alone.

These particular adverbials were selected because they had yielded unexpected combinations of conjunction insertions in our prior work (e.g., OR/SO with *in other words*). This is in contrast to adverbials like *therefore* and *nevertheless*, for which participants' conjunction combinations could be attributed to variation in the specificity of the conjunctions (SO/AND for *therefore*, BUT/AND for *nevertheless*). For our selection of a set of conjunctions to use as proxies for relation labels, we included all the coordinating conjunctions in English, as well as the subordinating conjunction BECAUSE as EXPLANATION relations are frequent.

All participants (N=28) were monolingual native English speakers who were selected following a pre-test to measure their ability to consistently insert conjunctions that captured the underlying coherence relations in a series of passages. All gave informed consent. They each received £50 for their time. Each participant saw one of two randomly ordered lists. Passages were presented in batches of 34, one batch per day for three days.

The materials were simplified variants of naturally occurring passages. Some were also manipulated systematically, in ways aimed at altering the availability of different coherence relations. Passages are available via the "dataset" link on the paper in the ACL anthology, and predictions about them are laid out in Sections 4.1–4.4.

4 Datasets

4.1 *In other words* Dataset

Rohde et al. (2016) report an OR∼SO response split for *in other words* when participants could insert only their top choice of conjunction. Figure 1 shows SO dominating participants' choice in all cases, but OR showing up among their choices in all but one passage (leftmost vertical bar). Additionally, several passages elicited BUT as the top choice of some participants.

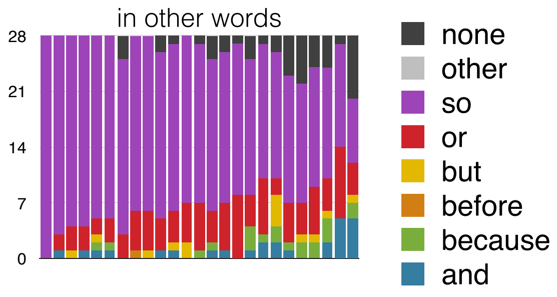

Figure 1: Stacked bar chart for conjunction insertions in passages with *in other words* (Rohde et al., 2016). Each vertical bar represents a passage with one response from each participant (N=28, no overlap with current participants).

The *in other words* passages of the current experiment tested two linked hypotheses: The first is that OR∼SO response splits arise from two components of the lexical semantics of the adverbial itself: its sense of an evoked alternative and its sense of a consequence via restatement, whereby the truth of the second segment holds because it provides a reformulated restatement of the first segment's content. For passage (2), this corresponds to the deforestation of 75,000 acres of tropical forest entailing the disappearance of an area the size of Central Park every 16 minutes.

The second hypothesis is that the prevalence of and substitutability between SO and OR in (2) depends on the immediately adjacency of the two segments. This was suggested by participant choices of BUT (cf. Figure 1), as well as the observation that *in other words* does not always license OR via its lexical semantics and SO via entailment, as shown in (6), where BUT has become more available. Note that none of the relations conveyed by these conjunctions (CONTRAST or CONCESSION for BUT, DISJUNCTION for OR, CONSEQUENCE for SO) are already conveyed by the adverbial itself, which for *in other words*) would be RESTATEMENT.

(6) Unfortunately, nearly 75,000 acres of tropical forest are converted or deforested every day. *I don't know where I heard that* ______ in other words an area the size of Central Park disappears every 16 minutes.

We tested these hypotheses by creating minimal pairs of 16 passages containing *in other words*. The pairs varied in the presence/absence of a metalinguistic comment intervening between the original description and its reformulation, as in (7)–(8).

(7) Typically, a cast-iron wood-burning stove is 60 percent efficient ______ in other words 40 percent of the wood ends up as ash, smoke or lost heat.

(8) Typically, a cast-iron wood-burning stove is 60 percent efficient. *How this is measured is unclear* ______ in other words 40 percent of the wood ends up as ash, smoke or lost heat.

For each passage, participants identified their preferred conjunction and then any others that they took to convey the same sense. Half the participants saw a given passage with no intervening metalinguistic comment, half with.

If our hypotheses are confirmed, it will show that manipulating the immediately preceding segment can shift participants' preference from relations associated with OR and SO (ALTERNATIVE and CONSEQUENCE) to relations of CONTRAST or CONCESSION. This would then be evidence that adjacency affects what coherence relations participants take to be available.

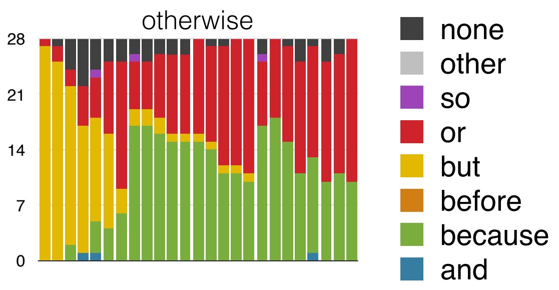

Figure 2: Stacked bar chart for participants' (N=28) conjunction insertions in *otherwise* passages (Rohde et al., 2016)

4.2 *Otherwise* Dataset

Rohde et al. (2016) report surprising response splits amongst BECAUSE∼BUT∼OR for *otherwise* in their conjunction-insertion data (Figure 2). Given that *otherwise* has several different functions (described below), we hypothesize that different response splits arise from the lexical semantics of *otherwise*, combined with inference as to the function of the *otherwise* clause in a given passage.

One function of *otherwise* is in ARGUMENTATION. Here, an *otherwise* clause provides a reason for a given claim, as in (9). Another function is in ENUMERATION, when the speaker first gives some preferred or more salient options, the *otherwise* clause introduces other alternative options, as in (10). A third use is in expressing an EXCEPTION to a generalization. Here, the main clause expresses a generalization, while *otherwise* clause specifies an exception (disjunctive alternative) to it, as in (11).

(9) Proper placement of the testing device is an important issue ______ otherwise the test results will be inaccurate.

(10) A baked potato, plonked on a side plate with sour cream flecked with chives, is the perfect accompaniment ______ otherwise you could serve a green salad and some good country bread.

(11) Mr. Lurie and Mr. Jarmusch actually catch a shark, a thrashing 10-footer ______ otherwise the action is light.

Results presented in (Rohde et al., 2017) for passages like (9) showed participant judgments of OR and BECAUSE, but not BUT. Passages like (10) yielded pairings of OR and BUT, but not BECAUSE. Lastly, passages like (11) yielded response splits between BUT and the less specific AND (Knott, 1996).

Note that due to overlaps in conjunction choice, some conjunctions cannot be unambiguously associated with a single use of *otherwise*: While BECAUSE may unambiguously signal that a participant has inferred ARGUMENTATION, OR might indicate inference of either ARGUMENTATION or

ENUMERATION. Thus we probe both participant choices of connectives and (via paraphrase) the use of *otherwise* that they take to hold.

We chose 16 passages for each use of *otherwise*, based on our own category judgments. For each passage, we asked participants to select the conjunction that best expressed how its two segments were related, and then any other connectives that they took to express the same thing.

A paraphrase task was then used as further evidence for the relation participants inferred in the *otherwise* passages. After completing a given session's batch of passages, participants were asked to select which of three options they took to be a valid paraphrase of the passage. Each use of *otherwise* was assigned a distinct paraphrase to link the left-hand and right-hand segments (LHS, RHS).

- ARGUMENTATION: "A reason for ⟨LHS⟩ is ⟨RHS⟩."
- EXCEPTION: "Generally ⟨RHS⟩. An exception is when ⟨LHS⟩."
- ENUMERATION: "There's more than one good option for ⟨goal⟩. They are: ⟨LHS⟩, ⟨RHS⟩."

We also allowed participants to choose a second paraphrase if they thought it appropriate.

4.3 *Instead* Dataset

Rohde et al. (2016) report a range of participant choices in conjunction-insertion passages involving *instead* (Figure 3). For passages on the left of the figure, participants uniformly chose BUT, while the passage on the far right yielded a strong preference for SO. Elsewhere, some chose BUT and some chose SO. (For the current experiment, we ignore the fact that AND can contingently substitute for either BUT or SO as a connective in text (Knott, 1996), focussing only on passages where participants explicitly choose BUT and/or SO.)

Rohde et al. (2017) report even more surprising participant responses to passages such as (12), where some participants selected both BUT and SO as equally expressing how the segments in the passage were related.

(12) There may not be a flight scheduled to Loja today ______ instead we can go to Cuenca. [BUT∼SO]

Neither the inter-participant split between BUT and SO in (Rohde et al., 2016) nor the intra-participant split between them (Rohde et al., 2017) can be explained in terms of *instead* itself, since

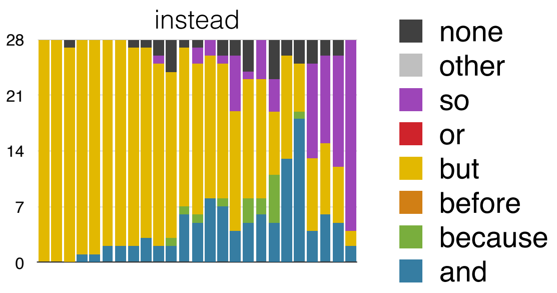

Figure 3: Stacked bar chart for participants' (N=28) conjunction insertions in *instead* passages (Rohde et al., 2016)

instead simply conveys that what follows is an alternative to an unrealised situation in the context (Prasad et al., 2008; Webber, 2013). The current experiment tests the hypothesis that this BUT∼SO split is a consequence of inference from properties of the segments themselves.

To test this hypothesis, we created 16 minimal pairs of passages containing *instead*, one of which emphasized the information structural parallelism between the clauses, as in (13a), and another variant (13b) that de-emphasized that parallelism in favor of a causal link implied by a downward-entailing construction such as *too X* (Webber, 2013). For each passage, half the participants saw the parallelism variant in the conjunction-insertion task, while half saw the causal variant.

(13) a. There was no flight scheduled to Loja yesterday ______ instead there were several to Cuenca.

b. There were too few flights scheduled to Loja yesterday ______ instead we went to Cuenca.

4.4 *After all* Dataset

In (Rohde et al., 2017), we reported a BECAUSE∼BUT response split for passages containing *after all*. We speculated that this may be because a passage such as (14) below presents an argument in which the second segment serves as a REASON (hence, BECAUSE) for the first segment, but also serves to CONTRAST with it (hence, BUT).

(14) Yes, I suppose there's a certain element of danger in it ______ (after all) there's a certain amount of danger in living, whatever you do.

We hypothesize that the BECAUSE∼BUT split cannot be a consequence of the adverbial *after all*, which the Cambridge Dictionary indicates is "used to add information that shows that what you have just said is true".[1] If REASON and/or CONTRAST

[1] https://dictionary.cambridge.org/us/dictionary/english/after-all

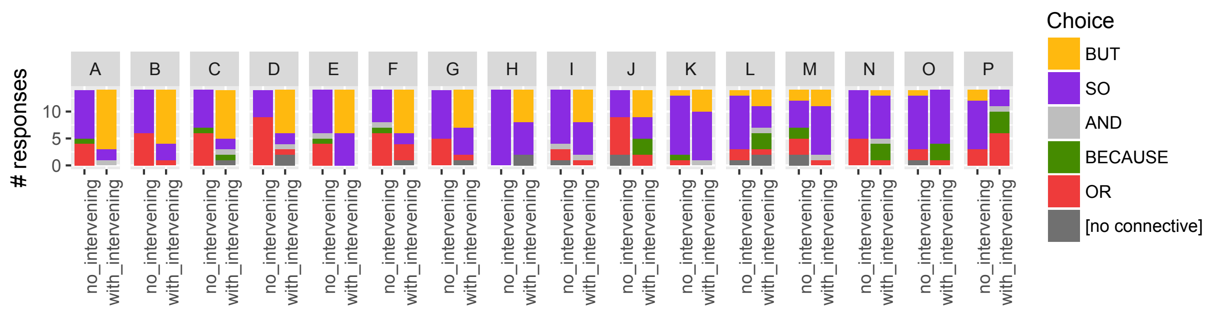

Figure 4: Distribution of participants' first choice of conjunction for passages with *in other words*. Each participant saw only one variant. Each vertical bar represents a passage with the responses from each participant, color-coded by conjunction.

are being conveyed, it can't be a consequence of *after all*. As such, this response split must depend on the reasoning that supports the inference of coherence between the two segments, separate from the adverbial itself.

We test the hypothesis that the response split is independent of the presence or absence of *after all*. Starting with 16 passages that originally contained *after all*, we created a variant of each passage without the adverbial. The conjunction insertion task was the same as with the other datasets.

5 Results

5.1 *In other words*: Inference and adjacency

Section 4.1 lays out the joint hypotheses that inferred relations in passages with *in other words* reflect two components of the lexical semantics of the adverbial (leading to the OR$\sim$SO split) and that the presence of intervening material before *in other words* reduces the availability of those relations, favoring BUT instead.

Figure 4 shows the predicted pattern: The no-intervening-content condition primarily yields OR/SO responses (with variation across passages on the OR-vs.-SO preference) with a relative increase in BUT responses in the intervening-content condition.[2] Passage B corresponds to the pair of examples (2)/(6), and passage C reflects (7)/(8).

For the analysis here and in Section 5.3, a relevant first-choice conjunction was chosen and the binary outcome of its insertion was modeled with a mixed-effect logistic regression. Here, the insertion of OR indeed varied with the presence/absence of intervening material ($\beta = -1.569$, $p < 0.005$).

We posit that increases in BUT associated with the intervening content indicate either an interruption of the meta-linguistic tangent or an intention to signal a contrast with the negative affect of the tangent itself (e.g., "I don't know where...", "frustrating way of putting it", "how this is measured is unclear"). We speculate that the presence of BECAUSE in passages with intervening content may arise when that content implies that the situation is somehow surprising, which in turn merits explanation (e.g., "it's an UNUSUAL role for her", "their ability to actually work sensitively is perhaps QUESTIONABLE", "it's STRANGE to think of a planet being born"). These hypotheses will themselves need to be tested.

[2]For Passage P in Figure 4, participants may have linked the *in other words* clause to the intervening material itself.

5.2 *Otherwise*: Inference from semantic features of segments

As noted in Section 4.2, passages containing *otherwise* were used to test how semantic properties of the segments themselves influenced conjunction choice. The categorization of passages by the researchers (16 ARGUMENTATION, 16 EXCEPTION, 16 ENUMERATION) predicts the conjunctions chosen by participants. In aggregate, ≈99% of responses to ARGUMENTATION passages were BECAUSE or OR or both. ≈92% of responses to EXCEPTION passages were BUT, AND, or both BUT and AND. And ≈98% of responses to ENUMERATION passages were BUT, AND, OR, or some subset thereof. For analysis, a mixed-effect logistic regression modeled the binary outcome of BUT insertion and showed significant variation across the three categories ($p < 0.001$). This measure captures the difference between pairs of categories: ARGUMENTATION permits BECAUSE and OR (hence BUT is rare) while ENUMERATION permits BUT and OR (hence BUT is present) and EXCEPTION favors BUT (hence BUT is very frequent). All pairwise comparisons yielded a main effect of category on this dependent measure (p's < 0.001).

Turning to individual passages, participant choices are shown in Figures 5–7. For ARGUMENTATION (Figure 5), the effect is uniformly strong, with all passages showing BECAUSE or OR as

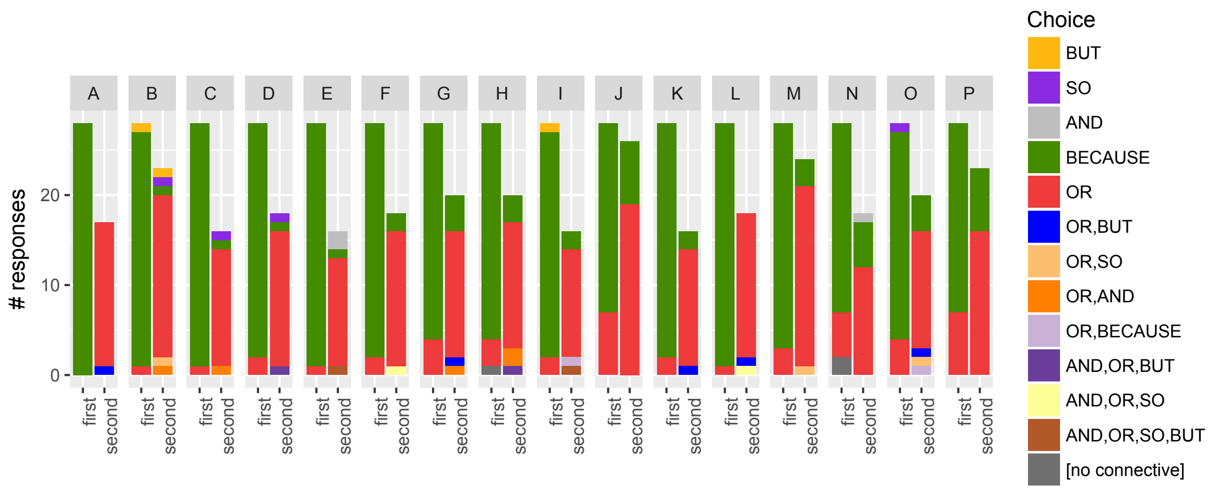

Figure 5: Distribution of first and second choice conjunctions for ARGUMENTATION *otherwise*. Labels such as "OR,BUT" are for multiple second choices. Each vertical bar represents a passage with the responses from each participant, color-coded by conjunction. Enlarged B/W versions of Figures 4–8 are available via the "notes" link on the paper in the ACL anthology.

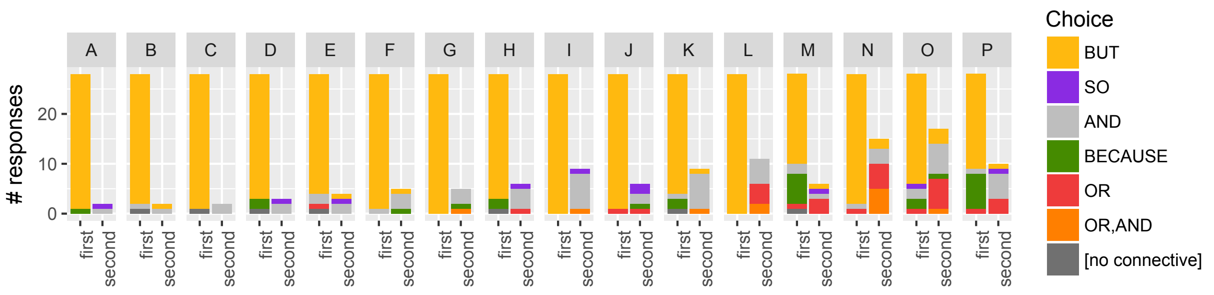

Figure 6: Distribution of first and second choice conjunctions for EXCEPTION *otherwise*. The label "OR,AND" in the legend implies both as second choices.

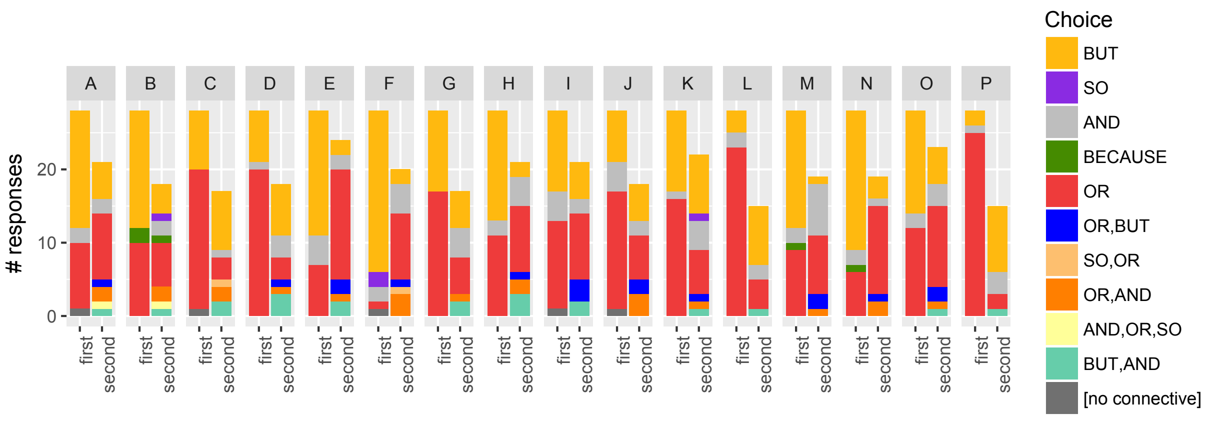

Figure 7: Distribution of first and second choice conjunctions for ENUMERATION *otherwise*. Labels in the legend such as "SO,OR" are for multiple second choices.

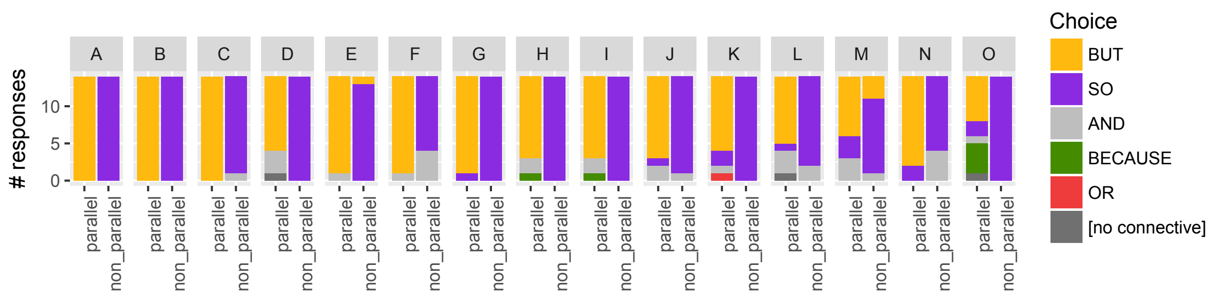

Figure 8: *Instead* passages, pairing a parallel variant and a causal variant. Each column shows the distribution of participants' first choice in the conjunction-insertion task. Each participant saw only one variant.

participants' top choice, with OR or BECAUSE chosen as equivalent (shown in the columns labelled "second"). For EXCEPTION (Figure 6), BUT is consistently the participants' top choice.

There are a few deviations from this near uniform endorsement of BUT for EXCEPTION (Figure 6, passages L–P). Any hypotheses, however, would require further experimentation to test. For example, in passage M (see (15)) and P (see (16)), participants rarely identified any conjunction as conveying the same sense as BUT. However, when their top choice was BECAUSE, they also selected OR as conveying the same sense. As noted above, BECAUSE and OR predominate with *otherwise* used in ARGUMENTATION. This raises the question of why passages M and P lead some participants to infer ARGUMENTATION and other participants, either EXCEPTION or ENUMERATION.

(15) Democrats insist that the poor should be the priority, and that tax relief should be directed at them _____ otherwise they lack a cogent vision of the needs of a new economy.

(16) He said that the proposed bill would give states more flexibility in deciding whether they wanted to use the Federal money for outright grants to municipalities or to set up loan programs _____ otherwise it left last fall's Congressional legislation unchanged.

Finally, though the pattern for ENUMERATION (Figure 7) is harder to see, combinations of BUT, OR and AND predominate as participants' top choices, with a few tokens of BECAUSE and SO, but too few to analyse as anything but noise.

The above results reflect researcher-assigned use labels. However, the confusion matrix in Table 1 shows that on the whole, participants agree with that assignment. The column labelled Multiple is for cases where participants offered two paraphrases. For ARGUMENTATION, at least one paraphrase always corresponded to EXCEPTION, while for ENUMERATION, it did so for most of these tokens (9/14). We comment on this below.

While there was less agreement when participants offered multiple paraphrases for researcher-assigned EXCEPTION, there may be too few tokens here to draw any kind of conclusion. In any case, the results for ARGUMENTATION and ENUMERATION agree both across participants (in what paraphrase they choose when they don't choose the researcher-assigned label) and within participants (in what pairs of paraphrases they gave for the original passage).

The above results support our hypothesis that variability in participants' choice of conjunctions follows from both the lexical semantics of *otherwise* and the relation that participants infer between the segments in the passage.

5.3 *Instead*: Inference from a single manipulated property

On aggregate, participants responded very differently to the parallel and causal variants of *instead* passages (cf. Section 4.3). Figure 8 shows that in all cases, the parallel variant yielded more BUT responses, whereas the non-parallel (causal) variant yielded significantly more SO responses (main effect of (non-)parallelism: β=−7.0008, p<0.001).[3]

Some of these results are very strong. For example, Passage A (17) drew all BUT responses for the

[3]We analyzed only 15 passages for *instead* and *after all*, due to a presentation error of the 16th for these adverbials.

	Participant			
Researcher	ARGUMENTATION	ENUMERATION	EXCEPTION	Multiple
ARGUMENTATION	401 (91.5%)	4	25	18
ENUMERATION	23	364 (81.4%)	46	14
EXCEPTION	21	29	393 (87.7%)	5

Table 1: Researcher labels assigned to *otherwise* passages vs. labels implied by participant paraphrases

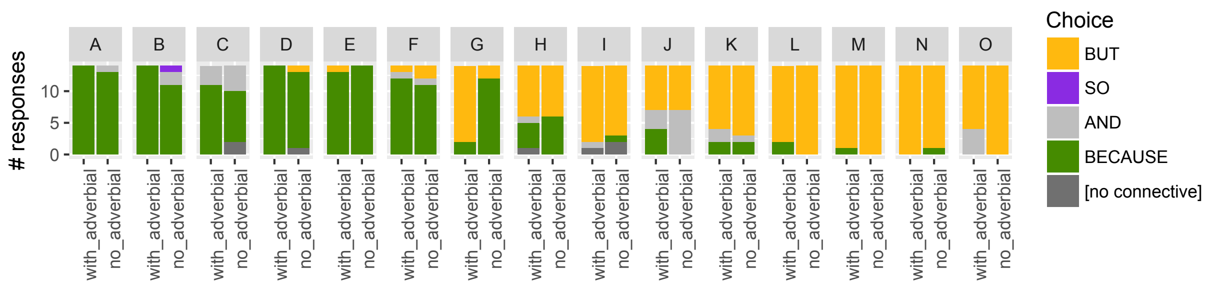

Figure 9: Distribution of first choice in conjunction selection task for passages with *after all*

parallel variant in (17a) and all SO responses for the causal variant in (17b), as did Passage B. In a few cases, however, the parallel variant drew variable responses, even while its causal variant drew strong SO responses. This is true of Passage O, with parallel and causal variants in (18a–b).

(17) a. They could have been playing football in the village green _____ instead they played in the street.

b. They didn't like playing football in the village green _____ instead they played in the street.

(18) a. Smugglers nowadays don't use overland passages _____ instead they use the seas to transport their goods.

b. Smugglers' overland passages nowadays are too visible _____ instead they use the seas to transport their goods.

One possible explanation is that participants varied in the role they assigned to the positive claim in the second segment of (18a) – either as a reason for the negative claim in the first segment (BECAUSE), as a contrast with that claim (BUT), or as its result (SO). Although manipulating the segment to enhance either parallelism or causality can change participant responses, it is clear that parallelism alone doesn't guarantee contrast.

5.4 *After all*: Adverb adds little to inference

Figure 9 shows participant choice of conjunction when *after all* is present and when it is absent. Their choice is largely the same for passages A–F and K–N, with and without the adverbial. As for passage O, since AND can contingently substitute for BUT (Knott, 1996), the response pattern can be considered the same as well. A by-passage correlation between the rate of BUT and BECAUSE responses across the two conditions confirms this similarity (R^2=.70, F(1,13)=30.98, p<0.001). The outlier is passage G:

(19) There was a testy moment driving over the George Washington Bridge when the toll-taker charged him $24 for his truck and trailer _____ after all it was New York.

With *after all*, the majority of participants chose BUT as best expressing how the two segments are connected, while without it, the majority chose BECAUSE. Whatever explanation we gave here would be pure speculation. We trust that the fact that the other 14 passages demonstrate the predicted effect provides sufficient evidence that splits in participant responses are not simply a result of the presence of a discourse adverbial.

6 Conclusion

While our previous work showed that multiple discourse relations can hold between two segments – relations at the same semantic level, simultaneously available to a reader – we provided no evidence as to what influences the particular relations that are taken to be available. Our current experiments have provided some such evidence. Specifically, we have shown that participant responses to systematically manipulated passages involving discourse adverbials can be explained in terms of both the lexical semantics of discourse adverbials and properties of the passages that contain them. As the conjunctions chosen by participants convey senses that differ from those of the discourse adverbials, we also provided evidence for the simultaneous availability of multiple coherence relations that arise from both explicit signals and inference. We hope the reader is now convinced that, in both psycholinguistic research on discourse coherence and computational work on discourse parsing, one needs to identify and examine evidence for coherence involving more than one discourse relation.

Abstract

We present a generative probabilistic model of documents as sequences of sentences, and show that inference in it can lead to extraction of long-range latent discourse structure from a collection of documents. The approach is based on embedding sequences of sentences from longer texts into a 2- or 3-D spatial grids, in which one or two coordinates model smooth topic transitions, while the third captures the sequential nature of the modeled text. A significant advantage of our approach is that the learned models are naturally visualizable and interpretable, as semantic similarity and sequential structure are modeled along orthogonal directions in the grid. We show that the method can capture discourse structures in narrative text across multiple genres, including biographies, stories, and newswire reports. In particular, our method can capture biographical templates from Wikipedia, and is competitive with state-of-the-art generative approaches on tasks such as predicting the outcome of a story, and sentence ordering.

1 Introduction

The ability to identify discourse patterns and narrative themes from language is useful in a wide range of applications and data analysis. From a perspective of language understanding, learning such latent structure from large corpora can provide background information that can aid machine reading. For example, computers can use such knowledge to predict what is likely to happen next in a narrative (Mostafazadeh et al., 2016), or reason about which narratives are coherent and which do not make sense (Barzilay and Lapata, 2008). Similarly, knowledge of discourse is increasingly important for language generation models. Modern neural generation models, while good at capturing surface properties of text – by fusing elements of syntax and style – are still poor at modeling long range dependencies that go across sentences (Li and Jurafsky, 2017; Wang et al., 2017). Models of long range flow in the text can thus be useful as additional input to such methods.

Previously, the question of modeling discourse structure in language has been explored through several lenses, including from perspectives of linguistics, cognitive science and information retrieval. Prominent among linguistic approaches are Discourse Representation Theory (Asher, 1986) and Rhetorical Structure Theory (Mann and Thompson, 1988); which formalize how discourse context can constrain the semantics of a sentence, and lay out ontologies of discourse relation types between parts of a document. This line of research has been largely constrained by the unavailability of corpora of discourse relations, which are expensive to annotate. Another line of research has focused on the task of automatic *script induction*, building on earlier work in the 1970's (Schank and Abelson, 1977). More recently, methods based on neural distributed representations have been explored (Li and Hovy, 2014; Kalchbrenner and Blunsom, 2013; Le and Mikolov, 2014) to model the flow of discourse. While these methods have had varying degrees of success, they are largely opaque and hard to interpret. In this work, we seek to provide a scalable model that can extract latent sequential structures from a collection of documents, and can be naturally visualized to provide a summary of the learned semantics and discourse trajectories.

In this work, we present an approach for extract-

[*]Work done while first author was an intern at Microsoft Research

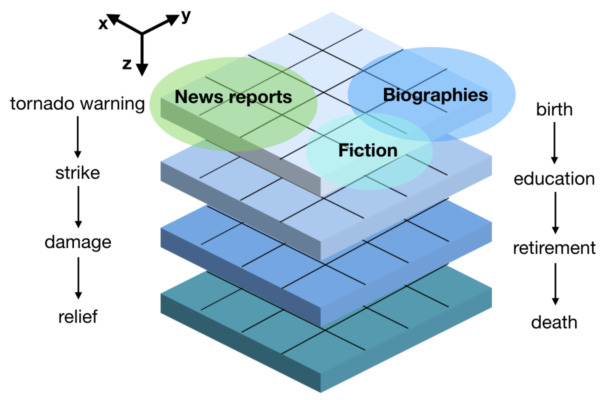

Figure 1: Modeling principle for Sequential Counting Grids. We design the method to capture semantic similarities between documents along XY planes (e.g., biographies might be more similar to literary fiction than news reports), as well extract sequential trajectories along the Z axes similar to those shown. The sequence of sentences in a document is latently aligned to positions in the grid, such that the model prefers alignments of contiguous sentences to grid cells that are spatially close.

ing and visualizing sequential structure from a collection of text documents. Our method is based on embedding sentences in a document in a 3-dimensional grid, such that contiguous sentences in the document are likely to be embedded in the same order in the grid. Further, sentences across documents that are semantically similar are also likely to be embedded in the same neighborhood in the grid. By leveraging the sequential order of sentences in a large document collection, the method can induce lexical semantics, as well as extract latent discourse trajectories in the documents. Figure 1 shows a conceptual schematic of our approach. The method can learn semantic similarity (across XY planes), as well as sequential discourse chains (along the Z-axis). The parameters and latent structure of the grid are learned by optimizing the likelihood of a collection of documents under a generative model. Our method outperforms state-of-the-art generative methods on two tasks: predicting the outcome of a story and coherence prediction; and is seen to yield a flexible range of interpretable visualizations in different domains of text. Our method is scalable, and can incorporate a broad range of features. In particular, the approach can work on simple tokenized text.

The remainder of this paper is organized as follows. In Section 2, we briefly summarize other related work. In Section 3, we describe our method in detail. We present experimental results in Section 4, and conclude with a brief discussion.

2 Related work

Building on linguistic theories of discourse and text coherence, several computational approaches have attempted to model discourse structure from multiple perspectives. Prominent among these are Narrative Event Chains (Chambers and Jurafsky, 2008) which learn chains of events that follow a pattern in a unsupervised framework, and the Entity grid model (Barzilay and Lapata, 2008), which represents sentences in a context in terms of discourse entities occurring in them and trains coherence classifiers over this representation. Other work extends these using better models of events and discourse entities (Lin et al., 2011; Pichotta and Mooney, 2015). Louis and Nenkova (2012) use manually provided syntactic patterns for sentence representation, and model transitions in text as Markov probabilities, which is related to our work. However, while they use simple HMMs over discrete topics, our method allows for a richer model that also captures smooth transition across them. Approaches such as Kalchbrenner and Blunsom (2013); Li et al. (2014); Li and Jurafsky (2017) model text through recurrent neural architectures, but are hard to interpret and visualize. Other approaches have explored applications related to modeling narrative discourse in context of limited tasks such as story cloze (Mostafazadeh et al., 2016) and identifying similar narratives (Chaturvedi et al., 2018).

From a large scale document-mining perspective, the question of extracting intra-document structure remains largely underexplored. While early models such as LDA completely ignore ordering and discourse elements of a documents, other methods that use distributed embeddings of documents are opaque (Le and Mikolov, 2014), even while they can in principle model sequential structure within a document. Methods such as HMM-LDA (Griffiths et al., 2005) and Topics-over-time (Wang and McCallum, 2006) address the related question of topic evolution in a stream of documents, but these approaches are too coarse to model intra-document sequential structure. In terms of our technical approach, we build on previous research on grid-based models (Jojic and Perina, 2011), which have previously been used for topic-modeling for images and text as unstructured bags-of-features.

3 Sequential CG model

In this section, we present our method, which we call **Sequential Counting Grids**, or **Sequential CG**. We first present our notation, model formulation and training approach. We discuss how the method is designed to incorporate smoothness and sequential structure, and how the method can be efficiently scaled to train on large document collections. In Section 3.2, we present a mixture model variant that combines Sequential CG with a unigram language model.

3.1 Model description

We represent a document as a sequence $\mathbf{s}$ of sentences, $\mathbf{s} = \{s_1, s_2 \dots s_D\}$, where D represents the number of sentences in the document. In general, we assume each sentence is represented as a multiset of features $s_i = \{c_z\}_i$, where c_z^i represents the count of the feature indexed by z in the ith sentence in the sequence.[1]

The Sequential CG consists of a 3-D grid G of size $E_x \times E_y \times E_z$, where E_x, E_y and E_z denote the extent of the grid along the X, Y and Z-axes (see Figure 1). Let us denote an index of a position in the grid by an integer-valued vector $\mathbf{i} = (i_x i_y i_z)$. The three components of the index together specify a XY location as well as a depth in the grid. The Sequential CG model is parametrized by two sets of parameters, $\pi_{\mathbf{i},z}$ and $\mathcal{P}_{\mathbf{ij}}$. Here, $\pi_{\mathbf{i},z}$ represents a multinomial distribution over the vocabulary of features z for each cell in the grid G, i.e. $\sum_z \pi_{\mathbf{i},z} = 1 \ \forall \ \mathbf{i} \in G$. To induce smoothness across XY planes, we further define histogram distributions $h_{\mathbf{i},z}$, which average the π distributions in a 2-D neighborhood $W_\mathbf{i}$ (of size specified by $W = [W_x, W_y]$) around the grid position $\mathbf{i}$. This notation follows Jojic and Perina (2011).

$$h_{\mathbf{i},z} = \frac{1}{W_x W_y} \sum_{\mathbf{i}' \in W_\mathbf{i}} \pi_{\mathbf{i}',z} \tag{1}$$

The generative model assumes that individual sentences in a document are generated by h distributions in the grid. Movements from one position $\mathbf{i}$ to another $\mathbf{j}$ in the grid are modeled as transition probabilities $\mathcal{P}_{\mathbf{ij}}$. The generative process consists of the following. We uniformly sample a starting location $\mathbf{i}_1$ in the grid. We sample words in the first sentence s_1 from $\pi_{\mathbf{i}1}$, and sample the next position $\mathbf{i}_2$ from the distribution $\mathcal{P}_{\mathbf{i}_1,:}$, and so on till we generate s_D. The alignments $\mathcal{I} = [\mathbf{i}_1, \mathbf{i}_2 \dots \mathbf{i}_D]$ of individual sentences in a document with positions in the grid are latent variables in our model.

Given the sequence of alignments $\mathcal{I}$ for a document, the conditional likelihood of generating s is given as a product of generating individual sentences:

$$p(s|\,\mathcal{I}) = \prod_d^D p(\{c_z^d\}|\,\mathbf{i}_d) = \prod_{d=1}^D \prod_z (h_{\mathbf{i}_d,z})^{c_z^d} \tag{2}$$

Since the alignments of sequences to their positions in the grids $\mathcal{I}$ are latent, we marginalize over these to maximize the likelihood of an observed collection of documents $\mathcal{S} := \{\mathbf{s}^t\}_{t=1}^T$. Here, T is the total number of documents, and t is an index over individual documents. Using Jensen's inequality, *any* distributions $q_\mathcal{I}^t$ over the hidden alignments $\mathcal{I}^t$ provide lower-bounds on the data log-likelihood.

$$\begin{aligned}\sum_t \log p(\mathbf{s}_t|\pi) &= \sum_t \log\Big(\sum_\mathcal{I} p(\mathbf{s}_t, \mathcal{I}|\pi)\Big) \\ &= \sum_t \log\Big(\sum_\mathcal{I} q_\mathcal{I}^t \frac{p(\mathbf{s}_t|\mathcal{I})p(\mathcal{I}))}{q_\mathcal{I}^t}\Big) \\ &\geq -\sum_t \sum_\mathcal{I} q_\mathcal{I}^t \log q_\mathcal{I}^t \\ &\quad + \sum_t \sum_\mathcal{I} q_\mathcal{I}^t \log\big(p(s|\mathcal{I}, \pi)p(\mathcal{I})\big)\end{aligned} \tag{3}$$

Here, $q_\mathcal{I}^t$ denotes a variational distribution for each of the data sequences $\mathbf{s}_t$. The learning algorithm consists of an iterative generalized EM procedure (which can be interpreted as a block-coordinate ascent in the latent variables $q_\mathcal{I}^t$ and the model parameters π and $\mathcal{P}$). We maximize the lower bound in Eqn 3 exactly by setting $q_\mathcal{I}^t$ to the posterior distribution of the data for the current values of the parameters π (standard E step). Thus, we have

$$\begin{aligned} q_\mathcal{I}^t &\propto p(\mathbf{s}|\mathcal{I})p(\mathcal{I}) \\ &= \Big[\prod_{d=1}^D \prod_z (h_{\mathbf{i}_d,z})^{c_z^d(t)}\Big]\Big[\prod_{d=2}^D \mathcal{P}_{\mathbf{i}_{d-1},\mathbf{i}_d}\Big]\end{aligned} \tag{4}$$

We do not need to explicitly compute the posterior distribution $q_\mathcal{I}^t = p(\mathcal{I}|\mathbf{s})$ at this point, but only use it to compute the relevant expectation statistics in the M-step. This can be done efficiently, as we

[1] These may simply consist of tokens (words, entities and MWEs) in the sentence, but can include additional information, such as sentiment or event annotations, or other discrete sentence-level representations

see next. In the M-step, we consider $q^t_{\mathcal{I}}$ as fixed, and maximize the objective in terms of the model parameters π. Substituting this in Eqn 3, and focusing on terms that depend on the model parameters (π and $\mathcal{P}$), we get

$$\begin{aligned}\mathcal{L}(\pi,\mathcal{P}) &\geq \sum_t \sum_{\mathcal{I}} q^t_{\mathcal{I}} \log\left(p(s|\mathcal{I},\pi)p(\mathcal{I})\right) + \mathcal{H}_q \\ &= \sum_t \sum_{\mathcal{I}} q^t_{\mathcal{I}} \Bigg(\sum_d \sum_z c^d_z(t) \log h_{\mathbf{i}_d,z} \\ &\qquad + \sum_d \log \mathcal{P}_{\mathbf{i}_{d-1},\mathbf{i}_d} \Bigg) \\ &= \sum_t \sum_{\mathcal{I}} \mathbb{E}_{q^t_{\mathcal{I}}} \Big[\sum_d \sum_z \mathbb{I}_{\mathbf{i}^t_d=\mathbf{i}} c^d_z(t) \log h_{\mathbf{i}_d,z} \Big] \\ &\quad + \sum_t \sum_{\mathcal{I}} \mathbb{E}_{q^t_{\mathcal{I}}} \Big[\sum_d \mathbb{I}_{\mathbf{i}^t_{d-1}=\mathbf{i},\mathbf{i}^t_d=\mathbf{j}} \log \mathcal{P}_{\mathbf{ij}} \Big]\end{aligned} \tag{5}$$

Maximizing the likelihood w.r.t. $\mathcal{P}$ leads to the following updates for the transition probabilities:[2]

$$\mathcal{P}_{\mathbf{ij}} = \frac{\sum_t \sum_d P(\mathbf{i}^t_{d-1} = \mathbf{i}, \mathbf{i}^t_d = \mathbf{j})}{\sum_t \sum_d P(\mathbf{i}^t_{d-1} = \mathbf{i})} \tag{6}$$

Here, the pairwise state-probabilities $P(\mathbf{i}^t_{d-1} = \mathbf{i}, \mathbf{i}^t_d = \mathbf{j})$ for adjacent sentences in a sequence can be efficiently calculated using the Forward-Backward algorithm. In Equation 5, rewriting the term containing h in terms of π using Eqn 1 (and ignoring constant terms W_xW_y), we get:

$$\begin{aligned}&\sum_t \sum_{\mathcal{I}} \mathbb{E}_{q^t_{\mathcal{I}}} \Big[\sum_d \sum_z \mathbb{I}_{\mathbf{i}^t_d=\mathbf{i}} c^d_z(t) \log \sum_{\mathbf{i}' \in W_{\mathbf{i}}} \pi_{\mathbf{i}',z} \Big] \\ &= \sum_t \sum_{\mathcal{I}} \sum_d P(\mathbf{i}^t_d = \mathbf{i}) \sum_z c^d_z(t) \log \sum_{\mathbf{i}' \in W_{\mathbf{i}}} \pi_{\mathbf{i}',z}\end{aligned} \tag{7}$$

The presence of a summation inside of a logarithm makes maximizing this objective for π harder. For this, we simply use Jensen's inequality introducing an additional variational distribution (for the latent grid positions within window $W_{\mathbf{i}}$), and maximize the lower bound. The final M-step update for π becomes:

$$\pi_{\mathbf{i},z} \propto \left(\sum_t \sum_d c^d_z(t) \sum_{\mathbf{k}|\mathbf{i} \in W_k} \frac{P(\mathbf{i}^t_d = \mathbf{k})}{h_{\mathbf{k},z}} \right) \pi_{\mathbf{i},z} \tag{8}$$

As before, the state-probabilities $P(\mathbf{i}^t_d = \mathbf{i})$ can be computed using the Forward Backward algorithm.

Intuitively, the expected alignments in the E-step are distributions over sequences of positions in the grid that best explain the structure of documents for the current value of Sequential CG parameters. In the M-step, we assume these distributions embedding documents into various parts of the grid as given, and update the multinomial parameters and transition probabilities. Modeling the transitions as having a Markov property allows us to use a dynamic programming approach (Forward Backward algorithm) to exactly compute the posterior probabilities required for parameter updates. We note that at the onset of the procedure, we need to initialize π randomly to break symmetries. Unless otherwise stated, in all experiments, we run EM to 200 iterations.

Correlating space with sequential structure: The use of histogram distributions h to generate data forces smoothness in the model along XY planes due to adjacent cells in the grid sharing a large number of parameters that contribute to their histograms (due to overlapping windows). On the other hand, in order to induce spatial proximity in the grid to mimic the sequential flow of discourse in documents, we constrain the transition matrix $\mathcal{P}$ (which specifies transition preferences from one position in the grid to another) to a sparse banded matrix. In particular, a position $\mathbf{i} = (i_x, i_y, i_z)$ in the grid can only transition to itself, its 4 neighbors in the same XY plane, and two cells in the succeeding two layers along the Z-axis ((i_x, i_y, i_{z+1}) and (i_x, i_y, i_{z+2})). This is enforced by fixing other elements in the transition matrix to 0, and only updating allowable transitions.

As an important note about implementation details, we observe here that the Forward-Backward procedure (which is repeatedly invoked during model training) can be naturally formulated in terms of matrix operations.[3] This allows training for the Sequential CG approach to be scalable for large document collections.

In our formulation, we have presented a Sequential CG model for a 3-D grid. This can be adapted to learn 2-D grids (trellis) by setting $E_y = 1$. In our experiments, we found 3-D grids to be better

[2]Since the optimal value for the concave problem $\sum_j y_j \log x_j$ s.t. $\sum_j x_j = 1$ occurs when $x^*_j \propto y_j$

[3]To explain, if $f^d_{1\times G}$ are forward probabilities for step d, and $O^{d+1}_{G\times G}$ are observation probabilities for step $d+1$, $f^{d+1} = f^d \times \mathcal{P} \times O^d$ computes forward probabilities for the next step in the sequence

in terms of task performance and visualization (for a comparable number of parameters).

3.2 Mixture model

The Sequential CG model described above can be combined with other generative models (e.g., language models) to get a mixture model. Here, we show how a unigram language model can be combined with Sequential CG. The rationale behind this is that since the Sequential CG is primarily designed to explain elements of documents that reflect sequential discourse structures, mixing with a context-agnostic distribution can allow it to focus specifically on elements that reflect sequential regularities. In experimental evaluation, we find that such a mixture model shows distinctly different behavior (see Section 4.1.1). Next, we briefly describe updates for this approach.

Let μ_z denote the multinomial distribution over features for the unigram model to be mixed with the CG. Let β_z be the mixing proportion for the feature z, i.e. an occurrence of z is presumed to come from the Sequential CG with probability β_z, and from the unigram distribution with probability $1 - \beta_z$. Further, let α_z^t be binary variable that denotes whether a particular instance of z comes from the Sequential CG, or the unigram model. Then, Equation 2 changes to:

$$p(s|\,\mathcal{I},\alpha) = \prod_{z,d}\Big((h_{\mathbf{i}_d,z})^{c_z^d}\beta_z\Big)^{\alpha_z^t}\big(\mu_z^{c_z^d}(1{-}\beta_z)\big)^{1-\alpha_z^t}$$

Since we do not observe α_z^t (i.e., which distribution generated a particular feature in a particular document), they are additional latent variables in the model. Thus, we need to introduce a Bernoulli variational distribution $q_{\alpha_{zt}}$. Doing this modifies relevant parts (containing $q_{\alpha_{zt}}$) of Equation 5 to:

$$\begin{aligned}&\sum_t\sum_{\mathcal{I}} q_{\mathcal{I}}^t\Bigg(\sum_z q_{\alpha_{zt}}\log\Big(\beta_z\prod_d h_{\mathbf{i}_d,z}^{c_z^d(t)}\Big)\\ &+(1-q_{\alpha_{zt}})\log\Big((1-\beta_z)\mu_z^{\sum_d c_z^d}\Big)\\ &+\sum_d\log\mathcal{P}_{\mathbf{i}_{d-1},\mathbf{i}_d}\Bigg)+\mathcal{H}_{q_{\alpha_{zt}}}\end{aligned} \tag{9}$$

This leads to the following additional updates for estimating $q_{\alpha_{zt}}$ (in the E-step)[4] and β_z (in the M-step).

[4]Since the optimal value for the concave problem $\sum_j x_j \log\frac{y_j}{x_j}$ s.t. $\sum_j x_j = 1$ occurs when $x_j^* \propto y_j$

$$q_{\alpha_{zt}} = \frac{\exp\Big(\sum_{\mathbf{i}}^{\mathcal{I}} P(\mathbf{i}_d^t{=}\mathbf{i})c_z^d(t)\log h_{\mathbf{i}_d,z}\Big)\beta_z}{\exp\Big(\sum_{\mathbf{i}}^{\mathcal{I}} P(\mathbf{i}_d^t{=}\mathbf{i})c_z^d(t)\log h_{\mathbf{i}_d,z}\Big)\beta_z{+}\mu_z^{\sum_d c_z^d}(1{-}\beta_z)}$$

In the M-step, β_z can be estimated simply as the fraction of times z is generated from the Sequential CG component.

$$\beta_z = \frac{\sum_t q_{\alpha_{zt}}}{\sum_t \mathbb{I}_z}$$

4 Evaluation

In this section, we analyze the performance of our approach on text collections from several domains (including short stories, newswire text and biographies). We first qualitatively evaluate our generative method on a dataset of biographical extracts from Wikipedia, which visually illustrates biographical trajectories learned by the model, operationalizing our model concept from Figure 1 in real data (see Figure 2). Next, we evaluate our method on two standard tasks requiring document understanding: story cloze evaluation and sentence ordering. Since our method is completely unsupervised and is not tailored to specific tasks, competitive performance on these tasks would indicate that the method learns helpful regularities in text structure, useful for general-purpose language understanding.

4.1 Visualizing Wikipedia biographies

We now qualitatively explore models learned by our method on a dataset of biographies from Wikipedia.[5] For this, we use the data previously collected and processed by Bamman and Smith (2014). In all, the original dataset consists of extracts from biographies of about 240,000 individuals. For ease of training, we trained our method on a subset of the 50,0000 shortest documents from this set. The original paper uses the numerical order of dates mentioned in the biographies to extract biographical templates, but we do not use this information. Figure 2 visualizes a Sequential CG model learned on this dataset for on a grid of dimensions $E = 8 \times 8 \times 5$, and a histogram window W of dimensions 3×3 . In general, we found that using larger grids leads to smoother transitions and learning more intricate patterns including hierarchies of trajectories, but here we show a model with a

[5]For all our experimental evaluation, we tokenize and lemmatize text using the Stanford CoreNLP pipeline, but retain entity-names and contiguous text-spans representing MWEs as single units

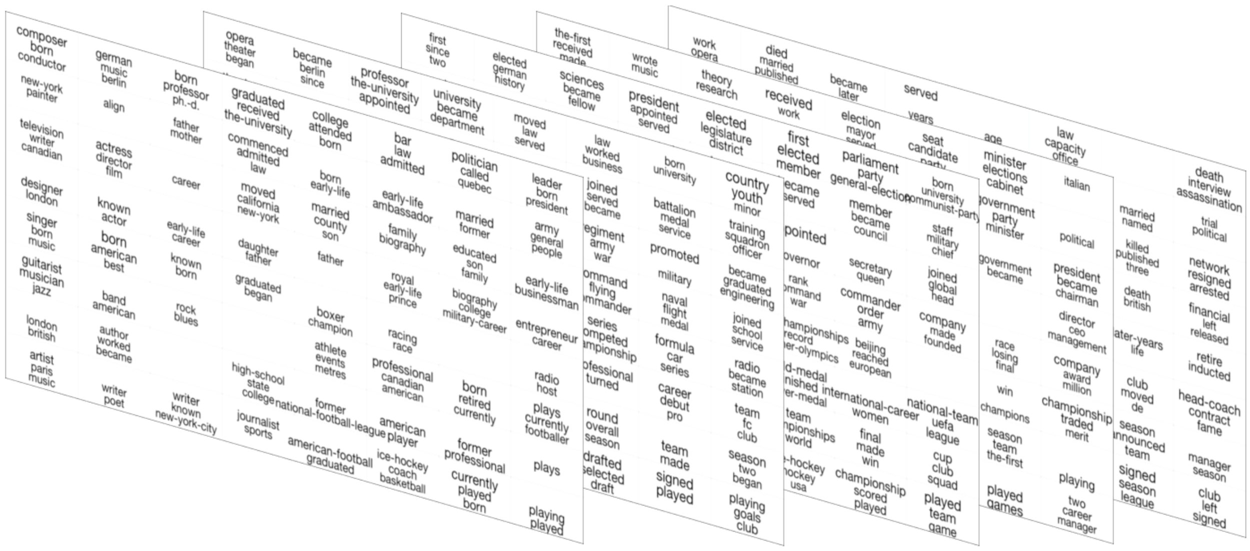

Figure 2: Visualization of a Sequential-CG model with grid size of $8 \times 8 \times 5$, trained on 50,000 documents from the Wikipedia biographies dataset. Cells in the grid show words with highest probabilities (empty cells may indicate that no word has a substantially higher probability than others).

smaller grid for ease of visualization. Here, the words in each cell in the grid denote the highest probability assignments in that cell. Larger fonts within a cell indicate higher probabilities.

We observe that the method successfully extracts various biographical trajectories, as well as capture a notion of similarity between them. To explain, we observe that the lower-right part of the learned grid largely models documents about sportpersons (with discernable regions focusing on sports like soccer, American football and ice-hockey). On the other hand, the left-half of the grid is dominated by biographies of people from the arts and humanities (inlcuding artists, writers, musicians, etc.). The top-center of the grid focuses on academicians and scientists, while the top-right represents biographies of political and military leaders. We note smooth transitions between different regions, which is precisely what we would expect from the use of the smoothing filter that incorporates parameter sharing across cells in the method. Further, as we go across the layers in the figure, we note the biographical trajectories learned by the model across the entire grid. For example, from the grid, the life trajectory of a football player can be visualized as being drafted, signing and playing for a team, and eventually becoming a head-coach or a hall-of-fame inductee.

4.1.1 Effects of mixing

The Sequential-CG method can be combined with other generative models in a mixture model, following the approach previously described in Section 3.2. A major reason to do this might be to allow the base model to handle general content, while allowing the Sequential-CG method to focus on modeling context-sensitive words only. Here, we empirically characterize the mixing behavior for different categories of words.

Figure 3 shows the mixing proportion of different words when the Sequential-CG model is combined with a unigram model. In the figure, the X-axis corresponds to words in the dataset with decreasing frequency of occurrence, whereas the Y-axis denotes the mixing proportions β_z learned by the mixture model. We note that the mixture model learns to explain frequent as well as the long-tail of rare words using the simple unigram model (as seen from low mixing proportion of Sequential-CG method). These regimes correspond to (1) stop-words and very common nouns, and (2) rare words respectively. In turn, this allows the Sequential-CG component to preserve more probability mass to explain the intermediate content words. Thus, the Sequential-CG component only needs to model words that reflect useful statistical sequential patterns, without expending modeling effort on background content (common words) or noise (rare words). For the long tail of infrequent words, we observe that Sequential CG is much more likely to generate verbs and adjectives, rather than nouns. This is as we would expect, since verbs and adjectives often denote events and sentiments, which can

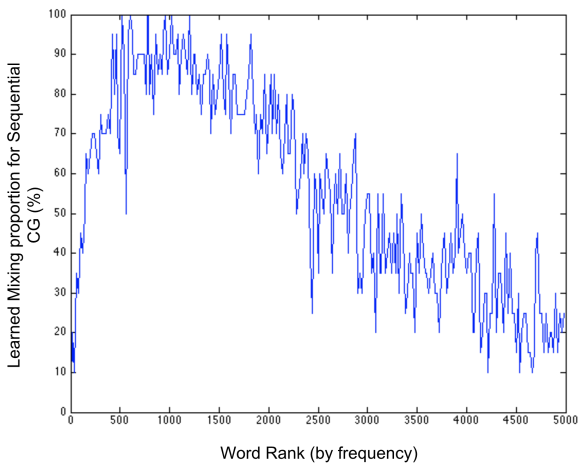

Figure 3: Learned mixing proportion (β_z) in the mixture model of Section 3.2 for words of different frequencies. β_z denotes the probability of a word being generated from the Sequential CG model (rather than from the Unigram model). The Sequential CG learns to model content words (with intermediate ranks), and conserves modeling effort by avoiding modeling both very common words (that occur across contexts), as well as rare words.

be important elements in discourse trajectories.

4.2 Story-cloze

We next evaluate our method on the story-cloze task presented by Mostafazadeh et al. (2016), which tests common-sense understanding in context of children stories. The task consists of identifying the correct ending to a four-sentence long story (called *context* in the original paper) and two possible ending options. The dataset for the task consists of a collection of around 45K unlabeled 5-sentence long stories as well as 3742 5-sentence stories with two provided endings, with one labeled as the correct ending. For this task, we train our method on grids of dimension $15 \times 15 \times 6$ (E), and histogram windows W of size 5×5 on the unlabeled collection of stories. At test time, for each story, we are provided two versions (a story-version v consists of the provided context c, followed by a possible ending e_1, i.e. $v = [c, e]$). For prediction, we need to define a goodness score S_v for a story-version.

In the simplest case, this score can simply be the log-likelihood $\log p_{SCG}(v)$ of the story-version, according to the Sequential-CG model. However, this is problematic since this is biased towards choosing shorter endings. To alleviate this, we define the goodness score by discounting the log-likelihood by the probability of the ending e itself, under a simple unigram model.

	Accuracy
Our Method variants	
Sequential CG + Unigram Mixture	0.602
Sequential CG + Brown clustering	0.593
Sequential CG + Sentiment	0.581
Sequential CG	0.589
Sequential CG (unnormalized)	0.531
DSSM	0.585
GenSim	0.539
Skip-thoughts	0.552
Narrative-Chain(Stories)	0.494
N-grams	0.494

Table 1: Performance of our approach on story-cloze task from Mostafazadeh et al. (2016) compared with other unsupervised approaches (accuracy numbers as reported in Mostafazadeh et al. (2016)).

$$S_v = \log p_{SCG}(c, e) - \log p_{uni}(e)$$

The predicted ending is the story-version with a higher score. Table 1 shows the performance of variants of our approach for the task. Our baselines include previous approaches for the same task: *DSSM* is a deep-learning based approach, which maps the context and ending to the same space, and is the best-performing method in Mostafazadeh et al. (2016). *GenSim* and *N-gram* return the ending that is more similar to the context based on *word2vec* embeddings (Mikolov et al., 2013) and n-grams, respectively. *Narrative-Chains* computes the probability of each alternative based on event-chains, following the approach of Chambers and Jurafsky (2008).

We note that our method improves on the previous best unsupervised methods for the task. This is quite surprising, since our Sequential-CG model in this case is trained on bag-of-lemma representations, and only needs sentence segmentation, tokenization and lemmatization for pre-processing. On the other hand, approaches such as *Narrative-Chains* require parsing and event-recognition, while approaches such as *GenSim* require learning word embeddings on large text corpora for training. Further, we note that predicting the ending without normalizing for the probability of the words in the ending results in significantly weaker performance, as expected. We train another

Recursive (2014)	0.864	0.976
Entity-Grid (2008)	0.904	0.872
Graph (2013)	0.846	0.635

Table 2: Performance of our approach on sentence ordering dataset from Barzilay and Lapata (2008).

variant of Sequential-CG with the sentence-level sentiment annotation (from Stanford CoreNLP) also added as a feature. This does not improve performance, consistent with findings in Mostafazadeh et al. (2016). We also experiment with a variant where we perform Brown clustering (Brown et al., 1992) of words in the unlabeled stories ($K = 500$ clusters), and include cluster-annotations as features for training the method. Doing this explicitly incorporates lexical similarity into the model, leading to a small improvement in performance. Finally, a mixture model consisting of the Sequential-CG and a unigram language model leads to a further improvement in performance. The performance of our unsupervised approach on this task indicates that it can learn discourse structures that are helpful for general language understanding.

The story-cloze task has recently also been addressed as a shared task at EACL (Mostafazadeh et al., 2017) with a significantly expanded dataset, and achieving much higher performance. However, we note that the proposed best-performing approaches (Chaturvedi et al., 2017; Schwartz et al., 2017) for this task are all supervised, and hence not included here for comparison.

Figure 4 shows examples where the model correctly identifies the ending. These show a mix of behavior such as sentiment coherence (identifying dissonance between 'wonderful surprise' and 'stolen') and modeling causation (police being called after being suspected).

4.3 Sentence Ordering

We next evaluate our method on the sentence ordering task, which requires distinguishing an original document from a version consisting of permutations of sentences of the original (Barzilay and Lapata, 2008; Louis and Nenkova, 2012). For this, we use two datasets of documents and their permutations from Barzilay and Lapata (2008), which are used as standard evaluation for coherence prediction tasks. These consist of (i) reports of accidents from the National Transportation Safety Bureau (we refer to this data as *accidents*), and (ii) newswire reports about earthquake events from the Associated press (we refer to this as *earthquakes*). Each dataset consists of 100 training documents, and about 100 documents for testing. Also provided are about 20 generated permutations for each document (resulting in 1986 test pairs for *accidents*, and 1955 test pairs for earthquakes). Documents in *accidents* consist of between 6 and 19 sentences each, with a median of 11 sentences. Documents in *earthquakes* consist of between 4 and 30 sentences each, with a median of 10 sentences.

Since the datasets for these tasks only have a relatively small number of training documents (100 each), we use Sequential-CG with smaller grids ($3 \times 3 \times 15$), and don't train a mixture model (which needs to learn a parameter β_z for each word in the vocabulary). Further, we train for a much smaller number of iterations to prevent overfitting ($K = 3$, chosen through cross-validation on the training set). During testing, since provided article pairs are simply permutations of each other and identical in content, we do not need to normalize as needed in Section 4.2. The score of a provided article is simply calculated as its log-likelihood. The article with higher likelihood is predicted to be the original.

Table 2 shows performance of the method compared with other approaches for coherence prediction. We note that Sequential-CG performs com-

TAIPEI, Taiwan (**AP**) An earthquake with a magnitude of 5.9 **jolted** Taiwan Friday.

The Central Weather Bureau recorded the quake at 11:17 a.m. (0317 GMT) and placed its **epicenter** in mountains 30 kilometers (18 miles) southeast of Taipei.

The quake was felt in part of northern and central Taiwan, and **shook** buildings in Taipei for a few seconds.

No damage or casualties were immediately reported.

The Central Weather Bureau said people in eastern Taiwan should prepare for **aftershocks.**

Figure 5: Example of newswire report about an earthquake event. Bold fonts represent words that align particularly well with the learned model at corresponding points in the narrative.

petitively with the state-of-the-art for generative approaches for the task, while needing no other annotation. In comparison, the HMM based approaches use significant annotation and syntactic features. Sequential-CG also outperforms several discriminative approaches for the task. In Figure 5 we illustrate the learned discourse trajectories in terms of the most salient features in each sentence. Words in bold are those identified by the model to be most context-appropriate at the corresponding point in the narrative. This is done by ranking words by the ratio between their probabilities ($\pi_{:,z}$) in the grid weighted by alignment locations of the document ($q^t_{\mathcal{I}}$), and unigram probabilities.

5 Conclusion

We have presented a simple model for extracting and visualizing latent discourse structure from unlabeled documents. The approach is coarse, and does not have explicit models for important elements such as entities and events in a discourse. However, the method outperforms some previous approaches on document understanding tasks, even while ignoring syntactic structure within sentences. The ability to visualize learning is a key component of our method, which can find significant applications in data mining and data-discovery in large text collections. More generally, similar approaches can explore a wider range of scenarios involving sequences of text. While here our focus was on learning discourse structures at the document level, similar methods can also be used at other scales, such as for syntactic or morphological analysis.

Abstract

Understanding temporal and causal relations between events is a fundamental natural language understanding task. Because a cause must occur earlier than its effect, temporal and causal relations are closely related and one relation often dictates the value of the other. However, limited attention has been paid to studying these two relations jointly. This paper presents a joint inference framework for them using constrained conditional models (CCMs). Specifically, we formulate the joint problem as an integer linear programming (ILP) problem, enforcing constraints that are inherent in the nature of time and causality. We show that the joint inference framework results in statistically significant improvement in the extraction of both temporal and causal relations from text.[1]

1 Introduction

Understanding events is an important component of natural language understanding. An essential step in this process is identifying relations between events, which are needed in order to support applications such as story completion, summarization, and timeline construction.

Among the many relation types that could exist between events, this paper focuses on the joint extraction of temporal and causal relations. It is well known that temporal and causal relations interact with each other and in many cases, the decision of one relation is made primarily based on evidence from the other. In Example 1, identifying the temporal relation between ***e1:died*** and ***e2:exploded*** is in fact a very hard case: There are no explicit temporal markers (e.g., "before", "after", or "since"); the events are in separate sentences so their syntactic connection is weak; although the occurrence time of ***e2:exploded*** is given (i.e., Friday) in text, it is not given for ***e1:died***. However, given the causal relation, ***e2:exploded*** caused ***e1:died***,it is clear that ***e2:exploded*** happened before ***e1:died***. The temporal relation is dictated by the causal relation.

Ex 1: Temporal relation dictated by causal relation.
More than 10 people ***(e1:died)*** on their way to the nearest hospital, police said. A suicide car bomb ***(e2:exploded)*** on Friday in the middle of a group of men playing volleyball in northwest Pakistan.
*Since **e2:exploded** is the reason of **e1:died**, the temporal relation is thus e2 being before e1.*

Ex 2: Causal relation dictated by temporal relation.
Mir-Hossein Moussavi ***(e3:raged)*** after government's efforts to ***(e4:stifle)*** protesters.
*Since **e3:raged** is temporally after **e4:stifle**, e4 should be the cause of e3.*

On the other hand, causal relation extraction can also benefit from knowing temporal relations. In Example 2, it is unclear whether the government stifled people because people raged, or people raged because the government stifled people: both situations are logically reasonable. However, if we account for the temporal relation (that is, ***e4:stifle*** happened before ***e3:raged***), it is clear that ***e4:stifle*** is the cause and ***e3:raged*** is the effect. In this case, the causal relation is dictated by the temporal relation.

The first contribution of this work is proposing a joint framework for **T**emporal and **C**ausal **R**easoning (TCR), inspired by these examples. Assuming the availability of a temporal extraction system and a causal extraction system, the proposed joint framework combines these two using a constrained conditional model (CCM) (Chang et al., 2012) framework, with an integer linear pro-

[1]The dataset and code used in this paper are available at `http://cogcomp.org/page/publication_view/835`

gramming (ILP) objective (Roth and Yih, 2004) that enforces declarative constraints during the inference phase. Specifically, these constraints include: (1) A cause must temporally precede its effect. (2) Symmetry constraints, i.e., when a pair of events, (A, B), has a temporal relation r (e.g., *before*), then (B, A) must have the reverse relation of r (e.g., *after*). (3) Transitivity constraints, i.e., the relation between (A, C) must be temporally consistent with the relation derived from (A, B) and (B, C). These constraints originate from the one-dimensional nature of time and the physical nature of causality and build connections between temporal and causal relations, making CCM a natural choice for this problem. As far as we know, very limited work has been done in joint extraction of both relations. Formulating the joint problem in the CCM framework is novel and thus the first contribution of this work.

A key obstacle in jointly studying temporal and causal relations lies in the absence of jointly annotated data. The second contribution of this work is the development of such a jointly annotated dataset which we did by augmenting the Event-Causality dataset (Do et al., 2011) with dense temporal annotations. This dataset allows us to show statistically significant improvements on both relations via the proposed joint framework.

This paper also presents an empirical result of improving the temporal extraction component. Specifically, we incorporate explicit time expressions present in the text and high-precision knowledge-based rules into the ILP objective. These sources of information have been successfully adopted by existing methods (Chambers et al., 2014; Mirza and Tonelli, 2016), but were never used within a global ILP-based inference method. Results on TimeBank-Dense (Cassidy et al., 2014), a benchmark dataset with temporal relations only, show that these modifications can also be helpful within ILP-based methods.

2 Related Work

Temporal and causal relations can both be represented by directed acyclic graphs, where the nodes are events and the edges are labeled with either *before, after*, etc. (in temporal graphs), or *causes* and *caused by* (in causal graphs). Existing work on *temporal* relation extraction was initiated by (Mani et al., 2006; Chambers et al., 2007; Bethard et al., 2007; Verhagen and Pustejovsky, 2008),

Ex 3: Global considerations are needed when making local decisions.

The FAA on Friday ***(e5:announced)*** it will close 149 regional airport control towers because of forced spending cuts. Before Friday's ***(e6:announcement)***, it ***(e7:said)*** it would consider keeping a tower open if the airport convinces the agency it is in the "national interest" to do so.

which formulated the problem as that of learning a classification model for determining the label of each edge locally (i.e., *local* methods). A disadvantage of these early methods is that the resulting graph may break the symmetric and transitive constraints. There are conceptually two ways to enforce such graph constraints (i.e., *global* reasoning). CAEVO (Chambers et al., 2014) grows the temporal graph in a multi-sieve manner, where predictions are added sieve-by-sieve. A graph closure operation had to be performed after each sieve to enforce constraints. This is solving the global inference problem greedily. A second way is to perform exact inference via ILP and the symmetry and transitivity requirements can be enforced as ILP constraints (Bramsen et al., 2006; Chambers and Jurafsky, 2008; Denis and Muller, 2011; Do et al., 2012; Ning et al., 2017).

We adopt the ILP approach in the temporal component of this work for two reasons. First, as we show later, it is straightforward to build a joint framework with both temporal and causal relations as an extension of it. Second, the relation between a pair of events is often determined by the relations among other events. In Ex 3, if a system is unaware of $(e5, e6)$=*simultaneously* when trying to make a decision for $(e5, e7)$, it is likely to predict that $e5$ is *before* $e7$[2]; but, in fact, $(e5, e7)$=*after* given the existence of $e6$. Using global considerations is thus beneficial in this context not only for generating globally consistent temporal graphs, but also for making more reliable pairwise decisions.

Prior work on *causal* relations in *natural language text* was relatively sparse. Many causal extraction work in other domains assumes the existence of ground truth timestamps (e.g., (Sun et al., 2007; Güler et al., 2016)), but gold timestamps rarely exist in natural language text. In NLP, people have focused on causal relation identification using lexical features or discourse relations. For

[2]Consider the case that "The FAA ***e5:announced***…it ***e7:said*** it would…". Even humans may predict that $e5$ is *before* $e7$.

example, based on a set of explicit causal discourse markers (e.g., "because", "due to", and "as a result"), Hidey and McKeown (2016) built parallel Wikipedia articles and constructed an open set of implicit markers called AltLex. A classifier was then applied to identify causality. Dunietz et al. (2017) used the concept of construction grammar to tag causally related clauses or phrases. Do et al. (2011) considered global statistics over a large corpora, the cause-effect association (CEA) scores, and combined it with discourse relations using ILP to identify causal relations. These work only focused on the causality task and did not address the temporal aspect.

However, as illustrated by Examples 1-2, temporal and causal relations are closely related, as assumed by many existing works (Bethard and Martin, 2008; Rink et al., 2010). Here we argue that being able to capture both aspects in a joint framework provides a more complete understanding of events in natural language documents. Researchers have started paying attention to this direction recently. For example, Mostafazadeh et al. (2016b) proposed an annotation framework, CaTeRs, which captured both temporal and causal aspects of event relations in common sense stories. CATENA (Mirza and Tonelli, 2016) extended the multi-sieve framework of CAEVO to extracting both temporal and causal relations and exploited their interaction through post-editing temporal relations based on causal predictions. In this paper, we push this idea forward and tackle the problem in a joint and more principled way, as shown next.

3 Temporal and Causal Reasoning

In this section, we explain the proposed joint inference framework, **T**emporal and **C**ausal **R**easoning (TCR). To start with, we focus on introducing the temporal component, and clarify how to design the transitivity constraints and how to enforce other readily available prior knowledge to improve its performance. With this temporal component already explained, we further incorporate causal relations and complete the TCR joint inference framework. Finally, we transform the joint problem into an ILP so that it can be solved using off-the-shelf packages.

3.1 Temporal Component

Let $\mathcal{R}_T$ be the label set of temporal relations and $\mathcal{E}$ and $\mathcal{T}$ be the set of all events and the set of all time expressions (a.k.a. timex) in a document. For notation convenience, we use $\mathcal{EE}$ to represent the set of all event-event pairs; then $\mathcal{ET}$ and $\mathcal{TT}$ have obvious definitions. Given a pair in $\mathcal{EE}$ or $\mathcal{ET}$, assume for now that we have corresponding classifiers producing confidence scores for every temporal relation in $\mathcal{R}_T$. Let them be $s^{ee}(\cdot)$ and $s^{et}(\cdot)$, respectively. Then the inference formulation for all the temporal relations within this document is:

$$\hat{Y} = \arg\max_{Y\in\mathcal{Y}} \sum_{i\in\mathcal{EE}} s^{ee}\{i \mapsto Y_i\} + \sum_{j\in\mathcal{ET}} s^{et}\{j \mapsto Y_j\} \quad (1)$$

where $Y_k \in \mathcal{R}_T$ is the temporal label of pair $k \in \mathcal{MM}$ (Let $\mathcal{M} = \mathcal{E} \cup \mathcal{T}$ be the set of all temporal nodes), "$k \mapsto Y_k$" represents the case where the label of pair k is predicted to be Y_k, Y is a vectorization of all these Y_k's in one document, and $\mathcal{Y}$ is the constrained space that Y lies in.

We do not include the scores for $\mathcal{TT}$ because the temporal relationship between timexes can be trivially determined using the normalized dates of these timexes, as was done in (Do et al., 2012; Chambers et al., 2014; Mirza and Tonelli, 2016). We impose these relations via equality constraints denoted as $\mathcal{Y}_0$. In addition, we add symmetry and transitivity constraints dictated by the nature of time (denoted by $\mathcal{Y}_1$), and other prior knowledge derived from linguistic rules (denoted by $\mathcal{Y}_2$), which will be explained subsequently. Finally, we set $\mathcal{Y} = \cap_{i=0}^{2}\mathcal{Y}_i$ in Eq. (1).

Transitivity Constraints. Let the dimension of Y be n. Then a standard way to construct the symmetry and transitivity constraints is shown in (Bramsen et al., 2006; Chambers and Jurafsky, 2008; Denis and Muller, 2011; Do et al., 2012; Ning et al., 2017)

$$\mathcal{Y}_1 = \big\{Y \in \mathcal{R}_T^n | \forall m_{1,2,3} \in \mathcal{M}, Y_{(m_1,m_2)} = \bar{Y}_{(m_2,m_1)}, \\ Y_{(m_1,m_3)} \in \text{Trans}(Y_{(m_1,m_2)}, Y_{(m_2,m_3)})\big\}$$

where the bar sign is used to represent the reverse relation hereafter, and Trans(r_1, r_2) is a set comprised of all the temporal relations from $\mathcal{R}_T$ that do not conflict with r_1 and r_2.

The construction of Trans(r_1, r_2) necessitates a clearer definition of $\mathcal{R}_T$, the importance of which is often overlooked by existing methods. Existing approaches all followed the interval representation of events (Allen, 1984), which yields 13 temporal relations (denoted by $\tilde{\mathcal{R}}_T$ here) as shown in Fig. 1. Most systems used a reduced set, for ex-

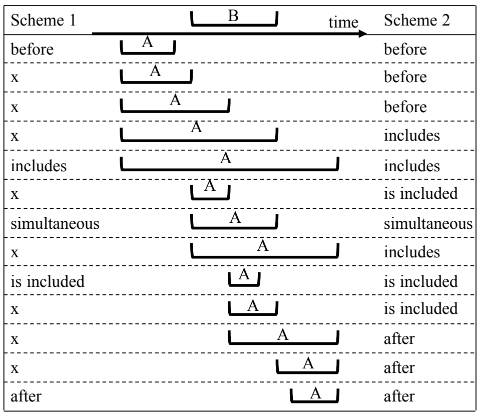

Figure 1: **Two possible interpretations to the label set of** $\mathcal{R}_T = \{b, a, i, ii, s, v\}$ for the temporal relations between (A, B). "x" means that the label is ignored. Brackets represent time intervals along the time axis. Scheme 2 is adopted consistently in this work.

11	**ii**	**v**	**b**, **a**, **ii**, **v**

Table 1: **Transitivity relations** based on the label set reduction scheme 2 in Fig. 1. If $(m_1, m_2) \mapsto r_1$ and $(m_2, m_3) \mapsto r_2$, then the relation of (m_1, m_3) must be chosen from Trans(r_1, r_2), $\forall m_1, m_2, m_3 \in \mathcal{M}$. The top part of the table uses r to represent generic rules compactly. Notations: before (**b**), after (**a**), includes (**i**), is included (**ii**), simultaneously (**s**), vague (**v**), and $\bar{r}$ represents the reverse relation of r.

ample, {*before*, *after*, *includes*, *is included*, *simultaneously*, *vague*}. For notation convenience, we denote them $\mathcal{R}_T = \{b, a, i, ii, s, v\}$. Using a reduced set is more convenient in data annotation and leads to better performance in practice.

However, there has been limited discussion in the literature on how to interpret the reduced relation types. For example, is the "*before*" in $\mathcal{R}_T$ exactly the same as the "*before*" in the original set ($\tilde{\mathcal{R}}_T$) (as shown on the left-hand-side of Fig. 1), or is it a combination of multiple relations in $\tilde{\mathcal{R}}_T$ (the right-hand-side of Fig. 1)? We compare two reduction schemes in Fig. 1, where scheme 1 ignores low frequency labels directly and scheme 2 absorbs low frequency ones into their temporally closest labels. The two schemes barely have differences when a system only looks at a single pair of mentions at a time (this might explain the lack of discussion over this issue in the literature), but they lead to different Trans(r_1, r_2) sets and this difference can be magnified when the problem is solved jointly and when the label distribution changes across domains. To completely cover the 13 relations, we adopt scheme 2 in this work.

The resulting transitivity relations are shown in Table 1. The top part of Table 1 is a compact representation of three generic rules; for instance, Line 1 means that the labels themselves are transitive. Note that during human annotation, if an annotator looks at a pair of events and decides that multiple well-defined relations can exist, he/she labels it *vague*; also, when aggregating the labels from multiple annotators, a label will be changed to *vague* if the annotators disagree with each other. In either case, *vague* is chosen to be the label when a single well-defined relation cannot be uniquely determined by the contextual information. This explains why a *vague* relation (v) is always added in Table 1 if more than one label in Trans(r_1, r_2) is possible. As for Lines 6, 9-11 in Table 1 (where *vague* appears in Column r_2), Column Trans(r_1,r_2) was designed in such a way that r_2 cannot be uniquely determined through r_1 and Trans(r_1,r_2). For instance, r_1 is *after* on Line 9, if we further put *before* into Trans(r_1,r_2), then r_2 would be uniquely determined to be *before*, conflicting with r_2 being *vague*, so *before* should not be in Trans(r_1,r_2).

Enforcing Linguistic Rules. Besides the transitivity constraints represented by $\mathcal{Y}_1$ above, we also propose to enforce prior knowledge to further constrain the search space for Y. Specifically, linguistic insight has resulted in rules for predicting the temporal relations with special syntactic or semantic patterns, as was done in CAEVO (a state-of-the-art method). Since these rule predictions often have high-precision, it is worthwhile incorporating them in global reasoning methods as well.

In the CCM framework, these rules can be represented as hard constraints in the search space for Y. Specifically,

$$\mathcal{Y}_2 = \left\{Y_j = rule(j), \forall j \in \mathcal{J}^{(rule)}\right\}, \tag{2}$$

where $\mathcal{J}^{(rule)} \subseteq \mathcal{MM}$ is the set of pairs that can be determined by linguistic rules, and $rule(j) \in$

$\mathcal{R}_T$ is the corresponding decision for pair j according to these rules. In this work, we used the same set of rules designed by CAEVO for fair comparison.

3.2 Full Model with Causal Relations

Now we have presented the joint inference framework for temporal relations in Eq. (1). It is easier to explain our complete TCR framework on top of it. Let W be the vectorization of all causal relations and add the scores from the scoring function for causality $s^c(\cdot)$ to Eq. (1). Specifically, the full inference formulation is now:

$$\hat{Y}, \hat{W} = \arg \max_{Y \in \mathcal{Y}, W \in \mathcal{W}_Y} \sum_{i \in \mathcal{EE}} s^{ee}\{i \mapsto Y_i\} \tag{3}$$
$$+ \sum_{j \in \mathcal{ET}} s^{et}\{j \mapsto Y_j\} + \sum_{k \in \mathcal{EE}} s^c\{k \mapsto W_k\}$$

where $\mathcal{W}_Y$ is the search space for W. $\mathcal{W}_Y$ depends on the temporal labels Y in the sense that

$$\mathcal{W}_Y = \{W \in \mathcal{R}_C^m | \forall i, j \in \mathcal{E}, \text{if } W_{(i,j)} = c, \text{ then } W_{(j,i)} = \bar{c}, \text{ and } Y_{(i,j)} = b\} \tag{4}$$

where m is the dimension of W (i.e., the total number of causal pairs), $\mathcal{R}_C = \{c, \bar{c}, null\}$ is the label set for causal relations (i.e., "causes", "caused by", and "no relation"), and $W_{(i,j)}$ is the causal label for pair (i, j). The constraint represented by $\mathcal{W}_Y$ means that if a pair of events i and j are labeled to be "causes", then the causal relation between j and i must be "caused by", and the temporal relation between i and j must be "before".

3.3 Scoring Functions

In the above, we have built the joint framework on top of scoring functions $s^{ee}(\cdot)$, $s^{et}(\cdot)$ and $s^c(\cdot)$. To get $s^{ee}(\cdot)$ and $s^{et}(\cdot)$, we trained classifiers using the averaged perceptron algorithm (Freund and Schapire, 1998) and the same set of features used in (Do et al., 2012; Ning et al., 2017), and then used the soft-max scores in those scoring functions. For example, that means

$$s^{ee}\{i \mapsto r\} = \frac{w_r^T \phi(i)}{\sum_{r' \in \mathcal{R}_T} w_{r'}^T \phi(i)}, \; i \in \mathcal{EE}, \; r \in \mathcal{R}_T,$$

where $\{w_r\}$ is the learned weight vector for relation $r \in \mathcal{R}_T$ and $\phi(i)$ is the feature vector for pair $i \in \mathcal{EE}$.

Given a pair of ordered events, we need $s^c(\cdot)$ to estimate the scores of them being "causes" or "caused by". Since this scoring function has the same nature as $s^{ee}(\cdot)$, we can reuse the features from $s^{ee}(\cdot)$ and learn an averaged perceptron for $s^c(\cdot)$. In addition to these existing features, we also use prior statistics retrieved using our temporal system from a large corpus[3], so as to know *probabilistically* which event happens before another event. For example, in Example 1, we have a pair of events, ***e1:died*** and ***e2:exploded***. The prior knowledge we retrieved from that large corpus is that ***die*** happens before ***explode*** with probability 15% and happens after ***explode*** with probability 85%. We think this prior distribution is correlated with causal directionality, so it was also added as features when training $s^c(\cdot)$.

Note that the scoring functions here are implementation choice. The TCR joint framework is fully extensible to other scoring functions.

3.4 Convert the Joint Inference into an ILP

Conveniently, the joint inference formulation in Eq. (3) can be rewritten into an ILP and solved using off-the-shelf optimization packages, e.g., (Gurobi Optimization, Inc., 2012). First, we define indicator variables $y_i^r = \mathbb{I}\{Y_i = r\}$, where $\mathbb{I}\{\cdot\}$ is the indicator function, $\forall i \in \mathcal{MM}$, $\forall r \in \mathcal{R}_T$. Then let $p_i^r = s^{ee}\{i \mapsto r\}$ if $i \in \mathcal{EE}$, or $p_i^r = s^{et}\{i \mapsto r\}$ if $i \in \mathcal{ET}$; similarly, let $w_j^r = \mathbb{I}\{W_i = r\}$ be the indicator variables for W_j and q_j^r be the score for $W_j = r \in \mathcal{R}_C$. Therefore, without constraints $\mathcal{Y}$ and $\mathcal{W}_Y$ for now, Eq. (3) can be written as:

$$\hat{y}, \hat{w} = \arg\max \sum_{i \in \mathcal{EE} \cup \mathcal{ET}} \sum_{r \in \mathcal{R}_T} p_i^r y_i^r + \sum_{j \in \mathcal{EE}} \sum_{r \in \mathcal{R}_C} q_j^r w_j^r$$
$$\text{s.t.} \quad y_i^r, w_j^r \in \{0, 1\}, \sum_{r \in \mathcal{R}_T} y_i^r = \sum_{r \in \mathcal{R}_C} w_j^r = 1$$

The prior knowledge represented as $\mathcal{Y}$ and $\mathcal{W}_Y$ can be conveniently converted into constraints for this optimization problem. Specifically, $\mathcal{Y}_1$ has two components, symmetry and transitivity:

$$\mathcal{Y}_1: \quad \forall i, j, k \in \mathcal{M}, \; y_{i,j}^r = y_{j,i}^{\bar{r}}, \text{ (symmetry)}$$
$$y_{i,j}^{r_1} + y_{j,k}^{r_2} - \sum_{r_3 \in \text{Trans}(r_1, r_2)} y_{i,k}^{r_3} \leq 1 \text{ (transitivity)}$$

where $\bar{r}$ is the reverse relation of r (i.e., $\bar{b} = a$, $\bar{i} = ii$, $\bar{s} = s$, and $\bar{v} = v$), and Trans(r_1, r_2) is defined in Table 1. As for the transitivity constraints,

[3]https://catalog.ldc.upenn.edu/LDC2008T19, which is disjoint to the test set used here. Please refer to (Ning et al., 2018a) for more analysis on using this corpus to acquire prior knowledge that aids temporal relation classification.

if both $y_{i,j}^{r_1}$ and $y_{j,k}^{r_2}$ are 1, then the constraint requires at least one of $y_{i,k}^{r_3}, r_3 \in \text{Trans}(r_1, r_2)$ to be 1, which means the relation between i and k has to be chosen from $\text{Trans}(r_1, r_2)$, which is exactly what $\mathcal{Y}_1$ is intended to do.

The rules in $\mathcal{Y}_2$ is written as

$$\mathcal{Y}_2 : y_j^r = \mathbb{I}_{\{rule(j)=r\}}, \forall j \in \mathcal{J}^{(rule)} \text{ (linguistic rules)}$$

where $rule(j)$ and $\mathcal{J}^{(rule)}$ have been defined in Eq. (2). Converting the $\mathcal{TT}$ constraints, i.e., $\mathcal{Y}_0$, into constraints is as straightforward as $\mathcal{Y}_2$, so we omit it due to limited space.

Last, converting the constraints $\mathcal{W}_Y$ defined in Eq. (4) can be done as following:

$$\mathcal{W}_Y : w_{i,j}^c = w_{j,i}^{\bar{c}} \leq y_{i,j}^b, \forall i, j \in \mathcal{E}.$$

The equality part, $w_{i,j}^c = w_{j,i}^{\bar{c}}$ represents the symmetry constraint of causal relations; the inequality part, $w_{i,j}^c \leq y_{i,j}^b$ represents that if event i causes event j, then i must be before j.

4 Experiments

In this section, we first show on TimeBank-Dense (TB-Dense) (Cassidy et al., 2014), that the proposed framework improves temporal relation identification. We then explain how our new dataset with both temporal and causal relations was collected, based on which the proposed method improves for both relations.

4.1 Temporal Performance on TB-Dense

Multiple datasets with temporal annotations are available thanks to the TempEval (TE) workshops (Verhagen et al., 2007, 2010; UzZaman et al., 2013). The dataset we used here to demonstrate our improved temporal component was TB-Dense, which was annotated on top of 36 documents out of the classic TimeBank dataset (Pustejovsky et al., 2003). The main purpose of TB-Dense was to alleviate the known issue of sparse annotations in the evaluation dataset provided with TE3 (UzZaman et al., 2013), as pointed out in many previous work (Chambers, 2013; Cassidy et al., 2014; Chambers et al., 2014; Ning et al., 2017). Annotators of TB-Dense were forced to look at each pair of events or timexes within the same sentence or contiguous sentences, so that much fewer links were missed. Since causal link annotation is not available on TB-Dense, we only show our improvement in terms of temporal performance on TB-Dense. The standard train/dev/test split of TB-Dense was used and parameters were tuned to optimize the F_1 performance on dev. Gold events and time expressions were also used as in existing systems.

#	System	P	R	F_1
	Ablation Study			
1	Baseline	39.1	56.8	46.3
2	+Transitivity[†]	42.9	54.9	48.2
3	+$\mathcal{ET}$	44.3	54.8	49.0
4	+Rules	45.4	58.7	51.2
5	+Causal	**45.8**	**60.5**	**52.1**
	Existing Systems[‡]			
6	ClearTK	53.0	26.4	35.2
7	CAEVO	**56.0**	41.6	47.8
8	Ning et al. (2017)	47.1	**53.3**	**50.0**

[†]This is technically the same with Do et al. (2012), or Ning et al. (2017) without its structured learning component.
[‡]We added gold $\mathcal{TT}$ to both gold and system prediction. Without this, Systems 6-8 had F_1=28.7, 45.7, and 48.5, respectively, same with the reported values in Ning et al. (2017).

Table 2: **Ablation study of the proposed system in terms of the standard temporal awareness metric**. The baseline system is to make inference locally for each event pair without looking at the decisions from others. The "+" signs on lines 2-5 refer to adding a new source of information on top of its preceding system, with which the inference has to be global and done via ILP. All systems are significantly different to its preceding one with p<0.05 (McNemar's test).

The contributions of each proposed information sources are analyzed in the ablation study shown in Table 2, where we can see the F_1 score was improved step-by-step as new sources of information were added. Recall that $\mathcal{Y}_1$ represents transitivity constraints, $\mathcal{ET}$ represents taking event-timex pairs into consideration, and $\mathcal{Y}_2$ represents rules from CAEVO (Chambers et al., 2014). System 1 is the baseline we are comparing to, which is a local method predicting temporal relations one at a time. System 2 only applied $\mathcal{Y}_1$ via ILP on top of all $\mathcal{EE}$ pairs by removing the 2nd term in Eq. (1); for fair comparison with System 1, we added the same $\mathcal{ET}$ predictions from System 1. System 3 incorporated $\mathcal{ET}$ into the ILP and mainly contributed to an increase in precision (from 42.9 to 44.3); we think that there could be more gain if more time expressions existed in the testset. With the help of additional high-precision rules ($\mathcal{Y}_2$), the temporal performance can further be improved, as shown by System 4. Finally, using the causal extraction obtained via (Do et al., 2011) in the joint framework, the proposed method achieved the best precision, recall, and F_1 scores in our ablation study (Systems 1-5). According to the McNemar's test (Everitt, 1992; Dietterich, 1998), all Systems 2-5 were significantly different to its preceding system with $p<0.05$.

The second part of Table 2 compares several state-of-the-art systems on the same test set. ClearTK (Bethard, 2013) was the top performing system in TE3 in temporal relation extraction. Since it was designed for TE3 (not TB-Dense), it expectedly achieved a moderate recall on the test set of TB-Dense. CAEVO (Chambers et al., 2014) and Ning et al. (2017) were more recent methods and achieved better scores on TB-Dense. Compared with these state-of-the-art methods, the proposed joint system (System 5) achieved the best F_1 score with a major improvement in recall. We think the low precision compared to System 8 is due to the lack of structured learning, and the low precision compared to System 7 is propagated from the baseline (System 1), which was tuned to maximize its F_1 score. However, the effectiveness of the proposed information sources is already justified in Systems 1-5.

4.2 Joint Performance on Our New Dataset

4.2.1 Data Preparation

TB-Dense only has temporal relation annotations, so in the evaluations above, we only evaluated our temporal performance. One existing dataset with both temporal and causal annotations available is the Causal-TimeBank dataset (Causal-TB) (Mirza and Tonelli, 2014). However, Causal-TB is sparse in temporal annotations and is even sparser in causal annotations: In Table 3, we can see that with four times more documents, Causal-TB still has fewer temporal relations (denoted as T-Links therein), compared to TB-Dense; as for causal relations (C-Links), it has less than two causal relations in each document on average. Note that the T-Link sparsity of Causal-TB originates from TimeBank, which is known to have missing links (Cassidy et al., 2014; Ning et al., 2017). The C-Link sparsity was a design choice of Causal-TB in which C-Links were annotated based on only explicit causal markers (e.g., "A happened *because* of B").

Another dataset with parallel annotations is CaTeRs (Mostafazadeh et al., 2016b), which was primarily designed for the Story Cloze Test (Mostafazadeh et al., 2016a) based on common sense stories. It is different to the newswire domain that we are working on. Therefore, we decided to augment the EventCausality dataset provided in Do et al. (2011) with a modified version of the dense temporal annotation scheme proposed in Cassidy et al. (2014) and use this new dataset to showcase the proposed joint approach.

	Doc	Event	T-Link	C-Link
TB-Dense	36	1.6k	5.7k	-
EventCausality	25	0.8k	-	580
Causal-TB	183	6.8k	5.1k	318
New Dataset	25	1.3k	3.4k	172

Table 3: **Statistics of our new dataset with both temporal and causal relations annotated**, compared with existing datasets. T-Link: Temporal relation. C-Link: Causal relation. The new dataset is much denser than Causal-TB in both T-Links and C-Links.

The EventCausality dataset provides relatively dense causal annotations on 25 newswire articles collected from CNN in 2010. As shown in Table 3, it has more than 20 C-Links annotated per document on average (10 times denser than Causal-TB). However, one issue is that its notion for events is slightly different to that in the temporal relation extraction regime. To construct parallel annotations of both temporal and causal relations, we preprocessed all the articles in EventCausality using ClearTK to extract events and then manually removed some obvious errors in them. To annotate temporal relations among these events, we adopted the annotation scheme from TB-Dense given its success in mitigating the issue of missing annotations with the following modifications. First, we used a crowdsourcing platform, CrowdFlower, to collect temporal relation annotations. For each decision of temporal relation, we asked 5 workers to annotate and chose the majority label as our final annotation. Second, we discovered that comparisons involving ending points of events tend to be ambiguous and suffer from low inter-annotator agreement (IAA), so we asked the annotators to label relations based on the starting points of each event. This simplification does not change the nature of temporal relation extraction but leads to better annotation quality. For more details about this data collection scheme, please refer to (Ning et al., 2018b) for more details.

4.2.2 Results

Result on our new dataset jointly annotated with both temporal and causal relations is shown in Ta-

	Temporal			Causal
	P	R	F_1	Accuracy
1. Temporal Only	67.2	72.3	69.7	-
2. Causal Only	-	-	-	70.5
3. Joint System	**68.6**	**73.8**	**71.1**	**77.3**
Enforcing Gold Relations in Joint System				
4. Gold Temporal	100	100	100	*91.9*
5. Gold Causal	*69.3*	*74.4*	*71.8*	100

Table 4: **Comparison between the proposed method and existing ones, in terms of both temporal and causal performances**. See Sec. 4.2.1 for description of our new dataset. Per the McNemar's test, the joint system is significantly better than both baselines with $p<0.05$. Lines 4-5 provide the best possible performance the joint system could achieve if gold temporal/causal relations were given.

ble 4. We split the new dataset into 20 documents for training and 5 documents for testing. In the training phase, the training parameters were tuned via 5-fold cross validation on the training set.

Table 4 demonstrates the improvement of the joint framework over individual components. The "temporal only" baseline is the improved temporal extraction system for which the joint inference with causal links has NOT been applied. The "causal only" baseline is to use $s^c(\cdot)$ alone for the prediction of each pair. That is, for a pair i, if $s^c\{i \mapsto \text{causes}\} > s^c\{i \mapsto \text{caused by}\}$, we then assign "causes" to pair i; otherwise, we assign "caused by" to pair i. Note that the "causal accuracy" column in Table 4 was evaluated only on gold causal pairs.

In the proposed joint system, the temporal and causal scores were added up for all event pairs. The temporal performance got strictly better in precision, recall, and F_1, and the causal performance also got improved by a large margin from 70.5% to 77.3%, indicating that temporal signals and causal signals are helpful to each other. According to the McNemar's test, both improvements are significant with $p<0.05$.

The second part of Table 4 shows that if gold relations were used, how well each component would possibly perform. Technically, these gold temporal/causal relations were enforced via adding extra constraints to ILP in Eq. (3) (imagine these gold relations as a special rule, and convert them into constraints like what we did in Eq. (2)). When using gold temporal relations, causal accuracy went up to 91.9%. That is, 91.9% of the C-Links satisfied the assumption that the cause is temporally before the effect. First, this number is much higher than the 77.3% on line 3, so there is still room for improvement. Second, it means in this dataset, there were 8.1% of the C-Links in which the cause is temporally *after* its effect. We will discuss this seemingly counter-intuitive phenomenon in the Discussion section. When gold causal relations were used (line 5), the temporal performance was slightly better than line 3 in terms of both precision and recall. The small difference means that the temporal performance on line 3 was already very close to its best. Compared with the first line, we can see that gold causal relations led to approximately 2% improvement in precision and recall in temporal performance, which is a reasonable margin given the fact that C-Links are often much sparser than T-Links in practice.

Note that the temporal performance in Table 4 is consistently better than those in Table 2 because of the higher IAA in the new dataset. However, the improvement brought by joint reasoning with causal relations is the same, which further confirms the capability of the proposed approach.

5 Discussion

We have consistently observed that on the TB-Dense dataset, if automatically tuned to optimize its F_1 score, a system is very likely to have low precisions and high recall (e.g., Table 2). We notice that our system often predicts non-vague relations when the TB-Dense gold is vague, resulting in lower precision. However, on our new dataset, the same algorithm can achieve a more balanced precision and recall. This is an interesting phenomenon, possibly due to the annotation scheme difference which needs further investigation.

The temporal improvements in both Table 2 and Table 4 are relatively small (although statistically significant). This is actually not surprising because C-Links are much fewer than T-Links in newswires which focus more on the temporal development of stories. As a result, many T-Links are not accompanied with C-Links and the improvements are diluted. But for those event pairs having both T-Links and C-Links, the proposed joint framework is an important scheme to synthesize both signals and improve both. The comparison between Line 5 and Line 3 in Table 4 is a showcase of the effectiveness. We think that a deeper reason for the improvement achieved via a joint framework is that causality often encodes

Ex 4: Cause happened after effect.
The shares fell to a record low of ¥60 and ***(e8:finished)*** at ¥67 before the market ***(e9:closed)*** for the New Year holidays.
As she ***(e10:prepares)*** to ***(e11:host)*** her first show, Crowley writes on what viewers should expect.

humans prior knowledge as global information (e.g., "death" is *caused by* "explosion" rather than *causes* "explosion", regardless of the local context), while temporality often focuses more on the local context. From this standpoint, temporal information and causal information are complementary and helpful to each other.

When doing error analysis for the fourth line of Table 4, we noticed some examples that break the commonly accepted temporal precedence assumption. It turns out that they are not annotation mistakes: In Example 4, ***e8:finished*** is obviously *before* ***e9:closed***, but ***e9*** is a cause of ***e8*** since if the market did not close, the shares would not finish. In the other sentence of Example 4, she prepares *before* hosting her show, but ***e11:host*** is the cause of ***e10:prepares*** since if not for hosting, no preparation would be needed. In both cases, the cause is temporally after the effect because people are inclined to make projections for the future and change their behaviors before the future comes. The proposed system is currently unable to handle these examples and we believe that a better definition of what can be considered as events is needed, as part of further investigating how causality is expressed in natural language.

Finally, the constraints connecting causal relations to temporal relations are designed in this paper as "if A is the cause of B, then A must be *before* B". People have suggested other possibilities that involve the *includes* and *simultaneously* relations. While these other relations are simply different interpretations of temporal precedence (and can be easily incorporated in our framework), we find that they rarely happen in our dataset.

6 Conclusion

We presented a novel joint framework, **T**emporal and **C**ausal **R**easoning (TCR), using CCMs and ILP to the extraction problem of temporal and causal relations between events. To show the benefit of TCR, we have developed a new dataset that jointly annotates temporal and causal annotations, and then exhibited that TCR can improve both temporal and causal components. We hope that this notable improvement can foster more interest in jointly studying multiple aspects of events (e.g., event sequencing, coreference, parent-child relations) towards the goal of understanding events in natural language.

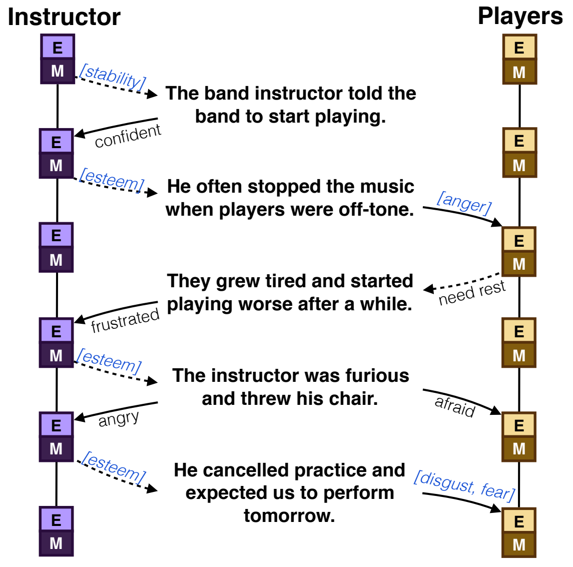
Abstract

Understanding a narrative requires reading between the lines and reasoning about the unspoken but obvious implications about events and people's mental states — a capability that is trivial for humans but remarkably hard for machines. To facilitate research addressing this challenge, we introduce a new annotation framework to explain naive psychology of story characters as fully-specified chains of mental states with respect to *motivations* and *emotional reactions*. Our work presents a new large-scale dataset with rich low-level annotations and establishes baseline performance on several new tasks, suggesting avenues for future research.



Instructor
Players

1 Introduction

Understanding a story requires reasoning about the causal links between the events in the story and the mental states of the characters, even when those relationships are not explicitly stated. As shown by the commonsense story cloze shared task (Mostafazadeh et al., 2017), this reasoning is remarkably hard for both statistical and neural machine readers – despite being trivial for humans. This stark performance gap between humans and machines is not surprising as most powerful language models have been designed to effectively learn local fluency patterns. Consequently, they generally lack the ability to abstract away from surface patterns in text to model more complex implied dynamics, such as intuiting characters' mental states or predicting their plausible next actions.

In this paper, we construct a new annotation formalism to densely label commonsense short stories (Mostafazadeh et al., 2016) in terms of the mental states of the characters. The resulting dataset offers three unique properties. First, as highlighted in Figure 1, the dataset provides a fully-specified chain of *motivations* and *emotional reactions* for each story character as pre- and post-conditions of events. Second, the annotations include state changes for entities even when they are not mentioned directly in a sentence (e.g., in the fourth sentence in Figure 1, players would feel *afraid* as a result of the instructor throwing a chair), thereby capturing implied effects unstated in the story. Finally, the annotations encompass both formal labels from multiple theories of psychology (Maslow, 1943; Reiss, 2004; Plutchik, 1980) as well as open text descriptions of motivations and emotions, providing a comprehensive mapping between open text explanations and label categories (e.g., "to spend time with her son"

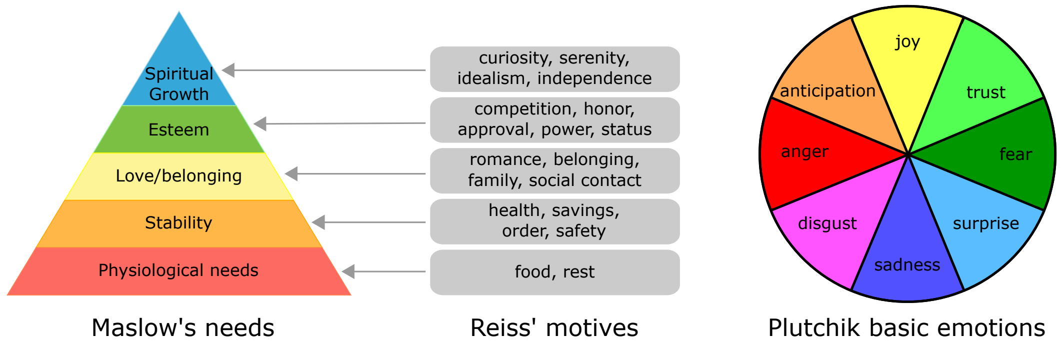

Figure 2: Theories of Motivation (Maslow and Reiss) and Emotional Reaction (Plutchik).

→ Maslow's category *love*). Our corpus[1] spans across 15k stories, amounting to 300k low-level annotations for around 150k character-line pairs.

Using our new corpus, we present baseline performance on two new tasks focusing on mental state tracking of story characters: *categorizing* motivations and emotional reactions using theory labels, as well as *describing* motivations and emotional reactions using open text. Empirical results demonstrate that existing neural network models including those with explicit or latent entity representations achieve promising results.

2 Mental State Representations

Understanding people's actions, motivations, and emotions has been a recurring research focus across several disciplines including philosophy and psychology (Schachter and Singer, 1962; Burke, 1969; Lazarus, 1991; Goldman, 2015). We draw from these prior works to derive a set of categorical labels for annotating the step-by-step causal dynamics between the mental states of story characters and the events they experience.

2.1 Motivation Theories

We use two popular theories of motivation: the "hierarchy of needs" of Maslow (1943) and the "basic motives" of Reiss (2004) to compile 5 coarse-grained and 19 fine-grained motivation categories, shown in Figure 2. Maslow's "hierarchy of needs" are comprised of five categories, ranging from *physiological needs* to *spiritual growth*, which we use as coarse-level categories. Reiss (2004) proposes 19 more fine-grained categories that provide a more informative range of motivations. For example, even though they both relate to the *physiological needs* Maslow category, the *food* and *rest* motives from Reiss (2004) are very different. While the Reiss theory allows for finer-grained annotations of motivation, the larger set of abstract concepts can be overwhelming for annotators. Motivated by Straker (2013), we design a hybrid approach, where Reiss labels are annotated as sub-categories of Maslow categories.

2.2 Emotion Theory

Among several theories of emotion, we work with the "wheel of emotions" of Plutchik (1980), as it has been a common choice in prior literature on emotion categorization (Mohammad and Turney, 2013; Zhou et al., 2016). We use the eight basic emotional dimensions as illustrated in Figure 2.

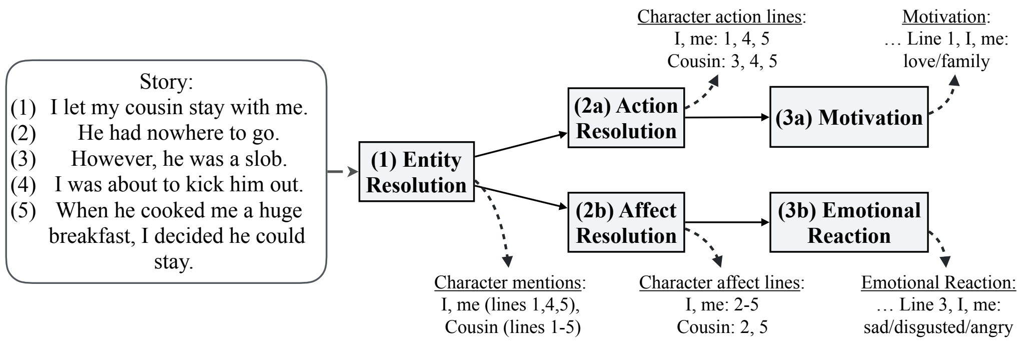
2.3 Mental State Explanations

In addition to the motivation and emotion categories derived from psychology theories, we also obtain open text descriptions of character mental states. These open text descriptions allow learning computational models that can *explain* the mental states of characters in natural language, which is likely to be more accessible and informative to end users than having theory categories alone. Collecting both theory categories and open text also allows us to learn the automatic mappings between the two, which generalizes the previous work of Mohammad and Turney (2013) on emotion category mappings.

3 Annotation Framework

In this study, we choose to annotate the simple commonsense stories introduced by Mostafazadeh et al. (2016). Despite their simplicity, these stories pose a significant challenge to natural language understanding models (Mostafazadeh et al., 2017).

[1]We make our dataset publicly available at https://uwnlp.github.io/storycommonsense/



Story:
(1) I let my cousin stay with me.
(2) He had nowhere to go.
(3) However, he was a slob.
(4) I was about to kick him out.
(5) When he cooked me a huge breakfast, I decided he could stay.
(1) Entity Resolution
(2a) Action Resolution
(2b) Affect Resolution
(3a) Motivation
(3b) Emotional Reaction
Character action lines: I, me: 1, 4, 5 Cousin: 3, 4, 5
Motivation: … Line 1, I, me: love/family
Character mentions: I, me (lines 1,4,5), Cousin (lines 1-5)
Character affect lines: I, me: 2-5 Cousin: 2, 5
Emotional Reaction: … Line 3, I, me: sad/disgusted/angry

Figure 3: The annotation pipeline for the fine-grained annotations with an example story.

In addition, they depict multiple interactions between story characters, presenting rich opportunities to reason about character motivations and reactions. Furthermore, there are more than 98k such stories currently available covering a wide range of everyday scenarios.

Unique Challenges While there have been a variety of annotated resources developed on the related topics of sentiment analysis (Mohammad and Turney, 2013; Deng and Wiebe, 2015), entity tracking (Hoffart et al., 2011; Weston et al., 2015), and story understanding (Goyal et al., 2010; Ouyang and McKeown, 2015; Lukin et al., 2016), our study is the first to annotate the full chains of mental state effects for story characters. This poses several unique challenges as annotations require (1) interpreting discourse (2) understanding implicit causal effects, and (3) understanding formal psychology theory categories. In prior literature, annotations of this complexity have typically been performed by experts (Deng and Wiebe, 2015; Ouyang and McKeown, 2015). While reliable, these annotations are prohibitively expensive to scale up. Therefore, we introduce a new annotation framework that pipelines a set of smaller isolated tasks as illustrated in Figure 3. All annotations were collected using crowdsourced workers from Amazon Mechanical Turk.

3.1 Annotation Pipeline

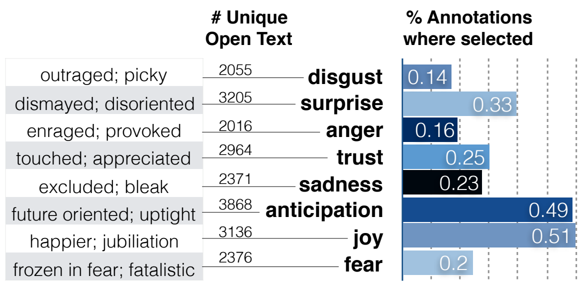
We describe the components and workflow of the full annotation pipeline shown in Figure 3 below. The example story in the figure is used to illustrate the output of various steps in the pipeline (full annotations for this example are in the appendix).

(1) Entity Resolution The first task in the pipeline aims to discover (1) the set of characters E_i in each story i and (2) the set of sentences S_{ij} in which a specific character $j \in E_i$ is explicitly mentioned. For example, in the story in Figure 3, the characters identified by annotators are "I/me" and "My cousin", whom appear in sentences $\{1, 4, 5\}$ and $\{1, 2, 3, 4, 5\}$, respectively.

We use S_{ij} to control the workflow of later parts of the pipeline by pruning future tasks for sentences that are not tied to characters. Because S_{ij} is used to prune follow-up tasks, we take a high recall strategy to include all sentences that at least one annotator selected.

(2a) Action Resolution The next task identifies whether a character j appearing in a sentence k is taking any action to which a motivation can be attributed. We perform action resolution only for sentences $k \in S_{ij}$. In the running example, we would want to know that the cousin in line 2 is not doing anything intentional, allowing us to omit this line in the next pipeline stage (3a) where a character's motives are annotated. Description of state (e.g., "Alex is feeling blue") or passive event participation (e.g., "Alex trips") are not considered volitional acts for which the character may have an underlying motive. For each line and story character pair, we obtain 4 annotations. Because pairs can still be filtered out in the next stage of annotation, we select a generous threshold where only 2 annotators must vote that an intentional action took place for the sentence to be used as an input to the motivation annotation task (3a).

(2b) Affect Resolution This task aims to identify all of the lines where a story character j has an emotional reaction. Importantly, it is often possible to infer the emotional reaction of a character j even when the character does not explicitly appear in a sentence k. For instance, in Figure 3, we want to annotate the narrator's reaction to line 2 even though they are not mentioned because their emotional response is inferrable. We obtain 4 an-



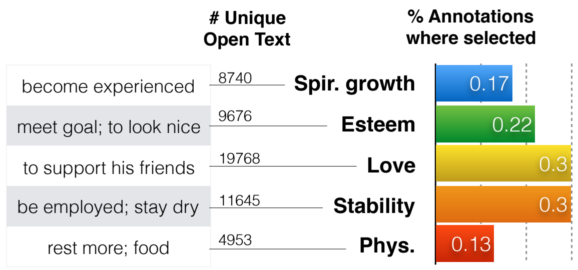


Figure 4: Examples of open-text explanations that annotators provided corresponding with the categories they selected. The bars on the right of the categories represent the percentage of lines where annotators selected that category (out of those character-line pairs with positive motivation/emotional reaction).

notations per character per line. The lines with at least 2 annotators voting are used as input for the next task: (3b) emotional reaction.

(3a) Motivation We use the output from the action resolution stage (2a) to ask workers to annotate character motives in lines where they intentionally initiate an event. We provide 3 annotators a line from a story, the preceding lines, and a specific character. They are asked to produce a free response sentence describing what causes the character's behavior in that line and to select the most related Maslow categories and Reiss subcategories. In Figure 3, an annotator described the motivation of the narrator in line 1 as wanting "to have company" and then selected the *love* (Maslow) and *family* (Reiss) as categorical labels. Because many annotators are not familiar with motivational theories, we require them to complete a tutorial the first time they attempt the task.

(3b) Emotional Reaction Simultaneously, we use the output from the affect resolution stage (2b) to ask workers what the emotional response of a character is immediately following a line in which they are affected. As with the motives, we give 3 annotators a line from a story, its previous context, and a specific character. We ask them to describe in open text how the character will feel following the event in the sentence (up to three emotions). As a follow-up, we ask workers to compare their free responses against Plutchik categories by using 3-point likert ratings. In Figure 3, we include a response for the emotional reaction of the narrator in line 1. Even though the narrator was not mentioned directly in that line, an annotator recorded that they will react to their cousin being a slob by feeling "annoyed" and selected the Plutchik categories for *sadness*, *disgust* and *anger*.

Table 1: Annotated data statistics for each dataset

3.2 Dataset Statistics and Insights

Cost The tasks corresponding to the theory category assignments are the hardest and most expensive in the pipeline (∼$4 per story). Therefore, we obtain theory category labels only for a third of our annotated stories, which we assign to the development and test sets. The training data is annotated with a shortened pipeline with only open text descriptions of motivations and emotional reactions from two workers (∼$1 per story).

Scale Our dataset to date includes a total of 300k low-level annotations for motivation and emotion across 15,000 stories (randomly selected from the ROC story training set). It covers over 150,000 character-line pairs, in which 56k character-line pairs have an annotated motivation and 105k have an annotated change in emotion (i.e. a label other than `none`). Table 1 shows the break down across training, development, and test splits. Figure 4 shows the frequency of different labels being selected for motivational and emotional categories in cases with positive change.

Agreements For quality control, we removed workers who consistently produced low-quality work, as discussed in the Appendix. In the categorization sets (Maslow, Reiss and Plutchik), we compare the performance of annotators by treating each individual category as a binary label (1

Figure 5: NPMI confusion matrix on motivational categories for all annotator pairs with color scaling for legibility. The highest values are generally along diagonal or within Maslow categories (outlined in black). We highlight a few common points of disagreement between thematically similar categories.

Label Type		**PPA**	**KA**	**% Agree w/ Maj. Lbl**
Maslow	Dev	.77	.30	0.88
	Test	.77	.31	0.89
Reiss	Dev	.91	.24	0.95
	Test	.91	.24	0.95
Plutchik	Dev	.71	.32	0.84
	Test	.70	.29	0.83

Table 2: Agreement Statistics (PPA = Pairwise percent agreement of worker responses per binary category, KA= Krippendorff's Alpha)

if they included the category in their set of responses) and averaging the agreement per category. For Plutchik scores, we count 'moderately associated' ratings as agreeing with 'highly' associated' ratings. The percent agreement and Krippendorff's alpha are shown in Table 2. We also compute the percent agreement between the individual annotations and the majority labels.[2]

These scores are difficult to interpret by themselves, however, as annotator agreement in our categorization system has a number of properties that are not accounted for by these metrics (disagreement preferences – joy and trust are closer than joy and anger – that are difficult to quantify in a principled way, hierarchical categories mapping Reiss subcategories from Maslow categories, skewed category distributions that inflate PPA and deflate KA scores, and annotators that could select multiple labels for the same examples).

To provide a clearer understanding of agreement within this dataset, we create aggregated confusion matrices for annotator pairs. First, we sum the counts of combinations of answers between all paired annotations (excluding `none` labels). If an annotator selected multiple categories, we split the count uniformly among the selected categories. We compute NPMI over the total confusion matrix. In Figure 5, we show the NPMI confusion matrix for motivational categories.

In the motivation annotations, we find the highest scores on the diagonal (i.e., Reiss agreement), with most confusions occurring between Reiss motives in the same Maslow category (outlined black in Figure 5). Other disagreements generally involve Reiss subcategories that are thematically similar, such as *serenity* (mental relaxation) and *rest* (physical relaxation). We provide this analysis for Plutchik categories in the appendix, finding high scores along the diagonal with disagreements typically occurring between categories in a "positive emotion" cluster (*joy*, *trust*) or a "negative emotion" cluster (*anger*, *disgust*,*sadness*).

4 Tasks

The multiple modes covered by the annotations in this new dataset allow for multiple new tasks to be explored. We outline three task types below, covering a total of eight tasks on which to evaluate.

[2]Majority label for the motivation categories is what was agreed upon by at least two annotators per category. For emotion categories, we averaged the point-wise ratings and counted a category if the average rating was ≥ 2.

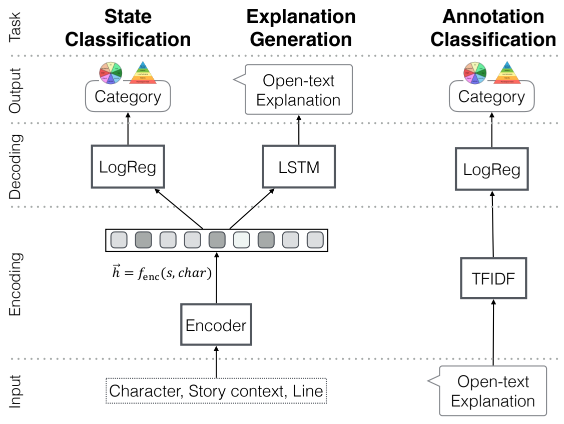

Figure 6: General model architectures for three new task types

Differences between task type inputs and outputs are summarized in Figure 6.

State Classification The three primary tasks involve categorizing the psychological states of story characters for each of the label sets (Maslow, Reiss, Plutchik) collected for the dev and test splits of our dataset. In each classification task, a model is given a line of the story (along with optional preceding context lines) and a character and predicts the motivation (or emotional reaction). A binary label is predicted for each of the Maslow needs, Reiss motives or Plutchik categories.

Annotation Classification Because the dev and test sets contain paired classification labels and free text explanations, we propose three tasks where a model must predict the correct Maslow/Reiss/Plutchik label given an emotional reaction or motivation explanation.

Explanation Generation Finally, we can use the free text explanations to train models to describe the psychological state of a character in free text (examples in Figure 4). These explanations allow for two conditional generation tasks where the model must generate the words describing the emotional reaction or motivation of the character.

5 Baseline Models

The general model architectures for the three tasks are shown in Figure 6. We describe each model component below. The state classification and explanation generation models could be trained separately or in a multi-task set-up.

In the state classification and explanation generation tasks, a model is given a line from a story $\mathbf{x}^s$ containing N words $\{w_0^s, w_1^s, \ldots, w_N^s\}$ from vocabulary V, a character in that story $e_j \in E$ where E is the set of characters in the story, and (optionally) the preceding sentences in the story $\mathbf{C} = \{\mathbf{x}^0 \ldots, \mathbf{x}^{s-1}\}$ containing words from vocabulary V. A representation for a character's psychological state is encoded as:

$$\mathbf{h}^e = \text{Encoder}(\mathbf{x}^s, \mathbf{C}[e_j]) \tag{1}$$

where $\mathbf{C}[e_j]$ corresponds to the concatenated subset of sentences in $\mathbf{C}$ where e_j appears.

5.1 Encoders

While the end classifier or decoder is different for each task, we use the same set of encoders based on word embeddings, common neural network architectures, or memory networks to formulate a representation of the sentence and character, $\mathbf{h}^e$. Unless specified, $\mathbf{h}^e$ is computed by encoding separate vector representations for the sentence ($\mathbf{x}^s \rightarrow \mathbf{h}^s$) and character-specific context ($\mathbf{C}[e_j] \rightarrow \mathbf{h}^c$) and concatenating these encodings ($\mathbf{h}^e = [\mathbf{h}^c; \mathbf{h}^s]$). We describe the encoders below:

TF-IDF We learn a TD-IDF model on the full training corpus of Mostafazadeh et al. (2016) (excluding the stories in our dev/test sets). To encode the sentence, we extract TF-IDF features for its words, yielding $v^s \in \mathcal{R}^V$. A projection and non-linearity is applied to these features to yield $\mathbf{h}^s$:

$$\mathbf{h}^s = \phi(W_s v^s + b_s) \tag{2}$$

where $W_s \in \mathcal{R}^{d \times H}$. The character vector $\mathbf{h}^c$ is encoded in the same way on sentences in the context pertaining to the character.

GloVe We extract pretrained Glove vectors (Pennington et al., 2014) for each word in V. The word embeddings are max-pooled, yielding embedding $v^s \in \mathcal{R}^H$, where H is the dimensionality of the Glove vectors. Using this max-pooled representation, $\mathbf{h}^s$ and $\mathbf{h}^c$ are extracted in the same manner as for TF-IDF features (Equation 2).

CNN We implement a CNN text categorization model using the same configuration as Kim (2014) to encode the sentence words. A sentence is represented as a matrix, $v^s \in \mathcal{R}^{M \times d}$ where each row is a word embedding x_n^s for a word $w_n^s \in \mathbf{x}^s$.

$$v^s = [x_0^s, x_1^s, \ldots, x_N^s] \tag{3}$$

$$\mathbf{h}^s = \text{CNN}(v^s) \tag{4}$$

where CNN represents the categorization model from (Kim, 2014). The character vector $\mathbf{h}^c$ is encoded in the same way with a separate CNN. Implementation details are provided in the appendix.

LSTM A two-layer bi-LSTM encodes the sentence words and concatenates the final time step hidden states from both directions to yield $\mathbf{h}^s$. The character vector $\mathbf{h}^c$ is encoded the same way.

REN We use the "tied" recurrent entity network from Henaff et al. (2017). A memory cell m is initialized for each of the J characters in the story, $E = \{e_0, \ldots, e_J\}$. The REN reads documents one sentence at a time and updates m_j for $e_j \in E$ after reading each sentence. Unlike the previous encoders, all sentences of the context $\mathbf{C}$ are given to the REN along with the sentence $\mathbf{x}^s$. The model learns to distribute encoded information to the correct memory cells. The representation passed to the downstream model is:

$$\mathbf{h}^e = \{m_j\}^s \tag{5}$$

where $\{m_j\}^s$ is the memory vector in the cell corresponding to e_j after reading $\mathbf{x}^s$. Implementation details are provided in the appendix.

NPN We also include the neural process network from Bosselut et al. (2018) with "tied" entities, but "untied" actions that are not grounded to particular concepts. The memory is initialized and accessed similarly as the REN. Exact implementation details are provided in the appendix.

5.2 State Classifier

Once the sentence-character encoding $\mathbf{h}^e$ is extracted, the state classifier predicts a binary label $\hat{y}_z$ for every category $z \in \mathcal{Z}$ where $\mathcal{Z}$ is the set of category labels for a particular psychological theory (e.g., disgust, surprise, etc. in the Plutchik wheel). We use logistic regression as a classifier:

$$\hat{y}_z = \sigma(W_z \mathbf{h}^e + b_z) \tag{6}$$

where W_z and b_z are a label-specific set of weights and biases for classifying each label $z \in \mathcal{Z}$.

5.3 Explanation Generator

The explanation generator is a single-layer LSTM (Hochreiter and Schmidhuber, 1997) that receives the encoded sentence-character representation $\mathbf{h}^e$ and predicts each word y_t in the explanation using the same method from Sutskever et al. (2014). Implementation details are provided in the appendix.

5.4 Annotation Classifier

For annotation classification tasks, words from open-text explanations are encoded with TF-IDF features. The same classifier architecture from Section 5.2 is used to predict the labels.

6 Experimental Setup

6.1 Training

State Classification The dev set D is split into two portions of 80% (D_1) and 20% (D_2). D_1 is used to train the classifier and encoder. D_2 is used to tune hyperparameters. The model is trained to minimize the weighted binary cross entropy of predicting a class label y_z for each class z:

$$\mathcal{L} = \sum_{z=1}^{Z} \gamma_z y_z \log \hat{y}_z + (1-\gamma_z)(1-y_z)\log(1-\hat{y}_z) \tag{7}$$

where Z is the number of labels in each of the three classifications tasks and γ_z is defined as:

$$\gamma_z = 1 - e^{-\sqrt{P(y_z)}} \tag{8}$$

where $P(y_z)$ is the marginal class probability of a positive label for z in the training set.

Annotation Classification The dev set is split in the same manner as for state classification. The TF-IDF features are trained on the set of training annotations D_t coupled with those from D_1. The model must minimize the same loss as in Equation 7. Details are provided in the appendix.

Explanation Generation We use the training set of open annotations to train a model to predict explanations. The decoder is trained to minimize the negative loglikelihood of predicting each word in the explanation of a character's state:

$$L_{gen} = -\sum_{t=1}^{T} \log P(y_t | y_0, ..., y_{t-1}, \mathbf{h}^e) \tag{9}$$

where $\mathbf{h}^e$ is the sentence-character representation produced by an encoder from Section 5.1.

6.2 Metrics

Classification For the state and annotation classification task, we report the micro-averaged precision (P), recall (R), and F1 score of the Plutchik, Maslow, and Reiss prediction tasks. We report the results of selecting a label at random in the top two rows of Table 3. Note that random is low because the distribution of positive instances for each

Model	Maslow			Reiss			Plutchik		
	P	R	F1	P	R	F1	P	R	F1

Table 3: State Classification Results

category is very uneven: macro-averaged positive class probabilities of 8.2, 1.7, and 9.9% per category for Maslow, Reiss, and Plutchik respectively.

Generation Because explanations tend to be short sequences (Figure 4) with high levels of synonymy, traditional metrics such as BLEU are inadequate for evaluating generation quality. We use the vector average and vector extrema metrics from Liu et al. (2016) computed using the Glove vectors of generated and reference words. We report results in Table 5 on the dev set and compare to a baseline that randomly samples an example from the dev set as a generated sequence.

6.3 Ablations

Story Context vs. No Context Our dataset is motivated by the importance of interpreting story context to categorize emotional reactions and motivations of characters. To test this importance, we ablate $\mathbf{h}^c$, the representation of the context sentences pertaining to the character, as an input to the state classifier for each encoder (except the REN and NPN). In Table 3, this ablation is the first row for each encoder presented.

Explanation Pretraining Because the state classification and explanation generation tasks use the same models to encode the story, we explore initializing a classification encoder with parameters trained on the generation task. For the CNN, LSTM, and REN encoders, we pretrain a generator to produce emotion or motivation explanations. We use the parameters from the emotion or motivation explanation generators to initialize the Plutchik or Maslow/Reiss classifiers respectively.

7 Experimental Results

State Classification We show results on the test set for categorizing Maslow, Reiss, and Plutchik states in Table 3. Despite the difficulty of the task, all models outperform the random baseline. Interestingly, the performance boost from adding entity-specific contextual information (i.e., not ablating $\mathbf{h}^c$) indicates that the models learn to condition on a character's previous experience to classify its mental state at the current time step. This effect can be seen in a story about a man whose flight is cancelled. The model without context predicts the same emotional reactions for the man, his wife and the pilot, but with context correctly predicts that the pilot will not have a reaction while predicting that the man and his wife will feel sad.

For the CNN, LSTM, REN, and NPN models, we also report results from pretraining encoder parameters using the free response annotations from the training set. This pretraining offers a clear performance boost for all models on all three prediction tasks, showing that the parameters of the encoder can be pretrained on auxiliary tasks providing emotional and motivational state signal.

The best performing models in each task are most effective at predicting Maslow *physiological* needs, Reiss *food* motives, and Plutchik reactions of *joy*. The relative ease of predicting motivations

	Maslow	Reiss	Plutchik
TFIDF	64.81	48.60	53.44

Table 4: F1 scores of predicting correct category labels from free response annotations

Random	56.02	45.75	40.23	39.98
LSTM	58.48	51.07	52.47	52.30
CNN	57.83	50.75	52.49	52.31
REN	**58.83**	**51.79**	53.95	53.79
NPN	57.77	51.77	**54.02**	**53.85**

Table 5: Vector average and extrema scores for generation of annotation explanations

related to food (and physiological needs generally) may be because they involve a more limited and concrete set of actions such as eating or cooking.

Annotation Classification Table 4 shows that a simple model can learn to map open text responses to categorical labels. This further supports our hypothesis that pretraining a classification model on the free-response annotations could be helpful in boosting performance on the category prediction.

Explanation Generation Finally, we provide results for the task of generating explanations of motivations and emotions in Table 5. Because the explanations are closely tied to emotional and motivation states, the randomly selected explanation can often be close in embedding space to the reference explanations, making the random baseline fairly competitive. However, all models outperform the strong baseline on both metrics, indicating that the generated short explanations are closer semantically to the reference annotation.

8 Related work

Mental State Annotations Incorporating emotion theories into NLP tasks has been explored in previous projects. Ghosh et al. (2017) modulate language model distributions by increasing the probability of words that express certain affective LIWC (Tausczik and Pennebaker, 2016) categories. More generally, various projects tackle the problem of generating text from a set of attributes like sentiment or generic-ness (Ficler and Goldberg, 2017; Dong et al., 2017). Similarly, there is also a body of research in reasoning about commonsense stories and discourse (Li and Jurafsky, 2017; Mostafazadeh et al., 2016) or detecting emotional stimuli in stories (Gui et al., 2017). Previous work in plot units (Lehnert, 1981) developed formalisms for affect and mental state in story narratives that included motivations and reactions. In our work, we collect mental state annotations for stories to used as a new resource in this space.

Modeling Entity State Recently, novel works in language modeling (Ji et al., 2017; Yang et al., 2016), question answering (Henaff et al., 2017), and text generation (Kiddon et al., 2016; Bosselut et al., 2018) have shown that modeling entity state explicitly can boost performance while providing a preliminary interface for interpreting a model's prediction. Entity modeling in these works, however, was limited to tracking entity reference (Kiddon et al., 2016; Yang et al., 2016; Ji et al., 2017), recognizing entity state similarity (Henaff et al., 2017) or predicting simple attributes from entity states (Bosselut et al., 2018). Our work provides a new dataset for tracking emotional reactions and motivations of characters in stories.

9 Conclusion

We present a large scale dataset as a resource for training and evaluating mental state tracking of characters in short commonsense stories. This dataset contains over 300k low-level annotations for character *motivations* and *emotional reactions*. We provide benchmark results on this new resource. Importantly, we show that modeling character-specific context and pretraining on free-response data can boost labeling performance. While our work only use information present in our dataset, we view our dataset as a future testbed for evaluating models trained on any number of resources for learning common sense about emotional reactions and motivations.

Acknowledgments

We thank the reviewers for their insightful comments. We also thank Bowen Wang, xlab members, Martha Palmer, Tim O'Gorman, Susan W. Brown, and Ghazaleh Kazeminejad for helpful discussions on inter-annotator agreement and the annotation pipeline. Abstract

In the era of big data, focused analysis for diverse topics with a short response time becomes an urgent demand. As a fundamental task, information filtering therefore becomes a critical necessity. In this paper, we propose a novel deep relevance model for zero-shot document filtering, named DAZER. DAZER estimates the relevance between a document and a category by taking a small set of seed words relevant to the category. With pre-trained word embeddings from a large external corpus, DAZER is devised to extract the relevance signals by modeling the hidden feature interactions in the word embedding space. The relevance signals are extracted through a gated convolutional process. The gate mechanism controls which convolution filters output the relevance signals in a category dependent manner. Experiments on two document collections of two different tasks (*i.e.,* topic categorization and sentiment analysis) demonstrate that DAZER significantly outperforms the existing alternative solutions, including the state-of-the-art deep relevance ranking models.

1 Introduction

Filtering irrelevant information and organizing relevant information into meaningful topical categories is indispensable and ubiquitous. For example, a data analyst tracking an emerging event would like to retrieve the documents relevant to a specific topic (category) from a large document collection in a short response time. In the era of big data, the potentially possible categories covered by documents would be limitless. It is unrealistic to manually identify a lot of positive examples for each possible category. However, new information needs indeed emerge everywhere in many real-world scenarios. Recent studies on dataless text classification show promising results on reducing labeling effort (Liu et al., 2004; Druck et al., 2008; Chang et al., 2008; Song and Roth, 2014; Hingmire et al., 2013; Hingmire and Chakraborti, 2014; Chen et al., 2015; Li et al., 2016). Without any labeled document, a dataless classifier performs text classification by using a small set of relevant words for each category (called "seed words"). However, existing dataless classifiers do not consider *document filtering*. We need to provide the seed words for each category covered by the document collection, which is often infeasible in the real world.

To this end, we are particularly interested in the task of zero-shot document filtering. Here, *zero-shot* means that the instances of the targeted categories are unseen during the training phase. To facilitate zero-shot filtering, we take a small set of seed words to represent a category of interest. This is extremely useful when the information need (*i.e.,* the categories of interest) is dynamic and the text collection is large and temporally updated (*e.g.,* the possible categories are hard to know). Specifically, we propose a novel **d**eep relev**a**nce model for **z**ero-shot document filt**er**ing, named DAZER. In DAZER, we use the word embeddings learnt from an external large text corpus to represent each word. A category can then be well represented also in the embedding space (called *category embedding*) through some composition with the word embeddings of the provided seed words. Given a small number of seed words provided for a category as input, DAZER is devised to produce a score indicating the relevance between a document and the category. It is intuitive to connect zero-shot document filtering with the task of ad-hoc retrieval. Indeed, by treating the seed words of each category as a query, the zero-shot document filtering is equivalent to ranking documents based on their relevance to the query. The relevance ranking is a core task in information retrieval, and has been studied for many years. Although they share the same formulation, these two tasks diverge fundamentally. For ad-hoc retrieval, a user constructs a query with a specific information need. The relevant documents are assumed to contain these query words. This is confirmed by the existing works that exact keyword match is still the most important signal of relevance in ad-hoc retrieval (Fang and Zhai, 2006; Wu et al., 2007; Eickhoff et al., 2015; Guo et al., 2016a,b).

For document filtering, the seed words for a category are expected to convey the conceptual meaning of the latter. It is impossible to list all the words to fully cover the relevant documents of a category. Therefore, it is essential to capture the conceptual relevance for zero-shot document filtering. The classical retrieval models simply estimate the relevance based on the query keyword matching, which is far from capturing the conceptual relevance. The existing deep relevance models for ad-hoc retrieval utilize the statistics of the hard/soft-match signals in terms of cosine similarity between two word embeddings (Guo et al., 2016a; Xiong et al., 2017). However, the scalar information like cosine similarity between two embedding vectors is too coarse or limited to reflect the conceptual relevance. On the contrary, we believe that the embedding features could provide rich knowledge towards the conceptual relevance. A key challenge is to endow DAZER a strong generalization ability to also successfully extract the relevance signals for unseen categories. To achieve this purpose, we extract the relevance signals based on the hidden feature interactions between the category and each word in the embedding space. Specifically, two element-wise operations are utilized in DAZER: element-wise subtraction and element-wise product. Since these two kinds of interactions represent the relative information encoded in hidden embedding space, we expect that the relevance signal extraction process could generalize well to unseen categories. Firstly, DAZER utilizes a gated convolutional operation with k-max pooling to extract the relevance signals. Then, DAZER abstracts higher-level relevance features through a multi-layer perceptron, which can be considered as a relevance aggregation procedure. At last, DAZER calculates an overall score indicating the relevance between a document and the category. Without further constraints, it is possible for DAZER to encode the bias towards the category-specific features seen during the training (*i.e.,* model overfitting). Therefore, we further introduce an adversarial learning over the output of the relevance aggregation procedure. The purpose is to ensure that the higher-level relevance features contain no category-dependent information, leading to a better zero-shot filtering performance.

To the best of our knowledge, DAZER is the first deep model to conduct zero-shot document filtering. We conduct extensive experiments on two real-world document collections from two different domains (*i.e.,* 20-Newsgroup for topic categorization, and Movie Review for sentiment analysis). Our experimetnal results suggest that DAZER achieves promising filtering performance and performs significantly better than the existing alternative solutions, including state-of-the-art deep relevance ranking methods.

2 Deep Zero-Shot Document Filtering

Figure 1 illustrates the network structure of the proposed DAZER model. It consists of two main components: *relevance signal extraction* and *relevance aggregation*. In the following, we present each component in detail.

2.1 Relevance Signal Extraction

Given a document $d = (w_1, w_2, ..., w_{|d|})$ and a set of seed words $\mathbb{S}_c = \{s_{c,i}\}$ for category c, we first map each word w into its dense word embedding representation $\mathbf{e}_w \in \mathbb{R}^{l_e}$ where l_e denotes the dimension number. The embedding representation is pre-trained by using a representation learning method from an external large text corpus. Since our aim is to capture the conceptual relevance, we simply take the averaged embedding of the seed words to represent a category in the embedding space: $\mathbf{c}_c = 1/|\mathbb{S}_c| \sum_{s \in \mathbb{S}_c} \mathbf{e}_s$.

Interaction-based Representation. It is widely recognized that word embeddings are useful because both syntactic and semantic information of words are well encoded (Mikolov et al., 2013; Pennington et al., 2014). The element-wise hidden feature difference is a kind of relative infor-

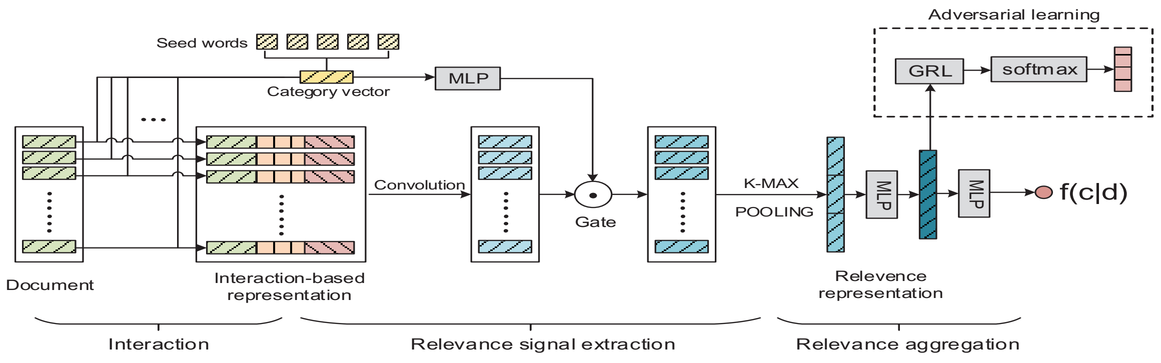

Figure 1: The architecture of DAZER

Examples
$\mathbf{c}_{atheism} - \mathbf{e}_{atheist} \approx \mathbf{c}_{baseball} - \mathbf{e}_{hitter}$
$\mathbf{c}_{autos} - \mathbf{e}_{toyata} \approx \mathbf{c}_{motorcycles} - \mathbf{e}_{yamaha}$
$\mathbf{c}_{baseball} - \mathbf{e}_{stadium} \approx \mathbf{c}_{med} - \mathbf{e}_{hosptial}$
$\mathbf{c}_{religion.misc} - \mathbf{e}_{faith} \approx \mathbf{c}_{med} - \mathbf{e}_{patient}$

Table 1: Examples by using embedding offset.

Examples
$\text{sign}(\mathbf{c}_{mideast} \odot \mathbf{e}_{muslim}) \approx \text{sign}(\mathbf{c}_{med} \odot \mathbf{e}_{doctor})$
$\text{sign}(\mathbf{c}_{space} \odot \mathbf{e}_{orbit}) \approx \text{sign}(\mathbf{c}_{hockey} \odot \mathbf{e}_{espn})$
$\text{sign}(\mathbf{c}_{electronics} \odot \mathbf{e}_{circuit}) \approx \text{sign}(\mathbf{c}_{pc} \odot \mathbf{e}_{controller})$
$\text{sign}(\mathbf{c}_{crypt} \odot \mathbf{e}_{algorithm}) \approx \text{sign}(\mathbf{c}_{space} \odot \mathbf{e}_{burning})$

Table 2: Examples by using element-wise product.

mation that captures the offset bettwen a word and a category in the embedding space. These embedding offsets contain more intricate relationships for a word pair. A well known example is: $\mathbf{e}_{king} - \mathbf{e}_{queen} \approx \mathbf{e}_{man} - \mathbf{e}_{woman}$ (Mikolov et al., 2013). Similar observations are made when we calculate the embedding offset between words and categories. Table 1 lists several interesting patterns observed for the embedding offsets between a category and a word in 20-Newsgroup dataset (ref. Section 3.2 for more details). We can see that the embedding offsets are somehow consistent with a particular relation between the two category-word pairs.

An effective way to measure the relatedness for two words is the inner product or cosine similarity between two corresponding word embeddings. This can be considered as a particular linear combination of corresponding feature products for the two embeddings: $rel(\mathbf{e}_1, \mathbf{e}_2) = \sum_i g(\mathbf{e}_1, \mathbf{e}_2, i)\mathbf{e}_{1,i} \cdot \mathbf{e}_{2,i} = \mathbf{g}(\mathbf{e}_1, \mathbf{e}_2)^T(\mathbf{e}_1 \odot \mathbf{e}_2)$ where $g(\mathbf{e}_1, \mathbf{e}_2, i)$ refers to the weight calculated for i-th dimension, and $\mathbf{g}(\mathbf{e}_1, \mathbf{e}_2) = [g(\mathbf{e}_1, \mathbf{e}_2, 1); ...; g(\mathbf{e}_1, \mathbf{e}_2, l_e)]$, $\odot$ is the element-wise product operation. The element-wise product between two embeddings is also a kind of relative information. The sign of a product of two embeddings in a specific dimension indicates whether the two embeddings share the same polarity in this dimension. And the resultant value manifests to what extent that this agreement/disagreement reaches. It is intuitive that the element-wise product offers some kinds of semantic relations. We conduct the element-wise product for each category-word pair in 20-Newsgroup dataset. Table 2 lists some interesting patterns we observe. The sign(x) function returns 1 when $x \geq 0$, otherwise return -1. Shown in the table, the sign pattern of the element-wise product encodes the relevance information between a category and its related words.

Inspired by these observations, we use these two kinds of element-wise interactions to complement the representation of a word in a document. Specifically, for each word w in document d, we derive its interaction-based representation $\mathbf{e}_w^c$ towards category c as follows:

$$\mathbf{e}_{c,w}^{diff} = \mathbf{c}_c - \mathbf{e}_w \tag{1}$$

$$\mathbf{e}_{c,w}^{prod} = \mathbf{c}_c \odot \mathbf{e}_w \tag{2}$$

$$\mathbf{e}_w^c = [\mathbf{e}_w \oplus \mathbf{e}_{c,w}^{diff} \oplus \mathbf{e}_{c,w}^{prod}] \tag{3}$$

where $\oplus$ is the vector concatenation operation. Note that these two kinds of feature interactions are mainly overlooked by the existing literature. The embedding offsets are used in deriving word semantic hierarchies in (Fu et al., 2014). However, there is no existing work incorporating these two kinds of feature interactions for relevance estimation. Here, we expect that these two kinds of feature interactions can magnify the relevance information regarding the category.

Convolution with k-max Pooling. We utilize

m convolution filters to extract the relevance signals for each word based on its local window of size l in the document. Specifically, after calculating the interaction-based representation $d = (\mathbf{e}_1^c, \mathbf{e}_2^c, ..., \mathbf{e}_{|d|}^c)$ for document d and category c, we apply the convolution operation as follows:

$$\mathbf{r}_i = \mathbf{W}_1 \mathbf{e}^c_{i-l:i+l} + \mathbf{b}_1 \tag{4}$$

where $\mathbf{r}_i \in \mathbb{R}^m$ is the hidden features regarding the relevance signal extracted for i-th word, $\mathbf{W}_1 \in \mathbb{R}^{m \times 3l_e(2l+1)}$ and $\mathbf{b}_1 \in \mathbb{R}^m$ are the weight matrix and the corresponding bias vector respectively, $\mathbf{e}^c_{i-l:i+l}$ refers to the concatenation from $\mathbf{e}^c_{i-l}$ to $\mathbf{e}^c_{i+l}$. Both l zero vectors are padded to the begining and the end of the document. With a local window of size l, the convolution operation can extract more accurate relevance information by taking the consecutive words (*e.g.,* phrases) into account. We then apply k-max pooling strategy to obtain the k most active features for each filter. Let $\mathbf{r}^j_{k-max}$ denote the k largest values for filter j, we form the overall relevance signals $\mathbf{r}_d$ extracted by all m filters through the concatenation: $\mathbf{r}_{c,d} = [\mathbf{r}^1_{k-max} \oplus \mathbf{r}^2_{k-max} \cdots \oplus \mathbf{r}^m_{k-max}]$.

Category-specific Gating Mechanism. Given a specific word w, the interaction-based representation $\mathbf{e}^c_w$ for each category c could be very different. Therefore, for a specific local context, the extracted relevance signal from a particular convolution filter could be also distinct for different categories. It is then reasonable to assume that the relevance signals for a specific category are captured by a subset of filters. We propose to identify which filters are relevant to a category through a category-specific gating mechanism. Given category c, category-specific gates $\mathbf{a}_c \in \mathbb{R}^m$ are calculated as follows:

$$\mathbf{a}_c = \sigma(\mathbf{W}_2 \mathbf{e}_c + \mathbf{b}_2) \tag{5}$$

where $\mathbf{W}_2 \in \mathbb{R}^{m \times 3l_e}$ and $\mathbf{b}_2 \in \mathbb{R}^m$ are the weight matrix and bias vectors respectively, $\sigma(\cdot)$ is the *sigmoid* function. With category-specific gating mechanism, Equation 4 can be rewritten as follows: $\mathbf{r}_i = \mathbf{a}_c \odot (\mathbf{W}_1 \mathbf{e}^c_{i-l:i+l} + \mathbf{b}_1)$

Here, $\mathbf{a}_c$ works as *on-off* switches for m filters. While $\mathbf{a}_{c,j} \rightarrow 1$ indicates that j-th filter should be turned on to capture the relevance singals under category c to its fullness, $\mathbf{a}_{c,j} \rightarrow 0$ indicates that the filter is turned off due to its irrelevance.

This collaboration of the convolution operation and gating mechanism is similar to the Gated Linear Units (GLU) recently proposed in (Dauphin et al., 2017). Given an input $\mathbf{X}$, GLU calculates the output as follow: $\mathbf{h}(\mathbf{X}) = (\mathbf{X}\mathbf{W} + \mathbf{b}) \odot \sigma(\mathbf{X}\mathbf{V} + \mathbf{c})$ where the first term in the right side refers to the convolution operation and the second term in the right side refers to the gating mechanism. In GLU, both the convolution operation and the gates share the same input $\mathbf{X}$. In contrast, in this work, we aim to identify which filters capture the relevance signals in a category-dependent manner. The experimental results validate that this category-dependent setting brings significant benefit for zero-shot filtering performance (ref. Section 3).

2.2 Relevance Aggregation

The raw relevance signals $\mathbf{r}_{c,d}$ are somehow category-dependent, since the relevant filters are category-dependent. The hidden features regarding the relevance are distilled through a fully-connected hidden layer with nonlinearity:

$$\mathbf{h}_{c,d} = g_a(\mathbf{W}_3 \mathbf{r}_{c,d} + \mathbf{b}_3) \tag{6}$$

where $\mathbf{W}_3 \in \mathbb{R}^{l_a \times 3km}$ and $\mathbf{b}_3 \in \mathbb{R}^{l_a}$ are the weight matrix and bias vector respectively, $g_a(\cdot)$ is the *tanh* function. This procedure can be considered as a relevance aggregation process. Then, the overall relevance score is then estimated as follow:

$$f(c|d) = tanh(\mathbf{w}^T \mathbf{h}_{c,d} + b) \tag{7}$$

where $\mathbf{w} \in \mathbb{R}^{l_a}$ and b are the parameters and bias respective.

2.3 Model Training

Adversarial Learning The hidden features $\mathbf{h}_{c,d}$ are expected to be category-independent. However, there is no guarantee that the category-specific information is not mixed with the relevance information extracted in $\mathbf{h}_{c,d}$. Here, we introduce an adversarial learning mechanism to ensure that no category-specific information can be memorized during the training. Otherwise, the proposed DAZER may not generalize well to unseen categories. Specifically, we introduce an category classifier over $\mathbf{h}_{c,d}$ to calculate the probability that $\mathbf{h}_{c,d}$ belongs to each category seen during the training: $p_{cat}(\cdot|\mathbf{h}_{c,d}) = softmax(\mathbf{W}_4 \mathbf{h}_{c,d} +$

$\mathbf{b}_4$) where $\mathbf{W}_4 \in \mathbb{R}^{C \times l_a}$ and $\mathbf{b}_4 \in \mathbb{R}^C$ are the weight matrix and bias vector for the classifier, C is the number of categories covered by the training set. We aim to optimize parameters $\phi = \{\mathbf{W}_4, \mathbf{b}_4\}$ to successfully classify $\mathbf{h}_{c,d}$ to its true category. Let θ denote the parameters regarding the calculation of $\mathbf{h}_{c,d}$, *i.e.,* $\theta = \{\mathbf{W}_1, \mathbf{W}_2, \mathbf{W}_3, \mathbf{b}_1, \mathbf{b}_2, \mathbf{b}_3\}$, ϕ is optimized to minimize the negative log-likelihood:

$$L_{cat}(\theta, \phi) = \frac{1}{|\mathbb{T}|} \sum_{(d,y) \in \mathbb{T}} -p_{cat}(y|\mathbf{h}_{y,d}) \tag{8}$$

where $\mathbb{T}$ denotes the training set $\{(d, y)\}$ such that document d is relevant to category y. On the other hand, we expect that $\mathbf{h}_{c,d}$ carries no category specific information, such that the classifier can not perform the category classification precisely. Hence, we add the Gradient Reversal Layer (GRL) (Ganin and Lempitsky, 2015; Ganin et al., 2016) between $\mathbf{h}_{c,d}$ and the category classifier. We can consider GRL as a pseudo-function $R_\lambda(\mathbf{x})$:

$$R_\lambda(\mathbf{x}) = \mathbf{x}; \quad \frac{\partial R_\lambda}{\partial \mathbf{x}} = -\lambda \mathbf{I} \tag{9}$$

It means that θ is optimized to make $\mathbf{h}_{c,d}$ indistinguishable by the classifier. In Equation 9, parameter λ controls the importance of the adversarial learning. DAZER is devised to return a relevance score, we utilize the pairwise margin loss for model training:

$$\begin{aligned} L_{hinge}(\theta, \delta) =& \frac{1}{|\mathbb{T}|} \sum_{(d,y) \in \mathbb{T}} \max(0, \Delta - f(y|d) \\ &+ f(y|d_y^-)) \end{aligned} \tag{10}$$

where document d_y^- is the negative sample for category y, Δ is the margin and set to be 1 in this work, and $\delta = \{\mathbf{w}, b\}$. Overall, the proposed DAZER is an end-to-end neural network model. The parameters $\Theta = \{\theta, \phi, \delta\}$ are optimized via back propagation and stochastic gradient descent. Specifically, we utilize Adam (Kingma and Ba, 2014) algorithm for parameter update over minibatches. The final objective loss used in the training is as follow:

$$L(\Theta) = L_{hinge}(\theta, \delta) + L_{cat}(\theta, \phi) + \lambda_\Theta \|\Theta\|_2 \tag{11}$$

where λ_Θ controls the importance of the regularizaton term.

Label	Seed Words
very negative	bad, horrible, negative, disgusting
negative	bad, confused, unexpected, useless, negative
neutral	normal, moderate, neutral, objective, impersonal
positive	good, positive, outstanding, satisfied, pleased
very positive	positive, impressive, unbelievable, awesome

Table 3: Seed words selected for Movie Review.

3 Experiment

In this section, we conduct experiments on two real-world document collections to evaluate the effectiveness of the proposed DAZER[1].

3.1 Existing Alternative Methods

Here, we compare the proposed DAZER against the following alternative solutions.

BM25 Model: BM25 is a widely known retrieval model based on keyword matching (Robertson and Walker, 1994). The default parameter setting is used in the experiments.

DSSM: DSSM utilizes a multi-layer perceptron to extract hidden representations for both the document and the query (Huang et al., 2013). Then, cosine similarity is calculated as the relevance score based on the representation vectors. Since we use pre-trained word embeddings from a large text corpus, we choose to replace the letter-tri-grams representation with the word embedding representation instead. We use the recommended network setting by its authors.

DRMM: DRMM calculates the relevance based on the histogram information of the semantic relatedness scores between each word in the document and each query word (Guo et al., 2016a). The recommended network setting (*i.e.,* LCH$\times$IDF) and parameter setting are used.

K-NRM: K-NRM is a kernel based neural model for relevance ranking based on word-level hard/soft matching signals (Xiong et al., 2017). We use the recommended setting as in their paper.

DeepRank: DeepRank is a neural relevance ranking model based on the query-centric context (Pang et al., 2017). The recommended setting is used for evaluation.

Seed-based Support Vector Machines (SSVM): We build a seed-driven training set by labeling a training document with a category if the document

[1] The implementation is available at `https://github.com/WHUIR/DAZER`

contains any seed word of that category. Then, we adopt a one-class SVM implemented by sklearn[2] for document filtering[3]. The optimal performance is reported by tuning the hyper-parameter.

3.2 Datasets and Experimental Setup

20-Newsgroup (20NG)[4] is a widely used benchmark for document classification research (Li et al., 2016). It consists of approximately 20K newsgroup articles from 20 different categories. The *bydate* version with $18,846$ documents is used here. As provided, the training set and test set contain 60% and 40% documents respectively.

Movie Review[5] is a collection of movie reviews in English (Pang and Lee, 2005). The scale dataset v1.0 is used in the experiments. Based on the numerical ratings, we split these reviews into five sentiment labels: *very negative, negative, neutral, positive* and *very positive*, which contains 167, 1030, 1786, 1682, 341 reviews respectively. For each sentiment label, we randomly split the reviews into a training set (80%) and a test set (20%).

Since our work targets at zero-shot document filtering for unseen categories, the word embeddings pre-trained by Glove over a large text corpus with total 840 billion tokens[6] are used across all the methods and the two datasets. The dimension of the word embeddings is $l_e = 300$. No further word embedding fine-tuning is applied. For both datasets, the stop words are removed firstly. Then, all the words are converted into their lowercased forms. We further remove the words whose word embeddings are not supported by Glove.

Evaluation Protocol. With the specified unseen categories, we take all the training documents of the other categories to train a model. Then, all documents in the test set are used for evaluation. For each unseen category, the task is to rank the documents of that category higher than the others. Here, we choose to report mean average precision (MAP) for performance evaluation. MAP is a widely used metric to evaluate the ranking quality. The higher the relevant documents are ranked, the larger the MAP value is, which means a better filtering performance. For all neural networks based models, the training documents from one randomly sampled training category work as the validation set for early stop. We report the averaged results over 5 runs for all the methods (excluding SSVM and BM25). The statistical significance is conducted by applying the student t-test.

Seed Word Selection. For 20NG dataset, we directly use the seed words[7] manually compiled in (Song and Roth, 2014). These seed words are selected from the category descriptions and widely used in the works of dataless text classification (Song and Roth, 2014; Chen et al., 2015; Li et al., 2016). For Movie Review, following the seed word selection process (*i.e.,* assisted by standard LDA) proposed in (Chen et al., 2015), we manually select the seed words for each sentiment label. Table 3 lists the seed words selected for each sentiment label for Movie Review dataset. There are on average 5.2 and 4.6 seed words for each category over 20NG and Movie Review respectively. It is worthwhile to highlight that no category information is exploited within the seed word selection process.

Parameter Setting. For DAZER, the number of convolution filters is $m = 50$ and $k = 3$ is used for k-max pooling. The dimension size for relevance aggregation is $l_a = 75$. The local window size l is set to be 2. The learning rate is 0.00001. The models are trained with a batch size of 16 and $\lambda_\Theta = 0.0001$, $\lambda = 0.1$.

3.3 Performance Comparison

For 20NG dataset, we randomly create 9 document filtering tasks which cover 10 out of 20 categories. For Movie Review, we take each sentiment label as an unseen category for evaluation. Table 4 lists the performance of 7 methods in terms of MAP for these filtering tasks. Here, we make the following observations.

First, the proposed DAZER significantly achieves much better filtering performance on all 14 tasks across the two datasets. The averaged MAP of DAZER over these 14 filtering tasks is 0.671. Note that only 5.2 and 4.6 seed words are used on average for each task. The second best performer is K-NRM, which achieves the second

Table 4: Performance of the 7 methods for zero-shot document filtering in terms of MAP. The best and second best results are highlighted in boldface and underlined respectively, on each task. † indicates that the difference to the best result is statistically significant at 0.05 level. Avg: averaged MAP over all tasks.

best on 7 tasks. Overall, the averaged performance gain for DAZER over K-NRM is about 30.8%.

Second, We observe that DSSM performs signficantly better for sentiment analysis than for topic categorization. As discussed in Section 4, DSSM is designed to perform semantic matching. Compared with topic categorization, sentiment analysis is more like a semantic matching task. SSVM delivers the worst performance on both datasets. This illustrates that the quality of the labeled documents is essential for supervised learning techniques. Apparently, recruiting training documents with the provided seed words in a simple fashion is error-prone. We also note that BM25 achieves inconsistent performance over the two kinds of tasks. It performs especially worse for sentiment analysis. This is reasonable because there are more diverse ways to express a specific sentiment. It is hard to cover a reasonable proportion of documents with limited number of sentimental seed words. In comparison, the proposed DAZER obtains a consistent performance for both topic categorization and sentiment analysis.

3.4 Analysis of DAZER

Component Setting. Here, we further discuss the impact of different component settings of DAZER on both 20NG and Movie Review datasets. Table 5 and 6 report the impacts of each component setting via an ablation test on the two datasets respectively. We can see that each component brings significantly positive benefit for document filtering. First, we can see that either element-wise subtraction or product contributes signifcantly to the performance improvement. Specifically, from Table 6, we can see that both the element-wise subtraction and element-wise product play equally on Movie Review dataset. On the other hand, it is observed that DAZER experiences significantly a much larger performance degradation on 20NG dataset. For example, a MAP of only 0.154 is achieved when $\mathbf{e}_{c,w}^{prod}$ is excluded from DAZER for the filtering task *space*. A much severer case is for the filtering task *baseball-hockey*. By excluding $\mathbf{e}_{c,w}^{prod}$, the MAP performance of DAZER is reduced from 0.782 to 0.045. That is, the element-wise product is more critical for extracting relevance signals for topical categorization. We also observe that these two hidden feature interactions together play a more important role for DAZER. For example, without both $\mathbf{e}_{c,w}^{diff}$ and $\mathbf{e}_{c,w}^{prod}$, DAZER only achieves a MAP of 0.126 for filtering task *space*. The large performance deterioration is also observed for other filtering tasks on 20NG dataset.

Either adversarial learning or category-specific gate mechanism enhances the filtering performance of DAZER, which validates the effectiveness of the two components for enhancing con-

ceptual relevance extraction. Also, without using adversarial learning, DAZER still achieves much better filtering performance than the existing baseline methods compared in Section 3.3. This observation is also held on 20NG dataset. This further validates that the two kinds of hidden feature interactions indeed encode rich knowledge towards the conceptual relevance.

Impact of Seed Words. It has been recognized that the less seed words incur worse document classification performance in the existing dataless document classification techniques (Song and Roth, 2014; Chen et al., 2015; Li et al., 2016). Following these works, we also use the words appearing in the category name of 20NG dataset as the corresponding seed words[8]. There are on average 2.75 seed words for a category of 20NG. Table 7 reports the MAP performace of each method on 20NG dataset. The experimental results show that all methods investigated in Section 3.3 experience signficant performance degradation for most filtering tasks. We plan to incorporate the pseudo-relevance feedback into DAZER to tackle the scarcity of the seed words. One possible solution is to enrich the architecture of DAZER to allow few-shot document filtering. That is, the filtering decisions of high-confidence are utilized to derive more seed words for better filtering performance.

4 Related Work

Document filtering is the task to separate relevant documents from the irrelevant ones for a specific topic (Robertson and Soboroff, 2002; Nanas et al., 2010; Gao et al., 2013, 2015; Proskurnia et al., 2017). Both ranking and classification based solutions have been developed (Harman, 1994; Robertson and Soboroff, 2002; Soboroff and Robertson, 2003). In earlier days, a filtering system is mainly devised to facilitate the document retrieval for the long-term information needs (Mostafa et al., 1997). The term-based pattern mining techniques are widely developed to perform document filtering. A network-based topic profile is built to exploit the term correlation patterns for document filtering (Nanas et al., 2010). Frequent term patterns in terms of fine-grained hidden topics are proposed in (Gao et al., 2013, 2015) for doucment filtering. Very recently, frequent term patterns are also utilized to perform event-based microblog filtering (Proskurnia et al., 2017). However, these approaches are all based on supervised-learning, which requires a significant amount of positive documents for each topic. In the era of big data, the information space and new information needs are continuously growing. Retrieval of the relevance information in a short response time becomes a fundamental need. Recently, many works have been proposed to conduct document filtering in an entity-centric manner (Frank et al., 2012; Balog and Ramampiaro, 2013; Zhou and Chang, 2013; Reinanda et al., 2016). The task is to identify the documents relevant to a specific entity that is well defined in an

Table 7: Performance of the 7 methods for zero-shot document filtering in terms of MAP. The words appearing in the category name are used as the seed words. The best and second best results are highlighted in boldface and underlined respectively, on each task.

external knowledge base. Specifically, Balog and Ramampiaro (2013) examine the choice of classification against ranking approaches. They found that ranking approach is more suitable for the filtering task. Following this conclusion, we formulate the zero-shot document filtering as a relevance ranking task. Many information needs may not be well represented by a specific entity. Hence, these entity-centric solutions are restricted to knowledge base related tasks.

Many ad-hoc retrieval models can be used to perform zero-shot document filtering. Indeed, traditional term-based document filtering approaches utilize many term-weighting schemes developed for ad-hoc retrieval. Traditional ad-hoc retrieval models mainly estimate the relevance based on keyword matching. BM25 (Robertson and Walker, 1994) can be considered as the optimal practice in this line of literature. The recent advances in word embedding offer effective learning of word semantic relations from a large external corpus. Several neural relevance ranking models are proposed to preform ad-hoc retrieval based on word embeddings. Both K-NRM (Xiong et al., 2017) and DRMM (Guo et al., 2016a) estimate the relevance based on the macro-statistics of the hard/soft-match signals in terms of cosine similarity between two word embeddings. DeepRank (Pang et al., 2017) first measures the relevance signals from the query-centric context of each query keyword matching point through convolutional operations. Then, RNN based networks are adopted to aggregate these relevance signals. These works achieve significantly better retrieval performance than the keyword matching based solutions and represent the new state-of-the-art. The relevance between a query and a document can also be considered as a matching task between two pieces of text. There are many deep matching models, *e.g.,* DSSM (Huang et al., 2013), ARC-II (Hu et al., 2014), MatchPyramid (Pang et al., 2016), Match-SRNN (Wan et al., 2016). These models are mainly developed for some specific *semantic matching* tasks, *e.g.,* paraphrase identification. Therefore, information like grammatical structure or sequence of words are often taken into consideration, which is not applicable to seed word based zero-shot document filtering.

5 Conclusion

In this paper, we propose a novel **d**eep relev**a**nce model for **z**ero-shot document filt**er**ing, named DAZER. To enable DAZER to capture conceptual relevance and generalize well to unseen categories, two kinds of feature interactions, a gated convolutional network and an category-independent adversarial learning are devised. The experimental results over two different tasks validate the superiority of the proposed model. In the future, we plan to enrich the architecture of DAZER to allow few-shot document filtering by incorporating several labeled examples.

Disconnected Recurrent Neural Networks for Text Categorization

Baoxin Wang
Joint Laboratory of HIT and iFLYTEK, iFLYTEK Research, Beijing, China
bxwang2@iflytek.com

Abstract

Recurrent neural network (RNN) has achieved remarkable performance in text categorization. RNN can model the entire sequence and capture long-term dependencies, but it does not do well in extracting key patterns. In contrast, convolutional neural network (CNN) is good at extracting local and position-invariant features. In this paper, we present a novel model named disconnected recurrent neural network (DRNN), which incorporates position-invariance into RNN. By limiting the distance of information flow in RNN, the hidden state at each time step is restricted to represent words near the current position. The proposed model makes great improvements over RNN and CNN models and achieves the best performance on several benchmark datasets for text categorization.

1 Introduction

Text categorization is a fundamental and traditional task in natural language processing (NLP), which can be applied in various applications such as sentiment analysis (Tang et al., 2015), question classification (Zhang and Lee, 2003) and topic classification (Tong and Koller, 2001). Nowadays, one of the most commonly used methods to handle the task is to represent a text with a low dimensional vector, then feed the vector into a softmax function to calculate the probability of each category. Recurrent neural network (RNN) and convolutional neural network (CNN) are two kinds of neural networks usually used to represent the text.

RNN can model the whole sequence and capture long-term dependencies (Chung et al., 2014). However, modeling the entire sequence sometimes can be a burden, and it may neglect key parts for text categorization (Yin et al., 2017). In contrast, CNN is able to extract local and position-invariant features well (Scherer et al., 2010; Collobert et al., 2011). Table 1 is an example of topic classification, where both sentences should be classified as *Science and Technology*. The key phrase that determines the category is *unsolved mysteries of mathematics*, which can be well extracted by CNN due to position-invariance. RNN, however, doesn't address such issues well because the representation of the key phrase relies on all the previous terms and the representation changes as the key phrase moves.

case1: *One of the seven great* ***unsolved mysteries of mathematics*** *may have been cracked by a reclusive Russian.*
case2: *A reclusive Russian may have cracked one of the seven great* ***unsolved mysteries of mathematics.***

Table 1: Examples of topic classification

In this paper, we incorporate position-invariance into RNN and propose a novel model named Disconnected Recurrent Neural Network (DRNN). Concretely, we disconnect the information transmission of RNN and limit the maximal transmission step length as a fixed value k, so that the representation at each step only depends on the previous $k-1$ words and the current word. In this way, DRNN can also alleviate the burden of modeling the entire document. To maintain the position-invariance, we utilize max pooling to extract the important information, which has been suggested by Scherer et al. (2010).

Our proposed model can also be regarded as a special 1D CNN where convolution kernels are replaced with recurrent units. Therefore, the maximal transmission step length can also be considered as the window size in CNN. Another difference to CNN is that DRNN can increase the window size k arbitrarily without increasing the number of parameters.

We also find that there is a trade-off between position-invariance and long-term dependencies in the DRNN. When the window size is too large, the position-invariance will disappear like RNN. By contrast, when the window size is too small, we will lose the ability to model long-term dependencies just like CNN. We find that the optimal window size is related to the type of task, but affected little by training dataset sizes. Thus, we can search the optimal window size by training on a small dataset.

We conduct experiments on seven large-scale text classification datasets introduced by Zhang et al. (2015). The experimental results show that our proposed model outperforms the other models on all of these datasets.

Our contributions can be concluded as follows:

1. We propose a novel model to incorporate position-variance into RNN. Our proposed model can both capture long-term dependencies and local information well.

2. We study the effect of different recurrent units, pooling operations and window sizes on model performance. Based on this, we propose an empirical method to find the optimal window size.

3. Our proposed model outperforms the other models and achieves the best performance on seven text classification datasets.

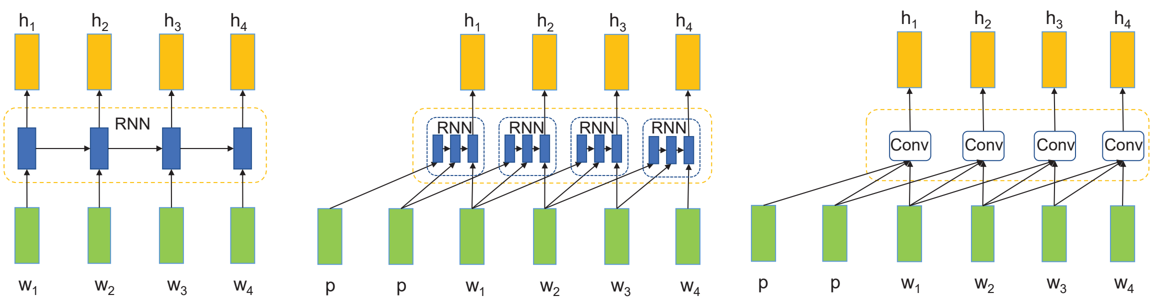
2 Related Work

Deep neural networks have shown great success in many NLP tasks such as machine translation (Bahdanau et al., 2015; Tu et al., 2016), reading comprehension (Hermann et al., 2015), sentiment classification (Tang et al., 2015), etc. Nowadays, nearly most of deep neural networks models are based on CNN or RNN. Below, we will introduce some important works about text classification based on them.

Convolutional Neural Networks CNN has been used in natural language processing because of the local correlation and position-invariance. Collobert et al. (2011) first utilize 1D CNN in part of speech (POS), named entity recognition (NER) and semantic role labeling (SRL). Kim (2014) proposes to classify sentence by encoding a sentence with multiple kinds of convolutional filters. To capture the relation between words, Kalchbrenner et al. (2014) propose a novel CNN model with a dynamic k-max pooling. Zhang et al. (2015) introduce an empirical exploration on the use of character-level CNN for text classification. Shallow CNN cannot encode long-term information well. Therefore, Conneau et al. (2017) propose to use very deep CNN in text classification and achieve good performance. Similarly, Johnson and Zhang (2017) propose a deep pyramid CNN which both achieves good performance and reduces training time.

Recurrent Neural Networks RNN is suitable for handling sequence input like natural language. Thus, many RNN variants are used in text classification. Tang et al. (2015) utilize LSTM to model the relation of sentences. Similarly, Yang et al. (2016) propose hierarchical attention model which incorporates attention mechanism into hierarchical GRU model so that the model can better capture the important information of a document. Wang and Tian (2016) incorporate the residual networks (He et al., 2016) into RNN, which makes the model handle longer sequence. Xu et al. (2016) propose a novel LSTM with a cache mechanism to capture long-range sentiment information.

Hybrid model Some researchers attempt to combine the advantages of CNN and RNN. (Xiao and Cho, 2016) extract local and global features by CNN and RNN separately. (Lai et al., 2015) firstly model sentences by RNN, and then use CNN to get the final representation. Shi et al. (2016) replace convolution filters with deep LSTM, which is similar to what is proposed in this paper. The main differences are as follows. Firstly, they regard their models as CNN and set a small window size of 3, while we propose to use a large window size. We argue that small window size makes the model lose the ability to capture long-term dependencies. Secondly, we utilize max pooling but not mean pooling, because max pooling can maintain position-invariance better (Scherer et al., 2010). Finally, our DRNN model is more general and can make use of different kinds of recurrent units. We find that using GRU as recurrent units outperforms LSTM which is utilized by Shi et al. (2016).



(a) RNN (b) DRNN (c) CNN

Figure 1: Three model architectures. In order to ensure the consistency of the hidden output, we pad $k-1$ zero vectors on the left of the input sequence for DRNN and CNN. Here window size k is 3.

3 Method

3.1 Recurrent Neural Network (RNN)

RNN is a class of neural network which models a sequence by incorporating the notion of time step (Lipton et al., 2015). Figure 1(a) shows the structure of RNN. Hidden states at each step depend on all the previous inputs, which sometimes can be a burden and neglect the key information (Yin et al., 2017).

A variant of RNN has been introduced by Cho et al. (2014) with the name of gated recurrent unit (GRU). GRU is a special type of RNN, capable of learning potential long-term dependencies by using gates. The gating units can control the flow of information and mitigate the vanishing gradients problem. GRU has two types of gates: reset gate $\mathbf{r}_t$ and update gate $\mathbf{z}_t$. The hidden state $\mathbf{h}_t$ of GRU is computed as

$$\mathbf{h}_t = (\mathbf{1} - \mathbf{z}_t) \odot \mathbf{h}_{t-1} + \mathbf{z}_t \odot \tilde{\mathbf{h}}_t \qquad (1)$$

where $\mathbf{h}_{t-1}$ is the previous state, $\tilde{\mathbf{h}}_t$ is the candidate state computed with new input information and $\odot$ is the element-wise multiplication. The update gate $\mathbf{z}_t$ decides how much new information is updated. $\mathbf{z}_t$ is computed as follows:

$$\mathbf{z}_t = \sigma(\mathbf{W}_z \mathbf{x}_t + \mathbf{U}_z \mathbf{h}_{t-1}) \qquad (2)$$

here $\mathbf{x}_t$ is the input vector at step t. The candidate state $\tilde{\mathbf{h}}_t$ is computed by

$$\tilde{\mathbf{h}}_t = tanh(\mathbf{W}\mathbf{x}_t + \mathbf{U}(\mathbf{r}_t \odot \mathbf{h}_{t-1})) \qquad (3)$$

where $\mathbf{r}_t$ is the reset gate which controls the flow of previous information. Similarly to the update gate, the reset gate $\mathbf{r}_t$ is computed as:

$$\mathbf{r}_t = \sigma(\mathbf{W}_r \mathbf{x}_t + \mathbf{U}_r \mathbf{h}_{t-1}) \qquad (4)$$

We can see that the representation of step t depends upon all the previous input vectors. Thus, we can also express the tth step state shown in Equation (5).

$$\mathbf{h}_t = GRU(\mathbf{x}_t, \mathbf{x}_{t-1}, \mathbf{x}_{t-2}, ..., \mathbf{x}_1) \qquad (5)$$

3.2 Disconntected Recurrent Neural Networks (DRNN)

To reduce the burden of modeling the entire sentence, we limit the distance of information flow in RNN. Like other RNN variants, we feed the input sequence into an RNN model and generate an output vector at each step. One important difference from RNN is that the state of our model at each step is only related to the previous $k-1$ words but not all the previous words. Here k is a hyperparameter called window size that we need to set.

Our proposed model DRNN is illustrated in Figure 1(b). Since the output at each step only depends on the previous $k-1$ words and current word, the output can also be regarded as a representation of a phrase with k words. Phrases with the same k words will always have the same representation no matter where they are. That is, we incorporate the position-invariance into RNN by disconnecting the information flow of RNN.

Similarly, we can get the state $\mathbf{h}_t$ as follows:

$$\mathbf{h}_t = RNN(\mathbf{x}_t, \mathbf{x}_{t-1}, \mathbf{x}_{t-2}, ..., \mathbf{x}_{t-k+1}) \qquad (6)$$

Here k is the window size, and RNN can be naive RNN, LSTM (Hochreiter and Schmidhuber, 1997), GRU or any other kinds of recurrent units.

3.3 Comparison with Convolutional Neural Network (CNN)

DRNN can be considered as a special 1D CNN which replace the convolution filters with recur-

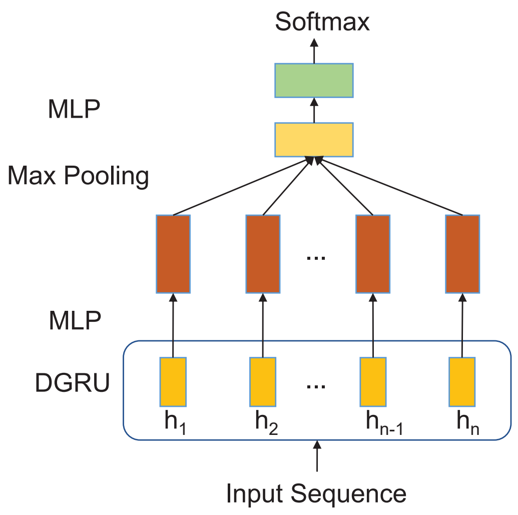


Figure 2: Model architecture

rent units. Let $\mathbf{x}_t$ denote the tth input word vector. Then for each position t we can get a window vector $\mathbf{c}_t$.

$$\mathbf{c}_t = [\mathbf{x}_t, \mathbf{x}_{t-1}, \mathbf{x}_{t-2}, ..., \mathbf{x}_{t-k+1}] \tag{7}$$

here, we concatenate k word vectors and generate vector $\mathbf{c}_t$. Then we can get the output of convolution as follows:

$$\mathbf{h}_t = \mathbf{W}\mathbf{c}_t + \mathbf{b} \tag{8}$$

where $\mathbf{W}$ is a set of convolution filters and $\mathbf{b}$ is a bias vector. Then a pooling operation can be applied after the convolutional layer and generate a fixed size vector (Kim, 2014). Similarly to RNN and DRNN, we can also represent the context vector of CNN as followings:

$$\mathbf{h}_t = Conv(\mathbf{x}_t, \mathbf{x}_{t-1}, \mathbf{x}_{t-2}, ..., \mathbf{x}_{t-k+1}) \tag{9}$$

Obviously, the parameters of convolution filters $\mathbf{W}$ increase as the window size k increases. By contrast, for DRNN the parameters do not increase with the increase of window size. Hence, DRNN can mitigate overfitting problem caused by the increase of parameters.

3.4 DRNN for Text Classification

DRNN is a general model framework, which can be used for a variety of tasks. In this paper, we only discuss how to apply DRNN in text categorization.

We utilize GRU as recurrent units of DRNN and get the context representation of each step. Every

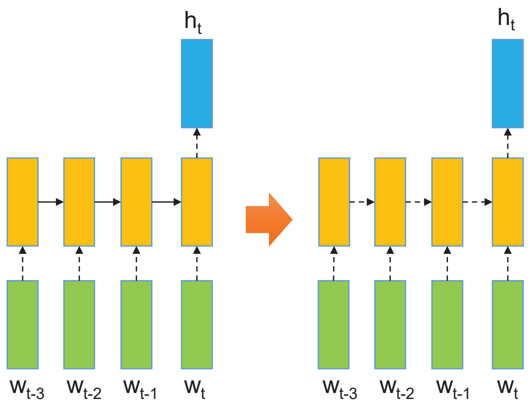

Figure 3: Dropout in DRNN. The dashed arrows indicate connections where dropout is applied. The left model only applies dropout in input and output layers, but the right model applies dropout in hidden states.

context vector can be considered as a representation of a text fragment. Then we feed the context vectors into a multi-layer perceptron (MLP) to extract high-level features as illustrated in Figure 2. Before feeding the vectors into MLP, we utilize Batch Normalization (Ioffe and Szegedy, 2015) after DRNN, so that the model can alleviate the internal covariate shift problem. To get the text representation vector, we apply max pooing after MLP layer to extract the most important information and position-invariant features (Scherer et al., 2010).

Finally, We feed the text representation vector into an MLP with rectified linear unit (ReLU) activation and send the output of MLP to a softmax function to predict the probability of each category. We use cross entropy loss function as follows:

$$H(y, \hat{y}) = \sum_i y_i \log \hat{y}_i \tag{10}$$

where $\hat{y}_i$ is the predicted probability and y_i is the true probability of class i.

To alleviate the overfitting problem, we apply dropout regularization (Srivastava et al., 2014) in DRNN model. Dropout is usually applied in the input and output layers but not the hidden states of RNN, because the number of previous states is variable (Zaremba et al., 2014). In contrast, our DRNN model has a fixed window size for output at each step, so we also apply dropout in the hidden states. In this paper, we apply dropout in the input layer, output layer, and hidden states. The Figure 3 shows the difference to apply dropout between

RNN and DRNN.

4 Experiments

4.1 Experimental Settings

Datasets Introduction We use 7 large-scale text classification datasets which are proposed by Zhang et al. (2015). We summarize the datasets in Table 2. AG corpus is news and DBPedia is an ontology which comes from the Wikipedia. Yelp and Amazon corpus are reviews for which we should predict the sentiment. Here *P.* means that we only need to predict the polarities of the dataset, while *F.* indicates that we need predict the star number of the review. *Yahoo! Answers* (Yah. A.) is a question answering dataset. We can see that these datasets contain various domains and sizes, which would be credible to validate our models.

Implementation Details We tokenize all the corpus with NLTK's tokenizer (Bird and Loper, 2004). We limit the vocabulary size of each dataset as shown in Table 3. The words not in vocabulary are replaced with a special token *UNK*. Table 3 also shows the window sizes that we set for these datasets.

We utilize the 300D GloVe 840B vectors (Pennington et al., 2014) as our pre-trained word embeddings. For words that do not appear in GloVe, we average the vector representations of 8 words around the word in training dataset as its word vector, which has been applied by Wang and Jiang (2016). When training our model, word embeddings are updated along with other parameters.

We use Adadelta (Zeiler, 2012) to optimize all the trainable parameters. The hyperparameter of Adadelta is set as Zeiler (2012) suggest that ϵ is $1e-6$ and ρ is 0.95. To avoid the gradient explosion problem, we apply gradient norm clipping (Pascanu et al., 2013). The batch size is set to 128 and all the dimensions of input vectors and hidden states are set to 300.

Corpus	Window size	Vocabulary size
AG	15	100k
DBP.	15	500k
Yelp P.	20	200k
Yelp F.	20	200k
Yah. A.	20	500k
Amz. F.	15	500k
Amz. P.	15	500k

Table 3: Experimental settings

4.2 Experimental Results

Table 4 shows that our proposed model significantly outperforms all the other models in 7 datasets. DRNN does not have too many hyperparameters. The main hyperparameter is the window size which can be determined by an empirical method.

The top block shows the traditional methods and some other neural networks which are not based on RNN or CNN. The linear model (Zhang et al., 2015) achieves a strong baseline in small datasets, but performs not well in large data. FastText (Joulin et al., 2017) and region embedding methods (Qiao et al., 2018) achieve comparable performance with other CNN and RNN based models.

The RNN based models are listed in the second block and CNN based models are in the third block. The D-LSTM (Yogatama et al., 2017) is a discriminative LSTM model. Hierarchical attention network (HAN) (Yang et al., 2016) is a hierarchical GRU model with attentive pooling. We can see that very deep CNN (VDCNN) (Conneau et al., 2017) performs well in large datasets. However, VDCNN is a CNN model with 29 convolutional layers, which needs to be tuned more carefully. By contrast, our proposed model can achieve

better performance in these datasets by simply setting a large window size.

Char-CRNN (Xiao and Cho, 2016) in the fourth block is a model which combines position-invariance of CNN and long-term dependencies of RNN. Nevertheless, they do not achieve great improvements over other models. They first utilize convolution operation to extract position-invariant features, and then use RNN to capture long-term dependencies. Here, modeling the whole sequence with RNN leads to a loss of position-invariance. Compared with their model, our model can better maintain the position-invariance by max pooling (Scherer et al., 2010). Table 4 shows that our model achieves 10-50% relative error reduction compared with char-CRNN in these datasets.

4.3 Comparison with RNN and CNN

In this section, we compare DRNN with CNN, GRU and LSTM (Hochreiter and Schmidhuber, 1997). To make these models comparable, we implement these models with the same architecture shown in Figure 2. We just replace the DRNN with CNN or RNN.

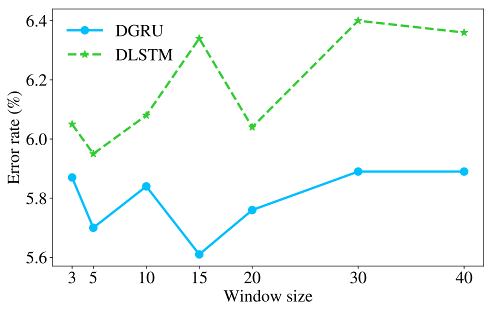
we firstly compare DRNN with CNN on AG dataset. Figure 4 shows that DRNN performs far better than CNN. In addition, the optimal window size of CNN is 3, while for DRNN the optimal window size is 15. It indicates that DRNN can model longer sequence as window size increases. By contrast, simply increasing the window size of CNN only results in overfitting. That is also why Conneau et al. (2017) design complex CNN models to learn long-term dependencies other than simply increase the window size of convolution filters.

In addition, we also compare our model with GRU and LSTM. The experimental results are shown in Table 5. Our model DRNN achieves much better performance than GRU and LSTM.

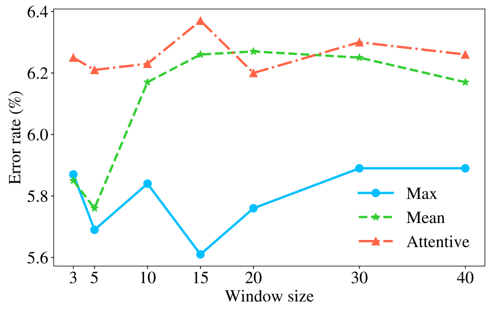
Qualitative Analysis To investigate why DGRU performs better than CNN and GRU, we do some error analysis on Yelp P. dataset. Table 6 shows two examples which have been both

case1: ***I love*** *Hampton Inn* ***but*** *this location is in serious need of remodeling and some deep cleaning. Musty smell everywhere.*
case2: ***Pretty good service***, ***but*** *really busy and noisy!! It gets a little overwhelming because the sales people are very knowledgeable and bombard you with useless techy information to I guess impress you?? Anyways I bought the Ipad 3 and it is* ***freaking awesome*** *and makes up for the store. I would give the Ipad 3 a gazillion stars if I could. I left it at home today and got really sad when I was driving away. Boo Hoo!!*

Table 6: Examples of error analysis. The case 1 is a negative review and case 2 is a positive review. The first example is misclassified by CNN and classified correctly by GRU. The second one is just the contrary. DGRU classify both examples correctly.



(a) Comparison of recurrent units



(b) Comparison of pooling methods

Figure 5: Component comparison

classified correctly by DRNN. The first example is misclassified by CNN and classified correctly by GRU. It is just contrary to the second example. Considering the first example, CNN may extract some key phrases such as *I love* and misclassifies the example as $Positive$, while GRU can model long sequence and capture the information after *but*. For the second example, however, GRU still captures the information after *but* and neglects the key phrases such as *pretty good service* and *freaking awesome*, which leads to the wrong classification.

DGRU can both extract the local key features such as *pretty good service* and capture long-term information such as the sentence after *but*, which makes it perform better than GRU and CNN.

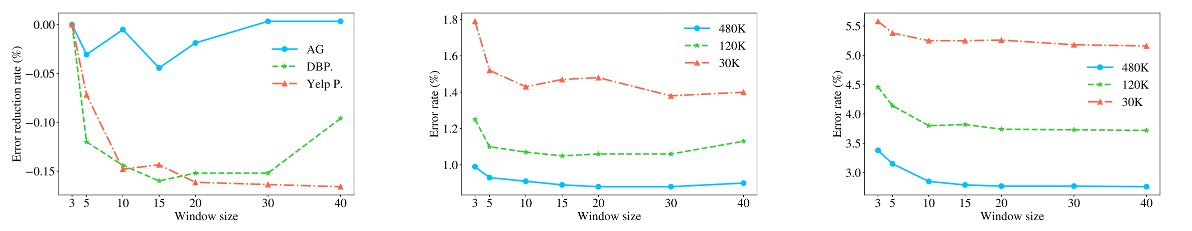
4.4 Component Analysis

Recurrent Unit In this part, we study the impact of different recurrent units on the effectiveness of DRNN. We choose three types of recurrent units: naive RNN, LSTM and GRU which have been compared by Chung et al. (2014). We carry out the experiments with different window sizes to eliminate the impact of window sizes. All the experiments in this part are conducted on the AG dataset.

We find that the disconnected naive RNN performs just a little worse than disconnected LSTM (DLSTM) and disconnected GRU (DGRU) when the window size is lower than 5. However, when the window size is more than 10, its performance decreases rapidly and the error rate becomes even more than 20%. We believe that it is due to vanishing gradient problem of naive RNN.

From Figure 5(a), we can see that window sizes affect the performance of DGRU and DLSTM. DGRU achieves the best performance when the window size is 15, while the best window size for DLSTM is 5. The performance of DGRU is always better than DLSTM no matter what the window size is. We also find that the DGRU model converges faster than DLSTM in the process of training. Therefore, we apply GRU as recurrent units of DRNN in this paper for all the other experiments.

Pooling Method Pooling is a kind of method to subsample the values to capture more important information. In NLP, pooling can also convert a variable-length tensor or vector into a fixed-length



(a) Different tasks (b) Different training sets of DBP. (c) Different training sets of Yelp P.

Figure 6: Window size analysis. For better comparing the trends of different tasks, (a) shows the error reduction rates with different window sizes. (b) and (c) show the error rates of DBP. and Yelp P. with different training set numbers.

one, so that it can be dealt with more easily. There're several kinds of pooling methods such as max pooling, mean pooling and attentive pooling (dos Santos et al., 2016).

We still conduct the experiments on AG dataset. Figure 5(b) shows the experimental results of three pooling methods along with different window sizes. From Figure 5(b), we can see that the DRNN model with max pooling performs better than the others. This may be because that max pooling can capture position-invariant features better (Scherer et al., 2010). We find attentive pooling is not significantly affected by window sizes. However, the performance of mean pooling becomes worse as the window becomes larger.

4.5 Window size analysis

In this section, we mainly study what factors affect the optimal window size. In addition to the recurrent units and pooling methods discussed above, we believe the optimal window size may be also related to the amount of training data and the type of task.

In order to study the factors that affect the optimal window size, we conduct experiments on three datasets: AG, DBP and Yelp Polarity. To eliminate the influence of differrnt training data sizes, we conduct experiments with the same training data size. From Figure 6(a) we can see that the type of task has a great impact on the optimal window size. For AG and DBPedia, the optimal window size is 15. However, for Yelp P. the optimal window size is 40 or even larger. The result is intuitive, because sentiment analysis such as Yelp often involves long-term dependencies (Tang et al., 2015), while topic classification such as AG and DBPedia relys more on the key phrases.

From Figure 6(b) and Figure 6(c) we can see the effect of different training data sizes on the optimal window size. Surprisingly, the effect of different training data sizes on the optimal window size seems little. We can see that for both DBPedia and Yelp corpus, the trend of error rate with the window size is similar. This shows that the number of training data has little effect on the choice of the optimal window size. It also provides a good empirical way for us to choose the optimal window size. That is, conducting experiments on a small dataset first to select the optimal window size.

5 Conclusion

In this paper, we incorporate position-invariance into RNN, so that our proposed model DRNN can both capture key phrases and long-term dependencies. We conduct experiments to compare the effects of different recurrent units and pooling operations. In addition, We also analyze what factors affect the optimal window size of DRNN and present an empirical method to search it. The experimental results show that our proposed model outperforms CNN and RNN models, and achieve the best performance in seven large-scale text classification datasets.

Abstract

Word embeddings are effective intermediate representations for capturing semantic regularities between words, when learning the representations of text sequences. We propose to view text classification as a label-word joint embedding problem: each label is embedded in the same space with the word vectors. We introduce an attention framework that measures the compatibility of embeddings between text sequences and labels. The attention is learned on a training set of labeled samples to ensure that, given a text sequence, the relevant words are weighted higher than the irrelevant ones. Our method maintains the interpretability of word embeddings, and enjoys a built-in ability to leverage alternative sources of information, in addition to input text sequences. Extensive results on the several large text datasets show that the proposed framework outperforms the state-of-the-art methods by a large margin, in terms of both accuracy and speed.

1 Introduction

Text classification is a fundamental problem in natural language processing (NLP). The task is to annotate a given text sequence with one (or multiple) class label(s) describing its textual content. A key intermediate step is the text representation. Traditional methods represent text with hand-crafted features, such as sparse lexical features (*e.g.,* n-grams) (Wang and Manning, 2012). Recently, neural models have been employed to learn text representations, including convolutional neural networks (CNNs) (Kalchbrenner et al., 2014; Zhang et al., 2017b; Shen et al., 2017) and recurrent neural networks (RNNs) based on long short-term memory (LSTM) (Hochreiter and Schmidhuber, 1997; Wang et al., 2018).

To further increase the representation flexibility of such models, attention mechanisms (Bahdanau et al., 2015) have been introduced as an integral part of models employed for text classification (Yang et al., 2016). The attention module is trained to capture the dependencies that make significant contributions to the task, regardless of the distance between the elements in the sequence. It can thus provide complementary information to the distance-aware dependencies modeled by RNN/CNN. The increasing representation power of the attention mechanism comes with increased model complexity.

Alternatively, several recent studies show that the success of deep learning on text classification largely depends on the effectiveness of the word embeddings (Joulin et al., 2016; Wieting et al., 2016; Arora et al., 2017; Shen et al., 2018a). Particularly, Shen et al. (2018a) quantitatively show that the word-embeddings-based text classification tasks can have the similar level of difficulty regardless of the employed models, using the concept of intrinsic dimension (Li et al., 2018). Thus, simple models are preferred. As the basic building blocks in neural-based NLP, word embeddings capture the similarities/regularities between words (Mikolov et al., 2013; Pennington et al., 2014). This idea has been extended to compute embeddings that capture the semantics of word sequences (*e.g.,* phrases, sentences, paragraphs and documents) (Le and Mikolov, 2014; Kiros et al., 2015). These representations are built upon various types of compositions of word vectors, ranging from simple averaging to sophisticated architectures. Further, they suggest that simple models are efficient and interpretable, and have the poten-

tial to outperform sophisticated deep neural models.

It is therefore desirable to leverage the best of both lines of works: learning text representations to capture the dependencies that make significant contributions to the task, while maintaining low computational cost. For the task of text classification, labels play a central role of the final performance. A natural question to ask is how we can directly use label information in constructing the text-sequence representations.

1.1 Our Contribution

Our primary contribution is therefore to propose such a solution by making use of the label embedding framework, and propose the *Label-Embedding Attentive Model* (LEAM) to improve text classification. While there is an abundant literature in the NLP community on word embeddings (how to describe a word) for text representations, much less work has been devoted in comparison to label embeddings (how to describe a class). The proposed LEAM is implemented by jointly embedding the word and label in the same latent space, and the text representations are constructed directly using the text-label compatibility.

Our label embedding framework has the following salutary properties: (*i*) Label-attentive text representation is informative for the downstream classification task, as it directly learns from a shared joint space, whereas traditional methods proceed in multiple steps by solving intermediate problems. (*ii*) The LEAM learning procedure only involves a series of basic algebraic operations, and hence it retains the interpretability of simple models, especially when the label description is available. (*iii*) Our attention mechanism (derived from the text-label compatibility) has fewer parameters and less computation than related methods, and thus is much cheaper in both training and testing, compared with sophisticated deep attention models. (*iv*) We perform extensive experiments on several text-classification tasks, demonstrating the effectiveness of our label-embedding attentive model, providing state-of-the-art results on benchmark datasets. (*v*) We further apply LEAM to predict the medical codes from clinical text. As an interesting by-product, our attentive model can highlight the informative key words for prediction, which in practice can reduce a doctor's burden on reading clinical notes.

2 Related Work

Label embedding has been shown to be effective in various domains and tasks. In computer vision, there has been a vast amount of research on leveraging label embeddings for image classification (Akata et al., 2016), multimodal learning between images and text (Frome et al., 2013; Kiros et al., 2014), and text recognition in images (Rodriguez-Serrano et al., 2013). It is particularly successful on the task of zero-shot learning (Palatucci et al., 2009; Yogatama et al., 2015; Ma et al., 2016), where the label correlation captured in the embedding space can improve the prediction when some classes are unseen. In NLP, labels embedding for text classification has been studied in the context of heterogeneous networks in (Tang et al., 2015) and multitask learning in (Zhang et al., 2017a), respectively. To the authors' knowledge, there is little research on investigating the effectiveness of label embeddings to design efficient attention models, and how to joint embedding of words and labels to make full use of label information for text classification has not been studied previously, representing a contribution of this paper.

For text representation, the currently best-performing models usually consist of an encoder and a decoder connected through an attention mechanism (Vaswani et al., 2017; Bahdanau et al., 2015), with successful applications to sentiment classification (Zhou et al., 2016), sentence pair modeling (Yin et al., 2016) and sentence summarization (Rush et al., 2015). Based on this success, more advanced attention models have been developed, including hierarchical attention networks (Yang et al., 2016), attention over attention (Cui et al., 2016), and multi-step attention (Gehring et al., 2017). The idea of attention is motivated by the observation that different words in the same context are differentially informative, and the same word may be differentially important in a different context. The realization of "context" varies in different applications and model architectures. Typically, the context is chosen as the target task, and the attention is computed over the hidden layers of a CNN/RNN. Our attention model is directly built in the joint embedding space of words and labels, and the context is specified by the label embedding.

Several recent works (Vaswani et al., 2017; Shen et al., 2018b,c) have demonstrated that simple attention architectures can alone achieve state-of-the-art performance with less computational time, dispensing with recurrence and convolutions entirely. Our work is in the same direction, sharing the similar spirit of retaining model simplicity and interpretability. The major difference is that the aforementioned work focused on self attention, which applies attention to each pair of word tokens from the text sequences. In this paper, we investigate the attention between words and labels, which is more directly related to the target task. Furthermore, the proposed LEAM has much less model parameters.

3 Preliminaries

Throughout this paper, we denote vectors as bold, lower-case letters, and matrices as bold, upper-case letters. We use $\oslash$ for element-wise division when applied to vectors or matrices. We use $\circ$ for function composition, and Δ^p for the set of one hot vectors in dimension p.

Given a training set $\mathcal{S} = \{(\mathbf{X}_n, \boldsymbol{y}_n)\}_{n=1}^N$ of pair-wise data, where $\mathbf{X} \in \mathcal{X}$ is the text sequence, and $\boldsymbol{y} \in \mathcal{Y}$ is its corresponding label. Specifically, $\boldsymbol{y}$ is a one hot vector in single-label problem and a binary vector in multi-label problem, as defined later in Section 4.1. Our goal for text classification is to learn a function $f : \mathcal{X} \mapsto \mathcal{Y}$ by minimizing an empirical risk of the form:

$$\min_{f \in \mathcal{F}} \frac{1}{N} \sum_{n=1}^{N} \delta(\boldsymbol{y}_n, f(\mathbf{X}_n)) \tag{1}$$

where $\delta : \mathcal{Y} \times \mathcal{Y} \mapsto \mathbb{R}$ measures the loss incurred from predicting $f(\mathbf{X})$ when the true label is $\boldsymbol{y}$, where f belongs to the functional space $\mathcal{F}$. In the evaluation stage, we shall use the $0/1$ loss as a target loss: $\delta(\boldsymbol{y}, \boldsymbol{z}) = 0$ if $\boldsymbol{y} = \boldsymbol{z}$, and 1 otherwise. In the training stage, we consider surrogate losses commonly used for structured prediction in different problem setups (see Section 4.1 for details on the surrogate losses used in this paper).

More specifically, an input sequence $\mathbf{X}$ of length L is composed of word tokens: $\mathbf{X} = \{\boldsymbol{x}_1, \cdots, \boldsymbol{x}_L\}$. Each token $\boldsymbol{x}_l$ is a one hot vector in the space Δ^D, where D is the dictionary size. Performing learning in Δ^D is computationally expensive and difficult. An elegant framework in NLP, initially proposed in (Mikolov et al., 2013; Le and Mikolov, 2014; Pennington et al., 2014; Kiros et al., 2015), allows to concisely perform learning by mapping the words into an embedding space. The framework relies on so called *word embedding*: $\Delta^D \mapsto \mathbb{R}^P$, where P is the dimensionality of the embedding space. Therefore, the text sequence $\mathbf{X}$ is represented via the respective word embedding for each token: $\mathbf{V} = \{\boldsymbol{v}_1, \cdots, \boldsymbol{v}_L\}$, where $\boldsymbol{v}_l \in \mathbb{R}^P$. A typical text classification method proceeds in three steps, end-to-end, by considering a function decomposition $f = f_0 \circ f_1 \circ f_2$ as shown in Figure 1(a):

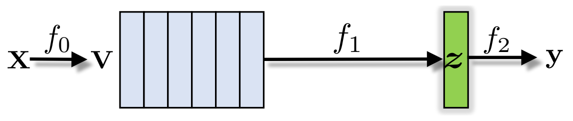
- $f_0 : \mathbf{X} \mapsto \mathbf{V}$, the text sequence is represented as its word-embedding form $\mathbf{V}$, which is a matrix of $P \times L$.
- $f_1 : \mathbf{V} \mapsto \boldsymbol{z}$, a compositional function f_1 aggregates word embeddings into a fixed-length vector representation $\boldsymbol{z}$.
- $f_2 : \boldsymbol{z} \mapsto \boldsymbol{y}$, a classifier f_2 annotates the text representation $\boldsymbol{z}$ with a label.

A vast amount of work has been devoted to devising the proper functions f_0 and f_1, *i.e.,* how to represent a word or a word sequence, respectively. The success of NLP largely depends on the effectiveness of word embeddings in f_0 (Bengio et al., 2003; Collobert and Weston, 2008; Mikolov et al., 2013; Pennington et al., 2014). They are often pre-trained offline on large corpus, then refined jointly via f_1 and f_2 for task-specific representations. Furthermore, the design of f_1 can be broadly cast into two categories. The popular deep learning models consider the mapping as a "black box," and have employed sophisticated CNN/RNN architectures to achieve state-of-the-art performance (Zhang et al., 2015; Yang et al., 2016). On the contrary, recent studies show that simple manipulation of the word embeddings, *e.g.,* mean or max-pooling, can also provide surprisingly excellent performance (Joulin et al., 2016; Wieting et al., 2016; Arora et al., 2017; Shen et al., 2018a). Nevertheless, these methods only leverage the information from the input text sequence.

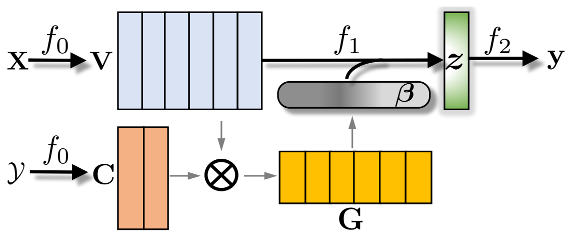
4 Label-Embedding Attentive Model

4.1 Model

By examining the three steps in the traditional pipeline of text classification, we note that the use of label information only occurs in the last step, when learning f_2, and its impact on learning the representations of words in f_0 or word sequences in f_1 is ignored or indirect. Hence, we propose a new pipeline by incorporating label information in every step, as shown in Figure 1(b):



(a) Traditional method



(b) Proposed joint embedding method

Figure 1: Illustration of different schemes for document representations $\boldsymbol{z}$. (a) Much work in NLP has been devoted to directly aggregating word embedding $\mathbf{V}$ for $\boldsymbol{z}$. (b) We focus on learning label embedding $\mathbf{C}$ (how to embed class labels in a Euclidean space), and leveraging the "compatibility" $\mathbf{G}$ between embedded words and labels to derive the attention score $\boldsymbol{\beta}$ for improved $\boldsymbol{z}$. Note that $\otimes$ denotes the cosine similarity between $\mathbf{C}$ and $\mathbf{V}$. In this figure, there are K=2 classes.

- f_0: Besides embedding words, we also embed all the labels in the same space, which act as the "anchor points" of the classes to influence the refinement of word embeddings.
- f_1: The compositional function aggregates word embeddings into $\boldsymbol{z}$, weighted by the compatibility between labels and words.
- f_2: The learning of f_2 remains the same, as it directly interacts with labels.

Under the proposed label embedding framework, we specifically describe a label-embedding attentive model.

Joint Embeddings of Words and Labels We propose to embed both the words and the labels into a joint space *i.e.,* $\Delta^D \mapsto \mathbb{R}^P$ and $\mathcal{Y} \mapsto \mathbb{R}^P$. The label embeddings are $\mathbf{C} = [\boldsymbol{c}_1, \cdots, \boldsymbol{c}_K]$, where K is the number of classes.

A simple way to measure the compatibility of label-word pairs is via the cosine similarity

$$\mathbf{G} = (\mathbf{C}^\top \mathbf{V}) \oslash \hat{\mathbf{G}}, \tag{2}$$

where $\hat{\mathbf{G}}$ is the normalization matrix of size $K \times L$, with each element obtained as the multiplication of ℓ_2 norms of the c-th label embedding and l-th word embedding: $\hat{g}_{kl} = \|\boldsymbol{c}_k\|\|\boldsymbol{v}_l\|$.

To further capture the relative spatial information among consecutive words (*i.e.,* phrases[1]) and introduce non-linearity in the compatibility measure, we consider a generalization of (2). Specifically, for a text phase of length $2r+1$ centered at l, the local matrix block $\mathbf{G}_{l-r:l+r}$ in $\mathbf{G}$ measures the label-to-token compatibility for the "label-phrase" pairs. To learn a higher-level compatibility stigmatization $\boldsymbol{u}_l$ between the l-th phrase and all labels, we have:

$$\boldsymbol{u}_l = \text{ReLU}(\mathbf{G}_{l-r:l+r}\mathbf{W}_1 + \boldsymbol{b}_1), \tag{3}$$

where $\mathbf{W}_1 \in \mathbb{R}^{2r+1}$ and $\boldsymbol{b}_1 \in \mathbb{R}^K$ are parameters to be learned, and $\boldsymbol{u}_l \in \mathbb{R}^K$. The largest compatibility value of the l-th phrase *wrt* the labels is collected:

$$m_l = \text{max-pooling}(\boldsymbol{u}_l). \tag{4}$$

Together, $\boldsymbol{m}$ is a vector of length L. The compatibility/attention score for the entire text sequence is:

$$\boldsymbol{\beta} = \text{SoftMax}(\boldsymbol{m}), \tag{5}$$

where the l-th element of SoftMax is $\beta_l = \frac{\exp(m_l)}{\sum_{l'=1}^{L}\exp(m_{l'})}$.

The text sequence representation can be simply obtained via averaging the word embeddings, weighted by label-based attention score:

$$\boldsymbol{z} = \sum_l \beta_l \boldsymbol{v}_l. \tag{6}$$

Relation to Predictive Text Embeddings Predictive Text Embeddings (PTE) (Tang et al., 2015) is the first method to leverage label embeddings to improve the learned word embeddings. We discuss three major differences between PTE and our LEAM: (*i*) The general settings are different. PTE casts the text representation through heterogeneous networks, while we consider text representation through an attention model. (*ii*) In PTE, the text representation $\boldsymbol{z}$ is the averaging of word embeddings. In LEAM, $\boldsymbol{z}$ is weighted averaging of word embeddings through the proposed label-attentive score in (6). (*iii*) PTE only considers the linear interaction between individual words and labels. LEAM greatly improves the performance by considering nonlinear interaction between phrase

[1]We call it "phrase" for convenience; it could be any longer word sequence such as a sentence and paragraph *etc.* when a larger window size r is considered.

and labels. Specifically, we note that the text embedding in PTE is similar with a very special case of LEAM, when our window size $r = 1$ and attention score $\boldsymbol{\beta}$ is uniform. As shown later in Figure 2(c) of the experimental results, LEAM can be significantly better than the PTE variant.

Training Objective The proposed joint embedding framework is applicable to various text classification tasks. We consider two setups in this paper. For a learned text sequence representation $\boldsymbol{z} = f_1 \circ f_0(\mathbf{X})$, we jointly optimize $f = f_0 \circ f_1 \circ f_2$ over $\mathcal{F}$, where f_2 is defined according to the specific tasks:

- *Single-label problem*: categorizes each text instance to precisely one of K classes, $\boldsymbol{y} \in \Delta^K$

$$\min_{f \in \mathcal{F}} \frac{1}{N} \sum_{n=1}^{N} \text{CE}(\boldsymbol{y}_n, f_2(\boldsymbol{z}_n)), \quad (7)$$

  where $\text{CE}(\cdot, \cdot)$ is the cross entropy between two probability vectors, and $f_2(\boldsymbol{z}_n) = \text{SoftMax}\,(\boldsymbol{z}'_n)$, with $\boldsymbol{z}'_n = \mathbf{W}_2 \boldsymbol{z}_n + \boldsymbol{b}_2$ and $\mathbf{W}_2 \in \mathbb{R}^{K \times P}, \boldsymbol{b}_2 \in \mathbb{R}^K$ are trainable parameters.

- *Multi-label problem*: categorizes each text instance to a set of K target labels $\{\boldsymbol{y}_k \in \Delta^2 | k = 1, \cdots, K\}$; there is no constraint on how many of the classes the instance can be assigned to, and

$$\min_{f \in \mathcal{F}} \frac{1}{NK} \sum_{n=1}^{N} \sum_{k=1}^{K} \text{CE}(\boldsymbol{y}_{nk}, f_2(\boldsymbol{z}_{nk}), \quad (8)$$

  where $f_2(\boldsymbol{z}_{nk}) = \frac{1}{1+\exp(\boldsymbol{z}'_{nk})}$, and $\boldsymbol{z}'_{nk}$ is the kth column of $\boldsymbol{z}'_n$.

To summarize, the model parameters $\boldsymbol{\theta} = \{\mathbf{V}, \mathbf{C}, \mathbf{W}_1, \boldsymbol{b}_1, \mathbf{W}_2, \boldsymbol{b}_2\}$. They are trained end-to-end during learning. $\{\mathbf{W}_1, \boldsymbol{b}_1\}$ and $\{\mathbf{W}_2, \boldsymbol{b}_2\}$ are weights in f_1 and f_2, respectively, which are treated as standard neural networks. For the joint embeddings $\{\mathbf{V}, \mathbf{C}\}$ in f_0, the pre-trained word embeddings are used as initialization if available.

4.2 Learning & Testing with LEAM

Learning and Regularization The quality of the jointly learned embeddings are key to the model performance and interpretability. Ideally, we hope that each label embedding acts as the "anchor" points for each classes: closer to the word/sequence representations that are in the same classes, while farther from those in different classes. To best achieve this property, we consider to regularize the learned label embeddings $\boldsymbol{c}_k$ to be on its corresponding manifold. This is imposed by the fact $\boldsymbol{c}_k$ should be easily classified as the correct label $\boldsymbol{y}_k$:

$$\min_{f \in \mathcal{F}} \frac{1}{K} \sum_{n=1}^{K} \text{CE}(\boldsymbol{y}_k, f_2(\boldsymbol{c}_k)), \quad (9)$$

where f_2 is specficied according to the problem in either (7) or (8). This regularization is used as a penalty in the main training objective in (7) or (8), and the default weighting hyperparameter is set as 1. It will lead to meaningful interpretability of learned label embeddings as shown in the experiments.

Interestingly in text classification, the class itself is often described as a set of E words $\{\boldsymbol{e}_i, i = 1, \cdots, E\}$. These words are considered as the most representative description of each class, and highly distinguishing between different classes. For example, the `Yahoo! Answers Topic` dataset (Zhang et al., 2015) contains ten classes, most of which have two words to precisely describe its class-specific features, such as "Computers & Internet", "Business & Finance" as well as "Politics & Government" *etc.* We consider to use each label's corresponding pre-trained word embeddings as the initialization of the label embeddings. For the datasets without representative class descriptions, one may initialize the label embeddings as random samples drawn from a standard Gaussian distribution.

Testing Both the learned word and label embeddings are available in the testing stage. We clarify that the label embeddings $\mathbf{C}$ of all class candidates $\mathcal{Y}$ are considered as the input in the testing stage; one should distinguish this from the use of groundtruth label $\boldsymbol{y}$ in prediction. For a text sequence $\mathbf{X}$, one may feed it through the proposed pipeline for prediction: (*i*) f_1: harvesting the word embeddings $\mathbf{V}$, (*ii*) f_2: $\mathbf{V}$ interacts with $\mathbf{C}$ to obtain $\mathbf{G}$, pooled as $\boldsymbol{\beta}$, which further attends $\mathbf{V}$ to derive $\boldsymbol{z}$, and (*iii*) f_3: assigning labels based on the tasks. To speed up testing, one may store $\mathbf{G}$ offline, and avoid its online computational cost.

Model	Parameters	Complexity	Seq. Operation
CNN	$m \cdot h \cdot P$	$O(m \cdot h \cdot L \cdot P)$	$O(1)$
LSTM	$4 \cdot h \cdot (h + P)$	$O(L \cdot h^2 + h \cdot L \cdot P)$	$O(L)$
SWEM	0	$O(L \cdot P)$	$O(1)$
Bi-BloSAN	$7 \cdot P^2 + 5 \cdot P$	$O(P^2 \cdot L^2/R + P^2 \cdot L + P^2 \cdot R^2)$	$O(1)$
Our model	$K \cdot P$	$O(K \cdot L \cdot P)$	$O(1)$

Table 1: Comparisons of CNN, LSTM, SWEM and our model architecture. Columns correspond to the number of compositional parameters, computational complexity and sequential operations

4.3 Model Complexity

We compare CNN, LSTM, Simple Word Embeddings-based Models (SWEM) (Shen et al., 2018a) and our LEAM *wrt* the parameters and computational speed. For the CNN, we assume the same size m for all filters. Specifically, h represents the dimension of the hidden units in the LSTM or the number of filters in the CNN; R denotes the number of blocks in the Bi-BloSAN; P denotes the final sequence representation dimension. Similar to (Vaswani et al., 2017; Shen et al., 2018a), we examine the number of compositional parameters, computational complexity and sequential steps of the four methods. As shown in Table 1, both the CNN and LSTM have a large number of compositional parameters. Since $K \ll m, h$, the number of parameters in our models is much smaller than for the CNN and LSTM models. For the computational complexity, our model is almost same order as the most simple SWEM model, and is smaller than the CNN or LSTM by a factor of mh/K or h/K.

5 Experimental Results

Setup We use 300-dimensional GloVe word embeddings Pennington et al. (2014) as initialization for word embeddings and label embeddings in our model. Out-Of-Vocabulary (OOV) words are initialized from a uniform distribution with range $[-0.01, 0.01]$. The final classifier is implemented as an MLP layer followed by a sigmoid or softmax function depending on specific task. We train our model's parameters with the Adam Optimizer (Kingma and Ba, 2014), with an initial learning rate of 0.001, and a minibatch size of 100. Dropout regularization (Srivastava et al., 2014) is employed on the final MLP layer, with dropout rate 0.5. The model is implemented using Tensorflow and is trained on GPU Titan X.

The code to reproduce the experimental results is at `https://github.com/guoyinwang/LEAM`

Dataset	**# Classes**	**# Training**	**# Testing**
AGNews	4	120k	7.6k
Yelp Binary	2	560 k	38k

DBPedia	14	560k	70k
Yahoo	10	1400k	60k

Table 2: Summary statistics of five datasets, including the number of classes, number of training samples and number of testing samples.

5.1 Classification on Benchmark Datasets

We test our model on the same five standard benchmark datasets as in (Zhang et al., 2015). The summary statistics of the data are shown in Table 2, with content specified below:

- `AGNews`: Topic classification over four categories of Internet news articles (Del Corso et al., 2005) composed of titles plus description classified into: World, Entertainment, Sports and Business.

- `Yelp Review Full`: The dataset is obtained from the Yelp Dataset Challenge in 2015, the task is sentiment classification of polarity star labels ranging from 1 to 5.

- `Yelp Review Polarity`: The same set of text reviews from Yelp Dataset Challenge in 2015, except that a coarser sentiment definition is considered: 1 and 2 are negative, and 4 and 5 as positive.

- `DBPedia`: Ontology classification over fourteen non-overlapping classes picked from DBpedia 2014 (Wikipedia).

- `Yahoo! Answers Topic`: Topic classification over ten largest main categories from Yahoo! Answers Comprehensive Questions and Answers version 1.0, including question title, question content and best answer.

We compare with a variety of methods, including (i) the bag-of-words in (Zhang et al., 2015); (ii) sophisticated deep CNN/RNN models: large/small word CNN, LSTM reported in (Zhang et al., 2015; Dai and Le, 2015) and deep CNN (29 layer) (Conneau et al., 2017); (iii) simple compositional methods: fastText (Joulin et al., 2016) and simple word embedding models (SWEM) (Shen et al., 2018a); (iv) deep attention models: hierarchical attention network (HAN) (Yang et al.,

Model	Yahoo	DBPedia	AGNews	Yelp P.	Yelp F.
Bag-of-words (Zhang et al., 2015)	68.90	96.60	88.80	92.20	58.00
Small word CNN (Zhang et al., 2015)	69.98	98.15	89.13	94.46	58.59

2016); (v) simple attention models: bi-directional block self-attention network (Bi-BloSAN) (Shen et al., 2018c). The results are shown in Table 3.

Testing accuracy Simple compositional methods indeed achieve comparable performance as the sophisticated deep CNN/RNN models. On the other hand, deep hierarchical attention model can improve the pure CNN/RNN models. The recently proposed self-attention network generally yield higher accuracy than previous methods. All approaches are better than traditional bag-of-words method. Our proposed LEAM outperforms the state-of-the-art methods on two largest datasets, *i.e.,* Yahoo and DBPedia. On other datasets, LEAM ranks the 2nd or 3rd best, which are similar to top 1 method in term of the accuracy. This is probably due to two reasons: (i) the number of classes on these datasets is smaller, and (ii) there is no explicit corresponding word embedding available for the label embedding initialization during learning. The potential of label embedding may not be fully exploited. As the ablation study, we replace the nonlinear compatibility (3) to the linear one in (2) . The degraded performance demonstrates the necessity of spatial dependency and nonlinearity in constructing the attentions.

Nevertheless, we argue LEAM is favorable for text classification, by comparing the model size and time cost Table 4, as well as convergence speed in Figure 2(a). The time cost is reported as the wall-clock time for 1000 iterations. LEAM maintains the simplicity and low cost of SWEM, compared with other models. LEAM uses much less model parameters, and converges significantly faster than Bi-BloSAN. We also compare the performance when only a partial dataset is labeled, the results are shown in Figure 2(b). LEAM consistently outperforms other methods with different proportion of labeled data.

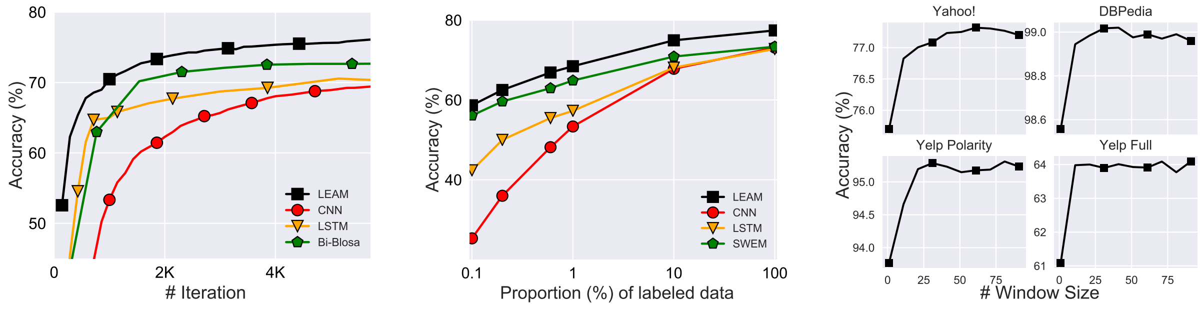
Model	# Parameters	Time cost (s)
CNN	541k	171
LSTM	1.8M	598
SWEM	61K	63
Bi-BloSAN	3.6M	292
LEAM	65K	65

Table 4: Comparison of model size and speed.

Hyper-parameter Our method has an additional hyperparameter, the window size r to define the length of "phase" to construct the attention. Larger r captures long term dependency, while smaller r enforces the local dependency. We study its impact in Figure 2(c). The topic classification tasks generally requires a larger r, while sentiment classification tasks allows relatively smaller r. One may safely choose r around 50 if not finetuning. We report the optimal results in Table 3.

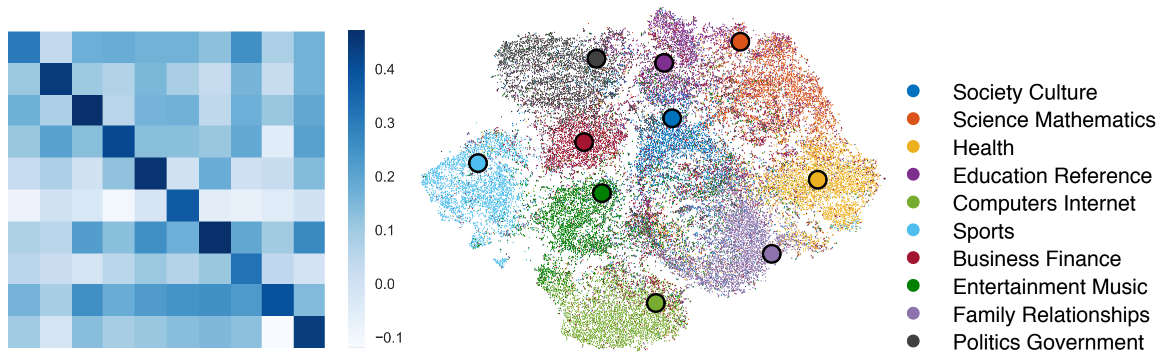
5.2 Representational Ability

Label embeddings are highly meaningful To provide insight into the meaningfulness of the learned representations, in Figure 3 we visualize the correlation between label embeddings and document embeddings based on the Yahoo dateset. First, we compute the averaged document embeddings per class: $\bar{z}_k = \frac{1}{|\mathcal{S}_k|}\sum_{i\in\mathcal{S}_k} z_i$, where $\mathcal{S}_k$ is the set of sample indices belonging to class k. Intuitively, $\bar{z}_k$ represents the center of embedded



(a) Convergence speed (b) Partially labeled data (c) Effects of window size

Figure 2: Comprehensive study of LEAM, including convergence speed, performance vs proportion of labeled data, and impact of hyper-parameter



(a) Cosine similarity matrix (b) t-SNE plot of joint embeddings

Figure 3: Correlation between the learned text sequence representation $\boldsymbol{z}$ and label embedding $\mathbf{V}$. (a) Cosine similarity matrix between averaged $\bar{\boldsymbol{z}}$ per class and label embedding $\mathbf{V}$, and (b) t-SNE plot of joint embedding of text $\boldsymbol{z}$ and labels $\mathbf{V}$.

text manifold for class k. Ideally, the perfect label embedding $\boldsymbol{c}_k$ should be the representative anchor point for class k. We compute the cosine similarity between $\bar{\boldsymbol{z}}_k$ and $\boldsymbol{c}_k$ across all the classes, shown in Figure 3(a). The rows are averaged per-class document embeddings, while columns are label embeddings. Therefore, the on-diagonal elements measure how representative the learned label embeddings are to describe its own classes, while off-diagonal elements reflect how distinctive the label embeddings are to be separated from other classes. The high on-diagonal elements and low off-diagonal elements in Figure 3(a) indicate the superb ability of the label representations learned from LEAM.

Further, since both the document and label embeddings live in the same high-dimensional space, we use t-SNE (Maaten and Hinton, 2008) to visualize them on a 2D map in Figure 3(b). Each color represents a different class, the point clouds are document embeddings, and the label embeddings are the large dots with black circles. As can be seen, each label embedding falls into the internal region of the respective manifold, which again demonstrate the strong representative power of label embeddings.

Interpretability of attention Our attention score $\boldsymbol{\beta}$ can be used to highlight the most informative words *wrt* the downstream prediction task. We visualize two examples in Figure 4(a) for the Yahoo dataset. The darker yellow means more important words. The 1st text sequence is on the topic of "Sports", and the 2nd text sequence is "Entertainment". The attention score can correctly detect the key words with proper scores.

5.3 Applications to Clinical Text

To demonstrate the practical value of label embeddings, we apply LEAM for a real health care scenario: medical code prediction on the Electronic Health Records dataset. A given patient may have multiple diagnoses, and thus multi-label learning is required.

Specifically, we consider an open-access dataset, `MIMIC-III` (Johnson et al., 2016), which

Table 5: Quantitative results for doctor-notes multi-label classification task.

contains text and structured records from a hospital intensive care unit. Each record includes a variety of narrative notes describing a patients stay, including diagnoses and procedures. They are accompanied by a set of metadata codes from the International Classification of Diseases (ICD), which present a standardized way of indicating diagnoses/procedures. To compare with previous work, we follow (Shi et al., 2017; Mullenbach et al., 2018), and preprocess a dataset consisting of the most common 50 labels. It results in 8,067 documents for training, 1,574 for validation, and 1,730 for testing.

Results We compare against the three baselines: a logistic regression model with bag-of-words, a bidirectional gated recurrent unit (Bi-GRU) and a single-layer 1D convolutional network (Kim, 2014). We also compare with three recent methods for multi-label classification of clinical text, including Condensed Memory Networks (C-MemNN) (Prakash et al., 2017), Attentive LSTM (Shi et al., 2017) and Convolutional Attention (CAML) (Mullenbach et al., 2018).

To quantify the prediction performance, we follow (Mullenbach et al., 2018) to consider the micro-averaged and macro-averaged F1 and area under the ROC curve (AUC), as well as the precision at n ($P@n$). Micro-averaged values are calculated by treating each (text, code) pair as a separate prediction. Macro-averaged values are calculated by averaging metrics computed per-label. P@n is the fraction of the n highestscored labels that are present in the ground truth.

The results are shown in Table 5. LEAM provides the best AUC score, and better F1 and P@5 values than all methods except CNN. CNN consistently outperforms the basic Bi-GRU architecture, and the logistic regression baseline performs worse than all deep learning architectures.

We emphasize that the learned attention can be very useful to reduce a doctor's reading burden. As shown in Figure 4(b), the health related words are highlighted.

6 Conclusions

In this work, we first investigate label embeddings for text representations, and propose the label-embedding attentive models. It embeds the words and labels in the same joint space, and measures the compatibility of word-label pairs to attend the document representations. The learning framework is tested on several large standard datasets and a real clinical text application. Compared with the previous methods, our LEAM algorithm requires much lower computational cost, and achieves better if not comparable performance relative to the state-of-the-art. The learned attention is highly interpretable: highlighting the most informative words in the text sequence for the downstream classification task.

Abstract

Topic models with sparsity enhancement have been proven to be effective at learning discriminative and coherent latent topics of short texts, which is critical to many scientific and engineering applications. However, the extensions of these models require carefully tailored graphical models and re-deduced inference algorithms, limiting their variations and applications. We propose a novel sparsity-enhanced topic model, Neural Sparse Topical Coding (NSTC) base on a sparsity-enhanced topic model called Sparse Topical Coding (STC). It focuses on replacing the complex inference process with the back propagation, which makes the model easy to explore extensions. Moreover, the external semantic information of words in word embeddings is incorporated to improve the representation of short texts. To illustrate the flexibility offered by the neural network based framework, we present three extensions base on NSTC without re-deduced inference algorithms. Experiments on Web Snippet and 20Newsgroups datasets demonstrate that our models outperform existing methods.

1 Introduction

Topic models with sparsity enhancement have proven to be effective tools for exploratory analysis of the overload of short text content. The latent representations learned by these models are central to many applications. However, these models have trouble to rapidly explore variations for the approximate inference methods of them. Even subtle variations on models can increase the complexity of the inference methods, which is especially apparent for non-conjugate models.

With the development of deep learning, many works combine topic models with neural language model to overcome the computation complexity of topic models (Larochelle and Lauly, 2012a; Cao et al., 2015; Tian et al., 2016). Most of these methods adopt multiple neural network layers to model the generation process of each document. Nevertheless, these methods yield the same poor performance in short texts as traditional topic models. There are also many works introducing new techniques such as word embeddings to traditional topic models. Word embeddings has proven to be effective at capturing syntactic and semantic information of words. Many works (Das et al., 2015; Hu and Tsujii, 2016; Li et al., 2016) have shown that the additional semantics in word embeddings can enhance the performance of traditional topic models. Yet these models have the same trouble in making extensions as traditional topic models.

Base on the above observations, we propose Neural Sparse Topical Coding (NSTC) by jointly utilizing word embeddings and neural network with a sparsity-enhanced topic model, Sparse Topical Coding (STC). We adopt neural network to model the generation process of STC to simplify the complex inference and improve flexibility, and incorporate external semantics provided by word embeddings to improve the overall accuracy. To illustrate the dramatic flexibility offered by the end-to-end neural network, we present three extensions base on NSTC. Our proposed models all benefit from both sides: 1) when compared with the neural based topic models, which stuck in the sparseness of word co-occurrence information, they show how the sparsity mechanism and word embeddings enrich the features and improve the performance; 2) while with topic models with sparsity enhancement, our models present how the black-box inference method of neural network accelerates the training process and increases the flexibility. To evaluate the effectiveness of our models by conducting experiments on 20 Newsgroups and Web Snippet datasets.

2 Related Work

Topic models with sparsity enhancement: The performance of traditional topic models are compromised by the sparse word co-occurrence information when applied in short texts. To overcome the bottleneck, there have been many efforts to address the problem of sparsity in short texts. Based on traditional LDA, (Williamson et al., 2010) introduced a *Spike and Slab* prior to model the sparsity in finite and infinite latent topic structures of text. To consider the dual-sparsity of topics per document and terms per topic, (Lin et al., 2014) proposed a dual-sparse topic model that addresses the sparsity in both the topic mixtures and the word usage. There are also some non-probabilistic sparse topic models, which can directly control the sparsity by imposing regularizers. For example, the non-negative matrix factorization (NMF) (Heiler and Schnörr, 2006) formalized topic modeling as a problem of minimizing loss function regularized by lasso. Similarly, (Zhu and Xing, 2011) presented sparse topical coding (STC) by utilizing the Laplacian prior to directly control the sparsity of inferred representations. Additionally, (Peng et al., 2016) presented sparse topical coding with sparse groups (STCSG) to find sparse word and document representations of texts. However, over complicated inference procedure of these sparse topic models make them difficult to rapidly explore variations.

Topic models with word embeddings: There are many works tried to incorporate word embeddings with topic models to improve the performance. (Das et al., 2015) proposed a new technique for topic modeling by treating the document as a collection of word embeddings and topics itself as multivariate Gaussian distributions in the embedding space. However, the assumption that topics are unimodal in the embedding space is not appropriate, since topically related words can occur distantly from each other in the embedding space. Therefore, (Hu and Tsujii, 2016) proposed latent concept topic model (LCTM), which modeled a topic as a distribution of concepts, where each concept defined another distribution of word vectors. (Nguyen et al., 2015) proposed Latent Feature Topic Modeling (LFTM), which extended LDA to incorporate word embeddings as latent features. (Li et al., 2016) focused on combing the local information of word embeddings and the global information of LDA, thus proposed a model TopicVec yielded by the variational inference method. However, these models also have trouble to rapidly explore variations.

Neural Topic Models: There are also some efforts trying to combine topic models with neural networks to represent words and documents simultaneously. (Larochelle and Lauly, 2012a) proposed a neural network topic model that is similarly inspired by the Replicated Softmax. (Cao et al., 2015) proposed a novel neural topic model (NTM) where the representation of words and documents are efficiently and naturally combined into a uniform framework. (Das et al., 2015) proposed a new technique for topic modeling by treating the document as a collection of word embeddings and topics itself as multivariate Gaussian distributions in the embedding space. To address the limitations of the bag-of-words assumption, (Tian et al., 2016) proposed Sentence Level Recurrent Topic Model (SLRTM) by using a Recurrent Neural Networks (RNN) based framework to model long range dependencies between words. Nevertheless, most of aforementioned works yield poor performance in short texts.

3 Neural Sparse Topical Coding

Firstly, we define that $D = \{1, ..., M\}$ is a document set with size M, $T = \{1, ..., K\}$ is a topic collection with K topics, $V = \{1, .., N\}$ is a vocabulary with N words, and $w_d = \{w_{d,1}, ..., w_{d,|I|}\}$ is a vector of terms representing a document d, where I is the index of words in document d, and $w_{d,n} (n \in I)$ is the frequency of word n in document d. Moreover, we denote $\beta \in \mathbb{R}^{N \times K}$ as a global topic dictionary for the whole document set with K bases, $\theta_d \in \mathbb{R}^K$ is the document code of each document d and $s_{d,n} \in \mathbb{R}^K$ is the word code of each word n in each document d. To yield interpretable patterns, (θ, s, β) are constrained to be non-negative.

3.1 Sparse Topical Coding

STC is a hierarchical non-negative matrix factorization for learning hierarchical latent representations of input samples. In STC, each document and each word is represented as a low-dimensional code in topic space, which can be employed in many tasks. Based on the global topic dictionary β of all documents with K topic bases sampled from a uniform distribution, the generative process of each document d is described as follows:

1. Sample the document code θ_d from a prior $p(\theta_d) \sim Laplace(\lambda^{-1})$.
2. For each observed word n in document d:
   (a) Sample the word code $s_{d,n}$ from a conditional distribution $p(s_{d,n}|\theta_d) \sim supergaussian(\theta_d, \gamma^{-1}, \rho^{-1})$.
   (b) Sample the observed word count $w_{d,n}$ from a distribution $p(w_{d,n}|s_{d,n} * \beta_n) \sim Poisson(s_{d,n} * \beta_n)$

To achieve sparse word codes, STC defines $p(s_{d,n}|\theta_d)$ as a product of two component distributions $p(s_{d,n}|\theta_d) \sim p(s_{d,n}|\theta_d, \gamma)p(s_{d,n}|\rho)$, where $p(s_{d,n}|\theta_d, \gamma)$ is an isotropic Gaussian distribution, and $p(s_{d,n}|\rho)$ is a Laplace distribution. The composite distribution is super-Gaussian: $p(s_{d,n}|\theta_d) \propto exp(\gamma||s_{d,n}\theta_d||_2^2 \rho||s_{d,n}||_1)$. With the Laplace term, the composite distribution tends to yield sparse word codes. For the same purpose, the prior distribution $p(\theta_d)$ of document codes is a Laplace prior. Although STC has closed form coordinate descent equations for parameters (θ, s, β), it is inflexible for its complex inference process.

3.2 Neural Network View of Sparse Topical Coding

We devote to rebuild STC with a neural network to simplify it's inference process via BackPropogation. After generating the topic dictionary from neural network, our model follows the generative story below for each document d:

1. For each word n in document d:
   (a) Sample a latent variable word code $s_{d,n} \sim f_g(d, n)$.
   (b) Sample the observed word count $w_{d,n}$ from $p(w_{d,n}|s_{d,n}, \beta_n) \sim Poisson(s_{d,n} * \beta_n)$

In our model, we have several assumptions:

1) To simplify our model and acclerate the inference process, we collapse the document code from our model. As illuatrated in (Bai et al., 2013) and STC paper (Zhu and Xing, 2011), we can naturally generate each document code via a aggregation of all sampled word codes among all topics, after inferring the global topic dictionary and the word codes of words belong to each document:

$$\theta_d = \sum_{d=1}^{D}\sum_{n=1}^{N_d} s_{d,nk}\,\beta_{kn} / \sum_{d=1}^{D}\sum_{n=1}^{N_d}\sum_{k=1}^{K} s_{d,nk}\,\beta_{kn};$$

2) We replace the composite super-Gaussian prior of the word codes and the uniform distribution of the topic dictionary with the neural network. In the topic dictionary neural network, we introduce the word semantic information via word embeddings to enrich the feature space for short texts;

3) Similar to STC, the observed word count is sampled from Poisson distribution, which is more appropriate for the discrete count data than other exponential family distributions.

3.3 Neural Sparse Topical Coding

In this section, we introduce the detailed layer structures of NSTC in Figure 1. We explicitly explain each layer of NSTC below:

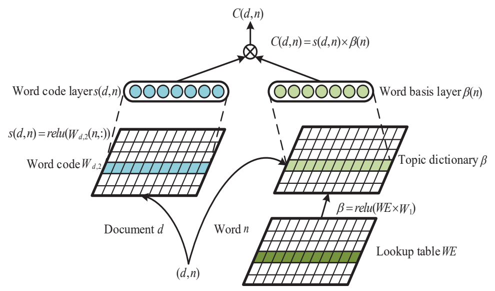

Figure 1: Schematic overview of *NSTC*.

Input layer (n, d): A word n of document $d \in D$, where D is a document set.

Word embedding layer $(WE \in \mathbb{R}^{N\times 300})$: Supposing the word number of the vocabulary is N, this layer devotes to transform each word to a distributed embedding representation. Here, we adopt the pre-trained embeddings by GloVe based on a large Wikipedia dataset[1].

Word code layers $(s_d \in \mathbb{R}^{N\times K})$: These layers generate the K-dimensional word code of input word n in document d.

$$s(d, n) = f_s(d, n) \tag{1}$$

where f_s is a multilayer perceptron. In order to achieve interpretable word codes as in STC,

[1]http://nlp.stanford.edu/projects/glove/

we constrain s to be non-negative, therefore we apply the relu activation function on the output of the neural network. Although imposing non-negativity constraints could potentially result in sparser and more interpretable patterns, we exert l_1 norm regularization on s to further keep the sparse assumption.

Topic dictionary layers ($\beta \in \mathbb{R}^{N \times K}$): These layers aim at converting WE to a topic dictionary similar to the one in STC.

$$\beta(n) = f_\beta(WE) \tag{2}$$

where f_β is a multilayer perceptron. We make a simplex projection among the output of topic dictionary neural network.We normalize each column of the dictionary via the simplex projection as follow:

$$\beta_{.k} = project(\beta_{.k}), \forall k \tag{3}$$

The simplex projection is the same as the sparsemax activation function in (Martins and Astudillo, 2016), providing the theoretical base of its employment in a neural network trained with backpropagation. After the simplex projection, each column of the topic dictionary is promised to be sparse, non-negative and united.

Score layer ($C_{d,n} \in \mathbb{R}^{1 \times 1}$): NSTC outputs the matching score of a word n and a document d with the dot product of $s(d,n)$ and $\beta(n)$ in this layer. The output score is utilized to approximate the observed word count $w_{d,n}$.

$$C(d,n) = s(d,n) * \beta(n) \tag{4}$$

Given the count $w_{d,n}$ of word n in document d, we can directly use it to supervise the training process. According to the architecture of our model, for each word n and each document d, the cost function is:

$$L = l(w_{d,n}, C(d,n)) + \lambda ||s_{d,n}||_1 \tag{5}$$

where l is the log-Poisson loss, λ is the regularization factors.

3.4 Extensions of NSTC

To future illustrate the benefits of a black box inference method, which allows rapidly explore new models, we present three variants of NSTC.

Deep l_1 Approximation. STC is based on the idea of sparse coding, in which the sparse code s of the input w can be obtained by solving the loss function for a given dictionary β. In (Gregor and LeCun, 2010), the parameterized encoder, named learned ISTA (LISTA) was proposed to efficiently approximate the l_1 based sparse code. Based on the consideration, we present a enhanced NSTC via employing the deep l_1 regularized encoder similar to LISTA, named NSTCE. We devise a feed-forward neural network as illustrated in Figure 2, to efficiently approximate the l_1 based sparse code s of the input w.

$$F(w_d; W_d, b_d) = relu(w_d * W_d + b_d) \tag{6}$$

The goal is to make the prediction of neural network predictor F after the fixed depth as close as possible to the optimal set of coefficients s^* in Eq.4. To jointly optimizing all parameters with the dictionary β together, we add another term to the loss function in Eq.4, and enforce the representation s to be as close as possible to the feed forward prediction (Kavukcuoglu et al., 2010):

$$\begin{aligned} L =& l(w_{d,n}, C(d,n)) + \lambda ||s_{d,n}||_1 \\ &+ \alpha \sum_n ||s_d - F(w_d; W_d, b_d)||_2^2 \end{aligned} \tag{7}$$

Minimizing the loss with respect to s produces a sparse representation that simultaneously reconstructs the word count and is not too different from the predicted representation.

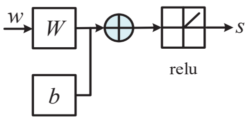

Figure 2: Deep l_1 encoder.

Group Sparse Regularization. Based on STC, (Bai et al., 2013) presented GSTC to discover document-level sparse or admixture proportion for short texts, in which the group sparse is employed to achieve sparse code at document level by taking into account the structure of bag of words. Here, we just need to add the group sparse regularization on the weight matrix, to make a neural network extension of GSTC, called NGSTC. We consider each column of s_d as a group.

$$L = l(w_{d,n}, C(d,n)) + \lambda \sum_{k=1}^{K} ||s_{d,.k}||_2 \tag{8}$$

Sparse Group Lasso. Similar to GSTC, STCSG (Peng et al., 2016) was proposed to learn sparse word and document codes, which relaxes the normalization constraint of the inferred representations with sparse group lasso. Base on STCSG, we propose a novel neural topic model called NSTCSG. We impose the sparse group lasso on the word code, and have the following cost function:

$$L = l(w_{d,n}, C(d,n)) + \lambda_1 ||s_{d,n}||_1 + \lambda_2 \sum_{k=1}^{K} ||s_{d,.k}||_2 \tag{9}$$

These three models have the same neural network structures as NSTC, and can be trained end to end with out re-deduced mathematical inference. Moreover, group and sparse group sparsity can help reduce the intrinsic complexity of the model by eliminating neurons as shown in Figure 3, and thus can help obtain practical speed ups in deep neural networks.

3.5 Optimization

For the first two models with the lasso regularizer, we can directly ulitize the end to end stochastic gradient descent (SGD) to perform optimizing. The last two optimizing objectives of NGSTC and NSTCSG are formed as a combination of both smooth and non-smooth terms, they can be solved via proximal stochastic gradient descent. The proximal gradient algorithm first obtains the intermediate solution via SGD on the loss only, and then optimize for the regularization term via performing Euclidean projection of it to the solution space, as in the following formulation:

$$\min_{s_{d,n}^{t+1}} R(s_{d,n}^{t+1}) + \frac{1}{2}||s_{d,n}^{t+1} - s_{d,n}^{t+\frac{1}{2}}||_2^2 \tag{10}$$

where R is the regularization, $s_{d,n}^{t+\frac{1}{2}}$ the intermediate solution obtained by SGD, $s_{d,n}^{t+1}$ is the variable to obtain after the current iteration. For the group lasso, the above problem has the closed-form solution. The proximal operator for the group lasso regularizer in Eq.8 is given as follow:

$$prox_{GL}(s_{d,nk}) = (1 - \frac{\lambda}{||s_{d,.k}||_2})_+ s_{d,nk} \tag{11}$$

The proximal operator for the sparse group lasso regularizer in Eq.9 is given as follow:

$$\begin{aligned} prox_{SGL}(s_{d,nk}) =& (1 - \frac{\lambda_2}{||sign(s_{d,.k}, \lambda_1)||_2})_+ \\ & sign(s_{d,nk}, \lambda_1) \end{aligned} \tag{12}$$

The detailed algorithm framework of NGSTC and NSTCSG is shown in Algorithm 1.

Algorithm 1 Training Algorithm for our models

```
Require: a document $d \in D$
1: $t = t + 1$
2: repeat
3:     Compute the partial derivatives of weight matrices,$s$, and $\beta$ with a non-regularized objective;
4:     Update weight matrices, $s$, and $\beta$ using SGD.
5:     Update $s$ using proximal operator
6:     Update $\beta$ using simplex projection.
7: until convergence
```

4 Experiments

4.1 Data and Setting

We perform our experiments on two benchmark datasets:

- **20Newsgroups**: is comprised of 18775 newsgroup articles with 20 categories, and contains 60698 unique words[2].
- **Web Snippet**: includes 12340 Web search snippets with 8 categories, we remove the words with fewer than 3 characters and with document frequency less than 3 in the dataset[3].

We compare the performance of the NSTC with the following baselines:

- **LDA** (Blei et al., 2001). A classical probabilistic topic model. We use the LDA package[4] for its implementation. We use the settings with iteration number $n = 2000$, the Dirichlet parameter for distribution over topics $\alpha = 0.1$ and the Dirichlet parameter for distribution over words $\eta = 0.01$.
- **STC** (Zhu and Xing, 2011). It is a sparsity-enhanced non-probabilistic topic model. We use the code released by the authors[5]. We set the regularization constants as $\lambda = 0.3, \rho = 0.0001$ and the maximum number of iterations of hierarchical sparse coding, dictionary learning as 100.

(a) (b) (c)

Figure 3: (a) Lasso: the Lasso penalty removes elements without optimizing neuron-level considerations (highlighted in red). (b) Group lasso: when grouping weights from the the same input neuron into each group, the group sparsity has an effect of completely removing some neurons (highlighted in red). (c) Sparse group lasso: it combines the advantages of the former two formulations, which can remove some neurons and elements (highlighted in red).

- **DocNADE** (Larochelle and Lauly, 2012b). An unsupervised neural network topic model of documents and has shown that it is a competitive model both as a generative model and as a document representation learning algorithm[6]. In DocNADE, the hidden size is 50, the learning rate is 0.0004 , the bath size is 64 and the max training number is 50000.

- **GaussianLDA** (Das et al., 2015). A new technique for topic modeling by treating the document as a collection of word embeddings and topics itself as multivariate Gaussian distributions in the embedding space[7]. We use default values for the parameters.

- **TopicVec** (Li et al., 2016). A model incorporates generative word embedding model with LDA [8]. We also use default values for the parameters.

Our three models are implemented in Python using TensorFlow[9]. For both datasets, we use the pre-trained 300-dimensional word embeddings from Wikipedia by GloVe, and it is fixed during training. For each out-of-vocab word, we sample a random vector from a normal distribution. In practice, we use a regular learning rate 0.00001 for both dataset. We set the regularization factor $\lambda = 1, \alpha = 1, \lambda_1 = 0.6, \lambda_2 = 0.4$. In initialization, all weight matrices are randomly initialized with the uniformed distribution in the interval $[0, 0.001]$ for web snippet, and $[0, 0.0001]$ for 20Newsgroups.

4.2 Classification Accuracy

We perform text classification tasks on Web Snippet dataset and 20Newsgroups. For the Web Snippet, we follow its original partition that consists of 10060 training documents and 2280 test documents. On 20Newsgroups, we we keep 60% documents for training and 40% for testing as in (Zhu and Xing, 2011). We adopt the SVM as the classifier with the document representations learned by topic models. Figure 4 reports the convergence curves of loss and accuracy over iterations. The results show that the loss and accuracy of our method can achieve convergence after almost 100 epochs on web snippets and 50 epochs on 20Newsgroups with appropriate learning rate. Table 1 reports the classification accuracy on both datasets under different methods with different settings on the number of topics $K = \{50, 100, 150, 200, 250\}$. We can found that 1) The NSTCSG yields the highest accuracy, followed by NGSTC, NSTCE and NSTC which all outperform the DocNADE, GLDA, STC and LDA. 2) The embedding based models (NSTCSG, NGSTC, NSTCE, NSTC, DocNADE and GLDA) generate better document representations than STC and LDA separately, demonstrating the representative power of neural networks based on word embeddings. 3) Sparse models (NSTCSG, NGSTC, NSTCE, NSTC and STC) are superior to non-sparse models NTM and LDA separately. It indicates that sparse topic models are more suitable to short documents. 4) The NSTCSG perform better than NGSTC, followed by NSTC, which illustrates both sparse group lasso and group lasso penalty are contribute to learning the document representations with clear semantic explanations. 5) The accuracies of DocNADE decrease with the increasing of the topic K. This is may because DocNADE may generate the document topic distribution with many indistinct non-zeros due to the data sparsity caused by the increasing number of topics. Notice that LDA has the same performance on the web snippet dataset.

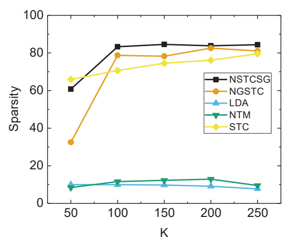
(a) word codes



(b) document codes

Figure 5: The average sparsity ratio of word and document codes.

4.3 Sparse Ratio

We further compare the sparsity of the learned latent representations of words and documents from different models on Web Snippet.

Word code: For each word n, we compute the average word code and average sparsity ratio of them as in (Zhu and Xing, 2011). Figure 5a presents the average word sparse ratio of word codes discovered by different models for Web Snippet. Note that the NGSTC can not yield sparse word codes but sparse document codes. We can see that 1) The NSTCSG learns the sparsest word codes, followed by NSTC and STC, which perform much better than NTM and LDA. 2) The word codes discovered by LDA and NTM are very dense for lacking the mechanism to learn the focused topics. The sparsity in both models is mainly caused by the data scarcity. 3)The representations learned by sparse models (NSTCSG, NSTC and STC) are much sparser, which indicates each word concentrates on only a small number of topics in these models, and therefore the word codes are more clear and semantically concentrated. 4) Meanwhile, the sparse ratio of STC and NSTC are lower than NSTCSG. It proves the sparse group lasso penalty can easily allow to provide networks with a high level of sparsity.

Document code: We further quantitatively evaluate the average sparse ratio on latent representations of documents from different models, as shown in Figure 5b. We can see that 1) The NSTCSG yields the highest sparsity ratio, followed by NGSTC and STC, which outperform NTM and LDA by a large margin. 2) The document codes discovered by LDA and NTM are still very dense, while the representations learned by sparse models (NSTC and STC) are much sparser. It indicates the sparse models can discover focused topics and obtain discriminative representations of documents. 3) Similar to the word code, NGSTC outperforms NGSTC and STC. It demonstrates that the sparse group lasso penalty can achieve better sparsity than group lasso and lasso. 4) The sparsity ratios of sparse models increase with the topic numbers. The possible reason is that the sparse models tend to learn the focused topic number which approaches to the real topic number, and an increasing number of redundant topics can be discarded. 5) The NSTCSG inherits the advantages of NSTC and NGSTC, which can achieve the sparse topic representations of words and documents.

4.4 Generative Model Evaluation

To further evaluate our models as a generative model of documents, we show the test document perplexity achieved by each topic model on the 20NewsGroups with 50 topic numbers in table 2. Notice that the topic number in TopicVec can not be specified to a fixed value, thus we follow the set in (Li et al., 2016) with 281 topics. In table 3, we show the top-9 words of learned focused topics in 20 Newsgroups datasets. For each topic, we list top-9 words according to their probabili-

ties under the corresponding topic. It is obvious that the learned topics are clear and meaningful. Such as *economics*, *hockey*, *games*, *play*, *ball* in the topic about sport. In Figure 6, we also use the 2-dimensional t-SNE method to get the visualization of the learned latent representations for Web Snippet and 20Newsgroups Dataset with 200 topics. For Web Snippet, we sample 10% of the whole dataset. For 20newsgroups, we sample 30% of the dataset. It is obvious to see that all documents are clustered into 8 and 20 distinct categories. It proves the semantic effectiveness of the documents codes learned by our model.

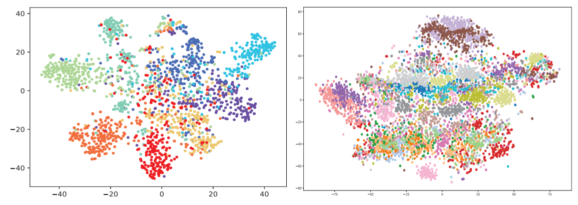

Figure 6: T-SNE embeddings of learned document representations for Web Snippet and 20News-Groups. Different colors mean different categories.

5 Conclusion

In this paper, we propose a novel neural sparsity-enhanced topic model NSTC, which improves STC by incorporating the neural network and word embeddings. Compared with other word embedding based and neural network based topic models, it overcomes the computation complexity of topic models, and improve the generation of representation over short documents. We present three variants of NSTC to illustrate the great flexibility of our framework. Experimental results demonstrate the effectiveness and efficiency of our models. For future work, we are interested in various extensions, including combining STC with autoencoding variational Bayes (AVB).

Document Similarity for Texts of Varying Lengths via Hidden Topics

Hongyu Gong[*] **Tarek Sakakini**[*] **Suma Bhat**[*] **Jinjun Xiong**[†]

Abstract

Measuring similarity between texts is an important task for several applications. Available approaches to measure document similarity are inadequate for document pairs that have non-comparable lengths, such as a long document and its summary. This is because of the lexical, contextual and the abstraction gaps between a long document of rich details and its concise summary of abstract information. In this paper, we present a document matching approach to bridge this gap, by comparing the texts in a common space of hidden topics. We evaluate the matching algorithm on two matching tasks and find that it consistently and widely outperforms strong baselines. We also highlight the benefits of the incorporation of domain knowledge to text matching.

1 Introduction

Measuring the similarity between documents is of key importance in several natural processing applications including information retrieval (Salton and Buckley, 1988), book recommendation (Gopalan et al., 2014), news categorization (Ontrup and Ritter, 2002) and essay scoring (Landauer, 2003). A range of document similarity approaches have been proposed and effectively used in recent applications including (Lai et al., 2015; Bordes et al., 2015). Central to the tasks discussed above is the assumption that the documents being compared are of comparable lengths.

Advances in language processing approaches to transform natural language understanding, such as text summarization and recommendation, have generated new requirements for comparing documents. For instance, summarization techniques (extractive and abstractive) are capable of automatically generating textual summaries by converting a long document of several hundred words into a condensed text of only a few words while preserving the core meaning of the original text (Kedzie and McKeown, 2016). Conceivably, a related aspect of summarization is the task of bidirectional matching of a summary and a document or a set of documents, which is the focus of this study. The document similarity considered in this paper is between texts that have significant differences not only in length, but also in the abstraction level (such as a definition of an abstract concept versus a detailed instance of that abstract concept).

Table 1: A Sample Concept-Project Matching

Concept
Heredity: Inheritance and Variation of Traits
All cells contain genetic information in the form of DNA molecules. Genes are regions in the DNA that contain the instructions that code for the formation of proteins.
Project
Pedigree Analysis: A Family Tree of Traits
Do you have the same hair color or eye color as your mother? When we look at members of a family it is easy to see that some physical characteristics or traits are shared. To start this project, you should draw a pedigree showing the different members of your family. Ideally you should include multiple people from at least three generations.

As an illustration, consider the task of matching a **Concept** with a **Project** as shown in Table 1. Here a **Concept** is a grade-level science curriculum item and represents the summary. A **Project**, listed in a collection of science projects, represents the document. Projects typically are long texts including an introduction, materials and procedures, whereas science concepts are much shorter in comparison having a title and a concise and abstract description. The concepts and projects are described in detail in Section 5.1. The matching task here is to automatically suggest a hands-on project for a given concept in the curriculum, such that the project can help reinforce a learner's basic understanding of the concept. Conversely, given a science project, one may need to identify the concept it covers by matching it to a listed concept in the curriculum. This would be conceivable in the context of an intelligent tutoring system.

Challenges to the matching task mentioned above include: 1) The mismatch in the relative lengths of the documents being compared – a long piece of text (henceforth termed *document*) and a short piece of text (termed *summary*) – gives rise to the vocabulary mismatch problem, where the document and the summary do not share a majority of terms. 2) The context mismatch problem arising because a document provides a reasonable amount of text to infer the contextual meaning of a term, but a summary only provides a limited context, which may or may not involve the same terms considered in the document. These challenges render existing approaches to comparing documents–for instance, those that rely on document representations (e.g., Doc2Vec (Le and Mikolov, 2014))–inadequate, because the predominance of non-topic words in the document introduces noise to its representation while the summary is relatively noise-free, rendering Doc2Vec inadequate for comparing them.

Our approach to the matching problem is to allow a multi-view generalization of the document, where multiple hidden topics are used to establish a common ground to capture as much information of the document and the summary as possible and use this to score the relevance of the pair. We empirically validate our approach on two tasks – that of project-concept matching in grade-level science and that of scientific paper-summary matching – using both custom-made and publicly available datasets. The main contributions of this paper are:

1. We propose an embedding-based hidden topic model to extract topics and measure their importance in long documents.
2. We present a novel geometric approach to compare documents with differing modality (a long document to a short summary) and validate its performance relative to strong baselines.
3. We explore the use of domain-specific word embeddings for the matching task and show the explicit benefit of incorporating domain knowledge in the algorithm.
4. We make available the first dataset[1] on project-concept matching in the science domain to help further research in this area.

2 Related Works

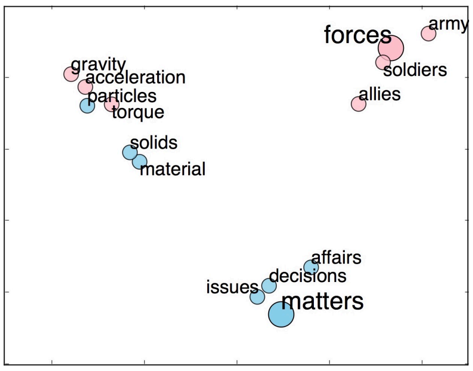
Document similarity approaches quantify the degree of relatedness between two pieces of texts of comparable lengths and thus enable matching between documents. Traditionally, statistical approaches (e.g., (Metzler et al., 2007)) and vector-space-based methods (including the robust Latent Semantic Analysis (LSA) (Dumais, 2004)) have been used for text similarity. More recently, neural network-based methods have been used for document representation and these include average word embeddings (Mikolov et al., 2013), Doc2Vec (Le and Mikolov, 2014), Skip-Thought vectors (Kiros et al., 2015), recursive neural network-based methods (Socher et al., 2014), LSTM architectures (Tai et al., 2015), and convolutional neural networks (Blunsom et al., 2014).

Considering works that avoid using an explicit document representation for comparing documents, the state-of-the-art method is Word Mover's Distance (WMD), which relies on pre-trained word embeddings (Kusner et al., 2015). Given these embeddings, the WMD defines the distance between two documents as the best transport cost of moving all words from one document to another within the space of word embeddings. The advantages of WMD are that it is hyper-parameter free and achieves high retrieval accuracy on document classification tasks with documents of comparable lengths. However, it is computationally expensive for long documents (Kusner et al., 2015).

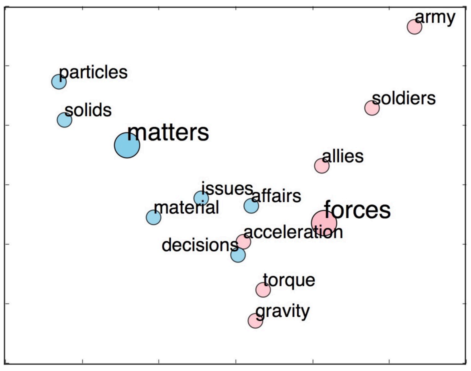
Clearly, what is lacking in prior literature is a study of document similarity approaches that match documents with widely different sizes. It is this gap in literature that we expect to fill by way of this study.

Latent Variable Models. Latent variable models including count-based and probabilistic models have been studied in many previous works. Count-based models such as Latent Semantic Indexing (LSI) compare two documents based on their combined vocabulary (Deerwester et al., 1990). When

[1]Our code and data are available at: `https://github.com/HongyuGong/Document-Similarity-via-Hidden-Topics.git`



(a) word geometry of general embedding



(b) word geometry of science domain embeddings

Figure 1: Two key words "forces" and "matters" are shown in red and blue respectively. Red words represent different senses of "forces", and blue words carry senses of "matters". "forces" mainly refers to "army" and "matters" refers to "issues" in general embedding of (a), whereas "forces" shows its sense of "gravity" and "matters" shows the sense of "solids" in science-domain embedding of (b)

documents have highly mismatched vocabularies such as those that we study, relevant documents might be classified as irrelevant. Our model is built upon word-embeddings which is more robust to such a vocabulary mismatch.

Probabilistic models such as Latent Dirichlet Analysis (LDA) define topics as distributions over words (Blei et al., 2003). In our model, topics are low-dimensional real-valued vectors (more details in Section 4.2).

3 Domain Knowledge

Domain information pertaining to specific areas of knowledge is made available in texts by the use of words with domain-specific meanings or senses. Consequently, domain knowledge has been shown to be critical in many NLP applications such as information extraction and multi-document summarization (Cheung and Penn, 2013a), spoken language understanding (Chen et al., 2015), aspect extraction (Chen et al., 2013) and summarization (Cheung and Penn, 2013b).

As will be described later, our distance metric for comparing a document and a summary relies on word embeddings. We show in this work, that embeddings trained on a science-domain corpus lead to better performance than embeddings on the general corpus (WikiCorpus). Towards this, we extract a science-domain sub-corpus from the WikiCorpus, and the corpus extraction will be detailed in Section 5.

To motivate the domain-specific behavior of polysemous words, we will qualitatively explore how domain-specific embeddings differ from the general embeddings on two polysemous science terms: *forces* and *matters*. Considering the fact that the meaning of a word is dictated by its neighbors, for each set of word embeddings, we plot the neighbors of these two terms in Figure 1 on to 2 dimensions using Locally Linear Embedding (LLE), which preserves word distances (Roweis and Saul, 2000). We then analyze the sense of the focus terms–here, *forces* and *matters*.

From Figure 1(a), we see that for the word *forces*, its general embedding is close to *army*, *soldiers*, *allies* indicating that it is related with violence and power in a general domain. Shifting our attention to Figure 1(b), we see that for the same term, its science embedding is closer to *torque*, *gravity*, *acceleration* implying that its science sense is more about physical interactions. Likewise, for the word *matters*, its general embedding is surrounded by *affairs* and *issues*, whereas, its science embedding is closer to *particles* and *material*, prompting that it represents substances. Thus, we conclude that domain specific embeddings (here, science), is capable of incorporating domain knowledge into word representations. We use this observation in our document-summary matching system to which we turn next.

4 Model

Our model that performs the matching between document and summary is depicted in Figure 2. It is composed of three modules that perform preprocessing, document topic generation, and relevance measurement between a document and a summary. Each of these modules is discussed below.

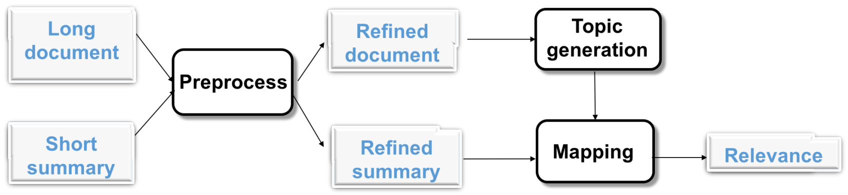


Figure 2: The system for document-summary matching

4.1 Preprocessing

The preprocessing module tokenizes texts and removes stop words and prepositions. This step allows our system to focus on the content words without impacting the meaning of original texts.

4.2 Topic Generation from Documents

We assume that a document (a long text) is a structured collection of words, with the 'structure' brought about by the composition of topics. In some sense, this 'structure' is represented as a set of hidden topics. Thus, we assume that a document is generated from certain hidden "topics", analogous to the modeling assumption in LDA. However, unlike in LDA, the "topics" here are neither specific words nor the distribution over words, but are are essentially a set of *vectors*. In turn, this means that words (represented as vectors) constituting the document structure can be generated from the hidden topic vectors.

Introducing some notation, the word vectors in a document are $\{\mathbf{w}_1, \ldots, \mathbf{w}_n\}$, and the hidden topic vectors of the document are $\{\mathbf{h}_1, \ldots, \mathbf{h}_K\}$, where $\mathbf{w}_i, \mathbf{h}_k \in \mathbb{R}^d$, $d = 300$ in our experiments.

Linear operations using word embeddings have been empirically shown to approximate their compositional properties (e.g. the embedding of a phrase is nearly the sum of the embeddings of its component words) (Mikolov et al., 2013). This motivates the linear reconstruction of the words from the document's hidden topics while minimizing the reconstruction error. We stack the K topic vectors as a topic matrix $\mathbf{H} = [\mathbf{h}_1, \ldots, \mathbf{h}_K] (K < d)$. We define the reconstructed word vector $\tilde{\mathbf{w}}_i$ for the word $\mathbf{w}_i$ as the optimal linear approximation given by topic vectors: $\tilde{\mathbf{w}}_i = \mathbf{H}\tilde{\boldsymbol{\alpha}}_i$, where

$$\tilde{\boldsymbol{\alpha}}_i = \underset{\boldsymbol{\alpha}_i \in \mathbb{R}^K}{\operatorname{argmin}} \|\mathbf{w}_i - \mathbf{H}\boldsymbol{\alpha}_i\|_2^2. \tag{1}$$

The reconstruction error E for the whole document is the sum of each word's reconstruction error and is given by: $E = \sum_{i=1}^{n} \|\mathbf{w}_i - \tilde{\mathbf{w}}_i\|_2^2$. This being a function of the topic vectors, our goal is to find the optimal $\mathbf{H}^*$ so as to minimize the error E:

$$\begin{aligned} \mathbf{H}^* &= \underset{\mathbf{H} \in \mathbb{R}^{d \times K}}{\operatorname{argmin}} \, E(\mathbf{H}) \\ &= \underset{\mathbf{H} \in \mathbb{R}^{d \times K}}{\operatorname{argmin}} \sum_{i=1}^{n} \min_{\boldsymbol{\alpha}_i} \|\mathbf{w}_i - \mathbf{H}\boldsymbol{\alpha}_i\|_2^2, \end{aligned} \tag{2}$$

where $\|\cdot\|$ is the Frobenius norm of a matrix.

Without loss of generality, we require the topic vectors $\{\mathbf{h}_i\}_{i=1}^K$ to be orthonormal, i.e., $\mathbf{h}_i^T \mathbf{h}_j = 1_{(i=j)}$. As we can see, the optimization problem (2) describes an optimal linear space spanned by the topic vectors, so the norm and the linear dependency of the vectors do not matter. With the orthonormal constraints, we simplify the form of the reconstructed vector $\tilde{\mathbf{w}}_i$ as:

$$\tilde{\mathbf{w}}_i = \mathbf{H}\mathbf{H}^T \mathbf{w}_i. \tag{3}$$

We stack word vectors in the document as a matrix $\mathbf{W} = [\mathbf{w}_1, \ldots, \mathbf{w}_n]$. The equivalent formulation to problem (2) is:

$$\begin{aligned} \min_{\mathbf{H}} \quad & \|\mathbf{W} - \mathbf{H}\mathbf{H}^T\mathbf{W}\|_2^2 \\ \text{s.t.} \quad & \mathbf{H}^T\mathbf{H} = \mathbf{I}, \end{aligned} \tag{4}$$

where $\mathbf{I}$ is an identity matrix.

The problem can be solved by Singular Value Decomposition (SVD), using which, the matrix $\mathbf{W}$ can be decomposed as $\mathbf{W} = \mathbf{U}\boldsymbol{\Sigma}\mathbf{V}^T$, where $\mathbf{U}^T\mathbf{U} = \mathbf{I}, \mathbf{V}^T\mathbf{V} = \mathbf{I}$, and $\boldsymbol{\Sigma}$ is a diagonal matrix where the diagonal elements are arranged in a decreasing order of absolute values. We show in the supplementary material that the first K vectors in the matrix $\mathbf{U}$ are exactly the solution to $\mathbf{H}^* = [\mathbf{h}_1^*, \ldots, \mathbf{h}_K^*]$.

We find optimal topic vectors $\mathbf{H}^* = [\mathbf{h}_1^*, \ldots, \mathbf{h}_K^*]$ by solving problem (4). We note that these topic vectors are not equally important, and we say that one topic is more important than another if it can reconstruct words with smaller error. Define E_k as the reconstruction error when we only use topic vector $\mathbf{h}_k^*$ to reconstruct the document:

$$E_k = \|\mathbf{W} - \mathbf{h}_k^* \mathbf{h}_k^{*T} \mathbf{W}\|_2^2. \qquad (5)$$

Now define i_k as the *importance* of topic $\mathbf{h}_k^*$, which measures the topic's ability to reconstruct the words in a document:

$$i_k = \|\mathbf{h}_k^{*T} \mathbf{W}\|_2^2 \qquad (6)$$

We show in the supplementary material that the higher the importance i_k is, the smaller the reconstruction error E_k is. Now we normalize i_k as $\bar{i}_k$ so that the importance does not scale with the norm of the word matrix W, and so that the importances of the K topics sum to 1. Thus,

$$\bar{i}_k = i_k / (\sum_{j=1}^{K} i_j). \qquad (7)$$

The number of topics K is a hyperparameter in our model. A small K may not cover key ideas of the document, whereas a large K may keep trivial and noisy information. Empirically we find that $K = 15$ captures most important information from the document.

4.3 Topic Mapping to Summaries

We have extracted K topic vectors $\{\mathbf{h}_k^*\}_{k=1}^K$ from the document matrix $\mathbf{W}$, whose importance is reflected by $\{\bar{i}_k\}_{k=1}^K$. In this module, we measure the relevance of a document-summary pair. Towards this, a summary that matches the document should also be closely related with the "topics" of that document. Suppose the vectors of the words in a summary are stacked as a $d \times m$ matrix $\mathbf{S} = [\mathbf{s}_1, \ldots, \mathbf{s}_m]$, where $\mathbf{s}_j$ is the vector of the j-th word in a summary. Similar to the reconstruction of the document, the summary can also be reconstructed from the documents' topic vectors as shown in Eq. (3). Let $\tilde{\mathbf{s}}_j^k$ be the reconstruction of the summary word $\mathbf{s}_j$ given by one topic $\mathbf{h}_k^*$: $\tilde{\mathbf{s}}_j^k = \mathbf{h}_k^* \mathbf{h}_k^{*T} \mathbf{s}_j$.

Let $r(\mathbf{h}_k^*, \mathbf{s}_j)$ be the relevance between a topic vector $\mathbf{h}_k^*$ and summary word $\mathbf{s}_j$. It is defined as the cosine similarity between $\tilde{\mathbf{s}}_j^k$ and $\mathbf{s}_j$:

$$r(\mathbf{h}_k^*, \mathbf{s}_j) = \mathbf{s}_j{}^T \tilde{\mathbf{s}}_j^k / (\|\mathbf{s}_j\|_2 \cdot \|\tilde{\mathbf{s}}_j^k\|_2). \qquad (8)$$

Furthermore, let $r(\mathbf{h}_k^*, \mathbf{S})$ be the relevance between a topic vector and the summary, defined to be the average similarity between the topic vector and the summary words:

$$r(\mathbf{h}_k^*, \mathbf{S}) = \frac{1}{m} \sum_{j=1}^{m} r(\mathbf{h}_k^*, \mathbf{s}_j). \qquad (9)$$

The relevance between a topic vector and a summary is a real value between 0 and 1.

As we have shown, the topics extracted from a document are not equally important. Naturally, a summary relevant to more important topics is more likely to better match the document. Therefore, we define $r(\mathbf{W}, \mathbf{S})$ as the relevance between the document $\mathbf{W}$ and the summary $\mathbf{S}$, and $r(\mathbf{W}, \mathbf{S})$ is the sum of topic-summary relevance weighted by the importance of the topic:

$$r(\mathbf{W}, \mathbf{S}) = \sum_{k=1}^{K} \bar{i}_k \cdot r(\mathbf{h}_k^*, \mathbf{S}), \qquad (10)$$

where $\bar{i}_k$ is the importance of topic $\mathbf{h}_k^*$ as defined in (7). The higher $r(\mathbf{W}, \mathbf{S})$ is, the better the summary matches the document.

We provide a visual representation of the documents as shown in Figure 3 to illustrate the notion of hidden topics. The two documents are from science projects: a genetics project, *Pedigree Analysis: A Family Tree of Traits* (ScienceBuddies, 2017a), and a weather project, *How Do the Seasons Change in Each Hemisphere* (ScienceBuddies, 2017b). We project all embeddings to a three-dimensional space for ease of visualization.

As seen in Figure 3, the hidden topics reconstruct the words in their respective documents to the extent possible. This means that the words of a document lie roughly on the plane formed by their corresponding topic vectors. We also notice that the summary words (*heredity* and *weather* respectively for the two projects under consideration) lie very close to the plane formed by the hidden topics of the relevant project while remaining away from the plane of the irrelevant project. This shows that the words in the summary (and hence the summary itself) can also be reconstructed from the hidden topics of documents that match the summary (and are hence 'relevant' to the summary). Figure 3 visually explains the geometric relations between the summaries, the hidden topics and the documents. It also validates the representation power of the extracted hidden topic vectors.

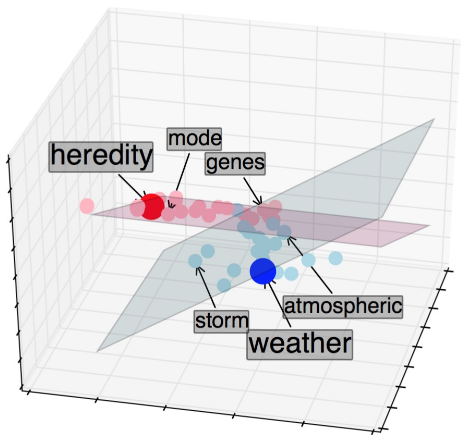

Figure 3: Words *mode* and *genes* from the document on genetics and words *storm* and *atmospheric* from document on weather are represented by pink and blue points respectively. Linear space of hidden topics in genetics form the pink plane, where summary word *heredity* (the red point) roughly lies. Topic vectors of the document on weather form the blue plane, and the summary word *weather* (the darkblue point) lies almost on the same plane.

5 Experiments

In this section, we evaluate our document-summary matching approach on two specific applications where texts of different sizes are compared. One application is that of concept-project matching useful in science education and the other is that of summary-research paper matching.

Word Embeddings. Two sets of 300-dimension word embeddings were used in our experiments. They were trained by the Continuous Bag-of-Words (CBOW) model in word2vec (Mikolov et al., 2013) but on different corpora. One training corpus is the full English WikiCorpus of size 9 GB (Al-Rfou et al., 2013). The second consists of science articles extracted from the WikiCorpus. To extract these science articles, we manually selected the science categories in Wikipedia and considered all subcategories within a depth of 3 from these manually selected root categories. We then extracted all articles in the aforementioned science categories resulting in a science corpus of size 2.4 GB. The word vectors used for documents and summaries are both from the pretrained word2vec embeddings.

Baselines We include two state-of-the-art methods of measuring document similarity for comparison using their implementations available in gensim (Řehůřek and Sojka, 2010).

(1) **Word movers' distance (WMD)** (Kusner et al., 2015). WMD quantifies the distance between a pair of documents based on word embeddings as introduced previously (c.f. Related Work). We take the negative of their distance as a measure of document similarity (here between a document and a summary).

(2) **Doc2Vec** (Le and Mikolov, 2014). Document representations have been trained with neural networks. We used two versions of doc2vec: one trained on the full English Wikicorpus and a second trained on the science corpus, same as the corpora used for word embedding training. We used the cosine similarity between two text vectors to measure their relevance.

For a given document-summary pair, we compare the scores obtained using the above two methods with that obtained using our method.

5.1 Concept-Project matching

Science projects are valuable resources for learners to instigate knowledge creation via experimentation and observation. The need for matching a science concept with a science project arises when learners intending to delve deeper into certain concepts search for projects that match a given concept. Additionally, they may want to identify the concepts with which a set of projects are related.

We note that in this task, science concepts are highly concise summaries of the core ideas in projects, whereas projects are detailed instructions of the experimental procedures, including an introduction, materials and a description of the procedure, as shown in Table 1. Our matching method provides a way to bridge the gap between abstract concepts and detailed projects. The format of the concepts and the projects is discussed below.

Concepts. For the purpose of this study we use the concepts available in the Next Generation Science Standards (NGSS) (NGSS, 2017). Each concept is accompanied by a short description. For example, one concept in life science is *Heredity: Inheritance and Variation of Traits*. Its description is *All cells contain genetic information in the form of DNA molecules. Genes are regions in the DNA that contain the instructions that code for the formation of proteins.* Typical lengths of concepts are around 50 words.

Projects. The website Science Buddies (Science-Buddies, 2017c) provides a list of projects from a variety of science and engineering disciplines such

Table 2: Classification results for the Concept-Project Matching task. All performance differences were statistically significant at $p = 0.01$.

method	topic_science	topic_wiki	wmd_science	wmd_wiki	doc2vec_science	doc2vec_wiki
precision	$\mathbf{0.758 \pm 0.012}$	0.750 ± 0.009	0.643 ± 0.070	0.568 ± 0.055	0.615 ± 0.055	0.661 ± 0.084
recall	$\mathbf{0.885 \pm 0.071}$	0.842 ± 0.010	0.735 ± 0.119	0.661 ± 0.119	0.843 ± 0.066	0.737 ± 0.149
fscore	$\mathbf{0.818 \pm 0.028}$	0.791 ± 0.007	0.679 ± 0.022	0.595 ± 0.020	0.695 ± 0.019	0.681 ± 0.032

as physical sciences, life sciences and social sciences. A typical project consists of an abstract, an introduction, a description of the experiment and the associated procedures. A project typically has more than 1000 words.

Dataset. We prepared a representative dataset 537 pairs of projects and concepts involving 53 unique concepts from NGSS and 230 unique projects from Science Buddies. Engineering undergraduate students annotated each pair with the decision whether it was a good match or not and received research credit. As a result, each concept-project pair received at least three annotations, and upon consolidation, we considered a concept-project pair to be a good match when a majority of the annotators agreed. Otherwise it was not considered a good match. The ratio between good matches and bad matches in the collected data was $44 : 56$.

Classification Evaluation. Annotations from students provided the ground truth labels for the classification task. We randomly split the dataset into tuning and test instances with a ratio of $1 : 9$. A threshold score was tuned on the tuning data, and concept-project pairs with scores higher than this threshold were classified as a good matches during testing. We performed 10-fold cross validation, and report the average precision, recall, F1 score and their standard deviation in Table 2.

Our topic-based metric is denoted as "topic", and the general-domain and science-domain embeddings are denoted as "wiki" and "science" respectively. We show the performance of our method against the two baselines while varying the underlying embeddings, thus resulting in 6 different combinations. For example, "topic_science" refers to our method with science embeddings. From the table (column 1) we notice the following: 1) Our method *significantly outperforms* the two baselines by a wide margin ($\approx$10%) in both the general domain setting as well as the domain-specific setting. 2) Using science domain-specific word embeddings instead of the general word embeddings results in the *best performance across all algorithms*. This performance was observed despite the word embeddings being trained on a *significantly smaller* corpus compared to the general domain corpus.

Besides the classification metrics, we also evaluated the directed matching from concepts to projects with ranking metrics.

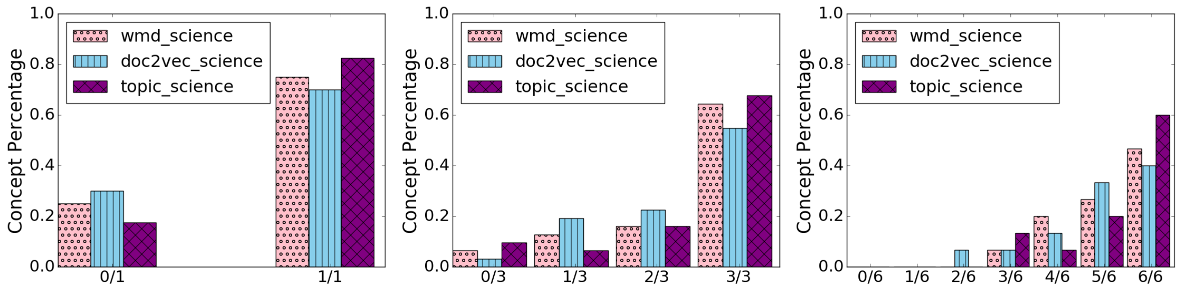
Ranking Evaluation Our collected dataset resulted in having a many-to-many matching between concepts and projects. This is because the same concept was found to be a good match for multiple projects and the same project was found to match many concepts. The previously described classification task evaluated the bidirectional concept-project matching. Next we evaluated the directed matching from concepts to projects, to see how relevant these top ranking projects are to a given input concepts. Here we use precision@k (Radlinski and Craswell, 2010) as the evaluation metric, considering the percentage of relevant ones among top-ranking projects.

For this part, we only considered the methods using science domain embeddings as they have shown superior performance in the classificaiton task. For each concept, we check the precision@k of matched projects and place it in one of k+1 bins accordingly. For example, for k=3, if only two of the three top projects are a correct match, the concept is placed in the bin corresponding to $2/3$. In Figure 4, we show the percentage of concepts that fall into each bin for the three different algorithms for k=1,3,6.

We observe that recommendations using the hidden topic approach fall more in the high value bin compared to others, performing consistently better than two strong baselines. The advantage becomes more obvious at precision@6. It is worth mentioning that wmd_science falls behind doc2vec_science in the classification task while it outperforms in the ranking task.

5.2 Text Summarization

The task of matching summaries and documents is commonly seen in real life. For example, we



(a) Precision@1 (b) Precision@3 (c) Precision@6

Figure 4: Ranking Performance of All Methods

use an event summary "Google's AlphaGo beats Korean player Lee Sedol in Go" to search for relevant news, or use the summary of a scientific paper to look for related research publications. Such matching constitutes an ideal task to evaluate our matching method between texts of different sizes.

Dataset. We use a dataset from the CL-SciSumm Shared Task (Jaidka et al., 2016). The dataset consists of 730 ACL Computational Linguistics research papers covering 50 categories in total. Each category consists of a reference paper (RP) and around 10 citing papers (CP) that contain citations to the RP. A human-generated summary for the RP is provided and we use the 10 CP as being relevant to the summary. The matching task here is between the summary and all CPs in each category.

Evaluation. For each paper, we keep all of its content except the sections of experiments and acknowledgement (these sections were omitted because often their content is often less related to the topic of the summary). The typical summary length is about 100 words, while a paper has more than 2000 words. For each topic, we rank all 730 papers in terms of their relevance generated by our method and baselines using both sets of embeddings. For evaluation, we use the information retrieval measure of precision@k, which considers the number of relevant matches in the top-k matchings (Manning et al., 2008). For each combination of the text similarity approaches and embeddings, we show precision@k for different k's in Figure 5. We observe that our method with science embedding achieves the best performance compared to the baselines, once again showing not only the benefits of our method but also that of incorporating domain knowledge.

6 Discussion

Analysis of Results. From the results of the two tasks we observe that our method outperforms two

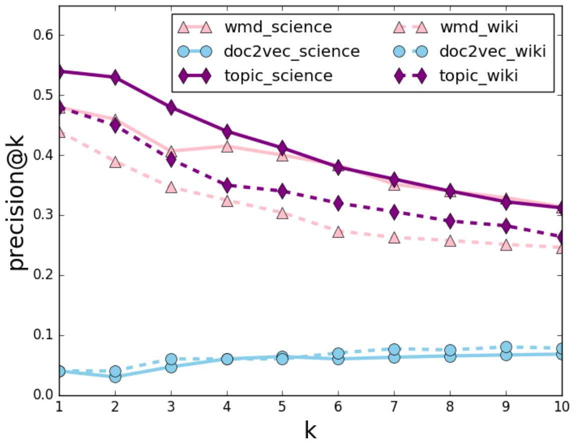


Figure 5: Summary-Article Matching

strong baselines. The reason for WMD's poor performance could be that the many uninformative words (those unrelated to the central topic) make WMD overestimate the distance between the document-summary pair. As for doc2vec, its single vector representation may not be able to capture all the key topics of a document. A project could contain multifaceted information, e.g., a project to study how climate change affects grain production is related to both environmental science and agricultural science.

Effect of Topic Number. The number of hidden topics K is a hyperparameter in our setting. We empirically evaluate the effect of topic number in the task of concept-project mapping. Figure 6 shows the F1 scores and the standard deviations at different K. As we can see, optimal K is 18. When K is too small, hidden topics are too few to capture key information in projects. Thus we can see that the increase of topic number from 3 to 6 brings a big improvement to the performance. Topic numbers larger than the optimal value degrade the performance since more topics incorporate noisy information. We note that the perfor-

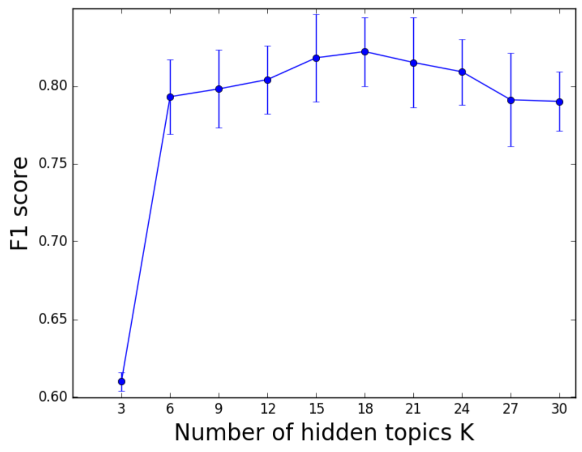

Figure 6: F1 score on concept-project matching with different topic numbers K

mance changes are mild when the number of topics are in the range of [18, 31]. Since topics are weighted by their importance, the effect of noisy information from extra hidden topics is mitigated.

Interpretation of Hidden Topics. We consider the summary-paper matching as an example with around 10 papers per category. We extracted the hidden topics from each paper, reconstructed words with these topics as shown in Eq. (3), and selected the words which had the smallest reconstruction errors. These words are thus closely related to the hidden topics, and we call them *topic words* to serve as an interpretation of the hidden topics. We visualize the cloud of such topic words on the set of papers about word sense disambiguation as shown in Figure 7. We see that the words selected based on the hidden topics cover key ideas such as *disambiguation*, *represent*, *classification* and *sentence*. This qualitatively validates the representation power of hidden topics. More examples are available in the supplementary material.

We interpret this to mean that proposed idea of multiple hidden topics captures the key information of a document. The extracted "hidden topics" represent the essence of documents, suggesting the appropriateness of our relevance metric to measure the similarity between texts of different sizes. Even though our focus in this study was the science domain we point out that the results are more generally valid since we made no domain-specific assumptions.

Varying Sensitivity to Domain. As shown in the results, the science-domain embeddings improved the classification of concept-project matching for

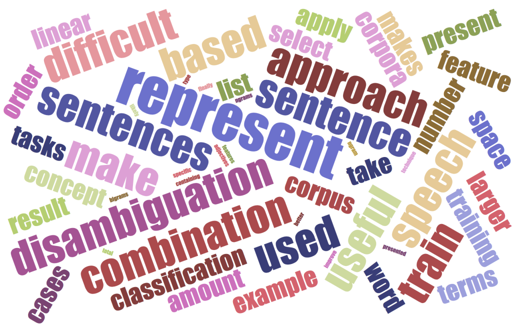

Figure 7: Topic words from papers on word sense disambiguation

the topic-based method by 2% in F1-score, WMD by 8% and doc2vec by 1%, thus underscoring the importance of domain-specific word embeddings.

Doc2vec is less sensitive to the domain, because it provides document-level representation. Even if some words cannot be disambiguated due to the lack of domain knowledge, other words in the same document can provide complementary information so that the document embedding does not deviate too much from its true meaning.

Our method, also a word embedding method, is not as sensitive to domain as WMD. It is robust to the polysemous words with domain-sensitive semantics, since hidden topics are extracted in the document level. Broader contexts beyond just words provide complementary information for word sense disambiguation.

7 Conclusion

We propose a novel approach to matching documents and summaries. The challenge we address is to bridge the gap between detailed long texts and its abstraction with hidden topics. We incorporate domain knowledge into the matching system to gain further performance improvement. Our approach has beaten two strong baselines in two downstream applications, concept-project matching and summary-research paper matching.

Abstract

Predicting a reader's rating of text quality is a challenging task that involves estimating different subjective aspects of the text, like structure, clarity, *etc.* Such subjective aspects are better handled using cognitive information. One such source of cognitive information is gaze behaviour. In this paper, we show that gaze behaviour does indeed help in effectively predicting the rating of text quality. To do this, we first model text quality as a function of three properties - organization, coherence and cohesion. Then, we demonstrate how capturing gaze behaviour helps in predicting each of these properties, and hence the overall quality, by reporting improvements obtained by adding gaze features to traditional textual features for score prediction. We also hypothesize that if a reader has fully understood the text, the corresponding gaze behaviour would give a better indication of the assigned rating, as opposed to partial understanding. Our experiments validate this hypothesis by showing greater agreement between the given rating and the predicted rating when the reader has a full understanding of the text.

1 Introduction

Automatically rating the quality of a text is an interesting challenge in NLP. It has been studied since Page's seminal work on automatic essay grading in the mid-1960s (Page, 1966). This is due to the dependence of quality on different aspects such as the overall structure of the text, clarity, *etc.* that are highly qualitative in nature, and whose scoring can vary from person to person (Person, 2013).

Scores for such qualitative aspects cannot be inferred solely from the text and would benefit from psycholinguistic information, such as gaze behaviour. Gaze based features have been used for co-reference resolution (Ross et al., 2016), sentiment analysis (Joshi et al., 2014) and translation annotation complexity estimation (Mishra et al., 2013). They could also be very useful for education applications, like evaluating readability (Mishra et al., 2017) and in automatic essay grading.

In this paper, we consider the following qualitative properties of text: Organization, Coherence and Cohesion. A text is **well-organized** if it begins with an introduction, has a body and ends with a conclusion. One of the other aspects of organization is the fact that it takes into account how the content of the text is split into paragraphs, with each paragraph denoting a single *idea*. If the text is too long, and not split into paragraphs, one could consider the text to be badly organized[1].

A text is **coherent** if it makes sense to a reader. A text is **cohesive** if it is well connected. Coherence and cohesion are two qualities that are closely related. A piece of text that is well-connected usually makes sense. Conversely, a piece of text that makes sense is usually well-connected. However, it is possible for texts to be coherent but lack cohesion. Table 1 provides some examples for texts that are coherent and cohesive, as well as those that lack one of those qualities.

There are different ways to model coherence and cohesion. Since coherence is a measure of how much sense the text makes, it is a semantic property of the text. It requires sentences within the text to be interpreted, by themselves, as well as with other sentences in the text (Van Dijk, 1980).

On the other hand, cohesion makes use of

[1]Refer supplementary material for example. We have placed it there due to space constraints.

Example	Comments
My favourite colour is blue. I like it because it is calming and it relaxes me. I often go outside in the summer and lie on the grass and look into the clear sky when I am stressed. For this reason, I'd have to say my favourite colour is blue.	Coherent and cohesive.
My favourite colour is blue. I'm calm and relaxed. In the summer I lie on the grass and look up.	Coherent but not cohesive. There is no link between the sentences. However, the text makes sense due to a lot of implicit clues (blue, favourite, relaxing, look up (and see the blue sky)).
My favourite colour is *blue*. *Blue* sports cars go **very fast**. Driving in **this way** is dangerous and can cause many *car crashes*. I had a *car accident* once and **broke my leg**. I was very sad because I had to miss a holiday in Europe because of **the injury**.	Cohesive but not coherent. The sentences are linked by words (that are in *italics* or in **bold**) between adjacent sentences. As we can see, every pair of adjacent sentences are connected by words / phrases, but the text does not make sense, since it first starts with blue, and describes missing a holiday due to injury.

Table 1: Examples of coherence and cohesion[2].

linguistic cues, such as references (demonstratives, pronouns, *etc.*), ellipsis (leaving out implicit words - Eg. Sam can type and I can [*type*] too), substitution (use of a word or phrase to replace something mentioned earlier - Eg. How's the croissant? I'd like to have **one** too.), conjunction (and, but, therefore, *etc.*), cohesive nouns (problem, issue, investment, *etc.*) and lexis (linking different pieces of text by synonyms, hyponyms, lexical chains, *etc.*) (Halliday and Hasan, 1976).

Using these properties, we model the overall text quality rating. We make use of a Likert scale (Likert, 1932) with a range of 1 to 4, for measuring each of these properties; the higher the score, the better is the text in terms of that property. We model the text quality rating on a scale of 1 to 10, using the three scores as input. In other words,

$$Quality(T) = Org(T) + Chr(T) + Chs(T) - 2,$$

where $Quality(T)$ is the text quality rating of the text T. $Org(T)$, $Chr(T)$, and $Chs(T)$ correspond to the $\underline{\textbf{Org}}$anization, $\underline{\textbf{C}}$o$\underline{\textbf{h}}$e$\underline{\textbf{r}}$ence, and $\underline{\textbf{C}}$o$\underline{\textbf{h}}$e$\underline{\textbf{s}}$ion scores respectively, for the text T, that are given by a reader. We subtract 2 to scale the scores from a range of 3 - 12, to a range of 1 - 10 for quality.

Texts with poor organization and/or cohesion can force readers to regress *i.e.* go to previous sentences or paragraphs. Texts with poor coherence may lead readers to fixate more on different portions of text to understand them. In other words, such gaze behaviour indirectly captures the effort needed by human readers to comprehend the text (Just and Carpenter, 1980), which, in turn, may influence the ratings given by them. Hence, these properties seem to be a good indicators for overall quality of texts.

In this paper, we address the following question: ***Can information obtained from gaze behaviour help predict reader's rating of quality of text by estimating text's organization, coherence, and cohesion?*** Our work answers that question in the affirmative. We found that using gaze features does contribute in improving the prediction of qualitative ratings of text by users.

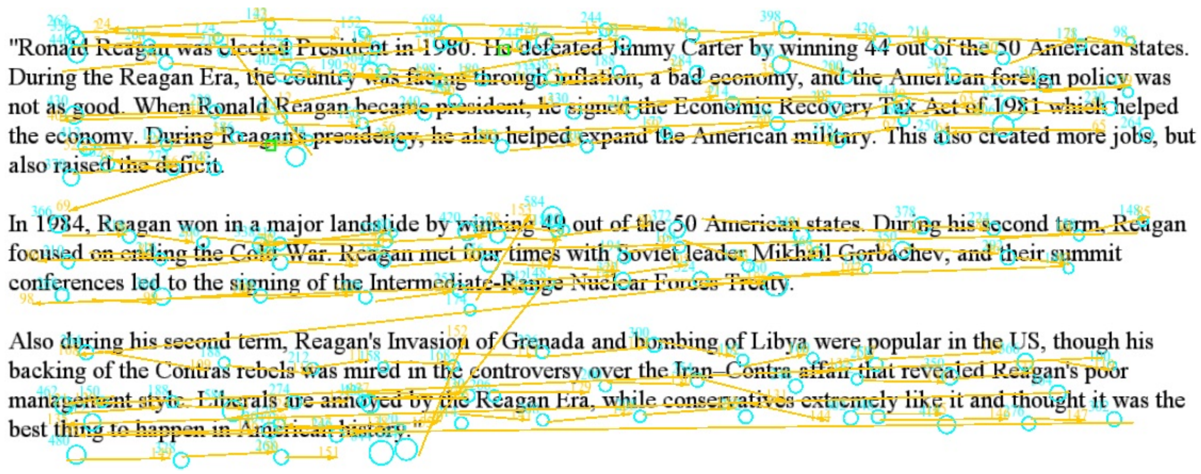
Our work has the following contributions. Firstly, we propose **a novel way to predict readers' rating of text** by recording their eye movements as they read the texts. Secondly, we show that **if a reader has understood the text completely, their gaze behaviour is more reliable**. Thirdly, **we also release our dataset**[3] to help in further research in using gaze features in other tasks involving predicting the quality of texts.

In this paper, we use the following terms related to eye tracking. The **interest area (IA)** is an area of the screen that is under interest. We mainly look at words as interest areas. A **fixation** takes place when the gaze is focused on a point of the screen. A **saccade** is the movement of gaze between two fixations. A **regression** is a special type of saccade in which the reader refers back to something that they had read earlier.

The rest of the paper is organized as follows. Section 2 describes the motivation behind our work. Section 3 describes related work in this field. Section 4 describes the different features that we used. Sections 5 and 6 describes our experiments and results. Section 6 also contains analysis of our experiments. Section 7 concludes our paper and mentions future work.

[2]We took the examples from this site for explaining coherence and cohesion: http://gordonscruton.blogspot.in/2011/08/what-is-cohesion-coherence-cambridge.html

[3]The dataset can be downloaded from http://www.cfilt.iitb.ac.in/cognitive-nlp/



"Ronald Reagan was elected President in 1980. He defeated Jimmy Carter by winning 44 out of the 50 American states. During the Reagan Era, the country was facing through inflation, a bad economy, and the American foreign policy was not as good. When Ronald Reagan became president, he signed the Economic Recovery Tax Act of 1981 which helped the economy. During Reagan's presidency, he also helped expand the American military. This also created more jobs, but also raised the deficit.

In 1984, Reagan won in a major landslide by winning 49 out of the 50 American states. During his second term, Reagan focused on ending the Cold War. Reagan met four times with Soviet leader Mikhail Gorbachev, and their summit conferences led to the signing of the Intermediate-Range Nuclear Forces Treaty.

Also during his second term, Reagan's Invasion of Grenada and bombing of Libya were popular in the US, though his backing of the Contras rebels was mired in the controversy over the Iran–Contra affair that revealed Reagan's poor management style. Liberals are annoyed by the Reagan Era, while conservatives extremely like it and thought it was the best thing to happen in American history."

Figure 1: Sample text showing fixations, saccades and regressions. This text was given scores of 4, 4, and 3 for organization, coherence and cohesion. The circles denote fixations, and the lines are saccades. Radius of the circles denote the duration of the fixation (in milliseconds), which is centred at the centre of the circle. This is the output from SR Research Data Viewer software.

2 Motivation

Reader's perception of text quality is subjective and varies from person to person. Using cognitive information from the reader can help in predicting the score he / she will assign to the text. A well-written text would not have people fixate too long on certain words, or regress a lot to understand, while a badly written text would do so.

Figure 1 shows the gaze behaviour for a sample text. The circles denote fixations, and the arrows denote saccades. If we capture the gaze behaviour, as well as see how well the reader has understood the text, we believe that we can get a clearer picture of the quality rating of the text.

One of the major concerns is *How are we going to get the gaze data?* This is because capability to gather eye-tracking data is not available to the masses. However, top mobile device manufacturers, like Samsung, have started integrating basic eye-tracking software into their smartphones (Samsung Smart Scroll) that are able to detect where the eye is fixated, and can be used in applications like scrolling through a web page. Start-ups, like Cogisen[4], have started using gaze features in their applications, such as using gaze information to improve input to image processing systems. Recently, SR Research has come up with a portable eye-tracking system[5].

3 Related Work

A number of studies have been done showing how eye tracking can model aspects of text. Word length has been shown to be positively correlated with fixation count (Rayner, 1998) and fixation duration (Henderson and Ferreira, 1993). Word predictability (i.e. how well the reader can predict the next word in a sentence) was also studied by Rayner (1998), where he found that unpredictable words are less likely to be skipped than predictable words.

Shermis and Burstein (2013) gives a brief overview of how text-based features are used in multiple aspects of essay grading, including grammatical error detection, sentiment analysis, short-answer scoring, *etc.* Their work also describes a number of current essay grading systems that are available in the market like *E-rater*® (Attali and Burstein, 2004). In recent years, there has been a lot of work done on evaluating the holistic scores of essays, using deep learning techniques (Alikaniotis et al., 2016; Taghipour and Ng, 2016; Dong and Zhang, 2016).

There has been little work done to model text organization, such as Persing et al. (2010) (using machine learning) and Taghipour (2017) (using neural networks). However, there has been a lot of work done to model coherence and cohesion, using methods like lexical chains (Somasundaran et al., 2014), an entity grid (Barzilay and Lapata, 2005), *etc.* An interesting piece of work to model coherence was done by Soricut and Marcu (2006) where they used a machine translation-based approach to model coherence. Zesch et al. (2015) use topical overlap to model coherence for essay grading. Discourse connectors are used as a heuristic to model cohesion by Zesch et al. (2015) and Persing and Ng (2015). Our work is novel because it makes use of gaze behaviour to model and predict coherence and cohesion in text.

In recent years, there has been some work in using eye-tracking to evaluate certain aspects of the text, like readability (Gonzalez-Garduño and Søgaard, 2017; Mishra et al., 2017), grammaticality (Klerke et al., 2015), *etc.*. Our work uses eye-tracking to predict the score given by a reader to a complete piece of text (rather than just a sentence as done by Klerke et al. (2015)) and show that the scoring is more reliable if the reader has understood the text.

4 Features

In order to predict the scores of the different properties of the text, we use the following text and gaze features.

4.1 Text-based Features

We use a set of text-based features to come up with a baseline system to predict the scores for different properties.

The first set of features that we use are **length and count-based features**, such as word length, word count, sentence length, count of transition phrases[6] *etc.* (Persing and Ng, 2015; Zesch et al., 2015).

The next set of features that we use are **complexity features**, namely the degree of polysemy, coreference distance, and the Flesch Reading Ease Score (FRES) (Flesch, 1948). These features help in normalizing the gaze features for text complexity. These features were extracted using Stanford CoreNLP (Manning et al., 2014), and MorphAdorner (Burns, 2013).

The third set of features that we use are **stylistic features** such as the ratios of the number of adjectives, nouns, prepositions, and verbs to the number of words in the text. These features are used to model the distributions of PoS tags in good and bad texts. These were extracted using NLTK[7] (Loper and Bird, 2002).

The fourth set of features that we use are **word embedding features**. We use the average of word vectors of each word in the essay, using Google News word vectors (Mikolov et al., 2013). The word embeddings are **300 dimensions**. We also calculate the mean and maximum similarities between the word vectors of the content words in adjacent sentences of the text, using GloVe word embeddings[8] (Pennington et al., 2014).

The fifth set of features that we use are **language modeling features**. We use the count of words that are absent in Google News word vectors and misspelled words using the PyEnchant[9] library. In order to check the grammaticality of the text, we construct a 5-gram language model, using the Brown Corpus (Francis and Kucera, 1979).

The sixth set of features are **sequence features**. These features are particularly useful in modeling organization (sentence and paragraph sequence similarity) (Persing et al., 2010), coherence and cohesion (PoS and lemma similarity). Pitler et al. (2010) showed that cosine similarity of adjacent sentences as one of the best predictors of linguistic quality. Hence, we also create vectors for the PoS tags and lemmas for each sentence in the text. The dimension of the vector is the number of distinct PoS tags / lemmas.

The last set of features that we look at are **entity grid features**. We define entities as the nouns in the document, and do coreference resolution to resolve pronouns. We then construct an entity grid (Barzilay and Lapata, 2005) - a 1 or 0 grid that checks whether an entity is present or not in a given sentence. We take into account sequences of entities across sentences that possess ***at least*** one 1, that are either bigrams, trigrams or 4-grams. A sequence with multiple 1s denote entities that are close to each other, while sequences with a solitary 1 denote that an entity is just mentioned once and we do not come across it again for a number of sentences.

4.2 Gaze-based Features

The gaze-based features are dependent on the gaze behaviour of the participant with respect to interest areas.

[6]`https://writing.wisc.edu/Handbook/Transitions.html`

[7]`http://www.nltk.org/`

[8]We found that using GloVe here and Google News for the mean word vectors worked best.

[9]`https://pypi.python.org/pypi/pyenchant/`

Fixation Features

The **First Fixation Duration** (FFD) shows the time the reader fixates on a word when he / she first encounters it. An increased FFD intuitively could mean that the word is more complex and the reader spends more time in understanding the word (Mishra et al., 2016).

The **Second Fixation Duration** (SFD) is the duration in which the reader fixates on a particular interest area the second time. This happens during a regression, when a reader is trying to link the word he / she just read with an earlier word.

The **Last Fixation Duration** (LFD) is the duration in which the reader fixates on a particular interest area the final time. At this point, we believe that the interest area has been processed.

The **Dwell Time** (DT) is the total time the reader fixates on a particular interest area. Like first fixation, this also measures the complexity of the word, not just by itself, but also with regard to the entire text (since it takes into account fixations when the word was regressed, *etc.*)

The **Fixation Count** (FC) is the number of fixations on a particular interest area. A larger fixation count could mean that the reader frequently goes back to read that particular interest area.

Regression Features

IsRegression (IR) is the number of interest areas where a regression happened before reading ahead and **IsRegressionFull** (IRF) is the number of interest areas where a regression happened. The **Regression Count** (RC) is the total number of regressions. The **Regression Time** (RT) is the duration of the regressions from an interest area. These regression features could help in modeling semantic links for coherence and cohesion.

Interest Area Features

The **Skip Count** (SC) is the number of interest areas that have been skipped. The **Run Count** (RC) is the number of interest areas that have at least one fixation. A larger run count means that more interest areas were fixated on. Badly written texts would have higher run counts (and lower skip counts), as well as fixation counts, because the reader will fixate on these texts for a longer time to understand them.

5 Experiment Details

In this section, we describe our experimental setup, creation of the dataset, evaluation metric, classifier details, *etc.*

5.1 Ordinal Classification vs. Regression

For each of the properties - organization, coherence and cohesion, we make use of a Likert scale, with scores of 1 to 4. Details of the scores are given in Table 2. For scoring the quality, we use the formula described in the Introduction. Since we used a Likert scale, we make use of ordinal classification, rather than regression. This is because each of the grades is a discrete value that can be represented as an ordinal class (where $1 < 2 < 3 < 4$), as compared to a continuous real number.

5.2 Evaluation Metric

For the predictions of our experiments, we use Cohen's Kappa with quadratic weights - quadratic weighted Kappa (QWK) (Cohen, 1968) because of the following reasons. Firstly, unlike accuracy and F-Score, Cohen's Kappa takes into account whether or not agreements happen by chance. Secondly, weights (either linear or quadratic) take into account distance between the given score and the expected score, unlike accuracy and F-score where mismatches (either 1 vs. 4, or 1 vs.2) are penalized the same. Quadratic weights reward matches and penalize mismatches more than linear weights.

To measure the Inter-Annotator Agreement of our raters, we make use of Gwet's second-order agreement coefficient (Gwet's AC2) as it can handle ordinal classes, weights, missing values, and multiple raters rating the same document (Gwet, 2014).

5.3 Creation of the Dataset

In this subsection, we describe how we created our dataset. We describe the way we made the texts, the way they were annotated and the inter-annotator agreements for the different properties.

Details of Texts

To the best of our knowledge there isn't a publicly available dataset with gaze features for textual quality. Hence, we decided to create our own. Our dataset consists of a diverse set of **30 texts**, from Simple English Wikipedia (**10 articles**), English Wikipedia (**8 articles**), and online news articles (**12 articles**)[10]. We did not wish to overburden the readers, so we kept the size of texts to

[10]The sources for the articles were `https://simple.wikipedia.org`, `https://en.wikipedia.org`, and `https://newsela.com`

Property	Grade	Guidelines
Organization	1	**Bad**. There is no organization in the text.
	2	**OK**. There is little / no link between the paragraphs, but they each describe an idea.
	3	**Good**. Some paragraphs may be missing, but there is an overall link between them.
	4	**Very Good**. All the paragraphs follow a flow from the Introduction to Conclusion.
Coherence	1	**Bad**. The sentences do not make sense.
	2	**OK**. Groups of sentences may make sense together, but the text still may not make sense.
	3	**Good**. Most of the sentences make sense. The text, overall, makes sense.
	4	**Very Good**. The sentences and overall text make sense.
Cohesion	1	**Bad**. There is little / no link between any 2 adjacent sentences in the same paragraph.
	2	**OK**. There is little / no link between adjacent paragraphs. However, each paragraph is cohesive
	3	**Good**. All the sentences in a paragraph are linked to each other and contribute in understanding the paragraph.
	4	**Very Good**. The text is well connected. All the sentences are linked to each other and help in understanding the text.

Table 2: Annotation guidelines for different properties of text.

approximately **200 words** each. The original articles ranged from a couple hundred words (Simple English Wikipedia) to over a thousand words (English Wikipedia). We first summarized the longer articles manually. Then, for the many articles over 200 words, we removed a few of the paragraphs and sentences. In this way, despite all the texts being published, we were able to introduce some poor quality texts into our dataset. The articles were sampled from a variety of genres, such as History, Science, Law, Entertainment, Education, Sports, *etc.*

Details of Annotators

The dataset was annotated by **20 annotators** in the **age** group of **20-25**. Out of the 20 annotators, the distribution was 9 high school graduates (current college students), 8 college graduates, and 3 annotators with a post-graduate degree.

In order to check the **eyesight** of the annotators, we had each annotator look at different parts of the screen. While they did that, we recorded how their fixations were being detected. Only if their fixations to particular parts of the screen tallied with our requests, would we let them participate in annotation.

All the participants in the experiment were **fluent speakers of English**. A few of them scored over 160 in GRE Verbal test and/or over 110 in TOEFL. Irrespective of their appearance in such exams, each annotator was made to take an English test before doing the experiments. The participants had to read a couple of passages, answer comprehension questions and score them for organization, coherence and cohesion (as either good / medium / bad). In case they either got both comprehension questions wrong, or labeled a good passage bad (or vice versa), they failed the test[11].

[11]25 annotators applied, but we chose only 20. 2 of the rejected annotators failed the test, while the other 3 had bad eyesight.

Property	**Full**	**Overall**
Organization	0.610	0.519
Coherence	0.688	0.633
Cohesion	0.675	0.614

Table 3: Inter-Annotator Agreements (Gwet's AC2) for each of the properties.

In order to help the annotators, they were given 5 **sample texts** to differentiate between good and bad organization, coherence and cohesion. Table 1 has some of those texts[12].

Inter-Annotator Agreement

Each of the properties were scored in the range of 1 to 4. In addition, we also evaluated the participant's understanding of the text by asking them a couple of questions on the text. Table 3 gives the inter-annotator agreement for each of the 3 properties that they rated. The column **Full** shows the agreement only if the participant answered both the questions correct. The **Overall** column shows the agreement irrespective of the participant's comprehension of the text.

5.4 System Details

We conducted the experiment by following standard norms in eye-movement research (Holmqvist et al., 2011). The display screen is kept **about 2 feet** from the reader, and the camera is placed midway between the reader and the screen. The reader is seated and the position of his head is fixed using a chin rest.

Before the text is displayed, we calibrate the camera by having the participant fixate on **13**

[12]The texts for good and bad organization are too long to provide in this paper. They will be uploaded in supplementary material.

points on the screen and validate the calibration so that the camera is able to predict the location of the eye on the screen accurately. After calibration and validation, the text is displayed on the screen in **Times New Roman** typeface with **font size 23**. The reader reads the text and while that happens, we record the reader's eye movements. The readers were allowed to take **as much time as they needed** to finish the text. Once the reader has finished, the reader moves to the next screen.

The next two screens each have a question that is based on the passage. These questions are used to verify that the reader did not just skim through the passage, but understood it as well. The questions were multiple choice, with 4 options[13]. The questions test literal comprehension (where the reader has to recall something they read), and interpretive comprehension (where the reader has to infer the answer from the text they read). After this, the reader scores the texts for organization, coherence and cohesion. The participants then take a short break (about 30 seconds to a couple of minutes) before proceeding with the next text. This is done to prevent reading fatigue over a period of time. After each break, we recalibrate the camera and validate the calibration again.

For obtaining gaze features from a participant, we collect gaze movement patterns using an SR Research Eye Link 1000 eye-tracker (monocular stabilized head mode, sampling rate 500Hz). It is able to collect all the gaze details that we require for our experiments. Reports are generated for keyboard events (message report) and gaze behaviour (interest area report) using SR Research Data Viewer software.

5.5 Classification Details

We also process the articles for obtaining the text features as described in Section 4. Given that we want to show the utility of gaze features, we ran each of the following classifiers with 3 feature sets - only text, only gaze, and all features.

We split the data into a training - test split of sizes **70%** and **30%**. We used a Feed Forward Neural Network with **1 hidden layer** containing **100 neurons** (Bebis and Georgiopoulos, 1994)[14]. The size of the input vector was **361 features**. Out of these, there were **49 text features**, plus **300 dimension word embeddings features**, **11 gaze features**, and **1 class label**. The data was split using stratified sampling, to ensure that there is a similar distribution of classes in each of the training and test splits. The Feed Forward Neural Network was implemented using TensorFlow (Abadi et al., 2015) in Python. We ran the neural network over **10,000 epochs**, with a learning rate of **0.001** in **10 batches**. The loss function that we used was the **mean square error**.

In order to see how much the participant's understanding of the text would reflect on their scoring, we also looked at the data based on how the participant scored in the comprehension questions after they read the article. We split the articles into 2 subsets here - $Full$, denoting that the participant answered both the questions correctly, and $Partial$, denoting that they were able to answer only one of the questions correctly. The readers showed $Full$ understanding in **269 instances** and $Partial$ understanding in **261 instances**. We used the same setup here (same training - test split, stratified sampling, and feed forward neural network). We omit the remaining **70 instances** where the participant got none of the questions correct, as the participant could have scored the texts completely randomly.

6 Results and Analysis

Table 4 shows the results of our experiments using the feed forward neural network classifier. The first column is the property being evaluated. The next 3 columns denote the results for the Text, Gaze and Text+Gaze feature sets.

Property	**Text**	**Gaze**	**Text+Gaze**
Organization	0.237	0.394	**0.563**
Coherence	0.261	0.285	**0.550**
Cohesion	0.120	0.229	**0.451**
Quality	0.230	0.304	**0.552**

Table 4: QWK scores for the three feature sets on different properties.

The QWK scores are the predictions which we obtain with respect to the scores of all the 30 documents, scored by all 20 raters. Textual features when augmented with gaze based features show significant improvement for all the properties.

[13]**Example Passage Text**: The text in Figure 1
Question: "How many states did Ronald Reagan win in both his Presidential campaigns?"
Correct Answer: "93" (44+49)

[14]We also used other classifiers, like Naive Bayes, Logistic Regression and Random Forest. However, the neural network outperformed them.

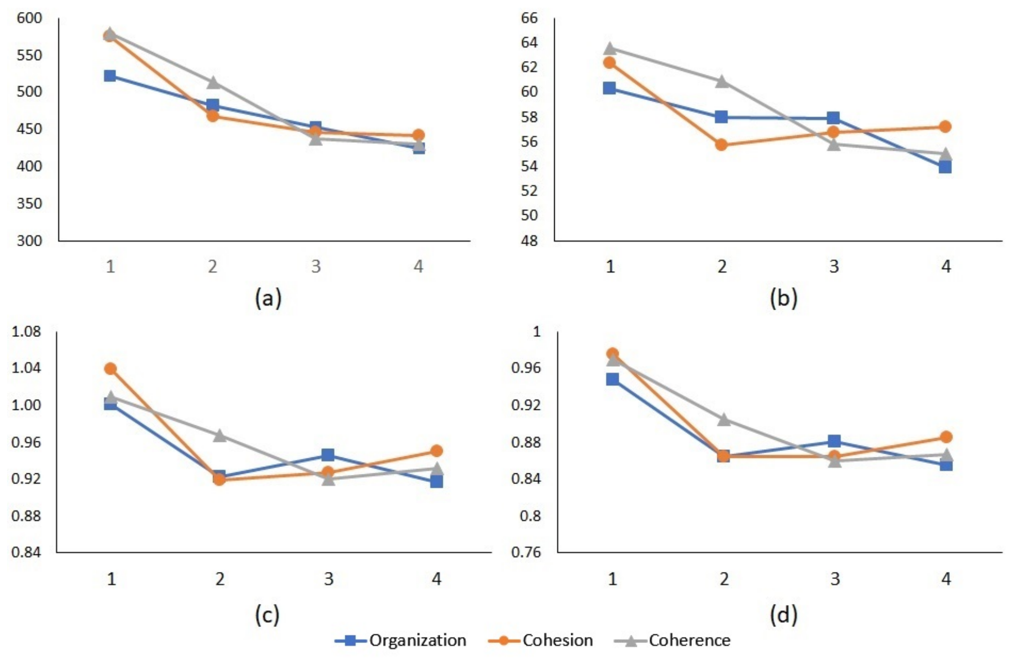

Figure 2: Relation between some of the different gaze features and the score. The gaze features are (a) RD, (b) SFD, (c) FC and (d) RC. For figures (a) and (b), the units on the y-axis are milliseconds. For figures (c) and (d) the numbers are a ratio to the number of interest areas in the text. The x-axis in all 4 graphs is the score given by the annotators.

We check the statistical significance of improvement of adding gaze based features for the results in Table 4. To test our hypothesis - that adding gaze features make a statistically significant improvement - we run the t-test. Our null hypothesis: Gaze based features do not help in prediction, any more than text features themselves, and whatever improvements happen when gaze based features are added to the textual features, are not statistically significant. We choose a significance level of $p < 0.001$. For all the improvements, we found them to be statistically significant above this α level, rejecting our null hypothesis.

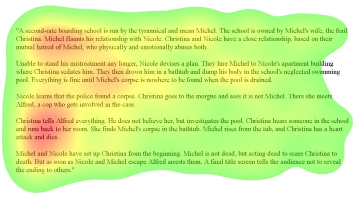
We also evaluate how the participant's understanding of the text affects the way they score the text. Table 5 shows the results of our experiments taking the reader's comprehension into account. The first column is the property being evaluated. The second column is the level of comprehension - $Full$ for the passages where the participant answered both the questions correctly, and $Partial$ for the passages where the participant answered one question correctly. The next 3 columns show the results using the Text feature set, the Gaze feature set, and both (Text+Gaze) feature sets. From this table, we see that wherever the gaze features are used, there is far greater agreement for those with $Full$ understanding as compared to $Partial$ understanding.

Property	**Comp.**	**Text**	**Gaze**	**Text+Gaze**
Organization	Full	**0.319**	**0.319**	**0.563**
	Partial	0.115	0.179	0.283
Coherence	Full	0.255	**0.385**	**0.601**
	Partial	**0.365**	0.343	0.446
Cohesion	Full	**0.313**	**0.519**	**0.638**
	Partial	0.161	0.155	0.230
Quality	Full	**0.216**	**0.624**	**0.645**
	Partial	0.161	0.476	0.581

Table 5: QWK scores for the three feature sets on different properties categorized on the basis of reader comprehension.

Figure 2 shows a clear relationship between some of the gaze features and the scores given by readers for the properties - organization, cohesion and coherence. In all the charts, we see that texts with the lowest scores have the longest durations (regression / fixation) as well as counts (of fixations and interest areas fixated).

Figure 3 shows the fixation heat maps for 3 texts whose quality scores were good (10), medium (6) and bad (3), read by the same participant. From these heat maps, we see that the text rated good has highly dense fixations for only a part of the text,



"A second-rate boarding school is run by the tyrannical and mean Michel. The school is owned by Michel's wife, the frail Christina. Michel flaunts his relationship with Nicole. Christina and Nicole have a close relationship, based on their mutual hatred of Michel, who physically and emotionally abuses both.

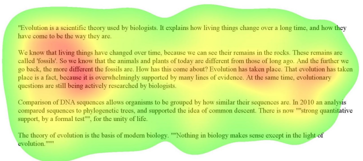
Unable to stand his mistreatment any longer, Nicole devises a plan. They lure Michel to Nicole's apartment building where Christina sedates him. They then drown him in a bathtub and dump his body in the school's neglected swimming pool. Everything is fine until Michel's corpse is nowhere to be found when the pool is drained.

Nicole learns that the police found a corpse. Christina goes to the morgue and sees it is not Michel. There she meets Alfred, a cop who gets involved in the case.

Christina tells Alfred everything. He does not believe her, but investigates the pool. Christina hears someone in the school and runs back to her room. She finds Michel's corpse in the bathtub. Michel rises from the tub, and Christina has a heart attack and dies.

Michel and Nicole have set up Christina from the beginning. Michel is not dead, but acting dead to scare Christina to death. But as soon as Nicole and Michel escape Alfred arrests them. A final title screen tells the audience not to reveal the ending to others."

(a) Good (rated 10)



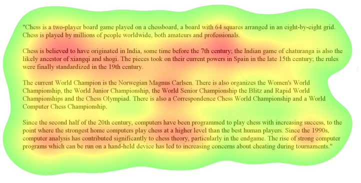
"Evolution is a scientific theory used by biologists. It explains how living things change over a long time, and how they have come to be the way they are.

We know that living things have changed over time, because we can see their remains in the rocks. These remains are called 'fossils'. So we know that the animals and plants of today are different from those of long ago. And the further we go back, the more different the fossils are. How has this come about? Evolution has taken place. That evolution has taken place is a fact, because it is overwhelmingly supported by many lines of evidence. At the same time, evolutionary questions are still being actively researched by biologists.

Comparison of DNA sequences allows organisms to be grouped by how similar their sequences are. In 2010 an analysis compared sequences to phylogenetic trees, and supported the idea of common descent. There is now ""strong quantitative support, by a formal test"", for the unity of life.

The theory of evolution is the basis of modern biology. ""Nothing in biology makes sense except in the light of evolution."""

(b) Medium (rated 6)



"Chess is a two-player board game played on a chessboard, a board with 64 squares arranged in an eight-by-eight grid. Chess is played by millions of people worldwide, both amateurs and professionals.

Chess is believed to have originated in India, some time before the 7th century; the Indian game of chaturanga is also the likely ancestor of xiangqi and shogi. The pieces took on their current powers in Spain in the late 15th century; the rules were finally standardized in the 19th century.

The current World Champion is the Norwegian Magnus Carlsen. There is also organizes the Women's World Championship, the World Junior Championship, the World Senior Championship the Blitz and Rapid World Championships and the Chess Olympiad. There is also a Correspondence Chess World Championship and a World Computer Chess Championship.

Since the second half of the 20th century, computers have been programmed to play chess with increasing success, to the point where the strongest home computers play chess at a higher level than the best human players. Since the 1990s, computer analysis has contributed significantly to chess theory, particularly in the endgame. The rise of strong computer programs which can be run on a hand-held device has led to increasing concerns about cheating during tournaments."

(c) Bad (rated 3)

Figure 3: Fixation heatmap examples for one of the participants from SR Research Data Viewer software.

as compared to the medium and bad texts. This shows that badly written texts force the readers to fixate a lot more than well-written texts.

6.1 Ablation Tests

In order to see which of the gaze feature sets is important, we run a set of ablation tests. We ablate the fixations, regressions and interest area feature sets one at a time. We also ablated each of the **individual gaze features**.

Property	Fixation	Regression	Interest Areas
Organization	-0.102	-0.017	**-0.103**
Coherence	-0.049	-0.077	**-0.088**
Cohesion	-0.015	**-0.040**	0.037
Quality	0.002	0.016	**-0.056**

Table 6: **Difference** in QWK scores when ablating three gaze behaviour feature sets for different properties.

Table 6 gives the result of our ablation tests on the three feature sets - fixation, regression and interest area feature sets. The first column is the property that we are measuring. The next 3 columns denote the **difference** between the predicted QWK that we got from ablating the fixation, regression and interest area feature sets. We found that the Interest Area feature set was the most important, followed by fixation and regression.

Among the individual features, **Run Count** (RC) was found to be the most important for organization and quality. **First Fixation Duration** (FFD) was the most important feature for coherence, and **IsRegressionFull** (IRF) was the most important feature for cohesion. We believe that this is because the number of interest areas that are fixated on at least once and the number of interest areas that are skipped play an important role in determining how much of the text was read and how much was skipped. However, for cohesion, regression features are the most important, because they show a link between the cohesive clues (like lexis, references, *etc.*) in adjacent sentences.

7 Conclusion and Future Work

We presented a novel approach to predict reader's rating of texts. The approach estimates the overall quality on the basis of three properties - organization, coherence and cohesion. Although well defined, predicting the score of these properties for a text is quite challenging. It has been established that cognitive information such as gaze behaviour can help in such subjective tasks (Mishra et al., 2013, 2016). We hypothesized that gaze behavior will assist in predicting the scores of text quality. To evaluate this hypothesis, we collected gaze behaviour data and evaluated the predictions using only the text-based features. When we took gaze behaviour into account, we were able to significantly improve our predictions of organization, coherence, cohesion and quality. We found out that, in all cases, there was an improvement in the agreement scores when the participant who rated the text showed full understanding, as compared to partial understanding, using only the Gaze features and the Text+Gaze features. This indicated that gaze behaviour is more reliable when the reader has understood the text.

To the best of our knowledge, our work is pioneering in using gaze information for predicting text quality rating. In future, we plan to use use approaches, like multi-task learning (Mishra et al., 2018), in estimating gaze features and using those estimated features for text quality prediction.

Multi-Input Attention for Unsupervised OCR Correction

Rui Dong **David A. Smith**
College of Computer Information and Science
Northeastern University
{dongrui, dasmith}@ccs.neu.edu

Abstract

We propose a novel approach to OCR post-correction that exploits repeated texts in large corpora both as a source of noisy target outputs for unsupervised training and as a source of evidence when decoding. A sequence-to-sequence model with attention is applied for single-input correction, and a new decoder with multi-input attention averaging is developed to search for consensus among multiple sequences. We design two ways of training the correction model without human annotation, either training to match noisily observed textual variants or bootstrapping from a uniform error model. On two corpora of historical newspapers and books, we show that these unsupervised techniques cut the character and word error rates nearly in half on single inputs and, with the addition of multi-input decoding, can rival supervised methods.

1 Introduction

Optical character recognition (OCR) software has made vast quantities of printed material available for retrieval and analysis, but severe recognition errors in corpora with low quality of printing and scanning or physical deterioration often hamper accessibility (Chiron et al., 2017). Many digitization projects have employed manual proofreading to further correct OCR output (Holley, 2009), but this is time consuming and depends on fostering a community of volunteer workers. These problems with OCR are exacerbated in library-scale digitization by commercial (e.g., Google Books, Newspapers.com), government (e.g., Library of Congress, Bibliothèque nationale de France), and nonprofit (e.g., Internet Archive) organizations. The scale of these projects not only makes it difficult to adapt OCR models to their diverse layouts and typefaces but also makes it impractical to present any OCR output other than a single-best transcript.

Existing methods for automatic OCR post-correction are mostly supervised methods that correct recognition errors in a single OCR output (Kolak and Resnik, 2002; Kolak et al., 2003; Yamazoe et al., 2011). Those systems are not scalable since human annotations are expensive to acquire, and they are not capable of utilizing complementary sources of information. Another line of work is ensemble methods (Lund et al., 2013, 2014) combining OCR results from multiple scans of the same document. Most of these ensemble methods, however, require aligning multiple OCR outputs (Lund and Ringger, 2009; Lund et al., 2011), which is intractable in general and might introduce noise into the later correction stage. Furthermore, voting-based ensemble methods (Lund and Ringger, 2009; Wemhoener et al., 2013; Xu and Smith, 2017) only work where the correct output exists in one of the inputs, while classification methods (Boschetti et al., 2009; Lund et al., 2011; Al Azawi et al., 2015) are also trained on human annotations.

To address these challenges, we propose an *unsupervised* OCR post-correction framework both to correct *single* input text sequences and also to exploit *multiple* candidate texts by simultaneously *aligning, correcting, and voting among input sequences*. Our proposed method is based on the observation that significant number of duplicate and near-duplicate documents exist in many corpora (Xu and Smith, 2017), resulting in OCR output containing repeated texts with various quality. As shown by the example in Table 1, different errors (characters in red) are introduced when the OCR system scans the same text in multiple editions, each with its own layout, fonts, etc. For example, `in` is recognized as `m` in the first output and `a` is recognized as `u` in the third output, while the second output is correctly recognized. Therefore, duplicated texts with diverse errors could serve as complementary information sources for each other.

OCR Output	eor**y that I have been slam in battle, for 1 sorry that I have been slain in battle, for I sorry tha' I have been s_uin in battle, f_r I
Original Text	sorry that I have been slain in battle, for I

Table 1: Example duplicate texts in OCR'd digital corpora

In this paper, we aim to train an unsupervised correction model via utilizing the duplication in OCR output. We propose to map each erroneous OCR'd text unit to either its high-quality duplication or a consensus correction among its duplications via bootstrapping from an uniform error model. The baseline correction system is a sequence-to-sequence model with attention (Bahdanau et al., 2015), which has been shown to be effective in text correction tasks (Chollampatt et al., 2016; Xie et al., 2016).

We also seek to improve the correction performance for duplicated texts by integrating multiple inputs. Previous work on combining multiple inputs in neural translation deal with data from different domains, e.g., multilingual (Zoph and Knight, 2016) or multimodal (Libovický and Helcl, 2017) data. Therefore, their models need to be trained on multiple inputs to learn parameters to combine inputs from each domain. Given that the inputs of our task are all from the same domain, our model is trained on a single input and introduces multi-input attention to generate a consensus result merely for decoding. It does not require learning extra parameters for attention combination and thus is more efficient to train. Furthermore, average attention combination, a simple multi-input attention mechanism, is proposed to improve both the effectiveness and efficiency of multi-input combination on the OCR post-correction task.

We experiment with both **supervised and unsupervised training** and with **single- and multi-input decoding** on data from two manually transcribed collections in English with diverse typefaces, genres, and time periods: newspaper articles from the Richmond (Virginia) Daily Dispatch (RDD) from 1860–1865 and books from 1500–1800 from the Text Creation Partnership (TCP). For both collections, which were manually transcribed by other researchers and are in the public domain, we aligned the one-best output of an OCR system to the manual transcripts. We also aligned the OCR in the training and evaluation sets to other public-domain newspaper issues (from the Library of Congress) and books (from the Internet Archive) to find multiple duplicates as "witnesses", where available, for each line. Experimental results on both datasets show that our proposed averarge attention combination mechanism is more effective than existing methods in integrating multiple inputs. Moreover, our noisy error correction model achieves comparable performance with the supervised model via multiple-input decoding on duplicated texts.

In summary, our contributions are: (1) a scalable framework needing no supervision from human annotations to train the correction model; (2) a multi-input attention mechanism incorporating aligning, correcting, and voting on multiple sequences simultaneously for consensus decoding, which is more efficient and effective than existing ensemble methods; and (3) a method that corrects text either with or without duplicated versions, while most existing methods can only deal with one of these cases.

2 Data Collection

We perform experiments on one-best OCR output from two sources: two million issues from the Chronicling America collection of historic U.S. newspapers, which is the largest public-domain full-text collection in the Library of Congress;[1] and three million public-domain books in the Internet Archive.[2]

For supervised training and for evaluation, we aligned manually transcribed texts to these one-best OCR transcripts: 1384 issues of the Richmond (Virginia) Daily Dispatch from 1860–1865 (RDD)[3] and 934 books from 1500–1800 from the

[1] `chroniclingamerica.loc.gov`: Historical newspapers also constitute the largest digitized text collections in the Australian National Library (Trove) and the Europeana consortium.

[2] `https://archive.org/details/texts`. Google Books and the Hathi Trust consortium also hold many in-copyright books and require licensing agreements to access public-domain materials.

[3] `dlxs.richmond.edu/d/ddr/`: the transcription from the University of Richmond includes all articles but only some advertisements.

Text Creation Partnership (TCP).[4] Both of these manually transcribed collections, which were produced independently from the current authors, are in the public domain and in English, although both Chronicling America and the Internet Archive also contain much non-English text.

To get more evidence for the correct reading of an OCR'd line, we aligned each OCR'd RDD issue to *other* issues of the RDD and other newspapers from Chronicling America and aligned each OCR'd TCP page to other pre-1800 books in the Internet Archive. To perform these alignments between noisy OCR transcripts efficiently, we used methods from our earlier work on text-reuse analysis (Smith et al., 2014; Wilkerson et al., 2015). An inverted index of hashes of word 5-grams was produced, and then all pairs from different pages in the same posting list were extracted. Pairs of pages with more than five shared hashed 5-grams were aligned with the Smith-Waterman algorithm with equal costs for insertion, deletion, and substitution, which returns a maximally aligned subsequence in each pair of pages (Smith and Waterman, 1981). Aligned passages that were at least five lines long in the target RDD or TCP text were output. For each target OCR line—i.e., each line in the training or test set—there are thus, in addition to the ground-truth manual transcript, zero or more **witnesses** from similar texts, to use the term from textual criticism.

In our experiments on OCR correction, each training and test example is a line of text following the layout of the scanned image documents[5]. The average number of characters per line is 42.4 for the RDD newspapers and 53.2 for the TCP books. Table 2 lists statistics for the number of OCR'd text lines with manual transcriptions and additional witnesses. 43% of the manually transcribed lines have witnesses in the RDD newspapers, and 64% of them have witnesses in the TCP books. In the full Chronicling America data, 44% of lines align to at least one other witness. Although not all OCR collections will have this level of repetition, it is notable that these collections, which are some of the largest public-domain digital libraries, do exhibit this kind of reprinting. Similarly, at least 25% of the pages in Google's web crawls are duplicates (Henzinger, 2006). Although we exploit text reuse, where available, to improve decoding and unsupervised training, we also show (Table 5) significant improvements to OCR accuracy with only a single transcript.

Dataset	# Lines w/manual	# Lines w/manual & witnesses
RDD	2.2M	0.95M (43%)
TCP	8.6M	5.5M (64%)

Table 2: Statistics for the number of OCR'd lines in million (M) from the Richmond Dispatch and TCP Books with manual transcriptions (Column 1) or with both transcriptions and multiple witnesses (Column 2).

3 Methods

In this section, we first define our problem in §3.1, followed by model description. In general, we train an OCR error correction model via an attention-based RNN encoder-decoder, which takes a single erroneous OCR'd line as input and outputs the corrected text (§3.2). At decoding time, multi-input attention combination strategies are introduced to allow the decoder to integrate information from multiple inputs (§3.3). Finally, we discuss several unsupervised settings for training the correction model in §3.4.

3.1 Problem Definition

Given a line of OCR'd text $\mathbf{x}$, comprising the sequence of characters $[x_1, \cdots, x_{T_S}]$, our goal is to map it to an error-free text $\mathbf{y} = [y_1, \cdots, y_{T_T}]$ via modeling $p(\mathbf{y}|\mathbf{x})$. Given $p(\mathbf{y}|\mathbf{x})$, we also seek to model $p(\mathbf{y}|\mathbf{X})$ to search for consensus among duplicated texts $\mathbf{X}$, where $\mathbf{X} = [\mathbf{x}_1, \cdots, \mathbf{x}_N]$ are duplicated lines of OCR'd text.

3.2 Attention-based Seq2Seq Model

Similar to previous work (Bahdanau et al., 2015), the encoder is a bidrectional RNN (Schuster and Paliwal, 1997) that converts source sequence $\mathbf{x} = [x_1, \cdots, x_{T_S}]$ into a sequence of RNN states $\mathbf{h} = [h_1, \cdots, h_{T_S}]$, where $h_i = [\overrightarrow{h}_i, \overleftarrow{h}_i]$ is a concatenation of both forward and backward hidden states at time step $i (1 \leq i \leq T_S)$. We have

$$\overrightarrow{h}_i = f(x_i, \overrightarrow{h}_{i-1}); \quad \overleftarrow{h}_i = f(x_i, \overleftarrow{h}_{i+1}), \quad (1)$$

here f is the dynamic function, e.g., LSTM (Hochreiter and Schmidhuber, 1997) or GRU (Cho et al., 2014).

The decoder RNN predicts the output sequence $\mathbf{y} = [y_1, \cdots, y_{T_T}]$, through the following dynamics and prediction model:

$$s_t = f(y_{t-1}, s_{t-1}, c_t); \quad (2)$$

[4] www.textcreationpartnership.org

[5] The datasets can be downloaded from http://www.ccs.neu.edu/home/dongrui/ocr.html

$$p(y_t|y_{<t}, \mathbf{x}) = g(y_{t-1}, s_t, c_t), \tag{3}$$

where s_t is the RNN state and c_t is the context vector at time t. y_t is the predicted symbol from the target vocabulary at time t via prediction function $g(\cdot)$. The context vector is given as a linear combination of the encoder hidden states:

$$c_t = \sum_{i=1}^{T_S} \alpha_{t,i} h_i; \quad \alpha_{t,i} = \frac{e^{\eta(s_{t-1}, h_i)}}{\sum_\tau e^{\eta(s_{t-1}, h_\tau)}} \tag{4}$$

where $\alpha_{t,i}$ is the weight for each hidden state h_i and η is the function that computes the strength of each encoder hidden state according to current decoder hidden state. The loss function is the cross-entropy loss per time step summed over the output sequence y:

$$L(\mathbf{x}, \mathbf{y}) = -\sum_{t=1}^{T_S} \log p(y_t|\mathbf{x}, y_{<t}) \tag{5}$$

3.3 Multi-input Attention

Given a trained Seq2Seq model $p(\mathbf{y}|\mathbf{x})$, our goal is to combine multiple input sequences $\mathbf{X}$ to generate the target sequence $\mathbf{y}$, i.e., to utilize information from multiple sources at decoding time. Assume that N relevant source sequences $\mathbf{X} = [\mathbf{x}_1, \cdots, \mathbf{x}_N]$ are observed, where each sequence $\mathbf{x}_l = [x_{l,1}, \cdots, x_{l,T_l}]$ $(1 \le l \le N)$ and T_l is the length of the l^{th} sequence. Then, a sequence of hidden states $\mathbf{h}_l = [h_{l,1}, \cdots, h_{l,T_l}]$ is generated by the encoder network for each input sequence $\mathbf{x}_l$. At each decoding time step t, the decoder searches through encoder hidden states $\mathbf{H} = [\mathbf{h}_1, \cdots, \mathbf{h}_N]$ to compute a global context vector c_t. Different strategies to combine attention from multiple encoders are described as follows.

Flat Attention Combination. Flat attention combination assigns a weight $\alpha_{t,l,i}$ to each encoder hidden state $h_{l,i}$ for each input sequence $\mathbf{x}_l$ as:

$$\alpha_{t,l,i} = \frac{e^{\eta(s_{t-1}, h_{l,i})}}{\sum_{l'=1}^{N} \sum_{\tau=1}^{T_{l'}} e^{\eta(s_{t-1}, h_{l',\tau})}}. \tag{6}$$

Therefore, the global context vector is given by

$$c_t = \sum_{l=1}^{N} \sum_{i=1}^{T_l} \alpha_{t,l,i} h_{l,i}. \tag{7}$$

Flat attention combination is similar to single-input decoding in that it concatenates all inputs into a long sequence, except that the encoder hidden states are computed independently for each input.

Hierarchical Attention Combination. The structure of hierarchical attention combination is presented in Figure 1. We first compute a context vector for each input as:

$$\mathbf{c}_{t,l} = \sum_{i=1}^{T_l} \alpha_{t,l,i} h_{l,i}; \quad \alpha_{t,l,i} = \frac{e^{\eta(s_{t-1}, h_{l,i})}}{\sum_{\tau=1}^{T_l} e^{\eta(s_{t-1}, h_{l,\tau})}}. \tag{8}$$

Then a global context vector c_t is computed as a weighted sum of all the context vectors:

$$c_t = \sum_{i=1}^{N} \beta_{t,l} c_{t,l}, \tag{9}$$

where $\beta_{t,l}$ is the weight assigned to each context vector $c_{t,l}$ and computed in different ways as follows:

(a) *Weighted Attention Combination.* In weighted attention combination, the weight for each context vector is given by its dot product with the decoder state in the transformed common space:

$$\beta_{t,l} = \frac{e^{\eta(s_{t-1}, c_{t,l})}}{\sum_{l'=1}^{N} e^{\eta(s_{t-1}, \mathbf{c}_{t,l'})}}. \tag{10}$$

(b) *Average Attention Combination.* In average attention combination, each input sequence is treated as equally weighted. Thus $\beta_{t,l} = \frac{1}{N}$ for each input sequence $\mathbf{x}_l$. It is more efficient than the weighted attention combination in that it does not need to compute a weight for each input.

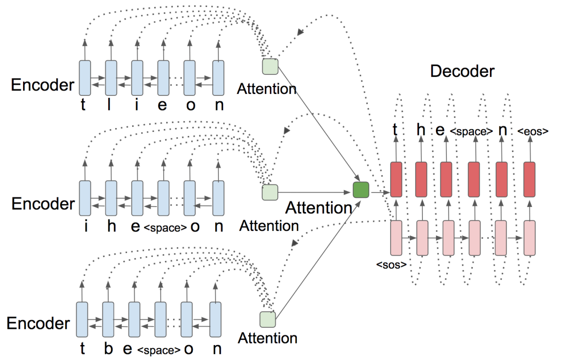

Figure 1: Hierarchical attention combination.

These attention-combination methods do not have parameters trained on multiple inputs and are only introduced at decoding time. In contrast, Libovický and Helcl (2017) and Zoph and Knight (2016) introduce parameters for each type of input and require training and decoding with the same number of inputs.

3.4 Training Settings

In this section, we introduce different settings for training our correction model, a single-input attention-based Seq2Seq model (§3.2), which transforms each OCR'd text line into a corrected version generated via different mechanisms.

Supervised Training. In this setting, the correction model is trained to map each OCR'd line into the corresponding manual transcription, i.e., the human annotation. We call the correction model trained in this setting Seq2Seq-Super.

Unsupervised Training. In the absence of ground truth transcriptions, we can use different methods to generate a noisy corrected version for each OCR'd line.

(a) *Noisy Training.* In this setting, the correction model is trained to transform each OCR'd text line to a selected high-quality witness. The quality of the witnesses is measured by a 5-gram character language model built on the New York Time Corpus (Sandhaus, 2008) with KenLM toolkit (Heafield, 2011). For each OCR'd line with multiple witnesses, a score is assigned to each witness by the language model, divided by the number of characters in it to reduce the effect of the length of a witness. Then a witness with the highest score is chosen as the noisy ground truth for each line. Those lines with low score for all witnesses are removed. We call the correction model trained in this setting Seq2Seq-Noisy.

(b) *Synthetic Training.* In this setting, the error correction model is trained to recover a manually corrupted out-of-domain corpus. We construct the synthetic dataset by injecting uniformly distributed insertion, deletion and substitution errors into the New York Times corpus. Firstly, the news articles are split into lines with random length between $[1, 70]$ following a Gaussian distribution $N(45, 5)$, which is similar to that of the real world dataset. Then, a certain number of lines are randomly selected and injected with equal number of insertion, deletion and substitution errors. The correction model is then trained to recover the original line from each corrupted line. We call this model Seq2Seq-Syn.

(c) *Synthetic Training with Bootstrapping.* In this setting, we propose to further improve the performance of synthetic training via bootstrapping. The correction model trained on synthetic dataset does not perform well when correcting a given input from real world dataset, due to their difference in error distributions. But it achieves comparable performance with the supervised model when decoding lines with multiple witnesses, since the model could further benefit from jointly aligning and voting among multiple inputs. Thus, with the multi-input attention mechanism introduced in §3.3, we first generate a high-quality consensus correction for each OCR'd line with witnesses via the correction model trained on synthetic data. Then, the a bootstrapped model is trained to transform those lines into their consensus correction results. We call the correction model trained in this setting Seq2Seq-Bootstrap.

4 Experiments

In this section, we first introduce the details of our experimental setup (§4.1). Then, the results of preliminary experiments comparing the performance of different options for the single-input Seq2Seq model and the multi-input attention combination strategies are presented in §4.2. The main experimental results for evaluating the correction model trained in different training settings and decoded with/without multi-input attention are reported and explained in §4.3. Further discussions of our model are described in §4.4.

4.1 Experimental Setup

We begin by describing the data split, training details, baseline systems, and evaluation metrics.

4.1.1 Training Details

For both RDD newspapers and TCP books, we randomly split the OCR'd lines into 80% training and 20% test either by the date of the newspaper or by the name of the books. For the RDD newspapers, we have 1.7M training lines and 0.44M test lines. For the TCP books, 2.8M lines are randomly sampled from the whole training set for different training settings to conduct a fair comparison with noisy training, and about 1.6M lines are used for testing.

Both the encoder and decoder of our model has 3 layers with 400 hidden units for each layer, where GRU is applied as the dynamic function. Adam optimizer with a learning rate of 0.0003 and default decay rates is used to train the correction model . We train up to 40 epochs with a minibatch size of 128 and select the model with the lowest perplexity on the development set. The decoder implements beam search with a beam width of 100.

4.1.2 Baselines and Comparisons

In preliminary experiments, we first compare the neural translation model (§3.2) with a commonly used Seq2Seq model, pruned conditional random fields (PCRF) (Schnober et al., 2016) on the single-input correction task. CRF models have been shown to be very competitve on tasks such as OCR post-correction, spelling correction, and lemmatization. After that, we compare the different multi-input attention strategies introduced in §3.3 on multi-input correction task to choose the best strategy for the main experiments.

In the main experiment, we compare the performance of correction models trained in different training settings and decode with and without multiple witnesses. Two ensembles methods, language model ranking (LMR) and majority vote (Xu and Smith, 2017), are also considered as unsupervised baseline methods. LMR chooses a single high-quality witness for each OCR'd line by a language model as the correction for that line. Majority vote first aligns multiple input sequences using a greedy pairwise algorithm (since multiple sequence alignment is intractable) and then votes on each position in the alignment, with a slight advantage given to the original OCR output in case of ties. We also tried to use an exact unsupervised method for consensus decoding based on dual decomposition (Paul and Eisner, 2012). Their implementation, unfortunately, turned out not to return a certificate of completion on most lines in our data even after thousands of iterations.

4.1.3 Evaluation Metrics

Word error rate (WER) and character error rate (CER) are used to compare the performance of each method. Case is ignored. Lattice word error rate (LWER) and lattice character error rate (LCER) are also computed as the oracle performance for each method, which could reveal the capability of each model to be applied to downstream tasks taking lattices as input, e.g., reranking or retrieval of the correction hypotheses (Taghva et al., 1996; Lam-Adesina and Jones, 2006). We compute the macro average for each type of error rate, which allows us to use a paired permutation significance test.

4.2 Preliminary Experiments

In this section, we conduct two preliminary experiments to study different options for both the single-input correction models and the multi-input attention combination strategies.

4.2.1 Single Input Correction Model

Model	CER	WER
None	0.18133	0.41780
PCRF$_{(order=5,w=4)}$	0.11403	0.25116
PCRF$_{(order=5,w=6)}$	0.11535	0.25617
Attn	**0.11028***	**0.23405***

Table 3: CER and WER on single-input correction for PCRF and Attn-Seq2Seq on RDD newspapers. Results from Attn-Seq2Seq that are significantly better than the PCRF are highlighted with *($p < 0.05$, paired permutation test). The best result for each column is in **bold**.

We first compare the attention-based Seq2Seq (Attn-Seq2Seq) model, with a traditional Seq2Seq model, PCRF, on single input correction task. As the PCRF implementation of Schnober et al. (2016) is highly memory and time consuming for training on long sequences, we compare it with Attn-Seq2Seq model on a smaller dataset with 100K lines randomly sampled from RDD newspapers training set. The trained correction model is then applied to correct the full test set. CER and WER of the correction results from both models are listed in Table 3. We can find that the Attn-Seq2Seq neural translation model works significantly better than the PCRF when trained on a dataset of the same size. The performance of the Attn-Seq2seq model could be further improved by including more training data or by multi-input decoding for duplicated texts, while the PCRF could only be trained on limited data and is not able to work on multiple inputs. Thus, we choose Attn-Seq2Seq as our error correction model.

4.2.2 Multi-input Attention Combination

We also compare different attention combination strategies on a multi-input decoding task. The results from Table 4 reveal that average attention combination performs best among all the decoding strategies on RDD newspapers and TCP books datasets. It reduces the CER of single input decoding by 41.5% for OCR'd lines in RDD newspapers and 9.76% for TCP books. The comparison between two hierarchical attention combination strategies shows that averaging evidence from each input works better than a weighted summation mechanism. Flat attention combination, which merges all the inputs into a long sequence when computing the strength of each encoder hidden state, obtains the worst performance in terms

Best result for each column is in **bold**.

of both CER and WER.

4.3 Main Results

We now present results on the full training and test sets for the Richmond Daily Dispatch newspapers and Text Creation Partnership books. All results are on the same test set. The multi-input decoding experiments have access to additional witnesses for each line, where available, but fall back to single-input decoding when no additional witnesses are present for a given line.

Table 5 presents the results for our model trained in different training settings as well as the baseline language model reranking (LMR) and majority vote methods. Multiple input decoding performs better than single input decoding for every training setting, and the model trained in supervised mode with multi-input decoding achieves the best performance. The majority vote baseline, which works only on more than two inputs, performs worst on both the TCP books and RDD newspapers. Our proposed unsupervised framework Seq2Seq-Noisy and Seq2Seq-Boots achieves performance comparable with the supervised model via multi-input decoding on the RDD newspaper dataset. The performance of Seq2Seq-Noisy is worse on the TCP Books than the RDD newspapers, since those old books contain the character long **s** [6], which is formerly used where **s** occurred in the middle or at the beginning of a word. These characters are recognized as **f** in all the witnesses because of similar shape. Thus, the model trained on noisy data are unable to correct them into **s**. Nonetheless, by removing the factor of long **s**, i.e., replacing the long **s** in the ground truth with **f**, Seq2Seq-Noisy could achieve a CER of 0.062 for single-input decoding and 0.058 for multi-input decoding on the TCP books. Both Seq2Seq-Syn and Seq2Seq-Boots work better on the RDD newspapers than the TCP books dataset. We conjecture that it is because the synthetic dataset is trained on (modern) newspapers, which are more similar to the nineteenth-century RDD newspapers. The long **s** problem also makes it more difficult for the model trained on synthetic data to work on the TCP books.

4.4 Discussion

In this section, we provide further analysis on different aspects of our method.

Does Corruption Rate Affect Synthetic Training? We first examine how the corruption rate of the synthetic dataset would affect the performance of the correction model. Figure 2 presents the results of single-input correction and multi-input correction tasks on the RDD newspapers and TCP books when trained on synthetic data corrupted with different error rate: 0.9, 0.12, 0.15. For both tasks, the character error rate increases a little bit when the correction model is trained to recover the synthetic date with higher corruption rate. However, the performance is more stable on the RDD newspapers than the TCP books when more errors are introduced.

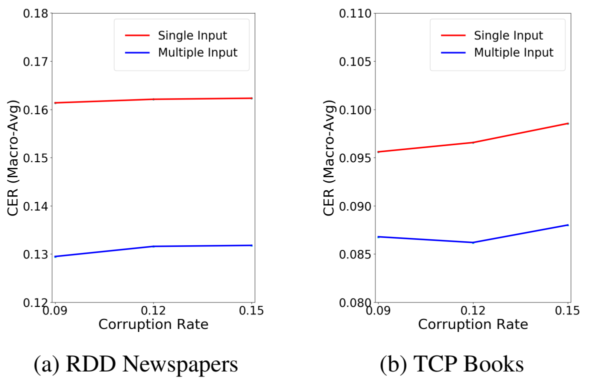

Figure 2: Performance of Seq2Seq-Syn trained on synthetic data with different corruption rates.

Does Number of Witnesses Matter for Multiple-Input Decoding? Here we want to study the impact of the number of witnesses on

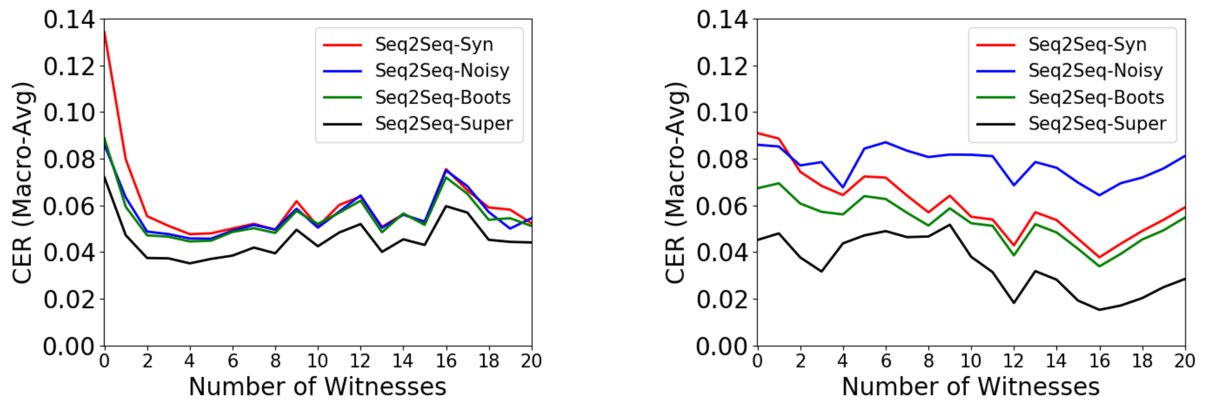
Table 5: Results from model trained under different settings on single-input decoding and multiple-input decoding for both the RDD newspapers and TCP books. All training is unsupervised except for supervised results in *italics*. Unsupervised training settings with multi-input decoding that are significantly better than other unsupervised counterparts are highlighted with * ($p < 0.05$, paired-permutation test). Best result among **unsupervised** training in each column is in **bold**.



(a) RDD Newspapers (b) TCP Books

Figure 3: Performance of different models on multiple decoding of lines with different number of witnesses.

the performance of multiple-input decoding. The test set is divided into subgroups with varying size according to their number of witnesses. Figure 3 presents the performance of multi-input correction on subgroups with different number of witnesses. We can see that supervised training achieves the best performance on each subgroup for both datasets. On the RDD newspapers, the performance of each training setting is significantly improved when the number of witnesses increases from 0 to 2, then the error rate tends to be flat when more witnesses are observed. For the TCP books, the character error rate for both Seq2Seq-Syn and Seq2Seq-Boots decreases with small fluctuation when the number of witnesses increases. Seq2Seq-Noisy performs the worst almost on all subgroups on the TCP books since all the witnesses suffers from the long **s** problem.

Can More Training Data Benefit Learning? Figure 4 shows the test results for our correction model trained on datasets of different size. As the size of the training set increases, the CER of our model decreases consistently for both single and multiple input correction on the RDD newspapers. However, the performance curve of correction model on TCP books dataset is flatter since it is larger overall than RDD newspapers.

5 Related Work

Multi-Input OCR Correction. Ensemble methods have been shown to be effective in OCR post-correction by combining OCR output from multiple scans of the same document (Lopresti and Zhou, 1997; Klein and Kopel, 2002; Cecotti and Belaïd, 2005; Lund et al., 2013). Existing methods aim at generating consensus results by aligning multiple inputs, followed by supervised methods such as classification (Boschetti et al., 2009; Lund et al., 2011; Al Azawi et al., 2015), or unsupervised methods such as dictionary-based selection (Lund and Ringger, 2009) and voting (Wemhoener et al., 2013; Xu and Smith, 2017). While supervised ensemble methods require human annotation for training, unsupervised selection methods work only when the correct word or character exists in one of the inputs. Furthermore, those methods could not correct single inputs.

Multi-Input Attention. Multi-input attention has already been explored in tasks such as machine translation (Zoph and Knight, 2016; Libovický and Helcl, 2017) and summarization (Wang and Ling, 2016). Wang and Ling (2016) propose to concatenate multiple inputs to generate a summary; this flat attention combination model might be affected by the order of input sequences. Zoph and Knight (2016) aims at developing a multi-source translation model on a trilingual corpus where the encoder for each language is combined to pass to the decoder; however, it requires the same number of inputs at training and decoding time since the parameters depend on the number of inputs. Libovický and Helcl (2017) explore different attention combination strategies for multiple information sources such as image and text. In contrast, our method does not require multiple inputs for training, and the attention combination strategies are used to integrate multiple inputs when decoding.

6 Conclusions

We have proposed an unsupervised framework for OCR error correction, which can handle both single-input and multi-input correction tasks. An attention-based sequence-to-sequence model is applied for single-input correction, based on which a strategy of multi-input attention combination is designed to correct multiple input sequences simultaneously. The proposed strategy naturally incorporates aligning, correcting, and voting among multiple sequences, and is thus effective in improving the correction performance for corpora containing duplicated text. We propose two ways of training the correction model without human annotation by exploiting the duplication in the corpus. Experimental results on historical books and newspapers show that these unsupervised approaches significantly improve OCR accuracy and, when multiple inputs are available, achieve performance comparable to supervised methods.

Abstract

Text in many domains involves a significant amount of named entities. Predicting the entity names is often challenging for a language model as they appear less frequent on the training corpus. In this paper, we propose a novel and effective approach to building a discriminative language model which can learn the entity names by leveraging their entity type information. We also introduce two benchmark datasets based on recipes and Java programming codes, on which we evaluate the proposed model. Experimental results show that our model achieves 52.2% better perplexity in recipe generation and 22.06% on code generation than the state-of-the-art language models.

1 Introduction

Language model is a fundamental component in Natural Language Processing (NLP) and it supports various applications, including document generation (Wiseman et al., 2017), text auto-completion (Arnold et al., 2017), spelling correction (Brill and Moore, 2000), and many others. Recently, language models are also successfully used to generate software source code written in programming languages like Java, C, etc. (Hindle et al., 2016; Yin and Neubig, 2017; Hellendoorn and Devanbu, 2017; Rabinovich et al., 2017). These models have improved the language generation tasks to a great extent, e.g., (Mikolov et al., 2010; Galley et al., 2015). However, while generating text or code with a large number of named entities (e.g., different variable names in source code), these models often fail to predict the entity names properly due to their wide variations. For instance, consider building a language model for generating recipes. There are numerous similar, yet slightly different cooking ingredients (e.g., *olive oil, canola oil, grape oil, etc.*—all are different varieties of oil). Such diverse vocabularies of the ingredient names hinder the language model from predicting them properly.

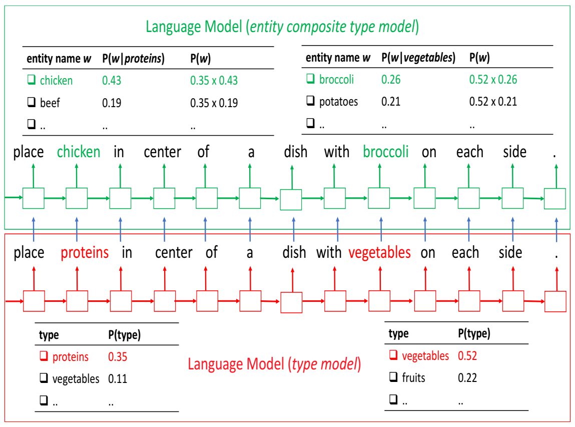
To address this problem, we propose a novel language model for texts with many entity names. Our model learns the probability distribution over all the candidate words by leveraging the entity type information. For example, oil is the *type* for named entities like olive oil, canola oil, grape oil, etc.[1] Such type information is even more prevalent for source code corpus written in statically typed programming languages (Bruce, 1993), since all the variables are by construct associated with types like integer, float, string, etc.

Our model exploits such deterministic type information of the named entities and learns the probability distribution over the candidate words by decomposing it into two sub-components: (i) *Type Model.* Instead of distinguishing the individual names of the same type of entities, we first consider all of them equal and represent them by their type information. This reduces the vocab size to a great extent and enables to predict the type of each entity more accurately. (ii) *Entity Composite Model.* Using the entity type as a prior, we learn the conditional probability distribution of the actual entity names at inference time. We depict our model in Fig. 1.

To evaluate our model, we create two benchmark datasets that involve many named entities. One is a cooking recipe corpus[2] where each recipe contains a number of ingredients which are cate-

[1] Entity type information is often referred as category information or group information. In many applications, such information can be easily obtained by an ontology or by a pre-constructed entity table.

[2] Data is crawled from http://www.ffts.com/recipes.htm.



Language Model (entity composite type model)
entity name w | P(w|proteins) | P(w)
chicken 0.43 0.35 x 0.43
beef 0.19 0.35 x 0.19
entity name w | P(w|vegetables) | P(w)
broccoli 0.26 0.52 x 0.26
potatoes 0.21 0.52 x 0.21
place chicken in center of a dish with broccoli on each side .
place proteins in center of a dish with vegetables on each side .
type | P(type)
proteins 0.35
vegetables 0.11
Language Model (type model)
type | P(type)
vegetables 0.52
fruits 0.22

Figure 1: **An example illustrates the proposed model. For a given context (i.e., types of context words as input), the *type model* (in bottom red block) generates the type of the next word (i.e., the probability of the type of the next word as output). Further, for a given context *and* type of each candidate (i.e., context words, corresponding types of the context words, and type of the next word generated by the *type model* as input), the *entity composite model* (in upper green block) predicts the next word (actual entity name) by estimating the conditional probability of the next word as output. The proposed approach conducts joint inference over both models to leverage type information for generating text.**

gorized into 8 super-ingredients (i.e., type); e.g., “proteins”, “vegetables”, “fruits”, “seasonings”, “grains”, etc. Our second dataset comprises a source code corpus of 500 open-source Android projects collected from GitHub. We use an Abstract Syntax Tree (AST) (Parsons, 1992) based approach to collect the type information of the code identifiers.

Our experiments show that although state-of-the-art language models are, in general, good to learn the frequent words with enough training instances, they perform poorly on the entity names. A simple addition of type information as an extra feature to a neural network does not guarantee to improve the performance because more features may overfit or need more model parameters on the same data. In contrast, our proposed method significantly outperforms state-of-the-art neural network based language models and also the models with type information added as an extra feature.

Overall, followings are our contributions:

- We analyze two benchmark language corpora where each consists of a reasonable number of entity names. While we leverage an existing corpus for recipe, we curated the code corpus. For both datasets, we created auxiliary corpora with entity type information. All the code and datasets are released.[3]
- We design a language model for text consisting of many entity names. The model learns to mention entities names by leveraging the entity type information.
- We evaluate our model on our benchmark datasets and establish a new baseline performance which significantly outperforms state-of-the-art language models.

2 Related Work and Background

Class Based Language Models. Building language models by leveraging the deterministic or probabilistic class properties of the words (a.k.a, class-based language models) is an old idea (Brown et al., 1992; Goodman, 2001). However, the objective of our model is different from the existing class-based language models. The key differences are two-folds: 1) Most existing class-based language models (Brown et al., 1992; Pereira et al., 1993; Niesler et al., 1998; Baker and McCallum, 1998; Goodman, 2001; Maltese et al., 2001) are generative n-gram models whereas ours is a discriminative language model based on neural networks. The modeling principle and assumptions are very different. For example, we cannot calculate the conditional probability by statistical occurrence counting as these papers did. 2) Our approaches consider building two models and perform joint inference which makes our framework general and easy to extend. In Section 4, we demonstrate that our model can be easily incorporated with the state-of-art language model. The closest work in this line is hierarchical neural language models (Morin and Bengio, 2005), which model language with word clusters. However, their approaches do not focus on dealing with named entities as our model does. A recent work (Ji et al., 2017) studied the problem of building up a dynamic representation of named entity by updating the representation for every contextualized mention of that entity. Nonetheless, their approach does not deal with the sparsity issue and their goal is different from ours.

Language Models for Named Entities. In some generation tasks, recently developed language models address the problem of predict-

[3]https://github.com/uclanlp/NamedEntityLanguageModel

ing entity names by copying/matching the entity names from the reference corpus. For example, Vinyals et al. (2015) calculates the conditional probability of discrete output token sequence corresponding to positions in an input sequence. Gu et al. (2016) develops a seq2seq alignment mechanism which directly copies entity names or long phrases from the input sequence. Wiseman et al. (2017) generates document from structured table like basketball statistics using copy and reconstruction method as well. Another related code generation model (Yin and Neubig, 2017) parses natural language descriptions into source code considering the grammar and syntax in the target programming language (e.g., Python). Kiddon et al. (2016) generates recipe for a given goal, and agenda by making use of items on the agenda. While generating the recipe it continuously monitors the agenda coverage and focus on increasing it. All of them are sequence-to-sequence learning or end-to-end systems which differ from our general purpose (free form) language generation task (e.g., text auto-completion, spelling correction).

Code Generation. The way developers write codes is not only just writing a bunch of instructions to run a machine, but also a form of communication to convey their thought. As observed by Donald E. Knuth (Knuth, 1992), *"The practitioner of literate programming can be regarded as an essayist, whose main concern is exposition and excellence of style. Such an author, with thesaurus in hand, chooses the names of variables carefully and explains what such variable means."* Such comprehensible software corpora show surprising regularity (Ray et al., 2015; Gabel and Su, 2010) that is quite similar to the statistical properties of natural language corpora and thus, amenable to large-scale statistical analysis (Hindle et al., 2012). (Allamanis et al., 2017) presented a detailed survey.

Although similar, source code has some unique properties that differentiate it from natural language. For example, source code often shows more regularities in local context due to common development practices like copy-pasting (Gharehyazie et al., 2017; Kim et al., 2005). This property is successfully captured by cache based language models (Hellendoorn and Devanbu, 2017; Tu et al., 2014). Code is also less ambiguous than natural language so that it can be interpreted by a compiler. The constraints for generating correct code is implemented by combining language model and program analysis technique (Raychev et al., 2014). Moreover, code contains open vocabulary—developers can coin new variable names without changing the semantics of the programs. Our model aims to addresses this property by leveraging variable types and scope.

LSTM Language Model. In this paper, we use LSTM language model as a running example to describe our approach. Our language model uses the LSTM cells to generate latent states for a given context which captures the necessary features from the text. At the output layer of our model, we use Softmax probability distribution to predict the next word based on the latent state. Merity et al. (2017) is a LSTM-based language model which achieves the state-of-the-art performance on Penn Treebank (PTB) and WikiText-2 (WT2) datasets. To build our recipe language model we use this as a blackbox and for our code generation task we use the simple LSTM model both in forward and backward direction. A forward directional LSTM starts from the beginning of a sentence and goes from left to right sequentially until the sentence ends, and vice versa. However, our approach is general and can be applied with other types of language models.

3 A Probabilistic Model for Text with Named Entities

In this section, we present our approach to build a language model for text with name entities. Given previous context $\bar{w} = \{w_1, w_2, .., w_{t-1}\}$, the goal of a language model is to predict the probability of next word $P(w_t|\bar{w})$ at time step t, where $w_t \in V^{text}$ and V^{text} is a fixed vocabulary set. Because the size of vocabulary for named entities is large and named entities often occur less frequently in the training corpus, the language model cannot generate these named entities accurately. For example, in our recipe test corpus the word "apple" occurs only 720 times whereas any kind of "fruits" occur 27,726 times. Existing approaches often either only generate common named entities or omit entities when generating text (Jozefowicz et al., 2016).

To overcome this challenge, we propose to leverage the entity type information when modeling text with many entities. We assume each entity is associated with an entity type in a finite set of categories $S = \{s_1, s_2, .., s_i, .., s_k\}$. Given a word w, $s(w)$ reflects its entity type. If the word is a named entity, then we denote $s(w) \in S$; otherwise the type function returns the words itself (i.e, $s(w) = w$). To simplify the notations, we use $s(w) \notin S$ to represent the case where the word is not an entity. The entity type information given by $s(w)$ is an auxiliary information that we can use to improve the language model. We use $s(\bar{w})$ to represent the entity type information of all the words in context $\bar{w}$ and use w to represent the current word w_t. Below, we show that a language model for text with typed information can be decomposed into the following two models: 1) a *type model* θ_t that predicts the entity type of the next word and 2) an *entity composite model* θ_v that predicts the next word based on a given entity type.

Our goal is to model the probability of next word w given previous context $\bar{w}$:

$$P\left(w|\bar{w};\theta_t,\theta_v\right), \tag{1}$$

where θ_t and θ_v are the parameters of the two aforementioned models. As we assume the typed information is given on the data, Eq. (1) is equivalent to

$$P\left(w, s(w)|\bar{w}, s(\bar{w});\theta_t,\theta_v\right). \tag{2}$$

A word can be either a named entity or not; therefore, we consider the following two cases.

Case 1: next word is a named entity. In this case, Eq. (2) can be rewritten as

$$\begin{aligned} &P\left(s(w) = s|\bar{w}, s(\bar{w});\theta_t,\theta_v\right) \times \\ &P\left(w|\bar{w}, s(\bar{w}), s(w) = s;\theta_v,\theta_t\right) \end{aligned} \tag{3}$$

based on the rules of conditional probability.

We assume the type of the next token $s(w)$ can be predicted by a model θ_t using information of $s(\bar{w})$, and we can approximate the first term in Eq. (3)

$$P(s(w)|\bar{w}, s(\bar{w});\theta_t,\theta_v) \approx P(s(w)|s(\bar{w}),\theta_t) \tag{4}$$

Similarly, we can make a modeling assumption to simplify the second term as

$$\begin{aligned} &P(w|\bar{w}, s(\bar{w}), s(w),\theta_v,\theta_t) \\ &\approx P(w|\bar{w}, s(\bar{w}), s(w),\theta_v). \end{aligned} \tag{5}$$

Case 2: next word is not a named entity. In this case, we can rewrite Eq. (2) to be

$$\begin{aligned} &P\left(s(w) \notin S|\bar{w}, s(\bar{w}),\theta_t\right) \times \\ &P\left(w|\bar{w}, s(\bar{w}), s(w) \notin S,\theta_v\right). \end{aligned} \tag{6}$$

The first term in Eq. (6) can be modeled by

$$1 - \sum_{s\in S} P(s(w) = s|s(\bar{w}),\theta_t),$$

which can be computed by the *type* model[4]. The second term can be again approximated by (5) and further estimated by an *entity composition model*.

Typed Language Model. Combine the aforementioned equations, the proposed language model estimates $P(w|\bar{w};\theta_t,\theta_v)$ by

$$P(w|\bar{w}, s(\bar{w}), s(w),\theta_v)\times \\ \begin{cases} P(s(w)|s(\bar{w}),\theta_t) & \text{if } s(w) \in S \\ (1-\sum_{s\in S} P(s(w){=}s|s(\bar{w}),\theta_t)) & \text{if } s(w) \notin S \end{cases} \tag{7}$$

The first term can be estimated by an *entity composite model* and the second term can be estimated by a *type model* as discussed below.

3.1 Type model

The *type model* θ_t estimates the probability of $P(s(w)|s(\bar{w}),\theta_t)$. It can be viewed as a language model builds on a corpus with all entities replaced by their type. That is, assume the training corpus consists of $x = \{w_1, w_2, .., w_n\}$. Using the type information provided in the auxiliary source, we can replace each word w with their corresponding type $s(w)$ and generate a corpus of $\mathcal{T} = \{s(w_i), s(w_2), .., s(w_n)\}$. Note that if w_i is not an named entity (i.e., $s(w) \notin S$), $s(w) = w$ and the vocabulary on $\mathcal{T}$ is $V^{text} \cup S$.[5] Any language modeling technique can be used in modeling the *type model* on the modified corpus $\mathcal{T}$. In this paper, we use the state-of-the-art model for each individual task. The details will be discussed in the experiment section.

3.2 Entity Composite Model

The *entity composite model* predicts the next word based on modeling the conditional probability $P(w|\bar{w}, s(\bar{w}), s(w),\theta_v)$, which can be derived by

$$\frac{P(w|\bar{w}, s(\bar{w});\theta_v)}{\sum_{w_s\in\Omega(s(w))} P(w_s|\bar{w}, s(\bar{w});\theta_v)}, \tag{8}$$

[4]Empirically for the non-entity words, $\sum_{s\in S} P(s(w) = s|s(\bar{w}) \approx 0$

[5]In a preliminary experiment, we consider putting all words with $s(w) \notin S$ in a category "N/A". However, because most words on the training corpus are not named entities, the type "N/A" dominates others and hinder the *type model* to make accurate predictions.

where $\Omega(s(w))$ is the set of words of the same type with w.

To model the types of context word $s(\bar{w})$ in $P(w|\bar{w}, s(\bar{w}); \theta_v)$, we consider learning a type embedding along with the word embedding by augmenting each word vector with a type vector when learning the underlying word representation. Specifically, we represent each word w as a vector of $[v_w(w)^T; v_t(s(w))^T]^T$, where $v_w(\cdot)$ and $v_t(\cdot)$ are the word vectors and type vectors learned by the model from the training corpus, respectively. Finally, to estimate Eq. (8) using θ_v, when computing the Softmax layer, we normalize over only words in $\Omega(s(w))$. In this way, the conditional probability $P(w|\bar{w}, s(\bar{w}), s(w), \theta_v)$ can be derived.

3.3 Training and Inference Strategies

We learn model parameters θ_t and θ_v independently by training two language models *type model* and *entity composite model* respectively. Given the context of type, *type model* predicts the type of the next word. Given the context and the type information of the all candidate words, *entity composite model* predicts the conditional actual word (e.g., entity name) as depicted in Fig 1. At inference time the generated probabilities from these two models are combined according to conditional probability (i.e., Eq. (7)) which gives the final probability distribution over all candidate words[6].

Our proposed model is flexible to any language model, training strategy, and optimization. As per our experiments, we use ADAM stochastic mini-batch optimization (Kingma and Ba, 2014). In Algorithm 1, we summarize the language generation procedure.

Algorithm 1: **Language Generation**

```
Input: Language corpus
       $\mathcal{X} = \{w_1, w_2, .., w_n\}$, type $s(w)$ of
       the words, integer number $m$.
Output: $\theta_t$, $\theta_v$, $\{W_1, W_2, .., W_m\}$
1  Training Phase:
2  Generate $\mathcal{T}$ = { $s(w_1), s(w_2), .., s(w_n)\}$
3  Train type model $\theta_t$ on $\mathcal{T}$
4  Train entity composite model $\theta_v$ on $\mathcal{X}$ using
     $[w_i; s(w_i)]$ as input
5  Test Phase (Generation Phase):
6  for $i = 1$ to $m$ do
7      for $w \in V^{text}$ do
8          Compute $P(s(w)|s(\bar{w}), \theta_t)$
9          Compute $P(w|\bar{w}, s(\bar{w}), s(w), \theta_v)$
10         Compute $P(w|\bar{w}; \theta_t, \theta_v)$ using Eq.(7)
11     end
12     $W_i \leftarrow \text{argmax}_w P(w|\bar{w}; \theta_t, \theta_v)$
13 end
```

4 Experiments

We evaluate our proposed model on two different language generation tasks where there exist a lot of entity names in the text. In this paper, we release all the codes and datasets. The first task is recipe generation. For this task, we analyze a cooking recipe corpus. Each instance in this corpus is an individual recipe and consists of many ingredients'. Our second task is code generation. We construct a Java code corpus where each instance is a Java method (i.e., function). These tasks are challenging because they have the abundance of entity names and state-of-the-art language models fail to predict them properly as a result of insufficient training observations. Although in this paper, we manually annotate the types of the recipe ingredients, in other applications it can be acquired automatically. For example: in our second task of code generation, the types are found using Eclipse JDT framework. In general, using DBpedia ontology (e.g., "Berlin" has an ontology "Location"), Wordnet hierarchy (e.g., "Dog" is an "Animal"), role in sports (e.g., "Messi" plays in "Forward"; also available in DBpedia[7]), Thesaurus (e.g., "renal cortex", "renal pelvis", "renal vein", all are related to "kidney"), Medscape (e.g., "Advil" and "Motrin" are actually "Ibuprofen"), we can get the necessary type information. As for the applications where the entity types cannot be extracted automatically by these frameworks (e.g., recipe ingredients), although there is no exact strategy, any reasonable design can work. Heuristically, while annotating manually in our first task, we choose the total number of types in such a way that each type has somewhat balanced (similar) size.

We use the same dimensional word embedding

[6]While calculating the final probability distribution over all candidate words, with our joint inference schema, a strong state-of-art language model, without the type information, itself can work sufficiently well and replace the *entity composite model*. Our experiments using (Merity et al., 2017) in Section 4.1 validate this claim.

[7] http://dbpedia.org/page/Lionel_Messi

(400 for recipe corpus, 300 for code corpus) to represent both of the entity name (e.g., "apple") and their entity type (e.g., "fruits") in all the models. Note that in our approach, the *type model* only replaces named entities with entity type when it generates next word. If next word is not a named entity, it will behave like a regular language model. Therefore, we set both models with the same dimensionality. Accordingly, for the *entity composite model* which takes the concatenation of the entity name and the entity type, the concatenated input dimension is 800 and 600 respectively for recipe and code corpora.

4.1 Recipe Generation

Recipe Corpus Pre-processing: Our recipe corpus collection is inspired by (Kiddon et al., 2016). We crawl the recipes from "Now Youre Cooking! Recipe Software" [8]. Among more than 150,000 recipes in this dataset, we select similarly structured/formatted (e.g, title, blank line then ingredient lists followed by a recipe) 95,786 recipes. We remove all the irrelevant information (e.g., author's name, data source) and keep only two information: ingredients and recipes. We set aside the randomly selected 20% of the recipes for testing and from the rest, we keep randomly selected 80% for the training and 20% for the development. Similar to (Kiddon et al., 2016), we preprocess the dataset and filter out the numerical values, special tokens, punctuation, and symbols.[9] Quantitatively, the data we filter out is negligible; in terms of words, we keep 9,994,365 words out of 10,231,106 and the number of filter out words is around $\sim$2%. We release both of the raw and cleaned data for future challenges. As the ingredients are the entity names in our dataset, we process it separately to get the type information.

Retrieving Ingredient Type: As per our type model, for each word w, we require its type $s(w)$. We only consider ingredient type for our experiment. First, we tokenize the ingredients and consider each word as an ingredient. We manually classify the ingredients into 8 super-ingredients: "fruits", "proteins", "sides", "seasonings", "vegetables", "dairy", "drinks", and "grains". Sometimes, ingredients are expressed using multiple words; for such ingredient phrase, we classify each word in the same group (e.g., for "boneless beef" both "boneless" and "beef" are classified as "proteins"). We classify the most frequent 1,224 unique ingredients, [10] which cover 944,753 out of 1,241,195 mentions (top 76%) in terms of frequency of the ingredients. In our experiments, we omit the remainder 14,881 unique ingredients which are less frequent and include some misspelled words. The number of unique ingredients in the 8 super ingredients is 110, 316, 140, 180, 156, 80, 84, and 158 respectively. We prepare the modified *type corpus* by replacing each actual ingredient's name w in the original recipe corpus by the type (i.e., super ingredients $s(w)$) to train the *type model*.

Recipe Statistics: In our corpus, the total number of distinct words in vocabulary is 52,468; number of unique ingredients (considering splitting phrasal ingredients also) is 16,105; number of tokens is 8,716,664. In number of instances train/dev/test splits are 61,302/15,326/19,158. The average instance size of a meaningful recipe is 91 on the corpus.

Configuration: We consider the state-of-the art LSTM-based language model proposed in (Merity et al., 2017) as the basic component for building the *type model*, and *entity composite model*. We use 400 dimensional word embedding as described in Section 4. We train the embedding for our dataset. We use a minibatch of 20 instances while training and back-propagation through time value is set to 70. Inside of this (Merity et al., 2017) language model, it uses 3 layered LSTM architecture where the hidden layers are 1150 dimensional and has its own optimization and regularization mechanism. All the experiments are done using PyTorch and Python 3.5.

Baselines: Our first baseline is ASGD Weight-Dropped LSTM (AWD_LSTM) (Merity et al., 2017), which we also use to train our models (see 'Configuration' in 4.1). This model achieves the state-of-the-art performance on benchmark Penn Treebank (PTB), and WikiText-2 (WT2) language corpus. Our second baseline is the same language model (AWD_LSTM) with the type information added as an additional feature (i.e., same as *entity composite model*).

[8]http://www.ffts.com/recipes.htm

[9]For example, in our crawled raw dataset, we find that some recipes have lines like "===MMMMM===" which are totally irrelevant to our task. For the words with numerical values like "100 ml", we only remove the "100" and keep the "ml" since our focus is not to predict the exact number.

[10]We consider both singular and plural forms. The number of singular formed annotated ingredients are 797.

Model	Dataset (Recipe Corpus)	Vocabulary Size	Perplexity
AWD_LSTM	original	52,472	20.23
AWD_LSTM *type model*	modified type	51,675	17.62
AWD_LSTM with type feature	original	52,472	18.23
our model	original	52,472	**9.67**

Table 1: **Comparing the performance of recipe generation task. All the results are on the test set of the corresponding corpus. AWD_LSTM (*type model*) is our *type model* implemented with the baseline language model AWD_LSTM (Merity et al., 2017). Our second baseline is the same language model (AWD_LSTM) with the type information added as an additional feature for each word.**

Results of Recipe Generation. We compare our model with the baselines using *perplexity* metric—lower perplexity means the better prediction. Table 1 summarizes the result. The 3^{rd} row shows that adding type as a simple feature does not guarantee a significant performance improvement while our proposed method significantly outperforms both baselines and achieves 52.2% improvement with respect to baseline in terms of perplexity. To illustrate more, we provide an example snippet of our test corpus: "place onion and ginger inside chicken . allow chicken to marinate for hour .". Here, for the last mention of the word "chicken", the standard language model assigns probability 0.23 to this word, while ours assigns probability 0.81.

4.2 Code Generation

Code Corpus Pre-processing. We crawl 500 Android open source projects from GitHub[11]. GitHub is the largest open source software forge where anyone can contribute (Ray et al., 2014). Thus, GitHub also contains trivial projects like student projects, etc. In our case, we want to study the coding practices of practitioners so that our model can learn to generate quality code. To ensure this, we choose only those Android projects from GitHub that are also present in Google Play Store[12]. We download the source code of these projects from GitHub using an off the shelf tool GitcProc (Casalnuovo et al., 2017).

Since real software continuously evolves to cater new requirements or bug fixes, to make our modeling task more realistic, we further study different project versions. We partition the codebase of a project into multiple versions based on the code commit history retrieved from GitHub; each version is taken at an interval of 6 months. For example, anything committed within the first six months of a project will be in the first version, and so on. We then build our code suggestion task mimicking how a developer develops code in an evolving software—based on the past project history, developers add new code. To implement that we train our language model on past project versions and test it on the most recent version, at method granularity. However, it is quite difficult for any language model to generate a method from the scratch if the method is so new that even the method signature (i.e., method declaration statement consisting of method name and parameters) is not known. Thus, during testing, we only focus on the methods that the model has seen before but some new tokens are added to it. This is similar to the task when a developer edits a method to implement a new feature or bug-fix.

Since we focus on generating the code for every method, we train/test the code prediction task at method level—each method is similar to a sentence and each token in the method is equivalent to a word. Thus, we ignore the code outside the method scope like global variables, class declarations, etc. We further clean our dataset by removing user-defined "String" tokens as they increase the diversity of the vocabularies significantly, although having the same type. For example, the word sequences "Hello World!" and "Good wishes for ACL2018!!" have the same type `java.lang.String.VAR`.

Retrieving Token Type: For every token w in a method, we extract its type information $s(w)$. A token type can be Java built-in data types (e.g., *int, double, float, boolean* etc.,) or user or framework defined classes (e.g., *java.lang.String, io.segment.android.flush.FlushThread* etc.). We extract such type information for each token by parsing the Abstract Syntax Tree (AST) of the source code[13]. We extract the AST type information of each token using Eclipse JDT framework[14]. Note that, language keywords like `for`, `if`, etc. are not associated with any type. Next, we prepare the type corpus by replacing the

[11]https://github.com

[12]https://play.google.com/store?hl=en

[13]AST represents source code as a tree by capturing its abstract syntactic structure, where each node represents a construct in the source code.

[14]https://www.eclipse.org/jdt/

variable names with corresponding type information. For instance, if variable `var` is of type *java.lang.Integer*, in the type corpus we replace *var* by *java.lang.Integer*. Since multiple packages might contain classes of the same name, we retain the fully qualified name for each type[15].

Code Corpus Statistics: In our corpus, the total number of distinct words in vocabulary is 38,297; the number of unique AST type (including all user-defined classes) is 14,177; the number of tokens is 1,440,993. The number of instances used for train and testing is 26,600 and 3,546. Among these 38,297 vocabulary words, 37,411 are seen at training time while the rests are new.

Configuration: To train both *type model* and *entity composite model*, we use forward and backward LSTM (See Section 2) and combine them at the inference/generation time. We train 300-dimensional word embedding for each token as described in Section 4 initialized by GLOVE (Pennington et al., 2014). Our LSTM is single layered and the hidden size is 300. We implement our model on using PyTorch and Python 3.5. Our training corpus size 26,600 and we do not split it further into smaller train and development set; rather we use them all to train for one single epoch and record the result on the test set.

Baselines: Our first baseline is standard LSTM language model which we also use to train our modules (see ‘Configuration’ in 4.2). Similar to our second baseline for recipe generation we also consider LSTM with the type information added as more features[16] as our another baseline. We further compare our model with state-of-the-art token-based language model for source code SLP-Core (Hellendoorn and Devanbu, 2017).

Results of Code Generation: Table 2 shows that adding type as simple features does not guarantee a significant performance improvement while our proposed method significantly outperforms both forward and backward LSTM baselines. Our approach with backward LSTM has 40.3% better perplexity than original backward LSTM and forward has 63.14% lower (i.e., better) perplexity than original forward LSTM. With respect to SLP-Core performance, our model is 22.06% better in perplexity. We compare our model with SLP-Core details in case study-2.

[15]Also the AST type of a very same variable may differ in two different methods. Hence, the context is limited to each method.

[16]LSTM with type is same as *entity composite model*.

Model	Dataset (Code Corpus)	Vocabulary Size	Perplexity
SLP-Core	original	38,297	3.40

bLSTM [*type model*]	modified type	14,177	2.58
bLSTM with type feature	original	38,297	6.11
our model (bLSTM)	original	38,297	**2.65**

Table 2: **Comparing the performance of code generation task. All the results are on the test set of the corresponding corpus. fLSTM, bLSTM denotes forward and backward LSTM respectively. SLP-Core refers to (Hellendoorn and Devanbu, 2017).**

5 Quantitative Error Analysis

To understand the generation performance of our model and interpret the meaning of the numbers in Table 1 and 2, we further perform the following case studies.

5.1 Case Study-1: Recipe Generation

As the reduction of the perplexity does not necessarily mean the improvement of the accuracy, we design a “fill in the blank task” task to evaluate our model. A blank place in this task will contain an ingredient and we check whether our model can predict it correctly. In particular, we choose six ingredients from different frequency range (low, mid, high) based on how many times they have appeared in the training corpus. Following Table shows two examples with four blanks (underlined with the true answer).

Example fill in the blank task
1. Sprinkle <u>chicken</u> pieces lightly with <u>salt</u>.
2. Mix egg and <u>milk</u> and pour over <u>bread</u>.

We further evaluate our model on a multiple choice questioning (MCQ) strategy where the fill in the blank problem remains same but the options for the correct answers are restricted to the six ingredients. Our intuition behind this case-study is to check when there is an ingredient whether our model can learn it. If yes, we then quantify the learning using standard *accuracy* metric and compare with the state-of-the-art model to evaluate how much it improves the performance. We also measure how much the accuracy improvement depends on the training frequency.

Table 3 shows the result. Our model outperforms the fill in the blank task for both cases,

Ingredient	Train Freq.	#Blanks	Accuracy Free-Form AWD_LSTM	Accuracy Free-Form Our	Accuracy MCQ AWD_LSTM	Accuracy MCQ Our
Milk	14, 136	4,001	26.94	**59.34**	80.83	**94.90**
Salt	33,906	9,888	37.12	**62.47**	89.29	**95.75**
Apple	7,205	720	1.94	**30.28**	37.65	**89.86**
Bread	11,673	3,074	32.43	**52.64**	78.85	**94.53**
Tomato	12,866	1,815	2.20	**35.76**	43.53	**88.76**
Chicken	19,875	6,072	22.50	**45.24**	77.70	**94.63**

Table 3: **Performance of fill in the blank task.**

i.e., without any options (free-form) and MCQ. Note that, the percentage of improvement is inversely proportional to the training frequencies of the ingredients—less-frequent ingredients achieve a higher accuracy improvement (e.g., "Apple" and "Tomato"). This validates our intuition of learning to predict the type first more accurately with lower vocabulary set and then use conditional probability to predict the actual entity considering the type as a prior.

5.2 Case Study-2: Code Generation

Programming language source code shows regularities both in local and global context (e.g., variables or methods used in one source file can also be created or referenced from another library file). SLP-Core (Hellendoorn and Devanbu, 2017) is a state-of-the-art code generation model that captures this global and local information using a nested cache based n-gram language model. They further show that considering such code structure into account, a simple n-gram based SLP-Core outperforms vanilla deep learning based models like RNN, LSTM, etc.

In our case, as our example instance is a Java method, we only have the local context. Therefore, to evaluate the efficiency of our proposed model, we further analyze that exploiting only the type information are we even learning any global code pattern? If yes, then how much in comparison to the baseline (SLP-Core)? To investigate these questions, we provide all the full project information to SLP-Core (Hellendoorn and Devanbu, 2017) corresponding to our train set. However, at test-time, to establish a fair comparison, we consider the perplexity metric for the same methods. SLP-Core achieves a perplexity 3.40 where our backward LSTM achieves 2.65. This result shows that appropriate type information can actually capture many inherent attributes which can be exploited to build a good language model for programming language.

6 Conclusion

Language model often lacks in performance to predict entity names correctly. Applications with lots of named entities, thus, obviously suffer. In this work, we propose to leverage the type information of such named entities to build an effective language model. Since similar entities have the same type, the vocabulary size of a type based language model reduces significantly. The prediction accuracy of the type model increases significantly with such reduced vocabulary size. Then, using the entity type information as prior we build another language model which predicts the true entity name according to the conditional probability distribution. Our evaluation and case studies confirm that the type information of the named entities captures inherent text features too which leads to learn intrinsic text pattern and improve the performance of overall language model.

Acknowledgments

We thank the anonymous reviewers for their insightful comments. We also thank Wasi Uddin Ahmad, Peter Kim, Shou-De Lin, and Paul Mineiro for helping us implement, annotate, and design the experiments. Abstract

Hypertext documents, such as web pages and academic papers, are of great importance in delivering information in our daily life. Although being effective on plain documents, conventional text embedding methods suffer from information loss if directly adapted to hyper-documents. In this paper, we propose a general embedding approach for hyper-documents, namely, `hyperdoc2vec`, along with four criteria characterizing necessary information that hyper-document embedding models should preserve. Systematic comparisons are conducted between `hyperdoc2vec` and several competitors on two tasks, *i.e.,* paper classification and citation recommendation, in the academic paper domain. Analyses and experiments both validate the superiority of `hyperdoc2vec` to other models w.r.t. the four criteria.

1 Introduction

The ubiquitous World Wide Web has boosted research interests on hypertext documents, *e.g.,* personal webpages (Lu and Getoor, 2003), Wikipedia pages (Gabrilovich and Markovitch, 2007), as well as academic papers (Sugiyama and Kan, 2010). Unlike independent plain documents, a hypertext document (hyper-doc for short) links to another hyper-doc by a hyperlink or citation mark in its textual content. Given this essential distinction, hyperlinks or citations are worth specific modeling in many tasks such as link-based classification (Lu and Getoor, 2003), web retrieval (Page et al., 1999), entity linking (Cucerzan, 2007), and citation recommendation (He et al., 2010).

To model hypertext documents, various efforts (Cohn and Hofmann, 2000; Kataria et al., 2010; Perozzi et al., 2014; Zwicklbauer et al., 2016; Wang et al., 2016) have been made to depict networks of hyper-docs as well as their content. Among potential techniques, distributed representation (Mikolov et al., 2013; Le and Mikolov, 2014) tends to be promising since its validity and effectiveness are proven for plain documents on many natural language processing (NLP) tasks.

Conventional attempts on utilizing embedding techniques in hyper-doc-related tasks generally fall into two types. The first type (Berger et al., 2017; Zwicklbauer et al., 2016) simply downcasts hyper-docs to plain documents and feeds them into `word2vec` (Mikolov et al., 2013) (`w2v` for short) or `doc2vec` (Le and Mikolov, 2014) (`d2v` for short). These approaches involve downgrading hyperlinks and inevitably omit certain information in hyper-docs. However, no previous work investigates the information loss, and how it affects the performance of such downcasting-based adaptations. The second type designs sophisticated embedding models to fulfill certain tasks, *e.g.,* citation recommendation (Huang et al., 2015b), paper classification (Wang et al., 2016), and entity linking (Yamada et al., 2016), *etc.* These models are limited to specific tasks, and it is yet unknown whether embeddings learned for those particular tasks can generalize to others. Based on the above facts, we are interested in two questions:

- What information should hyper-doc embedding models preserve, and what nice property should they possess?
- Is there a general approach to learning task-independent embeddings of hyper-docs?

To answer the two questions, we formalize the hyper-doc embedding task, and propose four criteria, *i.e., content awareness*, *context awareness*, *newcomer friendliness*, and *context intent aware-*

ness, to assess different models. Then we discuss simple downcasting-based adaptations of existing approaches w.r.t. the above criteria, and demonstrate that none of them satisfy all four. To this end, we propose hyperdoc2vec (h-d2v for short), a general embedding approach for hyper-docs. Different from most existing approaches, h-d2v learns two vectors for each hyper-doc to characterize its roles of citing others and being cited. Owning to this, h-d2v is able to directly model hyperlinks or citations without downgrading them. To evaluate the learned embeddings, we employ two tasks in the academic paper domain[1], *i.e.,* paper classification and citation recommendation. Experimental results demonstrate the superiority of h-d2v. Comparative studies and controlled experiments also confirm that h-d2v benefits from satisfying the above four criteria.

We summarize our contributions as follows:

- We propose four criteria to assess different hyper-document embedding models.
- We propose hyperdoc2vec, a general embedding approach for hyper-documents.
- We systematically conduct comparisons with competing approaches, validating the superiority of h-d2v in terms of the four criteria.

2 Related Work

Network representation learning is a related topic to ours since a collection of hyper-docs resemble a network. To embed nodes in a network, Perozzi et al. (2014) propose DeepWalk, where nodes and random walks are treated as pseudo words and texts, and fed to w2v for node vectors. Tang et al. (2015b) explicitly embed second-order proximity via the number of common neighbors of nodes. Grover and Leskovec (2016) extend DeepWalk with second-order Markovian walks. To improve classification tasks, Tu et al. (2016) explore a semi-supervised setting that accesses partial labels. Compared with these models, h-d2v learns from both documents' connections and contents while they mainly focus on network structures.

Document embedding for classification is another focused area to apply document embeddings. Le and Mikolov (2014) employ learned d2v vectors to build different text classifiers. Tang et al. (2015a) apply the method in (Tang et al., 2015b) on word co-occurrence graphs for word embeddings, and average them for document vectors. For hyper-docs, Ganguly and Pudi (2017) and Wang et al. (2016) target paper classification in unsupervised and semi-supervised settings, respectively. However, unlike h-d2v, they do not explicitly model citation contexts. Yang et al. (2015)'s approach also addresses embedding hyper-docs, but involves matrix factorization and does not scale.

Citation recommendation is a direct downstream task to evaluate embeddings learned for a certain kind of hyper-docs, *i.e.,* academic papers. In this paper we concentrate on context-aware citation recommendation (He et al., 2010). Some previous studies adopt neural models for this task. Huang et al. (2015b) propose Neural Probabilistic Model (NPM) to tackle this problem with embeddings. Their model outperforms non-embedding ones (Kataria et al., 2010; Tang and Zhang, 2009; Huang et al., 2012). Ebesu and Fang (2017) also exploit neural networks for citation recommendation, but require author information as additional input. Compared with h-d2v, these models are limited in a task-specific setting.

Embedding-based entity linking is another topic that exploits embeddings to model certain hyper-docs, *i.e.,* Wikipedia (Huang et al., 2015a; Yamada et al., 2016; Sun et al., 2015; Fang et al., 2016; He et al., 2013; Zwicklbauer et al., 2016), for entity linking (Shen et al., 2015). It resembles citation recommendation in the sense that linked entities highly depend on the contexts. Meanwhile, it requires extra steps like candidate generation, and can benefit from sophisticated techniques such as collective linking (Cucerzan, 2007).

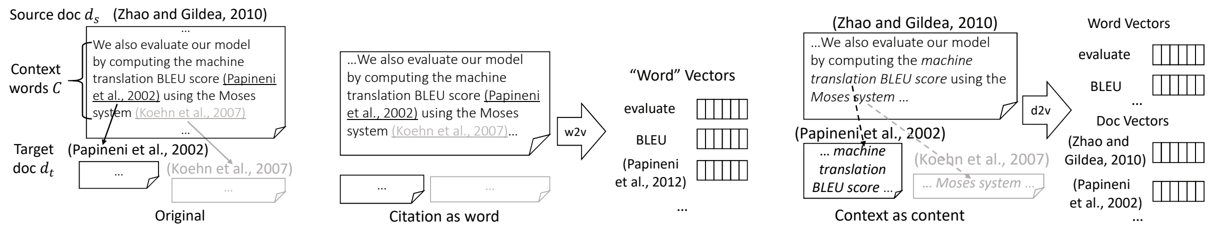
3 Preliminaries

We introduce notations and definitions, then formally define the embedding problem. We also propose four criteria for hyper-doc embedding models w.r.t their appropriateness and informativeness.

3.1 Notations and Definitions

Let $w \in W$ be a word from a vocabulary W, and $d \in D$ be a *document id* (*e.g.,* web page URLs and paper DOIs) from an id collection D. After filtering out non-textual content, a *hyper-document* H is reorganized as a sequence of words and doc ids,

[1]Although limited in tasks and domains, we expect that our embedding approach can be potentially generalized to, or serve as basis to more sophisticated methods for, similar tasks in the entity domain, *e.g.,* Wikipedia page classification and entity linking. We leave them for future work.



(a) Hyper-documents. (b) Citation as word. (c) Context as content.
