For KG embeddings, we follow (Zhang et al., 2019) and pre-train entity embeddings with TransE (Bordes et al., 2013) as the external knowledge. The maximum number of relevant entities selected for each textual token in a question is set to 5. Furthermore, we evaluate the side effects and additional latency of KnowLA. See Appendix B and Appendix C for more details.

4.4 Experiments on Multi-choice QA

To evaluate the effectiveness and robustness of KnowLA, we compare it to Llama 2 and Alpaca2 ($r = 16, 32$) on multi-choice QA. In addition to accuracy, we follow (Shwartz et al., 2020) and compute scores using cross entropy, which indicate the confidence of a model for correct answers. We use three KGs: WordNet, ConceptNet, and Wikidata. We also consider randomly initialized vectors as a baseline of KG embeddings.

Table 1 presents the results. Our KnowLA variants show the best performance across the three datasets. Furthermore, Alpaca2 ($r = 32$) outperforms Alpaca2 ($r = 16$), because more trainable parameters usually lead to better performance.

KAPING generally performs better than Contriever on CommonsenseQA. This indicates that the RAG methods rely on the quality of prompts retrieved from the knowledge sources. Both KAPING and Contriever are inferior to Alpaca2 ($r = 32$) on CommonsenseQA and SIQA, as invalid prompts may cause damage to the performance.

KnowLA is different from RAG methods. RAG methods retrieve text information to augment the input of LLMs, while KnowLA uses KG embeddings to improve the effectiveness of PEFT. KnowLA works in the finetuning phase of LLMs and does not change the input of LLMs. Our method with LoRA ($r = 16$) achieves better performance than all baselines, indicating that it can effectively work with PEFT to inject knowledge. Specifically, when combined with ConceptNet, it achieves an accuracy increase from 56.92% to 58.39% on CommonsenseQA, from 52.61% to 53.22% on SIQA, and from 28.93% to 30.19% on BBH. Since ConceptNet stores rich conceptual knowledge and more relation types compared to WordNet, its entity embeddings can better enhance Llama 2's reasoning ability. Furthermore, ConceptNet recognizes more relevant entities in the question than Wikidata. This suggests that extensive entity coverage in KnowLA brings a significant performance increase.

Additionally, the performance of KnowLA (random) is inferior to that of KnowLA with KGs, highlighting the greater utility of entity knowledge for LLMs. Based on the scores of each model on the correct answers, it can be seen that after incorporating KnowLA, all models assign higher confidence to the correct answers. Therefore, KnowLA can offer a certain degree of improvement for LLMs in commonsense reasoning.

4.5 Experiments on Closed-book QA

We evaluate KnowLA using WebQuestionSP and TriviaQA. Following the answer matching strategy in (Tan et al., 2023), we use the subtree labels provided by the constituent tree to extract all noun phrases from the textual answers, calculate their similarities, and determine the correctness of answers exceeding a certain threshold (e.g., 0.5).

The accuracy results are shown in Table 2. We

Case 1: Who is featured on Puff Daddy's Can't Hold Me Down?

Answer: Mase

Alpaca2: Puff Daddy's 1997 single "Can't Hold Us Down" features R&B singers Faith Evans and 112. It was released as the second single from Puff Daddy's debut album, No Way Out.

KnowLA (ConceptNet): The song "Can't Hold Me Down" by Puff Daddy features R&B singer Faith Evans and rapper Mase. The song was released in 1997 as the lead single from Puff Daddy's debut studio album, No Way Out.

KnowLA (WordNet): The song "Can't Hold Me Down" by Puff Daddy features R&B singer Faith Evans, rapper Mase, and R&B singer 112. It was released in 1997 as the lead single from Puff Daddy's debut album, No Way Out.

Case 2: In Lewis Carroll's poem The Hunting of the Snark, what did the elusive, troublesome snark turn into to fool hunters?

Answer: Boojum

Alpaca2: The elusive, troublesome snark was able to fool the hunters by transforming itself into a variety of shapes and forms. The snark was able to take the shape of a dragon, a boa constrictor, a rhinoceros, a hippopotamus, a crocodile, and a camel.

KnowLA (ConceptNet): The snark was able to fool hunters by transforming into a variety of shapes and forms. The snark first turned into a Boojum, a creature that could only be seen by those who believed in it.

KnowLA (Wikidata): The snark was able to fool the hunters by transforming into a variety of shapes and forms. The snark was able to take the shape of a beetle, a butterfly, a snake, a fish, a bird, and a mouse, all in an attempt to escape the hunters.

Figure 2: Examples of Alpaca2 and KnowLA for TriviaQA.

Methods	WebQuestionSP	TriviaQA
Alpaca2 ($r = 16$)	67.55	68.70
Alpaca2 ($r = 32$)	67.43	67.97
Contriever (Wikipedia)	-	68.71
KAPING (Wikidata)	67.11	66.05
KnowLA (Random)	67.68	69.34
KnowLA (WordNet)	67.43	69.27
KnowLA (ConceptNet)	**68.12**	**69.40**
KnowLA (Wikidata)	67.49	68.92

Table 2: Closed-book QA results on WebQuestionSP and TriviaQA. For KnowLA, $r = 16$.

find that Alpaca2 ($r = 16$) obtains better performance than Alpaca2 ($r = 32$). The reason may be that more parameters in LoRA are prone to overfitting in the closed-book QA tasks. Moreover, Contriever (Wikipedia) only slightly exceeds Alpaca2 ($r = 16$) and performs better than KAPING. This is because KAPING cannot guarantee the correctness of the extracted triples.

According to the results, KnowLA combined with WordNet improves the results from 68.70% to 69.27% on TriviaQA, while combined with ConceptNet, the performance is further enhanced to 69.40%. This indicates that the parameterized entity embeddings can enrich the textual representations. The experimental results demonstrate that the knowledge-enhanced textual representations after finetuning with LoRA can help mitigate the hallucination problem of Llama 2 to some extent.

On WebQuestionSP, KnowLA (WordNet) and KnowLA (Wikidata) produce similar results. Also, the two Alpaca2 models with different ranks perform similarly. This suggests that the reasoning ability of Alpaca2 is good on this task, and the performance does not change significantly after knowledge enhancement with KnowLA. We attribute this bottleneck to the model size and the training data of Llama 2 and Alpaca2.

Methods	BLEU	Rouge-1	Rouge-2	Rouge-L
Alpaca2 ($r = 16$)	0.1657	0.4094	0.2831	0.3892
Alpaca2 ($r = 32$)	0.1637	0.4048	0.2802	0.3851
KnowLA (Random)	0.1677	0.4110	0.2850	0.3897
KnowLA (WordNet)	0.1714	0.4143	0.2874	0.3927
KnowLA (ConceptNet)	**0.1747**	**0.4190**	**0.2922**	**0.3975**
KnowLA (Wikidata)	0.1703	0.4135	0.2895	0.3931

Table 3: Results on TruthfulQA. For KnowLA, $r = 16$.

4.6 Experiments on TruthfulQA

We use TruthfulQA to measure whether KnowLA is truthful in generating answers to questions. Here, we evaluate the content generated by the models based on the best answer provided by TruthfulQA, using the commonly used metrics BLEU, Rouge-1, Rouge-2, and Rouge-L. Table 3 shows the results.

Alpaca2 ($r = 32$) still underperforms Alpaca2 ($r = 16$). This further substantiates our conclusion that larger parameters do not necessarily guarantee the accuracy and reliability of the model's output. KnowLA (ConceptNet) performs best among these models, which indicates that the integration of our KnowLA with LoRA can mitigate the hallucination problem of Llama 2 to some extent and generate content of better quality.

Besides, we observe that KnowLA (ConceptNet) outperforms KnowLA (WordNet) in all evaluation tasks, and KnowLA (WordNet), in turn, surpasses KnowLA (Wikidata). This further indicates that the commonsense knowledge within ConceptNet is more suitable for both LoRA and Llama 2.

4.7 Case Study

Figure 2 presents some improved results of Alpaca2 by incorporating WordNet, ConceptNet, and Wikidata in KnowLA. In Case 1, we discover that after integrating ConceptNet and WordNet with KnowLA, the response precisely describes the correct answers. The contents generated by KnowLA (ConceptNet) and KnowLA (WordNet) are very similar. The content generated by Alpaca2 not only misses significant answers but also misinterprets the song "Can't Hold Me Down" in the question. Therefore, we believe that KnowLA helps the model better understand questions.

By examining the answers of the three models in Case 2, it can be observed that Alpaca2 does not provide an accurate and relevant response, which is similar to the content generated by KnowLA (Wikidata). They both generate deceptive answers. However, after incorporating ConceptNet, KnowLA accurately provides the correct answer in the response. According to Table 2, we believe that the enhancement is not accidental. Moreover, by examining the token-to-entity linking results, we find that *the answer entity "Boojum" does not exist in ConceptNet.* Therefore, we conclude that KnowLA can stimulate the underlying reasoning abilities of LLMs by working with LoRA.

4.8 Why Knowledgeable Adaptation Works?

We delve into why KnowLA collaborates effectively with LoRA, focusing on space alignment of KGs and LLMs, and knowledge recall in LLMs.

Perspective of Space Alignment. Our KnowLA incorporates pre-trained KG embeddings into a pre-trained LLM for instruction tuning with LoRA. We hereby investigate whether the two heterogeneous representation spaces of the KG and the LLM are aligned, to understand how KnowLA works. The results are illustrated in Figure 3, where the last column represents the "sentinel" entity. We first acquire the representations of the input tokens in a specific layer, e.g., the 32nd layer. Then, we retrieve the top five similar entity embeddings in the KG for each token. Next, to establish the relevance of each token and its corresponding entities, we calculate the attention weights between them. A larger weight suggests a stronger semantic correlation between the token and the mapped entity.

In the case of Llama 2 (depicted in the left part of Figure 3), the similarities between entity embeddings and token representations appear to be random, lacking any discernible patterns. However, after applying KnowLA, the results show improved accuracy specifically for the most relevant entities (i.e., e_1 on the x-axis). For token "underrated", the relevant entities in ConceptNet are "underrated", "underrate", etc. After finetuning, the token "underrated" exhibits the highest correlation with the entity "underrated". This observation indicates that KnowLA can effectively align the KG and the LLM through instruction tuning with LoRA.

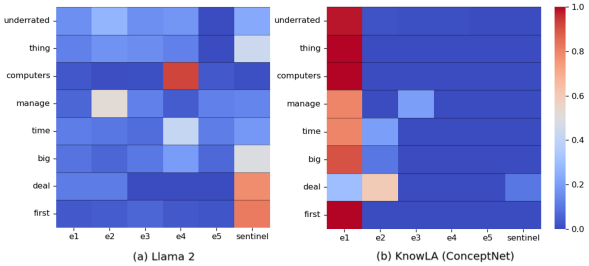

Figure 3: The similarity heatmap between the output representations of text tokens and their corresponding entity embeddings. The x-axis denotes the top-5 similar entities with tokens on the y-axis. (a) The left heatmap presents the similarity of Llama 2 without finetuning, and (b) the right heatmap presents the similarity after finetuning with our KnowLA (ConceptNet).

Perspective of Knowledge Recall. We study the role of KnowLA in activating an LLM's knowledge. According to (Li et al., 2023; Geva et al., 2021; Meng et al., 2022), the feed-forward network (FFN) layers, which constitute two-thirds of an LLM's parameters, primarily capture its own knowledge. So, we explore the impact of KnowLA on the FFN layers to see how KnowLA affects these layers in activating knowledge stored in the LLM.

We compute the differences between the hidden state representations of the last token before and after each FFN layer in the LLM. We analyze the trends in differences of all 32 layers after inserting KnowLA. We use the 100 questions from TriviaQA as queries to explore the knowledge stored in the FFN layers of Llama 2 (7B). The last token representation in each input aggregates information from all tokens. According to (Li et al., 2023), there is a positive correlation between the similarity of hidden states and the consistency of knowledge. Intuitively, we believe that higher differences in representations indicate the model's ability to capture more information from the FFN layers. Therefore, we extract the representations of the last token before and after each FFN layer

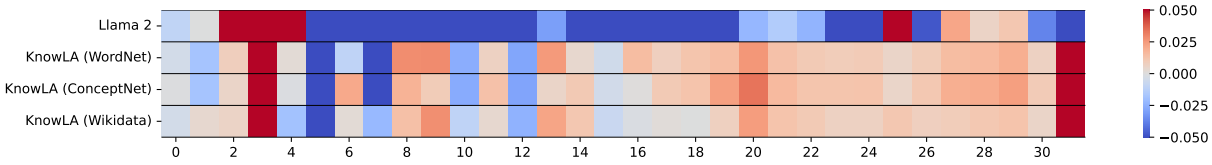

Figure 4: The heatmap indicates the capabilities of KnowLA and Llama 2 in capturing knowledge compared to Alpaca2, which is measured by averaging the changes in cosine similarities of the last token representations from 100 queries across all FFN layers. The x-axis denotes the 32 layers of Llama 2.

and compute the cosine similarities for Llama 2, KnowLA, and Alpaca2, which are denoted by s_1, s_2, and s_3, respectively. Given the token similarities, we further evaluate the capacities of KnowLA and Llama 2 in capturing hidden knowledge. The capacities are measured by $s_3 - s_2$ and $s_3 - s_1$.

The results are shown in Figure 4. The red color indicates that the representation of the last token, after introducing KnowLA and undergoing the FFN layers, exhibits a greater change compared to that of Alpaca2. The blue color shows the opposite. We think the representations with greater changes capture more internal knowledge.

After introducing entity embeddings, KnowLA enables the LLM to activate richer knowledge at the FFN layers. In contrast, Llama 2 captures less knowledge than Alpaca2. According to the work (Geva et al., 2021), lower FFN layers tend to capture shallow knowledge patterns, while higher FFN layers learn more semantic patterns. Our KnowLA demonstrates enhanced knowledge activation capabilities at the higher layers, and thus achieves superior results over Alpaca2. By examining the differences in similarity across the last 16 layers, we find that KnowLA (ConceptNet) shows the greatest similarity difference in the three KGs and performs best on TriviaQA. This further emphasizes that the introduction of ConceptNet substantially activates more knowledge stored internally in Llama 2.

4.9 Impact of KG Embedding Models

The KG embedding learning models are used to learn entity embeddings (Bordes et al., 2013; Nickel et al., 2011; Sun et al., 2019; Chen et al., 2023). We study the impact of embedding learning models for KnowLA. We obtain entity embeddings of ConceptNet by three representative KG embedding models: RESCAL (Nickel et al., 2011), TransE (Bordes et al., 2013), and RotatE (Sun et al., 2019). We show the results of KnowLA with these embeddings on the CommonsenseQA, SIQA, and BBH datasets in Table 4.

	CommonsenseQA		SIQA		BBH	
	Accuracy	Score	Accuracy	Score	Accuracy	Score
RESCAL	**58.39**	46.71	52.10	44.91	27.50	**25.96**
TransE	**58.39**	**48.19**	**53.22**	**46.81**	**30.19**	25.29
RotatE	57.58	46.05	52.00	44.65	27.31	24.94

Table 4: Comparison of KG embedding learning models on CommonsenseQA, SIQA, and BBH, which are pretrained on ConceptNet for Llama 2.

We can observe that the entity embeddings obtained by TransE achieve favorable results. This is attributed to the fact that the TransE embeddings have a good generalization ability and are thus more suitable for Llama 2. RotatE employs complex vector representations for entities and obtains subpar results on Llama 2. This suggests that aligning the complex space of entities with the semantic space of Llama 2 during finetuning is challenging, leading to a loss of original entity knowledge.

4.10 Robustness of KnowLA

We evaluate the robustness of KnowLA against three factors: On the foundation model side, we use LLaMA 1 as another LLM. On the instruction data side, we finetune Llama 2 using the Vicuna multi-round dialog data (Chiang et al., 2023) to get Vicuna2 and KnowLA (Vicuna2). On the PEFT method side, we use AdaLoRA (Zhang et al., 2023) to replace LoRA and get Alpaca2 (AdaLoRA) and KnowLA (AdaLoRA). On the rank side, we finetune Llama 2 using the Alpaca data with rank $r = 8$ and get Alpaca2 ($r = 8$) and KnowLA ($r = 8$).

Table 5 lists the performance of the above models on the commonsense reasoning dataset CommonsenseQA. We can see that the three KnowLA variants still outperform all baselines. This experiment shows that KnowLA is robust and can bring stable improvement when combined with different LLMs, instruction data, PEFT methods, and ranks.

	Methods	Accuracy	Score
LLM side	Alpaca1	56.59	46.03
	KnowLA (LLaMA 1)	**57.74**	**46.81**
Data side	Vicuna2	51.52	42.31
	KnowLA (Vicuna2)	**53.56**	**49.09**
PEFT side	Alpaca2 (AdaLoRA)	57.58	**46.67**
	KnowLA (AdaLoRA)	**57.66**	46.30
Rank side	Alpaca2 ($r = 8$)	56.92	46.25
	KnowLA ($r = 8$)	**57.74**	**46.93**

Table 5: Results with different LLMs, instruction data, PEFT methods, and ranks on CommonsenseQA

5 Conclusion

In this paper, we propose a knowledgeable adaptation method KnowLA. It works with LoRA and injects entity embeddings into an LLM in the PEFT process. Compared to Alpaca2, which is finetuned with LoRA alone, KnowLA with Llama 2 shows better performance on six benchmark datasets. We show that pre-trained KG embeddings are compatible with Llama 2. Moreover, we find that KnowLA can align the KG space and the LLM space, and activate the hidden knowledge related to input in LLMs, thereby achieving improved performance.

Limitations

Currently, our work only incorporates one KG to enhance PEFT. As KGs are incomplete by nature, integrating multiple KGs into our method may further improve performance with knowledge fusion and transfer. Recent work (Huang et al., 2022) reveals that multi-source KG embeddings are more expressive than the embeddings of a single KG. We show preliminary results in Appendix E.1 and will study multi-source KnowLA in future work.

We have not attempted other LLMs such as ChatGLM (Zeng et al., 2023) in this work. In the future, we will consider how to efficiently inject KG knowledge with smaller parameters. Additionally, we have observed that, with the introduction of random perturbations, Llama 2 seems to outperform Alpaca2 on some tasks. This discovery may provide interesting directions for future research.

Ethical Considerations

LLMs may produce incorrect and potentially biased content. Experiments show that our method can alleviate this problem to a certain extent, but LLMs will inevitably generate offensive answers. Therefore, extreme caution should be exercised if deploying such systems in user-facing applications. All datasets and models used in this work are publicly available under licenses.

A Datasets and KGs

The details of the datasets are described as follows:

- In **CommonsenseQA** (Talmor et al., 2019), each sample consists of a question, five candidate answers, and a correct answer. To run LLMs for CommonsenseQA, we adopt the same setting as in (Shwartz et al., 2020) and consider it as a text completion task. We test the LLMs with the validation dataset.
- **SIQA** (Sap et al., 2019) is a QA dataset about social commonsense, where each sample consists of a question, three candidate answers, and a correct answer. To evaluate prompt-based methods, we do not use the provided knowledge in the dataset. The settings are the same as in CommonsenseQA. We test the LLMs with the validation dataset.
- **BBH** (Suzgun et al., 2023) is a popular benchmark that focuses on tasks challenging for LLMs. To compare scores of different methods on correct answers, we select 15 multiple-choice QA datasets from this benchmark.
- **WebQuestionSP** (Yih et al., 2016) is a KBQA dataset that enhances the WebQuestion dataset

Datasets	Alpaca2 ($r = 16$)	KnowLA (ConceptNet)
Temporal sequences	14.80	15.20
Date understanding	72.00	73.20
Geometric shapes	9.20	19.20
Snarks	51.12	53.37
Logical deduction	35.20	36.40

Table 6: Results on knowledge-unrelated tasks

by annotating each answer with corresponding SPARQL queries and removing ambiguous, unclear, or unanswerable questions. In this paper, we treat it as a closed-book QA task.

- **TriviaQA** (Joshi et al., 2017) includes 95K question-answer pairs authored by trivia enthusiasts, which provide high-quality distant supervision for answering the questions. In this paper, we treat it as a closed-book QA task and select 7,500 questions from TriviaQA to test LLMs.
- **TruthfulQA** (Lin et al., 2022) is a benchmark to measure whether a language model is truthful in generating answers to questions.

The used KGs are introduced as follows:

- **WordNet** (Miller, 1995) is a lexical KG in English. Nouns, verbs, adjectives, and adverbs are arranged into synsets, each denoting a separate notion.
- **ConceptNet** (Speer et al., 2017) is a multilingual conceptual KG of things people know and computers should know.
- **Wikidata** (Vrandecic and Krötzsch, 2014) is a factual KG across diverse domains. It encompasses various entity types, including individuals, places, concepts, etc.

B Knowledge-Unrelated Tasks

We analyze the side effects of KnowLA on knowledge-unrelated tasks. In this experiment, five knowledge-unrelated tasks from BBH are picked. The results in Table 6 show that even if these tasks are knowledge-unrelated, our KnowLA can still improve the LLM. This is due to the enhanced ability of the LLM to activate its own knowledge.

C Additional Latency on Efficiency

Retrieving the embeddings of related entities during each finetuning step would slow down the training process. We move it to the data processing step. We use eight workers to process 50,538 training samples in parallel. During inference, we compare the overall inference time of KnowLA (ConceptNet) and Alpaca2 on CommonsenseQA using an A6000 GPU card. Table 7 shows the results.

Models	Data processing	Inference
Alpaca2	9 s	19.02 min.
KnowLA (ConceptNet)	16 s	19.20 min.

Table 7: Time overhead of Alpaca2 and KnowLA

Prompts	Alpaca2 ($r = 16$)	KnowLA (ConceptNet)
Below is an instruction that describes a task, paired with an input that provides further context. Choose a correct answer that appears in the candidate answers.	56.92	58.39
Below is an instruction that describes a task, paired with an input that provides further context. Please answer the following question.	52.74	54.95
Below is an instruction that describes a task, paired with an input that provides further context. Give an answer that appropriately completes the question.	53.73	56.10
Please answer the following question.	55.20	56.35

Table 8: Accuracy of KnowLA when using different prompts on CommonsenseQA

Alpaca2 spends 9 seconds on data processing, while KnowLA (ConceptNet) spends 16 seconds. During inference, KnowLA (ConceptNet) takes 19 minutes and 12 seconds, while Alpaca2 takes 19 minutes and 1 second. We believe that the additional latency caused by KnowLA is tolerable compared to the performance boost.

D Robustness to Different Prompts

We try different prompts to evaluate the robustness of KnowLA. Table 8 compares the accuracy of Alpaca2 ($r = 16$) and KnowLA on CommonsenseQA with different prompts. KnowLA outperforms Alpaca2 on all prompts, indicating its good robustness. We use the first prompt in the main experiments due to its superior performance.

E Discussion on Extension of KnowLA

We hereby discuss the extension of KnowLA to integrate multiple KGs for PEFT and incrementally incorporate knowledge updates in a KG.

E.1 Multiple KGs

To leverage multiple KGs and try to benefit from their potential knowledge transfer, we design a sim-

Methods	Accuracy	Score
KnowLA (WordNet)	58.07	**48.35**
KnowLA (ConceptNet)	**58.39**	48.19
KnowLA (Wikidata)	57.90	47.39
KnowLA (multiple KGs)	57.61	47.24

Table 9: Results of multiple KGs on CommonsenseQA

ple baseline that merges different KGs into a large graph using entity alignment (Sun et al., 2018) and learns entity embeddings from this large KG. If there is no entity alignment, we use entity embeddings from these KGs simultaneously. For balanced training, we limit the maximum number of related entities from each KG to two, and each token has up to six entity embeddings.

In this experiment, we merge WordNet, ConceptNet, and Wikidata. According to Table 9, the accuracy of this baseline on CommonsenseQA is 57.61, which is slightly lower than the result of KnowLA (ConceptNet). We think this straightforward baseline may not effectively leverage knowledge transfer between KGs. A more promising mechanism, e.g., Mixture of Experts (Shen et al., 2024), is necessary to combine multiple KGs. KnowLA is adaptable to integrate this improvement. We leave this direction for future work.

E.2 Knowledge Updates

Knowledge updates for KnowLA require the support of incremental learning for KGs and LLMs. When some new entities and triples are added to a KG, only a small number of parameters need to be re-trained to complete knowledge updates by using lifelong KG embedding learning (Cui et al., 2023) and continual PEFT (Wang et al., 2023).

Extremely Weakly-supervised Text Classification with Wordsets Mining and Sync-Denoising

Lysa Xiao
East China Jiao Tong University / Nanchang, Jiangxi
lissssaxiao@gmail.com

Abstract

Extremely weakly-supervised text classification aims to classify texts without any labeled data, but only relying on class names as supervision. Existing works include prompt-based and seed-based methods. Prompt-based methods prompt language model with instructions, while seed-based methods generate pseudo-labels with word matching. Both of them have significant flaws, including zero-shot instability and context-dependent ambiguities. This paper introduces SetSync, which follows a new paradigm, i.e. wordset-based, which can avoid the above problems. In SetSync, a class is represented with wordsets, and pseudo-labels are generated with wordsets matching. To facilitate this, we propose to use information bottleneck to identify class-relevant wordsets. Moreover, we regard the classifier training as a hybrid learning of semi-supervised and noisy-labels, and propose a new training strategy, termed sync-denoising. Extensive experiments on 11 datasets show that SetSync outperforms all existing prompt and seed methods, exceeding SOTA by an impressive average of 8 points.

1 Introduction

As a fundamental task in NLP, text classification has a wide range of real-world applications. However, the substantial annotation costs present significant challenges and obstacles to its practical implementation. As a result, extremely weakly-supervised text classification (WTC) has garnered considerable attention (Wang et al., 2023a), which requires no human-annotated datasets, but relies solely on the class names as supervision signals to perform the text classification task.

Generally, weakly-supervised text classification involves two main steps: pseudo-labels generation and text classifier training, as shown in Fig. 1. 1) Firstly, pseudo-labels for unlabeled texts are generated according to class names, which can be roughly divided into two major mainstream, namely *prompt* methods (Han et al., 2022a) and *seed* methods (Wang et al., 2021). The prompt methods generate pseudo-labels by prompting language models (e.g. GPT) with instructions, and the seed methods first expand the seed class names into a larger set of related words and then generate pseudo-labels with a matching strategy. Fig. 1 shows a specific example. 2) In the subsequent text classifier training step, the text classifier will be trained on generated pseudo-labels. The training strategies of the classifier mainly include fully-supervised training and self-training, where the former directly trains the classifier on pseudo-labeled data, and the latter utilizes self-training to exploit texts that are not assigned pseudo-labels.

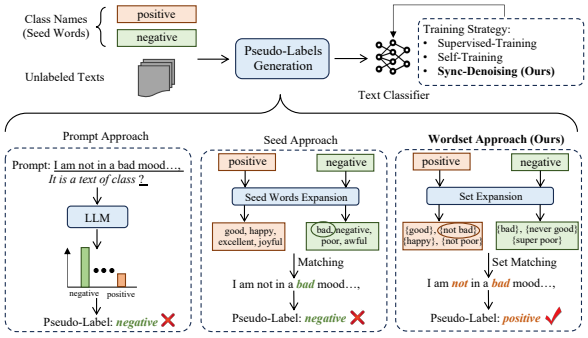

Figure 1: WTC consists of two major steps, namely pseudo-labels generation and classifier training. Firstly, we utilize wordset to generate pseudo-labels, which can avoid the problem of zero-shot instability in prompt methods and the context-dependent in seed methods. Moreover, we regard classifier training in WTC as a hybrid learning of semi-supervised and noisy-labels, and propose a new training strategy called sync-denoising.

Although previous methods have achieved some success, we observe that they are still sub-optimal: 1) Prompt methods tend to have a lower performance, as reported in a recent review (Wang et al., 2023a). This is because language models are known to exhibit bias towards text sequences more common in their pre-training data, which can lead

Proceedings of the 2024 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies (Volume 1: Long Papers), pages 7167–7179
June 16-21, 2024 ©2024 Association for Computational Linguistics

to instability in zero-shot settings. 2) Seed methods are known to be context-dependent and prone to ambiguity. For example, in the case of Fig. 1, the text "I am not in a bad mood" is an example of positive emotion being mislabeled as negative due to the presence of "bad" seed keywords in the negative class. In this case, the combination of "bad" and "not" can express the emotion accurately. Although there have been some methods to solve the context-dependency problem before (Mekala and Shang, 2020; Zhang et al., 2021), we believe that they are still not thorough and perfect enough. 3) Additionally, existing methods do not consider the noise of pseudo-labels in the training of classifier. Specifically, existing WTC works extensively utilize self-training to make full use of samples without any pseudo-labels (Meng et al., 2020b; Zhang et al., 2021). However, during the self-training, incorrect pseudo-labels will lead to the propagation and expansion of errors, ultimately contributing to a decrease in classifier performance.

In this paper, we solve the above problem with a novel framework called **SetSync**, where we embark on enhancing WTC from two primary perspectives: pseudo-labels generation based on word**sets** and classifier training with **sync**-denoising. To begin with, considering the context-dependency ambiguities in seed methods, we believe that individual seed words alone cannot effectively represent a category. Thus, we propose to utilize wordsets to represent a category and generate pseudo-labels, where a wordset is a collection that contains some keywords. For example, {not, bad} and {good} are two wordsets for class positive, while {never, good} is a wordset for class negative, as shown in Fig. 1. The previous seed word expansion can be seen as a special case of ours, where each wordset contains only one word. Thus, with the help of information bottleneck (IB) (Bayat and Wei, 2019) theory, we propose wordsets information bottleneck (WIB) to mine category-related wordsets. Information bottleneck was originally proposed for signal processing, attempts to find a short code of the input signal but preserve maximum information. Contrasting with the continuous nature of signal space, the space of words is inherently discrete. Applying IB directly to wordset mining will face problems such as high time complexity and difficulty in optimization. Therefore, we propose WIB in discrete space, which uses high-frequency filtering combined with frequent itemset mining for optimization.

Moreover, observing pseudo-labels, we can find it is a hybrid setting of semi-supervised and noisy-label learning, i.e. only a portion of the texts have pseudo-labels and they contain errors. Therefore, we propose a new training strategy, named sync-denoising to train the classifier, where noisy pseudo-labels and unlabeled data participate in training synchronously under a unified denoising framework. We assume that the noise levels of pseudo-labels and unlabeled data obey two independent Gaussian distributions and dynamically sample weights from them for denoising learning.

We conducted extensive experiments on 11 text benchmarks. Results show that our method substantially outperforms all existing seed-based and prompt-based methods, improving the accuracy of all 11 datasets by about 8 points on average.

2 Related Work

2.1 Weakly-supervised Text Classification

Weakly-supervised text classification (WTC) aims to use various weakly supervised signals to perform text classification. There are many sources of weak supervision signals, including: 1) external knowledge bases(Gabrilovich et al., 2007; Yin et al., 2019), 2) seed words(Meng et al., 2020b; Zhang et al., 2021; Mekala and Shang, 2020; Wang et al., 2021; Zhao et al., 2023a), 3) heuristic rules(Badene et al., 2019; Shu et al., 2020), 4) language models (prompt methods)(Holtzman et al., 2022; Han et al., 2022b). Among these, the most popular ones at present are seed-words and prompt methods, where the former generates pseudo-labels based on word matching, and the latter generates the class probability distribution of each text by prompting a large language model.

Different from existing seed-based and prompt-based methods, our SetSync belongs to a new paradigm, named wordset-based method, which can avoid the problem of zero-shot instability and context-dependent ambiguities in previous works.

2.2 Noisy and Semi-supervised Learning

Noisy-label learning and semi-supervised learning are two research areas that have received widespread attention. Noisy-label learning (NLL) mainly studies the learning of labels with errors or noise in a fully-supervised scenario. While semi-supervised learning (SSL) studies that only a part of the samples have labels, and these labels are all correct. For NLL, existing methods can be divided

into two major categories, i.e. loss correction (Han et al., 2020; Liu et al., 2020) and sample selection (Li et al., 2020; Albert et al., 2021). For SSL, pseudo-labeling methods with confidence thresholds have gained widespread adoption(Sohn et al., 2020b; Chen et al., 2023b), which train models using pseudo-labels with prediction confidences above thresholds while discarding others.

However, existing noisy-label learning assumes that all samples have a label, and semi-supervised learning assumes that the labels in the labeled data are totally correct. Neither is adequate for the data we are faced with, where only a small part of the data has labels, and these labels are noisy. In this paper, we propose a novel training strategy, named sync-denoising, to solve the above data setting, which jointly optimizes unlabeled and noisy labeled samples with a unified denoising framework.

3 Method

3.1 Problem Definition

The input of WTC consists of two parts: 1) a series of N unlabeled text $\mathcal{X} = \{x_1, x_2, ..., x_N\}$. 2) Class names for C categories, represented as $\mathcal{M} = \{m_1, m_2, ..., m_C\}$. Our goal is to train a text classifier, with only class names as supervision signals, whose performance is evaluated on an additional test set.

3.2 Framework

The framework of SetSync is shown in Fig. 2, which follows an iterative paradigm. The system is initialized with class names as wordsets. In each iteration, we first generate pseudo-labels for unlabeled texts with set matching. Then, we train the text classifier with the proposed sync-denoising. Finally, we perform wordset mining with the assistance of information bottleneck. The mined wordsets will be used to generate pseudo-labels for the next iteration. When the total number of iterations reaches the threshold, the iteration stops.

3.3 Pseudo-Labels Generation

Given the unlabeled texts $\mathcal{X} = \{x_1, x_2, ...x_N\}$ and wordsets $\mathcal{S} = \{\mathcal{S}^1, \mathcal{S}^2, ...\mathcal{S}^C\}$ for C classes, where $\mathcal{S}^c = \{s_1^c, s_2^c, ...s_T^c\}$ is T wordsets for class c, the pseudo-label for text x_i is generated with wordset matching as follows:

$$\hat{y}_i^l = \arg\max_c \{\sum_{j=1}^{T} \mathbb{I}(s_j^c \in x_i) | \forall (s_j^c \in \mathcal{S}^c)\} \quad (1)$$

where $\mathbb{I}(\cdot)$ is indicator function. Here, we count the number of wordsets of each category contained in text x_i. Typically, a text includes wordsets from a single category, which becomes the pseudo-label. While sometimes, a text contains wordsets from multiple classes, and we take the category with the most occurrences as the pseudo-label.

Initialization: At the beginning of the first round of training, we initialize the wordset $\mathcal{S}$ using the provided class names $\mathcal{M}$, that is $\mathcal{S}^c = \{s_1^c\}$, and $s_1^c = \{m_c\}$, i.e. for class c, it is initialized with one wordset that contains only a class name.

3.4 Sync-Denoising Training

According to Eq.(1), some texts will be assigned with pseudo-labels. However, there are still some texts that do not contain any wordsets, i.e. remain unlabeled, whose proportion of first-round is visualized in Fig. 3.

Such training data will bring two important issues: 1) How to leverage unlabeled texts without pseudo-labels. 2) How to learn in the presence of errors and noise in pseudo-labels. The former is a problem addressed by semi-supervised learning (SSL), while the latter is tackled by noisy-label learning (NLL). However, in SSL, it is assumed that all labels are correct, whereas in NLL, it is assumed that all samples have noisy labels. This highlights a difference in our assumptions.

Existing WTC works directly use self-training (an SSL method) to make use of unlabeled texts. However, we observe that such a strategy will lead to the further expansion and spread of pseudo-labeling errors, as shown in Fig. 3.

In this paper, we try to solve the learning in this data setting, where the training data consists of pseudo-labeled data $\hat{\mathcal{D}}_L = \{x_i^l, \hat{y}_i^l\}_{i=1}^{N_L}$ and unlabeled data $\mathcal{D}_U = \{x_i^u\}_{i=1}^{N_U}$, and the pseudo-labels $\{\hat{y}_i^l\}_{i=1}^{N_L}$ are noisy. We proposed a sync-denoising training strategy, which jointly optimize pseudo-labeled and unlabeled data through a unified denoising framework, where the sample weights of both are sampled through two independent Gaussian distributions.

3.4.1 Revisit Semi-supervised Learning

In recent research on semi-supervised learning (Sohn et al., 2020b; Chen et al., 2023a), the labeled data $\mathcal{D}_L$ and unlabeled data $\mathcal{D}_U$ are optimized with objective $\mathcal{L} = \mathcal{L}_s + \mathcal{L}_u$, where $\mathcal{L}_s$ is the supervised loss with ground-truth labels $\{y_i^l\}_{i=1}^{N_L}$ in

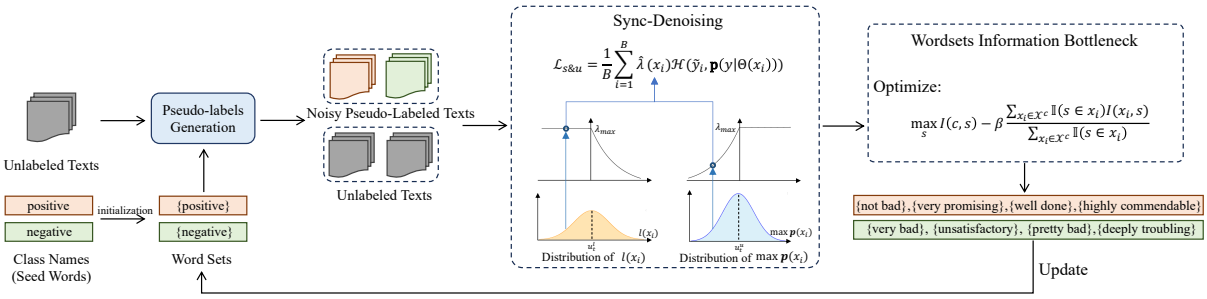

Figure 2: In SetSync, an iteration starts with class names as initial wordsets. Each iteration involves generating pseudo-labels via set matching, training the classifier with sync-denoising, and conducting wordset mining with wordsets information bottleneck. The mined wordsets are then updated to the initial sets for the next cycle.

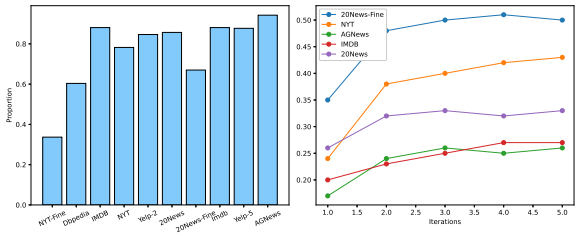

Figure 3: Left: The proportion of texts that keep unlabeled. Right: The proportion of errors in pseudo-labels gradually increases with iterations of self-training.

$\mathcal{D}_L$, and $\mathcal{L}_u$ is unsupervised loss with consistency between weak and strong augmentation in $\mathcal{D}_U$.

Formally, the supervised loss $\mathcal{L}_s$ of the cross-entropy loss $\mathcal{H}$ on B_L-sized batch is formulated as:

$$\mathcal{L}_s = \frac{1}{B_L}\sum_{i=1}^{B_L}\mathcal{H}(y_i^l, \mathbf{p}(y|x_i^l)) \tag{2}$$

where $\mathbf{p}(y|x_i^l) \in \mathbb{R}^C$ is the model's prediction.

For the unsupervised loss $\mathcal{L}_u$, the consistency between weak augmentation $\omega(x_i^u)$ and strong augmentation $\Omega(x_i^u)$ on B_U-sized batch of unlabeled data is constrained by the following formula:

$$\mathcal{L}_u = \frac{1}{B_U}\sum_{i=1}^{B_U}\lambda(x_i^u)\mathcal{H}(\widehat{\mathbf{p}}_i, \mathbf{p}(y|\Omega(x_i^u))) \tag{3}$$

where $\widehat{\mathbf{p}}_i = \arg\max \mathbf{p}(y|\omega(x_i^u))$, i.e. the one-hot pseudo-label generated from weak augmentation. $\lambda(x_i^u)$ is the binary or continuous weight of x_i^u, which is used to filter out samples that may be predicted incorrectly.

3.4.2 Synchronous Denoising

Here, we impose label-denoising training on SSL. Coincidentally, Eq.(3) utilize $\lambda(x_i^u)$ to filter unconfidence predictions, which inspires us to use the same paradigm to denoise noisy labeled data $\hat{\mathcal{D}}_L$. Hence, we employ a unified framework to simultaneously conduct denoising learning of labeled data and unsupervised learning of unlabeled data, both sharing the same optimization formula as follows:

$$\mathcal{L}_{s\&u} = \frac{1}{B}\sum_{i=1}^{B}\widehat{\lambda}(x_i)\mathcal{H}(\tilde{y}_i, \mathbf{p}(y|\Theta(x_i))) \tag{4}$$

In Eq.(4), we optimize both labeled and unlabeled data with weighted cross-entropy loss, where B is the batch size, and $\widehat{\lambda}(x_i)$ is the sample weight. $\Theta(x_i)$ is the mixture of weak and strong augmentation of sample x_i, formally $\Theta(x_i) = \{\omega(x_i), \Omega(x_i)\}$. In our unified framework, we simultaneously predict weak and strong augmentation samples, with different target $\tilde{y}_i$.

For target $\tilde{y}_i$, according to whether x_i is pseudo-labeled or unlabeled, it is formulated as:

$$\tilde{y}_i = \begin{cases} \hat{y}_i^l, & \text{if } x_i \in \hat{\mathcal{D}}_L \\ \arg\max \mathbf{p}(y|\omega(x_i)), & \text{if } x_i \in \mathcal{D}_U \end{cases} \tag{5}$$

where the pseudo-labels from Eq.(1) and prediction from weak augmentation is utilized as a target for pseudo-labeled and unlabeled data, respectively.

3.4.3 Dynamic Gaussian Weight

For the sample weight $\widehat{\lambda}(x_i)$, existing works of NLL measure the probability of label errors based on the magnitude of the loss function value (Kim et al., 2022). While the semi-supervised learning derives weight $\widehat{\lambda}(x_i)$ from the prediction confidence of x_i (Sohn et al., 2020a; Chen et al., 2023a).

Here, we go one step further. We assume that the underlying probability mass function of loss values in pseudo-labeled samples $\hat{\mathcal{D}}_L$ and the prediction confidence in unlabeled samples $\mathcal{D}_U$ obey two dynamic Gaussian distributions respectively, where the mean and variance are μ_t^l, σ_t^l for loss

values in $\hat{\mathcal{D}}_L$, and μ_t^u, σ_t^u for prediction confidence in $\mathcal{D}_U$. Since samples with higher loss values in $\hat{\mathcal{D}}_L$ are more prone to be erroneous than those with lower loss values, we can convert the deviation of the sample loss values from the mean μ_t^l of the Gaussian distribution into the probability of label correctness, which will be used as weight $\widehat{\lambda}(x_i)$. Similarly, the greater the prediction confidence in $\mathcal{D}_U$, the greater the probability of being correct. Therefore, $\widehat{\lambda}(x_i)$ can be derived as:

$$\widehat{\lambda}(x_i) = \begin{cases} \lambda_{\max} \exp(-\frac{(l(x_i)-\mu_t^l)^2}{2\sigma_t^{l\,2}}), \\ \qquad \text{if } x_i \in \mathcal{D}_L \text{ and } l(x_i) > \mu_t^l \\ \lambda_{\max} \exp(-\frac{(\max \mathbf{p}(x_i)-\mu_t^u)^2}{2\sigma_t^{u\,2}}), \\ \qquad \text{if } x_i \in \mathcal{D}_U \text{ and } \max \mathbf{p}(x_i) < \mu_t^u \\ \lambda_{\max}, \qquad \text{otherwise} \end{cases} \tag{6}$$

where $l(x_i)$ is the loss value of labeled sample x_i, and $l(x_i) = \mathcal{H}(\hat{y}_i^l, \mathbf{p}(y|\Theta(x_i))$. $\max \mathbf{p}(x_i)$ is the prediction confidence of unlabeled sample, and is an abbreviation of $\max \mathbf{p}(y|\Theta(x_i))$. $\lambda_{\max}$ is the max value of weight, which is a hyperparameter.

In Eq.(6), we applied distinct truncations to two Gaussian distributions. For pseudo-labeled data $\hat{\mathcal{D}}_L$, we truncate the part of the Gaussian distribution where the loss value $l(x_i)$ is less than the mean μ_t^l, making it $\lambda_{\max}$. For loss value that larger than μ_t^l, since it's more likely to have the wrong label, we down-weight it according to how far it deviates from μ_t^l. For unlabeled data $\mathcal{D}_U$, it is the opposite; Since higher confidence corresponds to lower error probability, we truncate in the opposite direction.

3.4.4 Parameter Estimation

Then, we estimate the parameters of two Gaussian distributions, i.e. μ_t^l, σ_t^l and μ_t^u, σ_t^u, separately. Since the training process is a dynamic process, the two Gaussian distribution are also changing dynamically. Therefore, our parameters are also updated with momentum. In particular, for μ_t^l, σ_t^l of labeled data, we calculate the empirical mean and variance of the loss values in the batch of t^{th} iteration as:

$$\mu_b^l = \frac{1}{B}\sum_{i=1}^{B} l(x_i) \qquad \sigma_b^l = \frac{1}{B}\sum_{i=1}^{B}(l(x_i) - \mu_b^l)^2 \tag{7}$$

Then, the parameters at t^{th} is estimated with EMA with unbiased variance as follows:

$$\begin{aligned} \mu_t^l &= \epsilon \cdot \mu_b^l + (1-\epsilon) \cdot \mu_{t-1}^l \\ \sigma_t^l &= \epsilon \cdot \frac{B}{B-1} \cdot \sigma_b^l + (1-\epsilon) \cdot \sigma_{t-1}^l \end{aligned} \tag{8}$$

where ϵ is a hyperparameter. Similarly, the parameters μ_t^u, σ_t^u for unlabeled data are also estimated in the same way. According to the real-time estimated Gaussian parameters, we employ Eq.(6) for the dynamic weight generation and utilize Eq.(4) to optimize the classifier.

3.5 Wordsets Information Bottleneck

As mentioned before, we found that seed words alone are not enough to accurately characterize a category, so we utilize wordsets to represent a category and generate pseudo-labels. In this paper, we propose to mine class-relevant wordsets with information bottleneck (IB) (Bayat and Wei, 2019).

Given the input signal X and label Y, the objective of IB is maximized to find the most informative yet compressed representation Z by optimizing:

$$\max_Z I(Y,Z) \quad s.t. I(X,Z) \le I_x \tag{9}$$

where $I(\cdot,\cdot)$ is mutual information, I_x is information constraint between X and Z. By introducing a Lagrange multiplier β, we can get the unconstrained form:

$$\max_Z I(Y,Z) - \beta I(X,Z) \tag{10}$$

where the hyperparameter β can be used to trade-off informativeness and compression.

Here, in wordset mining, we focus on mining the wordsets that is compressed with minimum information loss in terms of class properties, and we propose the wordsets information bottleneck (WIB). In particular, for a class c, the maximally informative yet compressed wordsets can be obtained with WIB by optimizing the following objective:

$$\max_s I(c,s) - \beta \frac{\sum_{x_i \in \mathcal{X}^c} \mathbb{I}(s \in x_i) I(x_i, s)}{\sum_{x_i \in \mathcal{X}^c} \mathbb{I}(s \in x_i)} \tag{11}$$

where s is the wordset to be solved. $\mathcal{X}^c$ is the set of texts predicted by the classifier to be class c. We use the average mutual information of a wordset and the text containing it to calculate $I(X,Z)$.

Unlike continuous space in signal processing, words are discrete space and non-derivable. To solve Eq.(11), an intuitive idea in discrete space is to enumerate all possible wordsets s and find the top ones. However, due to huge enumeration combinations in discrete space, it is not feasible.

Here, we combine high-frequency screening and frequent itemset algorithm to solve the approximate optimal solution of Eq.(11). Our method

is based on the prior knowledge that a category-specific wordset occurs with high frequency in this class, and the words included in the high-frequency wordset are also high-frequency. Therefore, we first use high-frequency screening to filter out low-frequency words, then use the frequent item set mining algorithm to mine high-frequency wordsets, and finally utilize Eq.(11) to evaluate the wordsets.

3.5.1 High-frequency Screening

Firstly, we need to build a high-frequency vocabulary Φ^c for each category c. To achieve this, we aggregate the texts predicted with class c by the trained classifier, which is denoted as $\mathcal{X}^c$. Then, we count the frequency of each word w_i in $\mathcal{X}^c$ as $TF(w_i)^c = \sum_{x_j \in \mathcal{X}^c} \mathbb{I}(w_i \in x_j)$. For each class c, we keep top Z_1 words with the highest $TF(w_i)^c$, which is denoted as Φ^c.

According to the high-frequency vocabulary Φ^c, we simplify the original texts by filtering low-frequency words. For each text x_i of class c, we keep only those words that appear in the vocabulary Φ^c, and the result is denoted as $\tilde{x}_i = \{w_i | w_i \in x_i \text{ and } w_i \in \Phi^c\}$. Through filtering operations, we can greatly reduce the number of words in each text, thus speeding up the mining process.

3.5.2 Frequent Wordsets Mining

According to the simplified texts $\tilde{x}_i$, we mine frequent itemsets in each class c. Treat each $\tilde{x}_i$ of class c as a transaction, and we use the FP-Growth (Borgelt, 2005) algorithm to mine frequent itemsets that appears in as many $\tilde{x}_i$ as possible. We choose FP-Growth for its better time complexity. Then, Z_2 itemsets with the highest support will be output from FP-Growth for class c, which is denoted as $\widetilde{\mathcal{S}}^c = \{\tilde{s}_1^c, \tilde{s}_2^c, ..., \tilde{s}_{Z_2}^c\}$, where the support of a itemset refers to the probability of occurrence of that itemset in all $\tilde{x}_i$ of class c.

3.5.3 Information Bottleneck Ranking

With the results $\widetilde{\mathcal{S}}^c$ from FP-Growth, we score each $\tilde{s}_i^c \in \widetilde{\mathcal{S}}^c$ with Eq.(11), where the mutual information is calculated using the representations of the last layer of trained classifier. For each class c, we keep the top T wordsets with the highest score and update them into the initialized wordsets. Then, with updated wordsets, we restart a new round of training. When the total number of iterations reaches M, the iteration stops.

4 Experiments

For experimental settings and hyperparameter, please refer to the Appendix.C.

4.1 Datasets

All our experimental settings and datasets follow a recent WTC benchmark(Wang et al., 2023b), which replicated WTC methods using standardized evaluation criteria, including seed-based and prompt-based approaches. Following the benchmark, we conducted experiments on 11 text datasets from diverse domains. and the input class names are also the same. More details can refer to Appendix.A.

4.2 Compared Methods

We compared seed-based and prompt-based methods following the benchmark(Wang et al., 2023b). Seed methods included LoT-Class (Meng et al., 2020b), X-Class (Wang et al., 2021), ClassKG (Zhang et al., 2021) and NPPrompt (Zhao et al., 2023a), while prompt methods included prompt baseline (Wang et al., 2023a), prompt+DCPMI (Holtzman et al., 2021) and prompt+ProtoCal (Han et al., 2023). Prompt methods use GPT-2, while seed methods use BERT (except NPPrompt-Roberta) as classifier. More details of compared methods can refer to Appendix.B.

4.3 Performance Comparison

The evaluation results are summarized in Tab.1. Our method achieved the highest average results, surpassing SOTA on most datasets regardless of whether BERT-base or BERT-large was used as the classifier. SetSync outperformed ClassKG by 9.0 points and the best prompt method (Prompt+DCPMI) by 24.70 points with BERT-base. With BERT-large, it exceeded previous SOTA (X-class) by 8.54 points on average. SetSync demonstrated strong performance on both short and long texts, highlighting its effectiveness and generalizability.

4.4 Ablation Study

We perform further module inspections, all experiments use BERT-base as the classifier.

4.4.1 Effect of Different Modules

We investigate the effectiveness of sync-denoising training and wordsets mining, and present the results in Fig. 4. We compared sync-denoising

with various training strategies, including fully-supervised, semi-supervised (self-training (Pseudo-Label, 2013), fixmatch (Sohn et al., 2020a), soft-match (Chen et al., 2023a)), and noisy-label learning (co-teaching (Han et al., 2018), SaFER (Qi et al., 2023)), reporting the performance of each round for each training strategy. From Fig. 4, we can see that: 1) Our sync-denoising training outerformed all other strategies. Fully-supervised training on pseudo-labeled data had the worst performance. Semi-supervised and noisy-label learning were slightly better than fully-supervised, but with limited improvement. 2) Classifier performance gradually improved with iterations in all strategies, which demonstrating the effectiveness of our word-sets mining algorithm. In addition,we observed that the 2^{nd} round typically showed the most significant improvement. This is mainly due to the use of mined wordsets to generate high-quality pseudo-labels, greatly improving the performance.

4.4.2 Different Noise Estimation

In sync-denoising training of classifier, we estimated pseudo-labeled data and unlabeled text's prediction noise using loss value and prediction confidence, respectively. We try to change it, with results shown in Tab. 2. We can see that using loss values to evaluate noise on pseudo-labeled data and using prediction confidence to evaluate unlabeled data achieved the best results. This is because for pseudo-label data, the loss value can be a good measure of the consistency between the model's prediction and the pseudo-label. For abnormal samples with incorrect labels, the consistency will be greatly reduced, so that its noise level can be eval-

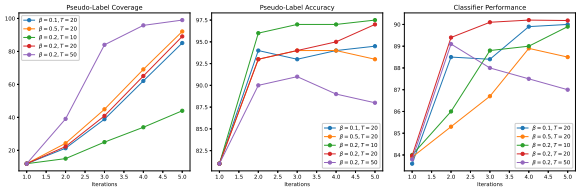

Figure 5: The influence of β and T of WIB.

Pseudo-Labels Generation	IMDB	Yelp-2	Yelp-5	AGNews
Random Selection	0.872	0.855	0.529	0.863

Score Accumulation	0.931	**0.925**	0.581	0.891
Majority Voting	**0.934**	0.919	**0.595**	**0.892**

Table 3: Pseudo-label accuracy in the second round with different pseudo-label generation methods.

uated. For unlabeled samples, the loss value is a measure of the consistency between weak and strong augmentation. Since most of the strong augmentation are difficult samples, the results are likely to be wrong. Therefore, this consistency is not as reliable as the prediction confidence.

4.4.3 Ablation on WIB

Here, we perform experiments on β and T in wordsets information bottleneck, where β is a lagrange multiplier that trade-off informativeness and compression, and T is the number of reserved wordsets in each round. We report the accuracy and coverage of the pseudo-labels, and the performance of classifier over iterations in Fig. 5. We can see that: 1) A higher T will bring higher pseudo-label coverage and also reduce pseudo-label accuracy. 2) A higher β will lead to higher compression, thereby extracting higher coverage wordsets. Likewise, higher compression ratios reduce accuracy. 3) Our system is robust to these hyperparameters, and these parameter selections can achieve high performance.

4.4.4 Ablation on Pseudo-Label Generation

We conduct further experiments on pseudo-label generation. When a text contains only one category of wordsets, its category is easy to determine. However, when a text contains multiple categories, we try to use different methods to determine its pseudo-labels, including random selection, score accumulation, length accumulation, majority voting. The length accumulation accumulates the total number of words in wordsets of each class. The score accumulation accumulates the scores of wordsets in each class, where the score is obtained from the previous round of WIB. Majority voting is formulated as Eq.(1). We report the second-round pseudo-labels accuracy in Tab.3. We can see that majority voting achieved relatively stable and good results in most cases, followed by score accumulation. Score accumulation may cause performance degradation in some cases due to the imbalance of scores between different categories.

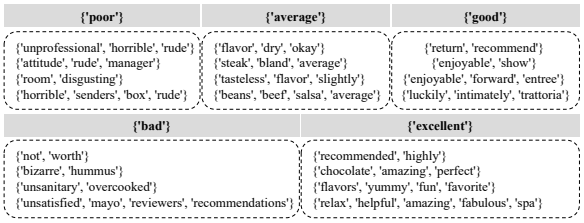

Figure 6: Wordsets example.The gray area represents the wordset initialized for the class, while the dashed lines indicate the wordsets updated after three iterations.

Model	AG News	DBPedia	IMDB	Yelp-2	Yelp-5
GPT-3	83.4	82.5	88.8	92.6	42.9
ChatGPT-3.5	83.8	92.0	92.7	**97.2**	**73.8**
SetSync (BERT-base)	**88.5**	**90.1**	90.9	93.3	45.9
SetSync (BERT-large)	87.3	89.3	**92.3**	94.1	51.6

Table 4: Performance comparison with ChatGPT.

4.5 Qualitative Analysis

Using the Yelp-5 dataset as an example, we initialized the wordset with class names and updated it over three iterations, as shown in Fig. 6. From the results, it is evident that our method employed a wordset to represent each category, allowing for a more accurate expression of nuanced sentiment compared to individual seed words. This explains our higher performance on the Yelp-5 dataset and enables a more granular and precise interpretation of sentiments, essential in effective dataset understanding and analysis.

4.6 Comparison with ChatGPT

We also conducted a comparative study with ChatGPT-3.5 and GPT-3. However, given the huge scale of the datasets, using ChatGPT-3.5 to predict all test sets of 11 datasets (about 60K texts) would incur a high cost. Therefore, we chose to conduct experiments on a part of the datasets. More experimental details can refer to Appendix.D, and the prompts for ChatGPT and GPT-3 can be found in Tab.7. The results are shown in Tab. 4. From the results, we can see that ChatGPT-3.5 can achieve the highest results on some datasets. Meanwhile, our method can surpass GPT-3 on all datasets and

beat ChatGPT-3.5 on some datasets.

5 Conclusion

In this paper, we introduce SetSync, which utilize wordsets to represent categories and generate pseudo-labels. To achieve this, we propose a class-relevant wordsets mining algorithm with wordsets information bottleneck. Moreover, we revisit the classifier training in WTC and propose a new training strategy, called sync-denoising, which jointly optimize unlabeled and noisy labeled samples with a unified denoising framework. Extensive experiment results on 11 datasets shows that SetSync substantially outperforms all existing methods.

A Details of Datasets

These datasets can be divided into the following four categories:

1) Sentiment Analysis:

- IMDB(Maas et al., 2011): Contains movie reviews from the IMDB website.it's a binary classification dataset (positive or negative)
- Yelp-2 and Yelp-5(Zhang et al., 2016): These datasets are derived from Yelp reviews. Yelp-2 is a binary classification dataset (positive or negative reviews), while Yelp-5 has a finer classification with five classes, rating reviews from one to five stars.

2) Topic Classification:

- AGNews(Zhang et al., 2016): Classifies news articles into four main topics: World, Sports, Business, and Science/Technology.
- 20News and 20News-Fine(Lang, 1995): Topic classification of newsgroup articles, covering a range of topics, with the "Fine" version offering more detailed classification.

3) Entity Recognition and Classification:

- DBpedia(Zhang et al., 2016): Entities extracted from Wikipedia, categorized into 14 different classes, used for multi-class classification and entity recognition.

4) News Text and Fine-grained Analysis:

- NYT, NYT-Fine, NYT-Topics and NYT-Loc(Meng et al., 2020a): Articles from The New York Times, used for various text analysis tasks. NYT for broader classification tasks, NYT-Fine for detailed analysis of sub-topics, NYT-Topics for thematic categorization of news into specific areas like politics or sports, and NYT-Loc for geographic-focused analysis.

B Details of Compared Methods

In this paper, the Compared Methods align with the published benchmark paper(Wang et al., 2023b) and include a comparison between the Seed and Prompt methods.

B.1 Seed Approach

The Seed methods, except for NPPrompt, are all based on Bert (base and large).

- LotClass(Meng et al., 2020b) expand related words using masked language models and matches texts by fine-tuning.
- Xclass(Wang et al., 2021) retrieves related words by searching for words with similar representations and matches texts with clustering-enhanced similarity.
- ClassKG(Zhang et al., 2021) Transform the dependency among related words into a keyword graph annotation task.
- NPPrompt(Zhao et al., 2021) based on Roberta, obtains related words by extracting embedding similarity from pre-trained language models, using them as prompts for a generative language model to make predictions, which are then aggregated for the final match.

B.2 Prompt Approach

All prompt methods are based on GPT-2 (small and medium).

- DC-PMI(Holtzman et al., 2022) uses empty prompts to gauge a language model's likelihood for predicting labels, refining predictions for each text.
- ProtoCal(Han et al., 2022b) works with unlabeled data, obtaining predictive likelihoods and clustering them to improve category predictions.

C Experimental Setting

The model training and evaluation is performed on NVIDIA RTX 4090. The classifier is implemented with 'bert-base-uncased' and 'bert-large-uncased', which follows the setting in benchmark. The classifier is optimized with AdamW (Loshchilov and Hutter, 2019), and the learning rate is 2e-6. The batch size B is set to 64. The number of wordsets mined each round T is set to 20. $\lambda_{\max}$ in Eq.(6) is set to 1. Momentum coefficient ϵ in Eq.(8) is set to 0.001. The initial value of μ_t and σ_t for labeled and unlabeled data is set to $\frac{1}{C}$ and 1.0. The trade-off coefficient β in Eq.(11) is set to 0.2. The parameter Z_1 to limit the size of Φ^c is set to 2000, and Z_2 to

Table 5: Dataset statistics.

Name	Domain	# Classes	||Unlabelled||	||Eval||	Imbalance
IMDB	Reviews/Sentiment	2	5000	5000	1.0
Yelp-2	Reviews/Sentiment	2	5600	3800	1.1
Yelp-5	Reviews/Sentiment	5	6500	5000	1.1
AGNews	News/Topic	4	6000	7600	1.0
20News	News/Topic	5	6254	5362	1.9
20News-Fine	News/Topic	17	5589	4792	1.3
NYT-S	News/Topic	9	4578	3925	17.1
NYT-S-Fine	News/Topic	26	4034	3459	96.3
NYT	News/Topic	5	5119	6400	30.7
NYT-Loc	News/Location	10	5119	6400	17.1
DBpedia	Wikipedia/Ontology	14	5600	7000	1.3

Table 6: Initial class name of each dataset.

Dataset	Seed Words/Initial class name
IMDB	positive; negative
Yelp-2	positive; negative
Yelp-5	poor; bad; average; good; excellent
AGNews	politics; sports; business; technology
20News	computer; sports; science; politics; religion
20News-Fine	atheism; graphics; Microsoft; IBM; Mac; motif; autos; motorcycles; baseball; hockey; encryption; electronics; medicine; space; Christian; guns; Arab
NYT	politics; art; business; science; sport
NYT-S-Fine	budget; gun; laws; gay; energy; environment; immigration; military; cosmos; insurance; stocks; bank; abortion; music; baseball; economy; television; golf; tennis; hockey; football; dance; movies; soccer; surveillance; basketball
NYT-S	business; politics; sports; health; education; estate; arts; science; technology
NYT-Loc	America; Iraq; Japan; China; Britain; Russia; Germany; Canada; France; Italy
DBpedia	company; education; artist; athlete; politician; transportation; place; nature; village; species; plant; album; movie; book

limit the output number from FP-Growth is set to 200. The wordsets change threshold Δ is set to 0.1. More details can refer to our code.

D Details of Compared ChatGPT

As the experiments of ChatGPT-3.5 on AG News, DBPedia, and IMDB have already been reported in a recent WTC work (Zhao et al., 2023b), we directly reference its results. To be fair, we reran our method on the test set they provided. Additionally, we have included additional experimental results for Yelp-2 and Yelp-5, where the prompts for ChatGPT is shown in Tab.7 and the experiments is based on the June 2023 version of ChatGPT.

E Limitation

The running time of our method may be longer than the seed methods, especially the mining part of frequent itemsets. However, through more stringent high-frequency filtering, the mining of frequent itemsets can be significantly accelerated, but the accuracy may be slightly lost. Our method requires multiple rounds of iteration, which also means that it will consume more time than non-iterative algorithms. However, we need to state that this running time is negligible compared to the time required for large-scale annotation.

Descriptions
AG News: The politics category is related to politics, government, and law. The sports category is related to sports, competition, and athletics. The business category is related to business, portfolio, economics, and money. The technology category is related to technology, software, system, and science.
DBPedia: The company category is related to company, corporation, enterprise, brand, and business. The school category is related to school, academy, university, and college. The artist category is related to artist, art, painter, musician, singer, and creative. The athlete category is related to athletes, sports, Olympic, and gym. The politics category is related to politics, government, and law. The transportation category is related to transportation, transport, vehicle, and traffic. The building category is related to buildings, construction, and structure. The mountain category is related to river, lake, bay, and mountain. The village category is related to village, town, and rural. The animal category is related to animal, wildlife, and nature. The plant category is related to plant, shrub, tree, and forest. The album category is related to album, lyrics, cd, and song. The film category is related to film, movie, cinema, and video. The book category is related to book, novel, and publication.
IMDB: The bad category is related to negative and bad reviews. The good category is related to positive and good reviews.
Yelp-2: The negative category is related to negative and bad reviews. The positive category is related to positive and good reviews.
Yelp-5: The poor category is related to extremely negative and terrible reviews. The bad category is related to negative and bad reviews. The average category is related to moderate or average reviews. The good category is related to positive and good reviews. The excellent category is related to highly positive and exceptional reviews.

Abstract

In the evolving landscape of Neural Machine Translation (NMT), the pretrain-then-finetune paradigm has yielded impressive results. However, the persistent challenge of Catastrophic Forgetting (CF) remains a hurdle. While previous work has introduced Continual Learning (CL) methods to address CF, these approaches grapple with the delicate balance between avoiding forgetting and maintaining system extensibility. To address this, we propose a CL method, named **F-MALLOC** (**F**eed-forward **M**emory **ALLOC**ation). F-MALLOC is inspired by recent insights highlighting that feed-forward layers emulate neural memories and encapsulate crucial translation knowledge. It decomposes feed-forward layers into discrete memory cells and allocates these memories to different tasks. By learning to allocate and safeguard these memories, our method effectively alleviates CF while ensuring robust extendability. Besides, we propose a comprehensive assessment protocol for multi-stage CL of NMT systems. Experiments conducted following this new protocol showcase the superior performance of F-MALLOC, evidenced by higher BLEU scores and almost zero forgetting.[1]

1 Introduction

In the pursuit of achieving state-of-the-art results in Neural Machine Translation (NMT), the reliance on large-scale parallel corpora has been pivotal (Bahdanau et al., 2015; Vaswani et al., 2017). However, practical application scenarios often present challenges, especially when translation is necessitated for specific domains with limited data resources (Chu and Wang, 2018; Saunders, 2022). Typically, the prevalent paradigm involves the initial pretraining of models on expansive general domain corpus, followed by finetuning for the target domain (Freitag and Al-Onaizan, 2016; Chu and Dabre, 2019).

Despite the efficacy of this pretrain-then-finetune paradigm, it has been demonstrated that fine-tuning on the target domain can result in significant performance degradation in the general domain, a phenomenon known as Catastrophic Forgetting (CF) (French, 1993). In response to this challenge, various Continual Learning (CL) approaches have emerged to address CF in NMT systems. Existing efforts primarily rely on regularization-based techniques to constrain the divergence of model parameters from their previous values (Khayrallah et al., 2018; Saunders et al., 2019; Cao et al., 2021). While these methods are mathematically elegant, they still face challenges related to forgetting. Alternatively, some approaches take an architecture-based framework, isolating parameters specific to different tasks to prevent forgetting (Gu et al., 2021; Liang et al., 2021; Huang et al., 2023). However, they require prior information on task numbers to allocate parameters and rely on external storage of model or mask matrices, limiting its extendibility and applicability.

In summary, the demand for a CL method for NMT systems that is both extendable and effective in preventing forgetting is pressing. To this end, we introduce a new CL method termed **F-MALLOC** (**F**eed-forward **M**emory **ALLOC**ation), which is inspired by recent insights that feed-forward layers emulate neural memories and encapsulate crucial translation knowledge (Geva et al., 2021; Huang et al., 2023). Therefore, we facilitate new knowledge learning and mitigate CF by allocating and protecting these memories. F-MALLOC first leverages a structural pruning method to trim the feed-forward layers of a pretrained NMT model, preserving memories that encapsulate crucial general domain knowledge. Subsequently, F-MALLOC proceeds to learn a set of non-exclusive task masks (Serrà et al., 2018), automatically allocating the

[1]The code and data for this work are available at https://github.com/WJMacro/ContinualMT.

Proceedings of the 2024 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies (Volume 1: Long Papers), pages 7180–7192

June 16-21, 2024 ©2024 Association for Computational Linguistics

'writable' memory capacity to upcoming tasks. The memories allocated in this manner are then designated as 'read-only'. F-MALLOC strategically blocks gradient flows through these 'read-only' memories, effectively mitigating the risk of forgetting.

Meanwhile, conventional CL evaluation protocols in the NMT area typically focus on a single stage of training, lacking a holistic perspective over multiple stages. Therefore, we introduce a comprehensive evaluation protocol for multi-stage CL in the NMT scenario. Our protocol incorporates metrics assessing forgetting mitigation and adaptation to novel tasks. To enhance robustness, we conduct tests with random task sequences, reducing biases from specific orders. This protocol provides a nuanced understanding of F-MALLOC and competing methods' performance over time in NMT.

Experiments conducted following the proposed protocol highlight the superior performance of F-MALLOC with high robustness. Additional analysis of F-MALLOC's memory allocation strategy reveals its effective utilization of task information, such as inherent difficulty or inter-task similarities, resulting in enhanced performance.

In summary, the contributions of this paper are as follows:

- We propose F-MALLOC, a multi-stage CL method that prevents forgetting and promotes new knowledge acquisition through feed-forward memory allocation. It requires no prior task information and minimal storage overhead.
- Through a tailored evaluation protocol for multi-stage CL in NMT systems, we enhance the understanding of system performance on both stability and plasticity.
- Further analysis of F-MALLOC's adaptive memory allocation strategy demonstrates its effectiveness in leveraging task difficulty and inter-task similarities to optimize capacity usage and encourage knowledge transfer.

2 Background

2.1 Feed-forward Layers Emulate Memory Networks

Feed-forward Layer. The prevalent architecture in NMT is the encoder-decoder Transformers(Vaswani et al., 2017), which is made of intertwined multi-head attention (MHA) and point-wise feed-forward layers. Our specific focus lies in the feed-forward layer, formally defined as:

$$\mathrm{FF}(x) = W^{(2)} \cdot \sigma(W^{(1)} \cdot x) \quad (1)$$

where $W^{(1)}, W^{(2)}$ represent learnable parameters (bias term omitted for simplification), and σ typically denotes the activation function, commonly ReLU.

Feed-forward layer as neural memory of knowledge. Recent research has explored the interpretability of feed-forward structures, noting a significant resemblance between the feed-forward layer and neural memory (Sukhbaatar et al., 2015). Treating parameter matrices $W^{(1)}$ and $W^{(2)}$ as keys and values respectively, the feed-forward layer can be seen as an unnormalized key-value memory (Sukhbaatar et al., 2019). Studies have delved into this similarity, with Geva et al. (2021) revealing that in feed-forward layers, each key correlates with textual patterns in training examples, while each value induces a distribution over the output vocabulary. In the context of Neural Machine Translation, Huang et al. (2023) demonstrates that feed-forward layers encapsulate crucial translation knowledge and can facilitate knowledge transfer between models.

3 Methods

3.1 Overview

Building upon prior research that characterizes feed-forward layers as neural memory repositories of knowledge, we posit a hypothesis that effective allocation and protection of these memories within feed-forward layers can facilitate both the acquisition of new knowledge and the prevention of forgetting. Our proposed method, F-MALLOC, is devised on the premise of this hypothesis.

F-MALLOC is specifically tailored to the feed-forward structure, with all other parameters held constant throughout the process. To preserve critical general domain knowledge while allowing flexibility for future task learning, we initiate the process with a structured pruning method (3.2). This method aids in eliminating unimportant memories, making them 'writable'. Subsequently, we introduce learnable task masks to manage these free memories (3.3). These task masks, acquired through learning, play a vital role in memory allocation for new tasks, designating them as 'read-only' to prevent alterations. For an overview of our method, please refer to Fig.1.

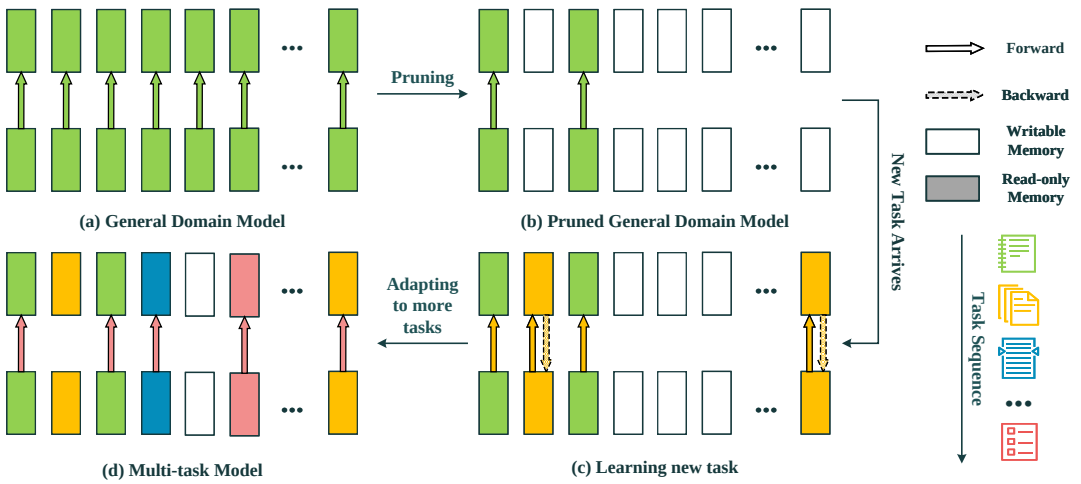

Figure 1: Illustration of F-MALLOC. For simplification, we depict a decomposed feed-forward layer. (a) **The Original General Domain Model:** Highlighting the general domain task in green. (b) **Pruned General Domain Model:** Post-pruning, pruned memories are 'writable' (depicted in white), while others are designated as 'read-only.' (c) **Learning a New Task:** The model learns to allocate some memories to the new task and mark them 'read-only' (depicted in yellow). 'read-only' memories remain available for future tasks' forward propagation. However, backward propagation through them is prohibited. (d) **Multi-task Model:** After learning all tasks, each task occupies a share of memory capacity. The forward pass of the last task is shown.

3.2 Preserving General Domain Knowledge

Pruning has demonstrated effectiveness in retaining essential parameters while eliminating unnecessary ones in neural networks. In this context, we adopt a structured pruning method, which is designed to preserve general domain knowledge. The pruning process calculates an importance score for each memory cell in the feed-forward layer, retaining only the most crucial ones.

Importance-based memory pruning. The pruning problem can be seen as finding an optimal mask under a sparsity constraint. To formalize this, we decompose the feed-forward layer into N key-value pairs, which we call a memory cell[2]. Subsequently, a mask is introduced to control the activation of them (Xia et al., 2022; Kwon et al., 2022):

$$\mathrm{FF}(x, m) = \sum_{i=1}^{N} m_i \odot W^{(2)}_{:,i} \cdot \sigma(W^{(1)}_{i,:} \cdot x) \qquad (2)$$

Here, N denotes the hidden dimension of the feed-forward layer, $m \in \{0,1\}^N$ represents the mask vector and $\odot$ denotes the Hadamard product.

A common approach to select unnecessary memory is to estimate the importance of different memories with gradient (Michel et al., 2019) or Fisher information (Liu et al., 2021). The precise calculation of the importance score typically demands the use of the same data and loss functions employed during model training, which is often impractical in CL scenarios where obtaining the training data of a pretrained model may be unfeasible.

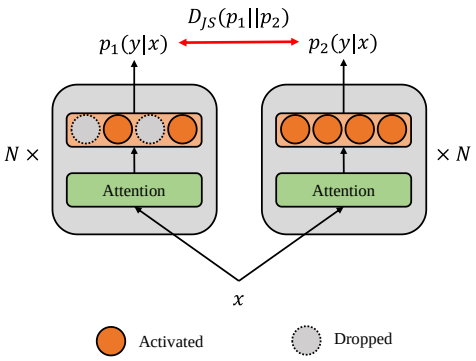

Figure 2: Illustration of estimating feed-forward memory importance via JS divergence.

To address this challenge, we propose an alternative approach employing Jensen–Shannon (JS) divergence. The method draws inspiration from the stochastic dropout mechanism (Hinton et al., 2012), which introduces randomness by eliminating a portion of units in each layer during training, mitigating co-adaptation and overfitting. In our

[2]We use memory and memory cell interchangeably.

approach, dropout is applied to the feed-forward layer, generating unique memory activations and distinct outputs during each forward pass. By comparing these outputs and computing the gradient of the divergence, we derive a novel importance score for memories.

As shown in Fig.2, we perform two forward passes, with or without dropout, of the input data x through the network, generating two distributions of model predictions, denoted as $\mathcal{P}_1(y|x)$ and $\mathcal{P}_2(y|x)$. We then calculate the JS divergence between these predictions:

$$\mathcal{L}_{\mathrm{JS}}(x) = \frac{1}{2}(\,\mathrm{KL}(\mathcal{P}_1(y|x), \mathcal{P}_2(y|x)) + \mathrm{KL}(\mathcal{P}_2(y|x), \mathcal{P}_1(y|x))) \tag{3}$$

where $\mathrm{KL}(\cdot,\cdot)$ denotes the Kullback–Leibler (KL) divergence. In practice, we adopt an external dataset $\mathcal{D}$ and estimate the average gradient of JS divergence, serving as an empirical importance score:

$$I_k = \mathbb{E}_{x\in\mathcal{D}}\left|\frac{\partial \mathcal{L}_{\mathrm{JS}}(x)}{\partial m_k}\right| \tag{4}$$

Following the derivation of the importance score, a binary mask is generated through a binarization function utilizing the s quantile of the importance score, denoted as $q_s(I)$, as the threshold:

$$m_k^G = \begin{cases} 1, & \text{if } I_k \geq q_s(I) \\ 0, & \text{if } I_k < q_s(I) \end{cases} \tag{5}$$

where s is the desired sparsity. Substituting this mask m^G into Formula 2 accomplishes the pruning.

3.3 Learning New Domain Continually

After the structure pruning stage, wherein specific feed-forward memories are pruned and marked 'writable' for future learning, we introduce a task mask mechanism to manage memory. Throughout the forward pass, these task masks govern the activation of feed-forward memory, conditioning the model for specific tasks. In the backward pass, the task masks are employed to suppress gradient updates to the 'read-only' memories, effectively preventing CF. Fig.3 provides an overview of this procedure.

Learning task mask to allocate 'writable' memory. To adapt to a new task t, a task mask m_l^t is learned. This task mask serves to conditionally activate the memories in the l-th feed-forward layer. We adopt the task-based hard attention mechanism

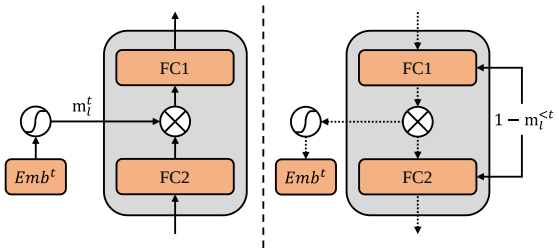

Figure 3: Illustration of new domain learning: forward (the left) and backward (the right) propagation. Here, we show the inner structure of the feed-forward layer.

proposed by Serrà et al. (2018) to train the mask. For each task t, a learnable task embedding e_l^t is introduced for each layer. The task mask m_l^t is defined as a gated version of the embedding vector e_l^t:

$$m_l^t = \sigma(\frac{e_l^t}{\tau}) \tag{6}$$

where σ represents a gate function, and τ is a temperature variable. We wish to learn a binary task mask that could be employed to allocate feed-forward memory in the same format as described in Eq.2.

To facilitate the efficient learning of task masks, we employ a sigmoid function with a temperature scalar to create a differentiable pseudo-gate function. The temperature scalar regulates the polarization or 'hardness' of the pseudo-step function. As $\tau \to 0$, the values of $m_{l,i}^t$ tend towards either 0 or 1, compelling the model to exploit allocated memories. Conversely, as $\tau \to \infty$, the values of $m_{l,i}^t$ approach 0.5, allowing the model to freely explore memories. Throughout the training process, we implement temperature annealing, transitioning from $\frac{1}{\tau_{max}}$ to τ_{max}. This dynamic adjustment aids the model in cyclically exploring memories while simultaneously exploiting activated memories. During the training process, the mask undergoes a gradual polarization, resulting in the occupation of useful memories.

The embedding is initialized with $\alpha m^G - |\mathcal{N}(0,1)|$, where α is a constant. This initialization enables the new domain to harness all the insights from the general domain's memories. Simultaneously, it initializes the excess capacity usage to zero at the outset of training, fostering minimal capacity utilization. Upon model convergence, we archive the acquired mask for future utilization.

Applying task mask to safeguard 'read-only' memory. To tackle the challenge of CF, our approach involves leveraging task masks acquired from previous tasks to influence the gradient. Before learning a new task, denoted as t, we aggregate all task masks from preceding tasks using an element-wise max (EMAX) operation and subsequently binarize the result with a threshold λ, as expressed by the following equation:

$$m_l^{<t} = \mathrm{I}_\lambda(\mathrm{EMAX}_{j<t}\{m_l^j\}) \tag{7}$$

Here, the subscript l denotes the layer index. In this specific context, task 0 corresponds to the general domain translation task, and the associated mask derived from structural pruning for the general domain is denoted as m^0. The aggregated binary mask $m_l^{<t}$ encapsulates critical memories designated as 'read-only' by previous tasks. The primary objective is to safeguard the parameters in these memories, preserving their functionality for previous tasks. To achieve this, we utilize the mask to adjust the gradient during the training of task t, as articulated in the following equation:

$$g_l^{'t} = g_l^t \odot (1 - m_l^{<t}) \tag{8}$$

where $\odot$ denotes the Hadamard product. This modification guarantees that memories crucial for previous tasks (entries with a value of 1 in $m_l^{<t}$) will have near zero gradients, thereby ensuring their preservation during the training of subsequent tasks.

4 Experiments

In our multi-stage CL experiments for NMT systems, we finetune a pretrained general domain model on T new domains successively[3]. The pretrained model is based on the WMT'19 German-English news translation task winner (Ng et al., 2019). To neutralize the impact of task order, we randomly generate five task order sequences and report the average result.

4.1 Data Preparation

In the context of structure pruning, we employ the WMT14 de-en translation data[4] as the external dataset. Additionally, we combine the WMT newstest datasets from 2019 to 2021[5] to form a comprehensive general domain test set. For the continual domain adaptation experiments, we utilize the OPUS multi-domains dataset (Koehn and Knowles, 2017), which has been re-split by Aharoni and Goldberg (2020). It includes German-English parallel data in five domains: Medical, Law, IT, Koran and Subtitles.

The details of all datasets mentioned above are shown in Appendix A.

4.2 Baseline and Implementation Details

Baseline systems. We incorporate eight competitive methods for comparison in our experiments, which can be categorized into two groups: Non-Continual Learning (Non-CL) methods and CL methods. In the Non-CL category, **(1) Single-domain** and **(2) Mixed-domain** directly finetune the pretrained model on single or mixed domain data, achieving the **upper bound** performance. **(3) Adapter (Bapna and Firat, 2019)** inserts Adapters on each transformer block of the general domain model. In the CL category, we have **(4) Sequential Fine-tuning** continual finetunes the pretrained model sequentially; **(5) EWC (Thompson et al., 2019; Saunders et al., 2019)** adds elastic weight consolidation term to regularize loss; **(6) KD(Khayrallah et al., 2018; Dakwale and Monz, 2017)** use knowledge distillation to transfer knowledge; **(7) Dynamic-KD(Cao et al., 2021)** involves dynamic adjustments to the weight of KD loss. **(8) PTE(Gu et al., 2021)** prune the general domain model and learn target domain with free parameters. We have extended the baseline method designed for a single stage to multiple stages. Further details on these methods can be found in Appendix B.

Implementation detail. In our proposed method, we exclusively finetune the Feed-forward layers in Transformers, keeping all other modules frozen throughout the procedure. During the structure pruning stage, we set the pruning sparsity to 0.2 for subsequent CL experiments (the same pruning sparsity is also used in PTE for fair comparison). When computing the proposed JS loss, we only activate the default dropout module for feed-forward activation. In the CL stage, the temperature hyperparameter τ_{max} is set to 400, following previous work (Serrà et al., 2018). We use $\alpha = 5.0$ in the embedding initialization. The binarize threshold λ in Eq.7 is set to 0.5. For more details please refer to Appendix C.

[3] In our experiments, a task is a domain. Hence, we use task and domain interchangeably.

[4] https://www.statmt.org/wmt14/translation-task.html

[5] https://www.statmt.org/

4.3 Metrics

We adopt the BLEU score to evaluate the translation performance. Recognizing that post-training BLEU may not sufficiently capture the nuances in multi-stage CL, we introduce two additional metrics: **Forgetting Ratio (FR)** and **Saturation Ratio (SR)**.

- Inspired by (Liu et al., 2020), FR is defined as:

$$\mathrm{FR}^t = \frac{1}{t-1}\sum_{i=1}^{t-1}\frac{a_i^i - a_i^t}{a_i^i} \tag{9}$$

  where $a_i^j, \forall i \leq j$ represents the BLEU on the i-th domain after learning of j-th domain[6]. This metric is employed to quantify the stability (the ability to prevent forgetting).

- SR is defined as:

$$\mathrm{SR}^t = 1 - \frac{a_t^t}{a_t^M} \tag{10}$$

  where, a_i^M represents the BLEU of i-th domain in a mixed-domain training fashion, commonly regarded as the **upper bound** of CL methods. The saturation rate highlights the system's plasticity (learning ability) when encountering a new task, with a higher rate indicating lower plasticity.

5 Results and Analysis

Table 1 presents the post-training performances of all nine systems across six domains. Notably, F-MALLOC consistently outperforms all CL baselines on average, with an impressively low forgetting rate of 0.71%. In comparison with regularization-based baselines, F-MALLOC demonstrates a better ability to alleviate forgetting and acquire new knowledge. When compared with the SOTA architecture-based method, PTE, F-MALLOC attains higher performance with minimal storage overhead and no prior information about task numbers.

Regrading the Non-CL baselines, although still trailing behind the upper bound performance, F-MALLOC demonstrates comparable performance to the strong baseline method, Adapter. These results collectively underscore the effectiveness of F-MALLOC in Continual Learning scenarios for Transformer-based Neural Machine Translation (NMT) systems.

For a more comprehensive analysis and comparison of various CL methods, the following subsections will use task sequence 0: IT → Koran → Law → Medical → Subtitles as a reference.

5.1 Comparison with CL methods

Table 2 presents the results for task sequence 0. Notably, among the prior CL methods, PTE stands out with the best performance, achieving a BLEU score of 39.58. In contrast, regularization-based methods exhibit inferior performance. The suboptimal results of KD-based approaches (KD and Dynamic-KD) can be attributed to the absence of sample replay in our experimental setting. Without a sample cache from previous tasks, KD struggles to effectively transfer knowledge from the preceding model to subsequent ones. Importantly, F-MALLOC surpasses all CL baselines, delivering the best results in both the BLEU score and forgetting rate.

Robustness against domain order. A horizontal comparison between Table 1 and Table 2 for the same method's performance reveals that regularization-base methods such as EWC and KD are sensitive to domain order, resulting in imbalanced performance on the initial and final tasks. In contrast, F-MALLOC exhibits notable resilience to variations in domain order, as evidenced by the balanced performance across different domain orders. This robustness is further substantiated by the low standard deviations presented in Appendix D.

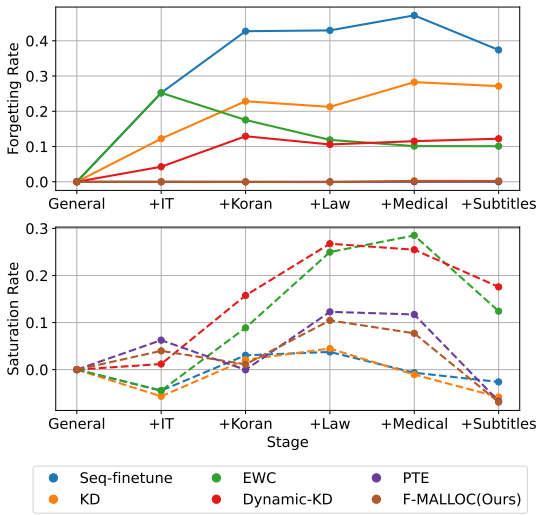

Figure 4: Forgetting rate and saturation rate across different training stages.

[6]This definition calculates the average proportion of performance degradation over all previously learned domains, excluding the latest one as it experiences no forgetting.

Category	Domain	General	IT	Koran	Law	Medical	Subtitles	Average	FR[%]	Additional storage
	Method	BLEU								
Non-CL	Single-domain	38.00	**48.80**	22.90	57.15	55.93	32.01	**42.47**	-	$T \cdot M$
	Mixed-domain	21.24	46.17	22.97	**60.35**	**55.98**	29.87	39.43	-	0
	Adapter	38.00	44.09	22.48	53.31	51.23	**32.05**	40.19	-	$T \cdot A$
CL	Seq-finetune	15.81	29.29	12.16	23.90	26.50	20.76	21.40	47.80	0
	EWC	24.57	36.93	17.61	46.14	43.92	25.01	32.36	11.47	$2M$
	KD	22.80	34.49	13.93	36.33	38.00	24.88	28.41	32.79	M
	Dynamic-KD	27.88	31.84	14.33	40.05	39.78	23.53	29.57	15.33	M
	PTE	37.00	42.82	**23.06**	52.65	49.59	31.69	39.47	-	$T \cdot M[bit]$
	F-MALLOC(Ours)	**39.54**	44.33	23.02	53.77	51.62	31.16	40.57	0.71	$T \cdot E$

Table 1: BLEU and FR for all domains post-training. The results are averages of 5 different task sequences (Non-CL baselines are independent of task order). The best results are highlighted in bold. The best CL results are highlighted with an underline. '-' indicates the corresponding methods have no forgetting. The specital tokens denote number of seen tasks(T), adapter size(A), model parameter size(M), binary mask size($M[bit]$) and task embedding size(E). Note that $M \gg M[bit] > A \gg E$.

Domain	Genearl	IT	Koran	Law	Medical	Subtitles	Average	FR[%]
Method	BLEU							
Seq-finetune	21.02	23.15	11.80	31.33	36.83	30.65	25.80	37.40
EWC	22.86	45.81	18.96	43.37	39.18	26.16	32.72	10.10
KD	25.91	29.52	13.40	40.31	44.68	31.61	30.91	27.14
Dynamic-KD	30.35	33.83	15.56	41.65	40.90	24.62	31.15	12.22
PTE	37.00	43.28	**22.98**	52.94	49.42	31.87	39.58	-
F-MALLOC(Ours)	**39.54**	**44.19**	22.81	**53.64**	**51.21**	**31.93**	**40.55**	**0.24**

Table 2: BLEU and FR of CL methods for all domains post-training using task sequence 0 (the domain training order corresponds to the sequence in the first row). The best results are highlighted in bold.

Trade-off between stability and plasticity. As depicted in Fig.4, both EWC and Dynamic-KD exhibit robust abilities to mitigate forgetting. However, they also demonstrate a high saturation rate, suggesting a compromise in their potential to adapt to additional tasks. In contrast, KD achieves a low saturation rate akin to Seq-finetune, but its forgetting rate is notably higher. This observation sheds light on the struggle of regularization-based methods to balance stability and plasticity. Crucially, F-MALLOC excels in both objectives, achieving a harmonious equilibrium between mitigating forgetting and maintaining adaptability.

5.2 Hyperparameter

Temp	BLEU	FR[%]	Sparsity	BLEU	FR[%]
$\tau_{max} = 50$	36.83	10.81	$s = 0.05$	39.09	0.40
$\tau_{max} = 100$	38.33	6.89	$s = 0.1$	39.87	0.15
$\tau_{max} = 200$	40.22	2.37	$\mathbf{s = 0.2}$	**40.55**	**0.24**
$\boldsymbol{\tau_{max} = 400}$	**40.55**	**0.24**	$s = 0.3$	40.01	0.85
$\tau_{max} = 800$	40.60	0.10	$s = 0.4$	39.88	2.02

Table 3: The effect of max temperature τ_{max} (left) and sparsity s (right). The value used in our experiments is highlighted in bold.

We explored the impact of annealing temperature τ_{max} and prune sparsity s. As outlined in Table 3, a small temperature results in a 'soft' mask value, contributing to increased FR. Good results were observed when $\tau_{max} \geq 400$. Continually increasing the temperature renders the annealing strategy ineffective, resulting in a slower convergence speed.

In terms of prune sparsity, low sparsity restricts the available capacity for subsequent tasks, while high sparsity adversely affects general domain performance, both contributing to diminished overall performance. Notably, the performance gap across varying prune sparsity levels is relatively small, highlighting the robustness of F-MALLOC.

5.3 Analyzing Memory Capacity Allocation

F-MALLOC employs a task mask mechanism for the dynamic allocation of feed-forward memories to different tasks. Therefore, by computing the accumulated task mask $m^{<t+1}$ and subsequently binarizing it, we can assess the proportion of allocated memories. As depicted in Fig.5, the capacity usage undergoes rapid growth in the initial training stage for all tasks, gradually converging at a stable rate thereafter.

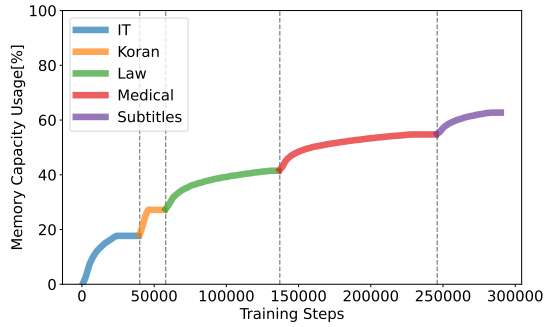

Figure 5: Feed-forward memory capacity usage in the training process of task sequence 0. Vertical dash lines indicate task switches.

	#Token	Init_loss	Capacity usage[%]
Koran	0.52M	3.455	12.25
IT	3.61M	2.398	17.68
Subtitles	6.25M	3.144	22.48
Medical	6.90M	2.284	23.15
Law	19.06M	1.616	22.69

Table 4: Stastics of data volume (#Token), task complexity(Init_loss) and average capacity usage.

Upon comparing different tasks, we present the statistics of data volume and task complexity for each domain alongside the corresponding average capacity usage in Table.4. Observing the table, we discern a trend of increased capacity usage with higher data volume. 'Law' stands out as an exception to this trend, having three times more tokens yet occupying a similar capacity as 'Subtitles' and 'Medical'. However, 'Law' is evidently the easiest domain, indicated by its lowest initial loss at the start of its training phase. Hence, its low capacity usage is justified by its relatively lower difficulty. Taken together, these observations suggest that our proposed method has acquired a rational and efficient memory allocation strategy, effectively leveraging the data volumes and inherent complexities of the tasks.

Towards the conclusion of the entire training process, approximately 40% of the feed-forward memory is still 'writable'. However, the best-performing baseline, PTE, has already exhausted model capacity. This emphasizes the potential of our proposed method to effectively accommodate additional tasks.

5.4 Knowledge Transfer and Domain Similarity from Memory Reusing

In our proposed method, we employ non-exclusive task masks, allowing feed-forward memories allocated to previous tasks to be reused by subsequent tasks. To investigate the inter-task relationship regarding the allocation of memories, we visually represent the overlap rate among task masks for different tasks. Specifically, we utilize the Jaccard similarity coefficient, defined as $\frac{|m^i \cap m^j|}{|m^i \cup m^j|}$, to assess the memory reuse between task t_i and t_j, $i < j$. The results, depicted in Fig.6, reveal a substantial proportion of memory reuse between different tasks. This observation underscores the effectiveness of our non-exclusive masking strategy in facilitating knowledge transfer between tasks.

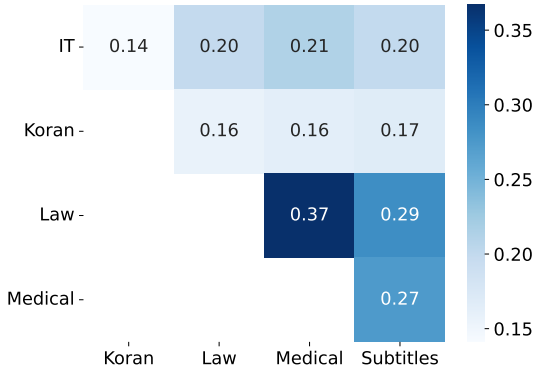

Figure 6: Percentage of memory reuse across tasks.

We further conducted a comparative analysis with the unsupervised domain clustering approach proposed by Aharoni and Goldberg (2020). The observed memory reuse rate aligns consistently with domain similarity. Specifically, Aharoni and Goldberg (2020) found that the 'IT' domain cluster attracted the largest number of outliers, primarily from the 'Law', 'Medical', and 'Subtitles' domains. We observed a corresponding pattern of higher memory reuse between these domains in Fig.6. Furthermore, their findings indicated that the 'Koran' domain cluster is isolated and attracts the smallest number of outliers, aligning with the notably lower memory reuse observed in our experiments for the 'Koran' domain. This alignment highlights the effectiveness of our approach in capturing and leveraging task similarities for improved knowledge transfer.

6 Related Work

CL for NMT. Recent work on CL of NMT can be divided into two categories: regularization-based and architecture-based. Regularization-based techniques address forgetting by incorporating penalty terms to constrain the divergence of model parameters from their previous values. Prominent meth-

ods, including Elastic Weight Consolidation (EWC) (Thompson et al., 2019; Saunders et al., 2019) and knowledge distillation (Dakwale and Monz, 2017; Khayrallah et al., 2018; Zhao et al., 2022; Cao et al., 2021), are widely acknowledged for their effectiveness in the fine-tuning process. Gu et al. (2022) introduced a hard Low Forgetting Risk restriction on all parameters. In contrast to these approaches, our method effectively mitigates forgetting by blocking gradients, showcasing a more efficient strategy.

Architecture-based methods involve dividing the model into disjoint task-specific components. For instance, Gu et al. (2021) prune the general domain model and subsequently finetune free parameters to adapt to the target domain. Another approach, as demonstrated by Liang et al. (2021), involves freezing Lottery Ticket Subnetworks to prevent forgetting. Additionally, Huang et al. (2023) propose utilizing external models' feed-forward layers and embeddings as a plug-in for knowledge transfer. In comparison to these methods, our approach stands out as it requires no pre-specification of task numbers or space allocation. Moreover, it avoids the need to store an external model or a mask matrix.

Unstructured Pruning for Transformers. For coarse-grained unstructured pruning of Transformer models, attention-head pruning (Voita et al., 2019; Michel et al., 2019), layer-dropping (Fan et al., 2020) and block pruning (Lagunas et al., 2021) have been popularly used. Our proposed pruning method shares similarities with the approach presented in Xia et al. (2022); Kwon et al. (2022), where a mask or diagonal matrix is introduced to facilitate pruning. However, our approach diverges in both the estimation of importance and the selection of modules earmarked for pruning..

7 Conclusion

This paper introduces F-MALLOC, a pioneering method for CL in NMT systems. By decomposing feed-forward layers into memory cells and implementing a strategic memory allocation approach, F-MALLOC proves effective in simultaneously enhancing new knowledge acquisition and alleviating forgetting. Evaluation with a specialized protocol for CL in NMT, positions F-MALLOC as a superior performer, showcasing substantial improvements, robustness, and extensibility compared to existing approaches. The method's ability to leverage task difficulty and inter-task similarities for enhanced performance represents a significant advancement not seen in previous methods. F-MALLOC not only contribute to the field of CL in NMT but also pave the way for more efficient and adaptable neural network architectures.

Limitations

Although our proposed F-MALLOC can effectively alleviate forgetting and exhibits high robustness and extensibility, there are several limitations in our current study: On the one hand, F-MALLOC utilizes a fixed-capacity Transformer, which may limit its capability to adapt to an unrestricted number of tasks. On the other hand, F-MALLOC is designed for domain incremental training. Thus, adding a new language can not be directly solved. We leave these problems for future research.

Table 5: Dataset statistics.

Here, we present detailed statistics for the datasets used in our experiments in Table 5, focusing on the translation direction EN → DE. We employ Moses scripts[7] for sentence tokenization and truecasing. Additionally, we utilize FastBPE[8] to apply Byte Pair Encoding (BPE)(Sennrich et al., 2016) to the tokenized data. The dictionary and BPE codes are sourced from the Fairseq WMT19 German-English news translation pretrained model(Ng et al., 2019).

B Baseline Details

Non-Continual Learning Methods. Each of these baselines constructs a distinct model (or module) for each task independently. Consequently, they do not encounter CF and lack knowledge transfer between tasks.

- **Single-domain** continues to train the general domain model on target domain data, respectively.
- **Mixed-domain** trains the general domain model on combined multi-domain data, which is considered the **upper bound** of CL methods.
- **Adapter (Bapna and Firat, 2019)** inserts adapters on each transformer block of the general domain model as proposed by Bapna and Firat (2019). We set the bottleneck dimension to 64 and only finetune the adapters.

Continual Learning Methods:

- **Sequential Fine-tuning** continues to train the general domain model on target domains sequentially, without incorporating any mechanism to address CF.
- **Elastic Weight Consolidation (EWC) (Thompson et al., 2019; Saunders et al., 2019)** is a popular regularization-based CL method that adopts elastic weights consolidation to introduce L_2 regularization, penalizing parameter changes. The training objective is:

$$\mathcal{L}_{\text{EWC}}(\theta) = \mathcal{L}_{\text{CE}}(\theta) + \alpha \sum_i F_i(\theta_i - \theta_i^G)^2$$

  In this equation, θ represents the model parameters, F is the diagnosis of the Fisher information matrix, and α is a hyperparameter controlling the strength of regularization. To extend this method to a multi-stage scenario, we adopt the accumulated Fisher information, as proposed by Huszár (2017).

- **Knowledge Distillation (KD) (Khayrallah et al., 2018; Dakwale and Monz, 2017)** introduces a regularization (reg) term into the training objective. The reg term is formulated in the spirit of knowledge distillation, minimizing the cross-entropy between the original (teacher) model's output distribution and that of the new (student) model. A hyperparameter α is introduced to interpolate the reg term and the NLL loss.

$$\mathcal{L}_{\text{EWC}}(\theta) = \mathcal{L}_{\text{CE}}(\theta) + \alpha \mathcal{L}_{\text{KD}}(\theta)$$

  In our experiments, the weight of the KD term is set to 0.1.

- **Dynamic Knowledge Distillation (Dynamic-KD) (Cao et al., 2021)** propose dynamically adjusting the weight of KD loss to better alleviate CF in a multi-stage CL scenario. The bias correction module is omitted due to its incompatibility with the pretrained model.
- **Prune Then Expand (PTE) (Gu et al., 2021)** employs unstructured pruning to trim the general domain model, followed by training the pruned parameters for the target domain. In the context of multi-stage CL, we uniformly distribute the pruned parameters across all subsequent tasks.

C Implementation Details

pretrained Model. All methods are implemented with the Fairseq toolkit (Ott et al., 2019). We

adopt the WMT'19 German-English news translation task winner (Ng et al., 2019) as the pre-trained general domain model. It is a Transformer encoder-decoder model (Vaswani et al., 2017) with 6 layers, 1,024-dimensional representations, 8,192-dimensional feed-forward layers, and 8 attention heads. Apart from WMT'19 training data, this model is trained on over 10 billion tokens of back-translation data and finetuned on the Newstest test sets from years before 2018. In our experiments, we do not use ensembles or n-best reranking.

Hyper-parameters. Unless explicitly stated otherwise, consistent hyperparameters are applied across all experiments. We utilize the Adam optimizer (Kingma and Ba, 2015) with the same learning rate scheduler as detailed in Vaswani et al. (2017). The learning rate is set to 1e-4 for all systems during the fine-tuning process. Training is stopped when there is no performance improvement for 5 consecutive validation steps.

For inference, we employ beam search with a beam size of 5 for all systems. The default parameter of BLEU is utilized in evaluation.

All experiments are done on 8 NVIDIA RTX 3090 GPUs.

D Standare Deviations

This section reports the standard deviations of the results in Table 1. We only include the CL baselines here, since Non-CL baselines' performance is independent of the domain order. As shown in Table 6, F-MALLOC achieves low standard deviations, indicating its robustness.

E Result in Different Domain Orders

Table 7 shows the performance of F-MALLOC along with two strong baselines, EWC and PTE, in other domain orders. F-MALLOC outperforms both EWC and PTE, highlighting its efficacy across different domain order scenarios.

Towards Reducing Diagnostic Errors with Interpretable Risk Prediction

Abstract

Many diagnostic errors occur because clinicians cannot easily access relevant information in patient Electronic Health Records (EHRs). In this work we propose a method to use LLMs to identify pieces of evidence in patient EHR data that indicate increased or decreased risk of specific diagnoses; our ultimate aim is to increase access to evidence and reduce diagnostic errors. In particular, we propose a Neural Additive Model to make predictions backed by evidence with individualized risk estimates at time-points where clinicians are still uncertain, aiming to specifically mitigate delays in diagnosis and errors stemming from an incomplete differential. To train such a model, it is necessary to infer temporally fine-grained retrospective labels of eventual "true" diagnoses. We do so with LLMs, to ensure that the input text is from *before* a confident diagnosis can be made. We use an LLM to retrieve an initial pool of evidence, but then refine this set of evidence according to correlations learned by the model. We conduct an in-depth evaluation of the usefulness of our approach by simulating how it might be used by a clinician to decide between a pre-defined list of differential diagnoses.[1]

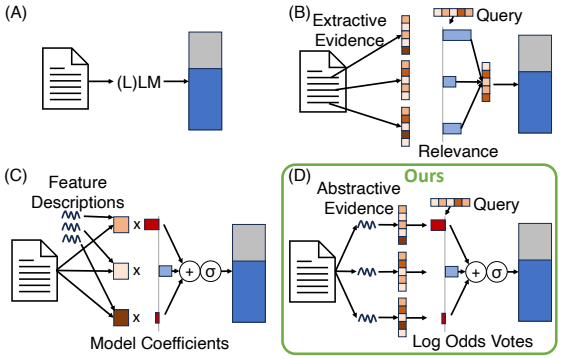

Figure 1: **Inherently "interpretable" approaches to prediction**. Typically, 'interpretable' models trade off between the expressiveness of intermediate representations and the faithfulness of the resulting interpretability to the models' true mechanisms. Our approach (D) manages to use very expressive intermediate representations in the form of abstractive natural language evidence while still maintaining true transparency during aggregation of this evidence. See Table 1 for more details.

1 Introduction

A major source of poor patient outcomes and unnecessary costs in healthcare are missed or delayed diagnoses. A recent report estimated that diagnostic errors result in around 795,000 serious harms annually (Newman-Toker et al., 2023). Furthermore, many diagnostic errors result from information transfer problems (Zwaan et al., 2010). This is unsurprising given "note bloat", i.e., the widespread problem of information overload in EHR notes, often due to copied or irrelevant information which obfuscates relevant information. All of this motivates the potential of providing more efficient mechanisms to access relevant information in EHRs as a means to reduce these errors.

One approach to helping practitioners make use of EHR is to train NLP models to provide predictions about patient risk for various illnesses (Rasmy et al., 2021; Li et al., 2021; Yang et al., 2023), but these systems are often lack transparency. Even when systems have high accuracy, clinicians may still prefer simple linear models as clinical deci-

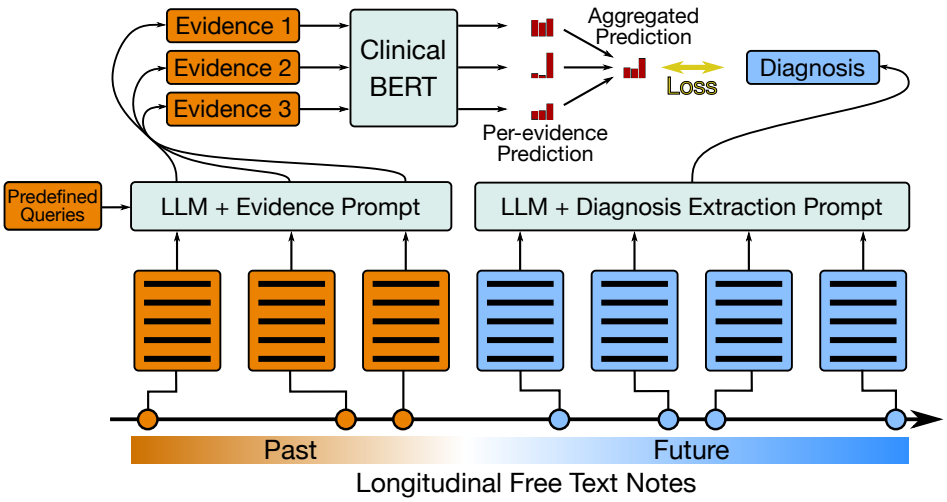

Figure 2: **Explainable Risk Prediction and Training.** An overview of our approach. Left: We retrieve evidence snippets from past notes with an LLM for predefined queries posed by a clinician. Then we use our risk prediction model to estimate risk of various diagnoses given each piece of evidence individually, and aggregate these scores. Right: We automatically extract diagnosis 'labels' from future reports with an LLM to use to train the risk predictor.

sion support tools (Goldstein et al., 2016). Prior work has focused on developing inherently interpretable[2] models with minimal tradeoff in predictive performance, e.g., in the general domain with Neural Additive Models (Agarwal et al., 2020) and in healthcare with GA^{2}Ms (Caruana et al., 2015). Recently, zero-shot instruction-tuned LLMs have been shown capable of extracting information from clinical text (Agrawal et al., 2022), which in turn facilitates interpretable predictions (McInerney et al., 2023; Alsentzer et al., 2023).

In this work, we combine the power and flexibility of zero-shot instruction-tuned LLMs with the transparency and modeling ability of Neural Additive Models (NAMs) to train a risk-prediction model that can also surface evidence to support predictions. We use an LLM (FLAN-T5-XXL; Chung et al. 2022) to generate abstractive "evidence" from EHR, which is then processed by a simpler model (Clinical BERT; Alsentzer et al. 2019) to produce features for a Neural Additive Model (Figure 2). This provides flexibility—the model can make inferences and condense information into fluent text snippets—but brings risk of "hallucinations".

This approach is "interpretable" insofar as it produces "evidence" in the form of human-understandable intermediate variables: Abstractive text with associated risks, providing insight into factors that informed predictions. Related approaches to "interpretability" (Figure 1) include using relevance scores to weight and combine information from different sentences (B), and those that use LLM prompts to infer feature values (C). Our approach permits greater flexibility than (C), while maintaining a more faithful interpretability in comparison to (B); see Table 1.

One complication is that we would like fine-grained, accurate labels to train our predictor (see section 4.1); ICD codes do not meet these criteria (Searle et al., 2020). Instead of ICD codes, which are noisy and temporally coarse (observed at the end of an encounter with discharge summaries), we propose to synthetically extract diagnosis labels from each report using an LLM. In some cases, this has been shown to be more aligned with true diagnoses (Alsentzer et al., 2023).

We focus our evaluation on how this system impacts clinical decision-making. Specifically, we examine settings where risk of misdiagnosis is high and the consequences severe. Our methods work within the confines of data present in electronic health record, which allows the model to be trained on any EHR. LLMs can be run locally and are only used for inference, so privacy and compute resources are not an issue.

Our contributions are summarized as follows:

Interpretable Risk Prediction with LLMs. We propose an approach to risk prediction that offers a particular form of interpretability in that it can expose faithful relationships between specific pieces of retrieved evidence and an output prediction.

[2]Interpretability is a famously ambiguous term; we are focused on having explicit measure of the contribution of individual pieces of evidence to an output.

Extracting Future Targets with LLMs. We present a method to extract target diagnoses for use in training from the unstructured text in the future of a patient's medical record that are more granular than ICD codes in the time dimension, and we validate with clinician annotations that the extracted labels are accurate.

In-depth Annotation of Usefulness. We validate how much evidence-wise interpretability can positively impact a clinician's expert judgement in high-impact settings which feature the greatest risk of misdiagnosis.

2 Dataset

We use MIMIC-III (Johnson et al., 2016a,b), an open-source dataset of EHRs from ICU patients. The ICU is one of the hospital settings (along with, e.g., the ER and Radiology) where misdiagnosis or delayed diagnosis are often caused by incomplete information, since clinicians typically do not have enough time to fully examine a patient's EHR.

In healthcare, cancer, infection, and vascular dysfunction (termed the "big three") account for about 75% of all mis-diagnosis-related harms (Newman-Toker et al., 2023). Within the ICU, the latter two categories mostly manifest as pneumonia, and pulmonary edema (which in this paper we treat as interchangeable with congestive heart failure). For this reason, we will focus on predicting the risk of ICU patients for cancer, pneumonia, and pulmonary edema. These are also conditions for which clinical correlation with notes from the past EHR is important for diagnosis. We use all patients in the MIMIC dataset so that we have both negative and positive examples of the conditions. We include additional details regarding the dataset and preprocessing in appendix section A.

3 An Interpretable Risk Prediction Model

We propose a multi-stage approach to risk prediction, capitalizing on a modern LLM, FLAN-T5-XXL (Chung et al., 2022; Wei et al., 2022) in this case, to implement each of the following steps.

Retrieval (Section 3.1). We generate abstractive evidence from free text notes by prompting an LLM with appropriate queries. The evidence snippets provide a form of interpretability, in that they can be inspected directly to verify predictions.

Risk Prediction (Section 3.2). We input the evidence into the risk predictor, which models relationships between the evidence and each of the potential diagnoses and outputs multi-label classification probabilities, i.e. the predicted risk that the patient will be diagnosed with each condition.

Evidence Re-ranking (Section 3.3). The retrieved evidence may still be too large a pool to review given the time constraints of the clinician. Therefore, we re-rank the evidence so as to only show that which promotes risk predictions that most deviate from the baseline risks of each condition.

To train risk prediction models we use use synthetic labels extracted from *future* notes in a patient's record (Section 4). Figure 2 provides an overview of our model and training approach.

3.1 Evidence Retrieval

Following prior work (Ahsan et al., 2023), we use a sequential prompting strategy to retrieve evidence that is relevant to a queried diagnosis or a risk factor. Specifically, we first ask the LLM for a binary response as to whether evidence for a condition exists; if the answer is affirmative, we then issue a second prompt tasking the LLM to generate supporting evidence. Formally, we define the evidence retrieved for report n and query q_i as follows:

$$e_{n,q_i} = \begin{cases} \text{GetEvidence}(r_n, q_i) \\ \quad \text{if EvidenceExists}(r_n, q_i) = \text{“yes”} \\ \texttt{null} \quad \text{otherwise} \end{cases} \tag{1}$$

where "GetEvidence" and "EvidenceExists" represent the corresponding prompt functions.

This approach does have limitations. For example, it cannot produce more than one snippet of evidence per report/query pair. Retrieved evidence may also be abstractive rather than extractive, which introduces the risk of model "hallucinations", but permits flexibility and interpretability (Ahsan et al., 2023). It also significantly reduces the amount of text (therefore requiring a relatively small context window) by going from all reports to sentence-length snippets for some reports. The resulting "summarization" in the form of evidence snippets is also controllable through the querying process and works zero-shot, i.e., it requires no specialized or in-domain training. Queries, in the form of the 3 diagnoses considered and risk factors written by a clinician co-author, are shown in appendix Table 5. We present further details regarding the evidence retrieval prompts in Appendix B.

Modeling Approach	Intermediate representation(s)	Aggregation	Interpretability
(A) Direct **Black-box** Prediction (e.g., zero/few-shot, fine-tuned LLM)	None	CLS or last token embedding + classification or LM head	No inherent interpretability
(B) Aggregating chunked input with **relevance weights**	*Extractive* text snippets	Weighted avg. of CLS embeddings + class. head	Positive, real-valued relevance scores per query
(C) **Logistic regression** with LLM-inferred features	*Inferred*, real-valued numbers relating to predefined natural language queries	Logistic regression	Negative and positive real-valued static model coefficients
(D) **Log odds voting** with LLM-inferred text snippets (ours)	*Inferred/abstractive* text snippets relating to predefined natural language queries	Neural Additive Model (conditioned on the query/condition vector)	Negative and positive real-valued dynamic impact scores

Table 1: Types of interpretability afforded by the different modeling approaches for EHR data visualized in Figure 1. Red and green denote negative and positive aspects of each model.

3.2 Risk Prediction

Because a patient can have more than one diagnosis, we treat risk prediction as a multi-label classification problem where each label corresponds to a diagnosis. To realize interpretability, we use a Neural Additive Model (Agarwal et al., 2020). Specifically, we do not model *interactions* between evidence snippets. Instead, we predict scores individually for each piece of evidence, and average these[3] to obtain a logit for risk prediction:

$$p(\hat{y}_i = 1|e_{1:E}) = \sigma(b_i + w_i \cdot (\frac{1}{E}\sum_{j=1}^{E} f_\theta^{\text{BERT}}(e_j))) \quad (2)$$

where $w_i \in \mathbb{R}^d$ is the embedding of diagnosis i, $e_{1:E}$ is the flattened list of evidence snippets[4] with `null` evidence omitted, f_θ^{BERT} is the ClinicalBERT (Alsentzer et al., 2019) `[CLS]` embedding function (which yields a d-dimensional vector), and $b_i \in \mathbb{R}$ is the bias for diagnosis i. The prior over conditions can be defined as the same equation excluding the evidence term: $p(\hat{y}_i) = \sigma(b_i)$, and the **relative risk** follows as $p(\hat{y}_i|e_{1:E})/p(\hat{y}_i)$.

While the bias could be learned, we instead simply set it to the inverse sigmoid of the observed prevalence of the disease in the training sample distribution: $b_i = \sigma^{-1}(\text{prevalence}_i^{\text{train}})$. This means that if we wanted to transfer the model to a new population, where the prevalence differed but the contributions of different evidence were assumed to remain, we could simply update the b_i term.

[3]Neural Additive Models typically use a sum instead of an average, but we found that given varying amount of evidence retrieved, it worked better to use an average.

[4]We add the query term used to retrieve the evidence and relative date of the evidence before serving it as input, which we describe in greater detail in Appendix C. Also note that we use evidence surfaced by all queries for all predictions.

Excluding interactions between evidence snippets is a sacrifice in model complexity, but it also allows us to compute an interpretable "vote" for any individual piece of evidence as

$$p(\hat{y}_i|e_j) = \sigma(b_i + w_i \cdot f_\theta^{\text{BERT}}(e_j)) \quad (3)$$

and compute an individualized relative risk for each piece of evidence using this value.

Conveniently, forcing the bias term to be the inverse sigmoid of the training prevalence, by definition, also means we can interpret the evidence term in Equations 2 and 3 as the **log odds ratio**, i.e., the difference between the logits when conditioning vs. not conditioning on the evidence. The model is effectively estimating this log odds ratio directly. This variable's expected value does not change if we sample conditions for training with a frequency different from the the natural prevalence of the conditions (Simon, 2001). Because of this, we can estimate the likelihood and the relative risk during inference on a differently sampled population by simply changing the bias term in the prior and in equations 2 and 3 to reflect the estimate of the natural prevalence of the conditions (Zhang and Kai, 1998), which we can get from the training set before sampling: $b'_i = \sigma^{-1}(\text{prevalence}_i^{\text{train}})$.

3.3 Evidence Re-ranking

Because of the simplicity of the risk prediction, we can use the internal variables it exposes to re-rank evidence. The intuition behind the re-ranking is that the most important evidence will be that which most changes our risk assessment from the prior over the diagnoses, and we would like the chosen metric to capture this across all of the potential diagnoses. We use Mean Squared Error (MSE) of the predicted logits with the logits of the prior $p(y)$.

This makes the formulation of the MSE metric simple as the mean (over Q conditions) of the squares of the log odds ratio for a piece of evidence:

$$\text{MSE}(\sigma^{-1}p(\hat{y}|e_j), \sigma^{-1}p(\hat{y})) = \frac{1}{Q}\sum_{i=1}^{Q}(w_i \cdot f_\theta^{\text{BERT}}(e_j))^2. \quad (4)$$

It is necessary to use the *log odds* ratio term in this score function because we care not only about increasing but also about decreasing the probability of a condition, so it makes most sense to compare and sum these two different effects in log space. The reason to choose MSE over other scores (e.g. the absolute distance) comes from the intuition that it is more important to see the evidence that is "very opinionated" about one condition rather than to see evidence that is "slightly opinionated" about many. Therefore, it is necessary to square this log odds ratio before averaging across conditions to reflect this idea when sorting evidence.

4 Certain Diagnosis Extraction

We make an assumption about the EHR of patients that eventually receive a diagnosis that there is some period of time in the record where a diagnosis is "uncertain" before it becomes "certain", and the eventual "certain" diagnosis is correct. Of course just because a diagnosis is definitive as noted by clinician in the record does not necessarily mean that it is correct—sometimes clinicians are wrong.

However, it is hard to detect such cases, so here we focus on reducing delayed diagnosis errors where we assume some evidence in the medical record from that "uncertain" period could have influenced a clinician to make a diagnosis or order a certain kind of test sooner than they did, or keep a diagnosis in the running list of differentials for longer. If notes are incorporated into the input where the diagnosis is already certain, the prediction problem becomes too easy, which is why a time-wise fine-grained label is necessary—such a label could more accurately weed out all of this obvious evidence. To extract these certain diagnoses with an LLM, we use three sequential prompts and a normalization step.

4.1 3-Stage Extraction with LLMs

In this section we describe the prompts for certain diagnosis extraction, which are shown in full in Appendix D. Following prior work (Ahsan et al., 2023), we first prompt the LLM with a binary question asking if there exists a confident diagnosis for a patient. If the answer is "yes", we then ask the model for the diagnoses. Unfortunately, creating a list of diagnosis terms from the answer to this prompt is not just a matter of parsing because we found that the model will often return extended phrases that are not easily mapped to diagnoses. Therefore, we issue one more prompt that only takes in the output of the previous prompt to create a structured list of diagnostic terms. We then parse this final output of the LLM into a list of strings.

4.2 Normalization

To normalize produced diagnostic terms, we take a two-step apporach. First we use string matching heuristics to handle easy cases. Then we embed sentences with `SentenceTransformers` (Wang et al. 2020; Reimers and Gurevych 2019; specifically, `all-MiniLM-L6-v2`) and calculate cosine similarities, matching a term in the parsed list to the most similar term (with similarity $>.85$) in the predefined set ("cancer", "pneumonia", and "pulmonary edema"). We ignore terms with no match.

5 Evaluation

Because our targets are synthetically generated using an LM, we first evaluate how well our labels align with the "ground truth" (Section 5.1). Next, we aim to evaluate how well the model can realistically help with risk prediction. Though it is straightforward to assess the accuracy of the risk prediction itself—we use the standard metrics of precision, recall, F1 and AUROC scores to compare to various uninterpretable baselines—it is not as easy to assess what we really care about: How helpful is the interpretability offered by the proposed model to clinicians (section 5.2)? For this we resort to manual evaluation by our clinical coauthors and develop bespoke interfaces to facilitate annotation.

5.1 Future Target Extraction

To evaluate how well the LLM extracts targets in the form of "confident" diagnoses, we enlist our clinical collaborators to annotate the precision with which the LLM infers "confident" diagnoses. In particular, for every report where one of the three diagnoses—cancer, pneumonia, and pulmonary edema—was automatically extracted, an ICU clinician is first tasked with answering the question "Is

[diagnosis] a confident diagnosis of the patient according to the report?". If the answer is "yes", they are asked: "Is it likely that this confident diagnosis could be identified in earlier reports?".

5.2 Risk Prediction Interpretability

To assess the viability of clinicians using this model in practice, we collect in-depth annotations intended to simulate the real-world use of this technology. We evaluate a number of baseline models and model ablations to assess the relative benefits of different model components.

Interface and Annotations To conduct annotations, we develop an interface that simulates as closely as possible the envisioned use case: A clinician is seeing an ICU patient's chart for the first time and trying diagnose the patient or determine what they are at risk of. The clinician may not have much time to spend with the patient's chart, so we ask clinician annotators to work quickly—specifically, to try and keep annotation time to a few minutes—and we record the amount of time they take to review the patient's record. When they are done, the annotation process starts, and though they are allowed to access the patient's notes, they are encouraged not to.

We first ask if a diagnosis is noted explicitly in the patient's record. Given that we are aiming to evaluated records where the diagnosis is not yet clear, we skip the rest of the annotations on the instance if a diagnosis is explicit. If not, we ask for estimates of the likelihood ("unlikely", "somewhat likely", or "very likely") of each of the possible conditions. Note that we explicitly do not show any model predictions until after this question, to avoid bias. Then, we show the annotator the model predictions and ask if the predicted risk for the conditions aligns with intuition.

Moving onto the evidence (appendix Figure 13), we allow the annotator to look at the sorted evidence one snippet at a time along with the individualized risk prediction only based on that snippet. The annotator notes the usefulness of the evidence with respect to each condition. If the evidence is useful, they are asked whether or not the impact of this evidence on the risk scoring (for the particular condition) aligns with intuition, and whether the annotator remembers seeing this piece of evidence during their initial review of the patient's notes. After two pieces of evidence, if the annotator feels like more evidence is needed to form a reasonable opinion of the patient's risk, they can request more evidence snippets (up to a maximum of 10), annotating each as they go. Finally, the annotator is asked if any of the evidence presented impacted their original assessment of likelihood.

Ablations While the task of risk prediction is standard, there is less work on the task of surfacing relevant evidence (abstracted or extracted) to support such predictions. Consequently, there is not a large set of baselines to serve as natural comparators to our approach. Therefore, in our analysis we focus on showing the importance of each component of our model through ablations. We can decompose our approach into two evidence retrieval components, generating the evidence, which we refer to as "**LLM Evidence**" and reranking it, which we refer to as "**Log Odds Sorting**". The following ablations show the importance of both of these components in identifying useful evidence.

We use prior work (Ahsan et al., 2023) as a starting point for generating the evidence, so it is natural to ask what that component can do by itself without re-ranking using the risk prediction scores for each piece of evidence. A natural comparison is to present the same evidence retrieved but in a *random* or *reverse chronological* order (as recency is probably important). But we can also use the model certainty in evidence, given that this has been shown to correlate with the utility of snippets (Ahsan et al., 2023). We adopt this approach for comparison and call it "**Confidence Sorting**".

It is also natural to question the importance of using the language model to abstractively generate evidence at all. We might instead simply use every sentence in the report as evidence and train our prediction model with this retrieved evidence, reranking it in the normal way ("Log Odds Sorting") with the prediction model's scores. We call this the "**All EHR**" model.

6 Results and Discussion

The majority of our results are based on annotations from 4 annotators on 24 instances and 3 models. Each instance has a maximum of 3 annotators, each annotating different models (assigned randomly). Table 2 reports detailed statistics.

Our main goal is to understand if our approach can retrieve better evidence. To this end, we plot the percentage of evidence annotated in each category of usefulness for each model in Figure 3.[5]

[5]Sometimes annotators noticed nearly duplicate evidence,

Annotator	LLM Evidence+Confidence Sorting				Raw EHR+Log Odds Sorting				LLM Evidence+Log Odds Sorting			
	Inst.	Evid.	Rep.	Percent Useful	Inst.	Evid.	Rep.	Percent Useful	Inst.	Evid.	Rep.	Percent Useful
1	8	20	195	5.0	5	14	81	7.1	6	13	154	30.8
2	2	6	26	50.0	2	5	72	40.0	5	14	162	35.7
3	4	13	105	23.1	6	17	224	35.3	5	14	119	42.9
4	5	16	132	18.8	6	20	127	20.0	4	12	85	41.7
Aggregated	19	55	458	24.2	19	56	504	25.6	20	53	520	37.8

Table 2: Annotations. We report the statistics for the number instances annotated, the amount of evidence snippets annotated, the total number of reports in the annotated instances, and the percent of evidence annotated as "Useful" and "Very Useful". Aggregated statistics are computed by summing over the annotators except in the case of "Percent Useful", where scores are macro-averaged over annotators. (This is slightly different from Figure 3 where percentages are macro-averaged, i.e., we combine all annotated evidence).

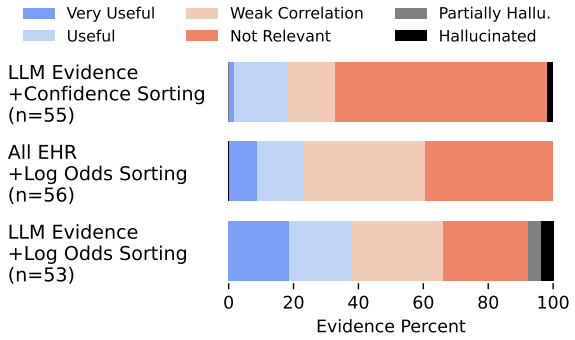

Figure 3: **Evidence Usefulness** (the maximum score across conditions) for our approach and two ablations. "LLM Evidence+Confidence Sorting" uses model evidence, but sorts by (length-normalized) log probability instead of the log odds. "All EHR+Log Odds Sorting" does not use LLM evidence and instead takes the last 1000 sentences in the record as evidence.

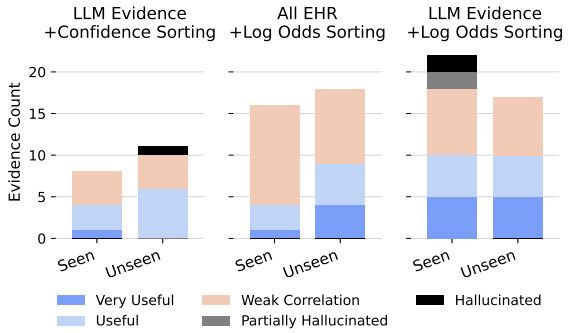

Figure 4: **Seen vs. unseen** evidence counts for all evidence that at least weakly correlates with a condition. Curiously, the LLM Evidence with Log Odds Sorting model has some hallucinated evidence that was seen by annotators. See section 6 for a discussion.

	Not Relevant	Weakly Correlated	Useful	Very Useful
LLM Conf.	0	1	0	0
Log Odds	0	1	3	0

Table 3: The original evidence ratings of hallucinations.

Though we record usefulness for each condition individually, here we combine these annotations by taking the maximum score across the conditions for each piece of evidence. To identify hallucinated evidence, we conducted post-hoc annotations with only the annotated LLM-generated evidence that was abstractive (42 of 108).[6] The results highlight the necessity of both the "**LLM Evidence**" retrieval component and the "**Log Odds Sorting**" method, as both other variants retrieve significantly less "Useful" and "Very Useful" evidence and more "Weakly Correlated" and "Not Relevant" evidence. We also find a relatively small number of hallucinations (5) and note where the hallucinated evidence was originally ranked in Table 3.

How much of the relevant retrieved evidence is redundant with the information already uncovered during the annotator's initial review of the patient? We plot evidence counts separately for seen vs unseen evidence in Figure 4 and find that there is a significant amount of unseen evidence that is useful and very useful in all models. It is interesting to note that some hallucinated evidence was "seen" by annotators. We believe this is most likely due to some hallucinated evidence having been potentially true of the patient at some point but not with respect to the specific report used to generate it (e.g. the generated evidence says the patient has a bleeding colon lesion, but the report says that the patient *no longer* has this; see Table 8 for more examples).

The rated usefulness of evidence does not necessarily matter if it does not affect the clinician's decision. An example of how these models might work in practice is when our LLM Evidence model

so we kept track of this evidence (a total of 21 snippets) and omitted it from the results.

[6]To annotate hallucinations, we provided a clinician the generated evidence alongside the report from which it was generated and asked if the evidence was hallucinated or partially hallucinated. Full results are in appendix Table 8.

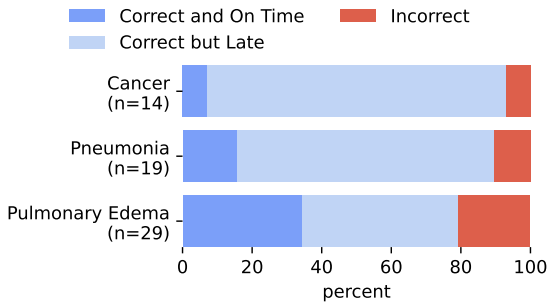

Figure 5: Synthetic label precision. For each confident diagnosis label extracted by the system, annotators check whether the diagnosis actually appears in the report (and is definitive), and subsequently if subjectively they believe that report is likely the *first* time the diagnosis was definitive based on the report language.

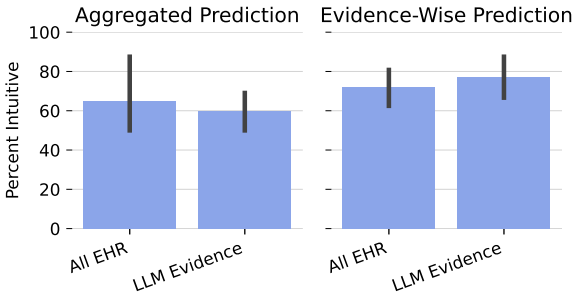

Figure 6: Intuitiveness of predictions macro-averaged across annotators.

with Confidence Sorting surfaced the following: "Atrial fibrillation with rapid ventricular response. Compared to the previous tracing atrial fibrillation is seen. Other findings are similar. The patient is at risk of pulmonary edema." In this case the annotator changed their estimate of the likelihood of pulmonary edema from unlikely to somewhat likely, and it turns out that pulmonary edema did appear in a future report.

We show all 7 instances where annotators changed their mind after viewing evidence in Appendix Table 7. Of these we find 2 instances (including the example above) where annotators' increased their likelihood of conditions that were extracted from future records, and 5 where condition(s) other than the synthetically labeled condition(s) were affected (mostly by increasing the annotators' risk assessments). Though more data should be collected, this indicates the model might improve annotator recall (though at some cost in precision); recall is arguably more important here.

Given that we are using synthetic labels of future diagnoses for both training and evaluation for risk prediction (discussed next), it is important to evaluate how well our labels align with ground truth. Given that ICD codes are not fine-grained enough and are not always accurate, we turn to manual annotations of precision for this evaluation. In Figure 5, we report the precision of these labels for being correct or for being "correct and on time". This second category is a stronger correctness in which the annotator also noted that the note where the label was detected subjectively seems to be the first note where that label should have been given as judged using the phrasing in the note.[7]

We see reasonable precision when using automatic labeling with the LLM pipeline (about 80 percent and above for all conditions). We also compute inter-annotator agreement for these annotations of precision across the 4 annotators by enforcing that 8 annotated predictions overlap for all the annotators. The Fleiss' Kappa score for these synthetic label annotations was .68 for the 3-category classification shown in Figure 5 and .86 for the 2-category classification obtained by simplifying the labels into just "Correct" or "Incorrect".

We would also like to assess how well our models' risk estimates aligns with the intuitions of clinicians with respect to the aggregated and individual predictions. Though for the aggregated prediction for an instance, we ask annotators to take the magnitude of the risk, not just the direction (i.e. increased compared to baseline or decreased compared to baseline) into account, for evidence-level predictions, we ask annotators to take the magnitude with a grain of salt and mostly judge based on the direction. This is because the magnitudes appeared to be somewhat artificially inflated potentially either due to the strong evidence trying to "compensate" for the evidence that does not actively contribute to the log odds (see Figure 12) or because of the sorting method.[8] Figure 6 shows that both models do reasonably well with respect to the aggregated and evidence-wise predictions, and both do slightly better on evidence-wise as opposed to aggregated predictions.

Finally, it is important to evaluate the actual prediction performance of our models on our synthetic

[7] It would be time-consuming to annotate this directly because it involves looking at a lot of prior notes.

[8] Future work might investigate how to bring make this *magnitude* more interpretable.

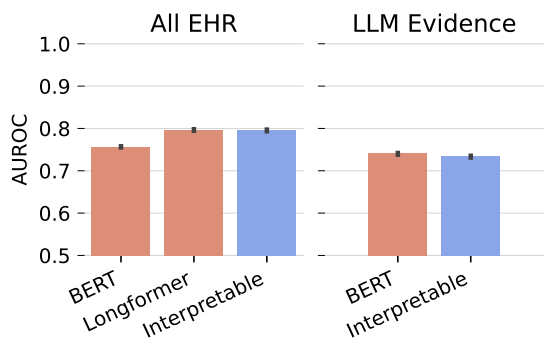

Figure 7: Macro-averaged risk prediction performance evaluated on synthetic labels and averaged over 5 random seeds for choosing the which time-point in the EHR to use prior to the diagnosis label. Error bars represent the standard deviation of the random seeds. Here, BERT and Longformer refer to Clinical BERT and Clinical Longformer.

labels. Here we also compare against baseline models that are not interpretable: BERT and Longformer. These black-box models are trained on both the All EHR and the concatenated retrieved LLM evidence. Figure 7 shows that including all evidence usually helps prediction performance, but using the blackbox vs interpretable models on the same input does not effect performance.

7 Conclusions

Clinicians should have access to all the pertinent information to make well-grounded decisions for diagnosing a patient, but currently they are inundated with (unstructured) information from the EHR. This is exacerbated by the time constraints faced by practitioners. We have proposed an approach that aims to facilitate efficient access to potentially important data within EHR; our method capitalizes on the capabilities of LLMs to produce digestable, abstractively generated text evidence, which is then consumed by a Neural Additive Model (NAM) to yield a prediction.

We find that using NAMs does not sacrifice predictive quality, but does enable models to surface useful evidence to clinicians. Using the LLM to create the starting set of evidence to feed into the NAM does sacrifice some performance, but it also significantly increases the usefulness of the evidence in comparison with using the raw sentences from EHR notes as evidence.

Further, we find that in some cases the surfaced evidence is able to change a clinician's mind, increasing the clinician's recall though decreasing precision, which warrants future work to improve on this system. One major concern is that this type of system could increase clinician's workload rather than decrease it. Future work should assess exactly how and when it might be beneficial to show snippets to clinicians.

8 Limitations

The proposed approach of combining abstractive LLM evidence with Neural Additive Models shows promise, but there are still many concerns that need to be addressed in future work. One of the biggest concerns is about the use of abstractive "evidence" produced by LLMs. Though our analysis does not find many hallucinations, their existence certainly poses risks and should be studied further in future work. Any hallucinated evidence could at best negatively impact trust of clinicians in the system and at worst mislead clinicians and negatively affect patient outcomes. We also did not experiment much with different prompts or models for producing this evidence given that our main focus was on validating the system-level approach rather than individual components.

Another limitation concerns the lack of a significant number of baseline models. Though not many baselines exist for a task that involves retrieving evidence supporting predictions in EHR, there are still potential baselines that use relevance weights or cosine similarity with clinical BERT that we could have included. However, due to the extensive amount of time needed for just one annotation on one model, we chose to focus on ablating over the LLM evidence retrieval and sorting method components of the model.

Finally, our analysis mostly relies on a relatively small amount of annotations from one dataset. This again stems from the time cost of annotations. Each annotator must first look through a whole patient's record to get a sense of the patient before even getting to any annotations. On average, this took almost 3 minutes, which is all before annotators even see any of the questions. Then, because the study focuses on just the top evidence presented for each instance, each annotator only annotates 3.2 evidence snippets on average per instance. This time-consuming process did limit the number of annotations we could obtain.

A Dataset and Preprocessing

We treat each patient as an instance and split the instances randomly into a training split for training the risk prediction model, a validation split for picking the best checkpoint and other hyperparmeter tuning, a test split for automatically evaluating the risk prediction, and an annotation split for annotations. After the first round of annotations, because we changed our model (see section E), we throw out all patients annotated in the first round so that the second and final round of annotations, which were used to compute all results, were conducted on a held-out set of instances. Instance order was randomized, so no bias resulted from throwing out the first set of instances annotated.

Each instance is randomly separated into a past and future. During training, repeated examples might have different samples time-points, but during evaluation and annotation, the same randomly-picked time-point is used across all evaluations and annotations. We also ignore examples longer than 200 reports for computational purposes. Given that this application's use case is for lengthy records, for annotations we restricted to instances with greater than 10 records for all but 3 annotated instances, which had already been completed.

During training, to overcome problems caused by data imbalance and for computational reasons, we randomly sub-sample 20% of the negative examples—i.e., examples that have none of the three considered conditions. For annotations, we sub-sample negatives such that each annotation has a 50% chance of having at least one positive condition of the three considered.

B Evidence Retrieval Details

We use the same prompts as in (Ahsan et al., 2023) for retrieving evidence of risks and signs. We also add an additional set of two prompts for retrieving evidence relating to a particular queried risk factor. The exact prompts used are as follows:

Evidence of Risk

Prompt 1:

> Read the following clinical note of a patient:
> <input>
> Question: Is the patient at risk of <query>? Choice: -Yes -No
> Answer:

Prompt 2:

> Read the following clinical note of a patient:
> <input>
> Based on the note, why is the patient at risk of <query>?
> Answer step by step:

Evidence of Signs

Prompt 1:

> Read the following clinical note of a patient:
> <input>
> Question: Does the patient have <query>? Choice: -Yes -No
> Answer:

Prompt 2:

> Read the following clinical note of a patient:
> <input>
> Question: Extract signs of <query> from the note.
> Answer:

Evidence of a Queried Risk Factor

Prompt 1:

> Read the following clinical note of a patient:
> <input>
> Question: Does the patient have <query>? Choice: -Yes -No
> Answer:

Prompt 2:

> Read the following clinical note of a patient:
> <input>
> What evidence is there that the patient has <query>?
> Answer:

C Risk Prediction Inputs

To provide some context of the evidence for the risk prediction model, we decided to add some metadata to the evidence when it was presented to the model with the hope that the model could use this context to make better predictions. In particular, we decided to include the query that was used to retrieve a piece of evidence, and the relative day of the report from which the evidence was retrieved in the following format:

<query> (<query_type>): “<evidence>” (day <relative_day>)

For example, if querying a diagnosis of “pneumonia” retrieved the evidence “the patient has a cough.” from a report 5 days prior to the current time-step, the evidence would be be presented to the model as:

pneumonia (diagnosis): “the patient has a cough.” (day -5)

D Certain Diagnosis Extraction Prompts

Prompt 1:

Read the following report:

<input>

Question: Is there a confident diagnosis of the patient’s condition? Choice: -Yes -No
Answer:

Prompt 2:

Read the following report:

<input>

Answer step by step: What is the correct diagnosis of the patient’s condition?
Answer:

We use Chain of Thought (CoT) prompting here because—similar to the evidence retrieval step—we want the model first to extract the parts of the report that refer to a diagnosis, as this seems to work better than going straight to the list of diagnoses. In initial experiments, using the CoT prompt appeared to more easily elicit these verbose extractions.

Prompt 3:

Here is a diagnosis of a patient:

<confident diagnosis>

Question: Provide a list of diagnostic terms or write none.
Answer:

E Prompting Problems

In our 3-stage prompting process, we initially had some problems with false positives in scenarios where pneumonia was negated (Figure 8). We discovered that this was because our 3rd prompt was originally:

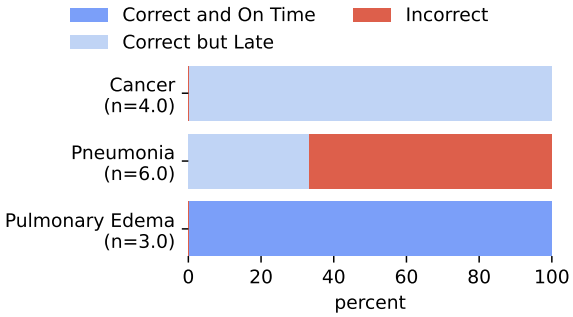

Figure 8: Synthetic labels on validation examples before correcting the prompting problem.

Here is a diagnosis of a patient:

<confident diagnosis>

Question: Based on this diagnosis, provide a list of diagnostic terms.
Answer:

This particular prompt sometimes produced positive synthetic labels for pneumonia when pneumonia was actually negated in the confident diagnosis generated by the previous prompt. We realized this when starting to annotate validation examples, so we changed our prompt (see section 4.1). We also noticed that some false positives might be caused by the model treating the admitting diagnosis as true, even though it can often be wrong according to the report text. To combat this, we added a preprocessing step before inserting the report into the confident diagnosis extraction prompts that removed the admitting diagnosis from the text. All of the test annotations used for the results do not include or overlap patients with the annotated examples which were used in this phase (chosen from the randomly shuffled annotation split) and precipitated these modifications.

F Description of Terms for Models and Settings

Table 4 shows all of the terms used to describe different models and settings.

G Experiments

We use Clinical BERT for the NAM prediction model. For all models, we train for up to 10 epochs on one Quadro RTX 8000 GPU and pick the best checkpoint (where checkpoints occur every 5 percent of an epoch). For the LLM for both

LLM Evidence	Models that use the evidence retrieved with an LLM.
All EHR	Models that use the all of the text in the EHR. For Interpretable Neural Additive Model, this text is split at the sentence level.
BERT or Longformer	Blackbox models that take either All EHR or LLM Evidence (concatenated) as input. BERT refers to Clinical BERT (Alsentzer et al., 2019) and Longformer refers to Clinical-Longformer (Li et al., 2023).
Interpretable	The proposed Interpretable Neural Additive Model, which can operate either on LLM Evidence or All EHR inputs.
Confidence Sorting	Sorting LLM Evidence by the length-normalized log-likelihood of the evidence under the LLM.
Log Odds Sorting	Sorting either LLM Evidence or All EHR inputs by the mean squared error of the predicted log odds (equation 4).

Table 4: Description of terms.

evidence retrieval and synthetic label extraction we use FLAN-T5-XXL (Chung et al., 2022; Wei et al., 2022). In the case of All EHR used as input to the interpretable NAM, we split sentences with NLTK.

H Usefulness of Queries

Unlike (Ahsan et al., 2023), we do not directly evaluate how relevant the retrieved evidence is to the query used to retrieve it; we instead focus on how relevant the evidence is to the risk predictions. However, we would like to examine which queries produce useful evidence. Figure 9 shows counts of evidence in each category separated across which query was used to retrieve that evidence. It seems as though the most useful evidence came from the three queries that directly ask about the condition for which we are predicting risk (the three left-most queries), but a few additional queries sometimes did prove useful.

I Full Prediction Performance

We report the full prediction performance in Table 6.

J Annotators Changing Their Minds

Table 7 presents all the occurrences of annotators changing their mind.

K Ablation over amount of evidence used

Figure 10 shows performance if we limit to a set amount of evidence that can be used in the Neural Additive Model's final aggregated score. This shows that the model performance is not affected until it is limited to using less than 20 snippets for predictions.

L Evidence Histograms

Figure 11 shows a histogram of the amount of evidence per each instance, and Figure 12 shows what the distribution over the log odds votes looks like.

M Annotation Interface

Figure 13 shows a screenshot of what the part of the interface dedicated to annotating evidence looks like.

N Hallucinations

Table 8 shows all of the annotated evidence that was subsequently marked as a hallucination along with an explanation of why it is a hallucination and other information about the evidence.

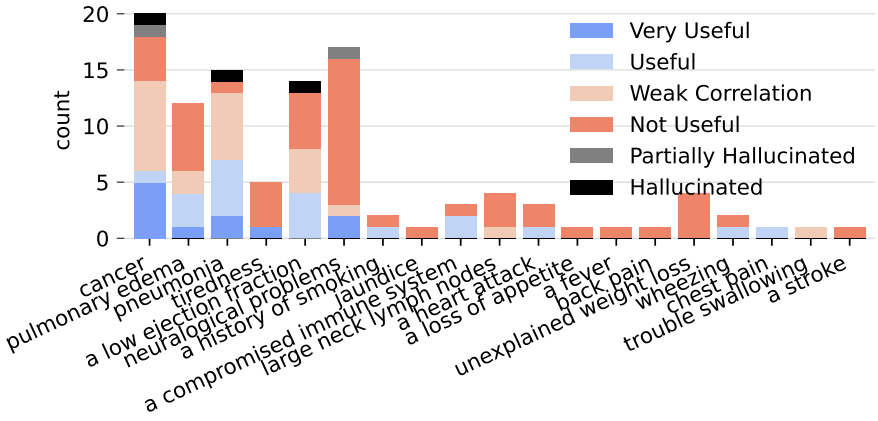

Figure 9: Usefulness per Query.

Diagnosis	Risk Factors
Pneumonia	a stroke, trouble swallowing, a compromised immune system, a high white blood cell count, a fever
Pulmonary Edema	a low ejection fraction, a heart attack, steroid use
Cancer	back pain, neuralogical problems, a history of smoking, night sweats, unexplained weight loss, a chronic cough with blood, large neck lymph nodes, a loss of appetite, jaundice, chest pain, hoarseness, tiredness, wheezing

Table 5: A non-exhaustive list of risk factors proposed by a clinician for use in queries.

	AUROC	Precision	Recall	F1
BERT (All EHR)	75.6 ± .19	65.6 ± 1.38	16.8 ± .38	26.8 ± .43
Longformer (All EHR)	79.6 ± .22	55.5 ± .32	28.8 ± .43	37.9 ± .38
Interpretable (All EHR)	79.5 ± .23	56.5 ± .57	20.5 ± .58	30.1 ± .60
BERT (LLM Evidence)	74.0 ± .27	51.6 ± 1.32	22.7 ± .27	31.5 ± .42
Interpretable (LLM Evidence)	73.3 ± .27	53.6 ± 1.09	15.0 ± .36	23.4 ± .48

Table 6: Macro-averaged **risk prediction performance** on the synthetic labels averaged over 5 different random seeds used for choosing the time-point in each patient that separates the past from the future.

Annotator	Model	Sorting	Changes	Best Evidence	Usefulness	Synthetic Label
2	LLM Evidence	Confidence Sorting	Pneumonia: Unlikely → Somewhat likely	There is a small right pneumothorax. There is extensive consolidation of the right upper lobe. Consolidation in the right lower lobe is mostly located in the superior segment. The left lung is grossly clear. There. Signs: There is extensive consolidation of the right upper lobe. Consolidation in the right lower lobe is mostly located in the superior segment. The left lung is grossly clear. There is no left pleural effusion. There is	Useful for **Pneumonia**	Pneumonia
4	LLM Evidence	Confidence Sorting	Pulmonary Edema: Unlikely → Somewhat likely	Atrial fibrillation with rapid ventricular response. Compared to the previous tracing atrial fibrillation is seen. Other findings are similar. The patient is at risk of pulmonary edema.	Useful for **Pulmonary Edema**	Pulmonary Edema
3	All EHR	Log Odds Sorting	Cancer: Unlikely → Very likely	Basal cell skin ca. [**27**].	Useful for **Cancer**	Pulmonary Edema
4	All EHR	Log Odds Sorting	Cancer: Unlikely → Somewhat likely	o.b.resident to see pt., pt.waiting for a "biopsy".	Useful for **Cancer**	Pulmonary Edema
4	All EHR	Log Odds Sorting	Pulmonary Edema: Somewhat likely → Unlikely, Pneumonia: Somewhat likely → Very likely	There is increased opacity in the. retrocardiac left lower lobe, as well as the right lower lobe, which could be. due to atelectasis, aspiration, or possibly pneumonia.	Very Useful for **Pneumonia**	
1	LLM Evidence	Log Odds Sorting	Pneumonia: Somewhat likely → Very likely	CXR showed L middle/lower lobe PNA, prob asp PNA.	Very Useful for **Pneumonia**	
4	LLM Evidence	Log Odds Sorting	Cancer: Unlikely → Very likely	CLL. Signs: id: pmh of CLL	Very Useful for **Cancer**	

Table 7: Examples of the 5 instances where annotators changed their mind based on evidence shown.

Evidence	Hallucination	Explanation	Query	Sorting	Seen	Rating
The patient has a bleeding colon lesion.	Yes	The report indicates that the patient used to have a bleeding colon lesion but no longer does.	cancer	Log Odds Sorting	Yes	Useful
The patient has a history of heart failure.	Yes	The report looks like it is cut off, and the only thing mentioned is a Coronary artery bypass graft (CABG).	a low ejection fraction	Log Odds Sorting	Yes	Useful
The patient has a history of sepsis.	Yes	Report says “R/O” meaning rule out sepsis.	pneumonia	LLM Confidence	No	Weakly Correlated
The patient has a mass in her breast.	Partially	The report header says that the patient has a mass, but the body of the report does not indicate this.	cancer	Log Odds Sorting	Yes	Weakly Correlated
The patient had a brain tumor removed.	Partially	Clinicians do not usually refer to pituitary adenomas (which the report indicates) as brain tumors.	neuralogical problems	Log Odds Sorting	Yes	Useful

Abstract

Social media, originally meant for peaceful communication, now faces issues with hate speech. Detecting hate speech from social media in Indian languages with linguistic diversity and cultural nuances presents a complex and challenging task. Furthermore, traditional methods involve sharing of users' sensitive data with a server for model training making it undesirable and involving potential risk to their privacy remained under-studied. In this paper, we combined various low-resource language datasets and propose MultiFED, a federated approach that performs effectively to detect hate speech. MultiFED utilizes continuous adaptation and fine-tuning to aid generalization using subsets of multilingual data overcoming the limitations of data scarcity. Extensive experiments are conducted on 13 Indic datasets across five different pre-trained models. The results show that MultiFED outperforms the state-of-the-art baselines by 8% (approx.) in terms of Accuracy and by 12% (approx.) in terms of F-Score.

1 Introduction

In the age of social computing utilizing social media as a communication tool motivated by anonymity and ease has grown significantly in size and significance (Kar and Debbarma, 2023). Microblogs provide instantaneous worldwide idea sharing, information acquisition, company promotion, etc. This encourages free speech and makes the world more connected. Unfortunately, it has also led to an increase in abusive interactions, such as cyberbullying, profanity, hate speech, etc., directed at specific people and groups (Wachs et al., 2022). In addition to detracting from important conversations, the increasing amount of inappropriate information on the internet has the potential to instigate aggressiveness, which can lead to violent real-world situations(Arango et al., 2022; Mathew et al., 2019). Social media platforms are forced to carefully monitor user postings and actions in order to halt the spread of hate speech (Chatterjee et al., 2023). Therefore, there exists a pressing necessity to establish effective automated frameworks for identifying hate speech, ensuring a proactive approach to its mitigation.

The majority of existing work in hate speech detection is based on European languages or languages with a wider international user base (Nozza et al., 2022; Demus et al., 2022; Battistelli et al., 2020). Whereas only a limited amount of work is done on other languages due to limited resources and linguistic nuances. Specifically, in India, we have 22 official languages and people like to communicate in their regional languages (Kalra and Dutt, 2020). This makes social media interactions lack formal structure and frequently involve grammatical errors, emoticons, spelling issues, etc. Moreover, the mixing of one or more languages that can even be code-mixed makes hate speech detection extremely challenging (Jayanthi et al., 2021; Agarwal et al., 2021). As a result, we have a limited digital presence of training data. Hence, a very limited amount of work focuses on hate speech detection in Indian languages. This motivated us to work on hate speech detection for Indian languages.

To address data scarcity for hate speech detection in Indian languages, various works sourced datasets from social media platforms (Ramesh et al., 2022; Gupta et al., 2022). Also, competitions such as HASOC [1] and IndoML [2] have been launched to promote research in Indian languages by providing high-quality datasets. However, the scale and linguistic coverage of these datasets is sparse (Gupta et al., 2022). Therefore, most of the works in hate speech are either based on monolingual datasets or utilize only a few languages. Consequently, the model trained in fewer languages might not yield accurate results in other languages (Röttger et al.,

[1] https://hasocfire.github.io/hasoc/2023/index.html
[2] https://indoml.in/

Proceedings of the 2024 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies (Volume 1: Long Papers), pages 7211–7221
June 16-21, 2024 ©2024 Association for Computational Linguistics

2022). To solve this, a few recent studies attempted to widen the coverage of training data by combining samples from multiple languages (Ranasinghe and Zampieri, 2021; Röttger et al., 2021; Saha et al., 2021). However combining various smaller datasets into one large-scale dataset may introduce inconsistency due to differences in annotation guidelines, data source platform, class imbalance, etc (Risch et al., 2021). In such scenarios, the performance of the centrally trained model may be highly impacted and biased. Therefore, adapting a single model to give a generalized performance in diverse domains while maintaining its effectiveness in each domain is challenging and complex.

Further, the success of a centralized computational framework relies on public datasets. But sensitive topics demand caution even with publicly available social media texts. The texts become private if a user makes their account private, impacting prior posts. Such privacy can be preserved if the model training utilizing these sensitive data happens at the user devices without the need to send the data to a common server. This is the motivation to use Federated Learning, suitable for sensitive data tasks emphasizing user privacy (Basu et al., 2022; Lin et al., 2022; Nagy et al., 2023). Apart from privacy risks, FL addresses user volume, info loss, and label imbalance (Gala et al., 2023; Gandhi et al., 2022). The objective of this paper is to design a generalized model using federated learning capable of detecting hate speech in multiple Indian languages. For this, we consider datasets from 13 Indian languages collected from various social media platforms. The publicly available different state-of-the-art BERT models such as XLM-RoBERTa (Conneau et al., 2020), multilingual-BERT (Devlin et al., 2019), MuRIL, Indic-BERT (Kakwani et al., 2020) similar to (Saha et al., 2021), and XLNet constitutes our centralized baselines for multilingual hate speech detection task. In summary, we make the following contributions:

- We aim to train and evaluate a classifier that effectively recognizes hate speech in a multilingual setting and gives generalized performance over unseen datasets.
- We utilize a fair selection approach for clients aiming for optimal performance across diverse datasets striking a balance between the personalized and generalized performance of the final model.
- We generate IID and non-IID dataset partitions across clients. These non-IID partitions replicate different types of distribution shifts (such as changes in labels, features, quantities, etc.) among clients, mirroring scenarios frequently encountered in real-world applications.
- We provide a comprehensive comparison between popular FL methods and state-of-the-art centralized methods for multilingual hate speech detection.
- We show that the model trained using federated learning gives better performance in diverse data environments which could be further scaled with acceptable performance variation along with preserving privacy of the user.

2 Related Work

Centralized Learning Previously, due to limited datasets, more focus was on non-Indian languages. Recently, more studies have attempted hate speech in Indian languages like Hindi (Shukla et al., 2022), Marathi (Patil et al., 2022a), Bengali (Das et al., 2022), etc. However, users often mix English with their native language (Code-Mixed data) for communication ease, complicating hate speech detection. Despite progress, research in bilingual, code-mixed, or multilingual tasks is nascent.

For example, (Fortuna et al., 2021) proposed standardization classes across publicly available datasets and studied the generalization capabilities of BERT, fastText, and SVM models. (Corazza et al., 2020) uses datasets for 3 different languages (English, Italian, and German) and trains different models such as LSTMs, GRUs, Bidirectional LSTMs, etc. The work claims to have a robust neural architecture for hate speech detection across different languages. Our work develops models that are far more generalizable and trained on a much larger dataset of languages. (Huang et al., 2020) constructed a multilingual Twitter hate speech corpus from 5 languages that they augmented with demographic information to study the demographic bias in hate speech classification. (Aluru et al., 2020) use datasets from 8 different languages and obtain their embeddings using LASER [3] and MUSE [4]. Though performance is decent across languages, fine-tuned models work best only for the

[3] https://github.com/facebookresearch/LASER
[4] https://github.com/facebookresearch/MUSE

8 languages. The Study focuses on low-resource performance, ignoring external impact. To address poor generalization of models due to biases in hate speech datasets, a suite of functional tests (HATECHECK) is introduced. HATECHECK offers insights into hate speech detection models but only tests English and modalities in text (Röttger et al., 2021). The extension of the English HATECHECK functional test suite is Multilingual HATECHECK (MHC), identifying model weaknesses for monolingual and cross-lingual applications, providing insights for the development of better multilingual hate speech detection models (Röttger et al., 2022).

Federated Learning Prior work on hate speech detection has primarily focused on privacy-agnostic machine learning paradigms, using centralized models for classification. In this work, we use a privacy-centric paradigm of machine learning, i.e., Federated Learning (FL). FL is a decentralized training strategy of machine learning models, a strategy reminiscent of parameter servers across a group of clients (McMahan et al., 2017). Clients train the model locally keeping data private from the server and peers. The parallel nature of training reduces the overall training time and enables training of models on a large corpus. This prevents the system from computational bottlenecks and minimizes the effect of heterogeneity in data on the global model performance (Zhu et al., 2021).
Recently several studies applied FL in many NLP tasks (Liu et al., 2021; Singh et al., 2022; Lin et al., 2022). The authors of (Basu et al., 2022) discussed training of NLP models and acknowledged the potential of methods like differential privacy, federated learning, and homomorphic encryption to handle sensitive data, e.g., medical records. However, the paper does not provide insights into the scalability or efficiency of the proposed framework for training NLP models on privacy-protected data. It is experimentally proved that FL ensures faster convergence when the number of clients is increased (Nagy et al., 2023). But the study lacks a discussion on framework limits in handling bigger datasets. In a similar study, the FL method is utilized as a privacy-preserving training paradigm for hate speech detection on eight datasets, surpassing centralized models aiming to address the lack of privacy in current approaches (Gala et al., 2023). Another study applied FL for multilingual emoji prediction in clean and attack situations, emphasizing its privacy and distributed advantages. However, it overlooks discussing how data distributions and biases could affect FL model performance (Gamal et al., 2023). Similar work is done in emoji detection for Hindi texts collected from Twitter considering FedProx (Li et al., 2020) and a modified version of CausalFedGSD (Francis et al., 2021) using federated approach (Gandhi et al., 2022).

How is Our Approach Different?

We explore cross-lingual meta-training in the domain of hate speech for both iid and non-iid configurations. Our proposed method of fair selection using federated learning, MultiFED, is a novel idea that can be further adapted for languages with no availability or limited availability of labeled data. We focus on resource maximization and domain generalization while transferring task-specific knowledge to low-resource languages. We carry out a large-scale study in multilingual hate speech detection across diverse domains on available hate speech datasets.

3 Methodology

3.1 Dataset Selection

This section provides a detailed description of the dataset used for experimentation. We created our multilingual dataset (*i.e. multicomb*) by combining datasets from 12 Indian languages and English, collected from various sources. Table 1 provides a detailed description of all the datasets.

Table 1: Detailed Description of Multicomb Dataset

Dataset	Language	IID			Non-IID		
		Hate	Non Hate	Total	Hate	Non Hate	Total
(Gupta et al., 2022)	Hindi	16152	16456	32608	8660	16456	25116
(Gupta et al., 2022)	Tamil	14429	13921	28350	7952	15571	23523
(Gupta et al., 2022)	Telugu	14397	14761	29158	7365	14761	22126
(Gupta et al., 2022)	Kannada	16045	15910	31955	8514	16890	25404
(Gupta et al., 2022)	Malayalam	12077	11629	23706	7622	13771	21393
(Romim et al., 2021)	Bengali	11000	11000	22000	7016	20000	27016
(Patil et al., 2022b)	Marathi	18750	18750	37500	9768	18750	28518
IndoML	Bhojpuri	8814	10304	19118	6831	16354	23185

IndoML	Punjabi	13000	12926	25926	6493	13000	19493
TRAC-1	English	7588	8331	15919	4792	8415	13207

Our *multicomb* dataset consists of 300K (approx.) texts consisting of two classes namely *hate* and *non-hate*. A brief description of the source of utilized datasets:

- The first set of datasets is taken from baseline paper (Gupta et al., 2022). In their work, they provided datasets in **Hindi, Tamil, Telugu, Kannada, and Malayalam** languages. The samples have been scraped from sharechat [5].

[5]https://sharechat.com/

- The second set of datasets has been taken from a competition, i.e., "Indian Symposium on Machine Learning (IndoML) [6]". In this, they provided datasets in various Indian languages for multiple tasks. We consider datasets in **Bhojpuri, Gujarati, Haryanvi, Odia, and Punjabi** languages.

- The dataset in **Bengali** has been taken from (Romim et al., 2021). The samples are comments collected from YouTube and Facebook comment sections.The **Marathi** dataset has been curated from Twitter and annotated manually (Patil et al., 2022b). And the **English** dataset has been taken from TRAC-1 [7].

  Note: For more details, readers are requested to follow the respective citations.

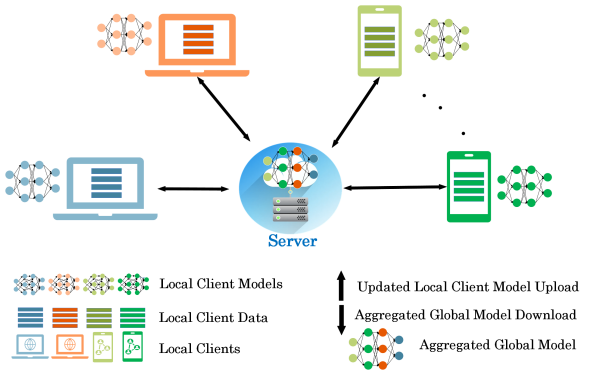

Figure 1: Federated Learning: An initial model shared by the server is fine-tuned locally on each client device and updated model is shared back to server for knowledge aggregation

3.2 Dataset-Client Partitioning

Three different training setups were carried out in this paper: traditional centralized training with no FL, FL with IID data, and FL with non-IID data.

In the centralized setup, we follow the dataset splits mentioned in (Gupta et al., 2022), i.e., balanced and unbalanced. In the balanced scenario, the number of training samples in both classes are equally distributed. However, in an unbalanced scenario, the number of samples are distributed in a 1:3 and 1:5 ratio (i.e., hate and non-hate). We randomly split *multicomb* in 80:10:10 ratio to form the training, validation, and test set and use this as the default split for all our experimental setups.

To create clients for FL experiments, we utilized the centralized split dataset as mentioned above. The balanced dataset is used to create FL clients with iid data (i.e., similar distribution of samples in both classes). Similarly, the unbalanced dataset is used to create FL clients with non-IID data (i.e., the distribution of samples in both classes follows a 1:3 and 1:5 ratio, hate and non-hate). It is worth mentioning that in both FL IID and non-IID, we carry out experiments while assuming that each client has samples from one language to follow real-world scenarios. Also, the validation and test splits are the same in both centralized and FL settings to make a fair comparison of results.

3.3 Models and Baselines

We evaluated our *multicomb* dataset by performing a series of experiments using 5 pre-trained transformer models in both centralized and federated settings.

A. Models Specifically, we employed state-of-the-art BERT models for this purpose: (1) XLM-RoBERTa (Conneau et al., 2020) is a multilingual variant of RoBERTa. (2) Multilingual-BERT (Devlin et al., 2019) was pre-trained on the top 104 languages with the largest Wikipedia, utilizing a masked language modeling (MLM) objective; (3) MuRIL (Khanuja et al., 2021) is a BERT model pre-trained on 16 Indian languages and their transliterated versions, using publicly available Wikipedia corpora; (4) IndicBERT (Kakwani et al., 2020) is a multilingual ALBERT model that received exclusive pre-training on 12 major Indian languages. (5) XLNet is an extension of the Transformer-XL model, trained using an auto-regressive approach to learn bidirectional contexts.

B. Baselines The state-of-the-art techniques that have been tested on our dataset are as follows.

1) Pre-Trained: All the state-of-the-art pre-trained BERT models.

2) Centralized: All the state-of-the-art BERT models in a centralized setting.

3) Finetuned (Gupta et al., 2022): In this, the authors randomly sample 5M comments out of the complete corpora and use these sampled comments for continued pretraining of the XLM-R model using masked language modeling (MLM) loss. We use the same strategy to finetune all BERT models.

For all the BERT models we use the tokenizers provided with each model. We measure their performance using weighted Accuracy, and weighted

F1 scores.

3.4 Fair Selection

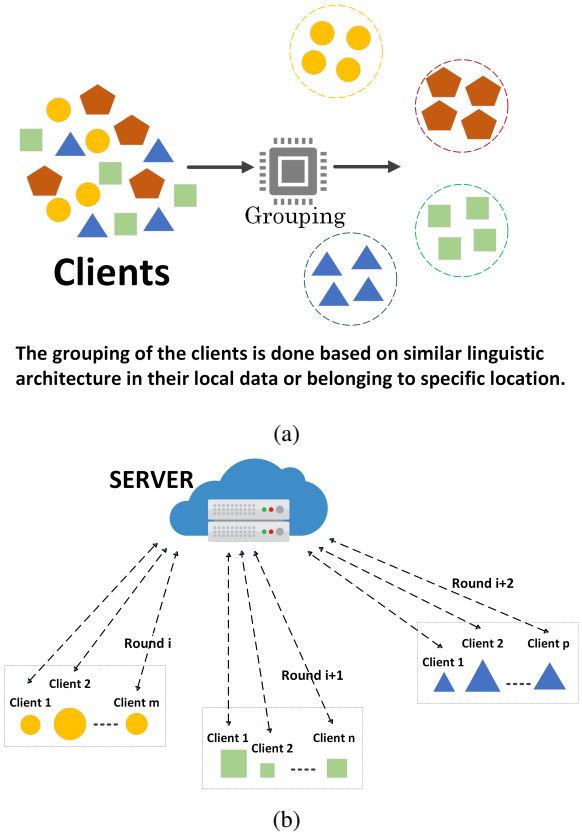

Figure 2: Fair Selection of Clients with Grouping

In FL setup, the clients are created by partitioning the *multicomb* dataset (3.2), which contains texts from various languages. To build a generalized model that performs optimally well on each language dataset is very complex. The generalization capability of any hate speech classifier is also affected when the training data is biased or contains samples where the definition of hate speech varies. To address this, we perform a grouping of clients based on their lexical similarity. Before the training phase, all the connected clients share a few local samples with the server. The server calculates the correlation among the clients using cosine similarity. Based on the similarity score, the group of clients is created (see Figure 2(a)). However, it may happen that the number of clients in few groups is too small or too high. Also, creating similar client groups may end up creating a large number of groups. To address this, we fixed the minimum number of clients in a group should not be less than 35 and more than 50.

After the groups are created, in each communication round, the server selects a group, and among the group, a set of clients are randomly selected to perform local training (see Figure 2(b)). These formed groups of similar clients can be considered as a set of independent and identically distributed (iid) clients. Hence, local training among similar clients minimizes the model weight divergence, which makes the model learn faster and doesn't hurt the accuracy much (Cao et al., 2022).

Additionally, we emphasize the selection of clients to be fair, diverse and increase the participation count of each participating client in the learning process. Adoption of the above approach for selection increases the coverage to diverse clients containing datasets from various languages. In our fair selection approach, all the groups are selected in sequence giving equal weightage to each data distribution, increasing coverage to all. We argue that without fair selection, the performance of the model may be biased towards the dataset of highly selected clients, and the idea of a generalized model will not be met.

3.5 Federated Training

Our proposed experimental investigation uses FL as a decentralized privacy-preserving approach instead of a centralized approach. This follows from the work (Nobata et al., 2016), which demonstrated that partitioning data into smaller segments can improve the classification performance overall. Following this we partitioned the entire dataset into several smaller segments as clients (described in section 3.2). In our work, we conceptualize client devices as users who witness and report hate speech. Before the experiments, we perform hyper-parameter tuning for the client learning rate, server-side learning rate, and proximal term (see Appendix B.1).

To initiate the process, a fraction 10%, 20%, or 30% of clients are selected randomly from 200 client devices in between two communication rounds. Then the locally computed model parameters by each client are aggregated by the server to compute new updated parameters. The FedAvg suffers from weight divergence and statistical heterogeneity. Therefore, to address this we use FedProx and FedOpt algorithms for the aggregation of parameters on the server side. FedProx adds a regularisation constant as the proximal term and FedOpt introduces a separate optimizer for the server-side model to account for data heterogeneity in an effort

to provide more reliable models.

3.5.1 Why Proposed FL Setup Outperforms?

In each iteration, a random set of clients are selected among the selected group and perform local training. In the next iteration, a different group is selected, and the local training continues on another set of random clients (see Figure 2(b)). The training of the hate speech detection model on a set of similar clients resembles the domain adaptation phenomenon because hate speech from common datasets can be considered as separate domains. Now, aggregation of updated parameters received from the clients after each iteration build a new global model to be given to a set of clients from different domain. This is similar to transfer learning that involves leveraging knowledge gained while solving one problem and applying it to a different but related problem. Similar analogy is used for pre-trained models where transfer learning can significantly improve model performance, especially when the pre-trained model has been trained on a large and diverse dataset. In a similar manner, we are initializing the model with parameters learned while trained on one domain and finetuning it on another domain in each iteration. This helps the model to build generalizability over diverse datasets and improves overall performance.

3.6 Implementation Details

We implement our proposed model on the Python-based Pytorch, deep learning library. As the evaluation metric, we employ Weighted Accuracy and Weighted F1-score (F1) for hate speech detection. We use Adam as an optimizer, softmax as a classifier for hate speech classifier, and the categorical cross-entropy as a loss function, We used learning rate 2e-5 and batch size 16, epochs 1, 5, 10, and carried out experiments for 100 rounds.

Table 2: Values of Hyperparameters in Various Algorithms (lr: Learning Rate, BS: Batch Size)

Algorithm	**FedAvg and FedProx**			**FedOpt**		
Model	**Client_lr**	**BS**	μ	**Client_lr**	**BS**	**Server_lr**
XLMR	2e-5	16	0.01	2e-5	16	0.01
mBERT	2e-5	16	0.01	2e-5	16	0.01
MuRIL	2e-5	16	0.01	2e-5	16	0.001
IndicBERT	2e-4	32	0.01	2e-4	32	0.001
XLNet	2e-6	32	0.001	2e-6	32	0.001

4 Results and Discussion

We assess the performance of our proposed MultiFED approach on five pre-trained BERT-based models under iid and non-iid data distribution settings. Firstly, we compare the generalized performance over the low-resource indic languages (see Table 3). Secondly, the trained models are also assessed on test data from each language individually giving the personalized performance (see Table 4). Please note that we reported the best results obtained in various experiments carried out for MultiFED.

Considering the performance for iid and non-iid settings from Table 3, we observe that the reported accuracy and f1-score vary by a small margin. This is due to the fact that the iid partitioning strategy divides an equal number of samples in each class while the non-iid partition carries unequal number of samples in each class. However, the total sample statistics in each client are similar in either setting. This is also evident from Table 1; the utilized datasets have a sufficient number of samples in each class. This is the reason for the robust performance of *Centralized* and *Finetuned* baselines in non-iid settings.

After the preliminary exploration, it is clearly visible that our proposed MultiFED framework outperformed the baseline by a margin of 7.78% & 11.58% in terms of accuracy and by 9.59% & 11.91% in terms of f1-score under iid and non-iid settings, respectively. We see that XLM-Roberta achieves the best performance in all experimental settings while XLNet gives suboptimal performance. It is interesting to observe the performance of baseline models that are pre-trained on various indic languages (such as **Muril** (Khanuja et al., 2021) and **Indicbert** (Kakwani et al., 2020)). Although these models are pre-trained on similar indic languages, XLMR and mBert beat them in most of the cases. This suggests the importance of continued training for domain adaptation. As evident from Table 8, FedProx gives better performance than FedAvg and FedOpt. Therefore, the results reported are experimented with using FedProx as the aggregation algorithm.

We also tested MultiFed on the centralized test data from each language separately to quantify the personalized performance of the proposed model (see Table 4). We observe that our proposed MultiFed model outperforms each baseline for most of the tested languages highlighting the importance of pretraining on domain-aligned partitioned data fractions. The linguistic patterns of few languages in our dataset are similar to each other. For exam-

ple, Hindi, Bhojpuri, Haryanvi, and Punjabi share the same linguistic space. Hence, the model trained may be better at handling data sparsity issues. It can generalize well to other languages, even if the other dataset of the same domain has limited samples. This is the reason for poor performance on English dataset. Similarly, we can relate the reason for higher performance on Bhojpuri, Haryanvi, Gujarati, and Odia despite of having lesser number of samples. In federated learning, the globally aggregated model contains the collective intelligence from each participating client. Therefore it is expected to give optimal performance on each client which is reported in Table 3. However, the performance of the federated model may not perform equally good on each dataset belonging to different domains (e.g., language) compared to the centrally trained model (e.g., Malayalam and Marathi). The reason for this biased performance lies in the imbalance of aggregated knowledge from each client due to the linguistic diversity of our *multicomb* dataset.

To understand this better, it is worth discussing the behavior of these utilized pre-trained models in our FL setup with different linguistic variability. All these models are pre-trained on large-scale diverse corpus of multilingual texts, including various Indian languages. Their capability to capture semantic similarity and differences across the languages tend to give significant performance across wide-range of languages without any extensive fine-tuning. However, the performance is dependent on the lexical similarity to the languages it was pre-trained. In this work, we fine-tuned these models using FL after creating groups of similar clients. Thus, these models leverage knowledge gained from one language to improve the performance in other facilitating the transferable characteristics across languages.

4.1 Sensitivity Analysis

In this section, we analyze the sensitivity of MultiFED under various hyperparameter values.

Table 5 shows the performance under different participation ratios C among {10%, 20%, 30%} for various model architectures on local epoch E=1 and FedProx. It is concluded that the performance increases on increasing C regardless of the model architecture. When C rises from 10% to 30%, the accuracy and f-score increases because the number of training rounds are increased for each client. However, few models report a drop in performance when C increases from 20% to 30%. This drop may be the result of overfitting occurring in some of the clients. Similarly, in Table 6 (reported for $C = 10\%$), we can relate the performance rise with the increasing number of local training epochs.

Table 7: Results Comparison of Proposed Federated Setting with Different Data Heterogeneity

Federated	α **= 0.5**		α **= 0.33**		α **= 0.2**	
Model	**Acc**	**F1**	**Acc**	**F1**	**Acc**	**F1**
XLMR	87.26	87.51	86.87	86.44	87.39	72.83
mBERT	87.24	86.92	85.67	84.88	87.66	72.88
MuRIL	86.92	86.20	86.98	86.37	88.01	74.59
IndicBERT	84.27	83.98	83.63	82.44	79.89	65.54
XLNet	68.20	68.00	68.41	64.54	62.76	58.72

Table 8: Results Comparison of Proposed Federated Setting with Different Algorithm

Federated	**FedOpt**		**FedAvg**		**FedProx**	
Model	**Acc**	**F1**	**Acc**	**F1**	**Acc**	**F1**
XLMR	85.33	84.72	86.35	85.86	86.87	86.44
mBERT	84.13	83.10	85.65	84.77	85.67	84.88
MuRIL	86.54	85.87	86.93	86.25	86.98	86.37
IndicBERT	83.45	82.55	83.32	82.28	83.63	82.44
XLNet	67.31	60.50	68.24	61.69	68.41	64.54

We also analyze MultiFED on different levels of data heterogeneity (α) on each language dataset, reported for $C = 20\%$ and $E = 1$. Here, α controls the degree of heterogeneity from 0.5 (or iid) to 0.33, and 0.2. Smaller α means a higher imbalance in the number of samples in each class. As shown in Table 7, the performance of all the models decreases as the imbalance in class is increased. It is worth mentioning, the accuracy for XLMR, mBert, and Muril when $\alpha = 0.33$ is lower than when $\alpha = 0.2$. However, if we closely look into the values of f-score, we conclude that the performance of all the models is better in the case of $\alpha = 0.33$. Similarly, Table 8 compares the performance of MultiFED in different aggregation scenarios. The experiments show that FedProx performs the best among the other algorithms as FedOpt is Well-suited for scenarios where the imbalance is not the primary concern (Ye et al., 2023). This is because FedProx employs a "proximal term" in the learning objective, penalizing deviations between local and global model parameters to promote the proximity of local models to the global one.

5 Conclusion

In this work, we propose a federated approach to hate speech detection, coined MultiFED, which aims to localize users' data and prevent it from being exposed while training models for hate speech detection. It also tackles the challenge of diverse linguistic data by personalizing the performance of clients. Through empirical experimentations, we find that Federated Learning along with preserving privacy achieves a higher performance level than centralized baselines in various scenarios. In future work, we intend to personalize the performance, improve fairness in the selection of clients, and reduce the resource consumption of each client.

Limitations

Federated Learning preserves the privacy of users and improves communication efficiency in the learning process. However, multiple iterations involved during federated training may pose significant challenges due to issues such as limited bandwidth, high latency, and high communication overhead. Also, the participating user devices may not have sufficient resources to complete the training process. How good the device may be, it may struggle to reach convergence and may limit its performance.

We train our models using Federated Learning in both iid and non-iid settings, reported accuracy, and f-score to quantify the bias introduced due to data heterogeneity. However, due to limited resources and the high clock time taken for its experimentation, we limited the number of rounds to 100. The performance may improve if more iterations may have been added. Additionally, we carried out experiments under the assumption that each participating client has sufficient resources to train and infer these heavy BERT models. Additionally, if the data in each client is imbalanced in terms of labels as well as in total dataset size, federated learning may fail to give performance better than its centralized counterpart.

Ethics Statement

Although Federated Learning can be a good choice to ensure anonymity for a user and their data, it still has many potential risks. In particular, a malignant user may initiate model threat attacks, which might compromise the integrity of the FL system and result in erroneous predictions. Furthermore, misclassification of the FL system is caused by attacks on model availability, which is more widespread and harmful than integrity breaches. One of the main privacy concerns for getting sensitive information unlawfully is the revelation of privacy data, which is caused by data leakage attacks that breach the confidentiality of training data. Additional benefits of federated learning include edge intelligence and personalization, which may enhance user experience and mitigate hate speech. However, in practical situations, it requires serious consideration to ensure that online conversations are healthy and that users may enjoy complete anonymity without worrying about data breaches.

Abstract

Zero-shot cross-lingual transfer, which implies finetuning of the multilingual pretrained language model on input-output pairs in one language and using it to make task predictions for inputs in other languages, was widely studied for natural language understanding but is understudied for generation. Previous works notice a frequent problem of generation in a wrong language and propose approaches to address it, usually using mT5 as a backbone model. In this work we compare various approaches proposed from the literature in unified settings, also including alternative backbone models, namely mBART and NLLB-200. We first underline the importance of tuning learning rate used for finetuning, which helps to substantially alleviate the problem of generation in the wrong language. Then, we show that with careful learning rate tuning, the simple full finetuning of the model acts as a very strong baseline and alternative approaches bring only marginal improvements. Finally, we find that mBART performs similarly to mT5 of the same size, and NLLB-200 can be competitive in some cases. Our final zero-shot models reach the performance of the approach based on data translation which is usually considered as an upper baseline for zero-shot cross-lingual transfer in generation.

1 Introduction

Multilingual pretrained language models (mPLMs) such as mBERT (Devlin et al., 2019), mBART (Liu et al., 2020), and mT5 (Xue et al., 2021) provide high-quality representations for texts in various languages and serve as a a universal backbone for finetuning on language-specific task data. The latter, however, is not always available for a language of interest, providing motivation for studying *zero-shot cross-lingual* capabilities of mPLMs. In this setting, the model is adapted, e.g. finetuned, on input-output pairs in a *source* language, usually English, and then applied in a zero-shot manner to make predictions for inputs in another *target* language, seen only at the pretraining stage.

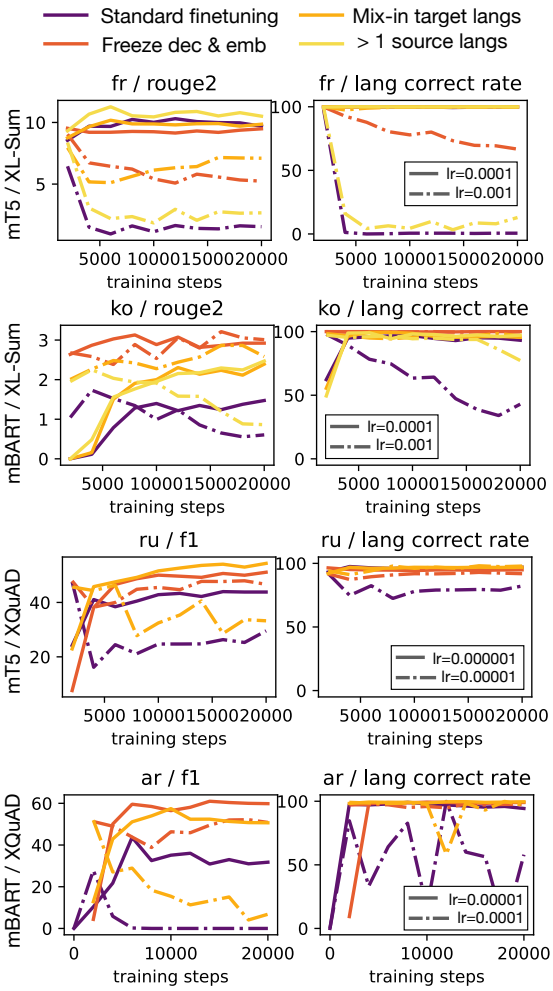

Figure 1: Learning rate plays a key role in cross-lingual transfer: decreasing LR almost completely eliminates generation in the wrong language with standard full finetuning, and often brings larger improvements that using complex adaptation methods developed to overcome this problem. Full results in Fig. 9–12 in Appendix.

While the described setting was broadly studied for natural language understanding tasks (Xue et al., 2021; Conneau et al., 2020; Artetxe et al., 2020a;

Proceedings of the 2024 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies (Volume 1: Long Papers), pages 7222–7238
June 16-21, 2024 ©2024 Association for Computational Linguistics

Pires et al., 2019; Wu and Dredze, 2019; Pfeiffer et al., 2020), work on zero-shot cross-lingual transfer in *generation* is more limited (Vu et al., 2022; Pfeiffer et al., 2023; Maurya et al., 2021; Li and Murray, 2023). Previous work highlight two main problems arising in this scenario: producing incoherent or irrelevant answers, and generating text in a wrong language. A series of potential solutions were proposed, such as freezing the parts of the weights during finetuning, utilizing parameter-efficient finetuning methods, mixing-in the unsupervised target language data together with the supervised source language data, or using more than one source language. A common strategy is also to perform an intermediate tuning of the model on the language generation task in a self-supervised manner (as opposed to denoising tasks used for pretraining).

However, despite listed efforts, the state of zero-shot cross-lingual generation still remains unclear and poses open questions:

- *Which adaptation method is most effective?* Methods proposed for mitigating generation in the wrong language, were all tested on different tasks and benchmarks, and not compared to methods from other works, making it hard to establish the best performing one.
- *What makes a better mPLM for zero-shot cross-lingual transfer?* Different models have different pretraining objectives, training and architectural choices. How do these factors impact the quality of the cross-lingual transfer in generation?
- *Importance of hyperparameters in downstream task adaptation.* None of the previous work studied the impact of hyper-parameters used during downstream task adaptation for zero-shot cross-lingual transfer in generation.
- *Finally, if we pick the best solutions from all of the three listed dimensions, how far in performance can we get?* Can we reach the performance of a strong baseline, data translation, consisting in translating the train data into target languages? Previous studies either did not reach its performance or did not compare to this baseline.

The contribution of this work is conducting a deep empirical study addressing the listed questions. We consider most commonly used multilingual encoder-decoder mPLMs, namely mT5 and mBART, as well as the translation model NLLB-200. We systematically study six adaptation methods, investigate the effect of intermediate tuning, pay attention to adaptation hyperparameters, and compare models and adaptation methods *in a unified setting*. We consider two tasks: summarization and questions answering (QA). Our main findings are as follows:

- Hyperparameter tuning plays a very important role in cross-lingual transfer in generation: while related works report a severe problem of generation in a wrong language after full finetuning, we find that simply reducing the learning rate helps to alleviate this problem almost completely, without hurting performance;
- Intermediate tuning substantially improves performance in the majority of cases;
- With carefully chosen learning rates and intermediate tuning when necessary, simple full finetuning is a very strong baseline for zero-shot cross-lingual transfer in generation. Improvements brought by more advanced methods are quite modest, and none of the methods consistently outperform full finetuning in all cases. The notable methods are freezing the model decoder and embeddings, which performs consistently well with mBART (but not with mT5), and using more than one source language, which performs consistently well with mT5 (but not with mBART);
- mBART and mT5 of similar sizes lead to comparable performance. Qualitatively, due to the specifics of the masking pretraining objective, mBART is better suited for tasks with long outputs while mT5 is for tasks with short outputs;
- NLLB-200 is surprisingly competitive in summarization, reaching performance of mT5 and mBART for high-resource Latin-alphabet languages, but lags behind in QA;
- The final performance of the zero-shot approach is the same or superior to the performance of the data translation approach, often considered as an upper baseline for cross-lingual transfer in generation. Notably, careful learning rate tuning coupled with intermediate tuning allows the zero-shot approach closely approach the performance of data translation simply with the full finetuning adaptation.

2 Related Work

All works on zero-shot cross-lingual transfer in generation underline (and try to address) the severe problem of generating in a wrong language at the test time. This problem is also referred to under terms catastrophic forgetting (of languages not participating in finetuning, Vu et al., 2022), source language hallucination (Pfeiffer et al., 2023), or accidential translation problem (Li and Murray, 2023). Vu et al. (2022) propose to overcome generation in a wrong language by using parameter-efficient finetuning instantiated by prompt-tuning (Lester et al., 2021). They also mix-in the unsupervised target language task together with the supervised source language task, and factorize learnable prompts into language and task components.

Pfeiffer et al. (2023) propose mmT5 (modular mT5), allocating a small amount of language-specific parameters in the model during pretraining and freezing them during task-specific finetuning. To alleviate generation in a wrong language, they freeze some additional mmT5 parameters during finetuning, e. g. the embedding layer and feed forward layers in Transformer decoder. Li and Murray (2023) argue that learning language-invariant representations during finetuning is harmful for cross-lingual generation and propose finetuning on the data from more than one source language to avoid generation in a wrong language, with mT5 as a backbone model. ZMBART (Maurya et al., 2021) is the only work which considers the other backbone model than mT5: they perform an intermediate tuning of mBART on an auxiliary unsupervised task on Hindi, Japanese and English. To avoid generation in a wrong language, they freeze embeddings and the Transformer decoder, and mix-in the data from auxiliary pretraining during finetuning.

In our work we are interested to compare all previously proposed approaches in a unified setting, to better assess the impact of different factors on the zero-shot cross-lingual transfer in generation.

Alternative approaches to zero-shot cross-lingual transfer include data translation approaches, often referred as *translate-train* and *translate-test* paradigms. The former one implies translating the train task data to target languages and finetuning the model on this translated data, and the latter one implies translating test input examples into the source language, generating outputs in the source language and translating them back into the target language. The drawbacks of these approaches include a high computational cost either at training or testing time, lack of high-quality translation models for low-resource languages, and potential inconsistencies between sentences in translation (Vu et al., 2022). Despite its computational cost, data translation is a strong approach which is usually considered as an upper baseline for zero-shot approaches. Another related field is *few-shot cross-lingual transfer in generation* which assumes access to a small amount of labeled examples in the target language (Schmidt et al., 2022; Lauscher et al., 2020; Zhao et al., 2021). This setting is out of scope of this study, but could be considered in the future work.

3 Methodology and experimental setup

Adaptation methods. We investigate the following adaptation methods:

- *Full finetuning*: all weights of the model are finetuned on the source language data;
- *Prompt tuning* (Vu et al., 2022): comprises prepending several learnable vectors ("prompt") to the list of embeddings of the text input and freezing all other model weights during finetuning. Parameter-efficient approaches were shown in the literature to be better suited for transfer learning than full finetuning.
- *Adapters* (Houlsby et al., 2019; Bapna and Firat, 2019): lightweight tuned modules inserted after each fully-connected and attention block of Transformer, when the rest of (pretrained) model weights are frozen. We consider adapters as the most widely used parameter-efficient adaptation approach in the literature;
- *Freezing of the decoder and embeddings* (Maurya et al., 2021): only weights in the encoder are finetuned. The motivation behind this approach is that the decoder should preserve capabilities of generating in various languages while the encoder will adapt the model to the task;
- *Mixing-in self-supervised data for target languages* (Lester et al., 2021; Maurya et al., 2021): during finetuning, task data instances in the source language will be alternated with self-supervised data instances in target languages. The motivation is that such a mixing will preserve model's capability of generation in target languages;
- *Using several source languages* (Li and Murray, 2023): performing finetuning on more than one

source language to better decouple task knowledge from language knowledge.

In the rest of the text term "full finetuning" refers to the finetuning of all weights on the English task data only, even though two last described methods also finetune all weights. We do not consider mmT5 as it was not publicly released and requires substantial resources for pretraining.

We also experiment with *intermediate tuning* (IT) of the model, used in several works and performed before finetuning on the task data. Standard encoder-decoder mPLMs rely on a self-supervised denoising training, where often the input corresponds to corrupted text (eg. with masked tokens or permuted sentences), and the output can follow some very specific structure (eg. a masked span rather than a full sentence, output containing special tokens, etc.). Therefore, in their raw form, these mPLMs are not necessarily well suited to receive well-formed text as an input and generate clean text as an output. IT performs finetuning on a language modeling-like task, e.g. predicting the continuation of a paragraph based on its beginning, to compensate for this gap. IT was shown to be necessary in Vu et al. (2022) for prompt tuning of mT5 and in Maurya et al. (2021) for full or partial finetuning of mBART. We systematically test the necessity of IT for all methods and models.

Models. We focus on encoder-decoder mPLMs as they are well suited for generation purposes, as opposed to encoder-only mPLMs such as mBERT or XLM-R. We leave the investigation of decoder-only mPLMs such as BLOOM (Scao et al., 2022) for future work. We consider mT5 and mBART as two most widely used mPLMs and NLLB-200 as a high-quality translation model:

- *mT5*: pretrained using the masked language modeling objective where parts of the input sequence are masked and the missing fragments act as targets[1]. mT5 is pretrained on the mC4 corpora, supports 101 languages, and does not use any language codes. Among released sizes from 300M to 13B we experiment with mT5-base (580M, most of the experiments) and mT5-Large (1.2B, additional experiment).
- *mBART (pt)*: pretrained using the denoising objective where parts of the input sequence are masked and the entire original sequence acts as a target (Liu et al., 2020; Tang et al., 2021). mBART is pretrained on Common Crawl (Conneau et al., 2020) corpora, supports 50 languages, has 680M parameters in total and uses language codes in both encoder and decoder sides. Both input sequence `X` and target sequence `Y` are prepended with the language code: `[lang_code, X]` and `[lang_code, Y]`, and at the inference time `lang_code` is forced as a first generated token. Our hypothesis is that the use of the language code in the decoder can help to alleviate the problem of generation in a wrong language.
- *mBART (tr)*: In addition to the *pretrained* version, we also consider mBART finetuned for *translation* (Tang et al., 2021).
- *NLLB-200*: translation model supporting 200 languages, pretrained on sentence-level data mined from the web and automatically paired using multilingual embeddings. NLLB-200 uses the same language code scheme as mBART and is released in various sizes from 600M to 54.5B, among them we consider 600M (distilled version). Our hypothesis is that translation-based pretraining may provide good representations for cross-lingual transfer as suggested by (Reid and Artetxe, 2023).

Evaluation. We select two generative tasks to evaluate cross-lingual zero-shot knowledge transfer:

- *XL-Sum*: news summarization on the XL-Sum dataset (Hasan et al., 2021). The model needs to generate a 1–2 sentences summary based on a 1–2 news paragraphs. The evaluation is performed with ROUGE-2 metric (Lin, 2004) computed on the test sets (first 2k examples per language).
- *XQuAD*: question answering dataset (Artetxe et al., 2020b), the model needs to generate a short phrase answer based on a paragraph and a question about it appended in the end of the paragraph. The evaluation is performed with F-measure comparing tokens in the gold answer and the model-generated answer, computed on publicly available development sets. For better metrics interpretability, we only consider questions for which groundtruth answers do not contain numbers and are correctly identified to be written in the target language.

[1] In contrast to English-centric T5, mT5 did not include supervised tasks in pretraining.

We select a representative subset of languages for each task[2], covering Latin- and non-Latin scripts, and report how do task-specific metrics evolve during adaptation. For better interpretability, in addition to the task metrics, we also consider (1) *lang. correct rate* metric (the percentage of outputs generated in the correct target language) and (2) *average sequence length* metric that allows us to spot some edge behaviour of the models.

Adaptation settings. For all adaptation methods we train models on English data for 20k steps with a batch size of 4000 tokens on a single A100 GPU, and run evaluation each 2k steps. We crop input sequences to the maximum length supported by models, which equals to 512 (mT5, NLLB-200) or 1024 tokens (mBART). We grid search the learning rate (LR) for each task-model-adaptation method combination, details are given below.

For *Intermediate tuning* (IT) we finetune models for 100k steps on the CommonCrawl data uniformly sampled across all target languages and English, with the batch size of 5k tokens and the LR chosen to optimize fluency of model generations, inspected manually. We use PrefixLM-inspired self-supervision from (Vu et al., 2022), where the continuation of the text needs to be predicted based on its beginning. It has shown more promising results in our preliminary experiments compared to self-supervised objective from (Maurya et al., 2021) (see details in Appendix B).

- *Prompt tuning*: we use the prompt dimension of 100 and initialize the prompt with randomly selected rows of the embedding matrix, following Vu et al. (2022).
- *Adapters*: we use the adapter dimension of 64 and insert adapters after each attention and fully-connected layer, following Bapna and Firat (2019).
- *Mixing-in target languages*: we use the same self-supervised objective as in IT and sample the corresponding data with probability 1% (all languages represented uniformly within this 1%), following Vu et al. (2022). We experimented with higher portions in Appendix C, as well as with mixing-in the pretraining task of the base model, and found that they lead to worse results.
- *Using several source languages*: we test this approach only on XL-Sum, because for XQuAD only English training data is available; for XL-Sum we use English, Japanese and Arabic, selecting them uniformly when forming mini-batches.

Hyperparameter tuning. We tune LR and decide on the necessity of IT, for each considered task-model-adaptation method combination. We initially grid searched LR for full finetuning, adapters and prompt tuning, for each task and model, without IT. The result of this step is the preliminary LR (PLR), and we utilize the PLR of full finetuning for other adaptation methods since they are also based on full finetuning. PLR usually corresponds to the highest LR which still enables generation in the correct language. After finding PLR, for each task-model-adaptation method combination, we select the best of four hyperparameter combinations: two options for LR (PLR and PLR $\times 10$) and two options for IT (used or not). Our intuition is that the use of advanced adaptation methodology or IT could potentially increase the LR which still does not lead to generation in the wrong language. In practice, this happened only once, for freezing of mBART in the summarization task.

For XL-Sum, we perform the described tuning on the validation sets, looking at the performance averaged over considered target languages, while the main evaluation is performed on the test sets. For XQuAD, only validation sets are publicly available so we perform tuning using held-out languages (Thai, Romanian, and Vietnamese). In Appendix D we show that performance on validation sets in target languages correlates with performance on validation sets in held-out languages and validation sets translated from English into target languages. This demonstrates that having validation sets in target languages is not necessary in practice which is important to enable fully zero-shot setting.

We report the resulting optimal settings in Table 3 in Appendix. We could not find information on the used LR in (Pfeiffer et al., 2023) and (Vu et al., 2022), to compare our chosen LRs with theirs. Maurya et al. (2021) and Li and Murray (2023) use a constant LR for all tasks, which are hard to compare to ours because of different data[3].

More details on the experimental setting are given in Appendix A.

[2]XL-Sum: Chinese, French, Korean, Russian, and Spanish. XQuAD: Arabic, Chinese, German, Russian, and Spanish

[3]Maurya et al. (2021) use LR=3e-5 larger than ours 1e-6, Li and Murray (2023) use LR=7e-5 close to ours 1e-4.

4 Experiments

First, we investigate the effect of the learning rate, intermediate tuning and the adaptation method for two most commonly used models, mT5 and mBART. Second, we compare them with other models and consider larger models. Finally, we present some qualitative examples and observations from manual inspection of predictions. In general, model predictions reaching highest metric values in our plots, form quite meaningful and reasonable responses to the considered tasks; more details in Section 5.

Effect of learning rate. We begin our study with analysing the effect of LR on the full finetuning on the English task data. With too small or too large LR the model does not learn even the English task because of too short steps or divergence. For the range of LRs when the English task is learned well, we observe that larger LRs lead to the effect reported in other works, when the model overfits to the source English language and generates answers in English when applied for inputs in other languages. However, *with the reduced LR, this effect almost completely eliminates and the model mostly generates in the target language*. This effect is demonstrated in Figure 1 on a subset of languages and in Fig. 9–12 in Appendix on all considered languages.

Figure 1 also shows a comparison of enhancements of full finetuning proposed in the literature, such as mixing-in target languages or freezing the decoder and embeddings. Even though these enhancements improve performance and percentage of outputs in the correct language with fixed LR, we find that *reducing LR in full finetuning often brings larger improvements*. Reducing LR for other methods makes them even stronger.

We note that performance in English is usually a little higher with larger LR. This may raise a hypothesis that for non-English languages, outputs generated with larger LR in English may be of higher semantic quality than the ones generated in the correct target language with smaller LR. In Appendix E we test this hypothesis and demonstrate that this is not the case.

Effect of intermediate tuning. For each combination of a task and an adaptation method, we compare the mT5-base/mBART task adaptation with and without intermediate tuning (IT).

We choose the best LR between PLR and PLR $\times 10$ (section 3). Results are presented in Table 1. We observe that *intermediate tuning substantially increases performance in the majority of cases*. In particular, IT appears to be essential for mBART with almost all adaptation methods and in all tasks, and important for mT5 in question answering. For mT5 in summarization, the use of IT does not increase performance, except with prompt tuning and freezing methods. We believe this is because these two approaches do not modify the decoder, which was trained only on masked spans targets during mT5 pretraining and was never exposed to realistic text targets, and IT closes this gap. This result is consistent with (Vu et al., 2022) and (Maurya et al., 2021).

	XL-Sum		XQuAD	
Method	mT5	mBART	mT5	mBART
Full finetuning	+0.1	+2.5	+6.3	+9.0
Ft + mix tgt langs	0	+0.6	+3.1	-8.3
Ft + >1 src langs	0	+1	n/a	n/a
Freeze emb & dec	+4.3	+4.1	+11.2	+1.3
Adapters	0	0	+1.0	+3.9
Prompt tuning	+7.5	+7.2	+26.8	+25.1

Table 1: Difference in performance between task adaptation with and without intermediate tuning, for various methods. Rouge-2 for XL-Sum, F-measure for XQuAD. *Main conclusion:* intermediate tuning brings performance improvements in the majority of cases, in almost all the rest cases it does not affect performance.

Comparison of adaptation methods. Figure 2 shows results (averaged over target languages) comparing adaptation methods for mT5-base and mBART models. Detailed per-language results are presented in Figure 8 in Appendix.

We observe that *with carefully chosen learning rates and intermediate tuning, simple full finetuning is a very strong baseline for zero-shot cross-lingual transfer in generation*. Improvements brought by the use of more advanced adaptation methods are rather modest, and *none of the adaptation methods consistently outperform full finetuning in all cases. The notable approach for mBART is freezing the decoder and embeddings*, proposed by Maurya et al. (2021) for this base model: freezing consistently outperforms full finetuning in all target languages in both tasks. However, this approach does not show such improvements for mT5. *For XL-Sum, using more than one source language proposed in (Li and Murray, 2023) for mT5, brings consistent improvement over target*

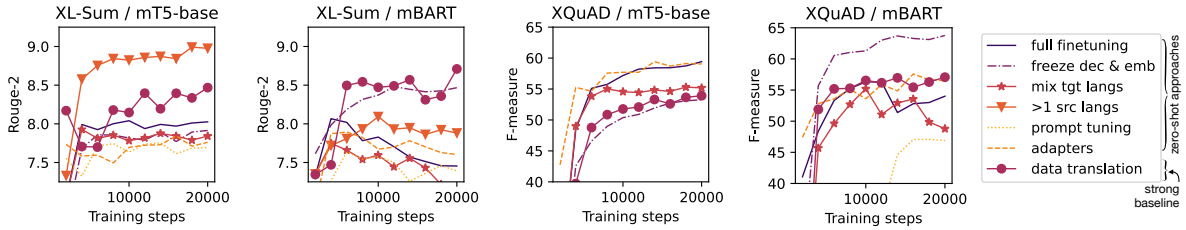

Figure 2: Comparison of adaptation methods, with tuned learning rates and intermediate tuning when it is needed. Results averaged across target languages and 2 runs. Language correct rate is close to 100% in almost all cases, due to hyperparameter tuning. The exception is prompt tuning of mT5 in the XQuAD task which is not shown because of too low performance. *Main conclusions*: (1) Straightforward full finetuning is a strong approach which reaches or approaches the performance of data translation in all cases. (2) None of other approaches outperform full finetuning *consistently* in all cases: using several sources languages works well for mT5 but not for mBART and freezing decoder works well for mBART but not mT5. (3) One of zero-shot approaches reaches or outperforms a strong and computationally expensive baseline, data translation, in all cases.

	XL-Sum		XQuAD	
Method	R2	LCR	F1	LCR
Large / IT + ft	9.9	99.8%	69.8	94.7%
Large / IT + ft >1 src lg	10.9	99.8%	n/a	n/a
Large / Data translation	10.8	99.8%	63.6	96.7%
Base / IT + ft	8.0	99.7%	59.4	92.9%
Base / IT + ft >1 src lg	9.0	99.8%	n/a	n/a
Base / Data translation	8.5	99.6%	53.9	95.3%

Table 2: Results for mT5-large model, averaged over target languages. Metrics: Rouge-2 for XL-Sum, F-measure for XQuAD, LCR: language correct rate. LCR is lower than 100% on XQuAD (partly) because of language identification errors for short sequences.

languages when used with mT5. For mBART this approach performs on par with using one source language. The obvious drawback of this approach is that multi-lingual data may be not available, e.g. this is the case for XQuAD.

Mixing-in unsupervised tasks for target languages often degrades performance and increases the length of predictions, see Appendix C. Prompt tuning often has difficulties learning an English task and substantially underperforms other adaptation methods on XQuAD. Adapters usually perform on par or slightly worse than full finetuning.

Comparison of models. Figure 2 allows us to compare mT5-base and mBART after tuning of hyperparameters and adaptation methods. These models incorporate comparable numbers of parameters. We observe that *mT5 and mBART reach the close level of performance in both tasks*. The same conclusion holds if we simply compare full finetuning runs of both models.

In Figure 3 we compare all four models we consider, adapted using full finetuning. We compare models without intermediate tuning, to avoid hindering model capabilities behind this additional step. We find that *translation-pretrained NLLB-200 performs well in summarization*, achieving performance of mT5 and mBART in Latin-language high-resource languages, French and Spanish, and performing on par with mBART without intermediate tuning in other languages[4]. We selectively inspected the predictions of NLLB and found that they indeed form meaningful summaries. However, in QA, NLLB-200 performs poorly, often (but not always) generating non-relevant answers. Translation-finetuned version of mBART performs poorly in all tasks, generating a lot of wrong language predictions.

Interestingly, the results do not support our initial hypothesis that the translation pretraining objective used in NLLB and architectural choices such as the use of language codes in mBART, could improve zero-shot knowledge transfer in generation.

Comparison versus data translation. Figure 2 also shows comparison versus the data translation[5] approach, when English training data is translated into target languages using the NLLB-3.3B model. We translate data sentence-by-sentence and grid search the LR for finetuning. The results show that after careful tuning, *the zero-shot approach reaches or outperforms the data translation approach in both considered tasks*. If we consider a simpler setting when only LR and the use of IT are tuned, i.e. comparing full finetuning and data translation

[4]Expect Chinese, for which NLLB-200 generates a lot of empty predictions. NLLB-200 was noticed previously in the literature to have issues with processing Chinese.

[5]Data translation is often referred as translate-train method.

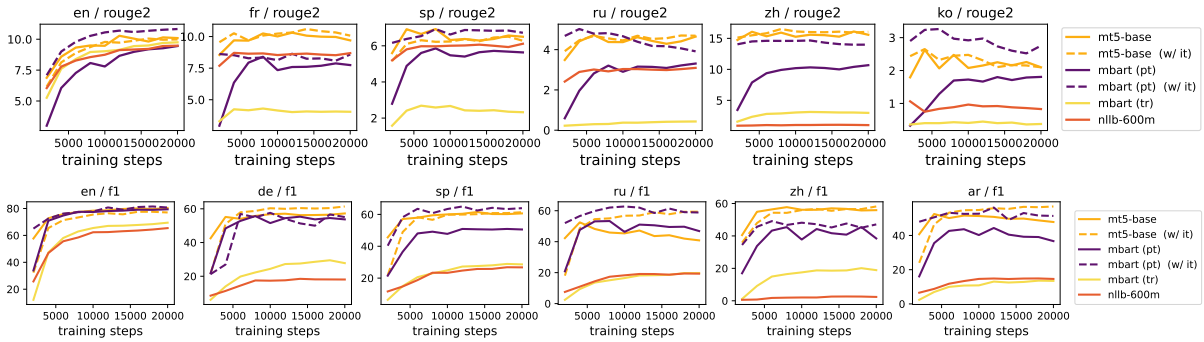

Figure 3: Comparison of base models with full finetuning. Each plot averaged over 3 runs. Correct language rate is close to 100%, due to hyperparameter tuning, in almost all cases except the translation-tuned version of mBART. pt: pretrained version of mBART, tr: translation-finetuned version of mBART. *Main conclusion:* mBART and mT5 of similar sizes perform on par; NLLB performs well in summarization for Latin-alphabet languages.

runs in Figure 2, we observe that the zero-shot approach closely approaches the data translation approach in summarization and performs on par in question answering. The XQuAD dataset is harder to automatically translate than XL-Sum, e.g. single words often present in targets may be translated into short full sentences.

Experiments with larger models. Table 2 reports results for the mT5-large model where we compare performance achieved with full finetuning after intermediate tuning versus training on translated data. We also include the leader approach of using several source languages for XL-Sum. We consider only mT5 because mBART is released in one size. We reduce LR to 0.00001 for the larger model, as the LR of 0.0001 used for the base model was sometimes producing English outputs. We also list mT5-base results for reference.

We find that the same conclusions hold for the mT5-large model as for mT5-base: reducing LR eliminates generation in the wrong language, and the zero-shot approach is on par or better than the data translation approach.

5 Inspection of predictions

We inspected a subset of predictions in French and Russian and found that models achieving highest scores in both tasks generate fluent, meaningful and reasonable predictions in a lot of cases, but sometimes have issues with factualness, grammaticality or hallucinations. Examples are shown in Figure 4. Analyzing effects of LR, we observe that increasing LR leads first to increase in code switching and then to wrong language generation, while *reducing LR leads to producing rudiments of pretraining in generation*. For example, models sometimes generate extra tokens used in pretraining, such as `<extra_id_{N}>` for mT5 or `<sep>` for mBART, see rows 2 and 4 in Figure 4. *In most cases this does not affect meaningfulness of predictions*, but in *rare* cases leads to mT5 producing incomplete sentences, which may look unreasonable in sum-

marization, e.g. "<extra_id_0> Guinea-Bissau President Alberto Dabo said." (translated from French). The reason is that in mT5 pretraining tokens <extra_id_{N}> were followed by fragments of input sentences. *The described effect is eliminated by intermediate tuning* (row 3 in Fig. 4).

In the same fashion, *mBART average lengths are closer to groundtruth average lengths than mT5 in summarization, and the reverse effect takes place in QA*. The reason is that in mT5 pretraining, the targets are only fragments masked in the input, which are shorter than targets in mBART pretraining represented by full sequences (they need to be reconstructed from the masked inputs).

Notably, data translation can produce translation-related errors, e.g. in rows 5 and 9 models generate a wrong male article "Un", probably because this was a dominating article in the translated data.

6 Conclusion

In this work, we conducted a deep systematic study of how to achieve high-performing zero-shot cross-lingual transfer in generation. Our study highlights the *high importance of careful learning rate tuning and the usefilness of the intermediate tuning*. We show that with these two ingredients, mT5 and mBART achieve strong results with simple full finetuning, i.e. closely approach the performance of translate-train in summarization and reach it in question answering. The performance gap in summarization is closed by using several source languages for mT5 and freezing decoder and embeddings for mBART. Translation-pretrained NLLB-200 shows surprisingly good performance in summarization but lags behind in question answering. We urge future works to pay more attention to hyperparameter tuning and to report more rigorously their experimental setup, as well as consider a wider spectrum of models and baselines in the experiments.

7 Limitations and broader impact

We aim at conducting a deep, thoughtful study of various design choices in zero-shot cross-lingual generation, but acknowledge the impossibility of considering all possible options, given the resource constraints. In particular, we could not perform full fine-grained grid search of LR for each task-model-adaptation method combination. Instead, we use a well-designed simplified strategy described in Section 3, which already gave strong results. In the same fashion, we had to limit our study to three models (we picked most commonly used models) and adaptation methods which do not require model pretraining, e.g. we do not consider mmT5 model. Nonetheless, we hope our study provides helpful insights on zero-shot cross-lingual transfer in generative tasks and shows that it can achieve the performance of the data translation method, which is usually considered as an unreachable upper baseline.

We do not anticipate any negative impact of our work and on the reverse hope that it will help to make higher-quality language technologies accessible to a broader set of languages.

8 Acknowledgments

We gratefully appreciate Alexandre Bérard's help in the project.

A Experimental setup

Data. We experiment with news summarization on the XL-Sum dataset (Hasan et al., 2021) (released under the CC BY-NC-SA 4.0 license) and question answering on the XQuAD dataset (Artetxe et al., 2020b) (released under the CC BY-SA 4.0 license). Both datasets were released for research puposes. The XL-Sum dataset was obtained by crawling BBC news in 44 languages, with corpus size per language varying from 1K (Scottish Gaelic) to 300K (English) article-summary pairs. Inputs are composed of 1–2 paragraphs and targets are usually 2–3 sentences. We evaluate on test sets and crop test sets larger than 2K samples, to 2K. The XQuAD dataset was obtained by translating SQuAD validation set (Rajpurkar et al., 2016) into 11 languages, thus all language corpora are parallel. We use this dataset for evaluation and train on the training set of SQuAD (80K training instances). Each input is composed of a paragraph and a question about this paragraph appended in the end of the paragraph. Each output is an answer to a question, a short segment copied from the paragraph.

Preprocessing and postprocessing. We tokenize data using each model's tokenizer. We crop model inputs and outputs to the maximum lengths supported by models, which equal to 1024 tokens for mBART and 512 tokens for mT5-base and NLLB-600M. Due to the design of pretraining, models may generate extra tokens such as `<extra_id_{N}>` for or `<sep>` for mBART. We remove such extra tokens from predictions before computing metrics.

Models and training. We consider three models: mT5 (base and large, released under the Apache License 2.0 license), mBART (MIT license), and NLLB-200 (cc-by-nc-4.0 license). All models allow use for research purposes. We train models on English data for 20k steps with batch size of 4000 tokens on a single A100 GPU, and conduct validation on considered target languages each 2k steps. We use Adam optimizer with standard inverse square root LR schedule and warm up of 4k steps, and update model parameters after each minibatch. We estimated the total computational budget of our experiments to be 4K GPU hours.

Hyperparameter search. For full finetuning, adapters and prompt tuning, we run a search over a range of LR. For each task and model (without intermediate tuning), we search the LR best for non English languages on average, looking at ROUGE-2 for summarization and F-measure for QA. We start with the set of three LRs: $\{10^{-k}, k = 3, 4, 5\}$. If the optimal $k^* \neq 4$ then we extend search correspondingly to $k = 2, 1$ or $k = 6, 7$ until performance stops improving. For full finetuning, after we find optimal k^* we also consider $3 \cdot 10^{-k^*}$. The motivation is that the optimal k^* usually corresponds to the maximal k that still allows generation in the correct language, and considering $3 \cdot 10^{-k^*}$ enables more accurate search for this maximum. We report chosen LRs for full finetuning and adapters in Table 3. For prompt tuning we chose LR of 0.01 for both tasks.

Evaluation. For summarization, we report the ROUGE-2 metric (Lin, 2004), and for QA, we report F-measure. In QA, a lot of answers contain numbers or English words which could inflate metrics even if the model does not generate in the correct language. Moreover, the accuracy of language identification decreases on short answers, resulting in false indication of generation in wrong language. To avoid these issues, we compute metrics in QA only over questions for which groundtruth answers do not contain numbers and are correctly identified to be written in the target language (∼50% of 1190 questions satisfy this criteria).

For ROUGE metric, we use the `gem-metrics` package. For F1 metric in XQuAD, we use the script provided by the dataset authors. To identify

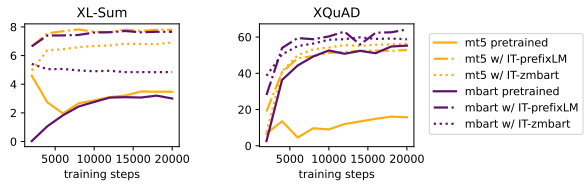

Figure 5: Comparison of self-supervised objectives for intermediate tuning, with freezing decoder and embeddings as an adaptation method. Task metric: Rouge-2 for XL-Sum, F1 for XQuAD. Correct language rate is close to 100% in all cases except pretrained mBART on XL-Sum.

language, we use `fasttext` library (Joulin et al., 2017, 2016) and its `lid.176.bin` model[6].

B Preliminary experiments with intermediate tuning

Figure 5 reports comparison of two self-supervised objectives for intermediate tuning: Prefix-LM and ZmBART-like objective. PrefixLM objective implies predicting the continuation of the chuck of text based on its beginning, while ZmBART-like objective implies citing random sentences from the input chunk of text. We compare two objectives using the freezing of the decoder and embeddings as an adaptation method, applied after intermediate tuning with the chosen objective, because we found intermediate tuning to be essential for this adaptation method in the preliminary experiments. Fine-tuning LR equals to the PLR defined in Section 4, intermediate tuning LR was chosen to optimize fluency of model generations, inspected manually. Intermediate tuning is performed on the CommonCrawl dataset.

We observe that for XL-Sum, the Prefix-LM objective leads to substantially higher Rouge-2 values, while for XQuAD both objectives lead to close results. Based on these results, we decided to use the Prefix-LM objective in all experiments.

C Preliminary experiments with mixing-in target languages

Figure 6 reports results of preliminary experiments with mixing-in a self-supervised task in target languages. For each base model, namely mT5-base and mBART, we consider its pretraining task and a Prefix-LM task used for intermediate tuning. We

[6] https://fasttext.cc/docs/en/language-identification.html

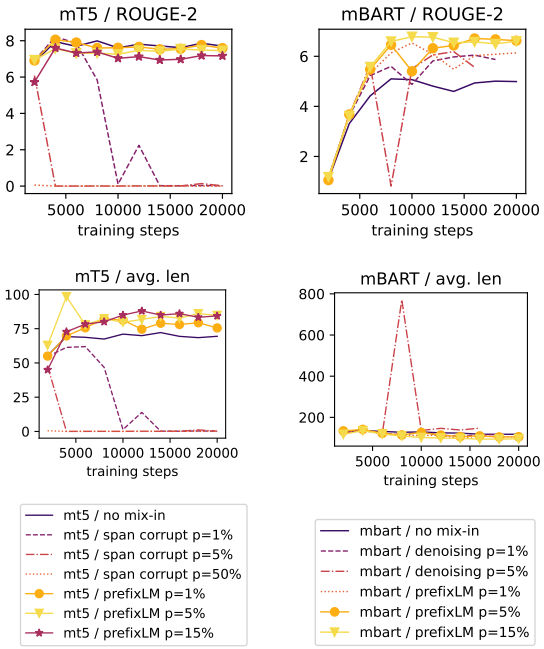

Figure 6: Preliminary experiments with mixing-in a self-supervised task for target languages. The probability in the legend denotes the probability of sampling target language examples when forming mini-batches. Two self-supervised tasks considered: Prefix-LM and the pretraining task of the model. Correct language rate is close to 100% in all cases

consider several options for the probability of sampling target language examples when forming mini-batches. CommonCrawl data is used for the self-supervised task. The experiment is conducted for the XL-Sum task, with LR being equal to the PLR defined in Section 4, without intermediate tuning.

For mt5, we observe that using the span corruption pretraining task leads to empty outputs with any mixing-in probability (with smaller probabilities this effect happens later in the training). This is because task examples do not contain any mask tokens, and empty generation is a default response of the pretrained mT5 to such inputs. Mixing-in PrefixLM task examples performs similarly to the standard finetuning of mT5, with mixing-in probability of 1% performing best, same as in (Vu et al., 2022). Qualitatively, mixing-in self-supervised task increases the length of generated outputs in the tasks of interest.

For mBART, all mixing-in strategies lead to modest improvements in performance, with PrefixLM task performing slightly better. All considered mixing-in probabilities lead to similar results. Based on these observations, we decided to use the

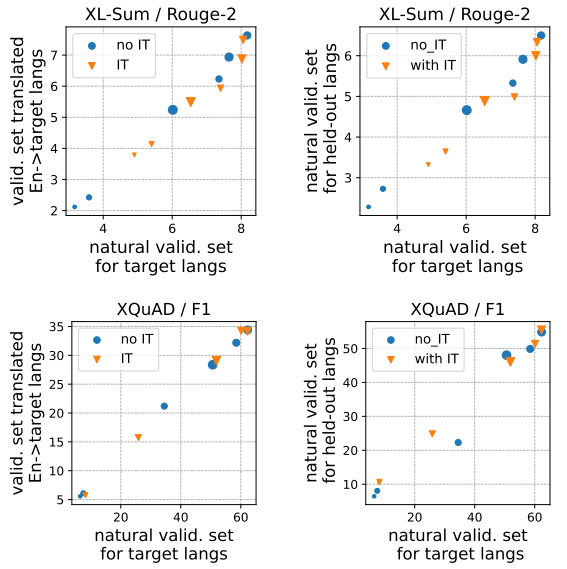

Figure 7: Correlation in performance on various validation sets. Each dot represents mT5-base finetuned on English data, with or without intermediate tuning (reflected with the shape and color of the point), and the size of the point reflects the learning rate. Natural valid. set means the validation set provided by the authors of the dataset.

PrefixLM task with mixing-in probability of 1% in our experiments.

D Comparing validation sets

Figure 7 demonstrates the correlation between performance measured on various validation sets. Performance on validation sets in target languages correlates with performance on validation sets in held-out languages and validation sets translated from English into target languages. This shows that having validation sets in target languages is not necessary in practice which is important to enable fully zero-shot setting.

E Additional experiment with translating English outputs into target languages

When reducing the LR for preserving generation in correct language, a reasonable question could be whether predictions of higher LR models are higher quality answers, but just in the wrong language, or simply hallucinations caused by data distribution shift. The premise for the former scenario is that on English data, performance with our chosen LR is usually slightly lower than with a larger LR.

We find that actually the later scenario takes place, by comparing performance of our chosen LR (best for non-English) and of the best LR for English with model predictions being translated into target languages using NLLB-3.3B[7], for last checkpoints of full models finetuning. According to Table 4, translated predictions of the higher LR model score lower than the (non-translated) predictions of the lower LR model. This result further advocates for the importance of careful LR tuning for full finetuning in zero-shot cross-lingual transfer in generation.

		Best-En LR + Tr.		Best-non-En LR	
		LR	**Score**	**LR**	**Score**
Sum	mT5	1e-3	4.02	1e-4	7.7
	mBART	1e-5	4.06	1e-6	5.34
	NLLB-200	1e-4	2.86	1e-5	4.62
QA	mT5	1e-4	46.2	1e-4	58.6
	mBART	1e-5	41.1	1e-5	46.6
	NLLB-200	1e-4	17.4	3e-5	18.2

Table 4: Comparison of best LR for non-English languages and best LR for English with model outputs being translated into target languages. Performance averaged over non-English languages, after 20k of full finetuning. Reported metric: Rouge-2 for summarization, F-measure for QA. mBART — pretrained version, no intermediate tuning is used in this experiment.

[7]NLLB-3.3B handles well inputs containing code switching which are frequent in predictions we are translating, and simply copies inputs which are already in the target language.

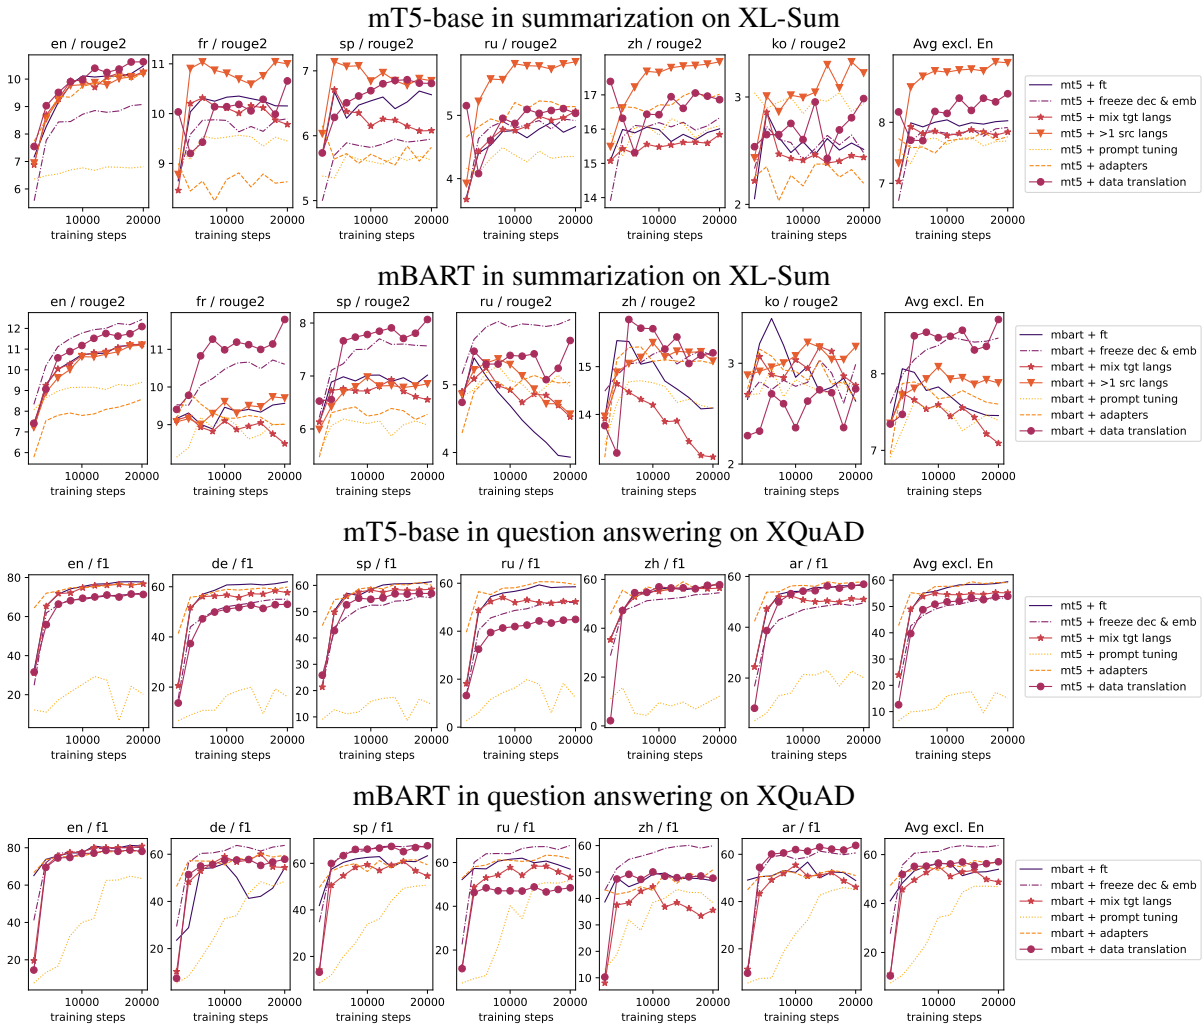

Figure 8: Per-language results on the comparison of adaptation methods. Each plot averaged over 2 runs. Correct language rate is close to 100% in all cases, due to the hyperparameter tuning, except prompt tuning of mT5 in the XQuAD task.

Abstract

To process novel sentences, language models (LMs) must generalize compositionally—combine familiar elements in new ways. What aspects of a model's structure promote compositional generalization? Focusing on transformers, we test the hypothesis, motivated by theoretical and empirical work, that deeper transformers generalize more compositionally. Simply adding layers increases the total number of parameters; to address this confound between depth and size, we construct three classes of models which trade off depth for width such that the total number of parameters is kept constant (41M, 134M and 374M parameters). We pretrain all models as LMs and fine-tune them on tasks that test for compositional generalization. We report three main conclusions: (1) after fine-tuning, deeper models generalize more compositionally than shallower models do, but the benefit of additional layers diminishes rapidly; (2) within each family, deeper models show better language modeling performance, but returns are similarly diminishing; (3) the benefits of depth for compositional generalization cannot be attributed solely to better performance on language modeling. Because model latency is approximately linear in the number of layers, these results lead us to the recommendation that, with a given total parameter budget, transformers can be made shallower than is typical without sacrificing performance.

1 Introduction

The number of possible sentences in natural language is enormous; regardless of the size of its training set, a language model (LM) will regularly encounter sentences it has never seen before. The ability to interpret such sentences relies on compositional generalization: the capacity to combine familiar words and syntactic structures in new ways (Montague, 1970; Fodor and Pylyshyn, 1988). Transformer LMs (Vaswani et al., 2017), while highly successful in many settings, often struggle when tested on benchmarks that require compositional generalization (Kim and Linzen, 2020). What architectural factors affect a transformer's ability to generalize compositionally?

In this paper, we test the hypothesis that increasing a transformer's depth—the number of layers it has—improves its performance on tasks that require compositional generalization. This hypothesis is motivated both by theoretical work, which has shown that adding layers increases the expressive capacity of neural networks in general (Raghu et al., 2017) and transformers in particular (Merrill et al., 2021), and by experimental work suggesting that deeper models generalize more compositionally than shallower ones (Mueller et al., 2022; Murty et al., 2023).

While existing empirical work lends some credibility to this hypothesis, to directly confirm it we must address the confound between depth and size (number of parameters). As each additional layer introduces a new set of parameters, deeper models are also larger, all else being equal, and LMs' performance on a wide variety of tasks is known to be correlated with their size (Kaplan et al., 2020; Hoffmann et al., 2022; Muennighoff et al., 2023). To address this confound, we construct classes of models with an equal total number of parameters but differing depths; we do so by reducing the model's feed-forward dimension to compensate for added depth. We pretrain all models as language models and fine-tune them on four compositional generalization tasks: the semantic parsing tasks COGS (Kim and Linzen, 2020), COGS-vf (Qiu et al., 2022a) and GeoQuery (Zelle and Mooney, 1996), and the English passivization portion of Multilingual Transformations (Mueller et al., 2022). In all of these tasks, the model is trained on a particular data distribution and is expected to generalize to

another distribution by composing together familiar elements in novel ways.

In addition to any possible direct effect on compositional generalization, depth may also be correlated with other factors which may themselves predict compositional generalization, such as language modeling loss during pretraining or in-distribution performance on the fine-tuning task. This complicates the interpretation of any relationship we might find between depth and generalization performance. To address this concern, we also investigate and correct for the effect of depth on language modeling performance and in-distribution loss.

We report the following findings, across three model size classes (41M, 134M, and 374M parameters):

1. In general, deeper models have lower perplexity (Section 3.1). The marginal increase in performance gained from additional layers diminishes rapidly as models get deeper, and performance begins to degrade when the feed-forward dimension approaches the dimensionality of the model's contextualized embeddings.

2. In general, deeper models display better compositional generalization (Section 3.2). Again, most of the benefit of depth accrues from the first few layers; for several of the compositional generalization benchmarks we use, performance saturates very quickly as models get deeper.

3. Deeper models generalize more compositionally even after correcting for the fact that their language modeling perplexity is lower and their in-distribution performance on the fine-tuning task is higher (Section 3.3).

4. Since transformers' latency is approximately linear in their depth, it is in many case more efficient to make a model wider rather than deeper, given a fixed parameter budget (Section 4).

2 Methodology

2.1 Constructing Families of Models with Equal Numbers of Parameters

To make a transformer deeper without increasing the total number of parameters, we need to also make it narrower. There are several ways to do so: we can reduce the size of the feed-forward dimension d_{ff}, reduce the size of the contextual embeddings d_{model}, or reduce the size of the attention outputs d_{attn} (see Appendix B for a diagram of a transformer layer annotated with dimensionality labels). Vaswani et al. (2017) coupled these variables at $d_{\text{model}} = d_{\text{attn}} = d_{\text{ff}}/4$. Most transformer LMs have adopted this ratio (Devlin et al., 2019; Kaplan et al., 2020; Hoffmann et al., 2022, *inter alia*), though Raffel et al. (2019) increased the size of d_{ff} relative to d_{model} and d_{attn} for their two largest models. By contrast, we vary d_{ff} with depth (while holding $d_{\text{model}} = d_{\text{attn}}$ constant). By keeping the attention mechanism identical across models of varying depths, we rule out the possibility that depth will be confounded with the capacity of the self-attention mechanism. We refer to $d_{\text{model}}/d_{\text{ff}}$, conventionally set to $1/4$, as the *feed-forward ratio*.

Deriving hyperparameter relations. As a starting point for our size classes of models, we use hyperparameters taken from T5-base and T5-large (Raffel et al., 2019) as well as a smaller model from Kim and Linzen (2020) which has identical layer-internal hyperparameters to T5-small but fewer layers.[1] We implement models using `t5x` (Roberts et al., 2022). We then calculate how much the feed-forward dimension must change to accommodate adding or removing layers. Starting from the formula in Kaplan et al. (2020), the number of parameters M in a layer is

$$M(d_{\text{ff}}) = 2d_{\text{model}}d_{\text{ff}} + 4d_{\text{model}}d_{\text{attn}} = \beta \cdot d_{\text{ff}} + A,$$

where the constant β represents the contribution of the parameters of the feed-forward block which projects vectors from $\mathbb{R}^{d_{\text{model}}}$ into $\mathbb{R}^{d_{\text{ff}}}$ and back into $\mathbb{R}^{d_{\text{model}}}$; and the constant A represents the parameters of everything aside from the feed-forward block, including the attention mechanism. The total parameter count of a full model N in terms of d_{ff} and n_{layers} is then

$$N(n_{\text{layers}}, d_{\text{ff}}) = n_{\text{layers}} \cdot M(d_{\text{ff}}) + 2d_{\text{model}}n_{\text{vocab}}.$$

Given initial values $(n^0_{\text{layers}}, d^0_{\text{ff}})$ which characterize the baseline model in each size class (e.g., T5-large), our goal is to find pairs $k, w(k)$ such that

$$N(n^0_{\text{layers}} + k, d^0_{\text{ff}} - w(k)) = N(n^0_{\text{layers}}, d^0_{\text{ff}}).$$

Solving for w as a function of k tells us how much to increase (or decrease) d^0_{ff} if we remove (or add)

[1] Unlike T5 and the original transformer, we implement GPT-style causal decoder-only language models; following Wang et al. (2022) we consider decoder-only models with half as many total layers as their encoder-decoder variants.

k layers from an existing model:

$$w(k) = \left\lfloor \left(1 - \frac{n^0_{\text{layers}}}{n^0_{\text{layers}} + k}\right)\left(d^0_{\text{ff}} + \frac{A}{\beta}\right)\right\rceil. \quad (1)$$

Since adding or removing k layers might require changing d^0_{ff} by a fractional amount, we round $w(k)$ to the nearest integer. Table 2 reports the exact hyperparameter values we use for each of our three size classes, derived from Equation 1 above, and Figure 1 shows each size class plotted as $(n_{\text{layers}}, d_{\text{ff}})$ pairs.

2.2 Datasets and Training

2.2.1 Language Modeling

We use the Colossal Clean Crawled Corpus (C4; Raffel et al. 2019) for pretraining. We use a context size n_{ctx} of 1024 tokens and a batch size of 128 sequences $\approx$ 131k tokens. We pretrain each model for 1M steps, resulting in a total training dataset of roughly 131B tokens.

2.2.2 Compositional Generalization

In compositional generalization datasets, models are tested on a distribution that contains novel combinations of pieces, each of which has been previously seen independently during training. We fine-tune our pretrained models on the training portion of the dataset for 10,000 steps with a batch size of 128. Validation loss continued to decrease throughout training runs on each dataset, so we report values from the end of each fine-tuning run without early stopping. We use the following datasets (for examples of instances of these tasks, see Table 1):

1. **COGS** (Kim and Linzen, 2020) is a semantic parsing dataset consisting of natural-language sentences paired with formal semantic representations. It is constructed such that the out-of-domain generalization distribution contains two generalization types: new combinations of familiar words (*lexical generalization*, such as using the word 'hedgehog' as the object of a sentence when this word has only been seen during training as a subject); or new combinations of familiar syntactic structures (*structural generalization*, such as relative clauses that are more deeply nested than seen in training).

2. **Variable-free COGS** (COGS-vf; Qiu et al. 2022a) is a simplified variant of COGS where the semantic representations do not use numbered variables (see Table 1 for a comparison between COGS and COGS-vf). Removing variables from the representation has the benefit of lowering the associated computational cost of training by making sequences shorter. This conversion has been previously shown to improve the performance of models by reducing the complexity of the output space (Qiu et al., 2022b), but comes at the cost of limiting the capacity of the formal language to represent phenomena that require coordination of variable identity, such as control and anaphor binding.

3. **GeoQuery** (Zelle and Mooney, 1996) contains natural-language questions about US geography paired with SQL-style database queries representing those questions. We report results on the GeoQuery Standard split.

4. **English passivization** (Mueller et al., 2022) is a dataset of English active-voice sentences paired with their passive-voice counterparts (adapted from Mulligan et al. 2021). This benchmark is designed to test whether models use shallow, positional heuristics or syntactically principled ones. While Mueller et al. (2022) implemented a number of transformations in different languages, we focus on the English Passivization task.

3 Results

3.1 Language Modeling

Deeper models have lower perplexity. Depth has a significant impact on language modeling performance. At the shallow end of the spectrum, increasing depth results in a dramatic improvement in perplexity (Figure 2). In Figure 3a we compare the perplexity of each model in a size class relative to that of the best-performing model of that size. In the extreme case, the perplexity of a single-layer model can be nearly twice that of the optimal model in the class. Moreover, as parameter count increases the disparity between the worse, shallower models and the better, deeper models increases as well: For 41M-parameter models the ratio between the perplexity of the single-layer model and that of the optimal (5-layer) model is 1.59; for the 134M-parameter models, the ratio is 1.86; and for the 374M-parameter models, the ratio is 1.99.

Performance increases most rapidly within the first few layers. While deeper models do, in general, perform better than shallower ones, the in-

Table 1: Examples of inputs (x) and targets (y) from each compositional generalization dataset.

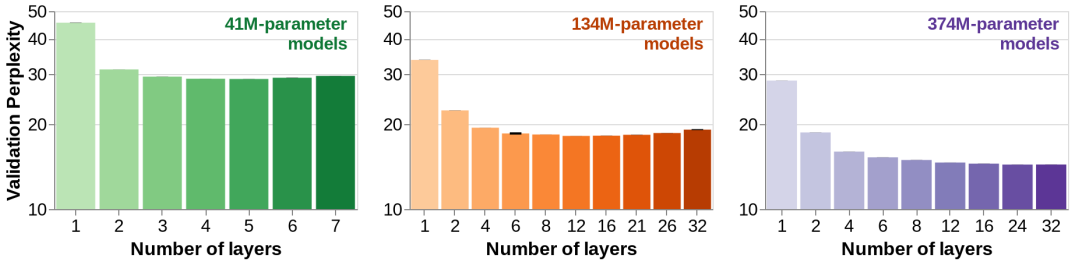
crease in performance that comes from adding layers diminishes rapidly as models become deeper (Figure 3a). The performance difference between 1-layer and 2-layer models is dramatic across all size classes; moving from 2 to 4 layers results in a much more modest performance improvement. We also note that as models get larger in our setup, they are able to make productive use of increasingly more layers: the optimal 41M-parameter model in our setup has 5 layers, while the optimal 134M-parameter model has 12; among 374M-parameter models, the 24-layer model had the best performance. At the same time, the pattern of the diminishing utility of depth holds even for the largest models we study.

Performance degrades when models become too narrow. At the deeper end of our scale, adding layers is not only unhelpful for performance, but begins to harm it (see the right-hand sides of each size-class curve in Figure 3a). As previously noted, the point at which trading width for depth becomes harmful is not an absolute function of depth, since the depth of the optimal model differs across classes. However, comparing the relative performance of models within a size class to the feed-forward ratio $d_{\text{model}}/d_{\text{ff}}$ shows that model performance begins to worsen once d_{ff} becomes smaller than d_{model} (to the right of the red dashed line in Figure 3b); when this happens, the affine projection of the vectors from $\mathbb{R}^{d_{\text{model}}}$ into $\mathbb{R}^{d_{\text{ff}}}$ becomes a non-injective map. In Section 5 we analyze the weight matrices of the affine transforms in the feed-forward network of each layer and demonstrate that as $d_{\text{model}}/d_{\text{ff}}$ increases the transforms become increasingly rank-deficient.

Larger models can tolerate more extreme feed-forward ratios. Varying d_{ff} while keeping d_{model} constant results in feed-forward ratios $d_{\text{model}}/d_{\text{ff}}$ which deviate significantly from the ratio of $1/4$, which is the de-facto standard in the literature (black vertical rule in Figure 3b). We find that smaller models are more sensitive to the particular value of the feed-forward ratio, and that for small models the standard ratio may not be optimal. Within the 41M-parameter size class there is a narrow range of feed-forward ratios in which model performance is within a few percentage points of the best-in-class model. As models get larger, this range expands leftward to include models which have increasingly wide feed-forward networks relative to the size of their contextual embeddings. In other words, larger models have more leeway to trade depth for width, becoming wider in proportion to their model dimension d_{model} without incurring large penalties for their perplexity. Furthermore, when $d_{\text{model}}/d_{\text{ff}} < 1$ the feed-forward ratio does not predict the relative perplexity of a model independent of its size.

3.2 Compositional Generalization

We next fine-tune the models pretrained in the previous section on the training portions of each compositional generalization dataset, and measure the full-sequence (exact match) accuracy of the models



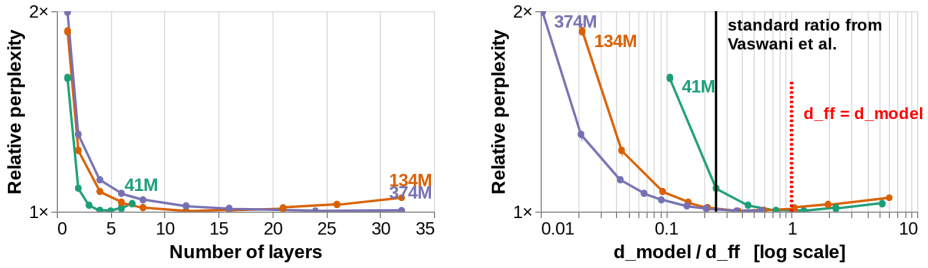


Figure 2: Deeper models achieve lower perplexities than shallower ones after equal amounts of training data regardless of size, but the benefits of adding layers diminish quickly with depth. Mean over 5 runs shown with error bars.

(a) (b)

Figure 3: Relative perplexity compared to the best model in each size class. **(a)** Perplexity goes down rapidly as models get deeper; only a few layers are needed to obtain most of the value of depth. **(b)** When $d_{\text{model}}/d_{\text{ff}} > 1$ (red dashed rule), perplexity slowly increases. As models get larger, the range of $d_{\text{model}}/d_{\text{ff}}$ ratios where performance is close-to-optimal expands leftward to include smaller and smaller values.

on the out-of-distribution generalization set.

Deeper models generalize better. As with language-modeling performance, deeper models tend to attain higher generalization accuracies than shallower models in the same size class (Figure 4). The effect of depth on compositional generalization is more variable than it is for language modeling, however: for COGS, COGS-vf, and GeoQuery there is some small non-monotonicity in the generalization accuracy as a function of depth. On English Passivization, the 41M- and 134M-parameter classes show largely-consistent trends where deeper models perform better than shallower ones; the 374M-parameter models show more significant non-monotonicity, though the deepest models do still outperform the shallowest ones.

The benefit of depth saturates quickly for some tasks. As with language modeling, most of the benefit of depth is gained by having only a few layers. For three of the tasks—COGS, COGS-vf, and GeoQuery—we see threshold depths after which generalization accuracy stays relatively constant as depth increases. These threshold depths are low and constant across model sizes, but vary by dataset: 4–6 layers for COGS, and 2–4 layers for COGS-vf and GeoQuery. Performance on COGS-vf appears to saturate with fewer layers than on COGS despite the fact that the two datasets express the same linguistic phenomena; this suggests that the saturation we observe on some datasets is closely linked to the complexity of the output representation independent from the complexity of the compositional generalization expressed in the data. On English Passivization, the impact of depth is more variable, which makes it difficult to identify a size-independent threshold.

The threshold effects suggest that some subsets of the datasets can be addressed with relatively simple models. We investigate this hypothesis by separately analyzing the models' performance on the two types of generalization cases included in COGS and COGS-vf: lexical generalization, where a familiar word needs to be interpreted in a familiar syntactic context in which it has not been observed; and structural generalization, where the syntactic structure is novel and needs to be constructed from familiar syntactic pieces. We find that even deep models at the largest model size systematically fail to generalize structurally (Figure 5); the benefit of

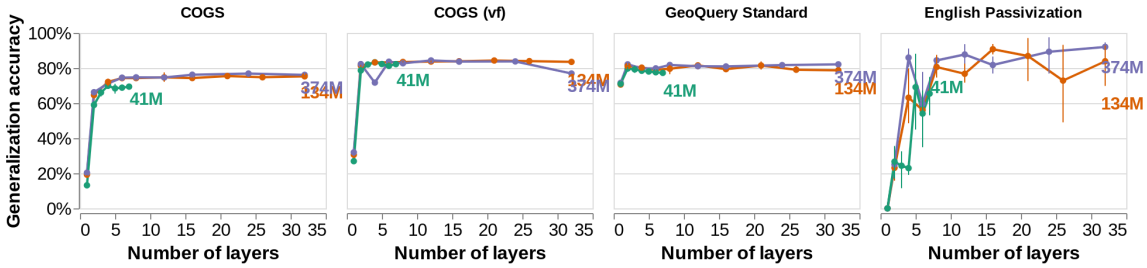

Figure 4: Deeper models generalize better than shallower models on compositional tasks across datasets and size classes. Error bars (easily visible only on the English Passivization data) report 95% confidence intervals in estimation of the mean, taken over 5 runs.

depth is largely limited to the easier lexical generalization cases. This supports the hypothesis that the saturated effect of depth is due to the existence of easier subsets of the datasets, and shows that increasing depth alone does not substantially improve the models' ability to learn the correct inductive bias for these structural tasks.

3.3 Depth Effects are Independent between Upstream and Downstream Tasks

We have shown that deeper models generalize better than shallower models do. But in Section 3.1 we also showed that deeper models attain lower validation perplexity in pretraining than shallower models; and deeper models achieve lower in-distribution loss on the fine-tuning tasks than shallower ones (Figure 7a). Both of these observations constitute potential confounds for the interpretation of the previous section: it could be that depth does not *directly* improve generalization accuracy, but only does so indirectly by improving language modeling performance or in-distribution accuracy on the fine-tuning task, which in turn lead to better generalization. To determine if this is the case, we correct for both of these potential confounds.

First, to correct for the deeper models' lower pretraining loss, we repeat our fine-tuning experiments using intermediate checkpoints of pretrained models that have equal validation perplexity within a size class. We pick the least-performant (i.e., shallowest) model within a size class as the reference model and note its validation perplexity at the end of pretraining. We then pick the intermediate checkpoints of all deeper[2] models at the point during pretraining when they achieved this reference perplexity (Figure 6a). Finally, we fine-tune each of these checkpoints on the compositional generalization tasks. We repeat this process for successively deeper reference models. We find that even when fine-tuning from checkpoints of equal validation perplexity, deeper models still generalize better than shallower models (Figure 6b).

Next, to correct for the fact that deeper models perform better than shallower ones on the in-distribution split of the compositional generalization tasks, we compare the models' generalization accuracy at points during fine-tuning when they have equal in-distribution loss. Figure 7b shows that even after adjusting for in-distribution performance, deeper models still achieve higher accuracy on the out-of-distribution generalization set than shallower models do.

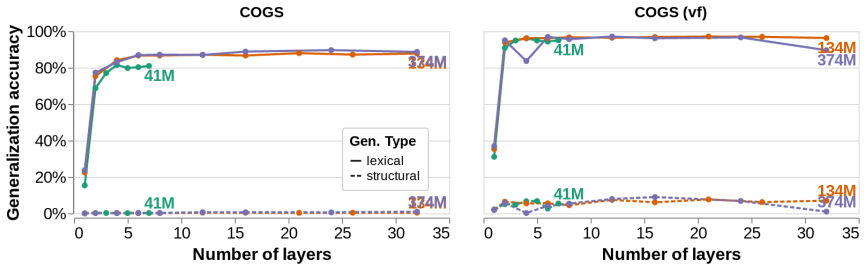
4 Training and Inference Latency

What are the practical implications of the fact that the benefit of depth saturates after a handful of layers? Empirically, the compute cost of training and running our equal-parameter models exhibits a strongly linear relationship with depth. Figure 8 shows (for our largest models) that the latency during training grows linearly with the depth of the model. The causes of this penalty are two-fold. First, our choice to use narrower feed-forward dimension for deeper models to maintain constant total parameter count leads to a slightly higher floating point operation (FLOP) count for deeper models. To see this, we start from the cost formula introduced in Kaplan et al. (2020):

$$C_{\text{forward}} = 2N + 2n_{\text{layers}}n_{\text{ctx}}d_{\text{attn}},$$

where N is total parameter count. Since both n_{ctx} and d_{attn} are constant for all models of a particular

[2]We only consider models deeper than the reference model since, in general, shallower models will never attain the perplexity of the reference model at the end of its pretraining. This assumption breaks down when considering the deepest models in each size class, but these are far deeper than the depth at which compositional generalization performance saturates, so we do not extensively explore this regime.



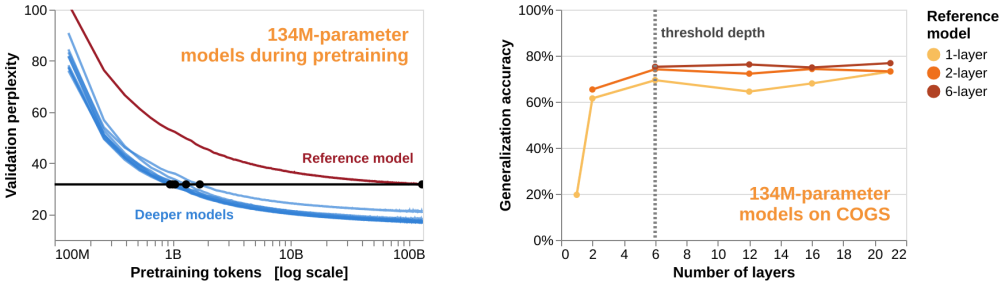


Figure 5: Increasing depth improves lexical generalization (solid lines) in both COGS and COGS-vf, but does not meaningfully improve structural generalization performance (dashed lines). Data shown is from a single run per condition.

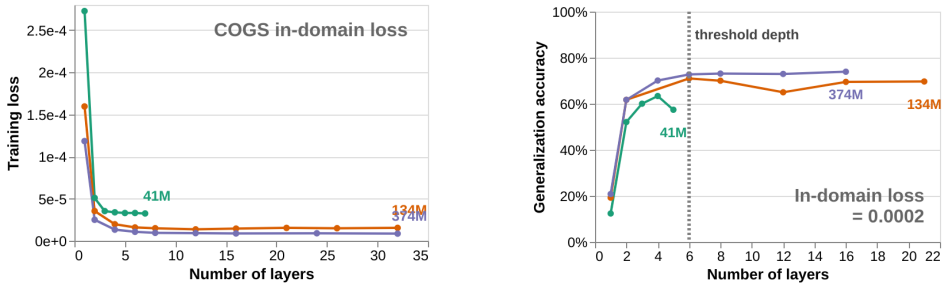
(a) (b)

Figure 6: **(a)** To correct for the potential effect of deeper models' lower pretraining loss on their generalization accuracy, we pick a reference model depth (red) and use checkpoints (black) from deeper models (blue) which have equal validation perplexity as the reference model does at the end of its pretraining. We then fine-tune these 'pretraining-corrected' checkpoints on the compositional tasks. **(b)** Even when fine-tuning checkpoints with equal validation perplexity, deeper models still generalize better than shallower models do up through six layers. The figure shows generalization accuracies from 134M-parameter models on COGS (single run per condition).

size (as d_{attn} and d_{ff} are decoupled from one another), the total FLOP count of a model is linear in depth, though this term is dominated by the $2N$ term unless model depth, attention size, or context length become very large.

The second and likely more important reason that deeper models are slower is because the computations at layer k depend on the results of the computations at layer $k-1$. Because of this sequential dependency, parallelism cannot be applied across layers (Tay et al., 2021).

Combined with the diminishing utility of depth for performance, the linear latency cost of depth as total size is kept constant leads us to the following practical recommendations:



1. When trying to minimize GPU-hours for fixed data volume, shallower models can train in far less time than deeper models while still attaining acceptable levels of performance relative to the best-performing model in a given size class.

2. With a fixed budget of GPU-hours for training, shallower models can train on more data than deeper models can over any fixed amount of time, since shallower models have lower latency, potentially resulting in better performance than deeper models trained on less data.

These benefits are not confined to training: deeper models also incur a per-layer cost during inference. This means that the penalty a deeper model pays must be amortized over the lifetime cost of using a model for inference. Here too, reducing the GPU-time spent on inference by using shallower models of comparable performance could reduce compute costs, both for cloud-served models and for on-device inference (Strubell et al., 2019; Pope et al., 2022; Gupta and Agrawal, 2022).

5 Analysis of Feed-Forward Transforms

At extreme feed-forward ratios, we observe that model performance degrades. We investigate the role that the feed-forward ratio plays in the observed performance of our models. When d_{ff} is smaller than d_{model}, this transform is lossy, but small values of d_{ff} could nevertheless impact performance even when d_{ff} is still larger than d_{model}.

(a) (b)

Figure 7: **(a)** Deeper models attain lower (better) in-domain loss values on compositional tasks. **(b)** Deeper models generalize better than shallower ones on COGS, even at points during fine-tuning when models have equal loss (0.0002) on the in-distribution portion of the dataset. Data shown is from a single run per condition.

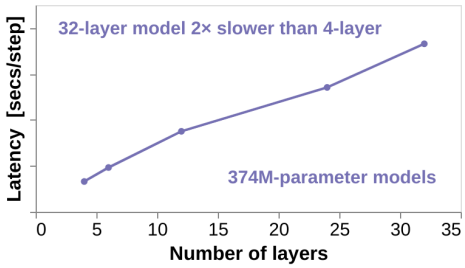


Figure 8: Deeper models train more slowly than shallower ones when controlling for total parameter count. We report relative latency [seconds per training step] for a subset of our 374M-parameter models that were trained on the same accelerator, showing a strongly-linear relationship between depth and latency. Similar relative trends are observed for other model sizes classes.

To determine if that is the case, we conduct rank analysis on the affine transforms which comprise the feed-forward block. For a given affine transform T, we compute the ordered singular values $\{\sigma_1, \sigma_2, \ldots, \sigma_k\}$ where $k = \min(d_{\text{model}}, d_{\text{ff}})$ is the rank of T and $\sigma_i \geq \sigma_{i+1}$. We then normalize each value by dividing by the ℓ_1 norm of $\{\sigma_1, \ldots, \sigma_k\}$ to calculate how much of T's image is accounted for by the best i-rank approximation of T for $i \leq k$. Figure 9 shows how in deeper models (i.e., those with increasingly large $d_{\text{model}}/d_{\text{ff}}$ ratios) the transforms become increasingly skewed away from making full-use of their available ranks.

6 Related Work

Compositionality. Previous work has explored the degree to which neural models exhibit compositional behavior by training or fine-tuning models on compositional tasks such as simple command sequences (Lake and Baroni, 2018) or semantic parsing (Kim and Linzen, 2020; Keysers et al., 2020). Other work has explored methods to improve the compositional behavior of models, including through data augmentation (Qiu et al., 2022a), larger models (Qiu et al., 2022b), and architectural changes (Gordon et al., 2019; Csordás et al., 2021; Ontanon et al., 2022). Our work complements these approaches by exploring a specific architecture change: increasing depth without changing total model size.

Impacts of depth. Theoretical work has shown that the expressive capacity of neural networks in general (Raghu et al., 2017) and transformer models in particular (Merrill et al., 2021) grows exponentially in depth. Empirical work also points to the role of depth in model performance. In a more general setting, Tay et al. (2021) found that scaling by depth is generally more helpful than scaling by width on downstream tasks, though they do not attempt to control for size. For compositional generalization in particular, Mueller et al. (2022) found that reducing depth was more harmful than reducing width for pretrained encoder-decoder models. Murty et al. (2023) observed that deeper transformer encoders often have more tree-like representations and higher parsing accuracies on some compositional tasks. Tempering these positive results, Veit et al. (2016) noted that in models with residual connections, even very deep networks leveraged only shallow subnetworks of roughly constant depth. Brown et al. (2022) also concluded that wide, shallow transformer models can attain roughly-equal performance to deeper ones. Both sets of results, however, are confounded by a lack of control for total parameter count. Very recently, Gromov et al. (2024) found that nearly half of the layers of deep language models can be pruned after training without substantially harming performance

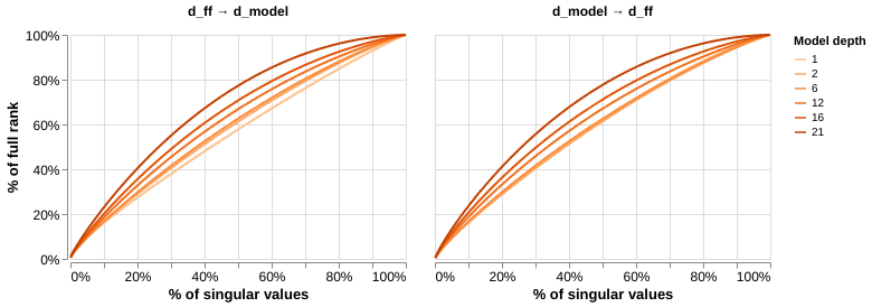

Figure 9: As models get deeper and $d_{\text{model}}/d_{\text{ff}}$ ratio gets larger (values between 0.01 for the shallowest model shown and 1 for the deepest), the input **(left)** and output **(right)** projections in the feed-forward block become increasingly close to rank-deficient transforms. A graph of $y = x$ here would indicate that models spread their rank equally across all singular values. Data from 134M-parameter models.

on downstream tasks.

Early-exit schemes. Early-exit research (Zhou et al. 2020; Schuster et al. 2022, *inter alia*) shows that deep models can dynamically be made shallower by skipping later layers of computation once a heuristic deems a computed representation "good enough." We view our work as complementing this approach; while early-exit reduces the computational cost of a model's inference on an input-dependent basis, our work shows that the cost can be reduced for all inputs during both training and inference. However, since we do not explore early-exit training or inference with our equal-parameter models here, it is possible that even our shallower models could benefit from early-exit schemes that would further reduce computational costs.

Controlling for model size. There are different possible approaches to studying the impact of hyperparameter choices without affecting the net model size. Kaplan et al. (2020) covaried number of layers n_{layers} with the contextual embedding dimension d_{model}, which they coupled to the attention-internal d_{attn} and feed-forward dimension at the standard ratio of $d_{\text{model}} = d_{\text{attn}} = d_{\text{ff}}/4$. They concluded that performance increases are largely driven by increasing the total parameter count of models, and that within "reasonable limits" language modeling perplexity is only weakly dependent on shape (though Tay et al. 2021 concluded that the same was not true for performance on downstream tasks, but did so without controlling for the impact of size). Our work investigates the role that depth plays on both pretraining and fine-tuning tasks while controlling for total parameter count.

7 Conclusion

Compositional generalization is essential for interpreting novel sentences. What aspects of the transformer LM architecture contribute to an inductive bias favoring compositional generalization? In a controlled experiment that teases apart depth from total number of parameters, we find that deeper transformers show better compositional generalization, and better language modeling performance, independent of their total number of parameters. At the same time, in most cases the usefulness of adding layers decreases rapidly as models get deeper: comparatively shallow models can achieve generalization accuracy on compositional tasks that is comparable to that of much deeper models, and language modeling perplexity within a few percentage points of the best-in-class model. Because deeper transformers have higher latency, this indicates that for a given parameter budget, shallower models can be significantly faster with a minimal sacrifice in performance.

8 Limitations

Attention heads. We do not investigate the role that attention heads play in compositional generalization broadly, nor how the function of heads changes with depth. Previous work (Michel et al. 2019, *inter alia*) showed that reducing the number of attention heads in a transformer (pre- or post-training) does not significantly harm performance. Mechanistic interpretability work has found that specific attention heads in transformers learn to compute task-specific functions (Voita et al., 2019; Htut et al., 2019; Olsson et al., 2022). Our findings here raise two questions which should be further investigated: first, does the relative unimportance of the *number* of attention heads still hold in regimes

when a model is significantly shallower and wider than convention; and second, do any of the attention heads in our models learn to perform specifically compositional computations, and does this vary as models get deeper or shallower?

Alternative approaches to controlling for total size. Our approach to controlling for total parameter count necessitates making depth-width tradeoffs. An alternative approach would be to construct Universal Transformers (Dehghani et al., 2018), where each model in a size class has a transformer layer with the same parameters repeated n_{layers} times. Such a weight-sharing approach would allow for deeper models to have arbitrarily-wide feed-forward networks, mitigating the impact of making models too narrow. While such weight sharing prevents models from performing different computation in different layers, such restriction may in fact be beneficial for compositional generalization where similar computations (e.g., combining two syntactic phrases to a larger phrase) may need to apply recursively at different scales.

Pretraining corpus effects. We consider models pretrained on natural-language data. For our particular choice of compositional generalization experiments, the presence of lexical items in both the pretraining corpus and the generalization datasets represents a potential confounder of generalization performance which could be mitigated by modifying compositional datasets (Kim et al., 2022). More generally, we do not study how the distribution of pretraining data affects the inductive biases conferred to LMs (Papadimitriou and Jurafsky, 2023). As a particular area of interest for future work, we point out the hypothesis that including source code in the pretraining corpus (OpenAI, 2023; Google et al., 2023) will improve compositional generalization.

Fine-tuning vs. in-context learning. We use fine-tuning to adapt our pretrained models to the compositional tasks. Due to its computational cost and task-specificity, fine-tuning is less useful in practice than in-context learning as model size grows (Brown et al., 2020). Because in-context learning only becomes reliable at scales far larger than we are able to train, we did not explore the effect of depth on compositional generalization accuracy in in-context learning (Si et al., 2022); we point this out as an avenue for future research.

9 Ethics Statement

Throughout our experimental process, we sought to comply with best practices to mitigate any risks associated with LLM research. We use open-source datasets which are inspectable by third-parties for issues such as bias, and toxicity. We do not release any public checkpoints for the models we train, so there is no risk to misuse of any created artifacts, though we note that we derive our implemented models from existing publicly-available T5 models. We train models on English-only natural-language data, and fuller exploration should be done to explore how language impacts the results found here.

A Design and Result Tables

Table 2 reports exact hyperparameters for the model classes trained. Table 3 displays pretraining and compositional generalization accuracy on all model sizes and tasks.

B Annotated Transformer Layer

Figure 10 shows the schematic for a single transformer layer. The layers input enters on the left and passes through the various model components (grey boxes), being combined with the residual connections before exiting right to subsequent layers. Blue boxes show the dimensionality of the vectors after transformation; we are primarily concerned with the size of the embedding vectors d_{model} and the internal dimension of the feed-forward block d_{ff}. The size of the vectors internal to the attention mechanism, d_{attn}, is not shown here but is usually set to be equal with d_{model}; we follow this convention here. Non-learned operations like addition, layer normalization, and the feed-forward network's nonlinearity are shown in grey circles.

Abstract

Questions posed by information-seeking users often contain implicit false or potentially harmful assumptions. In a high-risk domain such as maternal and infant health, a question-answering system must recognize these pragmatic constraints and go beyond simply answering user questions, examining them in context to respond helpfully. To achieve this, we study assumptions and implications, or *pragmatic inferences*, made when mothers ask questions about pregnancy and infant care by collecting a dataset of 2,727 inferences from 500 questions across three diverse sources. We study how health experts naturally address these inferences when writing answers, and illustrate that informing existing QA pipelines with pragmatic inferences produces responses that are more complete, mitigating the propagation of harmful beliefs.

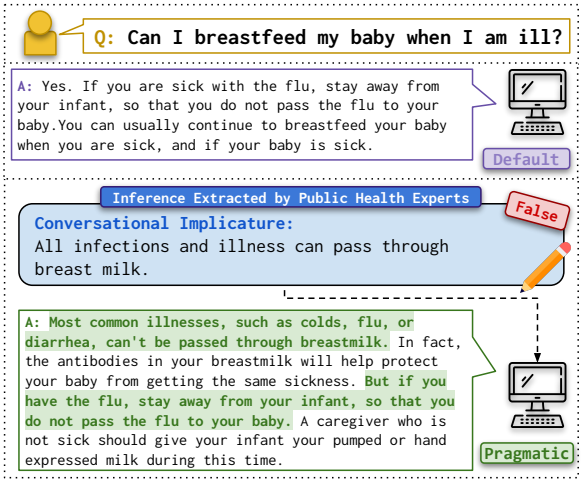

Figure 1: We ask public health experts to identify assumptions and implications from questions and find that incorporating them in a QA pipeline produces a more complete answer.

1 Introduction

Humans have varying information needs when they ask questions (Taylor, 1962). Sometimes these needs are easily inferred from the surface form, such as in factoid questions (e.g. *"Who is the 44th president of the United States"*). However, in a question such as "*Is there a good non-dairy baby milk I can supplement for my newborn?*", addressing the underlying false assumption "*Newborns can safely drink non-dairy milk*" **becomes part of satisfying the unexpressed information need**. Complete answers to these types of questions must not only address the surface question itself, but also "question the question", critically examining its *pragmatic needs*.

These needs become magnified in sensitive domains, such as consumer health or the legal domain. In these settings, addressing pragmatic needs of questions involves proactively addressing false assumptions or implications in questions to ensure that the asker does not continue holding inaccurate beliefs that they may act on. For example, a complete answer to the question about non-dairy milk for newborns should address that while non-dairy milk is viable for older babies, newborns and infants need human breast milk or dairy-based formula because they offer complete nutrition.

Language models have been shown to exhibit sycophancy (Sharma et al., 2023), sometimes adjusting responses to align with a human user's view. However, helpful QA systems should not only *challenge* false or subjective assumptions in questions (Kim et al., 2022) by verifying them against a vetted corpus, but also infer the asker's intent to make sure that its answer satisfactorily addresses their deeper information needs (Taylor, 1962), just as humans do.[1]

We construct a dataset[2] of 2,727 assumptions

[*] Equal contribution.

[1] "Pregnant" in our title also refers to its secondary definition, "full of meaning" (as in "a pregnant pause") alluding to the idea that questions are laden with implicit beliefs.

	Question	Expert-Annotated Pragmatic Inference & Veracity
ROSIE (Maternal Health QA System)	`Is it okay for my to color my hair after giving birth?`	Hair dye chemicals can pass through breast milk from mother to child. (`False/Unsure`)
	`What is the advantage for not having an epidural during the labor?`	Avoiding an epidural contributes to a more "natural" and unmedicated birthing experience. (`False/Unsure`)
	`What cough medicine is appropriate for breastfeeding mothers?`	Some cough medicines can be secreted in breast milk. (`True`)
Reddit	`Is it safe to lay on my stomach at 28 weeks of pregnancy?`	Sleeping on the stomach while pregnant may have potential risks (`False/Unsure`)
	`Is it bad to use different bottles/nipples during feedings?`	Using different bottles or nipples for feeding may compromise the baby's latch. (`False/Unsure`)
	`How can I increase the time between feedings for my 3-month-old baby?`	It may be possible to sleep through the night while still ensuring the baby is fed. (`True`)
Natural Questions	`When does the fetus begin to develop memory?`	Fetuses have the ability to form memories. (`True`)
	`What causes a rupture in the amniotic sac?`	There may be ways to prevent early amniotic sac rupture. (`False/Unsure`)
	`When do the clinical manifestations of an ectopic pregnancy appear?`	There may be clinical manifestations of an ectopic pregnancy that do not appear early on. (`True`)

Table 1: Health experts identify pragmatic inferences from questions from three sources: Reddit, Natural Questions (Kwiatkowski et al., 2019), and questions asked to our domain-specific QA system, ROSIE (Mane et al., 2023). They also determine the veracity of each inference and provide supporting evidence from a trusted web document.

and implications in 500 questions (§2) collected from three diverse sources to study (1) how humans embed such assumptions and implications in questions, and (2) the extent to which they are *naturally* addressed in answers written by public health experts. We then ground assumptions and implications, two primary ways humans embed beliefs in questions, in existing linguistic theory of presuppositions and implicatures respectively (§3). We refer to presupposition and implicature collectively as *pragmatic inference*. While recent work has focused on the task of detecting and addressing false *presuppositions* in open-domain QA (Yu et al., 2022), we find that false beliefs of question askers are more likely to present as implicatures than presuppositions (§4). We experiment with *inducing* pragmatic behavior in existing QA pipelines with state-of-the-art retrieval and machine reading models (§5). On questions with at least one highly plausible false pragmatic inference, our expert annotators rated responses from our pragmatic QA system as more helpful and informative.

Thus, QA systems of the future must proactively address assumptions and implications in questions as they are increasingly deployed in sensitive domains.

2 Collecting Assumptions and Implications in the Wild

In contrast with factoid QA, systems deployed in *sensitive* domains such as consumer health must proactively mitigate harm. In these settings, correcting false assumptions is *not optional*: systems must provide contextual answers that balance *information completeness* with brevity.

	Maternal Health QA	Reddit	Natural Questions
# questions	200	200	100
ans. length (# sent)	3.9	6.6	5.6
# inferences	1161	1114	452
% false/subjective	22.5	30.8	20.1
% true	77.5	69.2	79.9

Table 2: Dataset statistics stratified by question source.

Access to high quality healthcare in the United States vastly differs across socioeconomic backgrounds (Becker and Newsom, 2003). Such users are often likely to turn to accessible internet resources and—as of late—general purpose chatbots (Palanica et al., 2019). This motivates us to focus on maternal and infant care, a challenging area of consumer health where patients are concerned with *both* their own physical health as well as the health of their child.

To effectively study and induce pragmatic behavior in QA systems, the evaluation questions we choose must reflect real-world experiences and situations for which there may not be a straightforward answer explicitly addressed in a single web document. For example, answers to Natural Questions (Kwiatkowski et al., 2019, NQ)—a popular open-domain question-answering dataset—can be

found directly in short extracted text snippets from Wikipedia (Table 1). In contrast, effectively answering the subjective questions sourced from Reddit requires commonsense reasoning and domain knowledge while identifying the asker's intent.

We carefully construct a dataset of questions from three distributionally distinct sources: a domain-specific QA system we design and deploy to pregnant and postpartum participants we recruit (Mane et al., 2023), Reddit, and NQ. Then, we introduce an annotation scheme to elicit assumptions and implications from these questions, validate their plausibility, and finally collect supporting evidence to determine their veracity. Our final dataset contains 2,727 assumptions from 500 evaluation questions (Table 2). We also include 150 development questions used to train annotators and develop our QA systems.

2.1 Gathering a Diverse Set of Maternal and Infant Health Questions

Maternal Health QA System. We source questions come from a maternal and infant health-specific question answering system that we build (Mane et al., 2023), henceforth referred to as ROSIE. Users ask questions pertaining to pregnancy or infant health and are instructed that the QA system does not have any personalized knowledge of their individual medical history or pregnancy.

This system operates over a corpus of web documents we construct[3] from trusted sources including United States governmental and hospital organizations on maternal and infant health, and spans salient topics such as pregnancy and postpartum symptoms, developmental milestones, and infant safety. Our end-to-end QA system, ROSIE, uses a passage retriever and reranker to provide web passages as answers to study participants via a mobile application. We randomly sample 200 anonymized questions asked to ROSIE for our evaluation set and 50 questions for our development set.

Reddit. While the questions asked to ROSIE do reflect real-world experiences, they are asked *to an automatic system* and thus tend to include less situational detail or implicit content. We turn to Reddit[4] to capture long-tail questions that are about the diverse set of unique situations a new or expecting parent goes through. Table 1 highlights some distributional differences between questions from Reddit and other data sources. Our questions come from four popular subreddits about maternal and infant health: `r/BabyBumps`, `r/breastfeeding`, `r/NewParents`, `r/Mommit`, and `r/beyondthebump` from the `pushshift`[5] dump.

We develop a series of heuristics as a recall-oriented first step to identify questions with false or subjective assumptions. We begin by selecting questions where an upvoted comment shows assumption-correcting behavior or where a user invokes their medical expertise, identified by a select list of discourse markers (Appendix A). Of these, we only retain posts beginning with a "wh" word, filtering a few hundred thousand posts down to 2,858 questions.

As Reddit encourages community participation, many questions are "community seeking" as opposed to *information*-seeking. To identify information-seeking questions, we use GPT-3.5 (Ouyang et al., 2022) to filter medical questions from non-medical questions (Prompt A.1) then manually vet the final set of 297 questions. We randomly sample 200 questions for our evaluation dataset and 50 questions for our development set, discarding the rest.

Titles of Reddit posts are often a hook or a summary of the entire post. Using the 50 development questions, we use GPT-3.5 to minimally edit the titular question to include crucial details from the post description, providing a series of exemplars (Prompt A.2). These rewrites mainly include the age of a newborn or the stage of pregnancy from the description, but sometimes include small situational details that contextualize the question. Two authors validate all rewrites, keeping the original title wherever both authors agree that the rewrite changed the communicative goal of the asker.

Natural Questions. Lastly, we include maternal and infant health questions from NQ to study pragmatic aspects of factoid-style questions. We embed all questions in the train set of NQ using the `sentence-transformers` (Reimers and Gurevych, 2019) implementation of `all-mpnet-base-v2` (Song et al., 2020), including unanswerable questions (Asai and Choi, 2021). We identify 2500 answerable questions and 2500 unanswerable questions as maternal health-related by identifying the top 100 nearest

[3] Corpus available upon request. We use Barbaresi (2021) to scrape 408,000 web documents which we split into passages of 100 tokens following Karpukhin et al. (2020).

[4] https://www.reddit.com/

[5] https://github.com/Watchful1/PushshiftDumps

neighbors of 50 randomly sampled questions from the development sets of Reddit and ROSIE.[6] From this set, we randomly sample 100[7] questions for our evaluation set and 50 for our development set. Though obtained with a nearest neighbors approach, these questions greatly differ from those obtained from our previous sources, as they reflect the factoid QA-oriented tasks and goals of the original dataset creators (Table 2).

Collecting Human Answers from Health Experts. We recruit a team of twenty health experts using Upwork[8] to annotate our data including obstetricians and gynecologists (OB/GYNs), nurses, lactation consultants, and public health experts, many of whom have experience with patients. In addition, many of these expert annotators are either currently pregnant or postpartum or have been in the past. We ask a subset of six experts to write helpful and informative long-form answers to all 500 questions in our dataset (Figure 6, bottom panel). While annotators write answers from scratch, they must provide supporting web documents from the same list of verified sources we use to build the corpus for ROSIE.

2.2 Identifying Assumptions and Implications

Inferring *possible* assumptions, implications, and asker beliefs from patient questions in our domain are challenging. In the past, others have extracted assumptions using shallow signals from the surface form of a question (Kim et al., 2021; Parrish et al., 2021). While some assumptions or implications in our dataset can be inferred directly from the question expression, others require deeper domain or experiential knowledge (Table 1).

Eliciting these assumptions and implications from non-linguists is challenging as existing linguistic frameworks (§3.1) are inaccessible or cumbersome for those unfamiliar with the theoretical concepts behind them. As such, we operationalize large-scale data collection by asking five annotators from a *different* subset of our expert annotator pool to first write a list of subquestions that an answer to the original question would address (Figure 6, top panel). Doing so primes annotators to reason about the intent behind a question as well as the information needs of an asker. Then, we ask them to write a set of sentences reflecting possible beliefs or assumptions that the patient may hold (or, alternatively, beliefs that any complete answer to the question must address). We emphasize that the assumptions they write can be either medically or scientifically true or false.

Then, we *consolidate* the set of subquestions and human-written assumptions and beliefs into a single set of assumptions and implications using GPT-3.5 (Prompt B.1).

2.3 Annotating Inference Veracity

Lastly, we ask a new subset of eight expert annotators to annotate whether each assumption and implication in our dataset is medically or scientifically true, false, or subjective and provide a supporting web document from our list of verified sources along with a passage from the document (Figure 6, middle panel).

Validation. To verify that the assumptions and implications we extract are plausibly inferrable from the question, we recruit an additional pair of health experts, which we refer to as expert *validators*, to rate inferences.[9] We sample 100 assumptions and implications judged as false or subjective, and 100 true inferences and ask our expert validators to rate the plausibility of an inference on a 1–5 Likert scale based on how likely the question asker is to believe the assumption or implication. Henceforth, we refer to this sample of 200 inferences coming from 152 unique questions as INFERENCE-SAMPLE. Both annotators judge the majority of our inferences as plausible, with 80% and 95% rated with a score of at least 3 (see Figure 4 for the rating scale). Spearman's correlation between the two annotators is 0.69. See Appendix C for more detail.

3 Grounding Assumptions and Implications in Linguistic Theory

Assumptions and implications in our dataset map to two well-studied phenomena in linguistic pragmatics: presupposition and implicature (Grice, 1975; Stalnaker et al., 1977). We begin with a short primer of both types of *pragmatic inference* (§ 3.1) and then discuss the implications of both types in a QA setting (§ 3.2).

[6] We tried several different filtering heuristics, including keyword-based detection, but the nearest neighbors approach yielded the most topical questions.

[7] NQ questions make up a smaller proportion of our evaluation dataset as we avoid diverting large amounts of annotation resources to factoid-style questions.

[8] https://www.upwork.com/

[9] These expert validators were not a part of our dataset construction.

3.1 Two Types of Pragmatic Inference: Presupposition and Implicature

A sentence S is a *pragmatic inference* of a question Q if, depending on the *context* and *conversational goals* of discourse participants (Jeretic et al., 2020), a human would believe that the asker of Q believes or assumes S to be true. Henceforth, we refer to the assumptions and implications that we collect in our dataset as *pragmatic inferences*. We review the two most relevant types of pragmatic inferences: *presupposition* and *implicature*.

Presupposition. Presuppositions are implicit assumptions in utterances taken for granted by discourse participants (Beaver, 1997). The question *"What vitamins should I stop taking after becoming pregnant?"* presupposes *"I was taking vitamins before becoming pregnant."* Presuppositions can often be detected solely by the presence of a lexical or syntactic trigger (Levinson et al., 1983). In the example above, the word *stop* presupposes that an activity was already in motion. We refer to these presuppositions as "trigger-based".

As we observe during the collection of our dataset, domain or world knowledge is often needed to capture presuppositions in real-world data that are not apparent from lexical or syntactic cues (Abusch, 2002). For example, the question *"Are multiple ultrasounds dangerous for my baby?"* does not directly result in non-trivial trigger-based presuppositions. However, the asker of the question presupposes that the effects of an ultrasound are additive and hence asks about whether that additive effective is *dangerous*.

Implicature. Implicature is a type of pragmatic inference that is *suggested* by an utterance as opposed to part of its literal meaning (Grice, 1975). Consider the question *"Do most babies fit in newborn clothes?"* While the speaker understands that newborn clothes fit *some* babies, their question implies that not all babies fit in newborn clothes. As we discover, a significant portion of inferences in our dataset are *implied* from questions rather than presupposed, but detecting and generating implicatures remain understudied in NLP.

Some implicatures are related to lexical items or syntactic structure of utterances. For example, the statement *"These prenatal vitamins are in gumdrop form, but are healthy"* implies that gumdrops are usually *not* healthy. Others are a function of a speaker's intent, beliefs, and other contextual elements (Zheng et al., 2021). While they are a part of the content of an utterance, these implicatures are not *at-issue* (e.g. the main point under discussion (Potts, 2004; Koev, 2018)) and are not encoded by the linguistic properties of a sentence (Allott, 2018). Consider the question *"How can you tell the difference between postpartum depression and exhaustion?"*. Reasoning about asker belief, we may conclude that they are implying that the two conditions should be treated differently, as one is more serious than the other.

3.2 Presupposition and Implicature in QA

In a natural setting, as we discover, humans embed both presuppositions and implicatures nearly equally in questions (§4). However, from a linguistic perspective, they represent different levels of an asker's commitment to the propositional content of the inference (Peters, 2016). Presuppositions are already a part of an asker's world model. In contrast, implicatures are *likely* beliefs that may be negated in an asker's subsequent utterances. Consider the question *"Is it normal for my baby to move more than usual when closer to due date?"* with both the presupposition *"There are factors that contribute to changes in fetal movement as the due date approaches"* and the implicature *"It may not be necessary to be concerned if there is a significant increase in fetal movement close to the due date."* While both are false, the presupposition is stronger, and is clearly in need of addressing in a potential answer. As illustrated, these distinct phenomena must be dealt with differently when answering a question.

Related Work. Existing work in pragmatics in QA focuses on open-domain question answering. Kim et al. (2021) present the first study of presuppositions in Google search queries using the Natural Questions (NQ) dataset (Kwiatkowski et al., 2019) that are unanswerable due to false presuppositions. However, their system only addresses trigger-based presuppositions, overlooking the type of deeper presuppositions present in our dataset derived from world or domain knowledge. Other work has looked at Google queries with *questionable* assumptions (Kim et al., 2022) and false presuppositions in open-domain Reddit questions (Yu et al., 2022). Computational studies of implicature have only focused on specific types, such as scalar implicature (e.g., some $X \rightarrow$ not all X) (Schuster et al., 2020; Zheng et al., 2021; Kabbara and Che-

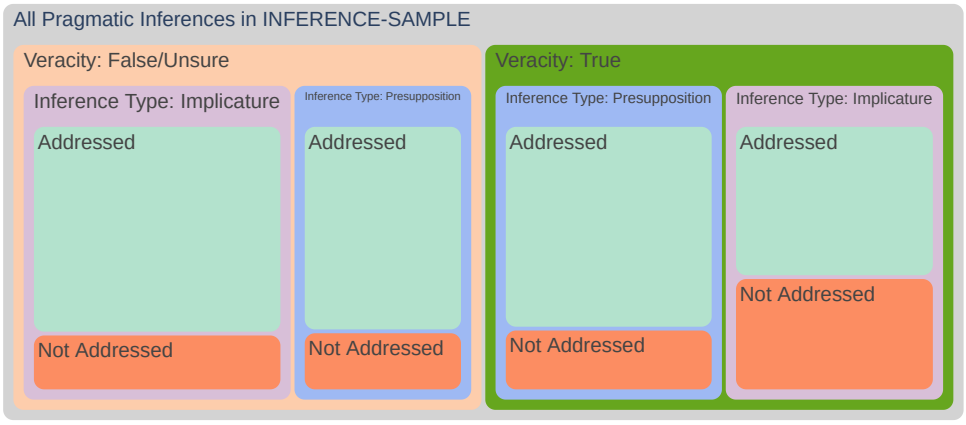

Figure 2: Tree-map (Shneiderman, 1992) visualizing the distribution of expert-annotated pragmatic inferences in INFERENCE-SAMPLE with their veracity, inference type, and whether or not they were addressed or not in the expert-written answer to the question from which they came from. When users make false or subjective inferences, they are more likely to do so as an implicature. Moreover, when an inference is false, it is more likely to be naturally addressed in an answer by public health experts.

ung, 2022; Jeretic et al., 2020). As a result of the context induced by our domain, implicatures in our dataset extend beyond scalar implicature.

4 How do people ask and answer questions?

Before we investigate the behavior of QA systems, we first study how humans embed pragmatic inferences in their questions (§4.1) as well as to what extent they are *naturally* addressed by human public health experts (§4.2).

4.1 Pragmatic Inference Type: Understanding Speaker Commitment

When users ask questions, how strongly are they committed to the inferences that experts identify in their questions? Presupposition is a phenomenon based on *mutual* acknowledgment of facts: when a human makes a presupposition, not only are they presuming the content of the inference, they are also signaling the belief that their *interlocutor* (here, a QA system) should believe it too.

On the other hand, implicatures are a softer way for humans to express uncertainty. For example, *"Which immunity injections can I skip for my baby?"* and *"Is it sufficient if my baby takes most immunity injections"* have the same underlying inference (*"It is okay to pick and choose vaccines"*), but is taken for granted in the first (presupposition), whereas loosely suggested in the second (implicature). We want to distinguish inferences—separating implicatures from presuppositions—in our questions to better characterize *so that we can prioritize addressing stronger false inferences.*

Annotation Framework. A pair of authors independently annotate all inferences in INFERENCE-SAMPLE as a presupposition or implicature by first determining whether it is a proposition about the world that the asker believes to be true, without which the question would not be felicitous (presupposition) or whether it involves deriving asker belief through communicative principles (implicature). Between authors, Cohen's kappa is $\kappa = 0.85$, indicating strong agreement. Author annotators adjudicated the final inference type (see Figure 2 for overall distribution), but individual annotator labels and adjudication rationales are preserved as a part of our dataset.

Findings. Presuppositions and implicatures are balanced in INFERENCE-SAMPLE (Figure 2), with a slight majority of inferences as implicatures, indicating that many inferences that health expert annotators identify are more subtle. When an inference is true, it is almost equally likely to be a presupposition or an implicature. However, when users make false or subjective (veracity marked "Unsure") inferences, **they are more likely to do so via implicature** (Figure 2). Past work has looked into generating and verifying *presuppositions* in open-domain QA, but identifying and addressing *implicatures* in an effort to make answers information-complete remains heavily underexplored. This finding highlights a key strength of our work: the ensuing context from our specific domain tests the usefulness of pragmatic inference in QA by allowing us to

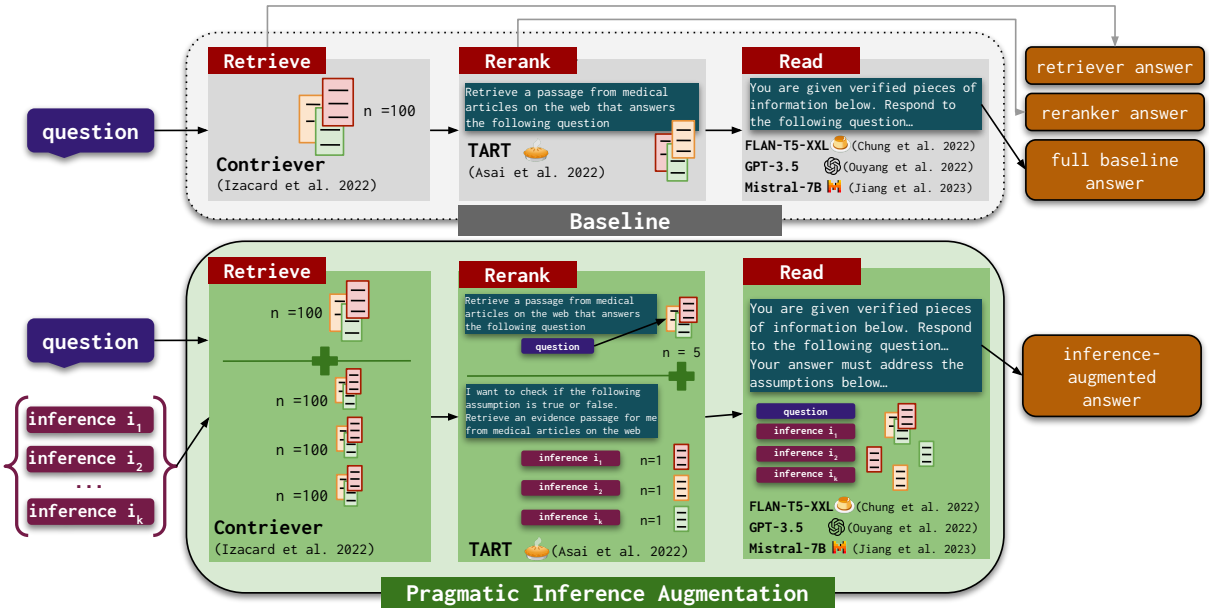

Figure 3: Our baseline and pragmatic inference-augmented QA pipelines. We experiment with retrieval, reranking, and reading stages and a variety of instruction-tuned and prompt-based models.

extract a greater range of inferences.

In settings that lack such context (e.g. single-turn open-domain QA), we are restricted to leveraging lexical or syntactic signals from the surface form of the question (Kim et al., 2021) since reasoning about asker belief is not possible without other contextual signals. For example, in the absence of additional context, the question *"Should I push grandparents for flu shot and tdap?"* may give rise to inferences involving the safety or effectiveness of these vaccines for the elderly. However, upon learning that this was asked in a web forum by a postpartum mother, we may reason that she believes her infant may be at risk for contracting the flu or other diseases if their grandparents handle them unvaccinated.

4.2 Addressing Inferences in Expert Answers

When health experts are tasked with *answering* questions, how likely are they to naturally address inferences that users implicitly make? Studying whether or not answers *naturally* address pragmatic inferences (§ 4.2) gives us better insight into the types of inference health experts, and in turn models, should prioritize when answering questions.

Annotation. We ask two annotators from our expert annotator pool to determine whether each inference in INFERENCE-SAMPLE is addressed, either implicitly or explicitly, by the human-written answer to its source question.

Findings. The majority of inferences in INFERENCE-SAMPLE are addressed by the human-written answer *naturally* (Figure 2). Importantly, **when an inference is false, it is more likely to be naturally addressed.** Moreover, a significant number of *true* inferences are also addressed by an answer, indicating that health experts not only aim to correct false or subject inferences but also prioritize completeness. This key finding supports one of the main arguments of this work: QA systems *must* address pragmatic inferences in their answers, just as humans do.

5 Inducing Pragmatic Behavior in QA

Inducing pragmatic behavior in QA systems is not straightforward. Existing systems are not trained to proactively reason about asker beliefs, since many popular QA datasets do not necessitate this type of behavior (e.g. factoid QA).

We experiment with eliciting model answers that address the pragmatic needs of questions, such as refuting false inferences, using the pragmatic inferences in our dataset. We inject inferences at each stage of the classic QA pipeline: passage retrieval, reranking, and machine reading (§5.1) and evaluate outputs against expert-written answers with both automatic and human evaluation (§5.2).

5.1 Experimental Setup

Corpus. We use the corpus from Mane et al. (2023) of 408,000 documents from verified web

sources on maternal health and infant care and augment the corpus with the sources that our expert annotators found while both writing answers and determining the veracity of inferences.

Baseline Models. As a baseline system, we use a retrieval, reranking, and reading-based QA pipeline. Contriever (TIzacard et al., 2022), an unsupervised dense passage retriever, identifies top relevant documents ($n = 100$) in our corpus given a question. Those documents are reranked using TART-full (Asai et al., 2022), a multi-task retrieval system with a cross-encoder architecture (Instruction E.1). TART is instruction-tuned, equipping it with the flexibility to redefine passage relevance for different tasks. We feed the top five reranked documents to three different reader models: FLAN-T5-XXL (Chung et al., 2022, 11 billion parameters), an instruction-tuned, *prompt*-based encoder-decoder model jointly trained on a multiple tasks with a standard answer extraction prompt from Mishra et al. (2022) (Instruction E.3), MISTRAL-7B (Jiang et al., 2023) (an open source large language model, Prompt E.4), and GPT-3.5 (Prompt E.4).

Augmenting Systems with Pragmatic Inferences. In addition to retrieving the top 100 passages using the question as input, we retrieve the top 100 passages for each pragmatic inference of the question ($i_1 ... i_k$) as well. Then, for each pragmatic inference i, we rerank the top 100 passages using a new inference-informed instruction (Instruction E.2) and select the top passage post-reranking. We augment the top five reranked passages from the question with these k top passages from each pragmatic inference to feed to each reader (Prompt E.5). During reading, we prompt MISTRAL-7B and GPT-3.5 to address all k assumptions when generating an answer.[10] To keep the same *number* of passages fed to readers in the baseline pipelines as in the inference-augmented pipeline, we add k extra passages to the top five existing ones. This ensures that while the volume of information presented to machine readers is the same in both pipelines, the nature of the content differs, allowing us to measure the utility of inference augmentation during retrieval and reranking. Figure 3 visualizes our baseline and inference-augmented QA pipelines.

[10]We do not use FLAN-T5-XXL here because it struggled with reading in the baseline setting.

5.2 Evaluation

We evaluate answers from seven pipeline variations against expert answers (Table 3): (1) The **No Reader** baselines consist of the top retrieved passage based on the input question (RETRIEVE-ONLY) and the top reranked passage from the input question (RERANK-ONLY), (2) three **Baseline Readers** (BASELINE-FLAN-T5-XXL, BASELINE-MISTRAL-7B, and BASELINE-GPT-3.5), and (3) two **Inference-Augmented** pipelines INFERENCE-MISTRAL-7B, and INFERENCE-GPT-3.5).

Automatic Evaluation Metrics. Three automatic evaluation metrics measure the quality of generated answers: ROUGE (Lin, 2004) (both F1 and recall),BLEURT (Sellam et al., 2020), and QAFACTEVAL (Fabbri et al., 2022), a more recent QA evaluation metric originally designed to measure the faithfulness of summaries. GPT-3.5 scores the strongest according to QAFACTEVAL, our main evaluation metric because it—of the three metrics—most closely captures information content. However, automatic evaluation of generated answers does *not* capture several higher-level semantic and pragmatic aspects of the question. Thus, we still need experts to validate the answers.

Human Judgments. We ask our expert *validators* to score answers from the top-performing baseline and inference-augmented pipeline (BASELINE-GPT-3.5 and INFERENCE-GPT-3.5, on QAFACTEVAL respectively). For each of the 152 questions in INFERENCE-SAMPLE, expert validators score both model outputs simultaneously from 1–5 based on completeness (instructions in Figure 5). Answers typically received a score of 1 when they were off-topic and missing crucial information, a score of 2 when they were topical but still missing crucial information, 3 when containing all essential information to the question, 4 when most information was present for completeness, and a score of 5 when the answer was information complete. Judging the information completeness of an answer is a subjective task, as reflected by the Spearman rank correlation between their annotations ($\rho = 0.34$). While the mean score of inference-augmented examples is comparable to baseline answers (4.43 vs. 4.45), annotators rated the inference-augmented answer as equivalent or better than its baseline counterpart in 75% of questions in INFERENCE-SAMPLE (see Table 5 for examples).

We further focus on annotator preferences on our

	No Reader		Baseline Reader			Inference-Augmented	
	RETRIEVE	RERANK	FLAN-T5-XXL	MISTRAL-7B	GPT-3.5	MISTRAL-7B	GPT-3.5
ROUGE-L (F1)	$15.6_{(10.3)}$	$17.5_{(10.3)}$	$15.89_{(13.7)}$	$17.4_{(5.1)}$	$18.7_{(6.0)}$	$16.2_{(4.8)}$	$18.6_{(5.9)}$
ROUGE-L (Recall)	$23.0_{(15.7)}$	$19.5_{(10.9)}$	$36.9_{(21.9)}$	$15.2_{(6.8)}$	$17.4_{(8.1)}$	$13.2_{(5.7)}$	$16.6_{(7.6)}$
BLEURT	$-0.72_{(0.34)}$	$-0.61_{(0.29)}$	$-0.79_{(0.45)}$	$-0.38_{(0.22)}$	$-0.37_{(0.22)}$	$-0.36_{(0.21)}$	$-0.38_{(0.22)}$
QAFACTEVAL	$0.69_{(1.05)}$	$0.76_{(0.80)}$	$1.16_{(1.5)}$	$1.02_{(0.65)}$	$1.15_{(0.73)}$	$0.96_{(0.62)}$	$1.17_{(0.75)}$
Human (/5)	-	-	-	-	4.43	-	4.45

Table 3: Mean and standard deviations of automatic (ROUGE, BLEURT, QAFACTEVAL) and human evaluation metrics per question. We report results for the top retrieved passage and the top reranked passage, and two modes with and without access to human-written assumptions. Inference-augmented models perform competitively with baselines, indicating the promise of inducing pragmatic behavior in QA models to mitigate harm.

original motivating population of questions—those with highly plausible, false assumptions. Both annotators rate inference-augmented answers higher than the default answers in the subset of questions with at least one *highly plausible*, (plausibility=5) *false* pragmatic inference (Table 4). We hypothesize that the similar ratings received by the two systems across *all* questions is due to shortcomings in the instruction-following capabilities of LLMs. Forcing the reader model to address pragmatic inferences distracts it from answering the question more completely, and does not always result in more helpful answers when the pragmatic inferences are true. These results illustrate the promise of inducing pragmatic behavior in QA models and represent a lower bound of their performance, as none of the models we experiment with were trained to optimize for addressing assumptions in questions.

6 Can inference extraction be automated?

While pragmatic inferences elicited from health experts are informed by their expertise, they are slow and costly to collect. Our QA experiments use *human-written inferences* to establish an upper bound of answer quality with existing models. However, a fully automatic pragmatic QA pipeline must first generate pragmatic inferences relevant to a question and *then* generate an answer that addresses the subset of false inferences. As such, we experiment with generating pragmatic inferences with GPT-3.5 (Ouyang et al., 2022) to understand to what extent automating the process is feasible with existing prompting and in-context learning.

Experimental Setup. We generate inferences with GPT-3.5 for all questions in INFERENCE-SAMPLE using seven in-context examples corresponding to 37 different pragmatic inferences, as more in-context examples yields diminishing returns (Liu et al., 2022). We select pragmatic inferences written by multiple expert annotators from diverse user questions and randomly shuffle them to prevent unwanted effects emerging from example order (Si et al., 2022), including exemplars from all three sources (ROSIE, Reddit, and NQ) to capture distributional differences in their pragmatic inferences. As humans naturally did, we let GPT-3.5 generate *varied* numbers of inferences per question.

Evaluation: Can GPT-3.5 generate human-like pragmatic inferences? For each inference in INFERENCE-SAMPLE, a pair of authors annotate whether or not each human-written assumption is semantically equivalent to at least one inference generated by GPT-3.5 (Prompt F.1) with a Cohen's kappa of $\kappa = 0.88$. Post-adjudication, 63% of inferences were not present among model generations. When stratifying by inference type, 53% of presuppositions and 71% of implicatures were not present. This illustrates that just as they are more difficult to detect, implicatures grounded in domain knowledge are more difficult for language models to generate.

7 Conclusion

We show that it is possible to induce pragmatic behavior in QA systems to correct latent false assumptions in the sensitive domain of maternal and infant health. Next-generation QA systems deployed in real-world settings *must* learn to address the pragmatics of user questions. Though we have shown the viability of *explicitly* inducing pragmatic behavior in models in this work, directions for future work include training retrievers to inherently search for evidence to address pragmatic inferences and readers to reason on top of such evidence to tactfully and effectively challenge user beliefs.

Acknowledgments

We thank Philip Resnik, Sweta Agarwal, Sathvik Nair, and other members of the University of Maryland CLIP lab for their helpful feedback. We also thank Ximena Marin Gutierrez, Marina Yue, Michelle Jasczynski, and Amara Channell Doig for their help in the development of ROSIE. We are grateful for our pool of expert annotators and for users of ROSIE participating in our clinical trial.

The study reported in this paper was supported by research grants from the National Institute on Minority Health and Health Disparities (grant number R01MD016037) and by the National Library of Medicine (grant number R01LM012849). The content is solely the responsibility of the authors and does not necessarily represent the official views of the National Institutes of Health. The funders had no role in study design, data collection and analysis, decision to publish, or preparation of the paper.

Limitations

Data are not multilingual. Although our participants who provide questions come from diverse socioeconomic and racial backgrounds, all of the data we collect are in English. In addition, since we require participants to be located in the United States, the questions provided by participants are only reflective of the healthcare needs of English-speaking residents in the United States.

Choice of a single domain. While our approach can be generalized to any other domain, all of our data and experiments are confined to a single domain (maternal and infant health). We have not validated that our conclusions generalize beyond this particular important domain.

Pragmatics can be annotator-dependent. Finally, some degree of pragmatic inference is always dependent on the annotator, and we have not validated that this is consistent across different annotator backgrounds.

Ethical Considerations

NLP systems are never a replacement for doctors or clinical expertise, especially in high-stakes settings. This work has grown out of collaboration with public health experts to help disseminate medically accurate but *contextual* information to new or expectant mothers with limited access to healthcare. Upon detection of false or potentially problematic assumptions, patients can then be referred to healthcare providers better able to provide information than current QA systems. All of our data was collected with IRB approval in consultation with public health professionals.

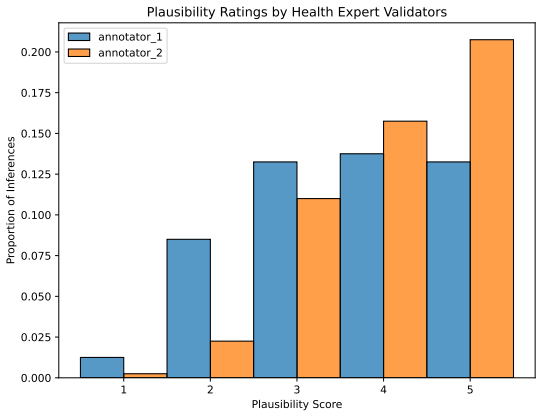

Figure 4: Ratings of expert validators of the plausibility of inferences written by health experts in our dataset. The majority of inferences are plausible.

A Reddit Question Filtering

A.1 Discourse Markers

Assumption Correcting Markers: "however,", "actually,", "as a matter of fact", "in fact", "not true", "despite what you", "on the contrary", "common misconception", "not exactly", "just to clarify", "you're confusing", "correct me if i'm wrong", "correct me if i am wrong", "you're wrong", "we have to remember that", "while that's true", "could be dangerous", "might not be the best thing"

Expertise Invoking Markers: "as a doctor", "as a medical professional", "i'm a doctor", "being a doctor", "as a nurse", "i'm a nurse", "i'm a medical professional", "being a nurse"

Prompt A.1: Medical vs. Non-Medical Question Identification

Prompt: You are an expert in maternal and infant health who specializes in finding out whether a question posed by a new or expecting mother is seeking opinion/community participation, or whether it is a medical question. Given a question, you must answer whether it is question seeking medical advice or if it is seeking personal anecdotes and sharing experience. If it's seeking medical advice, answer with "medical". Otherwise, answer "non-medical". If a question is under-specified, answer with "non-medical".

Prompt A.2: Reddit Question Rewriting

Prompt: You will be shown questions about maternal and infant health asked by users. Each question contains a TITLE and DESCRIPTION that elaborates on it, containing details that are both relevant and irrelevant to answering the question. Given a question TITLE and a DESCRIPTION, your task is to incorporate only the relevant details from the DESCRIPTION and rewrite the TITLE into a REWRITE. If there are no relevant details, return the TITLE. As a general rule, keep the rewrite as similar to the original question as possible. The rewrite should be a question in a single sentence.

Title: How to Stop Co-Sleeping

Description: ...

Rewrite: How to wean my 11-month-old out of Co-Sleeping?

B Consolidating Subquestions and Assumptions and Implications into Pragmatic Inferences

Prompt B.1: Question Consolidation

Prompt: Given questions asked by new or expecting mothers, your task is to identify the assumptions in them. For this task, you will be given a QUESTION asked by a new or expecting mother, some ASSUMPTIONS (as a list of beliefs or assumptions) in those questions identified by health experts, and some possible SUBQUESTIONS (as a list) that public health experts have identified to have the same information goals as the original question. Given all three of these, your task is to consolidate the SUBQUESTIONS and ASSUMPTIONS into a single, exhaustive list, called INFERENCES. Turning a SUBQUESTION into an inference may involve just turning it into a declarative sentence, or identifying the assumptions made in the SUBQUESTION. Finally, add the INFERENCES to the list of ASSUMPTIONS and remove any duplicates.

C Further Details on Inference Validation

Plausibility scores are the outcome of a three-stage process: (1) a pregnant or new mother holding a belief that is latent while asking a question, (2) a maternal health expert reasoning about these latent beliefs of the mother from the question text, and finally (3) a different expert estimating the likelihood of the beliefs extracted in Step 2 of this process.

The plausibility distribution in Figure 4 represents the results of Step 3. It is important to note that the humans involved in each step of the process are completely disjoint, and have little to no information about each other. In 90% of inferences, the validators agree that the extracted inferences in Step 2 are indeed plausible. The 10% of inferences

Your Task

The question below is asked by a pregnant or postpartum mother on a topic related to pregnancy and postpartum symptoms, developmental milestones, infant care, etc. We will present you with two answers to this question. **Please read the two answers and provide a score for each on a discrete scale from 1 to 5 evaluating the quality of answer completeness.** If both answers are similarly poor, or similarly strong, you can give them similar scores. A high quality answer should identify the information needs of the question and make sure any assumptions are addressed without excluding any major content you feel is necessary in a response to this question. Higher quality answers may provide more comprehensive information or include cautionary caveats.

Figure 5: Human evaluation instructions provided to two expert annotators.

	Mean Likert Score: Default Answer	Inference-Augmented
Expert Annotator 1	4.45	4.6
Expert Annotator 2	4.37	4.45

Table 4: Human preferences of answers on questions with at least one high-plausibility false assumption.

that validators found less plausible is more a reflection of the subjectivity of pragmatic inference in QA in general (see lines 686-690) than our usage of GPT-3.5 a textual transformation tool.

In fact, experts themselves can disagree about answers to questions or background inferences (a finding echoed in Xu et al. (2023)), so we include the plausibility study to reassure audiences that experts do find the inferences in our dataset plausible.

D Human Evaluation Details

Human Evaluation Annotation Instructions. See Figure 5 for annotator instructions.

Annotator preferences on questions with a highly plausible, false assumption. Human annotators prefer inference-augmented answers for questions with a highly plausible, false assumption. See Table 4.

E QA Model Prompts

E.1 Reranker Instructions

Prompt E.1: TART Baseline Instruction

```
Retrieve a passage from medical articles on the
web that answers the following question.
```

Prompt E.2: TART Pragmatic Inference Instruction

```
I want to check if the following assumption is
true or false. Retrieve an evidence passage for
me from medical articles on the web.
```

E.2 Reader Prompts

Prompt E.3: Flan-T5 Reader Prompt

```
You are an expert in maternal and infant health.
You are given a few passages below:

Context: {context}

Using information only from the passages
above, respond to the following question
with a helpful and complete answer. Use
information from multiple passages if necessary
to answer the question. Again, you are allowed
to only use information from the passages above.

Question: {question}
```

Prompt E.4: Mistral/GPT Reader Prompt

```
You are an expert in maternal and infant
health. You are given a few verified pieces of
information below:

Context: {context}

Using evidence only from verified pieces
of information above, respond to the following
question with a helpful and complete answer.
Use information from multiple sources above
if necessary to answer the question. In your
answer, do not reveal that you are fetching
information from these pieces of evidence. Use
information only from the verified sources
above, and not from any other sources.

Question: {question}
Answer:
```

Prompt E.5: Inference-Augmented Reader Prompt

```
You are an expert in maternal and infant
health. You are given a few verified pieces of
information below:

Context: {context}

Using information only from verified pieces of
information above, respond to the following
question with a helpful and complete answer.
As humans often make assumptions while asking
questions, your answer must address assumptions
made by the asker listed below.

Assumptions: {assumptions}

Use information from multiple sources above
if necessary to answer the question below and
address the ASSUMPTIONS. In your answer, do not
reveal that you are fetching information from
these pieces of evidence. Use information only
from the verified sources above, and not from
any other sources.
Question: {question}
Answer:
```

Question (Q)	Default Answer (A_D)	Pragmatic Inference-Augmented Answer (A_{IA})
When should I give my baby fever reducing meds after shots?	You should give your baby fever reducing medication after shots if they are experiencing discomfort or extreme discomfort due to the fever. However, it is important to note that in most cases, a child does not need to be medicated for a fever unless they are extremely uncomfortable. The most important thing to do when a child has a fever is to make sure they stay hydrated by drinking plenty of fluids. If you are unsure whether your child should receive medication to address the fever or other symptoms, it is recommended to consult with your child's healthcare provider.	**It is not recommended to give your baby fever reducing medication before or immediately after receiving shots. Studies have shown that giving medication prior to a vaccine visit may decrease the child's immune response to the vaccine. Fevers after vaccination are actually a sign that the immune system is responding to the vaccine.** If your baby develops a fever after receiving shots, it is generally not necessary to give them medication unless they are extremely uncomfortable. The most important thing to do when a child has a fever is to make sure they stay hydrated by drinking plenty of fluids. If you are unsure whether your baby should receive medication to address the fever or other symptoms, it is best to consult with your child's healthcare provider.
How warm can my bath be while staying safe for my 4-month-old baby?	To ensure the safety of your 4-month-old baby during bath time, it is recommended to fill the basin with water that feels warm, but not hot, to the inside of your wrist or elbow. The water temperature should be comfortable for your baby and should not pose a risk of burns or scalds. It is important to check the water temperature before placing your baby in the bath to prevent any potential harm.	The safe temperature for a baby may be different from that for an adult. It is important to ensure that the bathwater is warm, but not hot, for a 4-month-old baby. According to the provided information, the water should feel warm to the inside of your wrist or elbow. It is recommended to fill the basin with 2 inches of water at this warm temperature. This is to prevent the baby from getting burned or scalded by hot water. **It is important to note that babies are not as adaptable as adults to temperature change, and they can lose heat rapidly. Therefore, it is crucial to maintain a safe and comfortable water temperature for the baby during bath time.**
Can pregnancy tests be trusted?	According to pregnancy kit manufacturers, most at-home pregnancy tests are 98% to 99% accurate when used exactly as instructed. This means that positive results can generally be trusted. However, it is important to note that false negative results can occur if the test is taken too soon. Therefore, it is recommended to wait until a sufficient amount of time has passed since the possible conception before taking a pregnancy test to ensure more accurate results.	According to the information provided by pregnancy kit manufacturers, most at-home pregnancy tests are 98% to 99% accurate when used exactly as instructed. Positive results from these tests can be trusted. However, it is important to note that false negative results can occur if the test is taken too soon. **Blood tests, on the other hand, can detect pregnancy sooner and are the only tests that can show specific amounts of HCG in the body...**

Table 5: Outputs generated by a standard QA system and a QA systems informed by pragmatic inferences. Answers from the pragmatic system better explicate their underlying inferences.

F Inference Generation Prompt

Prompt F.1: Inference Generation Prompt

```
When humans ask questions, they often have
certain assumptions or implications that are
embedded in the questions. These assumptions
and implications may be true or false, and
they may or may not be present in the surface
form of the question. Given a question asked
by a new or expecting mother, your task
is to identify all relevant assumptions and
implications in these questions and write them
in a list titled INFERENCES. Each inference
under INFERENCES should be an independent
and declarative assertion that represents an
assumption or an implication that the speaker
makes while asking the question.
```

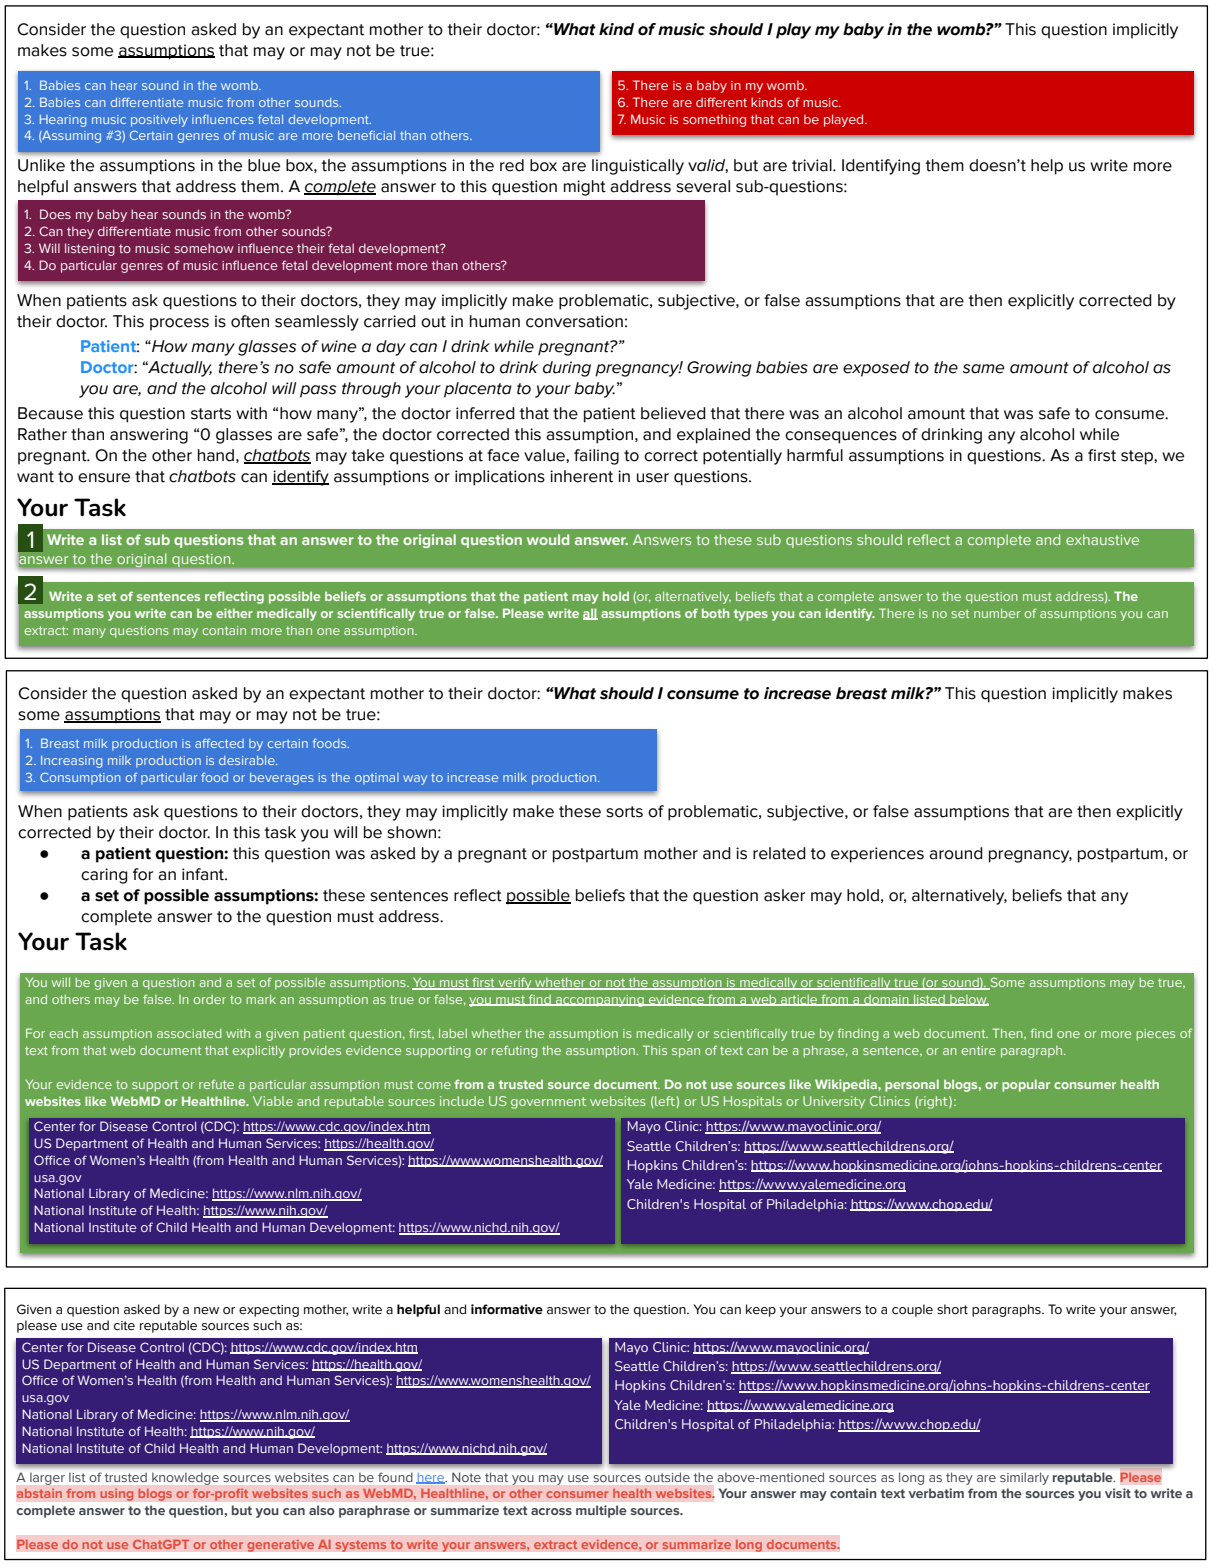

Figure 6: Instructions given to each annotator for each phase of annotation. First, we show questions to annotators and ask them to write sub questions and the assumptions present (top panel). Then, after passing these outputs to a prompt-based model to extract consolidated inferences, we ask a different set of annotators to *verify* the veracity of the inferences along with supporting evidence (middle panel). Simultaneously, we ask a third set of annotators to write answers to questions without any inference supervision (bottom panel).

Towards Explainability in Legal Outcome Prediction Models

Josef Valvoda
University of Cambridge
jv406@cam.ac.uk

Ryan Cotterell
ETH Zürich
ryan.cotterell@inf.ethz.ch

Abstract

Current legal outcome prediction models—a staple of legal NLP—do not explain their reasoning. However, to employ these models in the real world, human legal actors need to be able to understand the model's decisions. In the case of common law, legal practitioners reason towards the outcome of a case by referring to past case law, known as precedent. We contend that precedent is, therefore, a natural way of facilitating explainability for legal NLP models. In this paper, we contribute a novel method for identifying the precedent employed by legal outcome prediction models. Furthermore, by developing a taxonomy of legal precedent, we are able to compare human judges and neural models with respect to the different types of precedent they rely on. We find that while the models learn to predict outcomes reasonably well, their use of precedent is unlike that of human judges.

1 Introduction

Legal outcome prediction models have generated much interest in the past years (Aletras et al., 2016; Medvedeva et al., 2020; T.y.s.s et al., 2023; Valvoda et al., 2023a). Given a text transcript of the facts of a legal case, a legal outcome prediction model predicts whether a particular law has been breached. Researchers have evaluated these models in several jurisdictions, including the UK, USA, Switzerland, France, China, Japan, India and the European Court of Human Rights (ECtHR; Şulea et al., 2017; Chalkidis et al., 2019; Strickson and De La Iglesia, 2020; Malik et al., 2021; Niklaus et al., 2021; Chalkidis et al., 2022; Feng et al., 2022).

While legal outcome prediction models are interesting in the context of academic research (Valvoda et al., 2021), any real-world deployment of Legal AI necessitates a certain level of understanding of how the system works (Valvoda et al., 2023b). After all, it is the *reasoning* towards the outcome of the case, rather than the outcome itself, that is of tantamount importance in legal outcome prediction. There are two reasons for this. (1) To be able to use a legal outcome prediction model system in practice implicitly assumes explainability: lawyers are bound to provide advice that the client can depend on. This obligation is so extreme that a negligent lawyer themself can be sued for misconduct if they give faulty advice. Moreover, making legal decisions without understanding the reasoning behind them is unethical in many legal systems. For example, for a model to be used in practice it is a legal requirement in the EU under GDPR to know what the decision is based on. Thus, the ability to double-check any information a hypothetical legal AI assistant provides is paramount when building technology for legal professionals. (2) Explainability can create new use cases for legal outcome prediction models. Knowing how to reason towards a desired legal outcome is valuable for drafting legal arguments and, thus, a legal outcome prediction system could be deployed as an assistive technology in areas well beyond simply predicting outcomes (Sarker et al., 2019).

State-of-the-art legal outcome prediction models are nearly homogeneous at a technical level—they are all parameterized as neural network classifiers on top of pre-trained language models (LM). While their performance is remarkable at times, the reasoning embedded in the model is largely inscrutable. Despite the widespread recognition of the problem that unexplainable legal NLP systems pose (Hacker et al., 2020) and emerging work in the domain of case law summarization (Norkute et al., 2021), much remains to be done in order to build effective explainable legal NLP systems (Branting et al., 2019; Chalkidis et al., 2021). In particular, the existing work on explainable legal AI focuses on providing explanations by identifying relevant tokens (Xu et al., 2023), sentences (Malik et al., 2021) or paragraphs (Chalkidis et al., 2021), from the facts of the case. However, lawyers and judges typically reason at the level of a case.

In this paper, we address the lack of explainability of legal outcome prediction models in a manner inspired by legal reasoning. The law in the Anglo-American tradition is endowed with

Proceedings of the 2024 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies (Volume 1: Long Papers), pages 7269–7289
June 16-21, 2024 ©2024 Association for Computational Linguistics

a natural rationale—precedent—which produces a legal argument. Precedent is how judges and lawyers reason with respect to previous cases. Because precedent is binding, by citing previously decided cases, legal actors substantiate their arguments. Unlike existing explainability methods, our method produces an explanation in terms of legal precedent. This allows legal practitioners to easily inspect the legal reasoning the model employs. Furthermore, we develop a taxonomy of legal precedent, which allows us to categorize each training case in terms of its precedential operation. We can therefore pinpoint which kinds of precedential reasoning the models rely on.

We validate our proposed method by training several legal outcome prediction models and measuring the correlation between the precedent they use and that used by a human judge. Overall, our experiments reveal that the precedent used by a human judge has a weak positive correlation with the precedent our models rely on (the highest Spearman's ρ we observe is 0.18). We also discover that the model predictions positively correlate with one type of precedent in particular—the one where the outcome of the precedent case is the same as the outcome of the case at hand. However, for most of the categories of precedent, we find the models have a negligible or even negative correlation with the precedent applied by a human judge. Worse yet, model F_1 performance on predicting the outcome of a case is a poor proxy for its alignment with precedential reasoning; see Tab. 2. In other words, higher F_1 does not equal better alignment. Therefore, our results cast doubt on the real-world utility of the current outcome prediction models.

2 Precedent-based Interpretability

We now give an argument for why precedent-based interpretability is the right direction for improving the usability of legal outcome prediction models.

Why are existing methods insufficient? Many interpretability methods, such as linguistic probing, have been developed to investigate the linguistic capabilities of neural models (Hewitt and Manning, 2019; Belinkov, 2022; Pimentel et al., 2022). These methods often focus solely on the immediate input to the model. This is intentional because the goal of linguistic probing is to analyze the model in terms of how individual tokens affect the output. For example, if you want to know if and how a neural network's representations relate to a dependency parse of the input sentence, investigating the network's use of tokens in a sentence is a wise choice. In legal NLP, however, despite the recent rejuvenation of efforts in the field (Xu et al., 2023; Habernal et al., 2023), there is no generally accepted legal theory about how individual words or sentences affect the outcome of a case. We further elaborate on the related work in §9.

Why precedent? There is already a generally accepted method of legal reasoning—reasoning through legal precedent. However, precedent does not operate on the granularity of individual words or sentences. Instead, precedent relies on the relationship between the case at hand and previously decided cases. Importantly, precedent is a way of developing law. A decision rendered in a past case binds future decisions in a common law system. This binding precedent, which stems from the doctrine of *stare decisis*, literally *stand by the decision*, ensures the reliability of law by forcing judges to make consistent decisions (Duxbury, 2008; Lamond, 2016; Black, 2019).[1] While precedent plays an important role in deciding the outcome of a case in both common and civil law systems, it occupies the core of legal reasoning in common law jurisdictions, e.g., UK, USA, and India, and it is the focus of this paper.

Claims and Outcomes. Because precedent is binding law, it is used in legal argumentation. When a new legal case arises, there are two competing points of view presented to a judge: That of the plaintiff and that of the defendant. These are typically represented by lawyers working on behalf of either side. The first step in the process is establishing the **claims**, i.e., the laws that the plaintiff claims as violated. The claims are a starting point of the legal argument. The job of the lawyer on either side is to substantiate their claims. To do this, the lawyers rely on previous case law, i.e., the precedent. They will draw analogies to cases where their side has won, and distinguish their circumstances from the instances where their side has lost. The selection of past cases is therefore a large part

[1]There is also a non-binding precedent. It is typically contained in *obiter dicta* or the *other things said* in the court decisions. Its purpose is to hint at what the court might decide in the future given a legal point that falls outside the scope of the case under consideration. Another type of non-binding precedent is in cases that have been overruled by a subsequent judgment. In such instances, the case is considered outdated and the law contained within is obsolete. While this kind of precedent is important, we do not study them in this paper.

of the reasoning process for the lawyer. Lawyers present their arguments, substantiated with citations to precedent cases, to the judge, who again uses precedent in their argumentation. The judge will cite past cases, much like lawyers do, as part of their argument towards the **outcome** of a case. As a judge arrives at the decision, the case at hand will set a binding precedent and the process repeats.

Conclusion. Our position is that the best way to build explainable legal outcome prediction models is through the direct use of precedent. This way, both lawyers and judges can directly interpret and analyze the rationale provided by the model. Moreover, both lawyers and judges are already trained in reasoning about new cases with respect to old cases, so no additional training would be required.

3 Under the Influence

We now turn to the explainability method developed in this paper, which will allow us to identify the exact role precedent plays in the decisions made by neural legal outcome prediction models.

3.1 Preliminaries

Legal outcome prediction is a multilabel classification task. We start with the necessary notation and a generic description of a probabilistic legal outcome prediction model. Let $\mathcal{O} = \{+, -, \emptyset\}$ be a set of **legal outcomes**, whose elements correspond to a positive, negative and null outcome of a case, respectively. The null outcome occurs when a law has not been claimed by either party to the case. Let O be an outcome-valued random variable with instances $o \in \mathcal{O}$. Let $\mathcal{O}^K$ be the K-times Cartesian product of $\mathcal{O}$ where K is the number of legal Articles we consider. The elements of $\mathcal{O}^K$ are denoted as $\boldsymbol{o} \in \mathcal{O}^K$. Let $\boldsymbol{O}$ is a random variable ranging over $\mathcal{O}^K$. We write O_k for the random variable, ranging over $\mathcal{O}$, that corresponds to just the k^{th} article. For instance, if a judge finds that Article 3 has been breached, we write $O_k = +$. Now, let Σ be an alphabet.[2] The random variable $\boldsymbol{F}$ ranges over textual descriptions of **facts**, i.e., Σ^* for a vocabulary Σ. Elements of Σ^* are denoted as $\boldsymbol{f}$. For a case concerned with O_5 we might expect the following $\boldsymbol{f}$.

Example 1 (Article 5 - Right to a fair trial)**.** *Neither the applicants nor any of the other migrants in their group were provided with any information regarding the reason for or the length of their detention. They did not have a chance to appoint a lawyer and were not provided with an interpreter at any point during their detention.*

We focus on an **article-factored** probabilistic legal outcome predictor, which can be described by the following probability model

$$p_{\boldsymbol{\theta}}(\boldsymbol{O} = \boldsymbol{o} \mid \boldsymbol{F} = \boldsymbol{f}) = \prod_{k=1}^{K} p_{\boldsymbol{\theta}}(O_k = o_k \mid \boldsymbol{F} = \boldsymbol{f}) \tag{1}$$

parameterized by $\boldsymbol{\theta} \in \boldsymbol{\Theta}$. We further assume that $\boldsymbol{\Theta}$ is a compact subset of $\mathbb{R}^d$. The training dataset $\mathcal{D}_{trn} = \{\boldsymbol{z}^{(n)}\}_{n=1}^{N}$ is a set of N outcome–fact pairs where $\boldsymbol{z}^{(n)} = (\boldsymbol{f}^{(n)}, \boldsymbol{o}^{(n)})$. The test dataset $\mathcal{D}_{tst} = \{\boldsymbol{z}^{(m)}\}_{m=1}^{M}$ is a set of M outcome–fact pairs where $\boldsymbol{z}^{(m)} = (\boldsymbol{f}^{(m)}, \boldsymbol{o}^{(m)})$. Each training and test pair encodes a relationship between facts and law. The instance-level negative log-likelihood, i.e., the negative log-likelihood of a *single* training point $\boldsymbol{z}$, is denoted as $\ell_{\boldsymbol{z}}(\boldsymbol{\theta}) = -\log p_{\boldsymbol{\theta}}(\boldsymbol{z})$. Then, the average cross-entropy for the training set is given by

$$L(\boldsymbol{\theta}) = \frac{1}{N} \sum_{n=1}^{N} \ell_{\boldsymbol{z}^{(n)}}(\boldsymbol{\theta}) \tag{2}$$

A good value for the parameters $\boldsymbol{\theta}$ may be found by solving the following optimization problem

$$\boldsymbol{\theta}^{\star} = \operatorname*{argmin}_{\boldsymbol{\theta} \in \boldsymbol{\Theta}} L(\boldsymbol{\theta}) + \alpha \mathcal{R}(\boldsymbol{\theta}) \tag{3}$$

where $\mathcal{R}(\cdot)$ is a regularization function with strength $\alpha \geq 0$. Because $\boldsymbol{\Theta}$ is assumed to be compact and $L(\boldsymbol{\theta}) + \alpha \mathcal{R}(\boldsymbol{\theta})$ is a continuous function of $\boldsymbol{\theta}$ the argmin given in Eq. (3) is well-defined.

3.2 Influence Functions

In order to evaluate if and to what extent a model relies on any of the above categories of precedent, we need a way to identify how precedent cases affect the model's decision. In a legal outcome prediction model, the only cases that can be considered precedent are the training cases. A simple technique to measure the effect of a training case $\boldsymbol{z}$ on a test case $\boldsymbol{z}'$ would be to remove $\boldsymbol{z}$ from the training set $\mathcal{D}_{trn}$, retrain the model, and take $\boldsymbol{z}$'s importance to be the change in the loss $\ell_{\boldsymbol{z}}(\boldsymbol{\theta})$ for a test point $\boldsymbol{z}$. However, with over $N = 8000$ training cases, we would have to retrain the model N times to be able to estimate the importance of each case in the training set for the test cases $\boldsymbol{z}'$. This would be prohibitively slow.

[2] In principle, the alphabet Σ can be constructed over either characters, words or sub-word tokens, the last of which is what we do in our experiments.

As a tractable alternative to the above, Koh and Liang (2017) introduce a simple procedure that allows us to efficiently estimate the effect of a single $\boldsymbol{z}$ on the model parameters *without* retraining. We now describe their method, based on influence functions, in detail. Consider the following optimization problem, a modified version of Eq. (3)

$$\boldsymbol{\theta}_z^\star(\varepsilon) = \underset{\boldsymbol{\theta}\in\Theta}{\operatorname{argmin}} \underbrace{L(\boldsymbol{\theta}) + \alpha\mathcal{R}(\boldsymbol{\theta})}_{\stackrel{\text{def}}{=} L_{\mathcal{R}}(\boldsymbol{\theta})} + \varepsilon\ell_{\boldsymbol{z}}(\boldsymbol{\theta}) \quad (4)$$

It is not hard to see that Eq. (4) simply modifies the weight associated with $\boldsymbol{z}$ in the summation found in Eq. (3). Relying on Koh and Liang's (2017) method, we can approximate the effect of a very small ε on parameters $\boldsymbol{\theta}$ by taking a derivative of $\boldsymbol{\theta}_z^\star(\varepsilon)$ with respect to ε at evaluating it at $\varepsilon = 0$:

$$\frac{\mathrm{d}\boldsymbol{\theta}_z^\star}{\mathrm{d}\varepsilon}\Big|_{\varepsilon=0} = -\left(\nabla^2_{\boldsymbol{\theta}} L_{\mathcal{R}}(\boldsymbol{\theta}^\star)\right)^{-1} \nabla_{\boldsymbol{\theta}}\ell_{\boldsymbol{z}}(\boldsymbol{\theta}^\star) \quad (5)$$

See App. F for a derivation of Eq. (5).

Influence score. We are not directly interested in the new parameters themselves but rather in the effect of the change in parameters on the loss for a test point $\boldsymbol{z}'$. We can calculate this influence score using the chain rule:

$$\begin{aligned}\iota(\boldsymbol{z},\boldsymbol{z}') &\stackrel{\text{def}}{=} \frac{\mathrm{d}\ell_{\boldsymbol{z}'}(\boldsymbol{\theta}_z^\star)}{\mathrm{d}\varepsilon}\Big|_{\varepsilon=0} \\ &= \nabla_{\boldsymbol{\theta}}\ell_{\boldsymbol{z}'}(\boldsymbol{\theta}^\star)^\top \frac{\mathrm{d}\boldsymbol{\theta}_{\boldsymbol{z}}^\star}{\mathrm{d}\varepsilon}\Big|_{\varepsilon=0} \quad \text{(chain rule)} \quad (6) \\ &\stackrel{(a)}{=} -\nabla_{\boldsymbol{\theta}}\ell_{\boldsymbol{z}'}(\boldsymbol{\theta}^\star)^\top \left(\nabla^2_{\boldsymbol{\theta}} L_{\mathcal{R}}(\boldsymbol{\theta}^\star)\right)^{-1} \nabla_{\boldsymbol{\theta}}\ell_{\boldsymbol{z}}(\boldsymbol{\theta}^\star)\end{aligned}$$

where (a) results by plugging in Eq. (5). Thus, we can leverage Koh and Liang's method to measure the extent to which a precedent case bears on a new legal decision.

4 Taxonomy of Precedent

Precedent is more than just a binary category. Legal actors use it in a number of different ways to craft their arguments. To better evaluate how neural models of outcome use precedent, we develop a novel taxonomy of types of precedent.

4.1 Applied vs. Distinguished

The simplest way of categorizing the precedential relationship between two cases is to differentiate between application and distinction.[3]

Applied Precedent. We call a precedent case **applied** when a judge applies the precedent from a previous case. In such instances, the judge has relied on similar reasoning to that of the precedent case. As a result, the outcome of the case at hand is the same as the outcome of the precedent case. In practice, these are the precedent cases that a judge has cited as part of their argument, which have the same outcome as the case at hand.

Distinguished Precedent. We call a precedent case **distinguished** when a judge distinguishes their decision from a past case. When a precedent is distinguished, the judge has used the differences between the cases to inform their decision. In practice, these are the cases that a judge cites but have a different outcome than the case at hand.

4.2 Positive vs. Negative Precedent

Valvoda et al. (2023a) introduce a new perspective on how to model legal outcome prediction. By considering both the claims and the outcomes of cases, they define two types of legal outcomes: positive and negative.[4] Following their logic, we can further sub-divide the applied or distinguished precedent into the two categories below.

Positive Precedent. An outcome is positive when a law has been claimed as breached and a judge finds in favor of the claimant. When a new case cites a positive outcome case, the judge invokes a positive precedent. In the strictest sense, this means that if a new case arises from exactly the same facts as the precedent case before it, the judge will have to conclude the same law has been equally breached in both cases. In practice, no two cases are exactly the same. Therefore the positive precedent affects all subsequent similar cases by increasing the chances of successfully claiming a breach of the law that has been violated in the precedent case.

Negative Precedent. An outcome is negative when a law has been claimed as breached, but the judge finds it has not in fact been broken. When a new case cites a negative outcome case, the judge invokes a negative precedent. Much like with positive precedent, the court is bound by the negative precedent. Two cases with the same facts must reach the same outcome—positive or

[3] We focus on the major types of precedent. There are other forms of precedent we do not consider here. Specifically, modification of precedent and overruling. In future work, they would be a natural candidate for further exploration.

[4] This is not a new concept to lawyers or legal AI theorists. Lawlor (1963) already described these categories of precedent as *pro-precedent* and *con-precedent*.

	Applied		Distinguished	
	Cited	**Claimed**	**Cited**	**Claimed**
Pos.	2,012	643,377	114	54,099
Neg.	296	129,239	79	30,203

Table 1: Total number of cited cases per category of precedent under the per-case view of the precedent.

negative. Therefore, the scope of the law contracts through negative precedent.

4.3 Scope

Additionally, there are two axes along which we can define the scope of the precedent we will consider in §7.

Claimed vs. Cited. There are two ways to uncover the relevant precedent for a case. The first is to consider all the Articles that the lawyer has *claimed* as violated. To find these cases, we can look through all past cases and pick out those where the same Articles have been claimed. Because all cases in our corpus deal with the same subset of law, by the nature of precedent, all past decisions are all binding with respect to future ones. We call this the **claimed precedent**. However, in practice, considering all claimed precedent cases yields a large number of precedent cases. Thus, we also consider a more narrow view. Specifically, we focus on those cases the judge cites when drafting their judgment. We call this the **cited precedent**. Each approach has its limitations. Under the narrow view (cited precedent), we have a non-exhaustive list of cases that only show us the reasoning of a *single* judge.[5] Under the broader view (claimed precedent), we consider many cases that are not directly relevant to the facts of the case at hand. The claimed–cited distinction plays a crucial role in our analysis. Correlations are broken down into cited and claimed precedent in Tab. 2

Per-case vs. Per-article. A lawyer typically claims multiple Articles as violated, and, likewise, a judge may find that multiple Articles were breached. Thus, when selecting precedent cases, on one hand, we can consider those where all the claimed Articles are shared. Or, on the other hand, we can consider a piecemeal approach where we select all cases that share *at least* one Article. We call the former approach the **per-article approach** and the latter the **per-case approach**. The advantage of the per-case approach is that it selects for highly related cases because the cases have an identical set of claimed Articles. The advantage of the per-article approach is that it allows for a more detailed analysis—a case might be an important precedent with respect to a judge's decision on only a single Article. While we report our main results with per-case correlations, we include an analysis of per-article correlations in §8.2.

[5] A judgement may be given by a tribunal of judges, each giving a different argument. In our dataset, the reasoning towards the decision is reported as a single argument.

4.4 Recovering the Taxonomy

Conveniently, the above taxonomy can be recovered post hoc from the case transcripts. All we need is to construct a citation network. We can then identify the relationship between a cited case and the citing case as follows. First, we identify the outcomes of both the citing case and the cited case. If the positive outcomes of the cited case are the same as those of the citing case, there is a relationship of **applied-positive** precedent. If the negative outcomes are the same, the relationship is that of **applied-negative** precedent. To extract cases that constitute a distinguished precedent, we first identify if the case at hand and the cited case share the same claims. If they do, we move forward to distinguish between positive and negative outcomes. When the positive outcomes of the cited case are the same as the negative outcomes of the citing case, we label the relationship as **distinguished-positive**. Conversely, if the negative outcomes of the cited case are the same as the positive outcomes of the citing case, we label the relationship as **distinguished-negative**.

Note that because we consider positive and negative precedent separately, the relationship between any two cases can simultaneously be both positive and negative, though it can not be both applied and distinguished. Some cited cases might not fall under any of the above categories. We include an example of how we process cases into the taxonomy in App. B.

5 An Improved ECtHR Corpus

We modify the ECtHR corpus, a popular legal NLP dataset, for our experiments. Specifically, we use the scrape of the corpus from Valvoda et al. (2021). An ECtHR case can be separated into two sections: facts and arguments. The facts of the case, denoted $\boldsymbol{f} \in \Sigma^*$, contain text describing the events that had brought the claimant to court. This

section outlines the events that might give rise to a particular breach of law. Arguments of the case on the other hand contain a transcription of the reasoning the judge(s) employed in reaching the conclusion over whether or not a breach of law has actually occurred. The argument section is where the judges cite previous cases, i.e., the precedent.

We first extract the necessary citations to previous cases. Specifically, for every case in our dataset, we extract the names of all the cases cited in the arguments section. We use regular expressions for this purpose because citations in the ECtHR corpus follow a regular form.[6] The first author manually inspected the extracted citations to ensure a high-quality citation network. Then, we remove all the cases in the training set of our dataset that have *not* been cited. This step ensures that every training case is a precedent of at least one test case. Then we remove all the cases in the test set of our corpus which do not cite any precedent. We do this to ensure that, for each case in our test set of the corpus, there is a precedent cited from our training corpus. Details about the number of cases per Article and the split between the training, validation, and test set are contained in App. A.

6 Neural Models of Legal Outcome

We consider two different instantiations of Eq. (1), each of which corresponds to a different legal outcome prediction approach from the literature.

Simple model. Under Chalkidis et al.'s (2022) model, legal outcome prediction is treated as a binary classification task with the outcome of a case simplistically assumed to be either $+$ or an amalgamation of $-$ and $\emptyset$. Using a pre-trained language model as an encoder enc, we define the following model:

$$\mathbf{h} = \mathrm{enc}(\boldsymbol{f}) \tag{7a}$$

$$\mathbf{e} = \mathrm{W}_k^{(1)}\,\mathrm{ReLU}(\mathrm{W}^{(2)}\,\mathbf{h}) \tag{7b}$$

$$p(O_k = + \mid \boldsymbol{f}) = \mathsf{sigmoid}(\mathbf{e}_k)_+ \tag{7c}$$

where the multi-layer perceptron (MLP) is parametrized by $\mathrm{W}_k^{(1)} \in \mathbb{R}^{1\times d_2}$ and $\mathrm{W}^{(2)} \in \mathbb{R}^{d_2\times d_1}$. The input $\mathbf{h} \in \mathbb{R}^{d_1}$ is a high-dimensional representation of the facts computed by the encoder.

[6] ECtHR has issued a note on the rules on case citations here. In the ECtHR corpus, the earliest cases are from the year 2001 and the relevant citation styles they follow are the two used between 1999-2015 and from 2016 onwards. Both follow a regular format, allowing us to generate our citation dataset.

Joint model. We also implement Valvoda et al.'s (2023a) model, which treats outcome prediction as a three-way classification task:

$$\mathbf{h} = \mathrm{enc}(\boldsymbol{f}) \tag{8a}$$

$$\mathbf{e} = \mathrm{W}_k^{(3)}\,\mathrm{ReLU}(\mathrm{W}^{(4)}\,\mathbf{h}) \tag{8b}$$

$$p(O_k = o_k \mid \boldsymbol{f}) = \mathsf{softmax}(\mathbf{e}_k)_{o_k} \tag{8c}$$

where $\mathrm{W}_k^{(3)} \in \mathbb{R}^{3\times d_2}$ and $\mathrm{W}^{(4)} \in \mathbb{R}^{d_2\times d_1}$ are the parameters of the MLP. The advantage of this approach is that it directly models both positive and negative outcomes, which are closely related to positive and negative precedent. Thus, we expect the Joint model to be better at utilizing them.

Choice of enc**.** For both models, we consider two choices for the encoding $\mathrm{enc} : \Sigma^* \to \mathbb{R}^{d_1}$: (1) BERT (Devlin et al., 2019) and (2) LEGAL-BERT (Chalkidis et al., 2020). The full experimental details, e.g., hyperparameters, are given in App. D.

7 Results

We report our results in terms of Spearman's ρ. Overall, we find a weak positive correlation between judges' precedent and influence scores—the best correlation we find is 0.180. However, due to the fine-grained taxonomy, the results vary between different types of precedent. Inspecting the main results, contained in Tab. 2, we make the following six findings.

Finding #1. We observe that influence scores correlate more strongly with applied precedent than distinguished precedent. In fact, the distinguished precedent is negatively correlated with the influence scores in the case of the Simple model. Under the best Joint model, the highest correlation we find between the distinguished precedent and influence scores is nearly $4\times$ lower (0.020) when compared to the highest correlation we obtain for the applied precedent (0.079). Therefore, we conclude that current legal outcome prediction models struggle with distinguished precedent.

Finding #2. We find negative precedent correlates less strongly with influence scores than positive precedent. In the case of applied precedent, we observe a correlation with positive precedent of 0.180, which is more than $6\times$ larger than the correlation we observe with negative precedent (0.027). Therefore, we conclude the models struggle to utilize negative precedent in comparison.

				Applied		Distinguished		Overall
Type	**Language Model**	**F_1**		**Cited**	**Claimed**	**Cited**	**Claimed**	
Simple	BERT	0.64	**Positive**	0.013	0.148	-0.002	-0.012	0.137
			Negative	0.004	0.037	-0.002	-0.023	
	LEGAL-BERT	0.67	**Positive**	0.013	0.180	-0.003	-0.026	0.157
			Negative	0.003	0.027	-0.002	-0.023	
Joint	BERT	0.66	**Positive**	0.008	0.079	0.001	0.020	0.084
			Negative	0.003	0.023	0.001	0.002	
	LEGAL-BERT	0.68	**Positive**	0.008	0.078	0.000	0.020	0.085
			Negative	0.004	0.031	0.000	0.004	

Table 2: We report per-case Spearman's ρ between influence scores and our taxonomy of precedent, F_1 scores for the models under consideration and the *overall* correlation between influence scores and any type of precedent.

Finding #3. When analyzed through the lens of influence scores, neither model correctly emulates the full spectrum of precedential reasoning. While the influence scores under the Joint model correlate positively with every type of precedent, we observe an overall correlation of 0.085, which is weaker than the overall correlation of 0.157 that we observe with the Simple model's influence scores. Because the Simple model is negatively correlated with distinguished precedent, neither of the models under consideration seems to be able to robustly reason with the full set of precedential operations.

Finding #4. We observe that pre-training on legal data is beneficial for improving precedent correlations. The LEGAL-BERT-based models exhibit higher correlations with precedent when compared to the BERT-based models. Under the Simple model, in particular, we see an increase from a correlation of 0.137 to a correlation of 0.157 when we use LEGAL-BERT.

Finding #5. When we compare the correlation for cases a judge has cited with the correlation for claimed precedent cases, we observe that the latter approach magnifies the results. In the case of a positive correlation, the correlations become more positive. In the case of a negative correlation, the correlations become more negative. The effect is considerable—in many instances, the difference is more than an order of magnitude.

Finding #6. We find that higher F_1 scores do not directly translate to more human-like legal reasoning. Where the Joint models outperform the Simple models in terms of F_1, the overall ρ is higher for the Simple models. Overall, the worst model in terms of F_1 (Simple BERT: 0.64 F_1) exhibits a correlation of 0.14 with precedent. Whereas the best model in terms of F_1 (Joint LEGAL-BERT: 0.68 F_1) exhibits a correlation of merely 0.085 with the precedent.

Conclusion. In summary, we find that current models do well at encoding one particular type of precedent, applied-positive precedent, and not so well at the other types of precedent. We believe the culprit is the lack of sophisticated legal reasoning. To distinguish a case is to identify how two seemingly similar cases differ. This requires in-depth legal knowledge. Our work indicates that this level of legal understanding is beyond the capabilities of the current neural models of legal outcome prediction models.

8 Further Analysis

We extend our analysis with the following three studies to better understand the models' behavior. First, we analyze the precedent from the perspective of the model. Then, we analyze the model behavior per individual legal Article. Finally, in App. C, we develop a novel metric, which confirms the trends we report in §7 from the perspective of precedent retrieval.

8.1 Model-based Precedent

Current legal outcome predictors often fail to predict the correct outcomes. Therefore, the weak correlations reported above might simply be due to the model relying on the precedent which supports the outcome the model predicts, rather than the outcome a human judge has reached. To investigate this possibility, we develop two ways of selecting precedent in line with the models' prediction of the

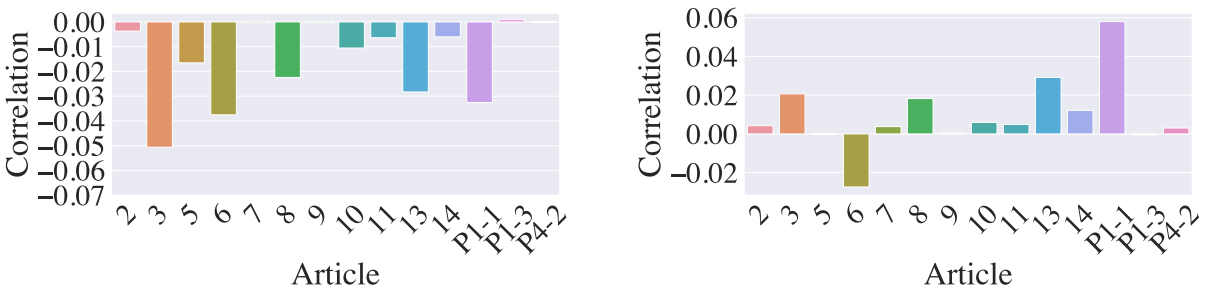

Figure 1: Per-article Spearman correlation between influence functions and cited negative-distinguished precedent. The Simple model is on the left and the Joint model is on the right; both models are LEGAL-BERT based.

Type	LM	Correct	Model
Simple	BERT	0.149	0.007
	LEGAL-BERT	0.183	0.032
Joint	BERT	0.138	0.010
	LEGAL-BERT	0.148	0.011

Table 3: Spearman's correlations for the correctly predicted cases and model-based precedent. The correlations are based on *overall* types of precedent.

outcome. First, we compute correlations for only those instances where the model has **correctly predicted** the outcome. Second, we select the precedent cases by taking the model outcome prediction as the ground truth. We call this approach **model-based**. Under both approaches, we study the same types of correlations as in §7. The overall Spearman correlations are reported in Tab. 3.

We find that the correlation with precedent is higher for correctly predicted cases. The best overall correlation for these instances improves from 0.157 to 0.183, a 17% improvement. On the other hand, the model-based results reveal a decrease in correlation with precedent. The best model under this paradigm achieves a correlation of only 0.011, more than an order of magnitude worse than the best model in Tab. 2. This suggests that the models agree with a human judge's choice of precedent more than with the precedent that would be consistent with the model's own predictions. This finding casts further doubt on the alignment of the models' reasoning with the doctrine of precedent. We report full results in App. G.

8.2 Per-article Analysis

So far, we have considered only per-case correlations. We now turn to the per-article results. We report our full per-article results in App. E. In general, we observe the same trends as those set out in §7. Nonetheless, we find interesting results for the negative distinguished precedent; see Fig. 9. We discuss these results in more detail below.

Under the Simple model, we observe that those Articles that are more heavily represented in the training data exhibit a lower correlation with negative distinguished precedent in comparison with those that are less heavily represented. For example, Articles 3, 6, 8, 10, 13 and P1-1, each of which has a large number of examples in the training set, correlate more negatively with negative distinguished precedent than their less well-represented counterparts. Therefore, we contend that it is unlikely that introducing additional training data will solve the problem of limited precedential reasoning in neural models of legal outcome. In fact, scaling up the data seems to result in less human-like behavior. Instead, our results suggest that we need to develop new models with a better legal inductive bias to address this issue.

When it comes to distinguished precedent, Joint model exhibits some aspects of such inductive bias. For most Articles, and Articles 8 and 13 in particular, the model seems to utilize distinguished precedent. Nonetheless, for Article 6, which is the most represented Article in the dataset, we still observe a negative correlation. While Joint model appears to be a step in the right direction in some respects, it is still far from using the precedent in a way a human judge would.

9 Related Work

In the wider NLP context, there is a considerable amount of research aimed at developing methods for unraveling what LMs know about language (Alain and Bengio, 2016; Shi et al., 2016; Ettinger et al., 2016; Bisazza and Tump, 2018; Liu et al., 2019; Pimentel et al., 2020). Sub-fields of

NLP dealing with sensitive information, such as biomedical NLP (Garcia-Olano et al., 2021; Jha et al., 2018; Moradi and Samwald, 2021; Sarker et al., 2019; Mullenbach et al., 2018), have set out to build their own explainable AI models to address the concerns about applying a black-box model to sensitive data.

In the past, legal AI researchers working on symbolic methods built explainable models of legal reasoning (Ashley, 1988; Aleven and Ashley, 1997; Rissland and Skalak, 1991; Branting, 1991). However, the most recent crop of models utilizing modern NLP methods are inherently opaque. Regardless of whether the domain is Chinese (Feng et al., 2022), Japanese (Yamada et al., 2023), Indian (Malik et al., 2021) or UK law (Valvoda et al., 2018), the machine learning models underlying the work in the area are not easily interpretable.

To address this shortcoming, straightforwardly adopting existing methodology from wider NLP is insufficient. After all, how well a model knows syntax can only go so far in explaining its legal decisions. Using more general methods, such as attention maps, is not particularly viable either. For instance, using attention to find where the model *looks* at legal facts does not provide a legally salient answer as to what the decision is based on (Mullenbach et al., 2018).

Setting aside the question of whether attention can be used for explainability in the first place (Serrano and Smith, 2019; Bastings and Filippova, 2020; Meister et al., 2021; Bibal et al., 2022), models of legal outcome prediction are trained to make decisions based on the facts of a case alone. While the facts of the case are important, inspecting the attention distribution over them can never provide a sufficient explanation. This is because lawyers and judges do not argue by highlighting which facts played a role in their decision. Instead, in their arguments, they justify their decision by relating the facts at hand to previous case decisions. This makes our work different from prior research in two aspects. (1) Where the existing Legal AI work focuses on providing explanations by identifying relevant tokens (Xu et al., 2023), sentences (Malik et al., 2021) or paragraphs (Chalkidis et al., 2021) of the facts of the case, we find the entire relevant cases. (2) Instead of looking inside the input to the model, i.e., at the facts, we look at the training data of the model.

10 Conclusion

We introduce a method based on influence functions for legal explainability. We created a taxonomy of precedent, used it to annotate the ECtHR dataset and ran a series of experiments to identify what precedential operations might be learned, or not, by outcome prediction models. We find that the models we train rely on one type of precedent in particular: applied precedent. This makes them very unlike human judges, who employ a full spectrum of precedential reasoning to justify the outcome of a case. To construct useful models of legal outcomes, we need to develop legally faithful models of law. We hope that our methodology can help in the search for such models.

Indeed, we see two concrete avenues toward legal NLP models that could better align with human precedential reasoning. (1) We can focus on creating more representative datasets of the tasks we would like to model. The facts in current datasets contain superficial indicators of the outcome—they are written as post-hoc justification. Using datasets built around legal briefs, instead of cases, could be a step towards mitigating this issue (Valvoda et al., 2023b). (2) We can better incorporate the court processes in our neural models. To induce precedential reasoning, a natural step would be to incorporate precedent retrieval as part of the model architecture. Much like a judge, the model should be able to explicitly select the precedent that its decision is based on.

Limitations

There are a number of limitations to our work which we would like to acknowledge. First, our work is limited to a study of the English version of the ECtHR corpus. Future work should investigate the French translations of the caselaw, which is available for all cases in the corpus. Additionally, one could experiment with the translations available in other languages, since every case is also translated into the official language of the defendant. Second, there are potential limitations to using our methodology in different jurisdictions. We report the details of our dataset and experiments in App. A and App. D, respectively. Training of the models requires a sufficiently large dataset which could be a limiting factor for smaller jurisdictions with fewer training cases available.

Ethics Statement

The models and methods in this paper are intended purely for scientific research. While we believe that one day legal AI could be a valuable tool in speeding up the legal process, the current state of the research, including ours, is far from being ready for real-world deployment. We would therefore caution anyone from using our work towards automating away the job of a human judge or lawyer. Our results in fact suggest that the current models behave unlike human judges when it comes to precedent. This makes them highly unsuitable for real-world deployment. See our work on legal ethics for a more detailed critique of the current state of Legal AI (Valvoda et al., 2023b).

Aknowledgments

This research is funded by the Nordic Programme for Interdisciplinary Research Grant 105178 and the Danish National Research Foundation Grant no. DNRF169. We would also like to thank Professor Ken Satoh for the fruitful discussions and feedback.

A Dataset Details

We report the breakdown of the dataset in Tab. 4 below. As you can see, the dataset is highly imbalanced, which is why we conduct our per Article analysis in §8.

B An Example of Our Taxonomy

To better understand how we taxonomize precedent, let us consider an imaginary case $\boldsymbol{o}$ with five precedent candidate cases $\boldsymbol{o}_1^{'}, \ldots, \boldsymbol{o}_5^{'}$. For the sake of simplicity, we will set these cases in an imaginary legal system, which only has four laws (i.e., $K = 4$). Below, we illustrate how we would assign the type of precedent to each candidate case:

$$\begin{aligned}
\boldsymbol{o} &= [\emptyset, +, -, \emptyset] && \text{(Case at hand)} \\
\boldsymbol{o}_1' &= [\emptyset, +, \emptyset, \emptyset] && \text{(Applied positive)} \\
\boldsymbol{o}_2' &= [\emptyset, \emptyset, -, \emptyset] && \text{(Applied negative)} \\
\boldsymbol{o}_3' &= [\emptyset, \emptyset, +, \emptyset] && \text{(Distinguished positive)} \\
\boldsymbol{o}_4' &= [\emptyset, -, \emptyset, \emptyset] && \text{(Distinguished negative)} \\
\boldsymbol{o}_5' &= [\emptyset, \emptyset, \emptyset, +] && \text{(No precedent)}
\end{aligned}$$

	Train	Validation	Test
No. of Cases	8344	904	913
Art 2	463	56	55
Art 3	1223	169	173
Art 5	1255	176	154
Art 6	4434	276	272
Art 7	24	2	3
Art 8	638	76	111
Art 9	37	4	4
Art 10	268	39	66
Art 11	102	29	33
Art 13	1124	77	71
Art 14	119	17	11
P1-1	1307	130	116
P1-3	43	4	1
P4-2	31	3	4

Table 4: The number of cases in the precedent corpus and the representation of each ECtHR Article.

C A New Evaluation Metric

We now develop a novel evaluation metric to determine the degree to which a case's influence corresponds to whether or not it was used as a precedent by the model. To map a case's influence to the binary decision of whether or not the case was used as precedent, we design a simple classifier. And, to deal with the imbalanced nature of the classification (there are far more non-relevant cases than relevant ones), we evaluate the classifier with F_1. We omit this analysis from the main text because the conclusions drawn from it are nearly identical to those made in the main with more standard methods.

We now define the classifier formally. Given an influence score $\iota(\boldsymbol{z}, \boldsymbol{z}') = x$, we construct the classifier:

$$p(C_n = 1) = \frac{\exp(ax_n + b)}{1 + \exp(ax_n + b)} \tag{9}$$

where $C_n = 1$ indicates the n^{th} training case is considered precedent. The function to the right of Eq. (9) is a sigmoid function. Thus, we know that the classification boundary induced by Eq. (9) is:

$$ax + b \geq 0 \implies x + \frac{b}{a} \geq 0 \implies x \geq -\frac{b}{a} \tag{10}$$

Therefore, under Eq. (9), any parameters a and b give us a real value $-\frac{b}{a}$ such that a case is predicted to be precedent iff its influence is greater than $-\frac{b}{a}$.

		Model	Rand.	Gain
Simple	BERT	0.25	0.18	+0.07
	L-BERT	0.27	0.18	+0.09
Joint	BERT	0.21	0.18	+0.03
	L-BERT	0.21	0.18	+0.03

Table 5: The F_1 scores achieved by our models on the precedent retrieval task on the ECtHR corpus.

To learn the two parameters $a = \theta_0, b = \theta_1$, we optimize the log-likelihood:

$$\sum_{n=1}^{N} \log p(C_n = 1) + \kappa ||\boldsymbol{\theta}||_2^2 \qquad (11)$$

where $\kappa > 0$ is a small positive number used to break ties.

Precedent Classifier Results. We report the results of the above classifier in Tab. 5. In comparison to the random baseline, the influence scores are consistently a better predictor of whether or not a case has been used as a precedent. This finding holds over all models under consideration. The results also confirm our previous findings—Valvoda et al.'s (2023a) model underperforms Chalkidis and Søgaard's (2022) model. Furthermore, we find that a classifier on top of a model's influence scores does not score highly on the precedent prediction task. To contextualize these results, however, we note the results of Task 1 of the past two years of COLIEE competition, which is similar to our precedent retrieval above (but over a different dataset), indicate that this is a difficult problem to solve even for legal information retrieval models. For context, the best-performing teams in 2021 and 2022 scored 0.19 F_1 and 0.37 F_1 respectively on the data from the Federal Court of Canada case law (Rabelo et al., 2022; Kim et al., 2023).

D Experimental Details

In this section, we provide the details of our experimental setup.

Language Model Encoders. We use two Transformer-based (Vaswani et al., 2017) pretrained language models for our experiments. Following Chalkidis et al. (2019, 2022) we choose to work with base versions of BERT and LEGAL-BERT architectures.

- We use BERT (Devlin et al., 2019) because it is both a popular language model for benchmarking NLP models and also places at the top of LexGLUE (Chalkidis et al., 2022) leaderboard for Task A—outcome classification, which most closely resembles what our models are trained for. It also performs the best in the recent reformulation of the task by Valvoda et al. (2023a).

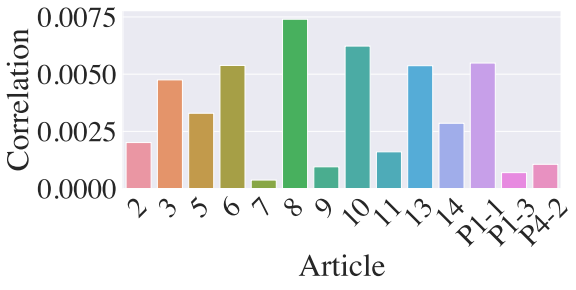
- Because BERT is not specifically trained on legal text, we additionally use LEGAL-BERT (Chalkidis et al., 2020), which has been fine-tuned on legal data. This allows us to see if exposure to legal language might affect the use of precedent by the model.

Training Procedure. The models are trained end-to-end by minimizing the cross-entropy between the model and the empirical distribution of the training data. We conduct a light hyper-parameter search over the learning rate $\{3e^{-4}, 3e^{-5}, 3e^{-6}\}$, size of hidden states d_2 in the MLP $\{50, 100, 200, 300\}$ and dropout rate $\{0.1, 0.2, 0.3, 0.4\}$. We train our models for a maximum of ten epochs with early stopping on validation loss.[7] The models are trained for a maximum of 2 hours on a single GPU. We report our results for the model that achieves the lowest loss on the validation set.

Influence Implementation. We rely on a PyTorch (Paszke et al., 2019) implementation of Koh and Liang's (2017) method,[8] a re-implementation of the original TensorFlow code by Pang Wei Koh.[9]

Calculating Correlations. We report our results in terms of Spearman's ρ. By calculating the influence score of every case in the training corpus on every decision in the test corpus, we can begin to quantify the use of precedent in neural models of legal outcome prediction by studying the correlation of the influence scores with our taxonomy of precedent; see §4. We store the scores as a vector $\boldsymbol{s} \in \mathbb{R}^M$, where M is the number of train cases times the number of test cases. Then, for each of our four categories of precedent, we create a binary vector $\boldsymbol{c} \in \{0, 1\}^M$. For each element in $\boldsymbol{s}$, $\boldsymbol{c}$ encodes whether the training case is that particular type of precedent 1 or not 0.

[7] We stop training when validation loss over an epoch stops improving.

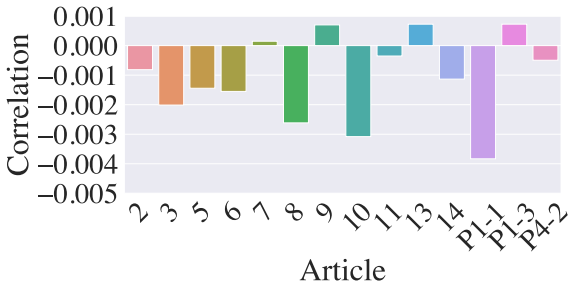


[8] A GitHub link to the implementation we rely on.

[9] A GitHub link to the original implementation by Koh.

We compute the correlation between $\boldsymbol{c}$ and $\boldsymbol{s}$ and report Spearman's ρ. Additionally, we compute the overall correlation over all types of precedent. To do this, we simply assign 1 in $\boldsymbol{s}$ to a case if it falls under *any* of the precedential categories.

E All Per-Article Results



Here we report the results of our per-article analysis. The correlations for individual legal Articles follow the trends reported in §7.

F Derivation of the Influence Score

We derive Eq. (5) below. Consider the following bivariate function of $\boldsymbol{\theta}$ and ε

$$F(\boldsymbol{\theta}, \varepsilon) \stackrel{\text{def}}{=} \nabla_{\boldsymbol{\theta}} L(\boldsymbol{\theta}) + \alpha \mathcal{R}(\boldsymbol{\theta}) + \varepsilon \ell_{\boldsymbol{z}}(\boldsymbol{\theta}) = 0 \tag{12}$$

Under suitable regularity conditions on F (Rudin, 1976, Chapter 9), the implicit function theorem guarantees us the following:

1. There exists a function $\boldsymbol{\theta}_z^\star(\varepsilon)$ of ε such that $F(\boldsymbol{\theta}_z^\star(\varepsilon), \varepsilon) = 0$ in a certain neighborhood;
2. $\boldsymbol{\theta}_z^\star(\varepsilon)$ is once differentiable with respect to ε on that neighborhood.

See Rudin (1976, Chapter 9) for more detailed treatment. We now seek to derive $\frac{\mathrm{d}\boldsymbol{\theta}_z^\star(\varepsilon)}{\mathrm{d}\varepsilon}$. We start with the linearity of the gradient

$$0 = \nabla_{\boldsymbol{\theta}}(L(\boldsymbol{\theta}_z^\star(\varepsilon)) + \alpha \mathcal{R}(\boldsymbol{\theta}_z^\star(\varepsilon)) + \varepsilon \ell_{\boldsymbol{z}}(\boldsymbol{\theta}_z^\star(\varepsilon))) = \nabla_{\boldsymbol{\theta}} L(\boldsymbol{\theta}_z^\star(\varepsilon)) + \alpha \nabla_{\boldsymbol{\theta}} \mathcal{R}(\boldsymbol{\theta}_z^\star(\varepsilon)) + \varepsilon \nabla_{\boldsymbol{\theta}} \ell_{\boldsymbol{z}}(\boldsymbol{\theta}_z^\star(\varepsilon)) \tag{13}$$

Consider the following manipulation based on taking a derivative with respect to ε:

$$0 = \frac{\mathrm{d}0}{\mathrm{d}\varepsilon} = \frac{\mathrm{d}\left(\nabla_{\boldsymbol{\theta}} L(\boldsymbol{\theta}_z^\star(\varepsilon)) + \alpha \nabla_{\boldsymbol{\theta}} \mathcal{R}(\boldsymbol{\theta}_z^\star(\varepsilon)) + \varepsilon \nabla_{\boldsymbol{\theta}} \ell_{\boldsymbol{z}}(\boldsymbol{\theta}_z^\star(\varepsilon))\right)}{\mathrm{d}\varepsilon} \tag{14a}$$

$$= \frac{\mathrm{d}\nabla_{\boldsymbol{\theta}} L(\boldsymbol{\theta}_z^\star(\varepsilon))}{\mathrm{d}\varepsilon} + \alpha \frac{\mathrm{d}\nabla_{\boldsymbol{\theta}} \mathcal{R}(\boldsymbol{\theta}_z^\star(\varepsilon))}{\mathrm{d}\varepsilon} + \frac{\mathrm{d}\varepsilon \nabla_{\boldsymbol{\theta}} \ell_{\boldsymbol{z}}(\boldsymbol{\theta}_z^\star(\varepsilon))}{\mathrm{d}\varepsilon} \tag{14b}$$

$$= \frac{\mathrm{d}\nabla_{\boldsymbol{\theta}} L(\boldsymbol{\theta}_z^\star(\varepsilon))}{\mathrm{d}\varepsilon} + \alpha \frac{\mathrm{d}\nabla_{\boldsymbol{\theta}} \mathcal{R}(\boldsymbol{\theta}_z^\star(\varepsilon))}{\mathrm{d}\varepsilon} + \nabla_{\boldsymbol{\theta}} \ell(\boldsymbol{z})(\boldsymbol{\theta}_z^\star(\varepsilon)) + \varepsilon \frac{\mathrm{d}\nabla_{\boldsymbol{\theta}} \ell_{\boldsymbol{z}}(\boldsymbol{\theta}_z^\star(\varepsilon))}{\mathrm{d}\varepsilon} \tag{14c}$$

$$= \nabla_{\boldsymbol{\theta}}^2 L(\boldsymbol{\theta}_z^\star(\varepsilon)) \frac{\mathrm{d}\boldsymbol{\theta}_z^\star(\varepsilon)}{\mathrm{d}\varepsilon} + \alpha \nabla_{\boldsymbol{\theta}}^2 \mathcal{R}(\boldsymbol{\theta}_z^\star(\varepsilon)) \frac{\mathrm{d}\boldsymbol{\theta}_z^\star(\varepsilon)}{\mathrm{d}\varepsilon} + \nabla_{\boldsymbol{\theta}} \ell_{\boldsymbol{z}}(\boldsymbol{\theta}_z^\star(\varepsilon)) + \varepsilon \nabla_{\boldsymbol{\theta}}^2 \ell_{\boldsymbol{z}}(\boldsymbol{\theta}_z^\star(\varepsilon)) \frac{\mathrm{d}\boldsymbol{\theta}_z^\star(\varepsilon)}{\mathrm{d}\varepsilon} \tag{14d}$$

Now, we have

$$-\nabla_{\boldsymbol{\theta}} \ell_{\boldsymbol{z}}(\boldsymbol{\theta}_z^\star(\varepsilon)) = \nabla_{\boldsymbol{\theta}}^2 L(\boldsymbol{\theta}_z^\star(\varepsilon)) \frac{\mathrm{d}\boldsymbol{\theta}}{\mathrm{d}\varepsilon} + \alpha \nabla_{\boldsymbol{\theta}}^2 \mathcal{R}(\boldsymbol{\theta}_z^\star(\varepsilon)) \frac{\mathrm{d}\boldsymbol{\theta}}{\mathrm{d}\varepsilon} + \varepsilon \nabla_{\boldsymbol{\theta}}^2 \ell_{\boldsymbol{z}}(\boldsymbol{\theta}_z^\star(\varepsilon)) \frac{\mathrm{d}\boldsymbol{\theta}}{\mathrm{d}\varepsilon} \tag{15a}$$

$$= \left(\nabla_{\boldsymbol{\theta}}^2 L(\boldsymbol{\theta}_z^\star(\varepsilon)) + \alpha \nabla_{\boldsymbol{\theta}}^2 \mathcal{R}(\boldsymbol{\theta}_z^\star(\varepsilon)) + \varepsilon \nabla_{\boldsymbol{\theta}}^2 \ell_{\boldsymbol{z}}(\boldsymbol{\theta}_z^\star(\varepsilon))\right) \frac{\mathrm{d}\boldsymbol{\theta}}{\mathrm{d}\varepsilon} \tag{15b}$$

Evaluating the expression at $\varepsilon = 0$, we arrive at

$$\frac{\mathrm{d}\boldsymbol{\theta}_z^\star(\varepsilon)}{\mathrm{d}\varepsilon}\Big|_{\varepsilon=0} = -\left(\nabla_{\boldsymbol{\theta}}^2 L(\boldsymbol{\theta}^\star) + \alpha \nabla_{\boldsymbol{\theta}}^2 \mathcal{R}(\boldsymbol{\theta}^\star)\right)^{-1} \nabla_{\boldsymbol{\theta}} \ell_{\boldsymbol{z}}(\boldsymbol{\theta}^\star) \tag{16}$$

where $\boldsymbol{\theta}^\star$ are the parameters obtained in Eq. (3).

G Additional Results

Abstract

Large language models (LLMs) are known to generate biased responses where the opinions of certain groups and populations are underrepresented. Here, we present a novel approach to achieve controllable generation of specific viewpoints using LLMs, that can be leveraged to produce multiple perspectives and to reflect the diverse opinions. Moving beyond the traditional reliance on demographics like age, gender, or party affiliation, we introduce a data-driven notion of *persona* grounded in collaborative filtering, which is defined as either a single individual or a cohort of individuals manifesting similar views across specific inquiries. As individuals in the same demographic group may have different personas, our data-driven persona definition allows for a more nuanced understanding of different (latent) social groups present in the population. In addition to this, we also explore an efficient method to steer LLMs toward the personas that we define. We show that our data-driven personas significantly enhance model steerability, with improvements of between $57\% - 77\%$ over our best performing baselines.

1 Introduction

In the recent past, Large Language Models (LLMs; Brown et al. 2020; Ouyang et al. 2022; OpenAI 2023; Touvron et al. 2023) have shown exceptional generation capabilities across a range of tasks (Zhao et al., 2023) that have led to their adoption in applications pertaining to multiple high-stakes fields such as healthcare (Singhal et al., 2023), education (Tan et al., 2023) and finance (Wu et al., 2023). Given this context, it is of utmost importance to avoid biases towards specific underrepresented populations, and leverage LLMs in a way that enables generation across a broad spectrum of viewpoints in a balanced way.

In practice, LLMs have been shown to generate responses that represent a wide range of opinions, with tendencies to over-represent the opinions of certain populations while under-representing those of others. For example, Santurkar et al. (2023) showed that LLMs under-represent the opinions of individuals aged 65 and over, Mormons, and the widowed, which constitute significant portions of the US population. The reason for this is that the typical fine-tuning of an LLM, done across datasets at hand, leads to a model gaining a randomized viewpoint based on the nature of the dataset.

Instead of fine-tuning towards such a randomized viewpoint, it is desirable to enable LLMs to have *controllable generation* that can be steered towards specific viewpoints. This can be leveraged to produce multiple perspectives and in turn encourage diversity through the curated inclusion of a broad spectrum of viewpoints. Such a diverse set of perspectives, enabled via controllable generation, can be extremely helpful in diminishing polarization and preventing the marginalization of the voices of minority groups.

Prior work has attempted to control LLM generation by aligning models toward demographic groups that are defined based on features such as age, gender, political party affiliation (Santurkar et al., 2023; Hwang et al., 2023; Simmons, 2022; Jiang et al., 2022; Feng et al., 2023; Salewski et al., 2023). However, we argue that a simple group definition based on demographic features might not be sufficient to represent the nuances of the underlying different social groups present in a given population.

In this paper, we present a new approach to achieve controllable generation of specific viewpoints using LLMs. We hypothesize that for a given dataset comprising of responses provided by a population of individuals to a set of questions, there is a space of differing characteristic opinions and beliefs. We map this space to an embedding

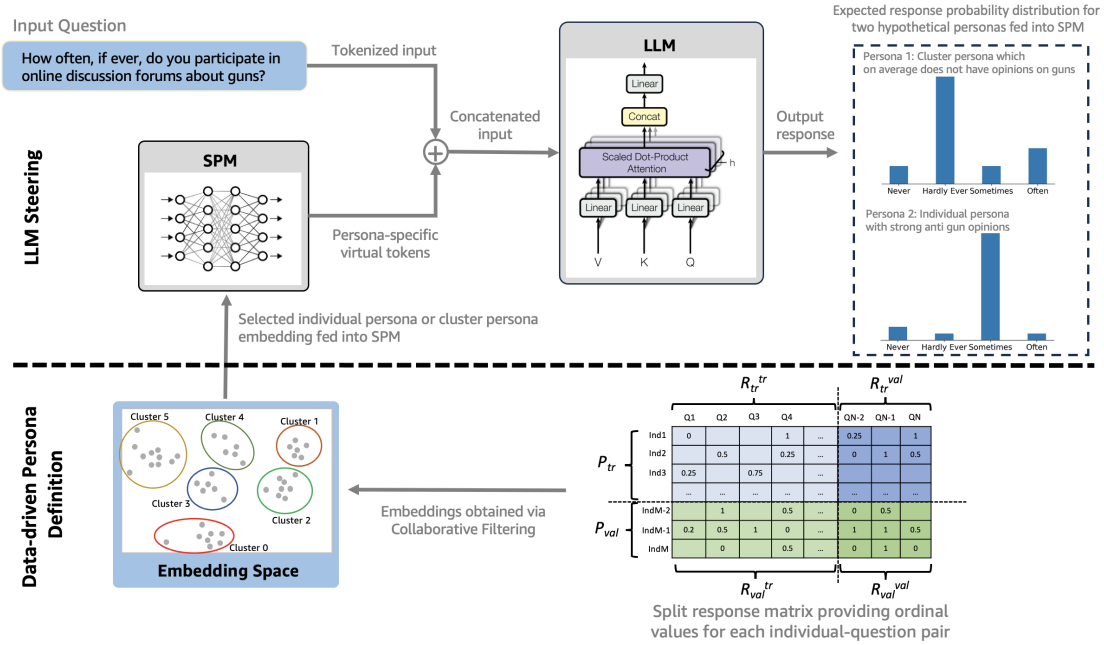

Figure 1: A schematic of our framework for steering LLMs toward data-driven personas. The bottom-half illustrates the formation of data-driven personas, and the top-half illustrates LLM steering. A persona is defined by generating individual embeddings via collaborative filtering. The persona can be a single individual embedding (grey dots) or the centroid of a group of embeddings, referred to as a cluster persona (denoted by the circled clusters). To steer the LLM we pass an embedding to a soft-prompting model (SPM), which maps the embedding to a set of persona-specific virtual tokens. Finally we prepend these virtual tokens to the tokenized input sequence and pass this into the LLM to obtain a persona-specific response.

space. We then propose the notion of *personas*, as examples from within this personality space. We use the term *persona* to refer to a portion of the embedding space which represents similar opinions and beliefs over a set of questions in our dataset of choice. This could range from a single individual embedding, referred to as an *individual persona*, to a group of individual embeddings represented by their centroid in embedding space, referred to as a *cluster persona*. To create this mapping we take a data-driven approach using collaborative-filtering to embed individuals into a continuous vector space which, to our knowledge, has not been done before. Compared to the use of traditional demographic traits, our definition of personas allows for nuanced understanding of different social groups in the population and makes the notion of steerability more meaningful.

Given these data-driven personas, we then propose an efficient algorithm to steer LLMs towards both an individual and a cluster persona. In particular, we learn a soft-prompting model (SPM) which maps the embedding of a persona to a set of virtual tokens. These virtual tokens are prepended before tokens mapping to the actual input text, to steer the responses of the LLMs.

We conduct a number of experiments using the OpinionQA dataset (Santurkar et al., 2023) to evaluate the efficacy of our persona definition and the LLM steering algorithm. Our experiments show that LLMs steered via personas can align to the opinions of individuals and groups better than baseline methods. In particular, the personas defined using our approach result in more accurate prediction of opinions when compared to the use of personas based on demographic-traits.

We summarize our **contributions** as follows:

- We propose a hitherto unexplored paradigm in steerable generation where, instead of predefined demographic features, we use a data-driven notion of a persona to modulate the generation process. In particular, we use collaborative-filtering to embed opinions of individuals within a dataset into a continuous vector space (individual personas), and then cluster groups of individuals with similar embeddings (cluster personas).

- We propose a simple model and an efficient algorithm to align LLMs with these personas

(both individuals and clusters).

- Finally, we benchmark our approach using a selected set of LLMs.

2 Related Work

Steering LLMs: In the recent past, several studies have investigated opinions expressed by LLMs (Santurkar et al., 2023; Durmus et al., 2023; Scherrer et al., 2023; Santy et al., 2023). For example, Santurkar et al. (2023) curated the OpinionQA dataset based on public opinion polls and evaluated the alignment of LLM opinions with 60 U.S. demographic groups. They found a substantial misalignment between the views reflected by current LLMs and those of U.S. demographic groups (we mention a cross section of these in Section 1). In another case, Scherrer et al. (2023) designed a survey comprising both high-ambiguity and low-ambiguity moral scenarios to study the moral beliefs encoded in different LLMs.

A variety of methods have also been proposed to steer the generation of LLMs toward specific opinions (Hwang et al., 2023; Simmons, 2022; Durmus et al., 2023; Argyle et al., 2023; Deshpande et al., 2023; Jiang et al., 2022; Feng et al., 2023). For instance, Santurkar et al. (2023) added demographic information (such as Democratic or Republican affiliations) to prompts in order to steer the opinions of LLMs toward those groups. Hwang et al. (2023) worked towards aligning LLMs with individuals by incorporating their past opinions. Simmons (2022) constructed four prompts based on combinations of *liberal* and *conservative* political identities, as well as moral and immoral stances, to steer the moral beliefs of LLMs. Jiang et al. (2022) fine-tuned LLMs using tweets authored by Democrats and Republicans to improve the model's alignment with the opinions of these groups.

In contrast to this prior work, which steer LLMs based on demographic traits, our approach using data-driven personas allows for a more expressive and nuanced understanding of the different social groups present in the overall population. This, in turn, enhances the applicability of model steerability.

Parameter-Efficient Fine Tuning: Given the rapid increase in size of LLMs, fine-tuning the full model has become costly, giving rise to various methods that only tune a portion of model parameters (Hu et al., 2021; Lester et al., 2021; Li and Liang, 2021; Liu et al., 2021, 2022; Zhang et al., 2023; Ozdayi et al., 2023). In one such approach, Hu et al. (2021) utlize low-rank decomposition to represent weight updates with two smaller matrices (called update matrices), and then only fine-tune the decomposition matrix. Several approaches have been proposed where virtual tokens can be tuned to align a model towards a specific task. Lester et al. (2021) trains a sequence of virtual tokens that have been prepended to the input whereas Li and Liang (2021) optimize a task-specific vector of virtual tokens called the prefix. Zhang et al. (2023) address the instability at the initial training phase using a learnable gate to control the effect of virtual tokens over generation.

3 Framework

In this section, we propose the notion of data-driven personas (Section 3.1) and an efficient algorithm for steering an LLM towards them (Section 3.2). An illustration of our process is shown in Figure 1.

3.1 Data-driven persona definition

Instead of relying on demographic information such as age, gender or party affiliation, we use collaborative filtering to embed all individuals into a continuous vector space based on their opinions. Then a *persona* is defined as a portion of the embedding space which represents similar opinions and beliefs. In particular, an *individual persona* is represented by a single individual embedding, while a *cluster persona* is represented by the centroid of a cluster of individuals.

Assume we have a set of questions $\mathcal{Q}$, consisting of multiple-choice questions that feature options with an ordinal structure. Furthermore, assume that we also have responses for these questions, given by a set of individuals $\mathcal{P}$. We represent these responses as a matrix R. If individual i responds to question j, the element $r_{i,j} \in [0, 1]$ represents the individual i's response, where the responses are mapped to the interval $[0, 1]$. If no response is given, $r_{i,j}$ is set to null. $\mathcal{R} = \{(i, j), \text{where } r_{i,j} \text{ is not null}, i \in \mathcal{P}, j \in \mathcal{Q}\}$ denotes the full set of responses. We utilize collaborative filtering (CF) to learn a continuous representation for each individual. More specifically, we denote the individual embeddings as $\{u_i \in \mathbb{R}^d, i \in \mathcal{P}\}$ and the question embeddings as $\{q_j \in \mathbb{R}^d, j \in \mathcal{Q}\}$ and optimize the following

objective:

$$\underset{\substack{\{u_i \in \mathbb{R}^d, i \in \mathcal{P}\} \\ \{q_j \in \mathbb{R}^d, j \in \mathcal{Q}\}}}{min} \sum_{(i,j)\in\mathcal{R}} \mathcal{L}(\langle u_i, q_j \rangle, r_{i,j}) \quad (1)$$

where $\mathcal{L}$ is a loss objective, *e.g.* the mean square error; $\langle\cdot\rangle$ denotes the inner product.

By optimizing the objective in (1), we obtain the converged embeddings $\{u_i \in \mathbb{R}^d, i \in \mathcal{P}\}$ that encode important information about individual opinions. We explore steerability towards individual embeddings (*individual personas*), as well as towards clusters of individuals with similar opinions within the overall population (*cluster personas*).

3.2 Steering LLMs towards data-driven personas

For steering LLMs towards the personas defined in Section 3.1, we draw from the *prefix-tuning* technique (Li and Liang, 2021) which prepends and tunes a set of prefix-vectors to each model layer that yields improvements in model generation towards specific tasks (Lester et al., 2021; Ozdayi et al., 2023; Li and Liang, 2021; Liu et al., 2021, 2022). In our approach, we use a separate model that we refer to as the soft-prompting model (SPM), to map a given embedding (of a persona) from our continuous vector space, to a set of prefix-vectors. These are prepended to the tokenized input (in this case the tokenized question) and enables the steering of the generation process towards that specific persona. A schematic of this process if shown in the top-half of Figure 1.

Unlike vanilla prefix-tuning which trains a single set of virtual tokens for a given task, our method uses a single SPM to generate a sets of virtual tokens for all personas in our dataset. This is beneficial in that it is cost effective and also performant, since personas with proximate embeddings often reflect analogous opinions.

We train the SPM by optimizing the following objective:

$$\underset{\theta\in\Theta}{min} \sum_{(i,j)\in\mathcal{R}} \mathcal{L}(\text{LLM}(f(u_i;\theta), \text{Q}_j), \text{R}_{i,j}) \quad (2)$$

where $\mathcal{R}$ is the set of responses, Q_j is the tokenized representation of question j, $R_{i,j}$ is the tokenized representation of the response of individual i to question j, u_i is the embedding of individual i, $f(\cdot;\theta)$ denotes the SPM parameterized by θ, and $\mathcal{L}$ denotes the loss objective, which in this case is cross entropy loss. During SPM training, the LLM weights are frozen and we only use individual embeddings, then during inference, we fix the weights of the SPM and steer the LLM generation towards the opinions of a specific persona by feeding its embedding as the input to the SPM.

To test the robustness of our technique to other prompting methods, we also test if our method works when using prompt-tuning (Lester et al., 2021) (as opposed to prefix-tuning Li and Liang 2021). For details, please see Appendix A.5.

4 Experimental results

In this section we present our data, experimental setup and empirical results on data-driven persona definition and LLM steerability.

4.1 Dataset Details

We use the OpinionQA dataset (Santurkar et al., 2023) which includes opinions of a diverse set of individuals over a wide range of different topics, for our work. The OpinionQA dataset is curated from 15 American Trends Panel polls, and encompasses responses from 18,339 participants to 1,476 multiple-choice questions across 23 different topics. A full list of topics covered by OpinionQA is provided in Appendix A.1. The demographic information for each participant (i.e., Race, Ideology, Education etc.) are included in the dataset and we also include this information in Appendix A.1.

The response options for each question in the OpinionQA dataset is presented as ordinals, and we map each option to a numerical value. For example, for one set of response options *Worry a lot*, *Worry a little*, and *Not worry at all*, we assign values of 0, 0.5, and 1, respectively. We then use the numerical values of the responses as labels in equation (1) to learn the individual embeddings.

4.2 Analysis of cluster personas

Here, we present an analysis of the cluster personas obtained from our data-driven approach described in Section 3.1.

Cluster Definition: We employ the matrix factorization approach (Eq. (1)) to perform collaborative filtering. We embed individuals and questions into a 16-dimensional space and employ mean square error as our training objective. The learned individual embeddings are referred to as *individual personas*. As for *cluster personas*, we cluster individual embeddings using K-Means clustering.

We run K-Means with varying numbers of clusters, denoted as k, and for each value of k, we replace individual embeddings with the centroids of each cluster to evaluate Eq. (1). This measures how well the cluster centroids can represent individuals and we use it as the criteria to select k. Specifically, we utilize the *elbow* heuristic (Bishop, 2006) to choose $k = 6$, and we label these clusters as Cluster-X, where X ranges from 0 to 5, which represent the six cluster personas that we choose.

For each cluster persona, we present the demographic composition across 13 different traits. We also detail the characteristics of opinions within each cluster, specifying questions for which a cluster disagrees with the overall population and questions where the clusters disagree with each other.

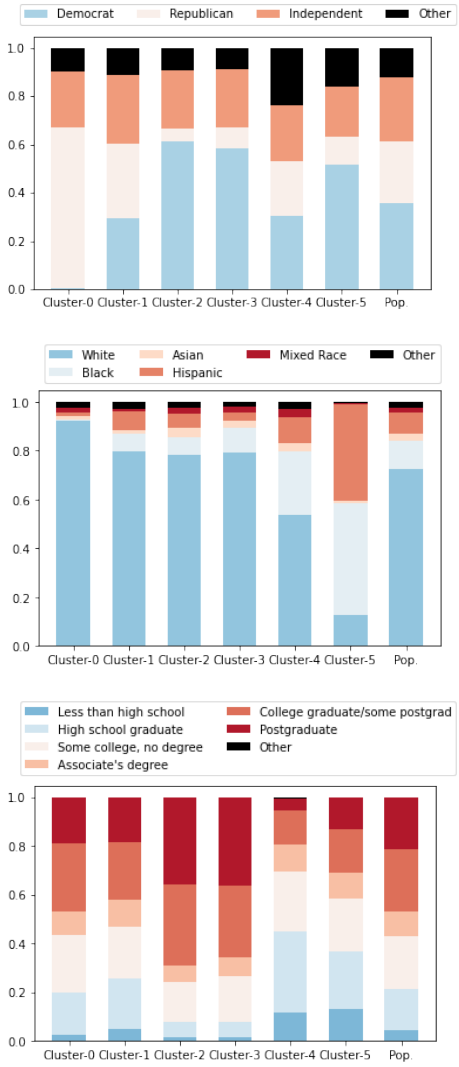

Figure 2: The Political Party, Race and Education composition (from top to bottom) of clusters and overall population.

Demographic Composition of Clusters: We calculate the demographic statistics for each cluster and summarize the results for Political Party, Race and Education composition in Figure 2 (compositions of other traits are summarized in Figure 3 in the Appendix A.5). Our analysis reveals that these clusters have distinct demographic compositions. For instance, in terms of political party, cluster-0 and cluster-1 lean toward Republican, while all other clusters lean toward Democrat. In terms of race, cluster-5 is dominated by Black and Hispanic races, while other clusters are dominated by the White race as in the overall population. In terms of education level, while cluster-0 and cluster-1 are dominated by members who received a college level education, cluster 2 and cluster-3 have a majority of members that have received post-graduate level education. In cluster-4 and cluster-5, the majority of members only received a high school level education. We also find that clusters are composed of a mixture of different demographic groups, which corroborates the fact that individuals with different demographic traits can hold similar opinions over many topics. This further verifies the necessity of defining groups based on actual opinion as opposed to depending solely on demographic characteristics.

Questions for which a cluster disagrees with the overall Population: To further investigate the characteristics of each cluster, we show questions where a cluster mostly disagrees with the opinion of the overall population. For each cluster, we calculate the response distribution to each question, where we denote the distribution of cluster c over question q as $D_{c,q}$ for $c \in [5], q \in \mathcal{Q}$. Similarly, we calculate the overall population response distribution over each question and denote it as D_q. For each question $q \in \mathcal{Q}$, we calculate the Total Variation (TV) between the cluster response distribution and the overall population response distribution $TV(D_{i,q}, D_q), i \in [5]$.

Note that a larger value of $TV(q)$ indicates a greater degree of disagreement between the cluster and the overall population for a given question. In Table 1, we show the three questions with the largest total variation between cluster response distribution and overall population response distribution for cluster-0. We show the corresponding questions for clusters 1 to 5 in Tables 12 to 16 respectively, in the Appendix. Taking Cluster-0 as an example, we find that its members feel that

Table 1: Comparison of responses between Cluster 0 and the overall population

Question	Cluster 0 Response	Overall Population Response
How much, if at all, do you think the following proposals would do to reduce economic inequality in the U.S.? Expanding government benefits for the poor	A great deal: 0.0% A fair amount: 2.27% **Not too much: 71.55%** Nothing at all: 26.16%	A great deal: 34.19% **A fair amount: 43.7%** Not too much: 19.83% Nothing at all: 2.26%
How much, if at all, do you think the ease with which people can legally obtain guns contributes to gun violence in the country today?	A great deal : 0.11% A fair amount: 22.86% **Not too much: 72.46%** Not at all: 4.55%	**A great deal : 46.86%** A fair amount: 38.02% Not too much: 14.51% Not at all: 0.6%
How well does the Democratic party represent the interests of people like you?	Very well: 0.0% Somewhat well: 0.0% Not too well: 11.94% **Not at all well: 88.05%**	Very well: 4.97% **Somewhat well: 44.87%** Not too well: 31.93% Not at all well: 18.21%

Table 2: Questions pertaining to immigration that exhibit the most disagreement among clusters

Question	Cluster	Response
If you were deciding what the federal government should do to improve the quality of life for future generations, what priority would you give to who come here legally? Allowing more immigrants into the U.S.	Cluster-0 Cluster-1 Cluster-2 Cluster-3 Cluster-4 Cluster-5	A lower priority (72.81%) Top priority (99.05%) Important, but not top priority (80.44%) Important, but not top priority (89.87%) Important, but not top priority (63.92%) Top priority (69.51%)
How much, if at all, do you think the following proposals would do to reduce economic inequality in the U.S.? Reducing illegal immigration	Cluster-0 Cluster-1 Cluster-2 Cluster-3 Cluster-4 Cluster-5	A great deal (60.63%) A great deal (95.58%) Not too much (68.95%) Not too much (68.67%) A fair amount (69.41%) A fair amount (69.67%)

expanding government benefits for the poor will not reduce economic inequality in the US, while we see over 75% individuals in the overall population believe helping the poor helps to reduce the economic inequality a great deal or a fair amount. They also believe that allowing people to easily obtain guns legally, does not contribute to gun violence in the country. In contrast, over 46% of the overall population believes that it does contribute to gun violence. Finally, when queried on how well the democratic party represented the interests of its members, 88.05% of individuals in cluster-0 responded with *Not at all well*. In contrast, only 18.21% of the overall population choose this option. Given that cluster-0 is mainly composed of Republicans, it is not surprising that the group has a clear mistrust of Democrats.

Questions that differentiate clusters: Finally, we show questions that elicit the most varied responses across the different clusters we have identified. More formally, we compute the average total variation between cluster pairs for each question as below:

$$TV_{Ave}(q) = \frac{1}{\binom{6}{2}} \sum_{0 \le i < j \le 5} TV(D_{i,q}, D_{j,q}) \quad (3)$$

Note that a larger value of $TV_{Ave}(q)$ indicates a greater degree of disagreement among clusters for that particular question. In Table 2, we present questions related to immigration topic that exhibit the greatest average total variation across clusters. The responses to these questions show interesting characteristics of each cluster. When considering the Immigration related topics, cluster-0, cluster-1 and cluster-5 have polarized attitudes, while the attitudes from other clusters are milder. In particular, Cluster-0 believes that a low priority should be assigned to allowing more legal immigrants, while placing importance on reducing the number of illegal immigrants. Cluster-1 and Cluster-5 believe that allowing more legal immigrants should be a top priority and that it is crucial to reduce illegal immigration. Cluster-2 and Cluster-3 assert that allowing more legal immigrants is not a top priority, and that reducing illegal immigration does not

significantly affect economic inequality. Cluster-4 believes that allowing more legal immigrants is not a top priority. However, it also believes that reducing illegal immigrants could reduce economic inequality. In addition to questions related to immigration, the clusters also show disagreement in other questions belonging to topics such as the Crime (Table 17) and Race (Table 18).

4.3 Steering LLMs towards personas

In this section, we benchmark the steerability of various LLMs toward personas defined in Sections 3.1. We follow the procedure described in Section 3.2 and use prediction accuracy for evaluating performance. Prediction accuracy, in this case, is defined as the macro average of individual prediction accuracy (i.e., the percentage of questions where the LLM correctly predicts a particular individual's responses, averaged over all individuals).

We compare the performance of our algorithm against the following baselines:

1. **Raw Q.** (Santurkar et al., 2023): LLMs are only prompted with questions.

2. **Demographics + Raw Q.** (Santurkar et al., 2023; Hwang et al., 2023): the demographic traits of each individual are provided as context information.

3. **Context + Raw Q.** (Hwang et al., 2023): a set of responses by the individual are provided as context information.

We randomly split the individuals in the OpinionQA dataset into train ($\mathcal{P}_{tr}$) and evaluation ($\mathcal{P}_{val}$) partitions (represented in blue and green respectively, in Figure 1). Accordingly, the responses in each partition can be referred to as $\mathcal{R}_{tr} = \{(i,j), \text{where } r_{i,j} \text{ is not null}, i \in \mathcal{P}_{tr}, j \in \mathcal{Q}\}$ and $\mathcal{R}_{val} = \{(i,j), \text{where } r_{i,j} \text{ is not null}, i \in \mathcal{P}_{val}, j \in \mathcal{Q}\}$. Next, we randomly split the response sets in each partition above, into their own train and validation sets, which leaves us with the four sets that can be denoted as $\mathcal{R}^{tr}_{tr}$, $\mathcal{R}^{val}_{tr}$, $\mathcal{R}^{tr}_{val}$ and $\mathcal{R}^{val}_{val}$ (represented in light-blue, dark-blue, light-green and dark-green respectively, in Figure 1).

For our method, we first use the responses in $\mathcal{R}^{tr}_{tr}$ to optimize Eq. (1) to get $U^*_{tr} = \{u_i \in \mathbb{R}^d, i \in \mathcal{P}_{tr}\}$ and $Q^* = \{q_j \in \mathbb{R}^d, j \in \mathcal{Q}\}$. Next, we use $\{u_i \in \mathbb{R}^d, i \in \mathcal{P}_{tr}\}$ and $\mathcal{R}^{tr}_{tr}$ to train the SPM (Eq. (2)). We then report the average prediction accuracy of our steered LLMs over $\mathcal{R}^{val}_{tr}$ in Table 3. For the **Context + Raw Q.** baseline, we use $\mathcal{R}^{tr}_{tr}$ to provide context questions. In particular, for a given question, we identify the K most closely related questions within the training set, that the individual has responded to, to serve as the context. The similarity of these questions is measured using cosine distance bewteen the embeddings of the question (we employ the `text-embedding-ada-002` (OpenAI, 2023) model created by OpenAI to obtain the embeddings). The **Raw Q.** and **Demographics + Raw Q.** baselines do not use the train split. As in the case of our steered LLMs, we report the average prediction accuracy over $\mathcal{R}^{val}_{tr}$ for all baselines.

4.3.1 Individual opinion prediction

In Table 3, we present the average prediction accuracy of our method compared against the baselines. Note that for the **Demographics + Raw Q.** baseline, we include 13 different demographic traits in the prompt, and for the **Context + Raw Q.** baseline, we set $K = 5$ (an ablation study of different K values is presented in Table 8). Our method outperforms all baselines significantly, with improvements of $57\% - 77\%$ over the best performing baseline for each model. We observe that when LLMs are provided with only the questions, their responses have low alignment with the individuals' responses. Including demographics traits in addition to responses to related questions tends to improve alignment. However, the LLMs still lack information about the individual which causes lower prediction accuracy. In contrast, our method, which steers the LLM utilizing the embeddings learned via CF, that encode knowledge about the overall opinions of a given individual, show higher prediction accuracy.

4.3.2 Effectiveness of the SPM

We verify the effectiveness of training the SPM by comparing the prediction accuracy with and without SPM training. As shown in Table 4, the prediction accuracy clearly increases when the SPM is trained. This justifies the use of the SPM to map individual embeddings to the LLM embedding space.

4.3.3 Performance of cluster personas

We explore how well cluster persona embeddings can predict an individual's opinion. For this, we replace an individual's embedding with their corresponding cluster embedding (**CE**). For an individual belonging to cluster i, their corresponding

Table 3: Prediction accuracy across baselines and our experimental method.

Model	Raw Q.	Demographic + Raw Q.	Context + Raw Q.	Individual Embeddings (Ours)
GPT-Neo-1.3B	32.54%	33.40%	33.82%	**59.99%**
GPT-Neo-2.7B	31.09%	34.32%	30.43%	**60.59%**
GPT-j-6B	26.50%	31.86%	39.34%	**61.84%**
Falcon-7B-Instruct	36.10%	38.40%	37.96%	**60.78%**

Table 4: Prediction accuracy with and without training the SPM.

Model	Random SPM Weights	Trained SPM Weights
GPT-Neo-1.3B	7.92%	**59.99%**
GPT-Neo-2.7B	8.31%	**60.59%**
GPT-j-6B	23.26%	**61.84%**
Falcon-7B-Instruct	38.20%	**60.78%**

cluster embedding is the centroid of the embeddings of *all* individuals belonging to the cluster i. The prediction accuracy is shown in the last two columns of Table 5. We see **CE**s get close performance as individual embeddings (around $8\%-12\%$ difference). Furthermore, we also compare **CE**s with the demographic group embedding (**DE**) in Table 5. **DE** is the centroid of individual embeddings belonging to the same demographic group. For instance, for an individual who belongs to the Democrat party, we use a demographic embedding that is the average of the embeddings of all the individuals who belong to the Democrat party. We see that the use of **CE**s provide improvements of between $0.23\% - 2.59\%$ over **DE**s. Note that for **DE**s, we consider the political party trait that consists of six parties and shows the highest prediction accuracy, compared to other demographic traits (shown separately in Table 9 in the Appendix). For **CE**s, we present results using six clusters in Table 5, which enables us to obtain better prediction accuracy than any demographic trait. As shown in Table 11 in the Appendix, increasing the number of clusters can yield much higher prediction accuracies.

4.3.4 Generalization to unseen individuals

We also run an ablation test to see if the steered LLM can generalize to **unseen individuals**. Here, we use responses from the set $\mathcal{R}^{tr}_{val}$ to get embeddings U^*_{val} for individuals in $\mathcal{P}_{val}$. $\mathcal{R}^{tr}_{val}$ contains a small number of responses for each individual and the question embeddings are fixed as Q^* (learned based on $\mathcal{P}_{tr}$ as defined in Section 4.3). Note that the SPM, trained on $\mathcal{P}_{tr}$, has not seen any responses from $\mathcal{P}_{val}$. We explore the use of different numbers of responses (K) from $\mathcal{R}^{tr}_{val}$ to generate the embeddings for the unseen individuals. In Table 6, we report the prediction accuracies for our models over $\mathcal{R}^{val}_{val}$ for these experiments and for our baselines. We see, even in the case of using a single response per individual, our method generalizes better to unseen individuals compared to the baselines. Furthermore, the prediction accuracies increase as we use more responses (K) to get more accurate embeddings. See Appendix A.5 for further results.

5 Conclusion

In this work, we present an approach for steerable generation using LLMs, where we utilize a data-driven notion of a persona to modulate the generation process. We proposed an simple model and efficient algorithm to align LLMs with these personas (both individuals and clusters). We validate the efficacy of our algorithm using the OpinionQA dataset. For a select set of LLMs we show that our method out-performs traditional steering mechanisms supporting our hypothesis that LLMs align with individuals' opinions better when leveraging our data-driven personas.

Limitations

There are some limitations to the work we present here. Firstly, we rely on the QA format to perform collaborative filtering and embed individuals into an embedding space. Secondly, we only test our approach over one dataset due to time and resource constraints. However, we note that our method should scale well to other similar datasets. Thirdly, in this work we only test prefx-tuning (Lester et al., 2021) and prompt-tuning (Lester et al., 2021) for steering LLMs. Other parameter efficient fine tuning methods such as LoRA (Hu et al., 2021), $(IA)^3$ (Liu et al., 2022) *etc.* can also be incorporated into our approach.

Table 5: Prediction accuracy with different types of personas. For Demographic Embedding results we present only the political party trait (PARTY) which consists of 6 groups (see other demographic traits in Table 9).

Model	Demographic Embeddings [PARTY (6)]	Cluster Embeddings [6 Clusters]	Individual Embeddings (Ours)
GPT-Neo-1.3B	55.16%	55.57%	**59.99**%
GPT-Neo-2.7B	55.66%	55.79%	**60.59**%
GPT-j-6B	55.64%	55.82%	**61.84**%
Falcon-7B-Instruct	52.87%	54.24%	**60.78**%

Table 6: Prediction accuracy computed on unseen individuals for baselines and our method (K is the number of responses we use to generate embeddings for unseen individuals).

Model	Raw Q.	Demographic + Raw Q.	Context + Raw Q.	K = 1	K = 5	K = 10	K = 20	K = 50	K = 100
GPT-Neo-1.3B	32.22%	33.57%	33.97%	40.02%	46.83%	49.97%	53.27%	56.18%	57.74%
GPT-Neo-2.7B	31.57%	33.94%	30.54%	40.40%	46.58%	48.75%	50.90%	52.66%	53.29%
GPT-j-6B	26.58%	32.10%	39.32%	41.41%	49.29%	52.19%	55.08%	57.73%	58.75%
Falcon-7B-Instruct	36.15%	38.22%	38.12%	39.11%	48.12%	51.16%	53.87%	56.76%	57.83%

Ethical Considerations

We fine tune the LLMs over a dataset encoding the opinions of individuals and we acknowledge that the LLMs could reflect and even intensify the biases held by certain individuals in the training set. A careful audit to the training data is necessary before training in practice.

A Additional details on the Dataset and the Experiments

A.1 Additional information on the OpinionQA dataset

We consider the coarse topics of OpinionQA which include: healthcare system, future, relationships and family, leadership, status in life, political issues, personal health, race, personal finance, crime or security, corporations, banks, technology and automation, self-perception and values, science, education, religion, discrimination, community health, immigration, global attitudes and foreign policy, economy and inequality, news, social media, data, privacy, job/career, gender and sexuality. The list of demographic traits available for each participant are: Education, Citizen, Marital, Income, Political Ideology, Region, Political Party, Sex, Age, Religion Attendance, Race and Religion.

A.2 Details of optimizing Eq. (1)

To optimize Eq. (1), we perform mini-batch gradient descent with the Adam optimizer (learning rate 0.001) and a batch-size of 2048. Furthermore, both individuals and questions are represented by 16-dimensional vector. For unseen users, we fix the question embedding and only optimize the individual embedding for new users.

A.3 Architecture of the SPM

The SPM that we use is a two-layer multilayer perceptron (MLP) with 32 hidden units. The output of the SPM is a vector of shape $[T, L\times 2\times D]$ where T is the number of virtual tokens, L is the number of layers and D is the token dimension. We follow the setting of prefix-tuning (Li and Liang, 2021) to insert virtual tokens before each transformer layer. Since the Falcon model uses multi-query attention (Shazeer, 2019), the output of the SPM becomes a vector of shape $[T, L\times 2\times D/H]$ where H is the number of heads. We set the number of virtual tokens to be 1 in our experiments. For training, we use the AdamW (Loshchilov and Hutter, 2017) optimizer with learning rate 0.001 and weight decay 0.001, and we train the SPM for 10 epochs with early stopping.

A.4 Prompt templates of baseline methods

In Table 3, we includes three types of baselines **Raw Q.**, **Demographics + Raw Q.** and **Context + Raw Q.**. For the **Raw Q.** baseline, only the question text is included in the prompt. For the **Demographics + Raw Q.** baseline, we prepend the demographics of an individual before the question text. An example prompt is shown on the left panel of Figure 4. For the **Context + Raw Q.** baseline, we prepend a set of responses provided by individual to other questions. An example prompt is shown on the right panel of Figure 4.

A.5 Additional experimental results

We provide further detail on our experimental results in this section.

In Figure 3, we show the demographic composition of clusters for other demographic traits not included in Figure 2.

In Table 9, we show the prediction accuracy when we use a single demographic-trait as the representation of an individual. We note that our method with the use of individual or cluster embeddings out-performs all demographic embeddings.

In Table 10, we present results obtained by using combinations of demographic groups to represent individuals. We note that individual or cluster embeddings out-performs the prediction accuracy of these combinations as well.

In Table 8 we show the prediction accuracy for the **Context + Raw Q.** baseline under different K values, *i.e.* the number of context samples.

As mentioned in Section 3.2, we draw from *prefix-tuning* tuning technique to implement our SPM. In order test the robustness of our method to other prompting methods, we also implement the SPM with the use of prompt-tuning (Lester et al., 2021). We show our results in Table 7.

Table 12-Table 16 show the top-3 questions that a cluster mostly disagrees with, when considering the overall population. Finally, Table 17 and Table 18 show the questions that have the largest disagreement among clusters for the Crime or Security and Immigration topics.

Table 7: Prediction accuracy across baselines and our experimental method showcasing the use of both *prefix-tuning* and *prompt-tuning* techniques.

CCSUM: A Large-Scale and High-Quality Dataset for Abstractive News Summarization

Abstract

Training a supervised news summarization model requires large amounts of high-quality training data consisting of news articles paired with reference summaries. However, obtaining such data is costly, and existing datasets contain considerable amount of noise. We present a new large-scale and high-quality dataset for supervised abstractive news summarization containing 1.3 million training samples, which we call CCSUM.[1] In creating this dataset, we take advantage of the journalistic inverted-pyramid style in news writing: In some articles, the first sentence can be considered a summary of the reported story. Accordingly, among 35 million CommonCrawl News articles, we identify pairs of articles about the same news story and use one article's first sentence as the summary for the other article. To ensure high quality, we apply strict filters whose parameters we optimize using Bayesian optimization. We show that the resulting dataset is more factual and informative than established summarization datasets; less than 1% of the summaries have major factual inconsistencies with the corresponding news articles, compared to 5.5% to 15.4% in existing datasets, according to our human evaluation. Summarization models trained on our dataset are more favored compared to those trained on CNN/Daily Mail. The proposed dataset can open new opportunities for future research in abstractive summarization.

1 Introduction

News summarization is the task of automatically converting news articles into concise summaries that correctly convey the main information of the articles. Particularly, in *abstractive* news summarization, summaries are generated as coherent reformulations of the articles' main points, rather than verbatim extraction of the articles' phrases and sentences. Abstractive news summarization has made

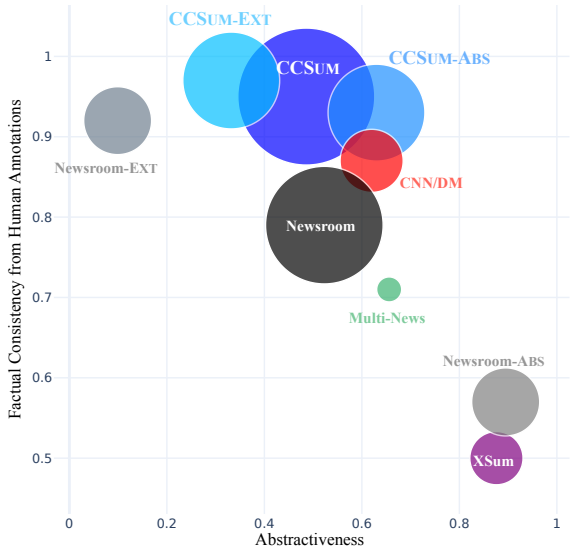

Figure 1: News summaries in our large-scale dataset CCSUM (variants: CCSUM-EXT and CCSUM-ABS) have higher factual consistency than those of existing datasets, while written in an abstractive style comparable to CNN/DM, Multi-News and Newsroom. Bubble size corresponds to dataset size. (Details in Section 4.)

significant progress since the advent of transformers (Vaswani et al., 2017): Summarization models have grown larger (Raffel et al., 2020), objective functions have evolved (Cao and Wang, 2021) and strategies for more factual (Zhu et al., 2021) or coherent (Gunel et al., 2020) summaries have been presented. However, the datasets on which abstractive news summarizers are trained have remained constant for several years. CNN/Daily Mail (CNN/DM; Hermann et al. (2015)) and XSum (Narayan et al., 2018) are used most frequently, Multi-News (Fabbri et al., 2019) and Newsroom (Grusky et al., 2018) have found adoption as well. While these datasets differ in size (Figure 1), they contain considerable amount of noise (Tejaswin et al., 2021). In human evaluations, summaries generated in zero-shot fashion by large language models have been preferred over sum-

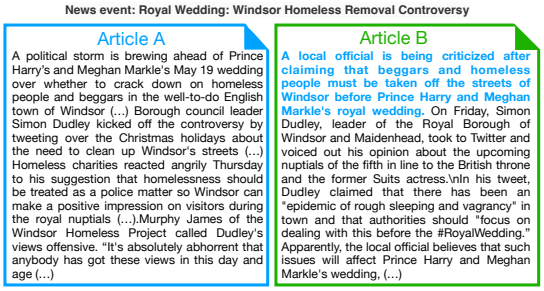

Figure 2: Articles covering the same news event, where Article B's first sentence can summarize Article A.

maries generated by supervised models trained on the above datasets (Goyal et al., 2023).

To mitigate these shortcomings, we introduce a new dataset for abstractive news summarization that is both large-scale and of high quality. It contains 1.3 million pairs of articles and summaries. Less than 1% of the summaries have major factual inconsistencies with the corresponding news articles, compared to 5.5% to 15.4% in existing datasets, according to our human evaluation in Table 3. 86.7% and 95.8% of the reference summaries in our dataset are rated "very good" in informativeness and coherence, compared to only 30.0% to 78.3% and 54.1% to 87.8%, respectively. Our human evaluation shows that summaries generated from a model trained on our dataset are preferred over models trained on CNN/DM, reducing the gap to zero-shot summaries from GPT-3.5 (OpenAI, 2023).

Our method is based on the insight that news articles often follow the journalistic principle of the inverted pyramid (Pöttker, 2003): Articles start with the most important information, followed by important details and, finally, background information and other facts. The most fundamental and important information is often contained in the first sentence—the lead sentence (see Figure 2). Accordingly, we pair the lead sentence from one article as summary for another article describing the same news story. In particular, we obtain 35 million news articles from CommonCrawl News and cluster them such that each cluster contains multiple articles that describes the same news story. In each cluster, we consider all pairs of articles; in each pair, we consider one article's lead sentence as the summary of the other article (Figure 3). This results in over 100 million candidate pairs, each one consisting of a full article and an associated lead sentence from a related article as its potential summary. Only a small percentage of these candidate pairs are of high quality. Therefore, we construct a multi-aspect filter involving automatic metrics of factual consistency, information coverage, abstractiveness, and other dimensions. We optimize this filter using Bayesian optimization and apply it to remove 99% of the candidate pairs, resulting in the final dataset of articles and lead sentence summaries, which we split into a train, dev, and test portion. We call this dataset CCSUM because it is derived from the CommonCrawl corpus. In summary, our contributions are:

1. We propose a method of constructing high-quality abstractive news summaries at scale, which resulted in CCSUM, a dataset of 1.3 million article-summary pairs for single-document abstractive summarization. CommonCrawl is a continuously crawled corpus, so our dataset can be expanded over time.

2. We benchmark CCSUM alongside established abstractive summarization datasets, and find that CCSUM is more factual and informative based on automatic and human evaluations.

3. We carry out summarization experiments on CCSUM to characterize its impact on summarization model training. We find that CCSUM-trained models are more favored compared to those trained with CNN/DM, narrowing the preference gap with GPT-3.5.

Our dataset can offer new opportunities for text generation research; this could include exploring the effects of model and data scaling, improving factual consistency in generated summaries, and developing better instruction-following models.

2 Related Work

CNN/Daily Mail (CNN/DM) (Hermann et al., 2015) is a widely used dataset consisting of news articles from the CNN and Daily Mail websites, paired with bullet-point descriptions. It has been used for summarization (See et al., 2017) by concatenating each description into a multi-sentence summary with 287k training samples. However, since the descriptions were not intended as summaries, some summaries are not coherent or may not accurately reflect the article content. **XSum** (Narayan et al., 2018) is a popular abstractive summarization dataset consisting of BBC news articles; the first sentence of each article is removed

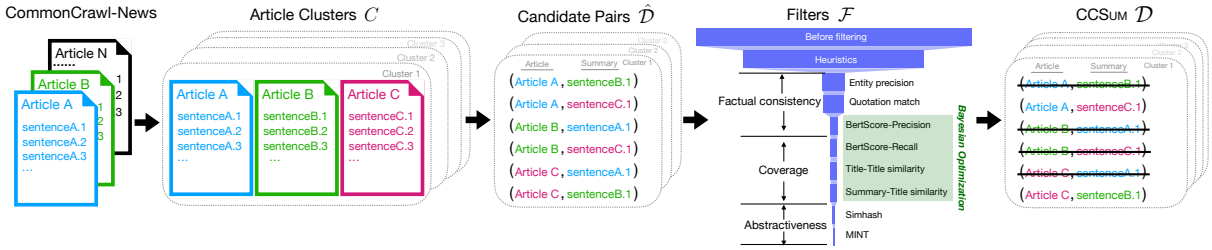

Figure 3: Process to construct the CCSUM dataset. News articles from CommonCrawl-News are clustered into news events, from which we generate candidate article-summary pairs, and apply extensive filtering to obtain the final dataset. For instance, out of 312,544 articles published between September 21 and September 23, 2020, 71,731 unique news events were identified, creating 1.8 million candidate pairs. After extensive filtering, 99% of these pairs were eliminated ensuring only high-quality pairs were included in the final dataset.

and used as summary for the remaining part of the article. Its training set has 204k samples. The introductory sentences were not intended to be abstractive summaries and might contain information not present in the article. **Newsroom** (Grusky et al., 2018) was constructed from web-scale crawling and uses the "description" field in each article's HTML metadata as the summary. The summaries are split into extractive, abstractive, and mixed bins, according to the density metric. The summaries tend to be noisy due to the inconsistent quality of HTML metadata. It contains 1.3 million training samples. **Multi-News** (Fabbri et al., 2019) pairs human-written news aggregation summaries with the articles originally linked from those summaries. This makes it a multi-document summarization dataset—in contrast to the other datasets discussed. It contains 44k training samples. **Gigaword** (Rush et al., 2015) pairs articles with their headlines, e.g., "five dead as powerful quake hits southern iran", rather than fully formulated summaries.

3 Dataset Construction

3.1 Overview

We derive the CCSUM dataset from 35 million news articles from the Common Crawl News[2] corpus, covering all English-language news articles from 2018 to 2022. Figure 3 illustrates our method for extracting high-quality abstractive summaries. This technique begins by clustering news articles $A_i \in \mathcal{A}$ into news events $\mathcal{C}$. Within each event, we create candidate article-summary pairs by selecting the first sentence from one article A_i^1 as a potential summary for another article A_j. Subsequently, as depicted in Figure 3, we define a set of summary quality filters and use Bayesian optimization to fine-tune their parameters. The final CCSUM dataset comprises only 1% of these candidate summaries that have successfully met all filter criteria.

3.2 Clustering for News Event Detection

We begin by grouping all news articles into three-day time windows $T_{[\mathrm{t_{min}},\mathrm{t_{max}})}$ based on their publication times to maintain the temporal coherence of articles within each news event. For articles in each time window $T_{[\mathrm{t_{min}},\mathrm{t_{max}})}$, we use sentence-BERT (Reimers and Gurevych, 2019) to encode the main text and perform soft clustering (Bezdek, 2013). Note that in soft clustering, an article can be assigned to multiple clusters, which allows us to over-generate candidate article-summary pairs followed-by strict filtering to obtain the final large-scale and high-quality dataset.

3.3 Candidate Summary Generation

We construct candidate summaries $\hat{\mathcal{D}} = \left\{\left(A_i, A_j^1\right) \mid i \neq j, A_i \in C, A_j \in C\right\}$ for each cluster C, where the first sentence A_j^1 from article A_j is proposed as an abstractive summary for article A_i. Given the combinatorial nature of this approach, a large number of candidate article-summary pairs are generated— three-day's articles generated over one million candidate summaries.

It should be emphasized that simply having semantic similarity between news articles does not ensure that the first sentence will effectively function as a high-quality abstractive summary of the other article. To address this, we have established a series of filters to ensure that the chosen abstractive summary is relevant, factual, and encapsulates the key points of the article. Figure 3 illustrates the data filtering funnel, highlighting how 99% of the initial article-summary candidates were eliminated to produce the final CCSUM dataset.

[2]https://commoncrawl.org/blog/news-dataset-available

3.4 Summary Quality Filter Definition

We define a set of metrics, denoted as $\mathcal{F}$, to evaluate the quality of each candidate article-summary pair $\left(A_i, A_j^1\right) \in \hat{\mathcal{D}}$. Each metric f_x is associated with a specific filter constraint, defined by some threshold λ_{f_x}. The final CCSUM dataset $\mathcal{D}$ consists of article-summary pairs from $\hat{\mathcal{D}}$ that successfully meet all filter criteria, where $\mathcal{D} = \left\{\left(A_i, A_j^1\right) \in \hat{\mathcal{D}} \mid \forall f_x \in \mathcal{F}, f_x\left(A_i, A_j^1\right) > \lambda_{f_x}\right\}$.

Heuristics. We first define a set of heuristics specifically designed to mitigate challenges raised by our candidate summary generation approach. For instance, we ensure the summary ends in proper punctuation and the summary contains at least one entity. More details are described in Appendix D.1.

Factual Consistency. A valid summary must accurately reflect the content of the original news article while avoiding introducing unsupported information. We use the following metrics for factual consistency: (i) *Entity precision* f_{ep} quantifies the proportion of entities in the summary that also appear in the article (Nan et al., 2021). This helps determine if the summary introduces entities absent from the original article. (ii) *BERTScore-Precision* (BS-Precision) $f_{\text{BS-P}}$ (Zhang et al., 2019). BertScore Precision works well to evaluate the factual consistency of an abstractive summary against an article (Pagnoni et al., 2021). We calculate BERTScores using both BERT (Devlin et al., 2018) and BART (Lewis et al., 2019; Yuan et al., 2021), as the models complement each other with different pre-training objectives. (iii) *Quotation exact match* f_{quo}: We use regular expression to detect quotations from the summary and ensure their presence in the article.

Coverage. A well-crafted summary should capture the key points of an article while avoiding extraneous details. We use the following metrics to measure coverage: (i) *BERTScore-Recall* (BS-Recall) $f_{\text{BS-R}}$ (Zhang et al., 2019) aligns tokens in the article with tokens in the candidate summary and computes the average similarity score over tokens in the article. (ii) *Title-title similarity* $f_{\text{t-t}}$ measures the semantic similarity between the article's title and the summary's title, using cosine similarity of sentenceBERT (Reimers and Gurevych, 2019) embeddings. This metric determines if the summary's topic aligns with that of the article. (iii) *Summary-title similarity* $f_{\text{s-t}}$ measures the semantic similarity between the candidate summary A_j^1 and the title of the article A_i.

Abstractiveness. A well-crafted abstractive summary should effectively synthesize and condense the content of an article, rather than merely replicating sentences or phrases from it. We use MINT f_{MINT} (Dreyer et al., 2023) and *Simhash* f_{simhash} (Charikar, 2002; Henzinger, 2006) to measure the abstractiveness of the candidate summary.

3.5 Bayesian Optimization

Given the wide range of filters defined in Section 3.4 and their intricate interactions, manually setting thresholds for each filter is impractical. We use Bayesian Optimization (Kushner, 1964) to address this challenge by performing constrained optimization over filter parameters (Frazier, 2018).

The Search Space. We perform filter parameter search on all the embedding-based metrics, i.e., BERTScore-Precision, BERTScore-Recall, title-title similarity and article-title similarity, which we denote as a vector λ. The remaining filter parameters are set as constant in Table 12 of the Appendix.

Collecting Human Annotations. Bayesian optimization requires a measurable objective function to optimize in the parameter space. We use human judgements on a held-out set of candidate article-summary pairs to guide the search for filter parameters. The intuition is that the ideal filter parameterization should maximize the recall of high-quality summaries while reducing the presence of low-quality summaries. We randomly select 1,000 examples from our candidate dataset $\hat{\mathcal{D}}$ for human annotation. Each candidate article-summary pair is annotated into one of the three categories: no factual error, minor factual error, and major factual error. Please refer to Appendix F.1 for the detailed annotation guidelines. We obtain an annotated dataset $\hat{\mathcal{D}}_{\text{labelled}}$ where each example (A_i, A_j^1, y) is associated with a factual consistency label y.

Optimization Objective. The optimization consists of a primary objective and two constraints. The primary objective is the recall of factually correct summaries $f_{\text{recall}}(\lambda, \hat{\mathcal{D}}_{\text{labelled}})$, where

$$f_{\text{recall}} = \frac{|\left\{(A_i, a_j^1, y) \in \mathcal{D}_{\text{labelled}} \mid y = \text{correct}\right\}|}{|\left\{(A_i, a_j^1, y) \in \hat{\mathcal{D}}_{\text{labelled}} \mid y = \text{correct}\right\}|} \quad (1)$$

However, focusing solely on recall could result in a trivial solution, i.e., removing all filters. Therefore,

	Total	Date range	EXT	ABS
Train	1,349,911	1/2018 - 12/2021	674,939	674,972
Val.	10,000	1/2022 - 5/2022	4,853	5,147
Test	10,000	6/2022 - 12/2022	5,053	4,947

Table 1: CCSUM Dataset overview.

we introduce two constraints to ensure that the final dataset is both large-scale and of high quality. The first constraint limits the major factual error rate $f_{\text{error}_{\text{major}}}(\lambda, \hat{\mathcal{D}}_{\text{labelled}})$, defined in Eq. 2, after filtering to be less than 3%.

$$f_{\text{error}_{\text{major}}} = \frac{|\{(A_i, a_j^1, y) \in D_{\text{labelled}} \mid y = \text{error}_{\text{major}}\}|}{|D_{\text{labelled}}|} \tag{2}$$

The second constraint focuses on the precision of factually correct summaries $f_{\text{precision}}(\lambda, \hat{\mathcal{D}}_{\text{labelled}})$, defined in Eq. 3. It requires that the percentage of factually correct summaries exceeds eighty percent after filtering.

$$f_{\text{precision}} = \frac{|\{(A_i, a_j^1, y) \in \mathcal{D}_{\text{labelled}} \mid y = \text{correct}\}|}{|\mathcal{D}_{\text{labelled}}|} \tag{3}$$

Eq. 4 defines the overall optimization objective:

$$\begin{aligned} \max_{\lambda} \quad & f_{\text{recall}}(\lambda, \hat{\mathcal{D}}_{\text{labelled}}) \\ \text{subject to} \quad & f_{\text{error}_{\text{major}}}(\lambda, \hat{\mathcal{D}}_{\text{labelled}}) < 0.03, \\ & f_{\text{precision}}(\lambda, \hat{\mathcal{D}}_{\text{labelled}}) > 0.8 \end{aligned} \tag{4}$$

Optimization Outcome. On a held-out set of annotated data, the optimize filter parameters improve the percentage of factually correct summaries from 89.5% before filtering to 94.8% after filtering. It also decreases the percentage of summaries with minor and major factual errors from 6.3% to 4.6% and from 4.2% to 1.5%, respectively. Human evaluation also shows the informativeness score improves from 98% to 99%. The final filter parameters are summarized in Table 13 of the Appendix. Our filtering mechanism can also be applied to existing datasets for quality improvements.

4 Dataset Overview and Evaluation

Table 1 presents an overview of the final dataset, which comprises 1,369,911 training examples. Please refer to Appendix A for more statistics.

Train/validation/test splits. The dataset is divided into training, validation, and testing segments, categorized by the publication date of each article (Table 1). This approach is designed to avoid the risk of news event leakage, where a summarization model might inadvertently recall and use details of a news event from the training set to generate summaries for the testing set, rather than relying on the content of the test articles themselves.

Abstractiveness. The dataset is divided equally into "extractive" and "abstractive" bins, which we denote as CCSUM-EXT and CCSUM-ABS, respectively, based on the median MINT score (0.4665).

4.1 Evaluation

We carry out automatic and human evaluation to benchmark the proposed dataset along with other abstractive summarization datasets—CNN/DM, XSum, Newsroom, and Multi-News.

4.1.1 Automatic Evaluation

The automatic evaluation results on the test split of each dataset are presented in Table 2. To ensure the CCSUM dataset is not over-fitting on the predefined filter metrics, we add SEAHORSE (Clark et al., 2023) metrics that were not part of the filtering process—Attribution for factual consistency, Comprehensible for text quality, and MainIdea for coverage, to complement other automatic metrics. These results indicate that CCSUM summaries score highest in factual consistency, are comprehensible, and capture the main points of the articles.

Factual consistency. We use BS-Precision and Attribution (Clark et al., 2023) to evaluate factual consistency. Table 2 shows that CCSUM has the highest scores on both metrics, measured on the entire dataset. Within each data subset, Newsroom-Ext has the best factuality score, closely followed by the CCSUM-Ext subset.

Abstractiveness. Abstractiveness quantifies the lexical abstraction in summaries; high MINT (Dreyer et al., 2023) and low density (Grusky et al., 2018) indicate high abstractiveness. CCSUM is the least abstractive when measured on the entire dataset. CCSUM-ABS has comparable MINT score to that of CNN/DM, and is slightly more abstractive when measured by density.

Comprehensible. We use the Comprehensible metric defined in SEAHORSE to measure if a summary is easy to understand. Summaries that are not comprehensible often feature incomplete sentence fragments or sentences marred by non-readable characters. In our analysis, all datasets, with the exception of Newsroom, received perfect scores in comprehensibility.

Dataset	Factual Consistency		Style			Content	
	BS-Precision	Attribution	MINT	Density	Comprehensible	MainIdea	BS-Recall
CNN/DM	0.740	0.658	0.623	3.645	1.000	0.709	0.501

Table 3: Benchmarking abstractive summarization datasets using human annotations (%).

Coverage. Both MainIdea and and BERTScore-Recall (BS-Recall) measure the extent to which summaries cover the articles' main contents. CCSUM has the highest coverage when measured on MainIdea, and is comparable to CNN/DM when measured on BS-Recall.

4.1.2 Human Evaluation

We also conducted a human annotation, focused on three aspects: (i) *factual consistency* where the summary has no factual errors and all the details in the summary are supported by the article, (ii) *informativeness* where the summary express the main points of the article and the summary content is important and relevant, and (iii) *coherence* where the summary has good structure and flow, is easy to follow, and facts in the summary are presented in logical order. We randomly selected 1,000 validation examples from each dataset for annotation.

The main results in Table 3 are in line with the automatic evaluation results (Section 4.1.1), showing that CCSUM exhibits high factual consistency, informativeness, and coherence. *Factual consistency:* CCSUM has the highest factual consistency rating, with 94.9% of summaries being free of factual inconsistencies, surpassing the next best dataset, CNN/DM, by a notable 8.2% in absolute terms. *Informativeness:* CCSUM has the highest informativeness rating, with 86.7% of summaries rated as "very good". The second-best in informativeness, Multi-News, receives a "very good" rating for 78.3% of its summaries. *Coherence:* CCSUM has the best coherence rating, where 95.8% of the summaries are rated as "very good'. The second-best dataset in coherence is XSum, with 87.8% of summaries rated as "very good". The full annotation results are shown in Table 14 of the Appendix.

5 Experiments

5.1 Summarization Models

We fine-tuned FLAN-T5-Large (Chung et al., 2022) models on the abstractive and extractive subsets of the CCSUM dataset, and compared with FLAN-T5-Large trained on the CNN/DM dataset. Note that although CNN/DM was included as a pretraining dataset for FLAN-T5-Large, the generated summarizes are highly extractive, suggesting the tradeoff with other pretraining tasks. In this experiment, we fine-tune FLAN-T5-Large specifically for abstractive summarization and evaluate on the CCSUM test set. We also include Pegasus (Zhang et al., 2020), Mixtral-Instruct (Jiang et al., 2024), and GPT-3.5 (OpenAI, 2023) as baselines.

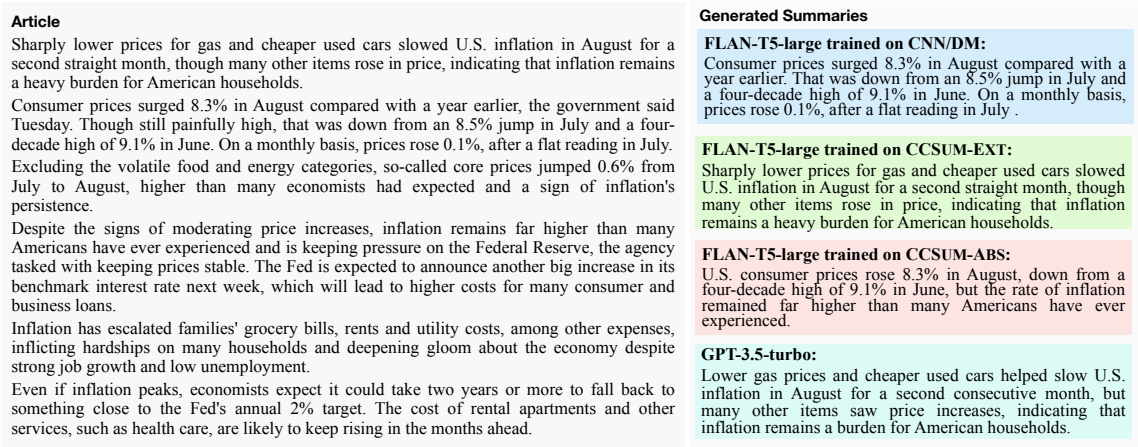

Figure 4: Example summaries generated by different systems.

	MainIdea	BS-Recall	Concise	MINT	ROUGE-L
CNN/DM	0.787	0.654	0.901	0.271	0.300
CCSUM-ABS	0.930	0.765	0.946	0.373	0.517
CCSUM-EXT	0.956	**0.797**	**0.994**	0.086	**0.560**
Pegasus	0.672	0.677	0.880	0.163	0.280
Mixtral-Instruct	0.992	0.751	0.985	**0.544**	0.381
GPT-3.5	**0.994**	0.753	0.983	0.458	0.415

Table 4: Automatic evaluation on generated summaries.

	Factual consistency			MINT
	no error	minor error	major error	
CNN/DM	97.2%	1.4%	1.4%	0.271
CCSUM-ABS	94.2%	4.8%	1.0%	0.343
CCSUM-EXT	98.8%	1.2%	0.0%	0.086
Pegasus	99.0%	1.0%	0.0%	0.163
Mixtral-Instruct	95.8%	3.4%	0.8%	0.544
GPT-3.5	95.6%	3.4%	1.0%	0.458

Table 5: Human evaluation on generated summaries.

5.1.1 Observations and Standard Evaluation

Observation 1. CCSUM *training leads to comprehensive summaries.* Models trained on CCSUM can comprehensively capture the main ideas of an article while avoiding unnecessary details. Automatic evaluation results in Table 4 demonstrate that CCSUM-trained models outperform those trained on CNN/DM in capturing the main ideas, as measured in MainIdea (Clark et al., 2023) and BERTScore-Recall (Zhang et al., 2019). CCSUM-trained models also have high Concise (Clark et al., 2023) scores. A comparative analysis in Figure 4 reveals that the summary produced by the CNN/DM-trained model misses the specific subject of the article, such as mistaking "U.S. consumer prices" for generic "consumer prices". In contrast, summaries generated by CCSUM-trained models clearly state the subject and capture the important point that "the rate of inflation remained far higher than many Americans have ever experienced." We find CCSUM-trained models better adhere to the journalistic writing style. More comparative summaries can be found in Appendix H.

Observation 2. CCSUM-ABS *yields more abstractive summaries than CNN/DM and Pegasus.* Although CCSUM-ABS has similar abstractiveness level with CNN/DM on the training data as shown in Table 2, models trained on CCSUM-ABS tend to generate more abstractive and concise summaries than that of CNN/DM according to the MINT (Dreyer et al., 2023) metric in Table 4. The sentence structure from CCSUM-ABS trained models is notably more complex than the simplistic language style of CNN/DM. CCSUM-ABS trained models also generate more concise summaries according to the Concise (Clark et al., 2023) metric in Table 4. Compared with Pegasus, the CCSUM-ABS models are better at capturing the main idea of an article and produce more concise summaries. We find that summaries generated by Mixtral-Instruct are notably more abstractive than those generated by other models. Mixtral-Instruct demonstrates a strong capacity in capturing the main ideas of an article while maintaining brevity. Note that details about Mixtral's pre-training or instruction-tuning data have not been disclosed.

Observation 3. CCSUM-EXT *training leads to highly-extractive summaries.* The automatic abstractiveness evaluation in Table 4 indicates that CCSUM-EXT-trained models output highly extractive summaries. CCSUM-EXT can be used as a

dataset for investigating generation-based extractive summarization models. It eliminates the need for sentence segmentation and is more robust to input noise, illustrated in Figure 13 of the Appendix.

Observation 4. Human annotations on factual consistency reveal the factuality-abstractiveness tradeoff. Table 5 summarizes the human annotation results on factual consistency. Our findings indicate that summaries generated by CCSUM-EXT are the most factual. Summaries generated by CCSUM-ABS show a similar level of major factual errors as those produced by GPT-3.5, but they exhibit a higher rate of minor factual errors. Mixtral-Instruct exhibits similar factual consistency ratings compared to GPT-3.5, where both models contain about 1% major factual error and 3.4% minor factual error. The CNN/DM-trained model has a higher factual correctness rate (92.2%) than CCSUM-ABS (94.2%) and GPT-3.5 (95.6%). Notably, there is a correlation between the level of abstractiveness (MINT) in a summary and its factual error rate. This correlation suggests that more abstractive summaries tend to have higher rates of factual errors, a finding consistent with previous research (Dreyer et al., 2023).

5.1.2 Human Preference Evaluation

We conduct a human preference evaluation to complement the results in Section 5.1.1. We ask human annotators to decide which of two summaries of a news article is better; see Appendix F for details. We first compare summaries between CCSUM-ABS and CNN/DM trained models. The findings (Table 6) show a clear preference for summaries generated by the CCSUM-ABS-trained model. This preference is shown both on the CNN/DM and the CCSUM test sets, though it is more pronounced on the CCSUM test set, hinting at a potential domain shift (Krishna et al., 2023) between these two datasets.

We also evaluate how summaries generated by models trained on CCSUM-ABS and CNN/DM fare against those produced by GPT-3.5. According to the results in Table 7, both the CNN/DM- and CCSUM-ABS-trained models are significantly less favored compared to GPT-3.5-generated summaries when the base model is FLAN-T5-Large. Increasing the size of the pre-trained model significantly narrows the performance gap between FLAN-T5 and GPT-3.5. Notably, human evaluators exhibited a slight preference for summaries generated by the FLAN-T5-XL (CCSum-Abstractive) over those produced by GPT-3.5. This is particularly noteworthy considering GPT-3.5 has been fine-tuned using human preferences and might be much larger than FLAN-T5-XL. The preference for FLAN-T5-XL (CCSum-Abs) underscores the value of the proposed CCSum dataset and its journalistic-style summaries. Moreover, the results suggest that the large-scale CCSum better benefits from increases in model size, narrowing the overall preference gap from 45% (70%-25%) to -3% (47%-50%). In contrast, CNN/DM reduces the overall preference gap from 63% (79%-16%) to 51% (74%-23%). Example preference annotations between GPT-3.5 and the CCSUM-trained FLAN-T5-XL model are showcased in Appendix H.1. Given that GPT-3.5 is closed-source without transparency into its training data and model size, the proposed CCSUM dataset enables the summarization research community to train better open-source models that can outperform its closed-source counterparts. The proposed CCSUM dataset can also be used as an instruction-tuning dataset to train better instruction-following summarization models. We show in Appendix J that a controllable-summarization model can be trained from CCSUM-ABS to generate summaries at different abstractiveness levels.

Test set	Preferred model	Overall	Content	Style
CCSUM	Tie	5.2%	8.8%	7.2%
	CCSUM-ABS	53.6%	39.8%	66.8%
	CNN/DM	41.2%	51.4%	26.0%
CNN/DM	Tie	3.6%	7.4%	5.2%
	CCSUM-ABS	49.0%	47.0%	46.4%
	CNN/DM	47.4%	45.6%	48.4%

Table 6: Human preference between CCSUM-ABS and CNN/DM trained FLAN-T5-Large models.

6 Conclusion

We present a large-scale and high-quality dataset, CCSUM, for supervised abstractive news summarization. It contains 1.3 million pairs of articles and reference summaries derived from 35 million news articles from CommonCrawl News. In creating this dataset, we cluster CommonCrawl News articles into news events from which we generate candidate article-summary pairs and apply strict filtering and a Bayesian optimization method that eliminates 99% of the candidate summaries. The human evaluation shows the proposed dataset has higher quality—in terms of factual consistency, in-

Preferred model	Overall	Content	Style
Tie	5%	10%	9%
FLAN-T5-Large (CNN/DM)	16%	21%	10%
GPT-3.5	79%	69%	81%
Tie	3%	6%	9%
FLAN-T5-XL (CNN/DM)	23%	25%	24%
GPT-3.5	74%	69%	67%
Tie	5%	8%	14%
FLAN-T5-Large (CCSum-Abs)	25%	20%	30%
GPT-3.5	70%	72%	56%
Tie	4%	6%	11%
FLAN-T5-XL (CCSum-Abs)	50%	48%	46%
GPT-3.5	47%	46%	44%

Table 7: Human preference between CCSUM-ABS, CNN/DM trained models vs. GPT-3.5.

formativeness, and coherence—than established abstractive summarization datasets. We train summarization models on CCSUM and compare them with models trained on CNN/DM. Our human evaluation shows that summaries generated from CCSUM-trained models are favored over models trained on CNN/DM, reducing the preference gap to zero-shot summaries from GPT-3.5. We hope the proposed CCSUM dataset provides new opportunities for future research in abstractive summarization.

Limitations

In our work, factual consistency errors are defined as information in the summary that is not supported by the article content. We do not consider the case of factual hallucinations (Cao et al., 2022) where the summary can be factual according to world knowledge, but cannot be entailed by the article.

We propose a large-scale and high-quality dataset for abstractive summarization. However, with the advent of large language models, which are instruction-tuned across a variety of tasks, it is difficult to determine the amount of supervised data required to obtain high-quality abstractive summarization models. The proposed dataset offers a new platform for text generation research, inviting further research into abstractive summarization in the context of large language models.

The proposed dataset has higher quality than established abstractive summarization datasets, yet it is important to acknowledge its imperfections. Specifically, it comprises 0.9% major factual error and 4.2% minor factual error. We hope our paper raises the awareness of quality issues in existing abstractive summarization datasets, and offers inspiration for automatic approaches to improve dataset quality. Currently, our filtering mechanism is constrained by the existing automatic summary quality metrics, and the dataset can be updated once better automatic metrics are available.

In our human preference evaluation in Section 5.1.2, we observe a strong preference towards GPT-3.5-generated summaries. Details about the training procedure for GPT-3.5 have not been published, but it is widely assumed that GPT-3.5 uses RLHF (Ouyang et al., 2022) to make the model outputs more favored by human annotators, which biases the preference annotation.

Although the proposed dataset construction approach is general and can be applied to any language, the CCSUM dataset focuses on English articles from the CommonCrawl News corpus.

Ethics Statement

The human annotations in this paper are provided by qualified Mechanical Turk workers. We provided fair pay to our annotators. For preference annotation, the workers take on average 90 seconds to complete one summary comparison. We pay the workers $0.35 per question and $0.10 bonus, which leads to a pay of $14 to $18 per hour.

Like other text generation systems, generative summarization systems can suffer from hallucinations, potentially leading to misinformation. We carefully evaluate the factual consistency of the generated summaries and use it as one of the main metrics for dataset benchmarking.

The proposed dataset is derived from the CommonCrawl News corpus. Like other news datasets, the dataset may contain biases inherent in the source material. This can be due to the nature of the news sources in CommonCrawl News.

A Dataset Statistics

A.1 Word Count Statistics

The article and summary length distribution of different abstractive summarization datasets is summarized in Table 8. The article length in CCSUM is similar to that of XSUM, and the summary length in CCSUM is longer than XSUM and Newsroom, but shorter than CNN/DM.

	Training examples	Article word count percentile			Summary word count percentile		
		25%	50%	75%	25%	50%	75%
CNN/DM	286,817	419	613	876	40	51	64
XSUM	204,045	179	295	492	18	21	24
Newsroom	995,041	276	522	839	16	22	30
MultiNews	44,972	798	1,289	2,057	169	218	260
CCSUM	1,349,911	210	307	438	26	30	35

Table 8: The article and summary length statistics of abstractive summarization datasets.

A.2 Multi-Reference Statistics

The soft clustering could produce multiple summary references for each news article. On average, each article corresponds to 1.36 summaries in our final CCSUM dataset, and 235,031 articles has more than one valid summary. Therefore, CCSUM can be used to study multi-reference summarization.

A.3 Domain Statistics

The final CCSUM dataset is comprised of 4,388 unique domains. The top 15 domains and their article count in the training set are summarized in Table 9.

A.4 Distribution of Automatic Metrics

Figure 5, 6, and 7 shows the distribution of MINT, BERTScore-Precision, and BERTScore-Recall scores in CCSUM, respectively.

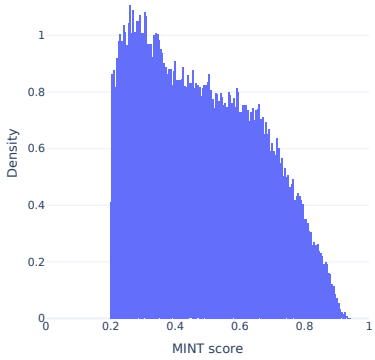

Figure 5: Distribution of the MINT scores in CCSUM.

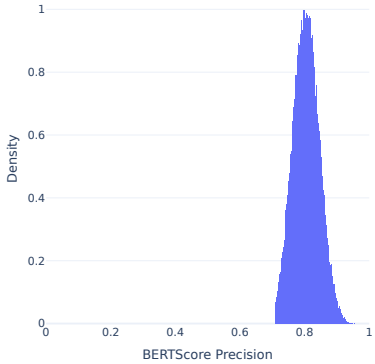

Figure 6: Distribution of the BERTScore-Precision scores in CCSUM.

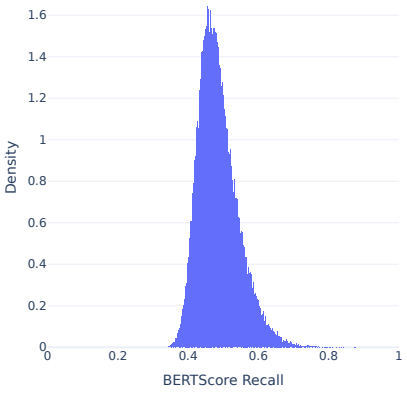

Figure 7: Distribution of the BERTScore-Recall scores in CCSUM.

B Example Summaries in CCSUM

Table 10 and Table 11 shows examples summaries in CCSUM-ABS and CCSUM-EXT, respectively.

Article	Summary
GADSDEN, Ala. – A fire has destroyed the home of a woman who accused U.S. Senate candidate Roy Moore of sexual misconduct. Authorities say, however, that there is no indication the blaze had anything to do with the allegations. Moore accuser Tina Johnson of Gadsden lost her home Wednesday in a fire that's under investigation by arson specialists in Etowah County. READ MORE: 2 more women accuse Republican Senate candidate Roy Moore of sexual misconduct A statement from the sheriff's office says authorities are speaking to a person of interest about the fire. The statement says investigators don't believe the fire is linked to Moore or the allegations against him. Johnson is among the women who publicly accused Moore of sexual misconduct. She told AL.com Moore groped her in his law office in 1991. Moore denied any wrongdoing, but he lost the race to Democrat Doug Jones.	The home of Tina Johnson, who accused former U.S. Senate candidate Roy Moore of groping her, was destroyed Wednesday in a fire that is being investigated as arson, though officials say they do not believe it is related to the Moore allegations.
Man charged with terrorism in stopping of Amtrak train LINCOLN, Neb. A Missouri man suspected of stopping an Amtrak train in southwest Nebraska has been charged with terrorism. Documents unsealed Wednesday in U.S. District Court in Lincoln say 26-year-old Taylor Wilson, of St. Charles, Missouri, has ties to a white supremacist group. He's charged with terrorism attacks and other violence against railroad carriers and mass transportation systems. His attorney in a related state case didn't immediately return a call Friday from The Associated Press. The eastbound train with about 175 people aboard halted early Oct. 22 in Oxford, Nebraska, about 200 miles southwest of Omaha. Court documents say a Furnas County deputy sent to the scene found Amtrak employees holding Wilson. The deputy says he found a loaded handgun in Wilson's waistband.	An armed man believed to have ties to white supremacist groups has been charged with terrorism after he stopped an Amtrak train in Nebraska.
UNITED NATIONS — The U.N. Security Council is set to hold an emergency meeting about Iran as the U.S. seeks to show support for anti-government protests in the Islamic Republic. The U.S. asked for the session, set for Friday afternoon. It's not yet clear what might come out of it. Members are divided in their views of the protests and could call a vote on whether to address the topic. U.S. Ambassador Nikki Haley has praised the demonstrators, saying "the U.N. must speak out" on their behalf. But Russia has warned against "external interference" in what it sees as an Iran's internal affairs. At least 21 people have been killed and hundreds arrested in a week of anti-government protests and unrest. Meanwhile, thousands of people took part in pro-government rallies Wednesday and Thursday. Copyright 2017 The Associated Press. All rights reserved. This material may not be published, broadcast, rewritten or redistributed. Sign up for BREAKING NEWS Emails privacy policy Thanks for subscribing!	The U.N. Security Council is planning an emergency meeting about Iran on Friday, after the U.S. asked the world body to show support for Iran's anti-government protesters.
Arsenal boss, Arsene Wenger, has insisted he is not planning to buy Pierre-Emerick Aubameyang as replacement for Alexis Sanchez. Sanchez has been linked with a move to Premier League rivals Manchester City this January, with his current deal set to expire at the end of the season. There have been speculations that Wenger will make a move for Aubameyang, who has scored 21 goals in all competitions this season, if the Chilean leaves. Wenger is, however, adamant it is not on the cards this month. "No, that is not a possibility," he told a press conference on Friday. Wenger also added that he is hopeful of keeping Theo Walcott, who has been linked with a return to Southampton. "I want him to stay. I heard about that but I want him to stay," he said.	Arsenal head coach Arsene Wenger has denied reports suggesting that the club will make a move for Pierre-Emerick Aubameyang in the current transfer window.
BANGKOK - Six Myanmar soldiers were injured in an insurgent attack in northern Rakhine state, where hundreds of thousands of Rohingya Muslims have fled to Bangladesh since the army launched a crackdown in August following militant attacks on police posts, officials said. The military said in a statement posted on the commander in chief's Facebook page that the attackers were from the Arakan Rohingya Salvation Army, the militant group blamed for the attacks on police posts. More than 20 insurgents using improvised explosives attacked the soldiers' truck, which was coming from Taungpyo township in northern Rakhine on Friday, the government said in a statement on its Facebook page. Six injured soldiers were taken to a military hospital, border guard police official Sann Oo said by phone Saturday. In the past, the military has retaliated against Rohingya following such attacks. A campaign of killings, rape and arson attacks by security forces and Buddhist-aligned mobs has sent more than 850,000 of Myanmar's 1.3 million Rohingya fleeing the country in recent years. Since Aug. 25 alone, when Myanmar's army began what it called "clearance operations" following the attacks on police posts, more than 650,000 Rohingya have fled to neighboring Bangladesh. The United Nations and the United States accuse Myanmar's military of human rights violations against Rohingya in Rakhine, including killings, rapes and the burning of homes. The U.N. has condemned the violence as ethnic cleansing.	Six Myanmar soldiers were wounded in an insurgent attack in northern Rakhine state, where government troops have been accused of "ethnic cleansing" that forced hundreds of thousands of Rohingya Muslims to flee into Bangladesh.

Table 10: Example summaries and their corresponding article in CCSUM-ABS.

Article	Summary
HELSINKI—A man in Stockholm picked up a suspected hand grenade from the ground and it detonated in his hand Sunday, killing him and injuring his companion, Swedish police said. The blast took place about 11 a.m. just outside the Varby Gard subway station in Huddinge, a residential district in greater Stockholm, said regional police spokesman Sven-Erik Olsson. "The man was seriously injured after he picked up something from the ground and this device exploded," Olsson said. The man, in his 60s, was rushed to hospital but later died while the woman, in her mid-40s, received minor wounds to her face and both legs, Olsson said. The couple had been cycling past the device when the man stopped to investigate it. Police said fragment damages on the victims and findings at the scene indicated the explosive could be a hand grenade, possibly an old one.	A man in Stockholm picked up a suspected hand grenade from the ground that detonated in his hand Sunday, accidentally killing him and injuring his female companion near a subway station.
CHICAGO A 26-year-old transgender Chicago woman serving a 10-year sentence for burglary is seeking a transfer from a male to a female prison where she says she'll be less vulnerable to abuse. A federal judge will hear testimony Friday on Deon "Strawberry" Hampton's transfer request. She says guards single her out for regular sexual abuse, taunting and beatings at the high-security men's prison she's at now in southern Illinois. Prison officials can assign such male-to-female transgender inmates to women's prisons, but it happens infrequently. Federal data from 2016 indicates there were no transgender prisoners in Illinois' two female prisons. There were 28 in the state's 24 male prisons. Testimony in Benton will include experts describing how Hampton has identified as female since she was 5.	A 26-year-old transgender woman serving a 10-year sentence in Illinois for burglary is seeking a rarely granted transfer to a female prison where she says she'll be less vulnerable to the kinds of sexual assault, taunting and beatings she's been subjected to in male prisons.
Washington Special counsel Robert Mueller is aware of an unsuccessful attempt by President Donald Trump to lobby Attorney General Jeff Sessions not to recuse himself from the Justice Department's Russia probe, The New York Times reported Thursday. The Times, citing two people with knowledge of the episode, said Trump had ordered White House counsel Don McGahn last March to stop Sessions from recusing himself from oversight of the investigation into Russian interference in the 2016 election. At the time, Sessions faced mounting calls for recusal given his support for the Trump campaign and the revelation of an omission during his confirmation hearing about contacts with Sergey Kislyak, who was the Russian ambassador to the US at the time. While widely reported on, the government did not confirm the existence of the investigation until then-FBI Director James Comey told the House Intelligence Committee later in March 2017 that there was an ongoing investigation into potential coordination between Trump's associates and Russia to influence the 2016 election. Sessions announced he would recuse himself from all matters relating to the investigation in early March. Politicians, including Republicans, praised the decision at the time, but Trump has publicly rebuked his attorney general and said he wished Sessions had not recused. Read More	President Donald Trump directed his White House counsel to tell Attorney General Jeff Sessions not to recuse himself from the Justice Department's investigation into potential ties between Russia and the Trump campaign.
Uber co-founder and former CEO Travis Kalanick plans to sell 29 percent of his stake in the ride-hailing service, a news report said Thursday. The deal is part of a transaction with investors including Softbank Group Corp. and would bring Kalanick about $1.4 billion, Bloomberg reported, citing unidentified sources. It said Kalanick previously said he never had sold Uber shares. Bloomberg didn't respond to an email seeking comment. Kalanick, who owns 10 percent of Uber, resigned as CEO last year following revelations of sexual harassment in the company, technological trickery designed to hinder regulators and a cover-up of a hacking attack that stole personal information of 57 million passengers and 600,000 drivers. Bloomberg said Kalanick offered to sell up to half his stake but reduced that due to limits in the agreement between Uber and the buyers. Uber was valued around $68.5 billion during a 2016 capital investment, but that dropped to somewhere above $48 billion in the SoftBank deal announced last week. Despite that, early investors stand to make significant gains.	Uber co-founder and former CEO Travis Kalanick will sell 29 percent of his stake in the ride-hailing service, a person briefed on the deal says.
The commander of a Colorado sheriff's deputy killed by a man with a history of mental health problems says the deputy tried to calmly help the gunman before being shot. Douglas County Sheriff Tony Spurlock spoke Friday at the funeral of 29-year-old Zackari Parrish in the Denver suburb of Highlands Ranch. Relaying what he heard on audio from body camera footage, Spurlock said Parrish pleaded with the gunman to let him help. Spurlock said he never heard anyone deal with such a situation more calmly. Parrish and three other deputies were shot after being called to the home of Matthew Riehl, an Army veteran and former Wyoming lawyer, for the second time early New Year's Eve. Parrish's funeral drew law enforcement officers from around Colorado and other states and followed a large procession on Interstate 25. People, some holding American flags, lined up to watch.	A Colorado sheriff's deputy killed by a man with a history of mental health problems tried to help the gunman before being shot, his boss said Friday at a funeral that drew law enforcement officers from around the state and elsewhere.

Table 11: Example summaries and their corresponding article in CCSUM-EXT.

C Additional Implementation Details

C.1 Data Preparation

C.1.1 Common Crawl News Data

We started the dataset construction from the Common Crawl News (CC-News)[3] dataset, which contains news articles from news sites worldwide. We use NewsPlease (Hamborg et al., 2017) to download the full Common Crawl News archive spanning from January 2018 to December 2022.

C.1.2 English Language Filter

We focus on the English subset of CC-News by filtering each article by its HTML meta-data to ensure the "language" tag is "en". However, we discovered many non-English articles are tagged as "en". To better filter articles by language, we apply an additional domain filter to identify and remove non-English domains. Among the 21,794 domains in CC-News, we randomly sample 10 articles from each domain, and assign the language as English if all articles from a domain are predicted as English with over 0.95 confidence by "langdetect" (Shuyo, 2010). This resulted in 9,999 English content domains with 58 million news articles in total.

C.1.3 Title and Content Filter

We apply a length filter to ensure each article's title is between 5 and 25 words and the main text contains at least 50 words. We also remove exact duplicates when two articles contain the same main text or when two articles have the same title and the first 200 characters of the main text are also identical. This process resulted in 35 million news articles.

C.1.4 Lead Sentence Detection and Cleaning

We use convolutional neural networks (Schweter and Ahmed, 2019) to detect sentence boundaries of each news article a_i and extract the first sentence a_i as a candidate summary for a different article $\{a_j \mid j \neq i\}$. This is implemented using Spark NLP (Kocaman and Talby, 2021) on a cluster of Amazon EC2 instances. We also use extensive regular expressions to remove datelines at the beginning of each lead sentence, such as a location, time or news providers. The primary purpose of the dateline is to indicate where and when a news story originated, and removing it does not interfere with understanding the news article.

[3]https://commoncrawl.org/blog/news-dataset-available

C.2 Clustering

We first encode the main text of each article into a semantic embedding using sentence transformers (Reimers and Gurevych, 2019) (all-mpnet-base-v2). We then perform soft clustering with faiss (Johnson et al., 2019) to group articles into clusters where every article's similarity to the centroid article is greater or equal to 0.9 in cosine similarity. We set the similarity threshold to 0.9 to ensure articles in the same cluster are semantically similar. Note that in soft clustering, an article can be assigned to multiple clusters, which allows us to over-generate candidate article-summary pairs that can be further filtered to obtain a large-scale and high-quality abstractive news summarization dataset.

D Filter details

D.1 CCSUM-specific Filter Heuristics

Domain difference f_{domain}. We require the candidate summary to come from a different domain than the article. Articles about a news topic from the same domain tend to be updates of the same event and could contain inconsistencies.

Summary entity count $f_{\text{entity_count}}(s_j)$: the summary is required to have at least one entity; otherwise, the lead sentence could be a generic introductory sentence that does not capture the main points of the article.

Summary word count $f_{\text{word_count}}$. We require the summary to contain at least 25 words.

Quotation exact match $f_{\text{quotation}}$. We use regular expression to detect quotations from the summary and ensure they are present as is in the article.

In addition to the above-mentioned filters, we also ensure the candidate summary ends in proper punctuation.

D.2 Filter Final Parameters

The full set of filters are defined in Table 12, where filter constraints with λ denote parameters to be optimized using Bayesian optimization. The final filters after optimization is summarized in Table 13. In our experiments, we apply filters in desceding order of computational complexity for computational efficiency.

D.3 Detailed Filter Funnel

Figure 8 depicts a detailed filtering funnel, including the individual heuristics and BERTScores with different base models.

Metric name	Notation f_x	Value Range	Filter Constraint A_x
Entity precision	f_{ep}	$[0, 1]$	$\{1\}$
BERTScore-Precision	$f_{\text{BS-P}}$	$[0, 1]$	$[\lambda_{\text{BS-P}}, 1]$
BERTScore-Recall	$f_{\text{BS-R}}$	$[0, 1]$	$[\lambda_{\text{BS-R}}, 1]$
Title-title similarity	$f_{\text{t-t}}$	$[0, 1]$	$[\lambda_{\text{t-t}}, 1]$
Summary-title similarity	$f_{\text{s-t}}$	$[0, 1]$	$[\lambda_{\text{s-t}}, 1]$
MINT	f_{MINT}	$[0, 1]$	$[0.2, 1]$
Simhash	f_{simhash}	$[0, 64]$	$(5, 64]$
Domain difference	f_{domain}	$\{\text{True}, \text{False}\}$	$\{\text{True}\}$
Summary entity count	$f_{\text{entity_count}}$	$[0, \infty)$	$[1, \infty)$
Summary word count	$f_{\text{word_count}}$	$[1, \infty)$	$[25, \infty)$
Quotation exact match $f_{\text{quotation}}$	$f_{\text{quotation}}$	$\{\text{True}, \text{False}\}$	$\{\text{True}\}$

Table 12: Overview of summary metrics and quality filters.

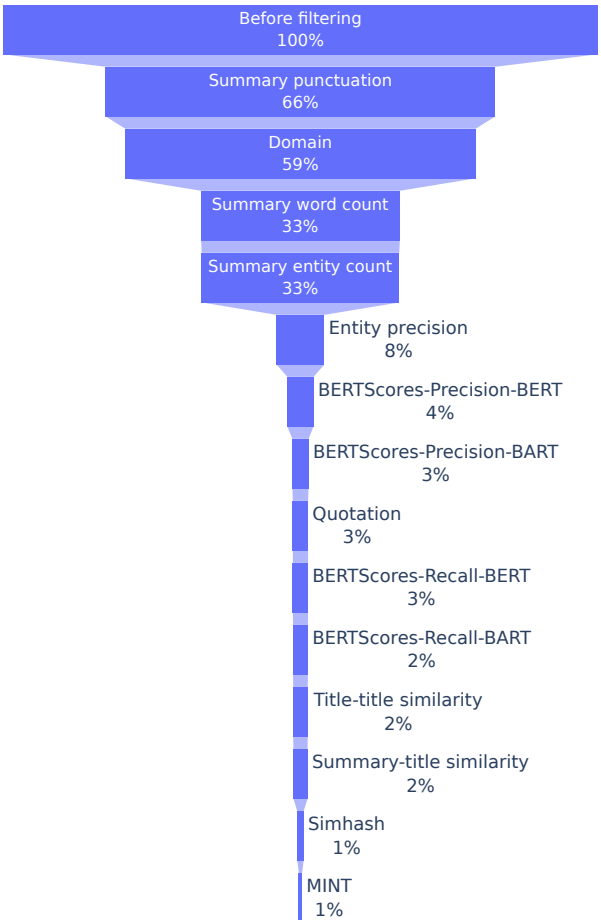

Figure 8: Detailed filter funnel.

Metric name	Constraint
Entity precision	$\{1\}$
BERTScore-Precision (bert-large-uncased)	$[0.708, 1]$
BERTScore-Precision (facebook/bart-large)	$[0.750, 1]$
BERTScore-Recall (bert-large-uncased)	$[0.344, 1]$
BERTScore-Recall (facebook/bart-large)	$[0.312, 1]$
Title-title similarity	$[0.361, 1]$
Summary-title similarity	$[0.375, 1]$
MINT	$[0.2, 1]$
Simhash	$(5, 64]$
Domain difference	$\{\text{True}\}$
Summary entity count	$[1, \infty)$
Summary word count	$[25, \infty)$
Quotation exact match	$\{\text{True}\}$

Table 13: Final summary filter parameters.

D.4 Bayesian Optimizatin Implementation Details

The optimization is carried out using Scikit-Optimize (Head et al., 2018) with the "gp_hedge" acquisition function that probabilistically chooses one of three acquisition functions at every iteration. We performed 1,000 iterations of optimization. When evaluating the filter configuration at each iteration, we return a negative constant if the constraints are violated and return $f_{\text{recall}}(\lambda, \hat{\mathcal{D}}_{\text{labelled}})$ otherwise.

E Detailed Dataset Annotation Results

Table 14 presents the detailed annotation results on the test split of each dataset. For informativeness and coherence annotation, five to one stars denote "very good', "good', "acceptable", "poor", and "very poor", respectively.

Dataset	Factual Consistency			Informativeness					Coherence				
	no error	minor	major	5-star	4-star	3-star	2-star	1-star	5-star	4-star	3-star	2-star	1-star
CNN/DM	86.7	7.8	5.5	63.6	29.7	5.7	0.7	0.3	63.9	28.9	6.5	0.5	0.2
XSum	50.3	35.4	14.3	45.0	33.2	14.5	4.0	3.3	87.8	9.4	1.5	0.4	0.9
Newsroom	78.9	8.4	12.7	43.9	23.3	19.6	7.5	5.7	62.8	20.3	11.5	3.7	1.7
Newsroom-ABS	56.5	12.6	30.9	30.0	18.6	23.7	13.8	13.8	54.1	20.4	13.8	7.5	4.2
Newsroom-EXT	92.2	5.4	2.4	59.0	24.0	12.6	3.3	1.2	66.8	18.6	13.5	0.9	0.3
Newsroom-MIX	88.0	7.2	4.8	42.6	27.3	22.5	5.4	2.1	67.6	21.9	7.2	2.7	0.6
Multi-News	71.3	13.3	15.4	78.3	17.5	3.4	0.1	0.7	87.5	9.5	2.6	0.1	0.3
CCSUM	94.9	4.2	0.9	86.7	10.6	1.9	0.8	0.0	95.8	3.2	0.9	0.1	0.0
CCSUM-EXT	96.9	2.4	0.6	87.6	9.6	2.4	0.4	0.0	94.9	3.5	1.4	0.2	0.0
CCSUM-ABS	92.9	5.9	1.2	85.9	11.6	1.4	1.2	0.0	96.7	2.9	0.4	0.0	0.0

Table 14: Benchmarking abstractive summarization datasets using human annotations (%). Five to one stars denote "very good', "good', "acceptable", "poor", and "very poor", respectively.

F Mechanical Turk Annotation Guidelines

In our Mechanical Turk annotations, we always assign three qualified annotators for each task and use their median as the final rating. The annotators are recruited from U.S., U.K., Australia, New Zealand, and Canada. For annotator qualification, we follow the procedure described in Dreyer et al. (2023). For preference annotation, the workers take on average 90 seconds to complete one summary comparison. We pay the workers $0.35 per question and $0.1 bonus, which leads to a pay of $14 to $18 per hour.

F.1 Factual Consistency

Figure 9 shows an example Mechanical Turk factual consistency annotation task, where an annotator is asked to annotate a candidate summary with respect to an article. We use sentenceBERT to highlight relevant article sentences in blue to assist the annotator. If an example is annotated as "Minor factual error" or "Major factual error," the annotator is required to explain the factual error in a few words before being able to submit the annotation.

F.2 Informativeness and Coherence

Figure 10 shows an example Mechanical Turk informativeness and coherence annotation. If an example is annotated as less than perfect rating, i.e., five stars, the annotator is required to explain why the summary is not informative or coherent.

Informative summaries express the main points of the articles; their content is important and relevant. You can give 1 to 5 stars:

- 1 star: Very poor. The summary does not express the main points of the articles. Summary content is unimportant or not relevant.
- 2 stars: Poor. The summary mostly does not express the main points of the articles. Summary content is mostly unimportant or not relevant.
- 3 stars: Acceptable. The summary expresses some main points of the articles. Some parts of the summary are important or relevant, others are not.
- 4 stars: Good. The summary mostly expresses the main points of the articles. Summary content is mostly important and relevant.
- 5 stars: Very good. The summary fully expresses the main points of the articles. Summary content is relevant and important.

Coherent summaries have good structure and flow, are easy to follow; facts are presented in logical order. You can give 1 to 5 stars:

- 1 star: Very poor. The summary has poor structure and flow or is not easy to follow. Facts are not presented in logical order.
- 2 stars: Poor. Most parts of the summary have poor structure and flow or are not easy to follow. Most facts are not presented in logical order.
- 3 stars: Acceptable. Parts of the summary have good structure and flow, are easy to follow, others are not. Some facts are presented in logical order.
- 4 stars: Good. The summary has good structure and flow, is easy to follow. Most facts are presented in logical order.

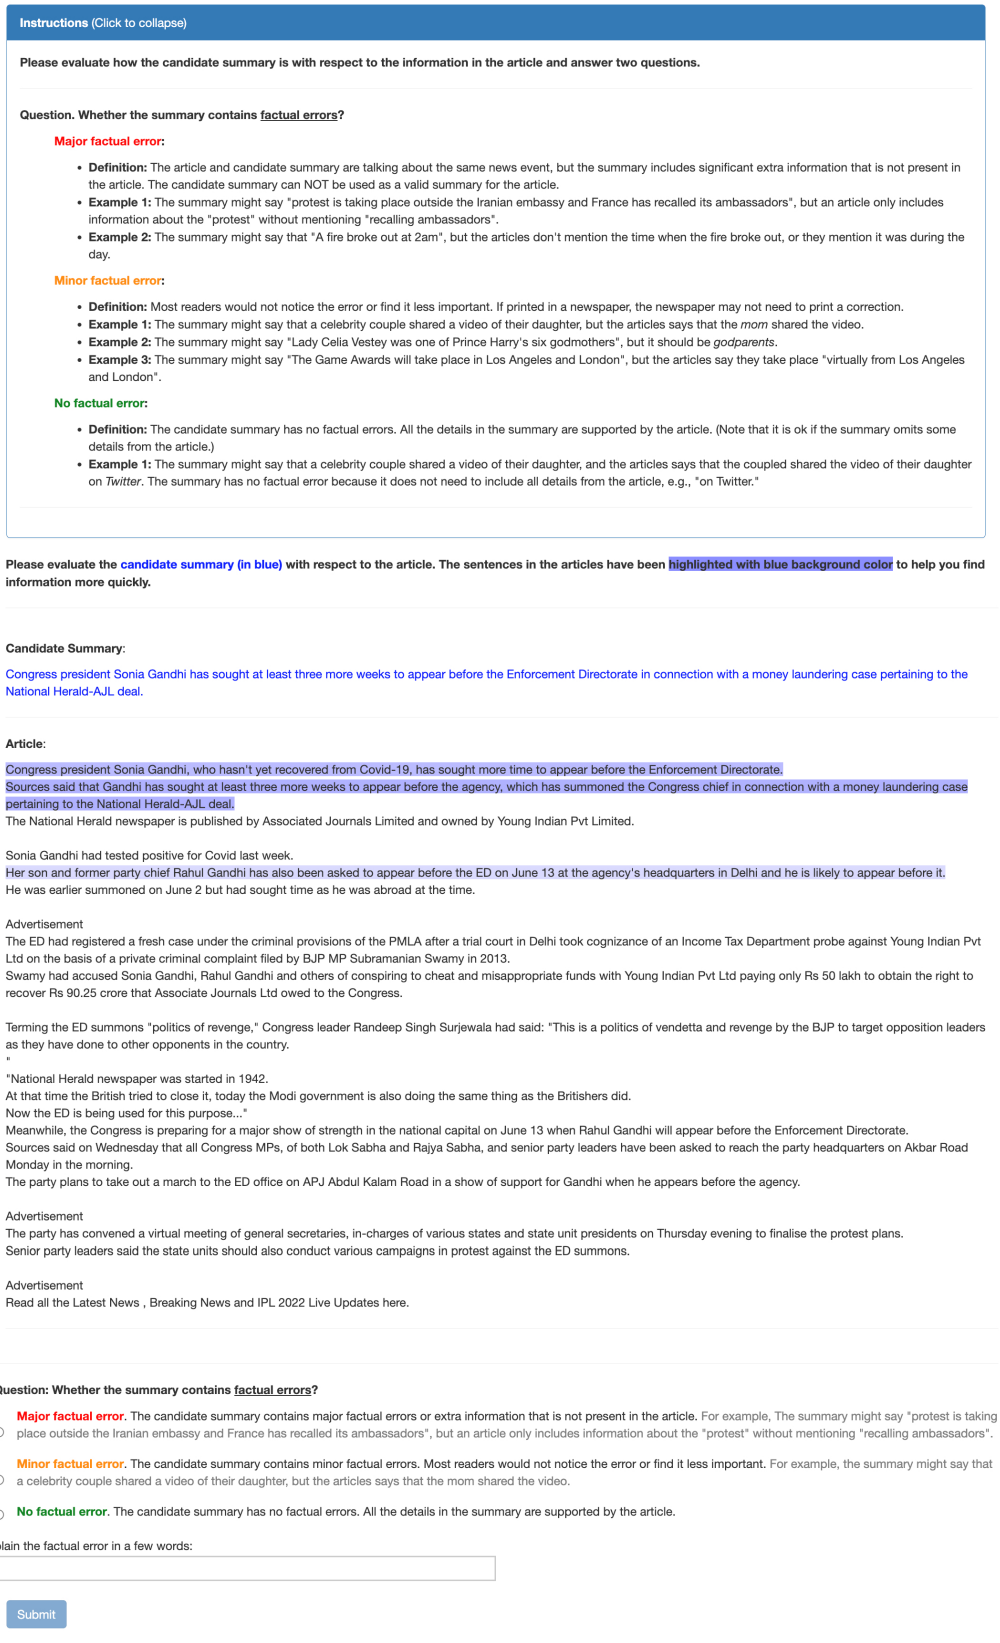

Figure 9: Mechanical Turk Annotation Guideline for Factual Consistency Annotations

- 5 stars: Very good. The summary has very good structure and flow, is very easy to follow. All facts are presented in logical order.

F.3 Pairwise Preference

Figure 11 shows an example Mechanical Turk preference annotation where a randomized pair of summaries is presented to the annotator.

F.4 Inter-Annotator Agreement

We use the average Cohen's Kappa to quantify inter-annotator agreement. Our findings show a fair level of annotator agreement, with a score of 0.291 on the overall metric when comparing FLAN-T5-Large (CNN/DM) with GPT-3.5. However, the agreement is slight (0.138) when comparing FLAN-T5-Large trained on CCSUM with that trained on CNN/DM.

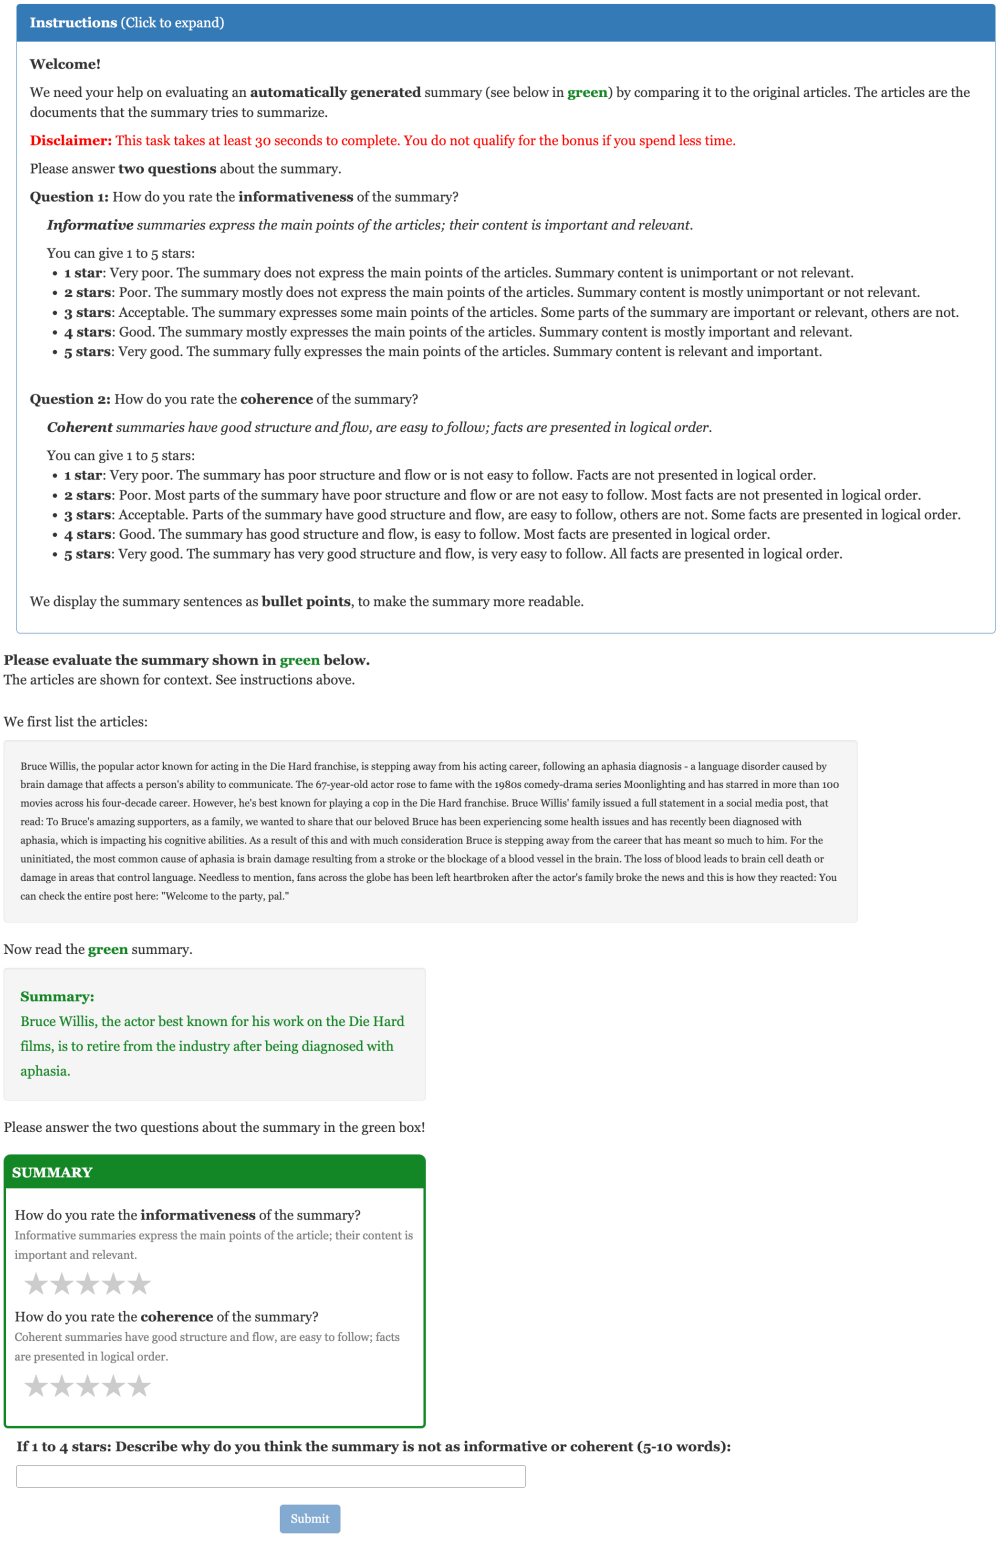

Figure 10: Mechanical Turk Annotation Guideline for Informativeness and Coherence Annotations

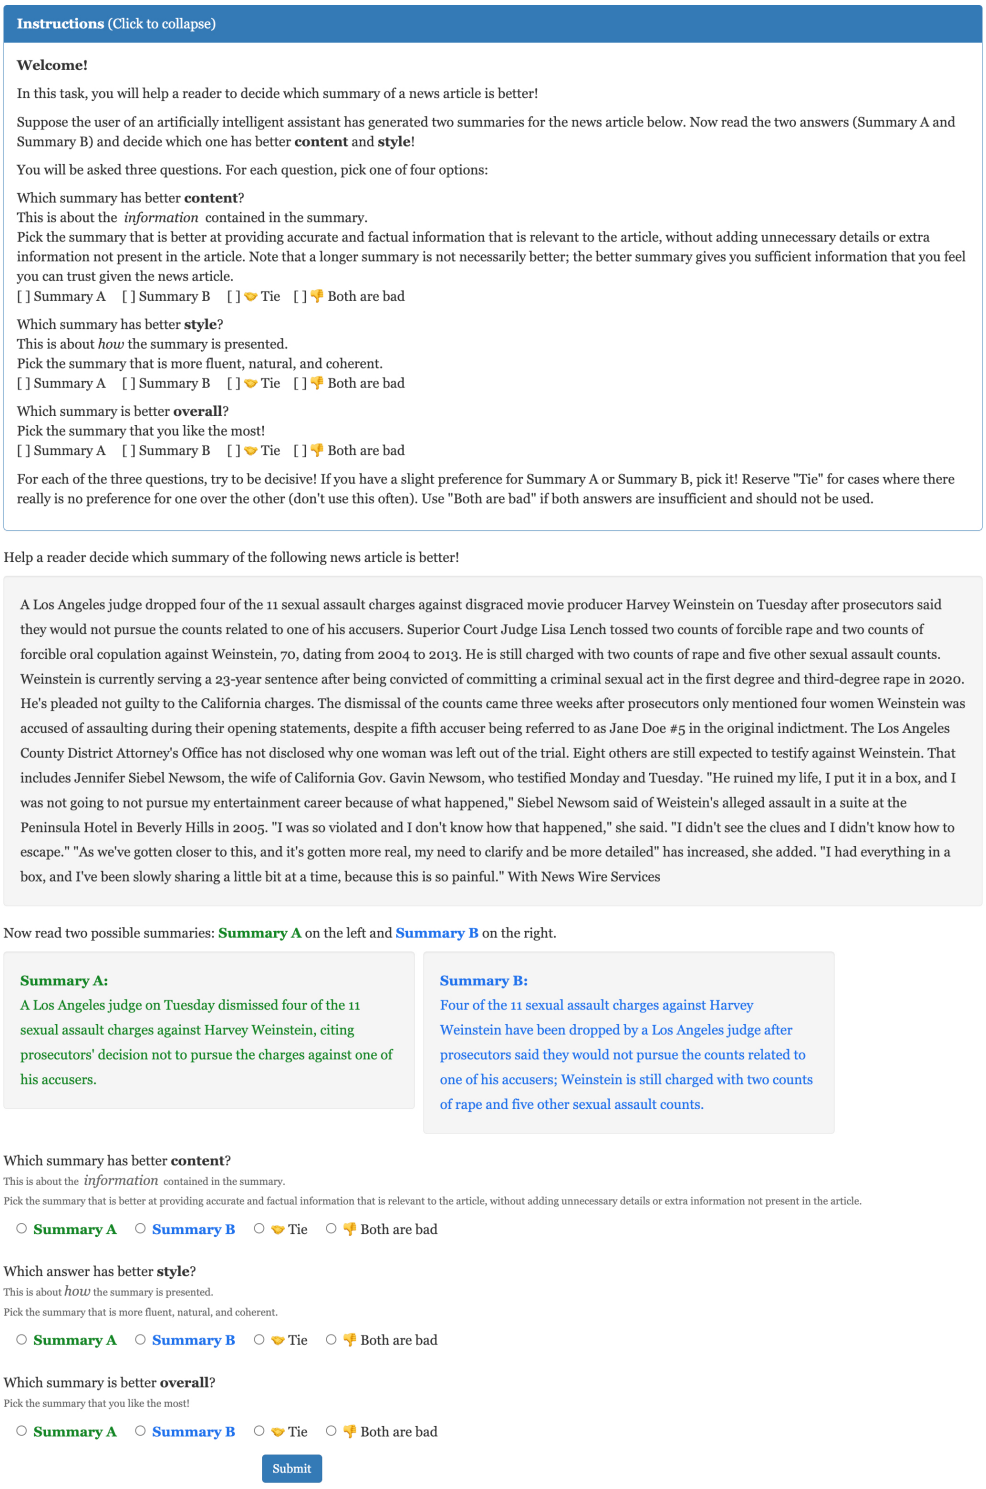

Figure 11: Mechanical Turk Annotation Guideline for Pairwise Preference Annotations

G Example Factual Consistency Errors in Abstractive Summarization Datasets

We show summary examples from each dataset that were annotated as major factual errors.

CNN/DM validation set. Table 15 shows a major factual error in the CNN/DM validation set.

Article	A JetBlue Airways pilot who had to be restrained during a 2012 flight after shouting about Jesus and al-Qaeda sued for more than $16 million Friday, claiming the airline failed to recognize and address his mental condition. The suit filed by former captain Clayton Osbon three years after his meltdown on a flight from New York to Las Vegas, comes amid increased scrutiny of how major airlines evaluate pilots' mental health in the wake of the allegedly intentional crash of a Germanwings . Osbon, 52, claims in the lawsuit that officials at JetBlue missed several indications that something was wrong with his mental health the day of the flight, noting he missed a pre-flight meeting for the first time in years and arrived to fly disheveled and disoriented. Scroll down for video . Restrained: Clayton Osbon, 52, pictured here being taken off a New York to Las Vegas flight after his breakdown, is suing JetBlue for failing to recognize he was mentally ill . Osbon moved slowly during pre-flight checks for the flight to Las Vegas from New York, and later relieved himself of duty after being told by the first officer he had missed several calls from air traffic control, the lawsuit adds. After a co-pilot locked Osbon out of the cockpit, he 'ran down the aisles screaming and ranting concerning imagined terrorism and the need for all on board on embrace religion.' The lawsuit alleges that JetBlue allowed the flight to continue for three hours and 'unnecessarily endangered the lives of Captain Osbon, the crew and the 135 passengers.' There were no injuries on the flight, which eventually made an emergency landing in Amarillo, Texas. The meltdown resulted from a complex partial brain seizure that 'severely impaired his ability to perform basic activities, caused him to hallucinate, and caused extreme feelings of paranoia and religious fervor,' according to the suit. The lawsuit also alleges the airline routinely ignored crew members' impairment, whether by alcohol, drugs or mental and emotional distress, in order to protect their careers. Hospitalized: Osbon, right, is led out by FBI agents after being released from Northwest Texas hospital in Amarillo following his mid-air breakdown . Veteran captain: Osbon, left, was an experienced pilot but a 'complex partial brain seizure' impaired his brain functions and caused him to hallucinate, according to the lawsuit . Nearly three dozen passengers sued JetBlue in 2012 for being 'grossly negligent' by allowing Osbon to fly with unchecked mental issues. JetBlue eventually settled the lawsuit in April of the following year for an undisclosed sum. After the flight was grounded in Texas, Osbon was indicted on charges of interfering with a flight crew and found not guilty by reason of insanity. Among other conditions of his sentence, Osbon was ordered not to board a commercial or private plane without permission from a probation officer. Osbon remains suspended on medical leave, no longer collecting what once was a more than $300,000 annual salary. The lawsuit states he has not suffered a seizure since beginning a regimen of prescription medication.
Summary	Clayton Osbon, 52, claims in a lawsuit the airline failed to recognize signs he was in mental distress before a flight in which he broke down shouting . The lawsuit claims Osbon missed a pre-flight meeting and arrived disheveled . The meltdown was caused by a seizure resulting from a lingering traumatic brain injury that occurred in Osbon's childhood, the lawsuit states . After relieving himself of duty during the flight, Osbon was locked out of the cockpit . He shouted at passengers about Jesus and al-Qaeda before being tackled and restrained .
Error	The article do not state the seizure was due to a brain injury during his childhood.

Table 15: Factual consistency error in the CNN/DM validation set.

Newsroom validation set. Table 16 shows a major factual consistency error in the Newsroom validation set, where the article doesn't the investment is low by European standards but is included in the summary.

Article	To infinity and beyond! BT Group channeled its inner Buzz Lightyear with a headline-grabbing set of investment pledges Thursday. Its standard "superfast" fiber-broadband package, called BT Infinity, will be extended and in some places superseded by "ultrafast" services. Together with investment in improving the 4G network of EE, the mobile business it has just bought, this will cost £6 billion ($8.7 billion) over three years.
Summary	For all of BT's eye-catching pledges, investment looks low by European standards.
Error	Article doesn't mention low investment by European standards.

Table 16: Factual consistency error in the Newsroom validation set.

XSum validation set. Table 17 shows a major factual consistency error in the XSum validation set, where the article doesn't state that profits jumped 21% as in the summary.

Article	It reported underlying pre-tax profits of £381m in the year to 2 May, with revenues up 6% to £9.9bn. The firm was formed last year by the merger of Carphone Warehouse and Dixons Retail. "This has been a terrific first year for Dixons Carphone," said the firm's chief executive Sebastian James. "We have seen excellent increases in both sales and profitability and we have made very encouraging progress with the tricky job of integrating these two great companies," he continued. In the UK and Ireland, where it trades under the Carphone Warehouse, Currys and PC World names, sales rose by 8UK sales were helped by the failure of rival mobile retailer Phones4U, which collapsed last September. Keith Bowman, equity analyst at Hargreaves Lansdown Stockbrokers: "Profitability at the group's core UK and Irish operations has enjoyed a solid increase, aided by gains in market share, whilst merger cost savings remain on track." In Greece, where Dixons Carphone trades under the Kotsovolos name, the firm said it recorded an increase in like-for-like revenues, with strong demand for large screen TVs. "We have a fantastic team in Greece," Mr James told the BBC. "They've been very entrepreneurial in thinking about every possible outcome, and how we would react to it." However, trading in southern Europe had struggled with like-for-like sales down 5%. The firm said its business in Spain continued to operate in a "tough marketplace". Earlier this month, Dixons Carphone announced a deal with US telecoms firm Sprint, which could lead to a joint venture opening up to 500 stores in the US.
Summary	Dixons Carphone has reported a 21% jump in profits in its first annual results since the merger that created the mobile phone and electrical goods firm.
Error	Article doesn't state that profits jumped 21%.

Table 17: Factual consistency error in the XSum validation set.

CCSUM validation set. Table 18 shows a major factual consistency error in the CCSUM validation set. The article states four new cases of monkeypox have been identified whereas the summary states only two new cases. This is a challenging example that failed to be detected by our filters. The article mentions "two people that had previously been suspected of having monkeypox have tested negative, but four new suspected cases were reported today." One might argue the four suspected cases is an increase of two cases from the previous two suspected cases, which makes it difficult to detect the factual consistency error.

Article	Toronto Public Health has confirmed the city's first case of monkeypox.The city has been investigating several suspected and probable cases, and today announced that one has been lab confirmed.Officials say the person is in stable condition and recovering in hospital.The city also says two people that had previously been suspected of having monkeypox have tested negative, but four new suspected cases were also reported today.That means there are four people with suspected cases and one person with a probable case, and public health officials say they are all recovering at home.Monkeypox is a rare disease that comes from the same family of viruses that causes smallpox, which the World Health Organization declared eradicated around the globe in 1980, but monkeypox generally does not spread easily between people and is transmitted through prolonged close contact.This report by The Canadian Press was first published May 26, 2022.
Summary	Toronto Public Health says there are two new suspected cases of monkeypox in the city, as well as one probable case of the virus that's under investigation.
Error	Two new suspected cases is inconsistent with article which says four

Table 18: Factual consistency error in the CCSUM validation set.

H Generated Summary Examples

Table 19 shows a set of comparative example summaries generated by different systems. We find the CCSUM-ABS-trained models produce more comprehensive summaries and properly states the main story in logical order. In comparison, the CNN/DM model's summary omits the name of the suspect. When compared with GPT-3.5 outputs, we notice the CCSUM-trained model produces very similar summaries with the first half of GPT-3.5 summary, except that GPT-3.5 includes more information in the second sentence "Weinstein is still charged with two counts of rape and five other sexual assault counts."

Article	A Los Angeles judge dropped four of the 11 sexual assault charges against disgraced movie producer Harvey Weinstein on Tuesday after prosecutors said they would not pursue the counts related to one of his accusers. Superior Court Judge Lisa Lench tossed two counts of forcible rape and two counts of forcible oral copulation against Weinstein, 70, dating from 2004 to 2013. He is still charged with two counts of rape and five other sexual assault counts. Weinstein is currently serving a 23-year sentence after being convicted of committing a criminal sexual act in the first degree and third-degree rape in 2020. He's pleaded not guilty to the California charges. The dismissal of the counts came three weeks after prosecutors only mentioned four women Weinstein was accused of assaulting during their opening statements, despite a fifth accuser being referred to as Jane Doe #5 in the original indictment. The Los Angeles County District Attorney's Office has not disclosed why one woman was left out of the trial. Eight others are still expected to testify against Weinstein. That includes Jennifer Siebel Newsom, the wife of California Gov. Gavin Newsom, who testified Monday and Tuesday. "He ruined my life, I put it in a box, and I was not going to not pursue my entertainment career because of what happened," Siebel Newsom said of Weistein's alleged assault in a suite at the Peninsula Hotel in Beverly Hills in 2005. "I was so violated and I don't know how that happened," she said. "I didn't see the clues and I didn't know how to escape." "As we've gotten closer to this, and it's gotten more real, my need to clarify and be more detailed" has increased, she added. "I had everything in a box, and I've been slowly sharing a little bit at a time, because this is so painful." With News Wire Services
FLAN-T5-Large (CCSUM-ABS)	A Los Angeles judge on Tuesday dismissed four of the 11 sexual assault charges against Harvey Weinstein, citing prosecutors' decision not to pursue the charges against one of his accusers.
FLAN-T5-Large (CNN/DM)	Judge Lisa Lench tossed two counts of forcible rape and two counts of forcible oral copulation. He is still charged with two counts of rape and five other sexual assault counts. The dismissal of the counts came three weeks after prosecutors only mentioned four women.
GPT-3.5	Four of the 11 sexual assault charges against Harvey Weinstein have been dropped by a Los Angeles judge after prosecutors said they would not pursue the counts related to one of his accusers; Weinstein is still charged with two counts of rape and five other sexual assault counts.

Table 19: Comparative summaries generated by different systems (I).

Table 20 shows another set of comparative summary examples. The summary from CNN/DM states "Fina" without any explanation, whereas the CCSUM-ABS trained summaries are easier to understand by using "Swimming's world governing body." We also notice that GPT-3.5's summary is more detailed.

Article	Fina also intends to establish a new 'open' category for swimmers whose gender identity differs from their birth sex Swimming's world governing body, Fina, has voted to ban all transgender athletes that have gone through any part of male puberty from taking part in elite women's races. Fina's new policy, which passed with 71Furthermore, Fina also aims to establish an 'open' category at its competitions for swimmers whose gender identities differ from their birth sex. The new policy will require that transgender competitors must have completed their transition by the time they are 12 years old in order to take part in women's competitions. Before casting their votes, Fina members heard a report from a transgender task force containing leading figures in the worlds of sport, medicine, and law. Speaking after news of the vote broke, Fina's executive director Brent Nowicki said that the governing body had "emphasized competitive fairness" in its approach to drafting the policy, which was comprehensive, science-based and inclusive. Elsewhere, Fina president Husain Al-Musallam claimed that the global authority was trying to "protect the rights of our athletes to compete" in addition to "protecting competitive fairness". "Fina will always welcome every athlete," Al-Musallam insisted. "The creation of an open category will mean that everybody has the opportunity to compete at an elite level." "This has not been done before, so Fina will need to lead the way. I want all athletes to feel included in being able to develop ideas during this process," he added. Sharron Davies, an ex-Great Britain swimmer who has continually argued against transgender participation in women's swimming, tweeted that she was "proud" of Fina and her sport for "doing the science, asking the athletes/coaches and standing up for fair sport for females". "Swimming will always welcome everyone no matter how you identify but fairness is the cornerstone of sport," she stressed. But LGBT advocacy group 'Athlete Ally' branded the new policy "discriminatory, harmful, unscientific and not in line with the 2021 IOC principles". "If we truly want to protect women's sports, we must include all women," said a tweet from the group, which has backed former UPenn college swimmer Lia Thomas in the past. Fina's new policy comes at a time when transgender participation in women's competitions is one of the most debated topics in sport and has only intensified with Thomas' success. In March, Thomas, who swam on the UPenn men's team before undergoing hormone replacement treatment in 2019, won the highest national college title in the US when taking part in the women's 500-yard freestyle, and she also broke several records at her former Ivy League college. In cycling, there has also been a furor over British cyclist Emily Bridges being allowed to take part in elite women's events or not. Moves from Fina's counterpart in the sport the UCI this week mean that she will have to wait until 2023 for this given that the body has doubled the period of time before a rider who has transitioned from male to female can take part in women's events to two years.
FLAN-T5-Large (CCSUM-ABS)	Swimming's world governing body has voted to ban transgender athletes who have gone through any part of male puberty from competing in elite women's races.
FLAN-T5-Large (CNN/DM)	Fina has voted to ban transgender athletes from taking part in women's races . The decision was made at an extraordinary general congress at the World Championships . Fina also intends to establish an 'open' category for swimmers whose gender identity differs from their birth sex .
GPT-3.5	Swimming's governing body, Fina, has voted to ban transgender athletes who have gone through any part of male puberty from competing in elite women's races, but also aims to establish an 'open' category for swimmers whose gender identity differs from their birth sex. The new policy requires transgender competitors to have completed their transition by the age of 12 in order to participate in women's competitions.

Table 20: Comparative summaries generated by different systems (II).

H.1 Human Preference between CCSUM-trained FLAN-T5-XL and GPT-3.5

H.1.1 Example Summaries where CCSUM-trained Models are Preferred over GPT-3.5

Table 21 and Table 22 showcase instances where the FLAN-T5-XL model model trained on CCSUM generates abstractive summaries that are more favored than those by GPT-3.5 across all three metrics—content, style, and overall—according to Mechanical Turk annotations.

In Table 21, both summaries are effective, but the CCSUM-based summary is slightly better. It is more specific in identifying the relationship between the perpetrator and the victim—"father" and "daughter", which is crucial in understanding the context of "honour killing." The CCSUM-based summary is also more specific in describing the relationship with "a Dalit boy" in contrast with "a Dalit guy."

In Table 22, the CCSUM-based summary provides specific and clear reasons for Bayern Munich's decision to sign Sadio Mane, making it more informative and accurate compared to the vague and less informative reason of being "a rare breed" in the GPT-3.5 summary.

Article	A man killed his daughter for loving a Dalit guy and surrendered to police in Karnataka's Mysuru district on Wednesday, authorities said, in what could be an honour killing.The tragic occurrence occurred inside the Periyapattana police station's jurisdiction. Suresh, the accused father, arrived in the police station on Tuesday and admitted to the crime, according to authorities.Suresh, a native of Kaggundi village in Mysuru district's Periyapatna taluk, murdered his 17-year-old daughter Shalini in the early hours of Monday. According to the police, the accused father strangled his daughter to death. Shalini was a second-year PUC student from the Vokkaliga community, which is considered an elite caste in Karnataka. She was in love with a Dalit kid from the nearby village of Mellahalli. According to investigators, they had been in love for the past three years. When the parents learned of it, they filed a complaint against the lad because the girl was a minor. At the police station, the girl made a statement against her parents.She told the cops she was in love with the boy and that she didn't want to go with her parents. She was taken to the Observation Home by the police. The daughter had contacted her parents and requested that they take her home some time ago. She told her parents when she got home that she still loves the lad and would only marry him.According to police, the father became enraged and strangled her to death on Monday. Later, he put his daughter's body in one of the Dalit boy's village's farmlands. The case is being looked at further.
FLAN-T5-XL (CCSUM-ABS)	A father killed his daughter for loving a Dalit boy and surrendered to police in Karnataka's Mysuru district on Wednesday in what could be an honour killing.
GPT-3.5	A man in Karnataka, India, killed his daughter for being in love with a Dalit guy and surrendered to the police, potentially constituting an honor killing.

Table 21: Example summary where CCSUM-ABS-trained models are preferred over GPT-3.5. (I).

Article	Bayern Munich chief, Oliver Kahn, has suggested why the club signed Sadio Mane from Liverpool. Bayern Munich officially confirmed the signing of Mane from Liverpool on Wednesday. Mane joined the Bundesliga champions on a three-year deal from Premier League giants Liverpool. In a tweet via his Twitter handle on Wednesday, Kahn said Mane's great successes at the international level made Bayern sign him. He tweeted: "We are happy that we could win Sadio Mané for the @FCBayern. "Thanks to his outstanding performances and his great successes at the top international level, he has been a player for many years that is very rare in the world." Mane recently won the Africa Cup of Nations, AFCON, with the Senegal national team and qualified them for this year's FIFA World Cup in Qatar."
FLAN-T5-XL (CCSUM-ABS)	Bayern Munich chief Oliver Kahn has said that Sadio Mane's outstanding performances and international success were the reasons behind the club signing him from Liverpool.
GPT-3.5	Bayern Munich president Oliver Kahn has revealed the reason the club decided to sign Liverpool forward Sadio Mane on Wednesday, stating that the player is a rare breed.

Table 22: Example summary where CCSUM-ABS-trained models are preferred over GPT-3.5. (II).

H.1.2 Example Summaries where GPT-3.5 is Preferred over CCSUM-trained Models

Table 23 and 24 showcase instances where GPT-3.5 summaries are more favored than CCSUM-trained FLAN-T5-XL models across all three metrics—content, style, and overall—according to Mechanical Turk annotations.

In Table 23, the summary from FLAN-T5-XL (CCSUM) is nearly the same with the first half of GPT-3.5 summary, but the GPT-3.5 summary is a compound sentence where the second clause contains additional information on the context of the visit, i.e., "as the West and wider Middle East seek to repair relations with Saudi Arabia amid financial strains caused by..."

In Table 24, the GPT-3.5 summary is better because it mentions the name of the subject "Jason Alexander" rather than describing it as "the man who...". The GPT-3.5 summary is also more informative that mentions the subject "was briefly married to Britney Spears in 2004," which was not included in the summary from FLAN-T5-XL (CCSUM).

Article	By Tamara Qiblawi, CNN Saudi Crown Prince Mohammed bin Salman has landed in the Turkish capital, Ankara, for a first visit to the country since the 2018 murder of journalist Jamal Khashoggi at the kingdom's Istanbul consulate. The visit began with a welcome ceremony, and will be followed by a one-on-one meeting between Turkish President Recep Tayyip Erdogan and the crown prince. The trip comes as the West and wider Middle East seek to repair relations with the oil-rich kingdom, in a bid to alleviate financial strains prompted by the pandemic and sky-high energy prices sparked by Russia's invasion of Ukraine. In April, Erdogan met the crown prince in the Saudi city of Jeddah, a visit that ended the years-long diplomatic standoff between the two countries. The crown prince — known as MBS — is the de facto ruler of Saudi Arabia. A wave of crackdowns on Saudi dissidents, which culminated in Khashoggi's murder by a 15-man hit squad, strained relations between Riyadh and multiple Western states and Turkey. However, then-US President Donald Trump stood by MBS — who was a lynchpin of Trump's Middle East policy — even as the CIA said they believed the crown prince approved the murder at the consulate. According to Turkish official sources, a Saudi forensic expert equipped with a bone saw dismembered Khashoggi's body after he was killed in the Istanbul consulate in October 2018. MBS denied involvement in the murder, which captured international headlines with lurid details of the killing. Erdogan spoke out strongly against the murder, launching a probe into the killing, and diplomatic relations between the two countries broke down. But a plummeting Turkish lira and inflation of more than 70% appear to have forced the Turkish President to change tack. For months, Ankara has made overtures to Riyadh — as well as Saudi's closest Gulf ally, Abu Dhabi — to mend relations, including ending Khashoggi's murder trial in April and transferring the case to Riyadh. Rights groups have condemned the move, arguing it would kill off the case. Khashoggi's fiancée, Hatice Cengiz, an outspoken advocate for justice for the slain Saudi critic, said her legal team would appeal the decision. "The fact that he came to our country does not change the fact that he is responsible for murder," Cengiz tweeted on Wednesday, referring to MBS' visit. During his US presidential campaign, Joe Biden vowed to turn MBS into a "pariah" over his rights record. As President, Biden has declined to communicate directly with the powerful prince, opting instead to speak to his official counterpart — the ailing King Salman. But soaring fuel prices in recent weeks sparked a U-turn in Biden's Saudi policy. Tense diplomatic relations drastically reduced US leverage in pushing Riyadh to pump more oil, until Biden ramped up diplomatic efforts and scheduled a first official visit to the kingdom, which is expected to happen in July. He is expected to meet MBS during the visit. The-CNN-Wire ™ & © 2022 Cable News Network, Inc., a WarnerMedia Company. All rights reserved. CNN's Isil Sariyuce contributed to this report.
FLAN-T5-XL (CCSUM-ABS)	Saudi Crown Prince Mohammed bin Salman arrived in Turkey on Wednesday for his first official visit since the murder of journalist Jamal Khashoggi in the Saudi consulate in Istanbul in October 2018.
GPT-3.5	Saudi Crown Prince Mohammed bin Salman has arrived in Turkey for a visit, marking his first trip to the country since the 2018 murder of journalist Jamal Khashoggi; the visit comes as the West and wider Middle East seek to repair relations with Saudi Arabia amid financial strains caused by the pandemic and high energy prices.

Table 23: Example summary where GPT-3.5 is preferred over CCSUM-ABS-trained FLAN-T5-XL. (I).

Article	The felony charge came from multiple incidents over time, an attorney said. The pair were married for less than three days in 2004. Example video title will go here for this video VENTURA, Calif. — A man once briefly married to Britney Spears who showed up uninvited at the pop starś wedding to longtime boyfriend Sam Asghari was charged Monday with felony stalking. Jason Alexander, 40, pleaded not guilty in Ventura County court to the charge, along with misdemeanor counts of trespassing, vandalism and battery. The three misdemeanor charges stemmed directly from Alexanderś attempt to get into the wedding, which he livestreamed on Instagram. The stalking charge involved repeated incidents over time, Spears attorney Mathew Rosengart said. “He’s going to — I hope, and I pledged my support — be very vigorously prosecuted," Rosengart said outside the hearing. “It’s a very serious matter. This was more than just a quote ‘wedding crash.’ This was an intrusion.” A judge issued a restraining order requiring Alexander, who appeared in court via video conference from jail, to stay at least 100 yards from Spears for three years. The judge set his bail at $100,000 and scheduled a Wednesday hearing on the issue. An email seeking comment from his public defender Matthew Terry was not immediately returned. Alexander was Spearsf́irst husband. The two were married for less than three days in 2004 before an annulment. Spears, 40, and Asghari, 28, were married Thursday at her home in Thousand Oaks, California, in front of several dozen guests including Selena Gomez, Drew Barrymore, Paris Hilton and Madonna. Alexander, who was a childhood friend of Spears, was streaming live on Instagram when he approached the house. He appeared in a mostly empty but decorated room, telling security Spears had invited him. Deputies responding to a trespassing call detained him, and he was arrested when they learned he had a warrant for his arrest in another county, the Ventura County Sheriffś Office said. Spears was previously married from 2004 to 2007 to Kevin Federline, with whom she shares two sons, ages 14 and 15. She met Asghari in 2016 on the set of the video for her song “Slumber Party.” Their wedding came nine months after Spears and Asghari were engaged, and nearly seven months after Spears won her freedom from a court conservatorship that controlled her life and affairs for more than 12 years. Spears posted about the nuptials on her Instagram and Twitter accounts the following day.
FLAN-T5-XL (CCSUM-ABS)	The man who was arrested after he showed up uninvited to Britney Spears’ wedding to Sam Asghari pleaded not guilty Monday to felony stalking and multiple misdemeanors.
GPT-3.5	Jason Alexander, a man who was briefly married to Britney Spears in 2004, has been charged with felony stalking after showing up uninvited at her recent wedding to Sam Asghari; he has also been charged with misdemeanor counts of trespassing, vandalism, and battery.

Table 24: Example summary where GPT-3.5 is preferred over CCSUM-ABS-trained FLAN-T5-XL. (II).

I Additional Experiment Details

I.1 Fine-tuning FLAN-T5

We use deepspeed (Rasley et al., 2020) to fine-tune FLAN-T5 models on eight Nvidia A100 GPUs. We use learning rate 1e-5 with the AdamW (Loshchilov and Hutter, 2017) optimizer. All FLAN-T5 models are fine-tuned for 2 epochs.

I.2 GPT-3.5 Prompts

We have tried different prompts to generate abstractive summaries using GPT-3.5, but many prompts lead to very long summaries that contains about one hundred words. The final prompt used in the experiment is "Summarize the following news article into one brief sentence: {article}."

I.3 Length Statistics of Generated Summaries

Table 25 summaries the output word count statistics of different summarization systems. We find that CCSUM-trained models generate longer summarizes than the pretrained FLAN-T5-Large, and shorter summarizes than that of CNN/DM or GPT-3.5.

	Percentile			
	25%	50%	75%	Std
FLAN-T5-Large	20.0	26.0	32.0	9.1
CNN/DM	35.0	41.2	47.0	10.5
GPT-3.5	32.0	41.6	49.0	13.7
CCSUM-ABS	26.0	29.0	32.0	5.1
CCSUM-EXT	27.0	31.7	36.0	7.5

Table 25: Word count statistics of generated summaries.

J Category-instruct summarization

We train a category-based instruction-following model (Ribeiro et al., 2023) to summarize a news article into different abstractiveness levels, e.g., "Summarize with abstractiveness level 8," where the requested abstractiveness level corresponds to the MINT $\times$ 10. Figure 12 depicts the relationship between the requested abstractiveness score and the actual abstractiveness score. We find that the model generates more abstractive summaries as we increase the requested abstractiveness score, but the received abstractiveness score is discounted by 25%, suggesting more research is needed to obtain more precise instruction-following summarization models. The proposed CCSUM dataset can be used in more controllable summarization tasks (Zhang et al., 2023).

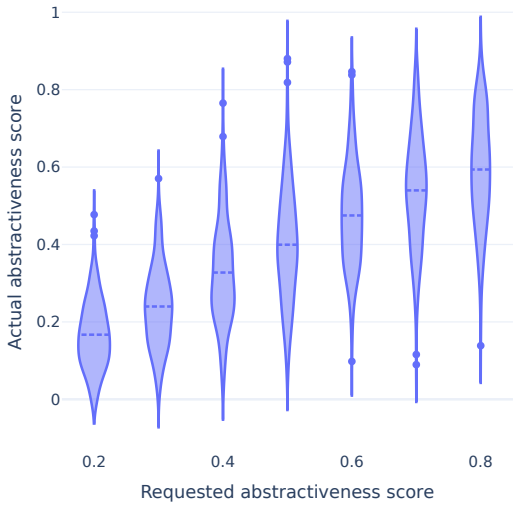

Figure 12: Requested abstractiveness score in user prompt vs. actual abstractiveness score in the summary.

K The De-noising Effect of CCSUM-EXT-trained models

Figure 13 shows that FLAN-T5-Large trained on CCSUM-EXT can effectively remove noise, in red, from the article when generating a highly extractive summary, which resolves the downsides of imperfect sentence segmentation.

Article without noise

Germany is in talks with Canada over options to export liquefied natural gas to Europe via a terminal on Canada's east coast, a German government official told Reuters on Tuesday.German Chancellor Olaf Scholz discussed the issue with Canadian Prime Minister Justin Trudeau on the sidelines of the summit held by The Group of Seven economic powers leaders this week, two other sources told Reuters. Berlin has been rushing to phase out Russian energy imports after Moscow's invasion of Ukraine and is looking for alternative supply routes and sources of energy. It has backed the construction of two LNG terminals and has rented four floating storage and regasification units as a stop-gap measure.

In May, Canadian Natural Resources Minister Jonathan Wilkinson said the Canadian government was in discussions with the companies behind two proposed east coast LNG export facilities to see how it could speed up the projects and help boost supply to Europe. Canada, the world's sixth-largest natural gas producer, does not have any east coast LNG facilities and only one under construction on its west coast. "In terms of CO2 footprint and proximity to European markets Canadian east coast projects are very well placed," one of the sources said. The second source said that Canadians were eager to develop new fields given high shale gas prices and recognised Germany's reputation as being environmentally friendly.

Germany consumes around 100 billion cubic meters of natural gas annually with around 55% of that coming from Russia and smaller volumes piped from Netherlands and Norway. Spanish oil major Repsol's regasification plant on Canada's east coast, through which it imports into the United States, could potentially have a liquefaction capacity installed to export directly into Northwest Europe, an industry source said. The office of Canadian Prime Minister Justin Trudeau was not immediately available for comment. Repsol told Reuters it is continuously exploring options to maximize the value of the terminal, with a particular focus on new lower-carbon opportunities to help meet market demand. "The company will look at any/all business that enhances or creates value at Saint John LNG, including the potential to add liquefaction capabilities to the existing facility," it added.

Summary:

Germany is in talks with Canada over options to export liquefied natural gas to Europe via a terminal on Canada's east coast, a German government official told Reuters on Tuesday.

Article with noise

Germany is in talks with Canada this is breaking news, come back to read more updates over options to export liquefied natural gas to Europe via a terminal on Canada's east coast, a German government official told Reuters on Tuesday.German Chancellor Olaf Scholz discussed the issue with Canadian Prime Minister Justin Trudeau on the sidelines of the summit held by The Group of Seven economic powers leaders this week, two other sources told Reuters. 10	0.0%	0.0%	0.0%	4.4%

Table 26: The distribution of the most relevant sentence index in the article w.r.t. the summary.

L Similarity between Reference Summary and Article Sentences

In Table 26, we have measured the distribution of the most relevant sentence (limited to the first ten sentences for simplicity) in relation to the summary. This measurement is based on cosine similarity using Sentence-BERT. Additionally, in Table 27, we've included the average cosine similarity between the reference summary and each of the first ten sentences of the article. To establish a baseline, we also calculated these statistics using summaries generated by GPT-3.5.

Our findings indicate that in the CCSum-Abs dataset, the reference summaries most closely resemble the first sentence of the article in 68.8% of cases. This is marginally lower than the 73% observed with GPT-3.5 summaries where the first sentence is most often the most relevant. Furthermore, our data shows a monotonous decrease in cosine similarity between the reference summary and the sentences in the article. These observations suggest that the CCSum dataset exhibits similar characteristics to GPT-3.5 in terms of the positional relevance of sentences in the article. We also report the statistics for the CNN/DM dataset by encoding the three-sentence summary into a single vector. The findings suggest that CCSum has a stronger lead-bias than CNN/DM. The positional relevance in CNN/DM is more distributed across various sentences, and there is a comparable monotonic decrease in cosine similarity.

Sentence	CCSum-Abs	CCSum-Ext	GPT-3.5	CNN/DM
1	0.73	0.75	0.79	0.56
2	0.55	0.56	0.60	0.47
3	0.45	0.45	0.48	0.43
4	0.42	0.41	0.47	0.41
5	0.39	0.35	0.42	0.39
6	0.34	0.33	0.37	0.40
7	0.31	0.32	0.38	0.39
8	0.30	0.29	0.34	0.36
9	0.27	0.24	0.31	0.37
10	0.24	0.24	0.28	0.35

Abstract

Supervised classification heavily depends on datasets annotated by humans. However, in subjective tasks such as toxicity classification, these annotations often exhibit low agreement among raters. Annotations have commonly been aggregated by employing methods like majority voting to determine a single ground truth label. In subjective tasks, aggregating labels will result in biased labeling and, consequently, biased models that can overlook minority opinions. Previous studies have shed light on the pitfalls of label aggregation and have introduced a handful of practical approaches to tackle this issue. Recently proposed multi-annotator models, which predict labels individually per annotator, are vulnerable to underdetermination for annotators with few samples. This problem is exacerbated in crowdsourced datasets. In this work, we propose **Annotator Aware Representations for Texts (AART)** for subjective classification tasks. Our approach involves learning representations of annotators, allowing for exploration of annotation behaviors. We show the improvement of our method on metrics that assess the performance on capturing individual annotators' perspectives. Additionally, we demonstrate fairness metrics to evaluate our model's equability of performance for marginalized annotators compared to others.[1]

1 Introduction

Supervised machine learning tasks often train on data provided by human annotators. To improve the quality of ground truth data, the data samples are labeled by multiple annotators, whose independent decisions are then aggregated, often by taking the majority label or average value. This approach works well in some tasks, like image recognition, where "objective" ground truth exists. Objective judgments should not be affected by individual differences among annotators and in practice, most people would perceive and classify them similarly, except for obvious errors or oversight (Basile et al., 2021a).

However, some annotation tasks are subjective by nature, and traditional approaches to aggregating annotations that ignore context and subjectivity may lose important information (Plank, 2022). For instance, individuals may differ about what they consider to be toxic or hate speech on social media, depending on their background and attitudes (Sap et al., 2022). As a result, not all annotators will agree when a particular message constitutes hate speech. Disagreement among annotators in subjective tasks is expected because, for each item, the annotation outcome depends on (1) the annotator's perspective and lived experience, (2) the item being evaluated, (3) the time and circumstances surrounding the annotation task, and (4) the clarity of the designed prompts or instructions given to annotators (Basile et al., 2021b; Denton et al., 2021). In addition, annotators vary in how much effort they put into the task, with prolific annotators labeling many samples and sparse annotators labeling few samples. A classifier that does not take variety in human labels into account risks overlooking minority perspectives by ignoring potentially informative differences between annotators and integrating the biases of a particular annotator pool.

Historically, most public datasets did not provide labels at the individual annotator level. This limited the ability of machine learning researchers to develop methods that take advantage of differences in annotator perspectives in subjective learning tasks. Recently, researchers have acknowledged the importance of incorporating this information and have released raw annotations, often accompanied by demographic information about the annotators. It has now become commonplace to include multiple annotations per item in published datasets (Frenda

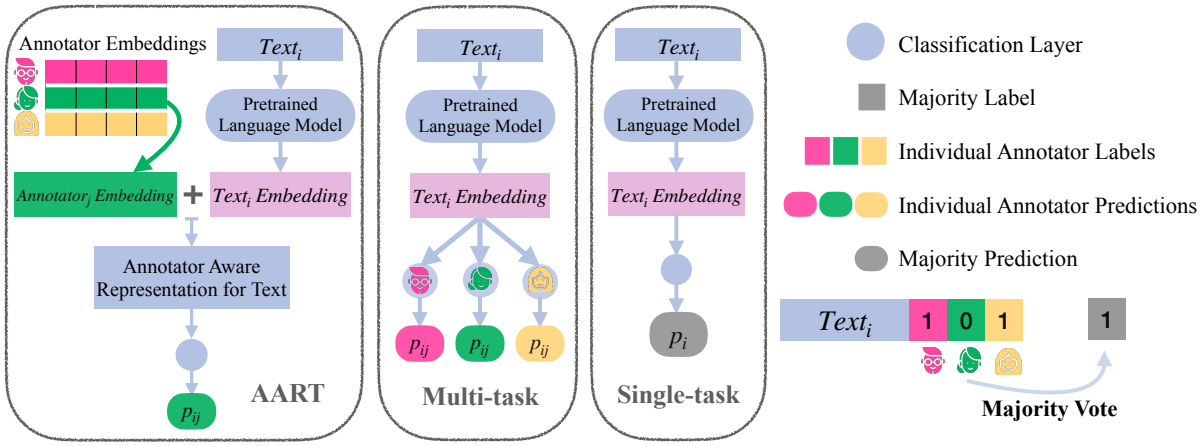

Figure 1: The architecture of AART compared to the multi-task and single-task approaches. Whereas a multi-task model incorporates annotator subjectivity by training entirely separate classification heads per annotator, AART represents annotator-specific biases as embeddings that are added to the text embeddings prior to classification. This new approach constrains the degrees of freedom and allows a common head across annotators, lending helpful inductive biases to sparse annotators.

et al., 2023; Sap et al., 2022; Prabhakaran et al., 2021; Denton et al., 2021). Recent studies have revealed that the aggregation of annotations exhibits detrimental biases toward specific groups of annotators (Prabhakaran et al., 2021; Aroyo et al., 2024).

Instead of adhering to the conventional notion that labels should be aggregated across all stages of AI pipelines, recent research advocates for leveraging the inherent diversity in human-assigned labels by pioneering innovative approaches to accommodate multiple votes per item at different stages of AI pipelines. This can be applied across domains such as model architecture design (Weerasooriya et al., 2023; Mostafazadeh Davani et al., 2022; Hayat et al., 2022; Gordon et al., 2022; Deng et al., 2023; Gordon et al., 2021), performance evaluation metrics (Basile et al., 2021b; Dumitrache et al., 2019; Gordon et al., 2021), or label aggregation, surpassing simplistic methods like averaging or majority voting (Aroyo and Welty, 2014; Dumitrache et al., 2018).

Despite some progress, few researchers have systematically tackled the problem of learning from multiple annotations. We address this gap by proposing a new approach for modeling annotator perspectives in subjective classification tasks via **Annotator Aware Representations for Texts (AART)**. Our approach learns annotator embeddings that represent their perspectives in downstream classification tasks (see §3 for more details). We demonstrate empirically that AART affords a more accurate and context-sensitive interpretation of subjective data at the individual annotator level.

We compare our approach to a widely recognized method (Mostafazadeh Davani et al., 2022) that captures differences in annotator judgments using a multi-task architecture consisting of a separate trainable classification-head per annotator. We show that the multi-task learning suffers from having under-trained classification heads for *sparse* annotators that contribute few annotations. Although this work marks an advance in the study of annotations of subjective tasks, its difficulties in accounting for differences in perspectives of infrequent, sparse annotators limits its utility in practical applications.

In contrast, our method captures the semantics inherent in subjective classification tasks, accounting for the diverse perspectives of annotators, including those who contribute few annotations. The AART architecture combines text embedding with annotator embeddings and provides this joint information to the classification layer. We couple this design choice with using the L2 regularizer in the loss, to prevent annotator embeddings from overfitting. Additionally, we use the contrastive loss to aid in learning from the similarities and dissimilarities of label choices among annotators, a capability lacking in Multi-task. Furthermore, in Section 4, we examine the learned annotation behaviors.

By leveraging metrics from algorithmic fairness, we demonstrate that the viewpoints of sparse annotators—who either contribute few samples or

select less popular labels—are accurately represented (See §4.5). This inclusivity is crucial for applications where the diversity of perspectives is essential for understanding patterns in subjective annotations. Practitioners can utilize this approach to anticipate how individuals and, by extension, subgroups would react to a particular input.

2 Related Work

Sources of Annotator Disagreement. Some previous research has shown aggregating the labels takes away the voice of minority socio-demographic groups (Prabhakaran et al., 2021). Al Kuwatly et al. (2020) conducted a study grouping annotators according to socio-demographic attributes and discovered biases in the annotations of personal attack corpora is linked to annotators' age, education, and first language. Similarly, (Sap et al., 2022) found that posts written in African American dialect were more likely to be labeled as offensive by conservative annotators. Furthermore, (Larimore et al., 2021) demonstrated that there are differing interpretations among white and non-white workers when annotating racially sensitive topics, indicating the importance of considering the perspectives of those affected when gathering annotations of racist language.

It is important to note that many public datasets lack information regarding the demographics of the annotators alongside their annotations. Moreover, even in cases where datasets do report annotator demographics, mostly there exists an imbalance in the representation of demographics among annotators (Orlikowski et al., 2023). For instance, while females constitute the majority of crowd workers in the US, they are significantly underrepresented in most other countries. Additionally, online platforms tend to attract a predominantly young demographic of annotators (Posch et al., 2022; Hara et al., 2019).

However, it is essential to recognize that relevant lived experience and mindset among annotators do not always perfectly align with demographic characteristics (Orlikowski et al., 2023). Waseem (2016) found that amateur annotators were more prone to mislabel content as racist or sexist compared to experts with backgrounds in feminism and anti-racism activism. This finding emphasizes the need for researchers to identify annotator behaviors beyond relying solely on demographic characteristics. Hence, some previous work has explored methods to identify groups of annotators with similar annotation behaviors. Wich et al. (2020) employed graph methods, and (Lo and Basile, 2023) conducted hierarchical clustering of annotators, while (Akhtar et al., 2020) and (Basile, 2021) utilized exhaustive-search algorithms to automatically group human annotators in order to maximize the inter-group differences in annotation patterns.

Modeling Annotator Disagreement. Examining annotation disagreement has been a subject of interest in previous research. One line of research treats disagreement as noise and attempts to minimize it in order to improve performance (Mokhberian et al., 2022; Hovy et al., 2013). However, another line of research argues in favor of embracing annotation disagreement, considering it as a valuable signal rather than entirely noise (Aroyo and Welty, 2015; Rodrigues and Pereira, 2018). Our paper explores the latter possibility.

Certain studies have demonstrated that the level of disagreement among annotators for each data point can be predicted based on the text itself (Kenyon-Dean et al., 2018). Additionally, incorporating demographic information of the annotators has shown even better performance (Wan et al., 2023).

Recent work for numerous tasks has proposed to approximate the full annotators' label distribution on each item, instead of aggregating, utilizing methods such as soft-label learning (Fornaciari et al., 2021; Uma et al., 2021, 2022).

Other research has developed approaches to model annotators for subjective tasks and to predict a personalized label for each annotator. Plepi et al. (2022) explore methods of personalization to model Reddit users and analyze the effect of their method on demographic groups. Akhtar et al. (2020) employ a comprehensive search approach to divide annotators into two groups based on their annotation patterns. They demonstrate the effectiveness of an ensemble model comprising two separate classifiers representing the perspectives of each group over the traditional single-task model, which merely observes aggregated labels. Mostafazadeh Davani et al. (2022) explored the effectively of three different multi-annotator architectures for predicting each annotator's labels. Deng et al. (2023) integrate annotator embeddings into their model design, yet they were unable to identify significant annotator patterns solely based on these embeddings without incorporating addi-

tional embeddings for representing annotation labels. Gordon et al. (2022) introduced the concept of jury learning, a recommender system approach that specifies the demographic composition of individuals, along with their respective proportions, tasked with determining the predictions of the classifier. For example, in the context of online hate speech detection, a jury learning model might recommend the inclusion of women and Black jurors, as they are often primary targets of online harassment. Drawing motivation from this line of work, our paper investigates a new approach to model the subjectivity of tasks through label variations among individual annotators. By training annotator-specific embeddings with a contrastive loss, we learn a latent space that captures similarities and differences in annotator behavior.

3 Methodology

This section presents the details of our proposed approach and baselines used for evaluation. Our proposed method ***AART*** (§3.2) learns separate representations for each annotator in an end-to-end fashion during the training phase of the main classification task. In the inference phase, we are able to predict personalized labels for each annotator based on the annotation behaviors observed during training. A commonly used method for learning subjective perspectives is ***multi-task*** model (§3.3) which trains a separate classification head for each of the annotators. Other than comparing our method to the multi-task model we also compare it to a ***single-task*** (§3.4) model which is fed the aggregated labels during training and is not aware of the variety of annotations for each item. The overall framework of these approaches is shown in Fig. 1.

3.1 Problem Definition

We consider an input corpus $\mathcal{D} = \{(x_i, a_j, y_{ij})\}$ that is composed of triplets, with elements coming from text items $X = \{x_i\}_{i=1}^{N}$, annotators $A = \{a_j\}_{j=1}^{M}$, and annotations $y_{ij} \in \{1, ..., Q\}$. Each (i, j) combination that appears (at most once) in $\mathcal{D}$ means that annotator a_j assigned label y_{ij} to the text item x_i. In most annotated datasets, many y_{ij} values are not available as annotators only label a portion of items.

Most traditional classification studies aim to predict the aggregated label that would be assigned to text x_i by the annotator pool $\{a_j\}_{j=1}^{M}$. This aggregated label is usually calculated via majority-voting or averaging. This fundamental model, referred to as the *single-task* model in this paper (See §3.4), solely considers and predicts the aggregated labels. In this study, however, we are interested in predicting the label that annotator a_j would assign to an unseen text item x_i, i.e., predict y_{ij} given a pair of annotator and item (x_i, a_j). We use the overarching term "multi-annotator models" to encompass these models, and we will describe our proposed multi-annotator model, *AART* (see §3.2), and the established *multi-task* (see §3.3) model found in prior literature.

All the approaches we investigate in this paper leverage pretrained transformer-based language models for encoding text (such as BERT (Devlin et al., 2019) and RoBERTa (Liu et al., 2019)). Given a text item x_i, we extract its generic representation by taking the embedding of the [CLS] token from the final layer of the language model, denoted as $e(x_i) \in \mathbb{R}^d$ (d is the size of the representation vector defined in the language model). This representation is then fine-tuned in conjunction with the other parameters of the model architectures during training.

3.2 Annotator-Aware Representations for Texts (AART)

We present a novel approach for incorporating annotator information into text representations for the purpose of learning an annotator's label on a given text instance. Our approach utilizes M annotator embeddings, with one randomly initialized embedding per annotator, as learnable parameters with the same dimensionality as the text embeddings. Given a text instance x_i and annotator a_j, the annotator-aware text embedding $g(x_i, a_j)$ is calculated as the sum of the text embedding $e(x_i)$ and annotator embedding $f(a_j)$, yielding $g(x_i, a_j) = e(x_i) + f(a_j)$. We also tried concatenating a one-hot encoding for each annotator with text embeddings which resulted in lower performance compared to taking the sum. Our idea draws inspiration from the positional encoding used by transformers (Vaswani et al., 2017), where a positional embedding of the same dimensionality as the token embedding is added to the token embedding at each position to form the sequence representation. A similar approach has been found effective in dialogue act classifications by learning speaker-turn embeddings in a conversation (He et al., 2021). We feed the annotator-aware representations of text $g(x_i, a_j)$

into a fully connected classification layer.

To train AART we propose the following objective function:

$$\mathcal{L} = \mathcal{L}_{CE} + \lambda \sum_{j} \|f(a_j)\|_2 + \alpha \sum_{j,j'} \mathcal{L}_C(j, j')$$

Where the first term is a cross-entropy loss for predicting the item-annotator labels y_{ij}, the second term is the regularizing L_2 norm for annotator embeddings, and the third term is contrastive loss. We calculate InfoNCE contrastive loss (Oord et al., 2018; Chen et al., 2020) on pairs of a_j and $a_{j'}$ that have both worked on the same text x_i. When two annotators a_j and $a_{j'}$ have assigned the same label to x_i we consider a_j and $a_{j'}$ as a positive pair and our loss will push them closer in the latent space. We consider a negative pair to be any two annotators that have assigned different labels to that item. The contrastive loss for a positive pair of annotators (j, j') is defined as below:

$$\mathcal{L}_C(j, j') = -\log \frac{\exp\left\{-\|a_j - a_{j'}\|_2^2/\tau\right\}}{\sum_{k \in \mathcal{N}_j \cup \{j'\}} \exp\left\{-\|a_j - a_k\|_2^2/\tau\right\}},$$

in which τ is a temperature constant and $\mathcal{N}_j$ is the set of all negatives for annotator j.

3.3 Multi-task Approach

The multi-task approach learns each annotator's labeling behavior via individual classification tasks, utilizing shared language model layers to derive a consistent representation of the input text, $e(x_i)$, for all annotators (Mostafazadeh Davani et al., 2022). To capture annotator-specific labeling behavior, this method has a separate fully connected layer specifically optimized for each annotator. However, the text encoding layers generating $e(x_i)$ are refined based on the outputs of all annotator tasks. The optimization objectives are formulated separately for each annotator as a cross-entropy loss function, which takes into account each annotator's available labels for each item x_i.

3.4 Single-task Approach

The baseline model embodies the typical approach of using a single-task classifier to predict the aggregated label for each instance. This model is constructed by adding a fully connected classification layer to the text embedding $e(x_i)$. The fully connected layer performs a linear transformation in order to predict the majority label. Unlike the multi-annotator models detailed in §3.2 and §3.3, the baseline model does not incorporate the individual annotator labels y_{ij}; rather, it directly predicts the aggregated label $\bar{y}_i$ for each item x_i.

4 Experiments

4.1 Datasets

The Multi-Domain Agreement dataset ($\mathcal{D}_{MDA}$): (Leonardelli et al., 2021) created an dataset for the task of offensive language detection. The dataset consists of 9,814 English tweets from three domains (Black Lives Matter movement, Election 2020, and COVID-19 pandemic). Each tweet was annotated for offensiveness by 5 annotators via Amazon Mechanical Turk.

English Perspectivist Irony Corpus ($\mathcal{D}_I$): The irony detection corpus, as presented by Frenda et al. (2023), encompasses 3,000 Post-Reply pairs extracted from social media. These pairs are evenly sourced from Twitter and Reddit, originating from five English-speaking countries: Australia, India, Ireland, the United Kingdom, and the United States. For Twitter data, the authors utilized the API geolocation service to distinguish the five English varieties. In the case of Reddit, data was gathered from specific subreddits, assuming the texts' origins: r/AskReddit (United States), r/CasualUK (United Kingdom), r/britishproblems (United Kingdom), r/australia (Australia), r/ireland (Ireland), r/india (India). The 74 annotators were balanced in terms of both gender and nationality, with approximately 15 raters assigned to each of the mentioned nationalities. Each rater labeled around 200 instances, resulting in a corpus containing 14,172 annotations, with a median of 5 annotations per instance.

The Racial Bias Toxicity Detection Corpus ($\mathcal{D}_{RB}$): Sap et al. (2019) have studied the effect of annotators' biases on their toxicity perceptions. They have confirmed in their work that determining what is harmful is a subjective task and annotators' racial biases can transmit to their annotations. They have gathered toxicity annotations for tweets on Amazon Mechanical Turk asking workers to determine whether a tweet (a) is offensive to them, and (b) could be seen as offensive to anyone. We work with the former as personal perspectives are more relevant to this study.

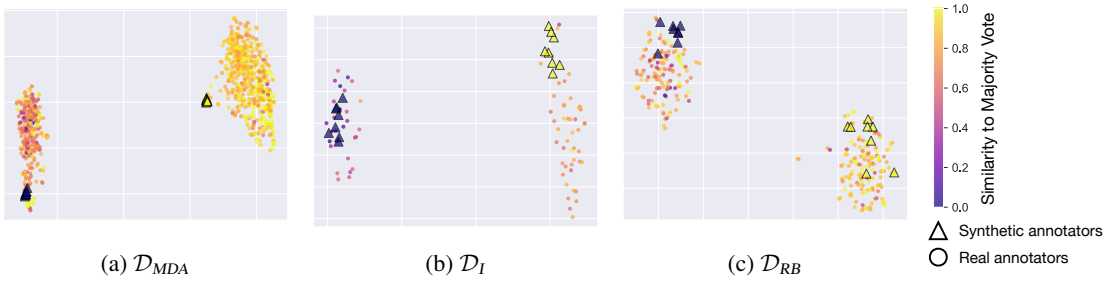
4.2 Evaluation Metrics



Annotator-level F1 This study is primarily motivated by the objective of safeguarding minority perspectives that might be overlooked when resolving annotator disagreements through the common practice of aggregating labels in machine learning. Consequently, it becomes crucial to demonstrate performance of model across all annotators, regardless of whether they have made substantial or minimal contributions to the annotated dataset. To address this, we introduce the metric of *Annotator-level F1* defined as the average macro F1 score across all annotators. The performance for each annotator a_j over items x_i appearing in the test split is calculated by comparing the existing ground truths y_{ij} to the model's predicted label for (x_i, a_j).

Global-level F1 The metric *Global-level F1* considers all pairs of item-annotator (x_i, a_j) appearing in the test set and calculates the macro F1 comparing their true label y_{ij} to the predicted label of the model for (x_i, a_j). In contrast to the Annotator-level F1, this metric implicitly gives preference to larger annotators, potentially overshadowing the performance of sparse annotators within the substantial contributions of prolific annotators.

Disagreement Measurement for Items In the context of multi-annotator models, a crucial consideration is whether the degree of disagreement in the predicted labels aligns with the actual degree of disagreement for each item. We follow the definitions from (Wan et al., 2023) for quantifying disagreement for each item. They introduce a continuous disagreement metric, quantifying the fraction of votes for an item that differs from the majority vote. For instance, if five votes for an item are recorded as 0,1,0,1,1, the disagreement is computed as 0.4. The disagreement scale ranges from 0 (complete unanimity in annotation results) to 1 (a significant divergence in opinions on annotation results). However, in the case of binary labels, the disagreement scale is confined to the range $[0, 0.5]$. Notably, we calculate predicted disagreement for each item exclusively based on annotators for whom ground truth information is available, aligning with the set of annotators used to calculate the ground truth disagreement per item.

4.3 Quantitative Analysis of Performance

Table 1 presents the numerical outcomes based on the metrics outlined in §4.2. The experimental setup is described in §A. Given that the primary motivation in this paper is to achieve equitable performance across all annotators, we initially focus on the *Annotator-level F1*. Across all three datasets, one of the two variants of the AART model (with or without the use of contrastive loss) consistently outperforms both single-task and multi-task models. This underscores the AART model's capacity to excel across diverse annotators, irrespective of

(a) $\mathcal{D}_{MDA}$ (b) $\mathcal{D}_I$ (c) $\mathcal{D}_{RB}$

Figure 2: The UMAP projection visualizes the annotator embeddings, with the colorbar indicating the fraction of annotator votes aligning with the majority vote. The smaller circles show the real annotators. Larger triangles represent two distinct sets of synthetic annotators integrated into the annotator pool for each dataset. Within each group of eight synthetic annotators, the yellow triangles consistently assign the majority vote, while the purple triangles consistently diverge from the majority. A distinct separation is evident between annotators aligning more closely with the majority opinion and those deviating further from the majority vote in their annotation patterns.

their contribution counts or other characteristics.

It's noteworthy that incorporating contrastive loss with AART proves particularly beneficial for the Irony detection dataset ($\mathcal{D}_I$). Without contrastive loss, the AART model faces challenges in converging on this dataset, possibly due to the inherent difficulty of automatically recognizing irony in text. The generally lower overall performances on $\mathcal{D}_I$ compared to the other two datasets affirm the challenging nature of this particular dataset. Meanwhile, the disparities in AART's performance with or without the contrastive loss on the other two datasets are marginal, indicating the overall benefit of including the contrastive loss in the training objective.

The *Global-level F1* metric assesses how well the predicted label for an annotator-item pair aligns with the true label. Notably, whenever the AART approach outperforms the two baselines on *Annotator-level F1*, it also excels on *Global-level F1*. This observation indicates that AART achieves a robust *Annotator-level F1* without merely overfitting to sparse annotators, maintaining a comprehensive understanding of item-annotator relationships across all pairs in the dataset.

The Pearson correlations between item-level labels disagreements, derived from true labels versus predicted labels, are presented in the third section of Table 1. The capacity to capture disagreements among annotators at the item level is a major advantage of multi-annotator models over conventional single-task models. The results demonstrate the effectiveness of utilizing contrastive loss ($\alpha > 0$) in improving the correlation of item-level disagreements when compared to the *AART* model, which does not employ contrastive loss ($\alpha = 0$). This enhancement is observed in the case of both $\mathcal{D}_I$ and $\mathcal{D}_{RB}$ datasets. However, in the case of $\mathcal{D}_{MDA}$, there is a marginal decline in performance, although it still outperforms the multi-task model.

4.4 Annotation Patterns Captured in Embeddings

In this section, we aim to gain a deeper understanding of the annotation patterns captured in the annotator embeddings. We are particularly interested in exploring whether the embeddings are influenced by the annotators' tendency to align with the majority opinion. To investigate this, we added two sets of eight synthetic annotators into the annotator pool for each dataset. Each synthetic annotator was exposed to $1/8$ of the data items. Within each set, eight annotators consistently provided the majority vote (determined from true labels) for the items, while the remaining eight consistently assigned a label different from the majority vote.

Upon completion of the AART training, we illustrate the embeddings in a 2D plot using UMAP projection (McInnes et al., 2018). Figure 2 demonstrates that the two groups of synthetic annotators exhibit distinct separation from each other. Also, the real annotators aligning more closely with the majority opinion and those deviating further from the majority vote in their annotation patterns are showing divergence in the embeddings. This observation shows the similarity to the majority opinion indeed plays a significant role in shaping the annotator embeddings.

We encourage future research to investigate additional patterns of similarity among annotators. These similarities may stem from shared demographic features or the conditions in which anno-

tators have been provided with prompts for the annotation task (Sap et al., 2019).

4.5 Fairness to Marginalized Annotators

Similarity to Majority			
	Single-Task	Multi-task	AART
$\mathcal{D}_{MDA}$	0.14 ± 0.02	0.07 ± 0.01	0.07 ± 0.01
$\mathcal{D}_{I}$	0.14 ± 0.02	0.12 ± 0.02	0.12 ± 0.02
$\mathcal{D}_{RB}$	0.20 ± 0.04	0.04 ± 0.03	0.05 ± 0.03
Count of Contributions			
	Single-Task	Multi-task	AART
$\mathcal{D}_{MDA}$	0.03 ± 0.02	0.14 ± 0.04	0.06 ± 0.02
$\mathcal{D}_{I}$	0.03 ± 0.02	0.03 ± 0.02	0.02 ± 0.02
$\mathcal{D}_{RB}$	0.07 ± 0.03	0.07 ± 0.05	0.03 ± 0.03

Table 3: Statistical Parity based on two sensitive attributes for the annotators: (1) Similarity to majority vote and (2) Count of Contributions. Mean and Standard deviations are reported based on running with 10 different random seeds.

In this section, we assess the model's ability to capture the perspectives of annotators who exhibit minority opinion, and those who contribute few annotations. We do this through the lens of Statistical Parity, a popular metric for algorithmic fairness (Mehrabi et al., 2021). Statistical parity measures the relative rate of a successful outcome for the majority group against that of the minority group. In separate experiments, we study the majority and minority groups from two perspectives: (1) the similarity of annotation selections compared to the majority vote and (2) the count of contributions. In (1), the grouping of annotators is determined by the fraction of annotations generated by a labeler that are equal to the majority vote of the items they annotated. The annotators that fall in the lowest 25th percentile in terms of similarity to the majority vote are considered in the minority group and the rest fall into the majority group. In (2), the minority group of annotators is determined by the lowest 25th percentile in terms of the number of contributions. We compare Statistical Parity across *Single-task*, *Multi-task*, and *AART*. Our interest lies in showing whether each method performs equally accurate for the sensitive group versus the rest of annotators.

Table 3 displays the results of disparity among the two groups of annotators. The lower disparity values indicates the predictions are more fair. Observing the grouping of annotators based on their similarity to majority behavior, we note that the Single-task approach which consistently predicts the majority vote exhibits the most significant disparity in accuracy between the two groups. Additionally, AART and Multi-task show similar levels of disparity, which is less compared to the Single-task approach. This observation confirms that aggregating labels causes unfairness in accuracy toward annotators whose opinions differ from the majority behavior. And motivates the use of unaggregated annotations and multi-perspective classification models instead of aggregated ground truths.

When we group annotators based on their count of contributions, Multi-task shows the most disparity among the sensitive group of annotators and others, while AART is more equitable than the other two methods. This observation confirms that Multi-task is limited for sparse annotators and performs poorly for them, whereas AART demonstrates more balanced performance among sparse and prolific annotators.

5 Discussion

Predicting a single label remains the most popular problem in classification applications. Previous studies have demonstrated that multi-annotator models can perform comparably to single-task models in predicting the aggregated labels (Mostafazadeh Davani et al., 2022; Hayat et al., 2022; Al Kuwatly et al., 2020). In the single-task model, the aggregated labels are computed directly, while in multi-annotator models, the aggregated label is derived by consolidating predictions across annotators. We assess the performance of predicting the aggregated label and present the results in Table 4. Our findings align with previous observations, indicating that all three models effectively predict single label outcomes.

An additional advantage of training multi-annotator models compared to single-task models is the ability to learn the entire label distribution rather than solely focusing on aggregated labels. This flexibility proves valuable in various real-world scenarios. As models are increasingly tailored for more personal, subjective use cases, a direct application of this work could be to predict personalized preferences for each annotator.

Furthermore, (Gordon et al., 2022) introduces an inference approach for trained multi-annotator models, advocating for the selection of a task-specific subset of annotators akin to a "Jury." For instance, for the task of toxicity detection in online posts, prioritizing votes from women and Black individuals—often targeted by online harassment—

Dataset	*Single-task*	*Multi-task*	*AART* ($\alpha = 0$)	*AART* ($\alpha > 0$)
Aggregated Label Performance				
$\mathcal{D}_{MDA}$	78.58±0.9	78.99±1.3	79.51±1.0	79.66±1.2
$\mathcal{D}_{I}$	64.05±2.9	65.47±2.5	60.22±9.4	64.95±2.1
$\mathcal{D}_{RB}$	81.09±3.5	81.43±3.1	81.43±3.5	81.02±1.6

Table 4: In this table the performance (F1) of the three models on predicting the aggregated label is reported. The single-task model computes the majority labels directly. For both the multi-task model and our proposed method (AART), we determined the majority of predictions across labels for each annotator.

could prove advantageous. Their goal with jury learning is to assist practitioners in acknowledging and incorporating annotator disagreement within the classifier pipeline. To achieve this, they encourage practitioners to form a jury that specifies the individuals or groups their classifiers should emulate.

Rather than completely disregarding the diversity present in human labels, our paper proposes an effective approach to predict individual perspectives while maintaining competence in predicting the aggregated label. Instead of eliminating disagreement at the initial stages of machine learning, our aim is to learn from the various perspectives of annotators. By embracing the diversity of opinions through data-driven pipelines, which enhances data transparency, we are able to present it to end-users and human decision-makers. This empowerment allows them to take corrective actions and interventions by leveraging common sense and contextual information.

6 Conclusion

This paper tackles the challenges posed by annotator disagreements in subjective tasks, where establishing a single ground truth is not straightforward. We propose an approach named Annotator Aware Representations for Texts (AART) for modeling annotators' perspectives. Our methodology combines representations of individual annotators with those of text in the classification task. By learning the embeddings of annotators through Cross Entropy loss, contrastive loss, and regularization, we capture their individual labeling patterns. We compare our approach to a popular multi-task architecture, which is constrained by under-trained classification heads for annotators with limited annotations. Through several experiments, we demonstrate that AART, despite its simplicity, effectively captures the semantics of textual data for classification tasks while accommodating different annotators' perspectives. Moreover, we show that AART is fair and equitable when it comes to marginalized annotators, who may have few labeled samples or provide votes that often differ from the majority votes for samples.

Limitations

The performance of the models outlined in this paper may be adversely affected when dealing with noisy annotations. This noise can arise from unclear instructions or insufficient attention from the worker. A limitation of this study, as well as many others focusing on designing multi-annotator models, is the tendency to overlook the high likelihood of certain annotators being unreliable. Differentiating between labeling noise and natural disagreement is a challenge that remains unaddressed in this work, and in numerous other studies. Additionally, the degree of overlap among items annotated by multiple individuals can enhance the learning process for multi-annotator models by exposing both similarities and differences among the annotators. Nevertheless, crowdsourced datasets are inherently imperfect and susceptible to noise or sparsity. It is imperative for future research to examine the robustness of multi-annotator models in the face of sub-optimal dataset features.

Ethical Considerations

This work seeks to improve AI systems by incorporating perspectives beyond just the most prolific annotators, as is currently done in most AI systems. This will encourage developers of subsequent AI systems to recruit more sparse annotators, as the difference in perspective they bring will advance the performance of their resulting models, rather than hinder it. This advances the ACM and ACL ethics code's core tenet that "all people are stakeholders in computing," and to "take action not to discriminate."[2] In this case, the discrimination would be against those who do not provide a wealth of annotations, due to time or other constraints.

[2]https://www.acm.org/code-of-ethics

As with any approach, there is the possibility that it could cause ethical harm. For example, a coordinated and nefarious minority could have amplified sway in our model compared to one that only focuses on the most prolific annotators. Furthermore, research has shown that large language models, such as the ones we use in this work, capture various biases that can harm our proposed model. Thus, the perspective we learn for each annotator is through the lens of these models, and it might be different from reality. Nevertheless, we maintain that this potential harm is vastly outweighed by the potential of incorporating all voices.

Acknowledgements

We express gratitude to the anonymous reviewers for providing valuable feedback and offering suggestions for our project. This work was funded in part by Defense Advanced Research Projects Agency (DARPA) and Army Research Office (ARO) under Contract No. W911NF-21-C-0002 and by the *Multilingual Perspective-Aware NLU* project in partnership with Amazon Alexa.

A Experimental Setup

Common parameters: We conducted our experiments using a shared server in our institution with a GPU NVIDIA GeForce RTX 2080 Ti 11GB.

Across all three approaches we set max sequence length to 100, training batch size to 100, and learning rate to $5e^{-5}$. The training steps use the Adam optimizer (Kingma and Ba, 2014) with a weight decay rate equal to 0.01. We use early stopping with 20 max number of epochs and we save the model parameters from the epoch with best annotator-level F1. For the language model we use "roberta-base" for $\mathcal{D}_{MDA}$ and $\mathcal{D}_I$ datasets. However, because the $\mathcal{D}_{RB}$ is a much smaller dataset (only contains 1309 text items) we use a language model pretrained on the task of offensiveness detection "cardiffnlp/twitter-roberta-base-offensive"[3]. We load the transformer models from HuggingFace Library (Wolf et al., 2020).

We initiate the splitting process with a train/dev/test split of 50/25/25 percent stratified on item-level disagreements, after which we transfer the items from dev and test splits annotated by an annotator which is unseen in the training set to augment the training data. We repeat the splitting with 10 random seeds.

AART parameters: We set $\tau = 0.07$ for contrastive loss and performed hyper-parameter search for $\alpha \in \{0.1, 0.2, 0.3\}$ and for $\lambda \in \{0.0, 0.1, 0.2\}$ which are respectively coefficients for contrastive loss and for L_2 norm regularization in the objective function.

Improving Factual Accuracy of Neural Table-to-Text Output by Addressing Input Problems in ToTTo

Barkavi Sundararajan and **Somayajulu Sripada** and **Ehud Reiter**
Department of Computing Science, University of Aberdeen
{b.sundararajan.21, yaji.sripada, e.reiter}@abdn.ac.uk

Abstract

Neural Table-to-Text models tend to hallucinate, producing texts that contain factual errors. We investigate whether such errors in the output can be traced back to problems with the input. We manually annotated 1,837 texts generated by multiple models in the *politics* domain of the ToTTo dataset. We identify the input problems that are responsible for many output errors and show that fixing these inputs reduces factual errors by between 52% and 76% (depending on the model). In addition, we observe that models struggle in processing tabular inputs that are structured in a non-standard way, particularly when the input lacks distinct row and column values or when the column headers are not correctly mapped to corresponding values.

1 Introduction

Table-to-Text generation refers to the task of generating natural language descriptions from tabular data (Parikh et al., 2020; Chen et al., 2020a,b) and is widely used in several application domains such as medical diagnosis (Pauws et al., 2018), financial (Zhu et al., 2023) and weather reporting (Sripada et al., 2002; Gkatzia et al., 2017; Upadhyay and Massie, 2022) and sports summaries (Thomson et al., 2020). Neural language models are known to generate fluent texts (Ji et al., 2023) but may generate outputs that are factually incorrect or unrelated to the provided input data. Such undesirable generation is called 'hallucination' (Wang and Sennrich, 2020; Raunak et al., 2021; Ji et al., 2023).

Previous studies on Table-to-Text tasks adopt traditional seq2seq methods to generate table descriptions (Wiseman et al., 2017; Puduppully et al., 2019; Rebuffel et al., 2019). Recently, Transformer based models (Devlin et al., 2019; Raffel et al., 2020; OpenAI, 2023) have shown remarkable progress in language generation from textual input (Badaro et al., 2023), however tabular data still needs more improvement to control hallucinations (Rebuffel et al., 2021). Neural models struggle with tabular data, especially when the inputs do not have distinct cell values from rows and columns mapped along with their respective headers. These input problems lead the model to generate more factual errors (Kasner and Dušek, 2024).

Using the ToTTo tabular dataset (Parikh et al., 2020), we identify and address input problems that are responsible for factual errors. Some common tabular input problems in the ToTTo are **i.** 'non-atomic' cell values, where a column contains multiple values such as leader name, party name and % of votes in one cell rather than a single indivisible value, **ii.** missing important cell values in the input (see Table 1) and **iii.** nested column headers and row headers in the Wikipedia tables[1] that lead to incorrect mapping of the cell values.

Table 1 presents a sample from ToTTo. Only the highlighted cells from Table 1a are passed to the model (as shown in Table 2). Passing Norton's % of votes and her party name (compare Table 1b to Table 1a) eliminates the hallucinated % of votes (see output for Table 1b); this correction is based on the input problem described in Sec. 5.2.

In this paper, we score the quality of output texts by manually annotating output errors instead of using automatic evaluation metric scores such as BLEU (Papineni et al., 2002), ROUGE (Lin, 2004), PARENT (Dhingra et al., 2019) and BLEURT (Sellam et al., 2020). We conducted a pilot study, where we fine-tuned T5-base and T5-large models (Raffel et al., 2020), analysing 1,677 *politics* domain texts from the ToTTo dataset through manual error analysis adopted from Thomson and Reiter (2020). These manual error annotations allowed us to identify patterns of errors in the generated text which were then traced back to input problems.

Our approach is summarised as follows:

(a) Original cells highlighted in Yellow as Input

1996 United States House of Representatives election

Party	Candidate	Votes	%
Democratic	Eleanor Holmes Norton (inc.)	134,996	90.00
Republican	Sprague Simonds	11,306	7.54

LLAMA 2-13B Output for tabular input a:
Eleanor Holmes Norton (inc.) won with **7.54%**[U] of the vote. Sprague Simonds was the Republican candidate and received **22.38%**[U] of the vote.

(b) Corrected Tabular data by including relevant cells

1996 United States House of Representatives election

Party	Candidate	Votes	%
Democratic	Eleanor Holmes Norton (inc.)	134,996	90.00
Republican	Sprague Simonds	11,306	7.54

LLAMA 2-13B Output for tabular input b:
Democratic Party candidate Eleanor Holmes Norton won with 90% of the vote. Republican Party candidate Sprague Simonds received 7.54%.

Table 1: ToTTo example: Highlighted cells in yellow are passed as input to the model. Passing the appropriate cells (i.e., % votes and party name) as input, as shown in Table 1b fixes the factual errors. Compare the Table 1b output (with no errors) to the Table 1a output (with NUMBER errors denoted by a superscript U).

<page_title> 1996 United States House of Representatives election </page_title> <table> <cell> Eleanor Holmes Norton (inc.) <col_header> Candidate </col_header> </cell> <cell> Republican <col_header> Party </col_header> </cell> <cell> Sprague Simonds <col_header> Candidate </col_header> </cell> <cell> 7.54 <col_header> % </col_header> </cell> </table>

Table 2: Linearized Input from (a) and (b) is passed as input to LLAMA 2-13B model. For example, we present the Linearized Input for Table 1a here. The corresponding input for Table 1b is not shown, but it will include all related cells highlighted in yellow in (b).

I. We systematically correct the tabular inputs for the *politics* domain in ToTTo to adhere to a standard form to ensure the generation of factual texts from neural models. The correction procedure is elaborated in Sec. 5.2 and is supplemented by pseudocode in App. D.

   (a) We apply this correction to a larger subset of 210 samples, resulting in a 62% decrease in factual errors for T5-base and a 57% decrease for T5-large in the generated text (Sec. 6.1).

   (b) We conduct experiments on LLAMA 2-7B and LLAMA 2-13B models (Touvron et al., 2023) with 40 challenging samples selected from the previous 210 samples. Tailoring zero-shot prompts for specific input and error annotation on 160 texts showed that correcting input reduces factual errors by 52% in LLAMA 2-7B and 76% in LLAMA 2-13B (Sec. 6.2).

II. The manual error annotation methodology adopted from Thomson and Reiter (2020) is detailed in App. B; this builds on the work of Sundararajan et al. (2022) for ToTTo *politics* domain outputs[2]. The inter-annotation agreement on the error annotation was good, with a Fleiss' Kappa of 0.622 (Sec. 7).

[2]Error annotation guidelines and sample annotations from our human evaluation is available at https://github.com/BarkaviSJ/totto_politics_human_annotations

1.1 Table to Text dataset, ToTTo

ToTTo is an open-domain English language dataset (Parikh et al., 2020), where the input X is taken from Wikipedia table T, which includes the table's metadata (such as title) and a set of highlighted cells, along with their headers. This structured information is flattened to create a linearized text representation of the table, as mentioned in Table 2. This crowdsourced dataset is paired with a natural language description, denoted as output Y, comprising a sequence of tokens $y_1, y_2, \ldots, y_n$, which provides a coherent summary of the content present in the input table X.

These input-output pairs from the ToTTo dataset can be used for fine-tuning or prompting the neural language models. As shown in Table 1a, the Input X is often observed to be problematic and fixing these problems is the main focus of this paper.

2 Related Work

Prior work on ToTTo: Wang et al. (2022) proposed a framework, LATTICE, that preserves the structural information of the cell values (tokens) within the same rows or columns, and by removing the attention mechanism flow for other unrelated tokens. Hu et al. (2023) incorporates content planning and generation from Su et al. (2021) and synthetically added noisy cells in their fine-tuning regime. While these approaches are model agnostic and improved automatic metric scores such as

BLEU (Papineni et al., 2002), PARENT (Dhingra et al., 2019) and BLEURT (Sellam et al., 2020) by few points in the leaderboard [3], the fundamental problem with the tabular input remains.

Chen et al. (2022) acknowledged that the target cells in the ToTTo tabular input are not always highlighted in their work titled 'Table Structure Understanding and Text Deliberation Approach'. They used a template to extract all facts from the raw table for 1.2K training samples (only for the inputs with rows and columns fewer than 8) and employed hierarchical multi-head attention to capture the structural information in their fine-tuning process. Though this approach promises to retain the facts from raw tables, it only addresses simpler tables with fewer than 8 rows and columns, still has limitations for longer tables, complex tabular structures and non-atomic tabular cells.

Our focus on correcting inputs aiming to achieve factually correct outputs aligns with the work of Dušek et al. (2019) on the E2E dataset (Novikova et al., 2017). Their study also demonstrated that improving inputs in an NLG dataset helps in improving model outputs.

Error Analysis: While the automatic metric scores such as BLEU, PARENT and BLEURT help evaluate the model's performance at a high level, relying solely on these metrics will not address specific weaknesses i.e., lower metric scores do not provide insights into specific error types in the output. We follow guidelines from van Miltenburg et al. (2021) to perform error analysis in NLG systems and investigate errors in the output at a more granular level by adopting the manual error annotation approach from Thomson and Reiter (2020); Sundararajan et al. (2022); Thomson et al. (2023).

Maynez et al. (2020) also emphasized automatic metrics are not sufficient to study the hallucination problem and provided a detailed study on intrinsic and extrinsic hallucination in abstractive summarization. We studied hallucination in our evaluation scheme by annotating different categories of errors in the output tokens (single token or group of tokens). Mapping our adopted methodology to Maynez et al. (2020)'s work, intrinsic is the main error category occurring when generated outputs are not faithful to the given input. It includes **WORD^{W}**, **NAME^{N}**, **DATE_DIMENSION^{D}**, **NUMBER^{U}**, **CONTEXT^{C}** and **OTHER^{O}**) from our error categories. Extrinsic refers to our **ADDITION^{A}** category (see App. B.3).

LLM prompts: Empirical evaluation of prompting strategies on the three large language models (LLMs) by Sivarajkumar et al. (2023) in clinical NLP found that tailoring task-specific prompt is crucial for achieving accuracy. In a study on Text-to-SQL, Chang and Fosler-Lussier (2023) investigated zero-shot prompting strategies, highlighting the significance of table representation. Their findings indicated that normalized database prompts outperformed unnormalized ones; this motivates our initial step of correcting tabular inputs to a standard form. In our work, we leveraged a recent LLM, LLAMA 2 (Touvron et al., 2023) and tailored our zero-shot prompt (Kojima et al., 2022) specific to the content of each table.

3 Pilot Study

3.1 Methodology

We only look at the *politics* domain on the ToTTo validation set. We build upon the work of Sundararajan et al. (2022) to identify the causes of output errors in T5 models. In this paper, we go beyond error annotations to fix these errors in our main study, both in T5 and LLAMA 2 models (detailed in Sec. 5).

The error categories mentioned in Sundararajan et al. (2022) are: **WORD^{W}**, **NAME^{N}**, **DATE_DIMENSION^{D}**, **NUMBER^{U}**, **OTHER^{O}**, **CONTEXT^{C}**, **NOT_CHECKABLE^{NC}** and **NON_ENGLISH^{NE}**. In this work, we excluded **NOT_CHECKABLE^{NC}** and introduced a new error category, **ADDITION^{A}**, which is used when the generated text has added words or phrases that diverge from the input. Definitions for all error categories are provided in App. B.3.

3.2 Insights from our Pilot Study

For the pilot study, we fine-tuned both the T5-base (T5-b) and the T5-large (T5-l) models on the ToTTo dataset by following the baseline approach (Kale and Rastogi, 2020). The hyperparameters and fine-tuning details for these two models are shown in App. A.

Our analysis (presented in Table 3) shows that:

No Error: 47% of the samples from T5-b and 60% of the samples from T5-l are error-free.

Omissions: Omissions occur when the generated text fails to mention some information from

[3] https://github.com/google-research-datasets/ToTTo

Category	T5-base (T5-b)		T5-large (T5-l)	
	Count	%	Count	%
No Error	358	47	450	60
Omissions	272	36	218	29
Errors	124	17	86	11
Total Count	754		754	

Table 3: Pilot Study analysis: T5-b and T5-l Models in ToTTo Politics Domain. 'Errors' category is the main focus of our work; 'omissions' are excluded.

the input (González Corbelle et al., 2022) without making any factual errors. If the output has errors and omissions, we classify it as an error. The T5-b had 36% omissions and T5-l had 29%.

Errors: Our analysis revealed that T5-b made factual errors in 17% and T5-l made factual errors in 11% of the total samples.

Hypothesis: Based on the insights from this analysis, we hypothesize that when tabular input data is structured in non-standard ways, models struggle to interpret these ambiguous inputs leading to generate factually inaccurate output. We test this hypothesis by addressing input problems related to non-standard tabular structures.

4 Input Problems

Due to the practical challenges involved in improving the tabular input for the entire dataset, which includes unique headers and tabular structures for each input, our focus is on analyzing a subset of samples containing errors. We examined 124 error samples from the T5-b and 86 error samples from T5-l models within the ToTTo *politics* domain, as identified in Table 3. We aim to segregate the errors originating from non-standard or illogical nested table structures. We categorize these input problems into two broad categories, as briefly elaborated upon in Sec. 4.1 and Sec. 4.2.

4.1 Generic Input Problems

Non-atomic tabular cell values: When a table cell contains multiple atomic values (see Table 4). Examples of such non-atomic forms include multiple leaders' names, votes, term dates, or election years all in a single cell. We further categorize these problems into 'single record lacking atomicity' and 'multiple records lacking atomicity' (shown in Fig. 2 in App. F) to demonstrate how the models struggle when records of multiple leaders lack atomicity.

Complex table type: When a table contains election results in sentence form, models struggle to interpret and generate meaningful texts because the sentence form data lacks the needed context (see Table 11 in App. F).

Insufficient input: In some cases, the necessary cells are not highlighted in the tabular input, resulting in incorrect outputs. Our analyses in Table 1 and Table 5 demonstrate that outputs become factually correct when relevant cells are included.

Longer table input: Models often struggle to generate accurate texts for lengthy table inputs, especially when the data is not in a standard form and lacks clear cell relationships.

4.2 Politics Domain-Specific Input Problems

Politics specific headers: In ToTTo, the use of symbols, for example, '+' or '-' instead of having clear semantic terms like *'swing percentage' or '% change compared to previous election'* as column headers caused 5% of errors. This lack of semantic guidance in the input made it difficult for models to accurately generate the correct output text (see Table 10 in App. F).

List of leader names in the input: In the *politics* domain, we observed a specific issue when input data contains a list of leader names. Models tend to favour the leader whose name appears first in the list (for example, either from the table title or as the first leader in highlighted cells), even if they have lost the election (see Table 13, Table 14, Table 15 in App. F). This becomes even more challenging when leader names are associated either with missing values (opponent leader's name or vote count) in other columns in the input or when the tabular cell values are non-atomic.

The manual fixes we applied to each of these input problems with examples are detailed in Sec. 5.2.

5 Main Study

5.1 LLAMA 2 Models

In our main study, in addition to T5 models, we included LLAMA 2-7B (L-7B) and LLAMA 2-13B (L-13B) models to test our hypothesis on non-standard tabular inputs. We received official model weights from Meta[4] and then quantized our

[4]We downloaded weights from https://ai.meta.com/resources/models-and-libraries/llama-downloads/ and quantized our models by following the installation instructions from https://github.com/ggerganov/llama.cpp.

(a) Input Table with Original Cells highlighted in Yellow

Page Title: 2014 United States Senate elections

Section Title: Elections leading to the next Congress

State	Candidates
Alaska	Dan Sullivan (Republican) 48.0% Mark Begich (Democratic) 45.8% Mark Fish (Libertarian) 3.7% Ted Gianoutsos (Independent) 2.0%
Virginia	Mark Warner (Democratic) 49.1% Ed Gillespie (Republican) 48.3% Robert Sarvis (Libertarian) 2.4%

(b) Input Table with Corrected Cells highlighted in Yellow

State	Candidates	Party	% votes
Alaska	Dan Sullivan	Republican	48.0%
Alaska	Mark Begich	Democratic	45.8%
Virginia	Mark Warner	Democratic	49.1%
Virginia	Ed Gillespie	Republican	48.3%

(c) Outputs Before and After Input Data Correction

T5-base before fix: Alaska: Dan Sullivan (R) defeated Mark Begich (D) 45.8% to^{W} **3.7%**^{U} and Ted Gianoutsos (Independent) 2.0%, and Virginia: Mark Warner won 49.1% to^{W} **2.4%**^{U}.

T5-base after fix: Alaska was won by Dan Sullivan (R) with 48.0% of the vote, and Virginia was won by Mark Warner (D) with 49.1% of the vote.

LLAMA 2-7B before fix: 2014 United States Senate elections were held on November 4^{A}, 2014. **The Republican Party gained control of the Senate for the first time since 2006. The Democrats lost their majority in the Senate and Republicans won a net gain of eight seats to take control of the chamber with a 54-46 majority. The Republicans also took control of the House of Representatives, giving them full control of Congress for the first time since 2010.**^{A}

LLAMA 2-7B after fix: In the United States Senate elections of 2014, Dan Sullivan (Republican) won in Alaska with 48.0% of votes against Mark Begich (Democratic) who got 45.8%. In Virginia, Mark Warner (Democratic) won with 49.1% of votes against Ed Gillespie (Republican) who got 48.3%.

Table 4: Fixing Multiple leaders' votes that are not atomic, as detailed in Sec. 5.2.1. 'Before fix' shows the errors produced by models with Table 4a as input and 'After fix' shows both models did not produce any factual error with Table 4b as input. The error tokens in outputs are annotated with respective error code in superscript (W for WORD, U for NUMBER and A for ADDITION errors).

LLAMA 2 models. We ran experiments using the full model weights and the model with 4-bit integer quantization for the ToTTo dataset (*politics* domain). Both produced comparable output quality with no difference in errors for the quantized models. Therefore, we finalized our experiments with 4-bit quantized models to save computational resources and used them for local inference on a MacOS CPU. We set the temperature to 0.0 as it produced fewer errors. Further details on data corrections for these models are discussed in Sec. 5.4.

5.2 Manual Fixes for Input Problems

We followed a systematic procedure to apply manual fixes to specific input problems, as discussed from Sec. 5.2.1 to Sec. 5.2.6. A supplementary pseudocode for these fixes is also provided in App. D. The algorithm 1 takes tabular data and title (metadata) from ToTTo as input parameters to execute six functions to gather insights and return with corrected tabular data. The first two functions, DATASIZEMANAGEABLEFORLONGTABLE and IDENTIFYLEADERNAMEORDER do not correct the tabular input but provide insights on the input problems leading to factual errors in the outputs. The other four functions correct the input problems as shown in algorithm 4, algorithm 5, algorithm 6 and algorithm 7.

5.2.1 Non-Atomic Cell Values

Correction: We corrected the input to store individual leader data, including votes, party, and election details, as a separate column variable. In Table 4a, when the 'candidates' column is not atomic, all models made errors for this tabular data. The corrections involved separating each leader's party and votes into separate columns (see Table 4b). We passed the leading two leaders' data, excluding the remaining leaders, in separate rows for the respective states (Alaska and Virginia). After input correction, T5-b and L-7B outputs in Table 4 were error-free. While some models omitted other candidate and election details, *all models corrected the previous factual errors after the correction.*

5.2.2 Complex Table Type

Correction: Complex tabular structures were generally difficult to correct because the election results are in sentence form e.g., see 'Results' column in Table 11 in App. F. We could only make corrections to the 'non-atomic' cell values in 'candidates' column. Three models generated 'the incumbent senator Coe I. Crawford lost renomination **to Edwin S. Johnson, a Democrat candidate**^{C}.' Losing renomination is when the current senator did not lose the seat to the opponent, but rather failed to be nominated in the primary to stand for reelection. This resulted in **CONTEXT**^{C} error, specifically *when the models made unsupported assumptions*

(a) Input Table with Original Cells highlighted in Yellow

Page Title: Minnesota Amendment 2

Section Title: Results

Choice	Votes	% Votes
Referendum failed No	1,588,752	53.84
Yes	1,362,030	46.16

(b) Input Table with Corrected Cells highlighted in Yellow

Choice	Votes	% Votes
Referendum failed No	1,588,752	53.84
Yes	1,362,030	46.16

(c) Outputs Before and After Input Data Correction

T5-base before fix The Minnesota Amendment 2 was approved[W] by 53.84 percent of voters, with a turnout of[C] 46.16 percent.

T5-base after fix: Minnesota Amendment 2 was defeated by 53.84 percent of voters, while 46.16 percent voted in favor of the measure.

LLAMA 2-7B before fix: 53.84% of Minnesota voters voted for[W] Amendment 2.

LLAMA 2-7B after fix: 53.84% of the voters voted no on Amendment 2, while 46.16% voted yes.%.

Table 5: Fixing Insufficient input problems, as detailed in Sec. 5.2.3. 'Before' shows WORD and CONTEXT errors due to missing choices of votes. 'After' shows these errors are resolved when these cell values are provided.

about the given input data, as defined in App. B. Even after correction, all models except L-13B made this CONTEXT[C] error (see Table 11d).

5.2.3 Insufficient Input

Correction: This is a data annotation problem because it is related to how the ToTTo dataset was created by pairing the sentence description and highlighting only a subset of cells from the Wikipedia table as Input (X). This problem is straightforward to fix by including the missing cells or headers from the tabular data.

In Table 5, when the choices for the Minnesota Amendment (i.e., 'Referendum failed No' and 'Yes' cells) were not included, all models incorrectly generated the favour of votes (*'approved'*, *'for'*) and made an unsupported assumption regarding the *turnout* percentage. As shown in Table 5, all models corrected the errors after including the vote choices.

5.2.4 Longer Table Input

Correction: When dealing with straightforward tabular data, it was easier to correct the input either by **i.** *correcting the cell values to ensure atomicity* and/or **ii.** *including the missing cells*. However, this longer tabular input not only had over 100 rows but also included complex structures with nested column headers and row headers which posed difficulties in correcting the input.

Large models such as L-13B and T5-l could process tables with fewer than 20 rows for straightforward inputs. However, T5-b and L-7B struggled to produce factual information even for 20 rows. In our correction procedure, we chose an upper limit of 20 rows and 10 columns to simplify the longer tabular input. A simplified example of this problem with fewer rows is shown in Table 16 in App. F.

5.2.5 ToTTo: Politics Specific

Correction: We included appropriate semantic cues in the headers to help the model differentiate between the generic percentage of votes and the swing percentage of votes. For other errors, we expanded the abbreviation of coalition party names to avoid errors. In Table 10 from App. F, the original input only had ± in the header, resulting in errors from all models including L-13B. After explicitly including '± seats compared to the previous election', both LLAMA 2 models corrected the previous error. However, both fine-tuned T5 models committed mistakes even after this correction.

Specific Semantic Generation Issue: In some cases, the model cannot determine whether a minister was 'shortest-lived' or 'longest-lived' only based on their lifespan, birth, and death years from the input. It *may require additional context* to produce accurate text. One such example is shown in Table 12. All models with the original data produced incorrect WORD[W]. After we included the 'Total time in office' cell and customized the prompt for LLAMA 2, both LLAMA 2 models corrected the WORD[W] error. However, both T5 models did not show any improvement after including this detail. This could be due to the strong influence of the patterns learned from the fine-tuning process for similar tabular structures.

5.2.6 List of Leader Names

Correction: We did not change the order of the leader's name in the title, but we addressed missing vote counts and leader names to map the relations for each record as shown in Table 13, Table 14, and Table 15 in the App. F.

In Table 14, the title leader 'Chuck DeVore' lost the election among four other party nominees. Both

T5 models made errors by focusing on *'Chuck DeVore' as the main candidate*, resulting in WORD^{W} and CONTEXT^{C} errors. NUMBER^{U} errors are present in all models due to missing votes. After including the votes and party details for all candidates, both LLAMA 2 models corrected all errors. However, both T5 models still made errors stating the title leader either defeated or being defeated by all candidates, possibly due to the *learned patterns during fine-tuning on the ToTTo dataset*.

In Table 15, the title leader, 'Joseph Haslet' ran as a candidate for Governor office in 1804 and 1807 but lost both elections. All models incorrectly generated Haslet won in both years. The correction is only limited to passing the party name and modifying the header from 'Subject' to 'Candidate'. Despite this change, all models continued to generate errors. Both T5 models struggled to generate the right winning candidate in 5 out of 11 samples (Fig. 2a) for this input with the same set of headers.

5.3 T5 Models on Corrected Data

Based on the insights gathered from different input problems in Sec. 4, we followed the procedure and manually corrected the original tabular input for 210 samples (taken from 124 and 86 'errors' category samples in Table 3). We ran both T5-b and T5-l models on the corrected data.

5.4 LLAMA 2 Models on Corrected Data

From the corrected data, as described in Sec. 5.3, we selected 40 challenging samples from the previous 210 samples as inputs to the LLAMA 2-7B (L-7B) and LLAMA 2-13B (L-13B) models. These samples were chosen to cover each of the input problem types described in Sec. 4, guaranteeing a thorough analysis. Within these 40 samples, 21 are associated with general input problems and the remaining 19 are specific to the *politics* input problems, as shown in Fig. 2c and Fig. 2d (in App. F).

We studied the *zero-shot* capabilities of L-7B and L-13B models for the 40 challenging samples. For each sample, we employed different prompts tailoring to the content of the tabular input (Kojima et al., 2022). Two common prompts we used are shown in App. C. For each sample and each of L-7B, and L-13B, we examined the outputs before and after correcting the tabular input.

6 Results and Discussion

We manually annotated the outputs from all models working on corrected input data, following the same procedure outlined in Sec. 3.1 and defined in App. B. In this section, we summarize the results of the total input data corrections and discuss them. The previous section also described and discussed error analysis locally while presenting individual corrections.

6.1 Error Reductions in T5 Models

The input corrections significantly reduced factual errors, as evident in Table 6, which provides a comparison of error counts 'before' and 'after' input data fixes for each error category. It should be noted that *no prompt or instruction* was provided to these two fine-tuned T5 models.

Category	T5-base (T5-b)		T5-large (T5-l)	
	Before	After	Before	After
WORD	62	20	31	12
NAME	13	3	12	2
DATE_DIMENSION	7	1	6	1
NUMBER	12	1	5	0
OTHER	5	2	2	0
CONTEXT	13	3	16	4
ADDITION	2	1	2	1
NON-ENGLISH	20	20	21	21
Total errors	134	**51**	95	**41**
Error reduction	**62%**		**57%**	

Table 6: Count of individual error annotations for 210 samples. The table compares the error counts between 'before' and 'after' applying input correction. Each sample can contain multiple errors.

6.2 Error Reductions in LLAMA 2 Models

In Table 7, we present the error analysis of 40 difficult samples, validated using L-7B and L-13B models with tailored prompts for each input. Outputs were manually error annotated, and the table compares the error counts before and after input correction. The *L-7B and L-13B* models showed **reductions of 52% and 76% in errors**, after addressing tabular input issues. The *T5-b and T5-l models* demonstrated **error reductions of 46% and 53%** respectively for the 40 difficult samples considered, which was shown for comparison purposes. The insights gathered from the individual error categories after input correction are mentioned below.

- WORD^{W} errors, predominantly incorrect verbs and prepositions, were most common among all models. Post-correction, the L-13B model reduced this error category by 77%, while the T5-b, T5-l, and L-7B models

Category	T5-base (T5-b) baseline		T5-large (T5-l) baseline		LLAMA 2-7B (L-7B)		LLAMA 2-13B (L-13B)	
	Before	After	Before	After	Before	After	Before	After
WORD	27	18	21	12	23	15	22	5
NAME	7	3	6	2	2	1	3	0
DATE_DIM	2	1	1	1	2	0	1	0
CONTEXT	8	3	7	2	6	2	4	0
NUMBER	4	1	1	0	7	1	6	1
OTHER	0	0	0	0	5	0	1	0
ADDITION	0	0	0	0	5	5	7	5
Total errors	48	**26**	36	**17**	50	**24**	45	**11**
Error reduction(%)	**46%**		**53%**		**52%**		**76%**	

Table 7: Individual error count for the 40 challenging samples selected from the previous 210 in Table 6. It shows the comparison of the errors annotated for original data versus corrected data in T5 and LLAMA 2 models.

Category	T5-base (T5-b) baseline		T5-large (T5-l) baseline		LLAMA 2-7B (L-7B)		LLAMA 2-13B (L-13B)	
	Before	After	Before	After	Before	After	Before	After
No error (Higher is better)	0	12	3	16	2	17	5	23
Omissions	0	6	3	8	2	4	4	8

Table 8: Comparison of 'No error' and 'Omissions' unique count for the same 40 samples. i. Increase in 'No error' count indicates error-free outputs after addressing input problems. ii. Some outputs stopped making factual errors after correction but instead omitted part of the input content, resulting in a higher omission count post-fix.

achieved reductions of 33%, 42%, and 34%, respectively.

- Input correction led to a reduction in NAME^{N} and CONTEXT^{C} errors across all models.
- The original input data exhibited more NUMBER^{U} errors in LLAMA 2 models compared to T5, which were significantly reduced after correction. Both LLAMA 2 models completely resolved DATE_DIMENSION^{D} and OTHER^{O} errors.
- ADDITION^{A} errors are more common in LLAMA 2 models than in T5. Despite including the prompt 'Use only the information mentioned in the input table data' and correcting the tabular data, both L-7B and L-13B models still produced five ADDITION errors each.

Table 8 shows two rows of data from our analysis of the 40 challenging samples. The first row shows that corrected data leads to an increased number of samples with 'no error' (Higher is better). However, the second row shows that omissions have increased after input corrections. We observed that the models omitted part of the information either when the corrected tabular data had multiple column variables for more than two records or when the tabular structure was complex. In the case of fine-tuned models, it learned to omit some information during the fine-tuning process. In our future work, we plan to study the reasons why this is happening.

6.3 Model-Specific Results for Different Input Problems

In App. E, Fig. 2 presents how the four models are performing before (left bars) and after input corrections (right bars) for each input problem type.

Non-atomic cell values: T5-l and L-13B models corrected over 90% of the errors for this problem type, single record and multiple records lacking atomicity (see red and green bars in Fig. 2, App. F). T5-b and L-7B models corrected over 60% of the errors but still struggled with a few samples even after correction. For example, Fig. 2b shows that T5-large was making more errors for the input problem type labelled 'Multiple records lacking atomicity' before correction (in red) and made significant reductions after correction (in green).

Complex table: Due to the limitations in some tabular inputs, which require additional context, T5-b could not fix the errors. T5-l omitted the error for one sample, while L-7B and L-13B models partially fixed this input problem (see Fig. 2).

Insufficient input: This data annotation problem fixed all factual errors in T5-b, T5-l and L-13B

ERROR	ALL AGREE	WORD	NAME	DATE_DIM	NUMBER	OTHER	CONTEXT	ADDITION	NO ERROR	TOTAL
WORD	17	0	0	0	2	0	9	3	0	31
NAME	3	0	0	0	0	0	2	0	0	5
DATE_DIM	1	0	0	0	0	0	2	0	0	3
NUMBER	2	2	0	0	0	0	0	0	0	4
OTHER	2	0	0	0	0	0	0	0	1	3
CONTEXT	7	9	2	2	0	0	0	6	0	26
ADDITION	12	1	0	0	0	0	5	0	0	18
NO ERROR	15	0	0	0	0	1	0	0	0	16

Fleiss' kappa overall agreement for three annotators, $k = (pa - pe)/(1 - pe)$ = 0.622

Table 9: Fleiss' Kappa coefficient: overall agreement on 60 samples among three annotators. 'All agree' column signifies unanimous agreement on error types, while other columns show unique error selections.

after correction except for L-7B which added additional information for one sample.

Longer table input: Large models such as L-13B, L-7B and T5-l corrected factual errors for straightforward inputs, especially for tables with fewer than 20 rows. However, T5-b struggled the most to produce factual information.

Politics specific semantic issue: For the corrected input, L-13B fixed the factual mistakes for 5 out of 8 samples and L-7B fixed factual errors for 4 out of 8 samples. Both T5 models corrected 3 out of 8 samples (see Fig. 2).

List of leader names: T5 models struggled the most to correct factual errors for this problem. After correction, the L-7B model corrected three samples but produced factual errors for the remaining eight samples. L-13B made factual errors only for two samples (see Fig. 2).

While some models struggle with specific inputs, particularly regarding leader name order, tables requiring additional context for complex tabular structures, and semantic issues with symbols, our overall results indicate that correcting tabular inputs improves model outputs.

7 Inter-Annotation Experiment

One of the authors manually annotated errors in 1,508 outputs before input correction and 169 problematic outputs after correction (a total of 1,677 from both T5 models). Similarly, the annotation for both LLAMA 2 models covered 160 outputs before and after input correction.

Two additional annotators annotated 60 outputs each, generated by four different models both before and after input correction. We provided them with a detailed document that included definitions of error categories, guidelines, tabular inputs and output texts for error annotation[5]. Annotators followed the guidelines and marked the errors. Each annotator spent approximately 3 hours to complete this experiment.

The annotated errors are shown in a confusion matrix in Table 9, where the 'all agree' column shows all annotators agreed on the same error type and other columns show how often each annotator selected a different error type. Although the correct token was usually chosen, disagreements primarily occurred in choosing CONTEXT, ADDITION and WORD error types, as shown in red in Table 9. This might be due to the potential similarities in the definitions of CONTEXT errors and ADDITION errors (see App. B.3). While WORD error is comparatively straightforward, one annotator chose CONTEXT errors instead of WORD errors for a few outputs. Cases where an annotator did not mark any errors were in the minority. The inter-annotation agreement on error category classification for 60 outputs, as shown by a Fleiss' kappa of 0.622, indicates substantial agreement between the three annotators.

8 Conclusion

This paper presented a study that quantitatively demonstrates that fixing input problems such as insufficient data and data records containing non-atomic content improves the factual accuracy of output text by as high as 76% for one of the study models. Correcting inputs also seems to improve the number of entirely error-free output texts. However, we still need to investigate why errors categorised as 'omissions' increase after input corrections. In our future work, we aim to explore other tabular datasets for problems with input data and study the generalization of the fixes explored in the current work.

[5]We release our error annotations from our human evaluation on https://github.com/BarkaviSJ/totto_politics_human_annotations.

Limitations

We acknowledge some limitations in this work. First, we only looked at ToTTo and our scope of corrections to tabular input is limited to errors identified within the *politics* domain of the ToTTo validation set. Second, we did not extend the correction of tabular input for the *politics* domain to the training split of the ToTTo dataset due to the time-consuming process of handling different table headers and metadata. Third, our experiment results are restricted to two specific models (T5 and LLAMA 2) and may not generalize to other models.

In our future work, we aim to simplify the definitions of the 'context' and 'addition' error categories, as the annotation experiment revealed disagreement in choosing these error types for some samples, despite annotators marking the same error token.

Ethics Statement

This work seeks to address input problems in non-standard tabular structures to reduce factual errors in the output text. We utilized the open-source dataset, ToTTo and maintained the same ground-truth generation as the original dataset. Our input correction did not introduce any further social bias to this dataset. We adopted an error annotation methodology to annotate factual errors and one of the authors performed manual error analysis for this complete study. We sought consent from two additional annotators, the annotators volunteered to participate and annotated errors for 60 output texts each. They had the right to withdraw from the study at any point without facing any consequences. We provided necessary guidelines, instructions and examples for them to annotate errors.

Acknowledgements

We thank Craig Thomson and Adarsa Sivaprasad for their hard work in helping with the annotations in this paper. We thank the anonymous reviewers for their detailed feedback and suggestions which have significantly improved this work. We also thank the NLG (CLAN) reading group at the University of Aberdeen for their invaluable feedback.

Appendices

A Model fine-tuning specifications

The first model, T5-base (T5-b), was fine-tuned on the *full ToTTo training set of 120,761 samples* on a commodity server with a GeForce RTX 2080 GPU. The training took around seven days. The second model, T5-large (T5-l), was fine-tuned on *a subset of 50,000 ToTTo samples* on a secure cloud instance with an NVIDIA A100 GPU, completing in around 48 hours. Both models were fine-tuned using a constant learning rate of 0.0001, with the encoder's maximum length set to 512 tokens and the decoder's maximum length set to 128 tokens for ToTTo's generation task (Kale and Rastogi, 2020). Single-precision floating-point format (FP32) was employed for training on their respective GPU servers. The batch size, beam size and training steps for each model are shown in Fig. 1.

Models	Batch size	Beam Size	Training steps
T5-base	2	10	180,000
T5-large	4	5	9,000

Figure 1: Model Specifications

B Inter-Annotation Procedure for Participants

B.1 Overview

The Input Data from the ToTTo dataset, includes the Page title, Section Title and a Table with highlighted cells in yellow. These key parameters are conditionally used for training the neural models to summarize a meaningful and factual Text (as Output) focusing on: (i). highlighted cells in the table (ii). their corresponding header values (iii) The main Title and (iv) The Section Title.

For each of these tabular input data, we provided outputs generated by different neural language models to annotators. Our goal is to evaluate whether the neural outputs remain faithful and produce factually accurate information based on the four parameters from the tabular input. The complete table, including the non-highlighted cells, is provided to offer a clearer understanding of the error annotation task.

B.2 Domain

The inputs provided are specific to the domain of *politics*, sourced from Wikipedia tables (as part of the open-domain ToTTo dataset). The political data within these tables is not limited to a single demography. Instead, it encompasses various details from the election processes across multiple countries, including:

- Election specifics such as Presidential, state, by-elections, council, district, Legislative Assembly, and other elections unique to particular countries.
- Information about Governors, Mayors, Ministers, and Ambassadors (about Foreign Affairs).
- Details regarding the Speaker of the Assembly.

The first item related to election details is predominantly used in this error annotation task.

B.3 Error Annotation guidelines

We are only interested if the highlighted cell values from the table were used to produce a factually correct sentence. Please also pay attention to the non-highlighted cells in the same row as the highlighted cells, as this might be required in some inputs to generate a meaningful sentence. Other non-highlighted values in the table are not expected to be used for your evaluation. Please read through the output texts and annotate cases for the error categories as mentioned below. Each error is denoted with a superscript for better readability.

NAME^{N}

- When names of the Party, Leader, place (Electorate), Ambassador etc., are wrong (mostly nouns).
- Annotation includes both single tokens or multiple tokens to include the complete names.
- Example Output text: **Urban Ahlin^{N}** is the Deputy Speaker of the Riksdag. Remarks: NAME error because the correct deputy speaker was Tobias Billström as per the tabular data.
- Example Output text: Kansas was won by Mitt Romney, Paul Ryan, **Barack Obama^{N}**, and **Joe Biden^{N}**, with Romney winning

59.66% of the popular vote, six electoral votes and 38.05 percent. In this example, Barack Obama and Joe Biden are two NAME errors because they did not win the election.

- In general, Wednesday[N] instead of Tuesday is a NAME error but May[D] instead of April is a DATE_DIMENSION error.

NUMBER[U]

- When the number of seats and/or the number of votes and/or % of votes are incorrect. A single token is marked as an error.
- When the A-party won with a majority of 5.5%. But the correct one is 4.4%. 5.5%[U] is a NUMBER error.
- Output: The voter turnout was 8,90%, with 10,052 votes. Remarks: The actual turnout was 81.90%[U]. Please note: the error here is NOT with the comma used as decimal (as it is an acceptable decimal operator for international use); Error because the number 81.90 was incorrect.

DATE_DIMENSION[D]

- When the Date and/or Month and/or Year are wrong in the generated text, it is annotated as one error.
- Example Output text: Cletus Avoka was the Minister for the Interior in the Mills government from 2009 to 2012[D]. Remarks: 2010 is the right end term of the year.
- As a general note, if the Output text did not capture Month and/or Date, but has the correct year, then this is NOT an ERROR. It could go to OMISSION with remarks, Omission of Date and Month.

WORD[W]

- When incorrect words such as verbs, prepositions, adjectives, adverbs and conjunctions are found in the output.
- Single token is marked as a WORD error in most cases. Multiple tokens are annotated when the auxiliary verb (was), an extension of a prepositional phrase (along with) and others are incorrect.
- Example Output text: Carly Fiorina defeated Republican Tom Campbell with 56.4% of the vote to DeVore's 19.3%, along with[W] Al Ramirez and Tim Kalemkarian. Remarks: Fiorina independently defeated all the leaders, so 'along with' is wrong.
- Example Output text: Ling won[W] the 2016 senate district against Democrat Josh Newman, with 49.6 percent of the vote. Remarks: Ling lost the election as per the tabular data.
- Some of the common WORD errors found in this data are *won, defeated, lost, succeeded*, adjectives such as *current* governor other prepositions (*since, in* and so on).

CONTEXT[C]

- When the model's output presents information that contradicts or makes *unsupported assumptions about the given input data*. Group of tokens/span of text are annotated as CONTEXT error.
- It can sometimes be tricky to check for this type of error. Please follow the below sequence before marking this error.
  - In case of simple misrepresentation based on the information in the input data, it would be easier to mark the token as NAME, NUMBER, DATE_DIMENSION or WORD error.
  - In the case of a complex table structure, the outputs are likely to mess up completely with the overall information in the provided input data. In this case, it is hard to mark individual errors. Please go ahead and mark the group of tokens/ span of text and annotate it as a CONTEXT error.
  - For example, the output is: In the 2006 election for mayor of Florence Pendleton[C], Michael D. Brown received 62,415 votes while Philip Pannell received 21,552 votes and write-in candidates[C] received 1,363 votes. Annotation remarks:
    * for mayor of Florence Pendleton[C] - the name of a person is misrepresented as electorate (jurisdiction) in the output.

* write-in candidates[C] - this implies there was more than one write-in candidate.

ADDITION[A]

- When the model's outputs have *added words, phrases, or details* that either diverge from the input's main topic or are unsupported by the given context.
- Single or group of tokens are annotated as ADDITION error.
- Example Output text: 2007 Algerian legislative election was held on May 17, 2007[A]. The results were as follows: 24 political parties won a total of 389 seats in the National Assembly. **Remarks:** The date and month are additional information, that are not provided in the input. This is marked as an ADDITION error. Other details in the output are correct.

OTHER[O]

- When the output repeats the same input multiple times producing garbage data. In some cases, when the table data has the political party name in the abbreviation, it produces garbage output. For example, when the tabular data has a party name in abbreviation, it tries to produce a strange output. Output text: GSSSDULSVDHSS[O] gained 5.31% of the vote
- When the output is incomplete for longer table input or when the output repeats the same input multiple times without producing a complete text.
- When punctuation symbols are placed in inappropriate places, for example, an apostrophe is missed for the Name of the Leader or Place.

NON-ENGLISH[NE]

- when the Unicode characters in non-English names are either replaced with special characters or when these Unicode characters are omitted.
- For example, Pawe Gra[NE] is a member of Sejm. **Remarks:** Paweł Graś is the correct name here.

C LLAMA 2 prompts

The below prompt is for the corrected tabular data when the input table has party name, candidate and votes.

> 'Given the input table data, the task is to: (i). Identify the party name, candidate name, and the number of votes received by each candidate. (ii). Determine the winner based on the highest number of votes. Then, put together the gathered information from (i) and (ii) into a single coherent sentence. Input table data: <Linearized table data>'

Below is one of the prompts used for the original table data without mentioning any specific fields.

> 'The task is to summarize the information from the given input table data into a single coherent sentence. Use only the information mentioned in the input table data. Input table data is: <Linearized table data>'

D Steps for Correcting ToTTo Tabular Input

In addition to the correction procedure detailed in Sec. 5.2, which provides examples of the corrections applied to each tabular input problems, we present a supplementary pseudocode in this section. In algorithm 1, we have a generic function that takes tabular data and title (metadata) from ToTTo as input parameters. This main algorithm executes six different functions.

The first two functions, DATASIZEMANAGEABLEFORLONGTABLE and IDENTIFYLEADERNAMEORDER provide insights on the input problems leading to factual errors in the outputs but do not correct the tabular input. The other four functions, namely CORRECTNONATOMICCELLS, UPDATEHEADERS, ADDRESSMISSINGVALUES, and REPLACESYMBOLS correct the input problems as presented in algorithm 4, algorithm 5, algorithm 6, and algorithm 7. We provide brief descriptions for each algorithm in the caption and comments.

E Input Problem Types for four models

Fig. 2 shows how each of the four models is performing before and after data corrections for each of the problem types. The left bars for each input

Algorithm 1 Manual Correction Procedure for ToTTo Tabular Input (elaborated in Sec. 5.2). This main function takes tabular data and title details as input parameters and returns the corrected tabular data. In all functions, we excluded row and column indices for simplicity and readability.

function MAINCORRECTIONPROCEDURE($tabularData, title$)
  if not DATASIZEMANAGEABLEFORLONGTABLE($tabularData$) **then**
    return "Please simplify the tabular data with fewer records", null
  end if
  $leaderName, recordedData \leftarrow$ IDENTIFYLEADERNAMEORDER($tabularData, title$)
  $correctionsMade \leftarrow$ **false**
  $correctionsMade \leftarrow$ CORRECTNONATOMICCELLS($tabularData$) **or** $correctionsMade$
  $correctionsMade \leftarrow$ UPDATEHEADERS($tabularData$) **or** $correctionsMade$
  $correctionsMade \leftarrow$ ADDRESSMISSINGVALUES($tabularData$) **or** $correctionsMade$
  $correctionsMade \leftarrow$ REPLACESYMBOLS($tabularData$) **or** $correctionsMade$
  if $correctionsMade$ **then**
    return ($tabularData$, "Leader Data: " + $recordedData$) ▷ Returns corrected input and leader data
  else
    return ($tabularData$, "Leader Data: " + $recordedData$) ▷ Returns original input (if no issues) and leader data
  end if
end function

Algorithm 2 Verify the number of rows and columns in Longer Tabular Input (discussed in Sec. 5.2.4). This function validates the maximum allowable number of rows and columns for the tabular data and returns true or false to the main function.

function DATASIZEMANAGEABLEFORLONGTABLE($tabularData$)
  $maxRows \leftarrow 20$
  $maxCols \leftarrow 10$
  return (length(*tabularData*) $\leq maxRows$) **and** (length(*tabularData*[0]) $\leq maxCols$)
end function

Algorithm 3 Identify Leader Name Order in Title and Table Rows (discussed in Sec. 5.2.6). This function verifies three main scenarios for the order of leader names in the input. It returns a tuple with title information for leader name and a list of leader names from tabular input depending on the scenario. Description for each scenario is briefly commented.

function IDENTIFYLEADERNAMEORDER(*tabularData*, *title*)
  $leaderNameFromTitle \leftarrow$ ExtractLeaderNameFromTitle(*title*)
  $leaderNamesFromRows \leftarrow [\,]$
  for each row **in** *tabularData* **do**
    for each cell **in** current row **do**
      if leader_name is found in cell **then**
        Add leader_name to $leaderNamesFromRows$ ▷ Record leader's names from rows
      end if
    end for
  end for
  ▷ Scenario 1: Leader's name found in title
  if leaderNameFromTitle is not None **then**
    $recordedData \leftarrow [\,]$ ▷ To store sequential order of leader names
    Add $leaderNameFromTitle$ to $recordedData$
    for each leader_name **in** *leaderNamesFromRows* **do**
      Add leader_name to $recordedData$
    end for
    return ($leaderNameFromTitle, recordedData$)
    ▷ for e.g., this could return ("b", ["a", "b", "c"])
  else
    ▷ Scenario 2: Leader's name not found in title
    if length of $leaderNamesFromRows > 0$ **then** ▷ if leader's name is in at least one row
      $recordedData \leftarrow$ "Leader name not in title"
      for each leader_name **in** *leaderNamesFromRows* **do**
        Add leader_name to $recordedData$
      end for
      return ($leaderNameFromTitle, recordedData$)
      ▷ for e.g., this could return (None, ["Leader name not in title", "a", "b", "c"])
    else
      ▷ Scenario 3: Leader name neither in title nor in rows
      return ($leaderNameFromTitle$, "Leader name not in table")
      ▷ for e.g., this could return (None, ["Leader name not in table"])
    end if
  end if
end function

Algorithm 4 Correct Non-Atomic Cells (discussed in Sec. 5.2.1). If a non-atomic cell is found, the `CorrectCell` function separates multiple atomic values into individual columns. We follow our manual correction procedure in `CellIsNonAtomic` and `CorrectCell`. The function returns the corrected tabular data along with a flag indicating if any corrections were made.

function CORRECTNONATOMICCELLS($tabularData$)
  $correctionsMade \leftarrow$ **false**
  for all row **in** $tabularData$ **do**
    for all $cell$ **in** row **do**
      if CellIsNonAtomic($cell$) **then**
        $correctedCell \leftarrow$ CorrectCell($cell$) ▷ Separate multiple values into individual columns
        $tabularData[cell] \leftarrow correctedCell$ ▷ Update the corrected cell value
        $correctionsMade \leftarrow$ **true**
      end if
    end for
  end for
  return ($tabularData, correctionsMade$)
end function

Algorithm 5 Update Column and Row Headers to Atomic cells (discussed in Sec. 5.2.4). For each cell, the tabular input has header_value as true or false. When the header value is true, we manually verify the function `HeaderIsIncorrect` and correct the logic in `UpdateHeader(cell)`. The function returns the corrected tabular data with corrections made flag.

function CORRECTHEADERS($tabularData$)
  $correctionsMade \leftarrow$ **false**
  for all row **in** $tabularData$ **do**
    for all $cell$ **in** row **do**
      if cell.header_value $=$ **true then**
        if HeaderIsIncorrect($cell$) **then**
          $correctedHeader \leftarrow$ UpdateHeader($cell$) ▷ Update column and row headers
          $tabularData[cell] \leftarrow correctedHeader$ ▷ Update the corrected header
          $correctionsMade \leftarrow$ **true**
        end if
      end if
    end for
  end for
  return ($tabularData, correctionsMade$)
end function

Algorithm 6 Address Missing cell Values (discussed in Sec. 5.2.3). For each row, we verify the missing cell values in `RowHasMissingValues` and pass the right cell values in `FillCellValues` through a manual process. The function returns the corrected tabular data with corrections made flag.

function ADDRESSMISSINGVALUES($tabularData$)
  $correctionsMade \leftarrow$ **false**
  for all row **in** $tabularData$ **do**
    if RowHasMissingValues(row) **then**
      $correctedRow \leftarrow$ FillCellValues(row) ▷ Pass missing cells in the row
      $tabularData[row] \leftarrow correctedRow$
      $correctionsMade \leftarrow$ **true**
    end if
  end for
  return $(tabularData, correctionsMade)$
end function

Algorithm 7 Replace Politics Domain-Specific Symbols and Abbreviate Party Names with Correct Semantics/words (discussed in Sec. 5.2.5). For all cells in the table, we verify `containsDomainSpecificSymbols` and `containsPartyAbbreviations` functions and correct the values using `substituteSymbolWithEquivalent` and `containsPartyAbbreviations` through a manual process. The function returns the corrected tabular data with corrections made flag.

function REPLACESYMBOLS(*tabularData*)
  $correctionsMade \leftarrow$ **false**
  for all $cell$ **in** *tabularData* **do**
    if containsDomainSpecificSymbols($cell$) **then**
      $correctedValue \leftarrow$ substituteSymbolWithEquivalent($cell$) ▷ Replace symbols with words
      $tabularData[cell] \leftarrow correctedValue$ ▷ Update the corrected cell value
      $correctionsMade \leftarrow$ **true**
    else if containsPartyAbbreviations($cell$) **then**
      $correctedValue \leftarrow$ abbreviatePartyNames($cell$) ▷ Abbreviate party names
      tabularData$[cell] \leftarrow correctedvalue$ ▷ Update the corrected cell value
      $correctionsMade \leftarrow$ **true**
    end if
  end for
  return $(tabularData, correctionsMade)$
end function

problem type represent output scores before data correction, while the right bars represent scores after data correction. Colour coding of output scores helps to identify and understand errors: green indicates no error, red indicates an error, and yellow indicates an omission.

The number of samples for each model differs because we focus on outputs only when the model had 'errors' or 'omissions' before correction. This approach emphasizes the actual improvement in corrections. For example, T5-large had errors in 37 samples before correction (left bar), the after-correction (right bar) also shows improvements for the same 37 samples.

F Input Data Corrections and Output Text

In this section, the input tabular data with outputs supplements the examples elaborated in Sec. 5.2 for each of the input problems as presented from Table 10 to Table 16.

(a) Input Table with Original Cells highlighted in Yellow

Page Title: 2012 Cardiff South and Penarth by-election
Section Title: By-election result

Party	**%**	±
Conservative	19.9	8.4
Liberal Democrat	10.8	-11.5

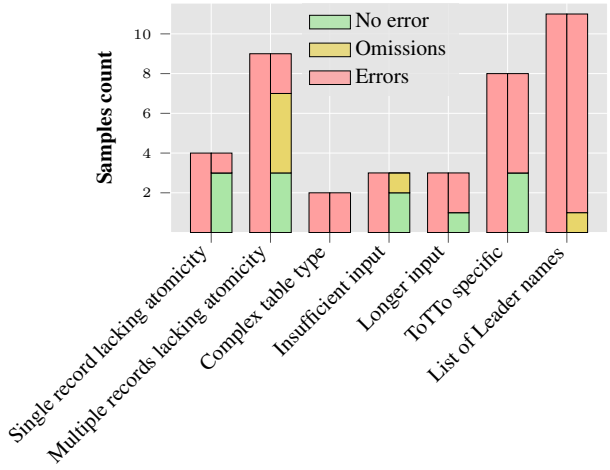
(b) Input Table with Corrected Cells highlighted in Yellow

Page Title: 2012 Cardiff South and Penarth by-election
Section Title: By-election result

Party	**%**	**± % difference with previous election**
Conservative	19.9	8.4
Liberal Democrat	10.8	-11.5

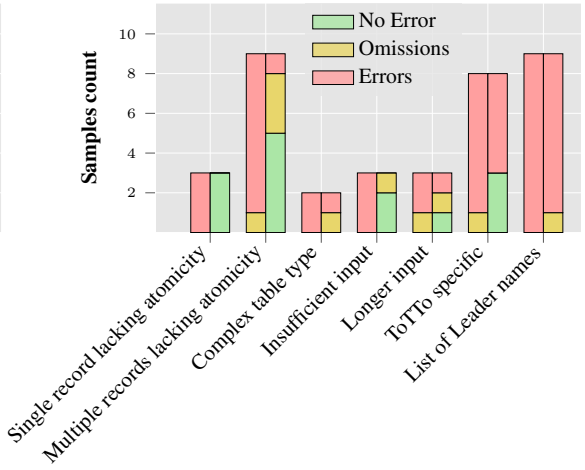
(c) Outputs Before and After Input Data Correction

T5-large before fix: In the 2012 Cardiff South and Penarth by-election, the Liberal Democrats **won**[W] 11.5% of the vote.



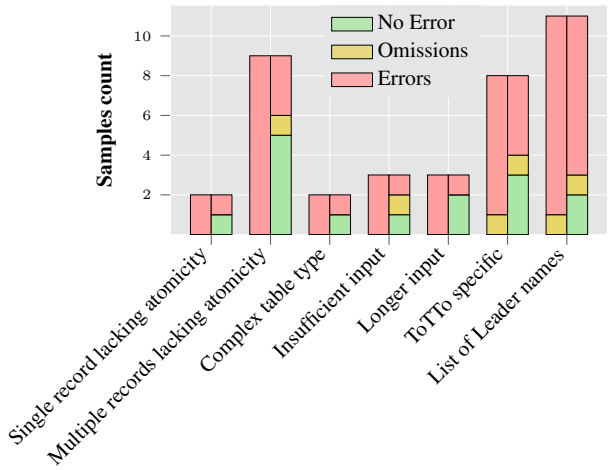
T5-large after fix: In the 2012 Cardiff South and Penarth by-election, the Liberal Democrats **lost by**[W] 11.5%.

LLAMA 2-13B before fix: 2012 Cardiff South and Penarth by-election was **won**[W] by the Liberal Democrats with a **margin**[W] of -11.5%.



LLAMA 2-13B after fix: 2012 Cardiff South and Penarth by-election saw Liberal Democrat candidate lose by 11.5% of the vote compared to the previous election.

Table 10: ToTTo specific: Swing percentage difference with previous election, as detailed in Sec. 5.2.5. Before fix represents the output generated from input Table 10a and after fix represents the output generated after explicitly changing the header, as shown in input Table 10b.



(a) T5-base: Error Analysis of 40 samples.

(b) T5-large model: Error Analysis of 37 samples.

(c) LLAMA 2-7B: Error Analysis of 38 samples.

(d) LLAMA 2-13B: Error Analysis of 35 samples.

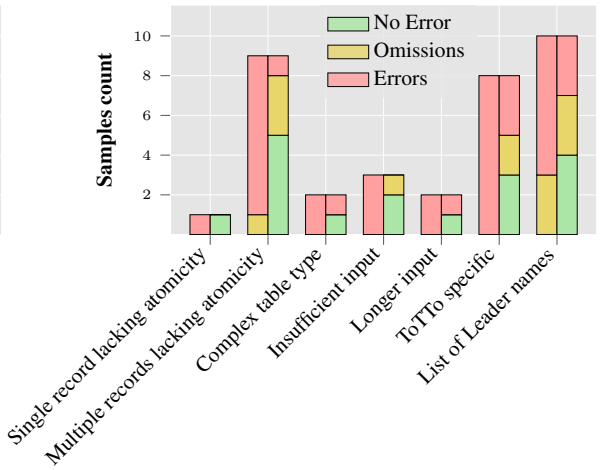


Figure 2: Comparison of different input problem types before (original data) and after data correction across four models. It shows the count of unique samples for three categories: (i) errors, (ii) omissions, and (iii) no errors.

(a) Input Table with Original Cells highlighted in Yellow

Page Title: 1914 United States Senate elections
Section Title: Races leading to the 64th Congress

State	Incumbent		Results	Candidates
	Senator	Party		
South Dakota	Coe I.Crawford	Republican	Incumbent lost renomination. New senator elected. Democratic gain.	Edwin S. Johnson (Democratic) 48.32% Charles H. Burke (Republican) 44.47%

(b) Outputs with Original Input before Input Data Correction

T5-base: In South Dakota, Republican Coe I. Crawford lost renomination to Democrat Edwin S. Johnson[C].

T5-large: South Dakota: Republican incumbent Coe I. Crawford lost his bid for the seat to Democratic challenger Edwin S. Johnson[C].

LLAMA 2-7B: 1914 United States Senate elections in South Dakota were held on November 3[A], 1914. Incumbent Republican Senator Coe I. Crawford lost renomination to Democratic candidate Edwin S. Johnson[C]. Johnson defeated Charles H. Dunnigan[N] by a margin of[W] 48.32% to 47.56%[U]. This was a Democratic gain from the previous election.

LLAMA 2-13B: 1914 United States Senate elections were held on November 3[A], 1914 to elect members of the United States Senate in various states. The Republican Party lost one seat and the Democratic Party gained one seat.

(c) Input Table with Corrected Cells highlighted in Yellow

Page Title: 1914 United States Senate elections
Section Title: Races leading to the 64th Congress

State	Incumbent Senator	Incumbent Party	Results	Candidate Senator	Candidate Party	Candidate votes %
South Dakota	Coe I.Crawford	Republican	Incumbent lost renomination. New senator elected. Democratic gain.	Edwin S. Johnson	Democratic	48.32%
South Dakota	Coe I.Crawford	Republican	Incumbent lost renomination. New senator elected. Democratic gain.	Charles H. Burke	Republican	44.47%

(d) Outputs After Input Data Correction

T5-base: In South Dakota, Republican Coe I. Crawford lost renomination to Democrat Edwin S. Johnson[C].

T5-large: South Dakota: Republican incumbent Coe I. Crawford lost his bid for the seat to Democratic challenger Edwin S. Johnson[C].

LLAMA 2-7B: 1914 United States Senate elections were held on November 3,[A] 1914. In South Dakota, Coe I. Crawford, the Republican incumbent Senator lost renomination to Edwin S. Johnson[C], a Democratic candidate. Charles H., the Republican candidate also ran for the seat but he was defeated by Johnson. Therefore, it is a Democratic gain in this election.

LLAMA 2-13B: 1914 United States Senate elections were held on November 3[A], 1914 to elect members of the United States Senate in various states. Races leading to the 64th Congress included South Dakota where Coe I. Crawford (Republican) lost renomination and Edwin S. Johnson (Democratic) was elected.

Table 11: Complex Table input problems, as detailed in Sec. 5.2.2. Difficult to fix this complex input type, yet LLAMA 2-13B produced most of the facts right except for ADDITION error. Lost renomination 'to Democrat candidate' is a CONTEXT error, because the model made unsupported assumptions about the given input. Losing renomination is when the current senator failed to be nominated in the primary to stand for reelection.

Republican	Tom Campbell	504,289	21.7
Republican	Chuck DeVore	452,577	19.3
Republican	Al Ramirez	42,149	1.8
Republican	Tim Kalemkarian	19,598	0.8

(c) Outputs Before and After Input Data Correction

T5-base before fix: DeVore **defeated**[W] Republican Tom Campbell with **56.4%**[U] of the vote, **Al Ramirez with 19.3%, and Tim Kalemkarian with 19.3%**[C].
T5-base after fix: DeVore **defeated**[W] Republican nominees Carly Fiorina (56.4%)**, Tom Campbell (21.7%), Al Ramirez (1.8%) and Tim Kalemkarian (0.8%)**[C].

T5-large before fix: DeVore was defeated by Republican Tom Campbell **(56.4%)**[U], **Al Ramirez (19.3%), and Tim Kalemkarian (21.7%)**[C].
T5-large after fix: DeVore was defeated in the U.S. Senate race by Republican nominees Carly Fiorina (56.4%), Tom Campbell (21.7%)**, Al Ramirez (1.8%) and Tim Kalemkarian (0.8%).**[C]

LLAMA 2-7B before fix: Chuck DeVore is a Republican candidate for the U.S. Senate in California. He received 19.3% of the vote in the primary election, which was held on June 8th, 2010. The other candidates were Carly Fiorina (56.4%), Tom Campbell **(24.1%)**[U] and Al Ramirez **(10.2%)**[U]. Tim Kalemkarian **did not run for this office**[C].
LLAMA 2-7B after fix: The number of votes for each leader is as follows: Carly Fiorina - 56.4% Tom Campbell - 21.7% Chuck DeVore - 19.3% Al Ramirez - 1.8% Tim Kalemkarian - 0.8%. Carly Fiorina won the Republican primary for U.S. Senate in California with 56.4 percent of the vote, followed by Tom Campbell at 21.7 percent and Chuck DeVore at 19.3 percent.

LLAMA 2-13B before fix: Carly Fiorina is the leading candidate for U.S. Senate with 56.4% of the vote, followed by Tom Campbell with **20.3%**[U], Chuck DeVore with 19.3%, and Al Ramirez with **4.0%**[U].
LLAMA 2-13B after fix: The Republican Party candidate who won the most votes in the U.S. Senate election was Carly Fiorina with 56.4% of the total votes.

Table 14: ToTTo specific input problems: List of Leader names for five leaders, as detailed in Sec. 5.2.6. All models swapped the defeated leader names and/or % of votes, resulting in WORD, NUMBER and CONTEXT errors. After including the party names and % of votes for all leaders, LLAMA 2 models corrected the errors. Fine-tuned T5 models still made errors. This could be because of the pattern learned from the fine-tuned training data of ToTTo.

434	...	...	...	...	**One term**
435	Adam M. Wyant	PA-22	WI-1	March 4, 1921	**One term**

(d) Outputs After Input Data Correction

T5-large after fix: There are 435 members of the United States House of Representatives in the 65th Congress.

LLAMA2-13B after fix: The table shows that there are 435 representatives in the 65th Congress, and they are ranked according to their seniority.

Table 16: Longer Table input problems, as detailed in Sec. 5.2.4.
(a). Original tabular input had 435 rows with term details and other details from nested headers (irrelevant details).
(b). The fine-tuned T5-large model hallucinated the output text with the irrelevant header information (nested header issue). LLAMA 2-13B also struggled to produce the right text and generated incomplete output. LLAMA 2-7B produced longer garbage output.
(c). First, we fixed the nested header by creating a separate column. Then, we only passed 20 records (first 10 rank and 426 to 435 rank) along with title information. We did not pass the irrelevant term details to the corrected data.
(d). This simplified input records with relevant header details (Rank) fixed the errors in both models.

CERET: Cost-Effective Extrinsic Refinement for Text Generation

Jason Cai, Hang Su, Monica Sunkara, Igor Shalyminov, Saab Mansour
AWS AI Labs
{cjinglun, shawnsu, sunkaral, shalymin, saabm}@amazon.com

Abstract

Large Language Models (LLMs) are powerful models for generation tasks, but they may not generate good quality outputs in their first attempt. Apart from model fine-tuning, existing approaches to improve prediction accuracy and quality typically involve LLM self-improvement / self-reflection that incorporate feedback from models themselves. Despite their effectiveness, these methods are hindered by their high computational cost and lack of scalability. In this work, we propose CERET, a method for refining text generations by considering semantic stability, entailment and inter-sample uncertainty measures. Experimental results show that CERET outperforms Self-consistency and Self-rerank baselines consistently under various task setups, by 1.6% in Rouge-1 for abstractive summarization and 3.5% in hit rate for question answering. Compared to LLM Self-rerank method, our approach only requires 9.4% of its latency and is more cost-effective. [1]

1 Introduction

Large Language Models (LLMs) like GPT (Brown et al., 2020), Claude, PaLM (Chowdhery et al., 2022; Anil et al., 2023), and Llama (Touvron et al., 2023) have showcased unprecedented capabilities in natural language understanding and generation. These models, with parameter counts reaching into the hundreds of billions, have become pivotal in advancing the frontier of natural language processing (NLP). Despite their impressive fluency and coherence, language models frequently generate content that is incomplete, biased, or misleading in their initial attempts across a variety of language generation tasks.

The key challenge is that while pre-training equips base models with broad linguistic knowledge, it does not necessarily impart the specialized skills needed for particular downstream tasks. Current methodologies for enhancing LLM generation largely involve resource-intensive approaches such as supervised fine-tuning (SFT), which relies heavily on domain-specific training data, or reinforcement learning from human feedback (RLHF), which necessitates extensive human annotations. However, curating large volumes of high-quality domain-specific data and human feedback often proves prohibitively expensive and time-consuming in practice, severely limiting the applicability of SFT and RLHF. By integrating feedback derived from the generated outputs, self-improvement / self-reflection approaches enhance generations in an iterative manner (Madaan et al., 2023; Yao et al., 2023a). These approaches empower the LLM to adapt to specific tasks and domains by learning from its own mistakes and successes. Nevertheless, the substantial cost linked to iterative inference poses challenges for scalability and applicability real-time systems.

This paper introduces CERET, a novel method designed to refine text generation in a rapid, low-resource manner to reduce the need for domain-specific training data or expensive human annotations. The cornerstone of CERET lies in its ability to enhance generated content by holistically considering three key scoring dimensions - semantic stability, entailment, and inter-sample uncertainty measures.

Semantic stability scoring quantifies the linguistic invariance among multiple candidate outputs generated by the base model for the same input, indicating higher confidence for more stable candidates. Entailment scoring leverages natural language inference (NLI) models to quantify the logical entailment relations between candidate outputs, preferring candidates that maximally entail others. Inter-sample uncertainty scoring penalizes candidates that are semantically similar to outputs for

[1] The source code and data samples are released at https://github.com/amazon-science/CERET-LLM-refine.

Proceedings of the 2024 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies (Volume 1: Long Papers), pages 7377–7390
June 16-21, 2024 ©2024 Association for Computational Linguistics

different inputs, a signal of greater uncertainty.

Our approach operates in a rapid, zero-shot manner without any domain-specific training data, reward modeling, or human feedback. The proposed scoring and refinement process encapsulates an efficient way to improve text generation across a diverse spectrum of NLP tasks, including abstractive summarization, dialogue response generation, and open-domain question answering. Through a rigorous series of experiments on standard datasets, CERET is empirically validated to significantly outperform baseline methods such as Self-consistency and Self-reranking across both summarization and QA tasks. Beyond its superior performance, CERET stands out for its practicality and cost-effectiveness, making it a promising solution for real-world applications where domain-specific resources and annotations are limited or unavailable. This paper not only presents CERET as a valuable novel contribution to the growing field of NLP but also underscores its potential impact on advancing the practical deployment of text generation across a myriad of domains. The main contributions are summarized as follows:

- CERET is proposed as a holistic framework for enhancing generation quality, encompassing semantic stability, entailment, and inter-sample uncertainty measures.
- The refinement process is data efficient and cost-effective, without the requirement for domain-specific training data or expensive annotations.
- The proposed approach can be applied across various natural language processing tasks, such as text summarization, dialogue response generation and question-answering systems.
- CERET is highlighted for its practicality and efficiency, presenting only a minor fraction of the usual latency associated with a single generation call, which positions it as a feasible solution for real-world applications.

2 Approach

2.1 System Architecture

CERET consists of three scoring methods, namely Semantic Stability Scoring, Entailment Scoring and Inter-sample Uncertainty Scoring, for calibrating the quality of LLM predictions. The overview of the proposed system is illustrated in Figure 1. Firstly, a diverse set of candidates are sampled from LLMs. Then each individual scoring method will produce a separate score from a certain perspective. Based on the scores in three dimensions, a linear weighted final confidence score is computed to measure the quality of each prediction. The prediction with the highest confidence score is selected as the final model prediction.

2.2 Semantic Stability Scoring

We first introduce an intra-sample scoring method, Semantic Stability Scoring, which is motivated by the need to enhance the confidence and reliability of sample generations produced by LLMs. The scientific rationale is inspired by Kuhn et al. (2023) and Yin et al. (2022), where it was shown that a sample generation exhibits higher confidence when it demonstrates considerable semantic stability or linguistic invariance among other generations. However, the semantic stability measured in Kuhn et al. (2023) involves clustering sampled generations for each sample, which is computationally expensive for real world applications at large scale.

In contrast, we propose a cluster-free method for semantic stability modeling. Specifically, Semantic Stability Scoring is formulated as the following: Given input data sample x, the model generates k predictions $(y_1, ..., y_k)$. For each y_i, a fixed pre-trained language model produces its corresponding embedding $e(y_i)$. In practice, we leverage RoBERTa (A Robustly Optimized BERT Pretraining Approach) (Liu et al., 2019) as the pre-trained language model, and the final hidden representation of "<s>" token from RoBERTa, is regarded as $e(y_i)$. To aggregate all intra-sample representations, we treat the average-pooled embedding $\bar{e}$ as a stability reference point:

$$\bar{e} = mean(e(y_1), ..., e(y_k)) \quad (1)$$

A lower distance between an embedding and the reference point implies a higher stability. We can employ Euclidean distance or cosine distance as the distance metric $||\cdot||$. The stability score s^i_{sta} is defined as the negative distance between $e(y_i)$ and the stability reference point $\bar{e}$:

$$s^i_{sta} = -||e(y_i) - \bar{e}|| \quad (2)$$

2.3 Entailment Scoring

Entailment scoring is another intra-sample scoring method, fully powered by entailment relation: "p

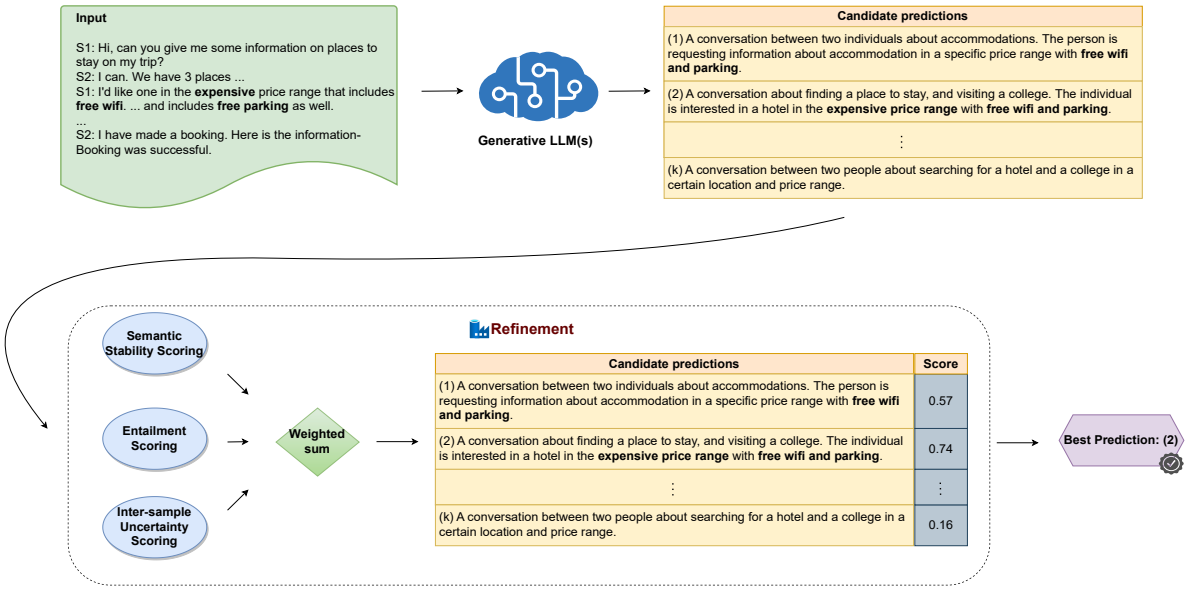

Figure 1: CERET overview

entails h" ($p \Rightarrow h$), if a human reading premise p would infer that hypothesis h is most likely true. This intrinsic connection to human inference aligns closely with the objective that language models should have the capacity to generate content that is not only syntactically accurate but also semantically meaningful. In the entailment scoring process, when an LLM generates k predictions $(y_1, ..., y_k)$, each prediction's entailment relation to others is quantified by a Natural Language Inference (NLI) model. The scalar value s_j^i reflects the degree to which the content of y_i logically entails y_j.

$$s_j^i = \text{ENT}(y_i, y_j) \tag{3}$$

Although the scalar function for entailment can be evaluated by the base LLM itself, such an approach leads to a higher computational cost. Hence, we resort to a more efficient and lightweight NLI model. Specifically, we adopt DeBERTa (Decoding-enhanced BERT with disentangled attention) (He et al., 2021) for this work. The NLI task is treated as a sequence classification problem: The texts y_i, y_j are concatenated, with special tokens as separators, to form the input to DeBERTa. The final hidden representations of pretrained DeBERTa are passed to a pooling layer and a classifier, to obtain softmax probability for three categories, namely Neutral, Entailment and Contradiction. The softmax probability for Entailment is used as $\text{ENT}(y_i, y_j)$.

A generation is plausible if it entails as many other sampled generations as possible. With the top k sampled model predictions, the entailment score for sample y_i is computed as follows:

$$s_{ent}^i = \frac{1}{k} \sum_{1 \le j \ne i \le k} s_j^i + LP(y_i) \tag{4}$$

Note that the preferred prediction will likely have rich information, and may be lengthy in certain situations. A length penalty $LP(y_i)$ is applied to this entailment score, in case lengthy outputs harm the expected conciseness.

$$LP(y_i) = 1 - (1 + q \cdot \text{len}(y_i))^p \tag{5}$$

where $0 \le q < 1$ and $p > 1$ are hyperparameters[2].

2.4 Inter-sample Uncertainty Scoring

In contrast to the methods above, the following is an inter-sample scoring method, which is inspired by uncertain region analysis. We first build an embedding space for all sampled predictions with a standalone model, e.g., RoBERTa. The rationale behind this inter-sample scoring method is that when a sampled prediction is located near predictions from different input data samples in

[2]In our practice, we chose q = 0 (i.e. no penalty). We found that our beam search sampled predictions generally have very comparable lengths. Nevertheless, the length penalty may benefit other datasets or decoding settings.

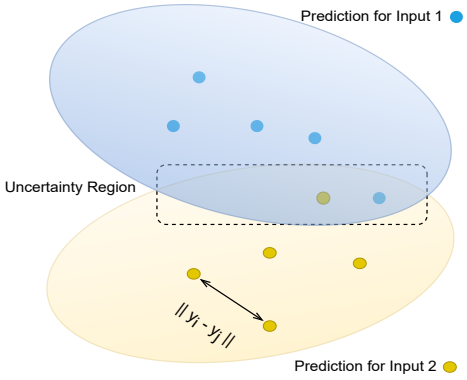

Figure 2: Inter-sample uncertainty region

the embedding space, this prediction is likely to be uncertain, illustrated in Figure 2. Uncertain predictions are down-weighted by a lower uncertainty score s_{unc}.

Suppose dataset D has size N. For each input x, top k predictions are generated by LLM(s), resulting in $k \cdot N$ predictions in total: $\{y_i\}_{1 \leq i \leq kN}$. The Euclidean distance of all possible prediction pairs $\|y_i - y_j\|, i \neq j$ are computed and cached. According to Euclidean distance, the nearest neighbor set $\mathcal{N}(i)$ is constructed for each prediction y_i. The inter-sample uncertainty score s^i_{unc} is computed as follows:

$$s^i_{unc} = -\sum_{j \in \mathcal{N}(i)} \frac{\mathbb{I}(\hat{x}_i \neq \hat{x}_j)}{(1 + \|y_i - y_j\|)} \quad (6)$$

where $\mathbb{I}(\cdot)$ is the indicator function. $\hat{x}_i$ denotes the input sample x for prediction y_i. Note that possibly $\hat{x}_i = \hat{x}_j$ when $i \neq j$. $||y_i - y_j||$ in denominator of Equation 6 is a regularization term, ensuring a further y_j is assigned with a lower weight for uncertainty. A negative sign is added to ensure that a higher score is better. In case when the dataset is large, the computation cost for obtaining pairwise Euclidean distances and nearest neighbors can be mitigated by limiting data size N to a certain batch (e.g., 1000). Additionally, the LLM generations in practice mostly have the number of sampled predictions $k \leq 20$. Thus the efficiency of this method can be maintained.

2.5 Computation of Final Score

All separate scores s_{sta}, s_{ent}, s_{unc} are transformed to the interval $(0, 1)$ by applying sigmoid function

$$\text{sigmoid}(x) = \frac{1}{1 + e^{-ux}} \quad (7)$$

where $u > 0$ is an additional scaling factor [3]. Since three scores have distinct ranges, u is applied to ensure their scaled ranges are comparable. The final confidence score is a linear weighted score based on three dimensions.

$$s = \alpha \cdot s_{sta} + \beta \cdot s_{ent} + \gamma \cdot s_{unc} \quad (8)$$

The coefficients α, β, γ are tuned on validation datasets. To mimic the properties of probability for intuitive interpretation, the following constraints are imposed:

$$\begin{cases} \alpha + \beta + \gamma = 1 \\ \alpha, \beta, \gamma \geq 0 \end{cases} \quad (9)$$

3 Experimental Setup

3.1 Datasets

We evaluate the proposed approach CERET on Abstractive Summarization and Question Answering (QA) tasks. For summarization, we consider two dialogue summarization datasets: TodSum (Zhao et al., 2021) and DialogSum (Chen et al., 2021), as dialogue summarization has been a challenging summaization use case due to its multi-speaker nature and varying structures. TodSum is a dialogue summarization dataset based on MultiWoz (Budzianowski et al., 2018). Out of 7 MultiWoz domains, it contains 5 and totals 9,906 dialogues. DialogSum is a multi-domain dataset, mostly consisting of casual/spoken style daily conversations. It is based on top of the existing datasets around English practice conversations and English listening comprehension exams. For TodSum and DialogSum, official validation/test sets are used throughout this work.

For QA, we use TriviaQA (Joshi et al., 2017) and Natural Questions (Lee et al., 2019, the NQ-Open version) datasets. TriviaQA contains 95,956 QA pairs with 40,478 unique answers and 662,659 evidence documents. It contains question-answer pairs from 14 trivia and quiz-league websites, with the associated Wikipedia pages as evidence sources. NQ-Open is an open-domain question answering benchmark, a subset of Natural Questions (Kwiatkowski et al., 2019) with short answers and with evidence documents discarded. It contains 91,535 QA pairs. For TriviaQA and Natural Questions, the official test set is only available for online

[3] For each scoring dimension, there is a dedicated value of u.

benchmarking. We split the official validation sets into validation/test sets with an 1:1 ratio for our experiments.

3.2 Baselines and Evaluation Metrics

We choose Vicuna v1.3 (Chiang et al., 2023) and Llama 2 chat (Touvron et al., 2023) as our base LLMs. Vicuna is an open-source chatbot, fine-tuned from Llama with supervised instruction fine-tuning using around 125K conversations collected from ShareGPT. Llama 2 was pretrained on publicly available online data sources and trained on 2 trillion tokens, and was initially created through supervised fine-tuning and then iteratively refined using Reinforcement Learning from Human Feedback (RLHF). Both Vicuna v1.3 and Llama 2 were released in mid 2023.

Given each input prompt, we generate k LLM predictions by beam search sampling (Vijayakumar et al., 2016), while setting a high temperature to encourage diversity and increase the scope for improvement. The beam search sampled predictions are considered as **No-refinement** baseline. We further considered two baselines. (1) **Self-rerank:** In the Self-rerank approach, all predictions generated by the base LLM and the task context are fed back into the base LLM itself. The model is then instructed to select the single best prediction from the candidate set. The Self-rerank baseline provides insight into the capabilities of the base LLM to refine its own output as a straightforward reranking task. (Prompt templates in Appendix D) (2) **Self-consistency:** The Self-consistency (Wang et al., 2023) approach determines the best prediction through a majority vote among all generated predictions, after marginalizing out reasoning paths. This is a cost-effective approach for refinement, but it can only be applied to tasks with fixed answers. Hence, it is included as a baseline for open domain QA tasks. Furthermore, we also report **Oracle** scores, which represent the *upper bound* of refinement/re-ranking performance: Given an input x, we obtain a candidate prediction set $\{y_i\}_i$, out of these y_i's, we choose the best one according to certain evaluation metric (E.g., Rouge, Exact Match, etc) to compute oracle performance .

On the QA tasks with a closed set of answers, we evaluate the models against **Hit Rate**: A prediction receives score 1 if it exactly matches one of multiple target answers, otherwise score 0 is assigned. On the summarization tasks assuming more open-ended model outputs, we evaluate the models against **Rouge-1/2/L** (Lin, 2004) and **BERTScore** (Zhang et al., 2020). Rouge[4] is a series of metrics counting the number of overlapping word n-grams in the reference and the generated summary, working on top of 1-/2-grams (as the index in the metric name denotes). Rouge-L is a variant of the metric based on the Longest Common Subsequence between the reference and the generated summary. BERTScore[5] is a semantic similarity metric working in the BERT (Devlin et al., 2019) embedding space by computing pairwise cosine similarities between each predicted summary's token and each reference summary's token.

3.3 Implementation Details

For the purpose of experimentation, we opt for 13B models for both Vicuna v1.3 and Llama 2. In the LLM beam search sampling phase, we set the temperature parameter t to 0.7, and for each input sample, we accumulate the top $k = 5$ LLM predictions for subsequent refinement. We activate the half-precision mode to enhance the efficiency of LLM generation. In order to preserve generation quality, quantization is not applied to the LLMs. The entirety of our experiments is performed with NVIDIA A100 GPUs, conducted in a single run. For TodSum dataset, the LLM generation time (from input to the end of beam search sampling) is 2.38/2.85 sec for Vicuna 1.3 and Llama 2 respectively.

Regarding the BERT models integrated into the CERET pipeline, we select base-sized models for efficiency, namely RoBERTa-base (125M) and DeBERTa-v3-base-mnli (184M). The coefficients α, β, γ for final weighted scoring are tuned on separate validation sets, where a grid search is conducted with step size of 0.1. In uncertainty scoring, we found the size of nearest neighborhood $s = 3, 5$ generally lead to satisfactory performance in validation sets, and it is finally set to 5 in all test settings. Note that after post-processing, the duplicate predictions are merged. A neighborhood of size 5 may represent more than 5 raw predictions.

4 Results and Analysis

4.1 Effectiveness and Efficiency

Abstractive Summarization. The experimental results for dialogue summarization are presented in

	Oracle	66.7	24.5

Table 2: Comparison of refinement methods for Question Answering tasks

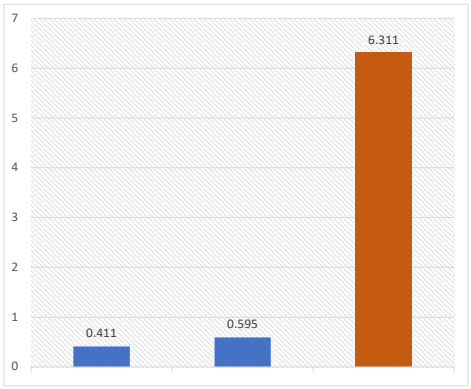

Figure 3: Latency (sec) per input sample. From left to right: *BERT inference, CERET, and LLM self-rerank.

Table 1. The initial performance of Vicuna v1.3 and Llama 2 chat in TodSum and DialogSum only result in moderate quality in generated summaries. However, the introduction of CERET brings obvious benefits into the enhancement of summarization outputs. Specifically, CERET achieves a decent improvement of 0.5-1.9 in Rouge-1 scores and 0.6-1.6 in BERTScore F1.

The method consistently outperforms Self-rerank, emphasizing the significance of leveraging semantic stability, entailment, and inter-sample uncertainty measures in refining large language model generations.

Question Answering. As shown in Table 2, the baseline performance of the LLM on TriviaQA and Natural Questions reflects a gap between the difficulty of these two tasks. Despite the fact that they are both evaluated in closed-book setting, Natural Questions dataset has lower hit rate as it contains various challenging open-ended questions (e.g., Q: "Philadelphia is known as the city of what?". A: "City of Brotherly Love") Regardless of the challenges, CERET is able to improve upon no-refinement baseline for 1.6-4.2 points in hit rate, which consistently surpasses the both Self-rerank and Self-consistency approaches, indicating its effectiveness across diverse knowledge domains.

Inference Efficiency. Efficient inference is a crucial aspect of deploying language models in real-world applications. We analyze and compare the inference efficiency of the proposed CERET method against LLM Self-rerank. We use latency (in seconds) per input sample as a metric for assessing the efficiency of different inference pipelines. We report results on the TodSum dataset. Since the validation/test sets have size ≤ 1000, we use the entire sets instead of small batches for Inter-Sample Uncertainty scoring.

As shown in Figure 3, CERET exhibits remarkable efficiency advantages compared to LLM Self-rerank. The latency required by CERET is only 9.4% of the latency observed in LLM Self-rerank[6]. The majority of the latency in the CERET pipeline is attributed to *BERT inference, where *BERT refers to RoBERTa and DeBERTa models. The efficient integration of these models within the CERET framework contributes to its overall effectiveness while maintaining a significantly reduced latency compared to Self-rerank approaches. The efficiency improvement is particularly noteworthy, especially considering the demands of real-time applications where low latency is imperative.

Overall Observations. Figure 4 provides a com-

[6]Both CERET and Self-rerank deal with predictions after LLM generation, and hence they don't include the beam search sampling time.

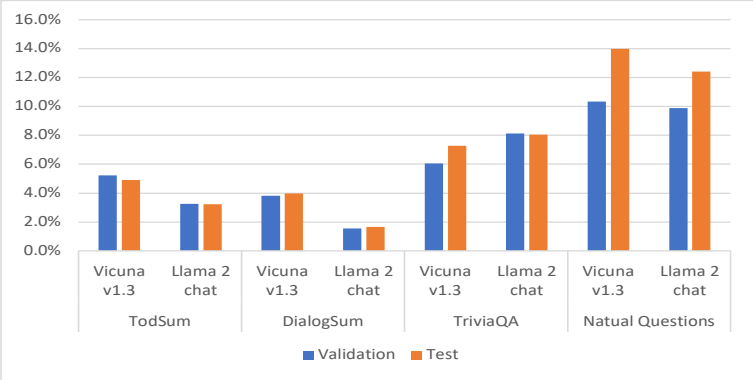

Figure 4: Relative performance gains on validation and test sets. The best coefficient combination is tuned on validation sets. Evaluation metrics: Rouge-1 for TodSum and DialogSum, and hit rate for Trivia QA and Natural Questions.

		Summarization - Rouge-1		QA - Hit rate	
Base LLM	**Refinement**	**TodSum**	**DialogSum**	**TriviaQA**	**Natual Questions**
Vicuna v1.3	No	38.78	32.67	57.82	18.61
	Semantic stability only	40.27	34.17	61.96	21.19
	Entailment only	40.67	32.30	57.66	18.51
	Uncertainty only	39.27	32.60	59.90	19.46
	CERET	40.69	34.27	61.96	21.19

Table 3: Ablation study of individual scoring dimensions

prehensive overview of the relative performance improvement achieved on both validation and test sets. The test performance gains observed are generally on par with the validation settings and, in certain instances, even surpass them, as in the case of Natural Questions. This suggests that the weight tuning strategy employed during validation exhibits robustness and generalizability when applied to test sets. The potential explanation for larger gains in certain test cases could be attributed to the random split of test sets, providing certain sets with more room for improvement.

The overall theme in the observed results is the consistently superior performance of CERET across all evaluated tasks. Furthermore, the consistency in performance gains between validation and test settings showcases the reliability and adaptability of the proposed CERET method across various settings in natural language processing tasks.

4.2 Ablations and Hyperparameter Analysis

Ablations. We systematically evaluate the impact of individual components within the CERET on both summarization and QA tasks, and present the findings in Table 3. The results indicate that all three scoring dimensions have positive contributions in certain task scenario, compared to no-refinement baseline. Notably, semantic stability alone improves summarization Rouge-1 scores from 38.78 to 40.27 and 32.67 to 34.17 for TodSum and DialogSum respectively. Similarly, for question-answering, semantic stability increases the hit rate from 57.82 to 61.96, and 18.61.67 to 21.19, which are promising improvements.

Various NLP tasks have their own unique characteristics, suggesting that effectiveness of specific refinement dimensions might vary. For example, when considering the TodSum task, the nuances of entailment play a pivotal role in summarization quality for task oriented dialogues, where entailment scoring leads to the most significant gains. We further observed uncertainty scoring exhibits the best improvement in Appendix A.

These insights underscore the synergies between semantic stability, entailment and uncertainty measures, highlighting their complementary roles in refining language model outputs. The comprehensive integration of these aspects in the CERET method showcases their collective impact, providing a flexible and contextually relevant refinement framework for various base LLMs and natural language processing tasks.

Hyperparameter Analysis. In Equation 8, coefficients α, β, γ are weights for three scoring dimensions respectively. To further investigate the sensitivity of non-trivial coefficients (when all co-

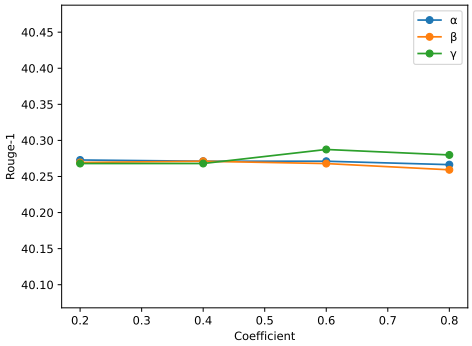

Figure 5: Sensitivity analysis of coefficients for TodSum

efficients are non-zero), a systematic approach was employed to assess the impact of individual coefficients on the overall model performance (Figure 5). A sensitivity analysis was conducted by keeping one coefficient, denoted as x, in a state of flux, while concurrently setting the other two coefficients, y and z, to be

$$y = z = \frac{1-x}{2}$$

Consider the green line in Figure 5: γ is set as the variable, the relationship $\alpha = \beta = \frac{1-\gamma}{2}$ is maintained. This variation allows for an in-depth exploration of the model's sensitivity to changes in each specific coefficient. illustrates that when all coefficients are non-zero, the model's performance remains relatively stable, with a fluctuation of Rouge-1 within 0.1, indicating the robustness to variations in individual coefficient values.

5 Related Work

Prompting strategy for LLM improvement/refinement. Improving LLM outputs by achieving behaviors close to reasoning has been explored before (Wei et al., 2022; Wang et al., 2023; Yao et al., 2023a,c; Madaan et al., 2023; Yao et al., 2023b; Gou et al., 2023; Akyurek et al., 2023). Wei et al. (2022) introduce a specific technique of formulating prompts for the model dubbed *Chain-of-Thought*. Essentially a series of intermediate reasoning steps that the model is asked to explicitly output, Chain of Thought significantly improves the ability of LLMs to perform complex reasoning.

Wang et al. (2023) propose a decoding strategy dubbed *Self-consistency* — under which the model, prompted in a chain-of-thought way, generates a set of sample predictions, or reasoning paths. The paths are then marginalized out, and the most consistent answer (the one which the most reasoning paths lead to) is selected as the final one. Huang et al. (2022) use this approach to improve LLMs without annotated data — they select the most consistent answer from the candidates pool, collect all the reasoning paths leading to that answer, and augment the trainset of the target model with the resulting data points. In contrast to Self-consistency, the *Self-Refine* approach of Madaan et al. (2023) assumes that the model iteratively provides verbal feedback on its own outputs, and incorporates it in the next generation round. Moreover, CRITIC (Gou et al., 2023) empowers Language Models (LLMs) to independently verify and improve their own outputs with external toolkits, similar to the way humans make use of tools. All the approaches above require prompt engineering, while we tackle the problem from another perspective.

Model confidence/uncertainty without self-feedback. A parallel line of work in improving LLM generation outputs is related to assessing the model confidence and the uncertainty of its predictions without iterative language model calls (Jiang et al., 2021; Lang et al., 2022; Wang et al., 2022; Kuhn et al., 2023; Ge et al., 2023; Jiang et al., 2023; Vernikos et al., 2023). Kuhn et al. (2023) define *semantic entropy*, a metric that incorporates linguistic invariance of the individual output candidates sharing identical meanings. This metric helps identify the correct model's predictions as evaluated on question answering task. LLM-Blender Jiang et al. (2023) adopts a two-stage design, rank-and-fuse, to generate highly confident and superior candidate outputs. Ge et al. (2023) use uncertainty estimation in order to create modified pseudolabels, and define uncertainty of a pseudolabel (obtained using stochastic dropout-based model inference) as its proximity to other different pseudolabels for the same data point. Training on the selected pseudolabels increases performance in binary and multiclass classification, as well as Natural Language Understanding tasks. Selecting high-confidence pseudolabels is also a key aspect of the co-training technique proposed by Lang et al. (2022), where both partial access and full access settings are studied. All these methods explore uncertainty/confidence from a certain perspective, while our approach combines the uncertainty/confidence with semantic stability and entailment, and we further proposed a framework

for these three dimensions and investigated their synergies.

6 Conclusions

Our proposed CERET is an efficient framework to enhance text generation without the need for domain-specific training data or expensive annotations. By considering semantic stability, entailment, and inter-sample uncertainty measures, our approach significantly improves the quality of text generation across multiple natural language processing tasks. The efficiency and cost-effectiveness of our approach suggest its potential for wide adoption in real-world applications.

7 Limitations

CERET can be potentially applied to a wide range of NLP problems, including dialogue response generation, open-ended common sense reasoning, and Natural Language Understanding (NLU) by text filling for text continuation. These topics require dedicated investigation and are not yet covered by this paper.

Our experiments show that beam search sampling almost always provides sufficient room for refinement, according to the oracle performance in Table 1 and Table 2. Nevertheless, in certain task or data scenarios, performances of no-refinement baseline and oracle prediction may be close to each other. In that case, the performance of CERET will be limited by oracle results.

Appendix

A Ethical Considerations

We have reviewed all licenses of public datasets, which allow the usage for research and paper publication. All datasets are sets are de-identified to ensure anonymity.

Our proposed method has a potential for substantial reductions in both the financial and environmental burdens associated with large language model improvement/refinement. Through minimizing the reliance on extensive data collection and human labeling, our approach serves as an effective safeguard for user and data privacy, mitigating the risk of information leakage during the construction of training corpora.

During the paper writing process, Generative AI was only used for language checking, paraphrasing and polishing.

B Additional Sensitivity Analysis

As described in 4.2 Hyperparameter Analysis, the sensitivity analysis is conducted by keeping one coefficient, x in a state of flux, while concurrently setting the other two coefficients, y and z, to be $y = z = \frac{1-x}{2}$. Empirical results on four datasets show that the performance variations are very limited, with fluctuations of Rouge-1 within 0.2, and hit rate within 0.4. This indicates the stability of the method to variations in individual coefficient values.

C Qualitative Analysis

Selected qualitative examples from both TodSum and TriviaQA datasets are presented in Table 4 and Table 5 respectively. Although the top 5 beam search sampled candidates are considered in experiments, in Table 4 and Table 5 we only present 3 most representative predictions.

In the example from TodSum, CERET is able to select the summary that contains key information "All Saints Church" and also mentions the phone number was provided. In fact, the prediction has the highest entailment score, which means it mostly implies other summaries. Regarding the examples from TriviaQA, the final score is largely determined by semantic stability: "Dotheboys Hall" and "Dotheboys" are close in semantic representation, and "Sir Cloudesley Shovell" (after parsing) actually appears 3 times in top 5 predictions.

D Prompt Templates

The relevant prompt templates for Abstractive Summarization, QA and Self-rerank are presented in Table 6, Table 7 and Table 8 respectively. We adopt Chain-of-Thought (CoT) prompting for open domain QA; while for Abstractive Summarization datasets, the key information is usually straightforward, hence we only include a length specification. Regarding LLM Self-rerank, we tested multiple additional instructions related to semantic stability, entailment/implication and uncertainty, and finally chose to include semantic stability only, as it produces most robust outcomes.

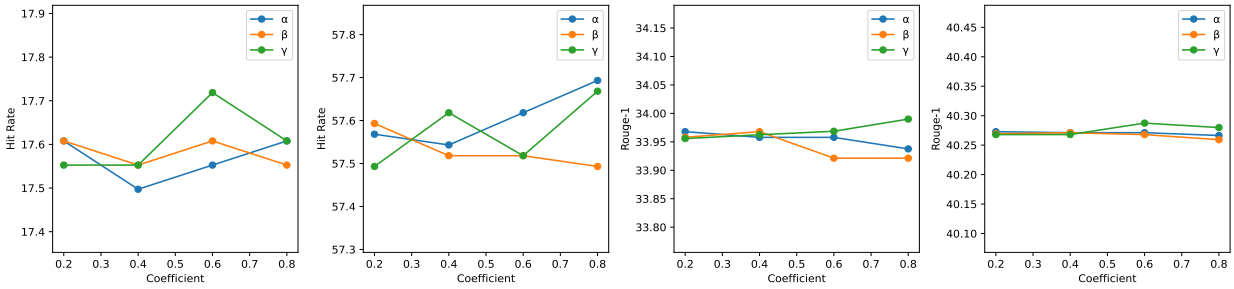

Figure 6: Sensitivity analysis of coefficients for Natural Questions, TriviaQA, DialogSum and TodSum (from left to right in order)

Input dialogue	
Hi there. Can you help me find a train from Norwich to Cambridge? There are several trains on that route. What time would you like to leave/depart? I would like to leave after 12:15 on a Sunday. I have a 12:16 departure from Norwich. Would you like me to book this for you? I'm not sure if I need to book just yet. Can you tell me the travel time for this please? Sure, TR5225 is a 79 minute trip and each seat costs 14.08 pounds. Can I help you with anything else today? Is there an All Saint's Church? I would like to visit it as well. Yes, all saints church is located t city cenre. It has free entrance. That sounds wonderful. Could I get the phone number along with the attraction type? It is listed as architecture, and their phone number is 012345678 Thank you so much! That is all the help I need for now. You are very welcome! Have a great day and I hope you enjoy your visit! Call for help anytime.	
LLM prediction	**score**
A person is seeking help to book a train ticket from Norwich to Cambridge on a Sunday at 12:16, and the agent provides information on the travel time, ticket cost, and the location of All Saints Church in the city center, with free entrance and a listed phone number for architecture enthusiasts.	0.83
A person is seeking information about trains from Norwich to Cambridge and asks about travel time, seat prices, and the location of All Saints Church, and the customer service representative provides the necessary information and offers to book the ticket.	0.61
The text is a conversation between a person looking for train information from Norwich to Cambridge and a train information provider, who provides information on train schedules, fares, and nearby attractions.	0.12
Ground truth	
The user asks duration of the train. This train leaves at 12:15 on sunday, departure is norwich and destination is cambridge. The user wants to know the phone number and type of the attraction. the attraction's name is All Saints Church.	

Table 4: Qualitative example: TodSum

Input question	
In the novel, "Nicholas Nickelby", by Charles Dickens, what was the name of the school, run by Wackford Squeers?

Abstract

We study the problem of automatically annotating relevant numerals (GAAP metrics) occurring in the financial documents with their corresponding XBRL tags. Different from prior works, we investigate the feasibility of solving this extreme classification problem using a generative paradigm through instruction tuning of Large Language Models (LLMs). To this end, we leverage metric metadata information to frame our target outputs while proposing a parameter efficient solution for the task using LoRA. We perform experiments on two recently released financial numeric labeling datasets. Our proposed model, **FLAN-FinXC**, achieves new state-of-the-art performances on both the datasets, outperforming several strong baselines. We explain the better scores of our proposed model by demonstrating its capability for zero-shot as well as the least frequently occurring tags. Also, even when we fail to predict the XBRL tags correctly, our generated output has substantial overlap with the ground-truth in majority of the cases.

1 Introduction

The U.S. Securities and Exchange Commission (SEC) mandates publicly traded companies to disclose periodic filings such as quarterly 10-Q & annual 10-K reports. These documents are important to finance professionals and investors who rely on SEC filings to make informed investment decisions. Each company is directed to follow the *Generally Accepted Accounting Principles* (GAAP) to report the metrics appearing in these documents and tag them using the *eXtensive Business Reporting Language* (XBRL) according to a well-defined taxonomy consisting of thousands of labels. In a recently released **FNXL** dataset (Sharma et al., 2023), such numerals are tagged from a large set of **2,794 labels**. Implementing XBRL tagging therefore requires advanced accounting skills to map financial data to the correct XBRL concepts. This requires hiring experts to meticulously review each document and assign appropriate labels which is neither a cost-effective nor a scalable solution. Fig. 1 shows various challenges involved with the task.

Prior works and their limitations: *FiNER* (Loukas et al., 2022) formulated the task of identifying relevant numerals from financial texts and labelling them with XBRL tags as an NER problem, and used a BERT-based sequence labelling approach. However, the label-set in FiNER consists of only 139 most frequently occurring XBRL tags. For practical purposes, a much larger number of XBRL tags/labels are needed to effectively annotate the diverse types of numerals present in these documents. More recently, the authors of FNXL dataset (Sharma et al., 2023), demonstrated the poor performance of FiNER when extended to thousands of labels. They also explored an extreme classification methodology, called AttentionXML. *None of these methods, however, exploit the rich metadata information available with XBRL tags*, to improve the classification performance. Table 1 provides example of XBRL tag documentations that can help with the labelling task. Among recent methods that utilize label metadata for better results, *GalaXC* (Saini et al., 2021), is a GNN-based extreme classification approach that embeds label metadata information in its document-label graph nodes. *Label Semantics* (Ma et al., 2022) is another generic approach that leverages entity descriptions to solve the standard NER task. However, none of these methods have been applied in the financial domain. We, therefore, adapt these models to use as additional baselines for our task.

Additionally, all the methods stated above *lack the capacity to identify unseen labels during inference* as they follow a discriminative paradigm. Generative models, on the other hand, display intrinsic zero-shot capabilities if trained effectively.

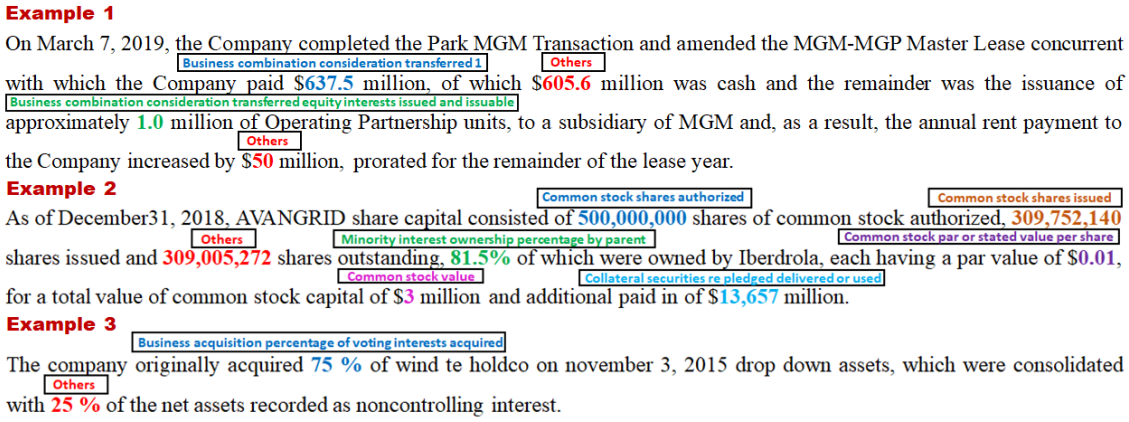

Figure 1: Demonstrating the challenges in the Extreme Financial Numeral Labelling (XFNL) task. Within a financial statement, there are scenarios where every numeral is associated with a distinct XBRL tag, such as in Example 2 (6 distinct tags). Then, there are cases where a mixture of both relevant and irrelevant numerals (tagged 'Others') coexist in the same statement, often within a very limited context, such as in Examples 1 & 3.

Tag	Documentation
common stocks shares issued	Total number of common shares of an entity that have been sold or granted to shareholders (includes common shares that were issued, repurchased and remain in the treasury). These shares represent capital invested by the firm's shareholders and owners, and may be all or only a portion of the number of shares authorized.
common stocks shares authorized	The maximum number of common shares permitted to be issued by an entity's charter and bylaws.

Table 1: Examples of (XBRL tag, documentation) pairs. We observe that the two tags differ by a single word only whereas their corresponding documentations vary significantly. We take advantage of this distinction while training our FLAN-FinXC variants. More such examples given in the Appendix A.1

In this space, LLMs have achieved impressive performances for a wide range of NLP tasks across several domains (Zhao et al., 2023), including finance (Wu et al., 2023; Yang et al., 2023).

FLAN-FinXC Framework: In this work, we show for the first time that generative models (LLMs) can achieve impressive results for the XFNL task. We systematically explore and propose FLAN-FinXC, a framework of Parameter-Efficient Instruction Tuning for Extreme Classification.

Our FLAN-FinXC framework consists of FLAN-T5 (Chung et al., 2022) models instruction-tuned with carefully-curated task-specific instructions, as shown in Fig. 2, to generate the appropriate XBRL tag documentations. We then make use of an unsupervised *Tag Matcher* module to predict the final XBRL tag for this generated documentation. We perform extensive experiments to devise a total of five different model variants as part of our proposed FLAN-FinXC framework, ranging from T5-Base to FLAN-T5-Large, and with varying training strategies. We observe that FLAN-T5-Large (instruction-tuned) achieves **9.4%** Macro-F1 gains and **3.5%** Hits@1 gains, over T5-Large (fine-tuned) for FNXL dataset, both models being architecturally same with 780M parameters. The same trend is also observed in FiNER data. This highlights the advantages of *Instruction Tuning* similar-sized LLMs over old-fashioned fine-tuning. Given that training larger models is costly, next we experiment with parameter-efficient (PEFT) techniques, specifically Prefix Tuning (Li and Liang, 2021) and LoRA (Hu et al., 2021), to instruction-tune our FLAN-T5-Large models.

Among these, we observe that FLAN-T5-Large with LoRA outperforms the Prefix-Tuned version with **2.4%** Macro-F1 gains and **5%** gains in Hits@1, giving the best performance for both the datasets.[1]

Taking advantage of the generative paradigm, parameter-efficient instruction tuning of LLMs, as well as our financial domain-specific novelty (through the use of XBRL tag documentations to improve extreme classification performance), our best model, **FLAN-T5-Large with LoRA**, outperforms the state-of-the-art *AttentionXML* model

[1]Experimenting with 100 NLP tasks, (Ding et al., 2023) had also made similar observations that LoRA can sometime even outperform full fine-tuning on certain tasks.

with **39.3%** Macro-F1 gains and **17.2%** Hits@1 gains, thereby achieving new state-of-the-art results for the XFNL task. We then present several interesting analyses to investigate the reasons for its considerably better performances. We find that our model achieves impressive zero-shot Macro-F1 scores of **58.89%** for the 67 XBRL tags that were unseen during training. Even for tags that appear fewer than 5 times in the training data, our model is able to achieve 41% Macro-F1 gains and 23% Hits@1 gains compared to *AttentionXML*. Qualitatively, among the instances where we fail to predict the correct XBRL tags, in around 60% of the cases, our generated tag documentations are very close to the ground truth documentations with Jaccard Similarity scores ranging between 0.6 and 0.85. The proposed model also achieves superior performance (15.22% Macro-F1 gain and 3.3% Hits@1 gains) in case of FiNER data containing only most frequent 139 labels.

Our contributions can be summarized as follows:

- We propose FLAN-FinXC, a generative framework, consisting of a suite of instruction-tuned FLAN-T5 models, varying in model sizes and training strategies, to tackle the XFNL task, which is a practically important problem in the finance domain. Different from the prior methods for the task, our models utilize the XBRL tag documentations, instead of considering the tags as just class labels.

- In addition to comparing with the state-of-the-art methods, we adopt several prior works (Label Semantics and GalaXC) for the task, along with devising our own competitive generative baselines (T5-Base and T5-Large).

- For both FiNER as well as FNXL datasets, our best model, **FLAN-T5-Large with LoRA**, achieves huge improvements over all the baselines. Additional advantages of our best model include substantial performance over rare labels, and its zero-shot capability to tag numerals with labels unseen during training. Our dataset and codes are publicly available at `https://github.com/subhendukhatuya/FLAN-FinXC`.

2 Related Works

One of the (re)emerging applications of NLP is in the field of Named Entity Recognition (NER), particularly for identifying and categorizing various entities within text. The categorization of different entities into labels can also be considered as an extreme classification task (Dahiya et al., 2021). In recent years, XBRL tagging has gained a special importance in financial domain, which involves tagging of numeric values. Datasets created for such a task are the FNXL dataset (Sharma et al., 2023) and FiNER (Loukas et al., 2022) which have a very large number of entity types compared to standard NER tasks and thus present challenges to the state-of-the-art NER models. (Sharma et al., 2023) reformulated this task as an extreme classification (You et al., 2019) problem with a pipeline approach. Financial domain-specific pre-trained language models (Shah et al., 2022) have been developed, which can be repurposed on financial tasks. Among LLMs pre-trained on financial text (FinLLMs), BloombergGPT (Wu et al., 2023) is a proprietary model that suffers from limited accessibility and lack of transparency in their data collections and training protocols. FinGPT (Yang et al., 2023) is an open-source FinLLM but only suitable for financial sentiment analysis, trading, forecasting and fraud detection tasks.

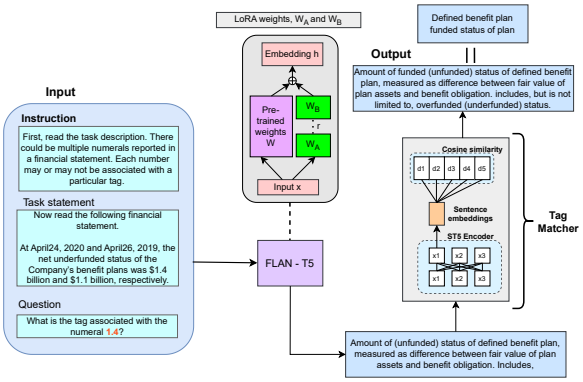

Figure 2: FLAN-FinXC Architecture. FLAN-T5 takes as input a task-specific instruction, the financial statement, and a question with a designated target numeral. FLAN-T5-generated tag documentation subsequently flows into the Tag Matcher that predicts the final tag for the given numeral.

3 Problem Formulation

We break the task of XFNL into two stages (with only the first stage requiring supervised training of models), as illustrated in Fig. 2, in order to take advantage of more elaborate XBRL tag documentations. We present a set of diverse annotated examples in Fig. 1. Some tag with documentation examples are shown in Table 1.

In the first stage, we formulate the problem as

a generative task using LLMs, where given a financial statement, and a question targeted towards a specific numeral occurring in the statement, the task is to accurately generate its appropriate XBRL *tag documentation* (not the tag) if the numeral is relevant and 'Other' if the numeral is irrelevant. Let $S_i = (w_i^1, ..., w_i^a, ...w_i^b, ..., w_i^n)$ be the i^{th} statement consisting of n tokens, where w_i^a and w_i^b be two different numerals with tag_i^a and tag_i^b being their respective XBRL tag documentations. We prepend an instruction prompt IP, containing a natural language description of the task, to the statement S_i, as shown in Fig. 2. A question Q_i^a is then appended to S_i asking for the tag to be determined for a specific numeral, say w_i^a. The modified input S_i^a therefore takes the shape $IP||S_i||Q_i^a$, where $||$ is a text concatenation operation. The target answer $genTag_i^a = LLM(S_i^a)$ for the LLM (FLAN-T5 in our case) therefore becomes: tag_i^a.

In the second stage, we obtain the final XBRL tag through a separate *Tag Matcher* module, since the entire documentation may not be generated exactly. Specifically, we obtain the embedding for $genTag_i^a$ using a pre-trained state-of-the-art sentence encoder. We obtain the same for the documentations corresponding to all the available tags. The one having the highest cosine similarity with the $genTag_i^a$ embedding is declared to be the predicted XBRL tag documentation, $predTag_i^a$.

4 Methodology

Our proposed framework **FLAN-FinXC** for the XFNL task is divided into two phases, as depicted in Fig. 2: a supervised generative phase, and an unsupervised documentation-to-tag matching phase. In the first phase, given a financial statement S_i, and a question Q_i^a asking for the XBRL tag (documentation) to be determined for a numeral w_i^a appearing in the sentence S_i, we instruction tune FLAN-T5 (Chung et al., 2022; Longpre et al., 2023) with carefully-curated task-specific instructions (see Fig. 2) to generate the tag documentation $genTag_i^a$. The model is trained to condition on the modified input S_i^a, as described in the previous section, to generate the target answer one token at a time using auto-regressive decoding. Cross-entropy loss between the generated and true tokens is minimized in the process. In our case, the entire output generated by the LLM corresponds to the tag description, hence no additional parsing is required.

Our choice for FLAN-T5 is based on the observation that FLAN-T5 models are pre-trained (using instruction tuning) on more than 1.8K tasks, and hence can significantly reduce the amount of fine-tuning steps required if adopted as starting checkpoints for learning new tasks. Additionally, they achieve strong zero-shot and few-shot performances in comparison to T5 (Raffel et al., 2020), their non-instruction-tuned counterpart.

Note that we train FLAN-T5 models to generate the *XBRL tag documentations* instead of the tag themselves (which is the final target) since the more elaborate documentations allow for a better distinction than their corresponding tags (see Table 1), thereby aiding in the extremely challenging XFNL task (as demonstrated in Fig. 1). Generating the lengthy tag documentations exactly is however difficult, and hence the generated documentation $genTag_i^a$ may not exactly match the ground truth. In the second phase of our proposed framework, we therefore leverage a pre-trained state-of-the-art sentence encoder, as the backbone of our *Tag Matcher* module, as depicted in Fig. 2. More specifically, we use Sentence-T5-XXL (Ni et al., 2021), pre-trained using contrastive loss, to generate 786-dim embeddings for $genTag_i^a$ as well as for each of the ground truth tag documentations. The ground truth tag documentation with the highest cosine similarity (between embeddings) with $genTag_i^a$ is considered to be the predicted tag documentation $predTag_i^a$. Since there exists a 1:1 mapping between XBRL tags and their corresponding documentations, the final predicted tag can be easily obtained from $predTag_i^a$.

In order to investigate the suitability of a generative paradigm for solving the task, we perform a systematic evaluation of several model variants, varying both model sizes and training strategies.

Non-FLAN Model Variants: First, we compare the fine-tuned performances of T5-Base (220M parameters) with T5-Large (780M parameters). Note that for fine-tuning, given a financial statement S_i, the modified input now becomes $S_i^a = S_i||Q_i^a$, where Q_i^a refers to the question targeted towards the numeral w_i^a appearing in S_i. The target (tag documentation) however remains the same.

FLAN-FinXC Model Variants: Next, we compare the instruction-tuned performance of FLAN-T5-Large with fine-tuned T5-Large, both models with identical architectures. Next, we instruction tune FLAN-T5-Large with PEFT techniques, namely Prefix Tuning and LoRA, respectively re-

quiring only 0.13% and 0.08% of model parameters to be updated. Finally, we instruction-tune FLAN-T5-Large with LoRA to achieve our best results.

5 Baselines

We compare the performance of our proposed models with the following baselines:

Baselines already applied for XBRL tagging: **(1) FiNER:** (Loukas et al., 2022) solved the task as a NER task, but only for top 139 frequent XBRL tags. We adapt this method for our use case (large number of labels). **(2) AttentionXML Pipeline:** (Sharma et al., 2023) tackled this problem using a BERT-based sequence-to-sequence tagger.

New baselines that we adopt for XBRL tagging: Additionally, we adopt two diverse methods for the task for XBRL tagging, which can utilize the label semantics of XBRL tags. **(3) GalaXC:** (Saini et al., 2021) applies collaborative learning over document-label graphs that allows additional information like label metadata to be incorporated. **(4) Label Semantics** (Ma et al., 2022) leverages the entity description to solve a standard NER task. Lastly, with the emergence of ChatGPT(OpenAI, 2022), we were curious to check ChatGPT's performance for this task for 500 random samples using *gpt-3.5-turbo* [2] API.

6 Dataset & Evaluation Metrics

Dataset: We perform our experiments on the recently released FNXL dataset (Sharma et al., 2023) containing 10-K documents[3] for 2,339 companies and FiNER (Loukas et al., 2022) dataset having most frequent (at least 1000 appearances) 139 labels. FNXL dataset contains a total of 79,088 sentences containing 142,922 annotated numerals, with a tag set of *2,794 distinct tags* that follows a heavy tail distribution. Further, the test set contains *67 XBRL tags that are not part of the train or validation sets*. Fig. 1 shows a few annotated examples from this dataset. Each tag is associated with a pre-defined textual description known as its 'tag documentation' (see Table 1). The tag documentations have an average length of 28 words and a maximum length of 273 words.

Metrics: To ensure a comprehensive evaluation of all models, we employ the following metrics: 1) Macro-Precision, 2) Macro-Recall, 3) Macro-F1, 4) Hits@1. In financial numeral labelling, where equal importance is given to all tags, macro based metrics (precision, recall, F1) are a good choice as it treats all classes equally, irrespective of their frequency. We report *Hits@1* metric to showcase the usability of this system from business perspective, recommending the *top tag* to domain experts.

7 Experimental Setup

For all our model variants (experiments performed on Tesla V100 32GB GPUs), we obtain the pre-trained checkpoints from the *Huggingface* Library[4]. For instruction tuning FLAN-T5-Large with Prefix Tuning, the *prefix length* was set to 20. For training the models with LoRA, the *rank* for the trainable decomposition matrices was set to 2. FLAN-T5-Large models were instruction-tuned for 10 epochs with a learning rate (lr) of $1e-4$ (training time: 1hr 22 minutes/epoch, inference time: 2 minutes/sample); with an lr of $1e-2$ with Prefix Tuning (training time: 29 minutes/epoch, inference time: 2 minutes/sample); and with an lr of $5e-4$ with LoRA (training time: 56 minutes/epoch, inference time: 2 minutes/sample). These hyperparameters were selected based on the best Macro-F1 results on the validation set.

Note that the tag information is *not* included in the input prompt. Rather, it is generated during the decoding phase based on the question asked. The input prompt containing the question gets encoded and it is much smaller than the maximum input context length. Hence, there is no truncation during encoding. The average tag information length is 28 tokens and we set the length of output to be generated to 30 tokens. Hence, in a few cases, truncation may occur during the decoding phase. However, the crucial tag information is typically present in the initial tokens, and our tag matcher ensures correct labels by comparing generated tags with the descriptions for all available tags in the dataset. Thus any potential truncation in a few cases does not pose any risk to our model's performance.

Instruction Selection: While experimenting, we gradually improved our instructions. First, we tried out a prompt without any task-specific instruction, thereby consisting of the input financial statement and the question for a given numeral. Then, we included a simple task description and repeated our experiments. Finally, we made the task description/instruction more elaborate which led us to ob-

[2] https://platform.openai.com/docs/models/gpt-3-5

[3] https://tinyurl.com/t43mwd5m

[4] https://huggingface.co/

tain the best results. On the target side, we tried out two variants, generating labels vs. generating the label descriptions. The latter resulted in significant performance improvement (refer Table 4). This iterative process of instruction selection was guided by the performance on the validation set.

8 Main Results

We report the results of our proposed model variants and various baselines in Table 2 for both FNXL and FiNER dataset. Among the baselines, FiNER does not perform well for large number of entity labels. On the other hand, while the 'Label Semantics' method leverages tag words within an NER framework, its scalability is constrained when dealing with a large number of entity labels, ultimately leading to poor performance. The AttentionXML pipeline performs better than all other baselines. GalaXC and 'Label Semantics' have very similar performance, with GalaXC giving slight edge. ChatGPT's performance for this complex task is not satisfactory.

We also demonstrate the advantage of training bigger models for extreme financial numeral labelling for FNXL dataset, by comparing the results of T5-Large (780M parameters, Macro-F1 60.11) with T5-Base (220M parameters, Macro-F1 54.21). Note that these baselines that we devise for the task, already outperform the existing state-of-the-art.

Next, we turn to different variations of our FLAN-FinXC framework (listed in the lower part of Table 2). First, we demonstrate the advantage of instruction tuning over fine-tuning by the fact that FLAN-T5-Large (Macro-F1 65.77) substantially outperforms T5-Large (Macro-F1 60.11) for FNXL dataset. Given that training larger models is costly, next we experiment with parameter-efficient (PEFT) techniques, specifically Prefix Tuning (Li and Liang, 2021) and LoRA (Hu et al., 2021), to instruction tune our FLAN-T5-Large models. Both techniques require only a small fraction of model parameters to be fine-tuned (0.13% with Prefix Tuning, and 0.08% with LoRA), thereby greatly reducing the computation cost and training times. Instruction tuning FLAN-T5-large with LoRA (Macro-F1 66.23) outperforms Prefix-Tuned version of the same model (Macro-F1 64.65) and has a slight edge over the model variant instruction-tuned without PEFT (Macro-F1 65.77). Our best results are obtained by instruction tuning FLAN-T5-Large with LoRA (only 0.08% of 780M parameters to be finetuned). This model outperforms the state-of-the-art *AttentionXML* model with **39.3%** Macro-F1 gains and **17.2%** Hits@1 gains, thereby achieving new state-of-the-art results for FNXL dataset. For FiNER dataset, we achieve 15.22% Macro-F1 gain and 3.3% Hits@1 gains.

9 Analysis

We now present different analyses of our best model (FLAN-T5-Large with LoRA), and the closest baseline (AttentionXML Pipeline). The following analysis is specific to the FNXL dataset, chosen for its more extensive range of labels compared to other datasets, emphasizing its practical relevance.

9.1 Performance on least frequent labels

Accurate tagging of infrequent labels in XBRL is crucial for reliable financial reporting, yet it presents challenges stemming from imbalanced data, scarce training instances, and sparse data distribution. We observe our FLAN-FinXC performs substantially better than AttentionXML for the rare labels. To demonstrate this, we group the tags into various buckets based on their frequency of occurrence in the training set.

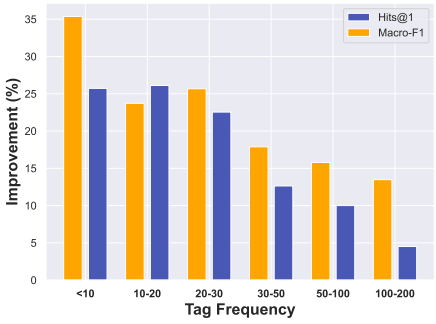

Figure 3: Relative improvement in performance achieved by FLAN-T5-Large with LoRA over AttentionXML Pipeline, for the least frequent labels under various frequency buckets

Fig. 3 shows the percentage improvement in Hits@1 and Macro-F1 that is achieved by FLAN-FinXC over AttentionXML Pipeline for the tags in every bucket. We see that our model can effectively identify and tag rare financial concepts. Notably, even for tags that appear fewer than 10 times in the training data, our model is able to achieve 35.3% improvement in Macro-F1 score and 25% in Hits@1 over the closest baseline.

Model	Dataset							
	FNXL (Sharma et al., 2023)				FiNER (Loukas et al., 2022)			
	M-P	M-R	M-F1	Hits@1	M-P	M-R	M-F1	Hits@1
FiNER (bert-base)	49.17	49.71	47.13	75.34	72.60	81.10	76.61	81.50
FiNER (sec-base)	47.76	48.87	46.20	74.67	81.11	83.20	82.14	82.30
Label Semantics	46.35	45.12	45.72	71.25	71.50	80.15	75.57	80.25
GalaXC	46.91	44.81	45.81	72.97	72.20	80.95	76.32	81.10
AttentionXML Pipeline	50.69	48.51	47.54	76.76	82.15	82.30	82.22	83.25
ChatGPT (500 samples)	11.13	7.68	9.08	19.6	20.12	15.67	17.61	22.35
T5-Base	59.94	49.48	54.21	79.21	86.92	84.35	85.61	83.45
T5-Large	61.87	58.46	60.11	83.26	88.12	85.10	86.58	84.12
FLAN-T5-Large	**66.21**	65.34	65.77	86.21	**92.10**	96.35	94.17	85.89
FLAN-T5-Large with Prefix-Tuning	65.10	64.21	64.65	85.69	90.18	94.35	92.21	85.12
FLAN-T5-Large with LORA	65.14	**67.36**	**66.23**	**89.98**	91.84	**97.85**	**94.74**	**86.03**

Table 2: Performance evaluation based on Macro & Hits@1 metrics for FNXL dataset and FINER dataset. The best performance is highlighted in bold, and the strongest baseline result is underlined.

9.2 Zero-Shot Capability

One of the key strengths of our proposed model is its zero-shot capability, i.e., its ability to generate tags/labels for which it has *not* been explicitly trained. While SOTA discriminative models in this domain often require specific fine-tuning or retraining to handle new tags, our generative model transcends these limitations.

Tag	F1-score
foreign currency transaction gain before tax	0.85
commercial paper at carrying value	0.85
accounts payable other current	0.80
recognition of deferred revenue	0.76
available for sale debt securities gross unrealized gain	0.66

Table 3: Zero-Shot Performance of FLAN-T5-Large with LoRA, for a few XBRL tags absent in the training set of FNXL dataset.

Recall that the test set included 67 new labels that were not present in the train set. We observe that our best model achieves a Macro-F1 of **58.89** over these 67 unseen labels, which is a commendable performance. Table 3 shows the performance (F1-score) of our best model for few such tags.

9.3 Ablation Study

We now try out various ablations over our best model to understand the significance of different modules. First, as ablations of our *Tag Matcher* module, we replace Sentence-T5-XXL (used in our best model) with Sentence-BERT (Reimers and Gurevych, 2019) to generate the embeddings for the XBRL tag documentations. We experiment with two versions of Sentence-BERT, one with 6 encoder layers and other with 12 encoder layers, and report our findings in Table 4. We observe a drop in performance (compared to our best model FLAN-FinXC with LoRA) in both cases, thereby showing the better efficacy of Sentence-T5-XXL over Sentence-BERT as sentence encoder.

Model	Macro-F1	Hits@1
FLAN-T5-Large with LoRA	66.23	89.98
w/ S-BERT-L12 as Tag Matcher	63.11	88.13
w/ S-BERT-L6 as Tag Matcher	62.87	87.72
w/o instruction prompt	56.46	76.55
w/o tag metadata	53.12	73.14

Table 4: Results for our ablation studies of FNXL dataset

Next, we instruction-tune FLAN-T5-Large (with LoRA) *without the instruction prompt* containing specific instructions for the XFNL task. Given a financial statement S_i, the modified input now becomes $S_i^a = S_i||Q_i^a$, where Q_i^a refers to the question targeted towards the numeral w_i^a appearing in S_i, and $||$ is a text concatenation operation. From the fourth row in Table 4, we observe a huge drop in performance (e.g., Macro-F1 drops from 66.23 to 56.46), thereby demonstrating the importance of aligning FLAN-T5 fine-tuning with task-specific instructions to tackle the challenging XFNL task.

Next, we experiment with setting the XBRL tags, instead of their documentations, as the target for

FLAN-T5-Large. In other words, we no longer use the tag metadata. Accordingly, the *Tag Matcher* module now compares the embeddings of the generated and ground truth tags (and not documentations). From the last row in Table 4, we again observe a drop in scores with 19.8% ↓ in Macro-F1 and 18.7% ↓ in Hits@1 compared to our best results. This confirms our hypothesis that the more elaborate tag documentations allow for a clearer distinction than the corresponding tags (possibly differing only in few words) while tackling the challenging extreme classification task.

Sentence	Ground truth tag	AttentionXML Pipeline prediction	FLAN-T5-Large with LoRA
As of December 31, 2019 and 2018, we had a cumulative translation loss, net of tax of $ 617 million and $ **466** million, respectively.	accumulated other comprehensive income loss foreign currency translation adjustment net of tax	accumulated other comprehensive income loss defined benefit pension and other postretirement plans net of tax ✗	accumulated other comprehensive income loss foreign currency translation adjustment net of tax ✓
We also have $**4.54** billion of non - cancelable contractual commitments as of December 31, 2019 related to network infrastructure	contractual obligation	unrecorded unconditional purchase obligation balance sheet amount ✗	contractual obligation ✓
At April 24, 2020, plan participants had approximately $ **14** million withheld to purchase the company's ordinary shares	others	share based compensation arrangement by share based payment award number of shares available for grant ✗	others ✓

Table 5: Challenging examples where AttentionXML predicts a wrong tag, while FLAN-T5-Large with LoRA predicts correctly.

Qualitative Analysis of predicted labels: Table 5 shows the predictions made by our best model and the closest baseline (AttentionXML) for a few challenging instances. Our proposed method classifies relevant numerals (first two examples) correctly and is able to find irrelevant numerals (the last example) and correctly tag that as *'Others'*, whereas the baseline struggles for each cases.

Error Analysis: To characterize the errors committed by our model, we ask – *when a model generates a wrong tag, how similar is the generated tag with the ground truth tag?* We quantify the similarity between a generated tag and the ground truth (GT) tag by the Jaccard similarity between the tag documentation words. Fig. 4 compares the errors by our best model and errors by the closest baseline. For a majority (60%) of errors by our best model, the wrongly predicted tag is very similar to the ground truth tag (Jaccard similarity between tags ≥ 0.6). Whereas, most of the tags wrongly predicted by AttentionXML are very different from the ground truth tags (Jaccard similarity between tags ≤ 0.4).

Sentence: Our Board of Directors declared quarterly dividends per share of $**1.45**, $1.32 and $1.15, which were paid in each of the four quarters of 2019, 2018, and 2017.
GT Tag Doc: aggregate dividends paid during the period for each share of common stock outstanding.
GT Tag: common stock dividends per share cash paid
FLAN-T5-Large with LoRA (Generated, No Tag Matcher): Aggregate dividends declared during the period for each share of common stock outstanding.
Predicted Tag: common stock dividends per share declared

Sentence: In fiscal year 2016, Bard paid the Company $**121** million towards the settlement of 11,000 of these claims.
GT Tag Doc: amount awarded from other party in judgment or settlement of litigation.
GT Tag: litigation settlement amount awarded from other party
FLAN-T5-Large with LoRA (Generated, No Tag Matcher): Amount awarded to other party in judgment or settlement of litigation
Predicted Tag: litigation settlement amount awarded to other party

Table 6: Examples to show that subtle differences between ground truth tag (GT) and the predicted tag. The few-word differences between Ground Truth (green) and predicted text (red) are highlighted. More such examples are in the Appendix A.3

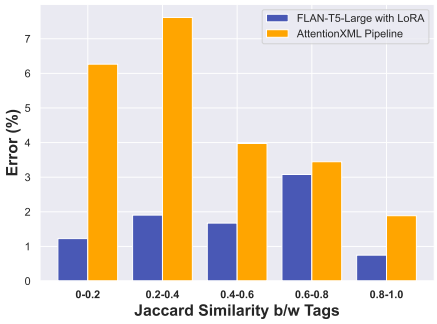

Figure 4: Comparing errors by best proposed model and those by the closest baseline. Even when our model generates incorrect tags, most of them are semantically very similar to the ground truth tags. But AttentionXML often generates completely unrelated tags.

Finally, Table 6 demonstrates instances where the predicted tag documentation closely resembled the ground truth (GT) tag documentation, but even minor variations led to a wrong final tag prediction. As illustrated in Table 6, subtle differences between *'from other party'* (in the GT tag, highlighted in green) and *'to other party'* (in the prediction, highlighted in red), or between *'dividends paid'* (in the

GT tag, highlighted in green) and *'dividends declared'* (in the prediction, highlighted in red) can lead to a wrong final tag prediction. To address these complexities, in future we plan to incorporate external financial knowledge.

9.4 Comparison with ChatGPT

We used ChatGPT (GPT-3.5 turbo) under a few-shot setting. For a fair comparison, we used the same prompt (shown in Fig. 2) that is used to instruction tune our proposed models. The ChatGPT prompt structure was: *<Instruction, Task statement, Question for a specific numeral>*. In order to guide ChatGPT what to generate, we augment the prompt with 5 exemplars of (input, desired output) pairs, thereby making it a 5-shot setting. Based on experimental observations, we set "desired outputs" to be the labels instead of label descriptions. Hence, in our final setting, no label descriptions were fed. On the same 500 test set samples used to report ChatGPT's performance (macro-f1 of 9.08) in Table 2, we obtain macro-f1 score of **58.25** of our best model when trained to generate labels (note that Table 4 last row reports scores on the full test set). We believe that ChatGPT's lower performance is owing to two main factors: 1) It is not fine-tuned; rather, we use it in a 5-shot (few-shot) setting. 2) ChatGPT was not specifically pretrained on financial data and the challenging nature of the FNXL dataset further makes it difficult. Further analysis can be found in Appendix A.2.

9.5 Experimental comparison among models

As stated previously, given the unavailability of generative baselines for the task, we had to first train and compare a suite of generative baselines as reported in Table 2. This initial step allowed us to establish a fair comparison among models of similar sizes before showcasing the incremental performance gains with larger models. Table 7 presents a comparison of the number of trainable parameters in the different baselines, including the ones (generative) we trained, and our best-performing model. Also, a comparison of training times per epoch of the different models is shown in Table 8. T5-Base (220M), the weakest generative baseline trained by us, is comparable with Label Semantics, the largest existing non-generative baseline (218M). From Table 2, T5-Base already outperforms Label Semantics with **18.56%** Macro-F1 and **11.17%** Hits@1 gains. T5-Base also outperforms AttentionXML (112M) substantially as reported above. Also, while FLAN-T5-Large (780M) is larger than AttentionXML, our best results are obtained when we instruction-tune FLAN-T5-Large with LoRA, thereby drastically reducing the number of trainable parameters (0.59M), substantially lesser than AttentionXML (112M). Yet, we significantly outperform AttentionXML with **39.3%** Macro-F1 and **17.2%** hits@1 gains.

Model	Trainable parameters
FINER	109M
Label Semantics	219M
GalaXC	41M
AttentionXML	112M
T5-Base	220M
T5-Large	739M
Flan-T5-Large	780M
Flan-T5-Large w/ LoRA	**0.59M**

Table 7: Comparison of number of trainable parameters between the baselines and FLAN-T5-Large with LoRA

Model	Training time per epoch
FINER	12 hours
Label Semantics	9 hours
GalaXC	1.2 hours
AttentionXML	4 hours
Flan-T5-Large w/ LoRA	**56 minutes**

Table 8: Comparison of training time per epoch between the baselines and FLAN-T5-Large with LoRA

10 Conclusion

This work proposes a generative approach to solve the financial numeric labelling task. We propose a novel FLAN-FinXC framework, that makes use of parameter-efficient instruction tuning of LLMs for this extreme labelling task. While comparing with the state-of-the-art models and various competitive baselines that we devise for the task, we find that our best model, Flan-T5-Large with LoRA, achieves huge improvements, providing a Macro-F1 of 66.23% as compared to the previously reported best numbers of 47.54% for FNXL dataset. For adapting to other tasks, our approach requires only minor task-specific modifications to the input prompt, and the target output. Moreover, our approach offers flexibility in using either the class labels or label descriptions, depending on the available data. As potential future directions, we believe the scope to include more financial knowledge and integrate a human-AI feedback loop would be the way forward to improve performance of this challenging task.

11 Limitations

In this work, we have not integrated external financial knowledge to address the subtle differences between tags as identified in our error analysis. Also, we have observed that labeling numerals solely based on sentence-level text (as done in this work) can be challenging, since the context depends on the surrounding paragraph, associated tables, and other elements which are not used in this work. Incorporating such elements as well as external financial domain knowledge into a financial numeral labeling model would be interesting future works.

A Appendix

In this section, we provide some supplementary materials that enhance the content presented in the main paper.

A.1 XBRL Tag Documentation

Each XBRL tag is associated with a pre-defined textual description known as its 'tag documentation'. Table 9 shows some more examples of XBRL tags and their documentations. Note that, while certain tag-pairs may exhibit subtle distinctions, their accompanying documentations vary significantly. Domain experts leverage the information provided in the documents during manual annotation. Our proposed model is also designed to utilize these documentations.

Tag	Documentation
common stocks shares issued	Total number of common shares of an entity that have been sold or granted to shareholders (includes common shares that were issued, repurchased and remain in the treasury). These shares represent capital invested by the firm's shareholders and owners, and may be all or only a portion of the number of shares authorized. Shares issued include shares outstanding and shares held in the treasury.
common stock shares authorized	The maximum number of common shares permitted to be issued by an entity's charter and bylaws.
tax credit carry forward amount	The amount of the tax credit carryforward, before tax effects, available to reduce future taxable income under enacted tax laws.
tax credit carry forward valuation allowance	Amount of valuation allowance pertaining to the deferred tax asset representing potential future taxable deductions from tax credit carryforwards for which it is more likely than not that a tax benefit will not be realized.
due to affiliate noncurrent	Amount of receivables owed to an entity that is affiliated with the reporting entity by means of direct or indirect ownership, which are usually due after one year (or one business cycle, if longer).
due to affiliate current and non current	Amount of payable due to an entity that is affiliated with the reporting entity by means of direct or indirect ownership.
notes payable related parties classified current	The amount for notes payable (written promise to pay), due to related parties. Used to reflect the current portion of the liabilities (due within one year or within the normal operating cycle if longer).
notes payable related parties current and non current	The amount for notes payable (written promise to pay), due to related parties.

Table 9: Examples of XBRL tag documentations. While some tag-pairs exhibit very subtle distinctions, their accompanying documentations vary significantly. Our model takes advantage of the distinctions between the tag documentations.

A.2 Comparison with ChatGPT

With the emergence of ChatGPT, we were curious to check its performance on this task using the same instruction prompt for a few samples. As can be seen from the examples in Table 10, ChatGPT struggles to correctly identify the appropriate tags in the majority of cases, and in some cases, it misunderstands the context entirely. This indicates that ChatGPT has still very limited performance in financial numerical tagging.

A.3 Error Analysis

Table 11 demonstrates instances where the generated tag documentation (by our best model) closely resembled the ground truth (GT) tag documentation, but even minor variations led to a wrong final tag prediction. In the financial domain, subtle word changes can drastically alter the context. As illustrated in Table 6, subtle differences between *'from other party'* (in the GT tag, highlighted in green) and *'to other party'* (in the prediction, highlighted in red), or between *'dividends paid'* (in the GT tag, highlighted in green) vs *'dividends declared'* (in the prediction, highlighted in red), or between *'cash outflow'* and *'cash inflow'*, *'loss'* vs *'damages'* can lead to a wrong final tag prediction.

Instruction: First, read the task description. There could be multiple numerals reported .... **Sentence:** Now read the following financial statement. At April24, 2020 the estimated fair value was $**27.1** billion compared to a principal value of$24.5 billion. **Question:** What is the tag associated with the numeral **27.1**? **GT Tag:** long term debt fair value **ChatGPT:** estimated fair value **FLAN-FinXC:** long term debt fair value
Sentence: Ordinary shares - par value $0.0001, **2.6** billion shares authorized, 1,345,400,671 and 1,341,074,724 shares issued and outstanding, respectively **Question:** What is the tag associated with the numeral **2.6**? **GT Tag:** common stock shares authorized **ChatGPT tag:** ordinary shares authorized **FLAN-FinXC:** common stock shares authorized
Sentence: Share Capital Medtronic plc is authorized to issue 2.6 billion Ordinary Shares, $0.0001 par value; 40 thousand Euro Deferred Shares, €1.00 par value; 127.5 million Preferred Shares, $0.20 par value; and **500** thousand A Preferred Shares, $1.00 par value. **Question:** What is the tag associated with the numeral **500**? **GT Tag:** preferred stock shares authorized **ChatGPT:** a preferred shares authorized **FLAN-FinXC:** preferred stock shares authorized
Instruction: ..... **Sentence:** At April26, 2019, $764 million of rebates were classified as other accrued expenses and $**432** million of rebates were classified as a reduction of accounts receivable in the consolidated balance sheets. **Question:** What is the tag associated with the numeral **432**? **GT Tag:** contract with customer refund liability current **ChatGPT:** rebates reduction of accounts receivable **FLAN-FinXC:** contract with customer refund liability
Sentence: As of December 31, 2018, we expect to receive total future rental income of $**203** million related to noncancelable subleases for abandoned facilities. **Question:** What is the tag associated with the numeral **203**? **GT Tag:** operating leases future minimum payments receivable **ChatGPT tag:** future rental income from noncancelable subleases **FLAN-FinXC:** operating leases rent expense sublease rentals 1

Table 10: Comparison between ChatGPT and our best FLAN-FinXC model variant's prediction

Instruction: First, read the task description. There could be multiple numerals reported in a financial statement.....**Sentence:** On January 15, 2020, the parties agreed to a settlement in principle to resolve the lawsuit, which will require a payment of $**550** million by us and is subject to approval by the court.
Question: What is the tag associated with the numeral **550**?
GT Tag Doc: amount of loss contingency liability. **GT Tag:** loss contingency accrual at carrying value
Flan-Large Generated: Amount awarded damages contingency liability.
Flan-Large +Tag Matcher: amount of damages awarded to the plaintiff in the legal matter.
Pred Tag-Words: loss contingency damages awarded value

Sentence: In fiscal year 2016, Bard paid the Company $**121** million towards the settlement of 11,000 of these claims. **Question:** What is the tag associated with the numeral **121**?
GT Tag Doc: amount awarded from other party in judgment or settlement of litigation. **GT Tag:** litigation settlement amount awarded from other party
Flan-Large Generated: Amount awarded to other party in judgment or settlement of litigation
Flan-Large +Tag Matcher: amount awarded to other party in judgment or settlement of litigation.
Pred Tag-Words: litigation settlement amount awarded to other party

---

Sentence: During the year ended December 31, 2017, we issued and repaid an aggregate of $**12.3** billion of commercial paper and had a maximum outstanding balance of $1.5 billion under our commercial paper program. **Question:** What is the tag associated with the numeral **12.3**?
GT Tag Doc: the cash outflow due to repaying amounts borrowed by issuing commercial paper.**GT Tag:** repayments of commercial paper
Flan-Large Generated: The cash inflow during to theing short borrowed under issuing commercial paper.
Flan-Large +Tag Matcher: the cash inflow from borrowing by issuing commercial paper.
Pred Tag-Words: proceeds from issuance of commercial paper

Sentence: Our Board of Directors declared quarterly dividends per share of $**1.45**, $1.32 and $1.15, which were paid in each of the four quarters of 2019, 2018, and 2017, respectively. **Question:** What is the tag associated with the numeral **1.45**?
GT Tag Doc: aggregate dividends paid during the period for each share of common stock outstanding.
GT Tag: common stock dividends per share cash paid
Flan-Large Generated: Aggregate dividends declared during the period for each share of common stock outstanding.
Flan-Large +Tag Matcher: aggregate dividends declared during the period for each share of common stock outstanding.
Pred Tag-Words: common stock dividends per share declared

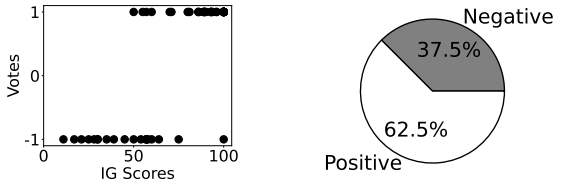
Instruction: .....**Sentence:** As of December 31, 2020, Duong met the held-for-sale criteria and loan receivable balance of $1.3 billion, net of CECL reserve of $**32** million was reclassified **Question:** What is the tag associated with the numeral **32**?
GT Tag Doc: amount of allowance for credit loss on accounts receivable. **GT Tag Words:** allowance for doubtful accounts receivable
Flan-Large Generated: othersmount of allowance for credit loss on financing receivable, A
Flan-Large +Tag Matcher: amount of allowance for credit loss on financing receivable, classified as noncurrent.
Pred Tag-Words: allowance for notes and loans receivable noncurrent

Table 11: Error cases. Examples to show the subtle difference between ground truth (shown in green color) and generated tag docs (shown in red color) and predicted tag.

Analysis of State-Level Legislative Process in Enhanced Linguistic and Nationwide Network Contexts

Maryam Davoodi
Purdue University
mdavoodi@purdue.edu

Dan Goldwasser
Purdue University
dgoldwas@purdue.edu



Abstract

State bills have a significant impact on various aspects of society, including health, education, and the economy. Consequently, it is crucial to conduct systematic research on state bills before and after they are enacted to evaluate their benefits and drawbacks, thereby guiding future decision-making. In this work, we developed the first state-level deep learning framework that (1) handles the complex and inconsistent language of policies across US states using generative large language models and (2) decodes legislators' behavior and implications of state policies by establishing a shared nationwide network, enriched with diverse contexts, such as information on interest groups influencing public policy and legislators' courage test results, which reflect their political positions.

1 Introduction

State policies affect our lives in many ways, such as our health, taxes, and rights. State legislatures can protect or limit our freedoms in areas like voting, reproduction, labor, and more. State laws also impact national issues, such as federal courts deferring to states on constitutional matters and federal laws responding to state laws (see Appendix A).

Thus, our goal is to build an NLP/ML framework for understanding state-level legislative process in the US. This can help the public to know how bills affect them, check if legislators vote consistently with their public views, and find out who influence them. While promising NLP/ML studies, e.g., (Feng et al., 2022; Davoodi et al., 2022), predict bill or vote outcomes using bill text and legislator information, they have limitations: most focus on centralized federal-level process, they miss out some state-level contextual information such as influence of local lobbyists, they use low quality and inconsistent state data, they lack support for non-vote prediction tasks, or they often use traditional NLP/ML architectures. Our framework addresses these limitations and improves the understanding of state legislative process and its implications:

(a) *(b)*

Figure 1: *Correlation between (a) Interest group (IG) scores of legislators and their voting on a bill favoring the IG and (b) Legislators' responses to a courage test question and their voting pattern on a related bill.*

Normalizing the language of state legislation. Our framework's first pillar addresses the inconsistency, verbosity, and complexity of state-level legislative data (LegiScan, 2023; NCSL, 2024). State bills vary in language and format for the same topic, making cross-state policy analysis difficult. They are also lengthy and detailed, obscuring the main points and implications of the bills. State bills often require domain knowledge to comprehend, limiting their accessibility for the public. Therefore, we normalize and optimize state legislative data by using Generative LLMs, e.g., OpenAI GPT (OpenAI, 2023). This *involves* generating consistent summaries of bills, enriching legislator's data, and identifying potential winners/losers of bills. This way, we can better compare similar policies across different states and topics. We evaluate the quality of LLM summaries by comparing them with expert-written ones and explore the feasibility of using open-source LLMs (Appendix C).

Capturing inter- and intra-state contexts. We also aim to understand how state bills relate to other external factors (e.g., cross-state effects). Thus, our framework adheres to two design principles: (1) We study all 50 US states, unlike most recent studies that focus on a few states (Davoodi et al., 2020). (2) We find and include important inter-state and intra-state entities that affect

Proceedings of the 2024 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies (Volume 1: Long Papers), pages 7404–7422
June 16-21, 2024 ©2024 Association for Computational Linguistics

state policies and were ignored before. Specifically, we include *Interest Groups (IGs)* that lobby legislators for their values and affect the making and passing of bills on issues like health care. IGs assign scores to legislators based on their policy alignment, which can indicate their future voting patterns (Figure 1a). Also, we use Political Courage Tests (PCTs) that ask candidates to state their positions on issues related to their session, which can reveal the genuine preferences of legislators who may conceal them for electoral/partisan motives (Figure 1b, Appendix D).

Efficient abstraction and embedding. To operationalize our work, we construct a new text-attributed graph abstraction to represent different entities and relations in state legislative process in a highly normalized linguistic and broadened network contexts (Figure 2). On top of this abstraction, we enable diverse prediction tasks, beyond predicting legislators' votes, such as predicting legislators' courage test results and interest group impacts that both have real-world use-cases (Section 6). We argue that such tasks are interdependent and can benefit from joint learning and representation. To efficiently deliver these, we develop a new shared text and graph embedding architecture (Figure 3), designed to handle longer legislative texts and unseen entities more effectively. The first in kind that combines the benefits of an efficient non-generative LLM, OpenAI Ada (OpenAI, 2023), with that of a widely-adopted heterogeneous GNN, RGCN (Schlichtkrull et al., 2018), to jointly generate contextualized text and graph representations for nodes and relations.

Technical contributions: In summary, we present the following technical contributions:

- Modeling state policies in wider intra-/inter-state contexts overlooked by prior studies (Section 3).
- Using LLMs to solve linguistic issues in state legislative data for the first time (Section 4).
- Creating a new dataset and nationwide abstraction of state legislative process and defining two new prediction tasks (Section 5).
- Developing an efficient joint LLM and GNN embedding and prediction architecture, better supporting long texts and unseen nodes (Section 6).
- Showing our architecture's superior performance over robust text and graph baselines (Section 7).

2 Related Works

We discuss promising studies that have influenced our work (Further discussion in Appendix D).

Bill progression classification. One research direction aims to predict the likelihood of a congress bill passing a certain legislative stage, e.g., clearing a committee, which is a challenge that most bills fail to meet. For instance, Yano et al. 2012 use features related to the bill's significance and bill's co-sponsors, to estimate the committee outcome. Eidelman et al. 2018 conduct a similar analysis for state bills and show the benefits of integrating bill text with minimal contextual info. on legislators.

Roll-call (vote) classification. A related research direction is to model how federal legislators vote. Kraft et al. 2016; Patil et al. 2019 capture ideological preferences of US congress members for this task. Karimi et al. 2019; Kornilova et al. 2018 incorporate bills' text and metadata of the sponsors. Feng et al. 2022; Mou et al. 2021, 2023 build better models for Congress legislators based on their info. on social networks (Wikipedia, Twitter) and expert knowledge websites (Think tanks). While Davoodi et al. 2020, 2022 conduct similar studies for 3 US states but with key limitations (see Section 1).

LLM applications. The evolution of LLMs, like OpenAI's GPT and Ada, has significantly improved core NLP tasks and enabled new applications. For instance, GPT-3 made accurate data annotation possible despite biases (Ding et al., 2022). GPT-3.5 enhanced this with better summarization of complex user reviews (Bhaskar et al., 2023). GPT-4 takes it further, enabling assessments of second-language proficiency aligned with standards such as the CEFR (Yancey et al., 2023).

3 Broadening Political & Social Contexts

Our goal is to build a model that can better understand legislators' behavior and the impact of policies within and across states. Thus, we abstract the state legislative process (detailed in Appendix A) using a text-attributed graph and enrich it with diverse political-social contexts, derived from our ablation study (Section 7). In the next section, we apply our generative LLM optimization on the graph to handle the linguistic challenges.

3.1 Nationwide Legislative Graph: Properties

Our proposed legislative graph abstraction, shown in Figure 2, comes with four unique properties: Our model is nationwide, interconnecting all 50 states,

allowing us to compare legislative activities across different states, e.g., abortion regulation (Ballotpedia, 2024). It incorporates multiple types of heterogeneous entities, such as legislators, interest groups, and political courage tests, with varying levels of influence and involvement in the policy process. It contains rich textual information for each node in the graph, such as bills with titles and summaries or interest groups with mission statements. This enables us to extract meaningful insights from the data. Additionally, it captures the relationships among the nodes, such as co-sponsorship, endorsement, or opposition, that reflect the alignment or conflict between them. Next, we describe some key components of our graph.

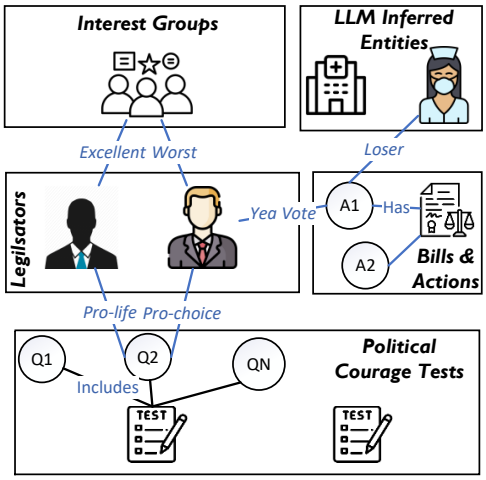


Figure 2: *LLM-optimized, contextualized, and nationwide legislative graph for analyzing state-level policies.*

3.2 Modeling Legislators & Revisiting Bills

Legislators and bills are the most important components of the legislative process. A state bill has metadata such as title, official synopsis, status, and sponsors, as well as a list of actions that track its progress through different stages (e.g., introduction, committee referral, floor vote). We add both bills and their actions as nodes in the graph and connect them with edges that indicate the temporal order of the actions. We also add edges between legislators and actions to represent their voting behavior and between legislators and bills to model sponsorship.

Adopting bill highlights for normalizing state bills. A major obstacle for legislative data analysis in the US is the inconsistency among different states (LegiScan, 2023; NCSL, 2024). Each state has its own way of writing, naming, summarizing, and categorizing bills, making it hard to compare and contrast them. Also, we have seen bill titles and synopses can be missing, misleading or vague. Unlike existing works, we propose to use bill highlights or summaries of legislation written by a group of legislative researchers as a better alternative in the graph as well as *ground-truth* to evaluate our LLM generated ones (Section 4). These researchers (VoteSmart, 2023) read the text of the bill and then write consistent summaries that extract the most important information from each bill and present it in a clear way (Examples in Appendix C). Bill highlights are more informative and accurate than bill titles and synopses. Also, they normalize our data across different US states and make it easier to understand the impact and implications of each bill. *Our experiments show bill highlights can boost the performance of two bill classification tasks by up to 3.5 F1 points, compared to the official titles and synopses* (Appendix B.4).

3.3 Incorporating Interest Groups (IGs)

Our legislative graph incorporates the data of interest groups (IGs) that operate at different levels (Figure 2): *within a state*, *across multiple states*, and *nationwide*. This allows us to gain insights into state policies, which were overlooked in previous NLP/ML studies at the state level. IGs advocate for causes or groups. They lobby directly or indirectly to sway legislators' votes. They offer information, expertise, or resources to help legislators. They also influence public opinion through media or petitions to pressure legislators to align with their interests. To capture all these interactions, we represent IGs as nodes in the graph and include a textual description of their activities, drawn from their public mission statement or other sources on the Internet, into these nodes. For example, this is a part of textual info. associated with an IG in Indiana:

> **Name:** "Florida Planned Parenthood PAC", **Description:** The Florida Planned Parenthood PAC is the political arm of Planned Parenthood organizations in Florida and is a separate segregated political action committee, which supports state candidates who support access to safe/legal abortion and family planning health services...

IG relations (scores). We also study how IGs affect legislators through their public ratings of legislators. An IG score is a percentage that interest groups give to legislators based on various factors, e.g., money donations and historical voting alignment (See Appendix B). We collect these scores for all legislators and model them as relations in the graph (Figure 2). IGs publish these scores to influ-

ence legislators' future actions. We divide scores into four categories: Worst: 0-25 Bad: 26-50%, Good: 51-75%, Excellent: 76-100%; and create corresponding relation types between IGs and legislators in the graph. This is a sample IG score:

> **"RatingText"**:"Representative Bob Heaton supported the interests of the Citizens Action Coalition of Indiana 32 percent in 2021.", **"rating"**: "32", **"Id"**: "1062", **"timespan"**: "2021", **"ratingName"**: "Lifetime Positions", **"Category"**: "Agriculture and Food"

3.4 Incorporating Political Courage Tests

To better understand state legislators' voting behaviour, we need to know their motivations, priorities, and commitments. Political courage tests (PCTs), detailed in Appendix B.3, can reveal these by asking them challenging questions–more effective than their social network information (Appendix D). These questions measure how much legislators respect democracy, human rights, and the rule of law. They also test how they deal with unpopular issues, IGs, and minority rights. Some frequently asked PCT questions are as follows:

> **(1)** Do you support the prohibition of public funds for organizations that perform abortions?
> **(2)** Should background checks be required on gun sales between private citizens at gun shows?
> **(3)** Do you support pro-life or pro-choice legislation?

PCTs do not provide a clear way to compare different legislators or to identify patterns and trends in their behavior. This is where our graph modeling can offer a significant advantage. By representing the PCT and its questions as nodes in a graph, and linking them to the legislators who answer them (Figure 2), we can create a rich and dynamic representation of the political landscape. This allows us to (a) better identify the similarities and differences between legislators based on their answers; (b) easier analyze the relationships and influences among legislators, IGs, and issues; and (c) better predict how legislators might react to new legislation based on their past performance. In this work, our focus is on 2-choice (Yes/No) and 4-choice questions, making up 95% of the tests on average.

4 LLM-Based Legislative Graph Optimization

Before utilizing the legislative graph for training and inference tasks, we implement a data optimization phase. This phase is realized using a generative Large Language Model (LLM) and includes: (a) normalizing the textual attributes of nodes to address linguistic challenges such as their verbosity, complexity, and inconsistencies across states; (b) enhancing the nodes with additional textual information where necessary; and (c) uncovering and formalizing latent relationships embedded within the nodes' textual data. These steps are crucial for improving performance, as they enable a more cohesive understanding of policies and legislative actions related to the same topic at both intra- and inter-state levels (Section 7).

4.1 LLM Approach to Bill Summarization

In Section 3, we discussed the benefits of adopting bill highlights written by researchers, which serve to normalize the language of state policies across the US. However, our dataset includes these highlights for only a selection of state bills (see Section 5). To enhance practicality and performance, it is necessary to scale these highlights to a larger number of bills, including new ones—for instance, to potentially retrain our model with an expanded dataset or to process new bills at inference time. For this purpose, we utilize a generative LLM to produce highlights for state bills, a task that would be highly tedious for humans. LLMs assist us by reading the full text of a bill and producing a concise summary that capture its main points, objectives, and impacts. We experimented with different prompting strategies for `GPT-3.5-turbo-16k` to summarize bills. Initially, we posed separate questions and compiled the responses, but this approach resulted in repetitive content. As a result, we refined our prompt to extract a comprehensive highlight, including the potential winners and losers of a bill, in a single query. The advantages of identifying winners and losers will be detailed shortly. We have assessed the quality and efficacy of these AI-generated highlights in Appendix C.

> **Prompt**: What are the detailed highlights, as well as the potential winners and losers, of House Bill HB 5 titled 'Prohibits Abortions After 15 Weeks' in Florida?

> **Highlights (Full version in Appendix C.3)**
>
> 1. **Abortion Prohibition:** The bill prohibits abortions after 15 weeks of pregnancy, except in cases where the mother's life is at risk or if there are lethal fetal anomalies.
> 2. **Criminal Penalties:** It imposes criminal penalties on healthcare providers who perform abortions after 15 weeks, with potential charges ranging from a third-degree felony to a first-degree felony,...
> 3. **Informed Consent and Ultrasounds:** The bill requires healthcare providers to perform an ultra-

sound and allow the pregnant person to view it before performing an abortion. ...

4. **Reporting Requirements:** The bill imposes additional reporting requirements on healthcare providers who perform abortions, including reporting specified information to the state's Agency for Health Care Administration.

Potential Winners:

1. **Pro-Life Advocates:** Supporters of the bill argue that it protects the rights and lives of unborn children, and they view any limitation on abortion as a step in the right direction.

2. **Religious and Conservative Groups:** ...

Potential Losers:

1. **Abortion Rights Advocates:** Those who support a woman's right to choose may oppose this bill, as it limits access to abortions beyond the 15-week.

2. **Healthcare Providers:** ...

4.2 LLM Augmentation of Legislative Data

LLMs can help us further enhance the state data quality by filling in the gaps in two scenarios: (1) We apply GPT to enrich or augment the textual features of entities. For example, some actors (e.g., bill sponsors) may have hidden agendas or motivations that are not clearly expressed in the bill or its related documents. LLMs can assist by generating more information, better exposing the background, affiliations, and goals of these actors. (2) State-level data is not flawless, and some entities may lack certain attributes (e.g., the mission statement of IGs). We use GPT to create synthetic information for such entities. To achieve this data augmentation, we have devised prompts, as follows:

Prompt: What are the highlights of the political interests of Legislator Scott Thomas Wilk in CA?

Scott Thomas Wilk is a Republican legislator from CA who represents the 21st Senate District. Some of the highlights of his political interests and priorities include:

1. **Education:** Wilk has been a strong advocate for education and improving educational opportunities for Californians. He has expressed support for increasing funding for K-12 schools, ensuring access to quality higher education, and promoting career and technical education.

2. **Veteran Support:** ....

3. **Water and Natural Resources:** ....

4. **Fiscal Responsibility:** Wilk emphasizes the need for fiscal responsibility in the California state government. He supports reducing government waste, lowering taxes, and promoting policies that encourage economic growth and job creation.

Prompt: What is the mission statement of Florida Planned Parenthood PAC?

The mission statement of Florida Planned Parenthood PAC is to protect, promote, and enhance reproductive health care access and rights for all individuals in Florida. They strive to elect candidates who support comprehensive reproductive health care, including access to safe and legal abortion, affordable birth control, and comprehensive sex education ....

4.3 Extracting Winner/Loser Relations

The third use-case of LLM in our study is to uncover hidden relations within the legislative process across the US. Specifically, as part of generating bill highlights, we utilize LLM to extract winner and loser entities produced by the bill. These entities represent the groups or individuals that either benefit from or are adversely affected by the bill's proposed policy. We depict them as nodes in the legislative graph, along with a brief summary of their interests (see Figure 2). Additionally, we establish links between these entities and relevant bill actions using winner/loser relations. Our ablation study demonstrates the value of these synthetic relations (Section 7), enabling us to compare and contrast bills across different US states, identifying similarities and differences in their content and impact. Furthermore, our LLM method outperforms expert MTurk workers in the same annotation task (Appendix C.2). Recent research (Davoodi et al., 2022) relies on such human-based winner/loser analysis of state bills, which is not scalable.

5 Data Collection

To realize and optimize the legislative graph, we have built a scraper that can extract various data on state legislation, legislators, interest groups, and courage tests from different sources, particularly, Vote Smart (VoteSmart, 2023). Specifically, we have obtained 7K pieces of legislation covering the period from 2019 to 2022. These bills have undergone 16.9K actions. We analyze the 9K main and second floor actions (see Appendix A.1). VoteSmart does not include every legislation from every state legislature; Rather, their research team tracks topical legislation, as well as, unique and novel legislation (i.e. legislation that addresses things never previously addressed by any state legislature). Moreover, we have obtained different information on 7237 legislators, including their biogra-

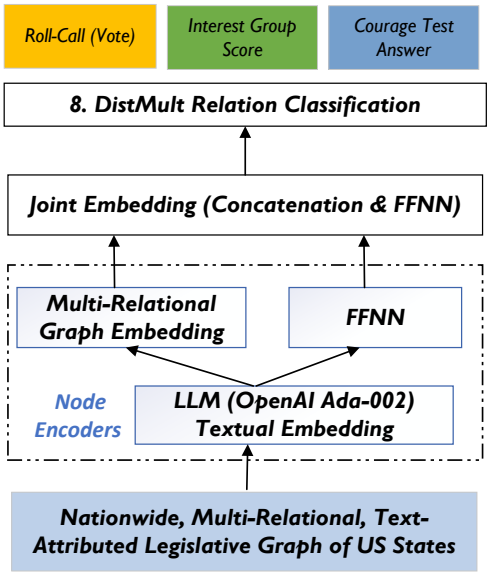

Figure 3: *Joint LLM and GNN embedding architecture on nationwide legislative graph (Properties in Sec. 6.2)*

phy, political party, religion, and etc. Furthermore, we collected detailed information on 1421 Interest Groups (IGs) including their textual attribute such as mission. We have observed 61K ratings between different pairs of legislators and IGs. Combining the courage test results from all US states, we have observed legislators answering 2216 unique questions. In total, 902 legislators participated in a test. Overall, we have also LLM-extracted 300 entities and 3K winner/loser relations after pruning single-time used entities. As part of our future work, we plan to use LLM to further scale the number of bills in our dataset. *For details on data collection and processing, see Appendix B and the Ethics Section.*

6 Classification Tasks & Architecture

Next, we explore three important political science applications as relation prediction tasks on the legislative graph (Figure 2). Our optimized legislative graph, utilizing generative LLM techniques, already enhances model performance in these tasks (as detailed in Section 7). To achieve further gains, crucial in our problem domain (see the Ethics section), we develop an efficient joint text and graph (LLM + GNN) embedding architecture.

6.1 Political and Legislative Tasks on Graph

1. Roll-call (RC) Prediction. Our first task involves predicting legislators' votes on bill actions and subsequently *aggregating* them to determine the fate of each action. This is key to understand the dynamics of state politics. It reveals what affects legislative behavior, such as party, ideology, voters, interest groups, etc. It also can inform the public on the outcome and implications of state legislation prior to voting.

2. Political Courage Test (PCT) Prediction. It is crucial to know legislators' answer to PCT questions, which measure their risk-taking on controversial issues. However, many legislators avoid these tests (Appendix B.3). Thus, predicting their answers can help to: (a) Know their true values, goals, and actions. (b) Compare different legislators (e.g., in parties) and spot any agenda inconsistencies. (c) Motivate legislators to take the test and share their views, thereby gaining trust with voters.

3. Interest Group (IG) Impact Prediction. Our final task is to predict the IG scores of legislators, which is useful in at least two scenarios: (a) Interest groups (IGs) can use these scores to identify allies or opponents among newly elected legislators by leveraging the broader context in the legislative graph (e.g., winners/losers, courage tests). (b) The public can estimate how IGs interact with their legislators, especially when one or both parties are new and the score has not yet been established.

Dependency. These three relation type prediction tasks are interdependent and leverage the same shared textual and graph contexts within the legislative graph. For instance, the outcomes of the PCT and IG scores can hint at the voting behaviors of legislators (see Figure 1). Thus, we employ a single architecture to address all these tasks.

6.2 Efficient Joint LLM and GNN Embedding

We predict these relation types with an efficient joint text and graph architecture (Figure 3) that has three novel aspects: **(1)** It handles longer legislative texts by using the latest non-generative LLM, while exploiting our bill text highlighting system (Section 7). **(2)** It better deals with unseen nodes in the graph, by utilizing the LLM representation of nodes (Ethics Section). **(3)** It jointly generates and optimizes text and graph embedding, without losing the textual context during in graph embedding like previous methods (Feng et al., 2022; Mou et al., 2021). Next, we explain our architecture from bottom to up.

6.2.1 LLM-Based Text Embedding

Our architecture (Figure 3) leverages LLMs to produce textual representations of the nodes and relations in the legislative graph. Each node has some

text associated with it, e.g., GPT bill highlight, legislator's political interest, and etc. We prepare and feed this text to LLM to make and freeze a textual embedding for each node. While we support different LLM providers (the Ethics Section), we chose to use `text-embedding-ada-002` from OpenAI. Ada can encode up to 8K tokens into a 1538-dimensional vector and has a longer max sequence length than models such as RoBERTa (Liu et al., 2019), thus enabling our architecture to fully exploit GPT bill highlights.

6.2.2 LLM-Attributed Graph Embedding

We leverage the nationwide context/structure of our graph by passing it through a popular heterogeneous GNN, RGCN (Schlichtkrull et al., 2018). Our goal is to obtain effective graph embeddings for nodes and relations, thereby enriching RGCN training with LLM (OpenAI Ada in Figure 3). In this approach, we extract the text embedding of each node from OpenAI Ada and use it as the initial graph embedding in RGCN for boosting performance. The RGCN model performs graph convolutions, allowing it to learn representations of nodes within our legislative graph, which contains multiple relations. Specifically, RGCN aggregates and weighs input features from nodes and their neighbors based on relation types. It then applies a convolutional layer to refine these features, creating new representations. By repeating these steps across layers, we achieve deeper and more expressive node embeddings. RGCN effectively captures the rich and complex information present in our the legislative graph data using this formula:

$$h_i^{(l+1)} = ReLU\left(W_0^{(l)} h_i^{(l)} + \sum_{r \in R} \sum_{j \in N_i^r} \frac{1}{c_{i,r}} W_r^{(l)} h_j^{(l)}\right)$$

Here, $h_i^{(l)}$ is the hidden representation of node i at layer l, $W_0^{(l)}$ and $W_r^{(l)}$ are learnable weight matrices for layer l, R is the set of relation types, N_i^r is the set of neighbors of node i under relation type r, and $c_{i,r}$ is a normalization constant.

6.2.3 Joint Text & Graph Optimization

We aim to *retain* the important linguistic and textual contexts of nodes, which can be lost through RGCN layers. So we feed nodes' LLM-based (OpenAI Ada) text embedding through FFNN to preserve it. Then, we join and optimize the text and graph embedding of the node from RGCN and FFNN. Finally, we predict the relation types, e.g., (legislator, bill action), (legislator, PCT question), and (IG, legislator). We use DistMult (Yang et al., 2014), a factorization model that measures the plausibility of a triple (entity1, relation, entity2) by computing the dot product of their embeddings with relation-specific weights. Here, our loss function consists of (a) cross-entropy loss of the relation classification; (b) L2 regularization of the RGCN weights; and (c) L2 regularization of the FFNN.

7 Experiments

This section assesses our framework's core aspects: the joint LLM and GNN embedding architecture's performance gains against strong baselines; the benefits of normalizing and optimizing state-level legislative data with a generative LLM; a performance comparison over three legislative tasks;an ablation study on integrating wider social and political context into the graph; and a performance analysis using data splits that mimic real-world legislative conditions.

7.1 Experimental Setup

Implementation. We used the Deep Graph Library (DGL, 2023) to build both our model and baselines. OpenAI served as our LLM provider, chosen for its efficiency (refer to our feasibility study on open-source providers in Appendix C.4). We used `text-embedding-ada-002` for generating embeddings and `GPT-3.5-turbo-16k` models[1] for our legislative graph optimization. The embedding dimension of Ada is 1536. Both the FFNN and the RGCN (4-layer) models convert the Ada embeddings into a 256-dimensional space. We use Adam optimizer with a learning rate of 0.01.

Data Splits. To evaluate our model, we divide the graph (formed over 50 US states) into train/eval and test sets based on the bill nodes, using 80% of them for training and validation. We select the 20% of the test nodes in three ways: (1) Randomly; (2) By date, where we use bills after a certain date for testing; and (3) By party, where test bills come from either Blue or Red states (Appendix B). For these splits, for each observed (positive) relation, we generate a corresponding negative sample.

Metric. We choose Macro F1 over accuracy due to imbalanced data in our prediction tasks.

7.2 Details of Baseline Models

We build and study three types of robust baselines:

[1]We wrote this paper before GPT 4 was available.

Type	Embedding	Raw Graph			LLM-Opt Graph		
		RC	IG	PCT	RC	IG	PCT
Text	BoW	59.8	59.3	58.4	62.8	64.2	61.9
	RoBERTa	67.3	65.2	63.8	69.1	68.6	66.3
	Ada	72.1	71.3	70.8	75.1	74.3	72.5
Graph	DeepWalk	63.3	61.8	61.3	65.7	63.6	62.2
	GCN	65.2	63.7	62.4	66.5	64.2	63.8
	RGCN	70.2	69	68.1	72.2	71.3	69.4
Joint	Ada+ Txt. RGCN	74.4	75.3	72.8	77.8	77.1	74.9

Table 1: *Random split. Performance (Avg. Macro F1× 100 in 10 runs) of models with and without our LLM-based legislative graph opt. in Roll-call (RC), Interest Group (IG), and Political Courage Test (PCT) tasks.*

1. **Text models:** We create text classifiers for each task using a Random Forest on embeddings from three models: **(a) BoW** utilizes the top 5K uni/bi-grams. **(b) RoBERTa-Large**, a small language model (SLM). **(c) Ada**, the latest OpenAI non-generative LLM. For the roll-call (RC) task, we directly determine bill actions' fate by computing the embedding of (bill highlight, sponsors), without vote aggregation. When predicting interest group (IG) scores, we calculate the embedding of (legislator, IG). For predicting courage test (PCT) responses, we generate embedding of (legislator, PCT question).

2. **Graph models**: We train relation classifiers with edge embeddings from: **(a) DeepWalk** (Perozzi et al., 2014), a model that ignores relations and forms SkipGram on random walk node sequences. **(b) GCN**, a standard 4-layer GCN model with random node features. **(c) RGCN**, the relational version of the GCN.

3. **Joint models:** In our ablation study (Section 7.6), we examine weaker versions of our joint text and graph model, limited to the roll-call prediction task. Specifically: **(a) EX-IG** excludes interest group (IG) relations and nodes. **(b) EX-PCT** omits the courage test contexts. **(c) EX-WL** removes the winner/loser (WL) relations and nodes.

7.3 Benefit of Joint Text and Graph Model

To understand the benefit of our joint LLM and GNN model in isolation, we first *disable* our generative LLM-based optimization on the legislative graph for all the models. We look at the roll-call task results in Table 1 for the random split on the raw graph and notice the following: (1) Comparing the text-based models, Ada (LLM) achieves 4.8 points higher F1 than RoBERTa (SLM). This is because Ada is trained on a larger text corpus and is speculated to have 7.63× more parameters. More importantly, Ada handles longer legislative texts (i.e., researcher-written bill highlight) by having 16× larger max sequence length (both having similar embedding size, 1024 for Roberta and 1536 for Ada). (2) Among the graph models, RGCN better captures different relation types in the graph, thus delivering higher performance compared to GCN/DeepWalk that are relation agnostic models. (3) Our joint model outperforms the leading individual text or graph models by 2.3 and 4.2 points, respectively. It effectively maintains the textual and relational contexts of policy-making in the legislative process, thereby merging the strengths of the individual models.

7.4 Effect of LLM-Based Graph Optimization

Next, we *activate* our generative LLM-based optimization on the legislative graph and revisit the roll-call task as shown in Table 1. We observe that: (1) Our optimization improves all baseline models and our own, owing to the normalization of legislative language across US states. (2) The optimization has a reduced impact on RoBERTa compared to Ada. RoBERTa is further hindered by its shorter max sequence length, which limits its ability to utilize the GPT-generated highlights that are, on average, longer than those authored by the researchers in the previous experiment. Conversely, the Ada model sees a 3-point increase in F1 score, due to its advanced features, including a larger number of parameters, enhanced training data, etc. (3) Baseline graph models fail to consider the textual attributes of nodes improved by our optimization, leading to only a modest enhancement derived from the winner/loser relationships identified by GPT. (4) Our joint text and graph model continues to surpass other models in this task, achieving an F1 score of 77.8.

7.5 Analysis of PCT and IG Score Prediction

Next, we focus on the performance of the other two tasks presented in Table 1. For all models, regardless of the inclusion of our LLM-based graph optimization, we observe that predicting legislators' responses to a political courage test (PCT) is more challenging than predicting their scores for a certain IG. These PCT questions require legislators to declare their positions on divisive issues during state elections. At times, they address very

specific issues, for which the legislative graph may not provide adequate context (e.g., related bills and votes). This lack of context poses a challenge to the models' learning capabilities and their ability to make accurate predictions. However, IGs have broader agendas (e.g., see the IG mission statement in Section 3). As a result, all models show improved performance on this task, benefiting from a more comprehensive contextual information.

	Joint Model Variations			
	BEST	*EX-IG*	*EX-PCT*	*EX-WL*
Avg. Macro F1	77.8	75.7	76.2	76.3

Table 2: *Weaker versions of the joint model (random split). Ablation study on the impact of different contextual information in the LLM optimized legislative graph.*

7.6 Ablation Study on Legislative Graph

Our legislative graph abstraction, which incorporates various social and political contexts, enhances the understanding of the state-level legislative process. These contexts improve both baseline and joint models across the three prediction tasks. Here, we detail how each component affects the F1 score in the roll-call task (Table 2). In our joint model with the LLM-optimized graph (F1 of 77.8, Table 1), removing IG relations (**EX-IG**) decreases the F1 score by 2.1 points, while excluding courage test relations (**EX-PCT**) and winner/loser relations (**EX-WL**) reduces it by 1.6 and 1.5 points, respectively. Removing multiple contexts simultaneously can diminish the advantages of our joint model over the best text model (Ada). Overall, the text models are unaffected by the exclusion of these contexts, except when utilizing the textual winner/loser information in the GPT bill highlights. To preserve the joint model's superiority, adjusting our loss function has proven effective. We can apply weights to the graph and text components' losses in our model to rely more on the textual embeddings. Note that the baseline graph model (RGCN) experiences a comparable performance drop when different contextual information is excluded.

7.7 Impact of Party- and Time-based Splits

Finally, we compare different models with the time and party split over the LLM-optimized graph. Here we present the results for the best model in each category (shown in Table 3) and make some observations: (1) All models show a lower F1 score when they face a more realistic situation that may include significantly higher unseen nodes—not observed in training data, e.g., newly elected legislators. (2) The time-based split gave us more unseen nodes, which leads to more performance loss. (3) In the party-based splits, we had more Red states than Blue states in our training data (in both settings), so we observed a slightly higher F1 score when the test bills are from Red states. (4) Generally, the baseline graph model (RGCN) performs significantly worse than the text models. This is attributed to its default method of managing and approximating the embeddings of unseen nodes, which is suboptimal and involves combining the embeddings of potential neighboring nodes based on relational weights. Our joint model handles unseen nodes better thanks to our LLM-based entity alignment (Ethics Section), thereby outperforming both the graph and text baselines.

Type	Embedding	Time	Party (Blue)	Party (Red)
Text	Ada	72.1	73.7	74.2
Graph	RGCN	68.5	69.2	70
Joint	Ada+ Txt. RGCN	74.8	75.8	76.5

Table 3: *Time and party-based graph splits. Performance (Avg. Macro F1× 100 in 10 runs) of best models in each category for the Roll-call task when LLM-based legislative graph optimization is enabled.*

8 Summary

In this paper, we introduce an efficient framework for analyzing the state-level legislative process. This framework interconnects legislative activities across U.S. states by creating a national network that includes often-overlooked elements such as interest groups and political stances. Moreover, it is the first to tackle the linguistic complexities of state legislative data by utilizing generative LLMs to normalize, summarize, and enhance this information for improved policy analysis. In addition, we develop a legislative graph abstraction and define several key prediction tasks concerning the interactions between legislators, bills, and interest groups. We design an effective joint LLM and GNN architecture to handle these tasks, which is built to accommodate unseen nodes and support longer texts, thus further leveraging the enhanced linguistic and network contexts. The next section discusses framework limitations and ethical aspects.

Limitations and Ethical Considerations

One of the main challenges of our work is to analyze state legislation in a responsible and ethical way. We are aware that the outcomes of our research and the applications of our models can have significant impacts on how people perceive and evaluate government policies on crucial issues such as health and education. Thus, we want to address limitations and ethical aspects of our work, both in terms of the data we use and the model we develop:

A. Model-Specific Challenges & Considerations

Scaling training and inference:. We aim to improve the inference speed of our joint LLM and GNN model (Yang et al., 2020), which is heavier than a pure LLM or GNN approach. To achieve this, we will explore different techniques, such as graph knowledge distillation (KD), to transfer knowledge from a large and complex teacher model to a smaller and simpler student model. Moreover, we will use more efficient distributed training platforms, such as DeepSpeed (Microsoft, 2023a), offering lower memory and bandwidth requirements than DGL, while maintaining the accuracy and convergence of the original models.

Choice of specific LLM and GNN: Our joint text and graph architecture supports various LLM and GNN providers. We chose OpenAI GPT/Ada and RGCN as our LLM and GNN models, respectively, due to their popularity and performance. This allowed us to stay focused on our contributions, e.g., the benefits of optimizing legislative graph data using generative LLMs; and handling key political science tasks using our shared LLM and GNN architecture. For the latter, we compared our approach with the solo LLM models, which are unable to prioritize key contexts and players in the legislative process, and the solo GNN models, which miss out on crucial linguistic dependencies and information. In Appendix C.4, we explore the possibility of using open-source models, e.g., Phi-2 and Llama-2, in our framework.

Improving handling of unseen entities. RGCN uses neighbor estimation and inductive inference to handle unseen nodes. To realize that in our framework, initially, we established neighborhood relations for unseen nodes by performing heuristic exact matches on their textual attributes (e.g., party of legislators). Later, we improved this by devising an LLM-based entity alignment algorithm. To determine neighbors of an unseen node, we sample a finite set of nodes of the same type in the same US state. Then, we compute cosine similarity over the node's LLM (Ada) text embedding and that of other nodes in the graph. This gives our text-attributed RGCN a very effective set of neighbors to generate the graph embedding of each unseen node based on that of its neighbors. Injecting the unseen nodes in the train graph and further fine-tuning the model could be a future improvement.

B. Data-Specific Limitations & Considerations

Select bill actions. In this study, we have focused on "floor vote" or "roll call vote" that is a vote taken by the full membership of either chamber of the state legislature on a bill that has been debated on the floor. Our framework supports other bill actions, detailed in Appendix A.1, e.g., Introduction, Committee Review, Governor's Action.

Handling abstain votes. We did not consider abstain votes (marked as absent or N/A) in our study. While our proposed model can handle them, we did not study them as they are very rare. We think predicting abstain votes is an interesting problem that deserves further exploration in future work.

Data source licensing and bias. In our study, we have gathered state-level legislative data primarily from Vote Smart (VoteSmart, 2023). As a non-profit organization, Vote Smart offers free, trustworthy, and unbiased info. about U.S. political figures. They analyze public data from diverse sources, including legislative votes, campaign funding reports, public speeches, interest group ratings, and personal backgrounds. Additionally, VoteSmart actively promotes API usage and supports 3rd party development to empower civic engagement and informed decision-making during elections.

Data Leakage and copy-cat bills. Copycat bills are model bills that are replicated across states, often by interest and lobbying groups (ALEC, 2023). These bills present an intriguing challenge for political science research. However, we believe that they did not significantly impact our study and results. Our dataset, based on Vote Smart, only includes topical and novel legislation, excluding copycat bills (Section 5). Even if such bills were present in our dataset, our evaluation remains fair and consistent, as all models utilize the same data. Looking ahead, we aim to extend our architecture to identify and classify copycat bills as a new task. Achieving this would require either automatic (LLM) or human annotation of state bills.

A Appendix: State Legislative Process

In this appendix, we provide a more detailed discussion on the state-level legislative process and its importance.

A.1 Background

In this paper, we focused on "floor vote" or "roll call vote", as explained in the Ethics section. A state bill is a proposed law that must go through several stages in both houses of the legislature before becoming a law. The process is similar for the House (upper chamber) and the Senate (lower chamber), but with some variations. The main stages are: (1) Introduction: A legislator proposes a bill and gives it to the clerk of their respective house. The bill gets a number, a title, and a committee. (2) Committee Review: The committee reviews the bill and decides whether to support it, oppose it, or make changes to it. The committee can also ignore the bill and let it die. (3) Floor action: The house votes on the bill after debating and amending it. The bill needs a majority vote to pass and go to the other house. (4) Second floor action: The second house repeats the same steps as the first house. If the second house agrees with the first house, the bill goes to the governor. If the second house disagrees with the first house, they can try to reach a compromise through a conference committee. (5) Governor's action: The governor can sign the bill into law, veto it, or do nothing. The legislature can override the governor's veto with a two-thirds vote in both houses.

A.2 National Impact of State Legislation

The impact of state bills and laws is not limited to the state level. They also influence national matters, as federal courts often respect the states' decisions on constitutional questions (see examples of the federal abstention doctrine in Table 4). Moreover, some state laws have inspired or provoked the enactment of federal laws (See examples in Table 5).

1	In Sprint Communications, Inc. v. Jacobs (2013), the Supreme Court said that federal courts should not hear a case about a state agency's regulation of telecom rates, as the state had a specific process for reviewing and appealing such issues.
2	In Google LLC v. Oracle America, Inc. (2021), the Supreme Court did not review a state court decision that said that Google's use of Oracle's software code was fair use under federal copyright law, because the state court followed federal law correctly and there was no disagreement with other federal rulings.

Table 4: *Examples of the abstention doctrine, a principle that guides federal courts to avoid deciding constitutional issues if there is a state law issue that could resolve the case.*

1	The state of California passed a legislation in 2018 that mandated ISPs to not discriminate any web traffic based on its origin or content. This legislation was a response to the FCC's decision to revoke net neutrality, which had ensured equal access to the internet for all users. The California legislation inspired other states to propose similar laws, and also triggered a discussion in Congress about whether to reinstate net neutrality at the national level.
2	Several states have legalized the use of marijuana for recreational purposes by adults since 2012, when Colorado and Washington became the first ones to do so. This has created a contrast with the federal ban on cannabis, and has increased the demand for the federal government to change its drug policy. The legal marijuana industry also poses challenges and opportunities for regulation, public health and safety, and states' rights.

Table 5: *Some examples of how state bills have inspired or influenced the enactment of federal laws.*

B Appendix: Data & Experimental Details

Here, we include more details about our dataset as well as experiments:

B.1 Categorizing States: Red, Purple, Blue

In Section 7, we categorized each U.S. state as red, purple, or blue. However, there is no definitive or official way to classify states as red, purple, or blue based on solely their state legislatures. Different sources may use different criteria or thresholds to determine the color of a state. For example, some sources may consider a state purple if it has a divided government, meaning the governor and at least one chamber of the state legislature belong to different parties. Other sources consider a state purple if it has a close partisan balance in both chambers of the state legislature, meaning neither party has a large majority. We adopt the definition of partisan lean proposed by (FiveThirtyEight, 2023). This metric represents the average margin difference between a state's voting pattern and the national average in congressional and gubernatorial elections. It incorporates data from both presidential and state-legislative election results:

- **Red states:** States with a partisan lean of R+10 or more

- **Blue states**: States with a partisan lean of D+10 or more.
- **Purple states:** States with a partisan lean between R+10 and D+10.

Using this method, here is the list of red, purple, and blue state. As can be seen from the list, there are more red states than blue or purple states:

- **Red states (22):** Alabama, Alaska, Arkansas, Idaho, Indiana, Kansas, Kentucky, Louisiana, Mississippi, Missouri, Montana, Nebraska, North Dakota, Ohio, Oklahoma, South Carolina, South Dakota, Tennessee, Texas, Utah, West Virginia, Wyoming.
- **Blue states (13):** California, Connecticut, Delaware, Hawaii, Illinois, Maryland, Massachusetts, New Jersey, New York, Oregon, Rhode Island, Vermont, Washington.
- **Purple states (15):** Arizona, Colorado, Florida, Georgia, Iowa, Maine, Michigan, Minnesota, Nevada, New Hampshire, North Carolina, Pennsylvania, New Mexico, Virginia, Wisconsin.

B.2 Calculating Interest Group (IG) Scores

We explained how our model benefits from and uses the interest group (IG) scores of legislators in Sections 3 and 6. Here, we provide additional details on how these IG scores are calculated and processed by Vote Smart. These scores are often publicized by interest groups (IGs) in an attempt to influence the future behavior of legislators. The IG scores we collected from Vote Smart are represented as percentages ranging from 0 to 100. There are several ways in which these scores are adjusted by Vote Smart

- The vast majority of the interest groups use a 0-100 system for rating candidates, so Vote Smart simply consumes the rating already provided to it.
- Some interest groups provide a list of recent legislation that the interest group was for and against and show how each legislator voted on that legislation. Vote Smart easily takes this data and calculates a percentage that represents how often a legislator voted in favor of the interest group's legislative position (most interest groups that actually list a 0-100 score do so through this exact method).
- Some interest groups use letter grades to rate candidates. If this is the case Vote Smart uses a basic linear equation to turn these grades into numbers on a 0-100 scale. Vote Smart assigns the lowest possible letter grade a score of "0", the highest possible grade a score of "100", and then use an equation to assign scores for all other possible grades the candidate could receive.
- Some interest groups have other ways of rating candidates. Vote Smart studies any such rating system carefully and try to develop a fair way to turn the rating into a number on a 0-100 scale. If there is no fair or accurate way to translate the rating to a 0-100 grade, Vote Smart simply does not post it.

B.3 Details of Political Courage Tests (PCT)

In Section 5, we provided an overview of the Political Courage Tests (PCTs) data that we have gathered. Here, we delve into more details on how these tests have evolved over time and why we should infer legislators' response to them (Section 6). The PCT asks state candidates who want to be elected to answer questions about different topics that will be crucial in the upcoming term. The test is made with the help of more than 200 experts from different fields and political views. The test answers are shown on Vote Smart's website, helping voters learn more about their options. The test also encourages candidates be honest and responsible for their views. Overall, these tests are optional and usually available during elections. If candidates take them, their answers are shared with the public. Also, the questions in the PCT could be slightly different across states and election years.

Predicting legislators' responses to these tests are crucial, as the number of candidates who take the PCT has gone down, from 72% in 1996 to 48% in 2008 and to 20% in 2016 (WashingtonMonthly, 2023). The reason is that candidates from both parties are scared that their rivals will use their answers to attack them in ads. Rep. Anne Gannon, a Democratic leader in the Florida House of Representatives, said: "We tell our candidates not to do it. It sets them up for a hit piece.". To change this, Vote Smart has tried to make motivate candidates to take the test, and allows them to skip up to 30% of the questions (Journal, 2023). Note that If a candidate does not select a response to any part or all of any question, it does not necessarily indicate that

the candidate is opposed to that particular item.

B.4 Evaluation Details: Need for Normalizing Language of State Bills

State legislative texts often exhibit inconsistent, verbose, and complex language (Sections 1, 3). Here, we present an experiment to underscore the necessity of normalizing the text and language used in these bills. To achieve this, we employed a text embedding and classification architecture (The text model based on Roberta, as discussed in Section 7). Next, we compared various ways of representing state legislation: Official title, Official synopsis, and Bill highlights crafted by a centralized team of political science researchers from Vote Smart. The latter option ensures a consistent language across all bills, regardless of the legislator responsible for drafting them. We then applied our study to two classification tasks: (1) Predicting roll-call outcomes (pass/fail); (2) Identifying sharp splits in votes based on the ideological or demographic orientation of legislators, as in (Davoodi et al., 2020). Our results revealed that bill highlights significantly enhance the performance of both classification tasks when compared to using the official titles and synopses. We observed a rather significant improvement of up to 3.5 points in the F1 score.

C Appendix: Additional Evaluation and Experiments

In this appendix, we detail some additional evaluation on our framework:

C.1 Evaluation of LLM-Generated Bill Highlights

We also conducted a brief study on the problem of hallucination. Specifically, We investigated the impact of applying LLM-based optimization to textual information within our legislative graph. Our focus centered on cases where GPT-generated bill highlights contained factually incorrect or unsupported information. In the Ethics section, we discussed the potential risks associated with these phenomena. To evaluate the accuracy of GPT-generated highlights, we conducted a small-scale measurement. We randomly sampled 150 bills and compared the GPT highlights against two ground-truth sources: (1) Highlights written by the Vote Smart researchers; and (2) The full text of the bills. During this evaluation, two annotators assessed the factual correctness of the GPT highlights, without considering informativeness, coherence, or fluency. In 95% of the sampled bills (based on the majority vote), we discovered that GPT-generated highlights were accurate—sometimes even surpassing researcher-written highlights.This finding is further supported by the F1 performance results of our classification tasks (such as roll-call prediction) before and after enabling GPT-based optimization on the legislative graph (Section 7). As part of our future work, we aim to better understand any potential biases introduced by GPT-based summaries into our system. We plan to explore more sensitive classification tasks, including predicting gender-charged voting splits (Davoodi et al., 2020). Additionally, we are considering using MTurk to compare LLM-generated highlights with those written by experts for select bills (Similar to our study in Appendix C.2). It's worth noting that atomic evaluation metrics such as ROUGE and BLEU are not sufficient, as they focus solely on simple n-gram-based matches between the generated summary and the ground truth.

C.2 Evaluation on LLM-based Winner/loser Extraction

In Section 7, we conducted an ablation study on the effect of each additional context within our graph. We showed that adding GPT-generated winners/losers from bill texts to the graph improves our roll-call prediction performance. Here, we use the crowd-sourcing technique, similar to (Davoodi et al., 2022), to further study the effectiveness of our approach:

Questions/Tasks
How many female justices are currently on the US Supreme Court?
Which party currently holds the majority of seats in the US Senate?
What is the main topic of the following bill? *Prevention and control of, emergency and involuntary commitment for, and treatment programs and services for drug dependence.*
Select the entities that would lose benefits from this bill? *Requires Oregon Health Authority to commission independent study of costs and impacts of operating basic health program in Oregon. Specifies parameters of study. Requires a report to Legislative Assembly by November 30, 2014. Appropriates money from General Fund to authority for contract costs to conduct study. Declares emergency, effective on passage.*

Table 6: *Sample questions from our Political Science qualification test.*

Setup and results. We conducted a comparison between the LLM-extracted results and human annotations. We used MTurk to identify the stakeholders who would gain or lose from the bills' policy, regardless of its legislative outcome. Since annotating state bills was difficult for typical MTurk workers, we created a Political Science Qualification test with different tasks (e.g., Sentiment analysis, winner/loser extraction, political knowledge). Table 6 provides an overview of some of the tasks. Then, we selected annotators (mostly US-based) who passed the test with 80% accuracy and added them to our pool. The test had a 30-minute time limit and no retries. We assigned 3 annotators from our pool to each bill highlight (ground-truth Vote Smart) and asked them to assess the impact of bill policies on the stakeholders (the list of stakeholder for each bill was extracted from our LLM analysis). Then, we determined the winners and losers of each bill based on the majority of annotators' choices. If there was still no consensus, we break the tie randomly. Finally, we compared the human-based annotation results from MTurk with those from GPT for 150 bills. In 40% instances where there were differences, we found out that the LLM results were accurate 85% of the time. This further confirmed our method is more accurate and less expensive than human annotation.

C.3 Example of GPT-Generated Bill Highlights

Table 8 shows a sample state bill that were summarized by the GPT 3.5 model.

C.4 Open Source Models: A Case Study of Phi-2 and Llama-2

We built our framework using closed-source OpenAI LLMs (Ada and GPT 3.5), but it can work with any language model that satisfies our performance and reliability criteria. We also explored the possibility of using open source models in our framework (e.g., to reduce the inference cost). We specifically selected the 3.7B parameter Phi-2 (Microsoft, 2023b) from Microsoft and the 7B parameter Llama-2 from Meta as potential alternatives.

Choice of models. These models have much fewer parameters (by an order of magnitude) than the GPT 3.5 model that we used in our study, but they have demonstrated remarkable performance in particular benchmarks. According to Microsoft: "Phi-2 outperforms LLMs such as the 7B Mistral, 13B Llama-2, and even the 70B Llama-2 on some benchmarks. It also matches or surpasses the performance of Google Gemini Nano 2, which is larger in size. The benchmarks include various tasks such as reasoning, language comprehension, mathematics, coding challenges, and more.".

Open Source LLMs	% of summarized test bills			
	0	2	4	8
Llama-2 (13B)	77.8	77.6	75.4	72.1
Phi-2 (2.7B)	77.8	76.2	74.3	70.4

Table 7: *Impact on the F1 performance when incorporating open-source models into our framework during inference for bill highlight generation. Our joint text and graph model was trained using the random split and for the roll-call (RC) task in Table 1.*

Implementation details. We used LM Studio (studio, 2024) to run these open source models with minimal code modification in our framework. LM studio is a solution designed for running and experimenting with different LLMs locally. We opted for LM Studio due to its chat interface, OpenAI-compatible local web server, and seamless integration with HuggingFace models. We communicate with LM Studio by sending HTTP requests to its OpenAI compatible API endpoint locally.

Experimental setup. We present a limited experiment to investigate the feasibility and performance of these models. Due to some challenges that we will explain shortly, we did not train our joint text and graph architecture with these language models; Instead, we use them at the inference stage for generating bill highlights (but not for augmenting the other data in the legislative graph in Section 4). Specifically, we retrieve our model checkpoint trained for roll-call task (Table 1). Then, for a small fraction of bills in the test dataset, we tasked Phi-2/ LLama-2 with creating bill highlights. We continue to rely on GPT for the remaining bills and all legislators during the roll-call inference, *In essence, bill highlights can be generated using various methods during inference, including manual human annotation.* Our underlying OpenAI Ada and RGCN model continue to generate the embeddings and model score in the roll-call prediction task. Finally, we evaluate our joint model's performance using the average F1 score.

Analysis. The open source models Phi-2 and Llama-2 exhibit declining F1 scores based on the increasing proportion of test bills they summarize, as indicated in Table 7. Our observations highlight a decline in the F1 performance when we utilize them, even if only partially,

for summarizing a small subset of bills. Upon analyzing the bill highlights generated by these models (through random sampling, similar to our analysis in Appendix C.1), we identified three primary issues impacting the classification performance: *(1) Incomplete capture of highlights:* These models occasionally fail to capture the essential aspects of bills, resulting in superficial or empty highlights. For instance, in Table 9 and Table 10, both Phi-2 and Llama-2 produced inadequate highlights for an abortion bill when compared to GPT and our ground-truth (Table 8). *(2) Incorrect or overly detailed winners/losers:* Another problem arises when these models generate lists of potential winners or losers associated with bills. We observed a highly detailed and exaggerated list of winners/losers in some cases. In the case of the abortion bill, Llama-2 included unborn children as winners. This issue impacts the underlying efficiency in generating embeddings for these bills. *(3) Factual errors and lack of frequent updates:* More importantly, these models struggle with summarizing newer bills, potentially due to infrequent updates or limited training data. Consequently, their summaries may contain factual errors (such as incorrect dates) or irrelevant information (fake highlights not mentioned in the bill). Consider the case of state bill LD51 titled "An Act To Enact the Maine Insurance Data Security Act" in Maine during 2021. Phi-2 failed to identify any winners or losers for this bill. More importantly, it made a year-related mistake in its summary. Llama-2 inaccurately asserted that insurers were required to notify the Maine Office of the Attorney General (OAG), within 72 hours of detecting a security breach involving sensitive information. However, this requirement was absent from the actual full text of the bill. Notably, GPT did not make any error when summarizing the same bill.

Readiness. While these two open-source models could indeed serve as viable alternatives to the OpenAI GPT model in various problem domains, their performance remains uncertain for our political science problem. Factual error in summarizing bills could significantly impact the public or legislative bodies. Currently, using them for training or scaling up during inference would undermine the purpose of bill summarization in our work, compared to using the official abstract. As part of our future work, we intend to explore even larger open-source models, such as the 70B Llama-2, to overcome these limitations. Additionally, we plan to evaluate the efficiency of these open-source models as an alternative to OpenAI Ada for embedding.

D Appendix: Further Discussion on Related Work

In Sections 1 and 2, we discussed the most recent NLP/ML studies that have developed promising methodologies allowing vast amounts of legislative text to be analyzed and incorporated into models of legislative behavior. However, they have some key limitations: most focus on the centralized federal-level process, miss out on some state-level contextual information (e.g., the influence of local lobbyists), use low-quality and inconsistent state data, have limited support for non-vote prediction tasks, or often rely on traditional NLP/ML architectures. In this section, we delve into additional works that were not fully covered in our related work section 2 due to space limitations.

Incorporating social network contexts. Some recent studies at the congressional level have integrated social context and valuable expert knowledge in the roll-call prediction task. Feng et al. 2022 builds a heterogeneous information network for Congress legislators based on their social network info (Wikipedia information) and expert knowledge (two political think tanks). It uses an RGCN network to embed this network and predict votes. Mou et al. 2021 creates a similar network to predict the voting behavior of Congress legislators using their public statements on Twitter. Mou et al. 2023 employs the same dataset but develops a Pretrained Language Model (PLM) based on legislator's profile (e.g., ideology) and behavior (e.g., voting pattern) to examine different political science tasks (e.g., roll-call prediction). In addition, Spell et al. 2020 develops an embedding model that predicts the frequency and sentiment of congress legislator tweets based on the text of Trump's tweets. It claims that ideal points estimated from votes do not capture this aspect of political preferences for members of Congress. Pujari and Goldwasser 2021 create a joint embedding model for politicians, twitter posts and event information to predict legislators' interest group grades based on their votes. Roy et al. 2021 use both text and twitter network information to predict moral stances by politicians using a neuro-symbolic modeling approach (Pacheco and Goldwasser, 2021)

We use political courage tests to measure the

Title	Prohibits Abortions After 15 Weeks
Synopsis	A vote to pass a bill that prohibits abortions after 15 weeks with no exceptions for rape, incest, or human trafficking.
VoteSmart	• Prohibits a physician from performing an abortion for individual if they determine that the gestational age of the fetus is more than 15 weeks, without exceptions for rape, incest, or human trafficking (Sec. 4). • Requires the director of any medical facility in which abortions are performed to submit a monthly report each month to the state legisalture documenting the medical and surgical procedures done including the number of abortions (Sec. 5). • Specifies that this act shall take effect July 1, 2022 (Sec. 8).
GPT	House Bill HB 5, titled "Prohibits Abortions After 15 Weeks in FL," aims to restrict access to abortions in the state of Florida by prohibiting the procedure after 15 weeks of pregnancy. Here are some detailed highlights of the bill, as well as potential winners and losers: **Highlights:** 1. **Abortion Prohibition:** The bill prohibits abortions after 15 weeks of pregnancy, except in cases where the mother's life is at risk or if there are lethal fetal anomalies. 2. **Criminal Penalties:** It imposes criminal penalties on healthcare providers who perform abortions after 15 weeks, with potential charges ranging from a third-degree felony to a first-degree felony, depending on the circumstances. 3. **Informed Consent and Ultrasounds:** The bill requires healthcare providers to perform an ultrasound and allow the pregnant person to view it before performing an abortion. They must also provide certain information to the patient about the ultrasound images. 4. **Reporting Requirements:** The bill imposes additional reporting requirements on healthcare providers who perform abortions, including reporting specified information to the state's Agency for Health Care Administration. **Potential Winners:** 1. **Pro-Life Advocates:** Supporters of the bill argue that it protects the rights and lives of unborn children, and they view any limitation on abortion as a step in the right direction. 2. **Religious and Conservative Groups:** The bill aligns with the beliefs and values of religious and conservative groups that oppose abortion. **Potential Losers:** 1. **Abortion Rights Advocates:** Those who support a woman's right to choose may oppose this bill, as it limits access to abortions beyond the 15-week mark. 2. **Healthcare Providers:** The bill puts healthcare providers in a difficult position by potentially subjecting them to criminal charges if they perform abortions after 15 weeks, even in cases where the pregnant person's health is at risk.

Table 8: *Abortion Bill: Comparing bill title, synopsis, researcher-written highlights and GPT-generated highlights.*

Title	Prohibits Abortions After 15 Weeks
Synopsis	A vote to pass a bill that prohibits abortions after 15 weeks with no exceptions for rape, incest, or human trafficking.
Phi-2	House Bill HB 5, titled "Vote to pass a bill that prohibits abortions after 15 weeks with no exceptions for rape, incest, or human trafficking," aims to restrict access to abortion in Florida. Here are the detailed highlights of the bill and potential winners and losers: **Highlights:** 1. Prohibits abortions after 15 weeks of pregnancy, with no exceptions for rape, incest, or human trafficking **Potential Winners:** 1. **Pro-life advocates:** The passage of this bill is a victory for pro-life advocates who are passionate about protecting the rights of unborn babies. It reflects their efforts to restrict access to abortion and promote the value of human life from conception until birth. 2. **Parental rights:** This bill supports parental rights by allowing parents or guardians to be notified before an abortion is performed on a minor, ensuring that they have the opportunity to make informed decisions about their child's healthcare. **Potential Losers:** 1. **Women seeking abortions:** The passage of this bill limits access to safe and legal abortion for women who are 15 weeks pregnant. It may force them to carry a pregnancy to term or seek unsafe alternatives if they cannot travel out of state. 2. **Healthcare providers:** This bill places additional restrictions on healthcare providers, requiring them to adhere to specific guidelines when performing abortions after 15 weeks. This may impact their ability to provide comprehensive and timely care to patients. 3. **Rape and incest victims:** The bill does not make any exceptions for victims of rape or incest, which can have serious implications for those who are already vulnerable. 4. **Human trafficking victims:** Similarly, the bill's lack of exceptions for rape and incest can have serious implications for members of the LGBTQ+ community, who may be more likely to experience sexual violence and its aftermath. 5. **Low-income individuals and families:** The bill's restrictions on abortion access may disproportionately impact low-income individuals and families, who may have limited access to healthcare resources and support. Overall, the passage of House Bill HB 5 has significant implications for reproductive rights in Florida, and highlights the ongoing debate around access to safe and legal abortion in the United States.

Table 9: *Abortion Bill: Phi-2 generated bill highlights.*

Title	Prohibits Abortions After 15 Weeks
Synopsis	A vote to pass a bill that prohibits abortions after 15 weeks with no exceptions for rape, incest, or human trafficking.
Llama-2	House Bill HB 5, also known as the "Pro-Life Act," aims to prohibit abortions after 15 weeks of gestation in Florida. Here are some potential winners and losers of this bill: **Highlights:** 1. **N/A** **Potential Winners:** 1. **Anti-abortion groups:** The bill would greatly restrict access to abortion, which is a fundamental right guaranteed by the US Constitution. This would be a huge victory for anti-abortion groups, who have long sought to limit or ban abortion in Florida and across the country. 2. **Unborn children:** By prohibiting abortions after 15 weeks, the bill would save the lives of thousands of unborn children who might have been terminated through abortion. This could be seen as a moral victory for those who believe that every life is precious and should be protected. 3. **Pro-Life lawmakers:** The passage of HB 5 would be a major achievement for pro-life lawmakers in Florida, who have been working tirelessly to restrict abortion access. It would demonstrate their commitment to protecting the unborn and upholding their pro-life beliefs. 4. **Religious groups:** Many religious groups, particularly those with strong anti-abortion stances, would likely view the passage of HB 5 as a moral victory. They might see it as a way to uphold their religious beliefs and values, which may prioritize the protection of human life. **Potential Losers:** 1. **Women's rights groups:** The passage of HB 5 would be a significant blow to women's rights groups in Florida, who have long advocated for reproductive freedom and access to safe and legal abortion. They may see this bill as an attack on their constitutional rights and a violation of the autonomy of women to make decisions about their own bodies. 2. **Obstetricians and gynecologists:** The ban on abortions after 15 weeks would directly impact obstetricians and gynecologists, who may lose business and face legal challenges if they continue to provide abortion services beyond that gestation limit. 3. **Women's health clinics:** Women's health clinics that provide abortion services could be forced to close their doors or risk being sued for violating the new law. This would result in the loss of access to reproductive healthcare for thousands of women in Florida. 4. **Pro-Choice lawmakers:** The passage of HB 5 would be a significant defeat for pro-choice lawmakers who have been working to protect and expand access to safe and legal abortion. They may see this bill as an attack on their constituents' rights and a violation of the US Constitution. It is important to note that HB 5, or any other anti-abortion legislation, is likely to face legal challenges and could be blocked by court orders before it can be implemented. Additionally, there may be political fallout for lawmakers who support such bills, as they may lose votes and face backlash from constituents who value reproductive freedom.

Table 10: *Abortion Bill: Llama-2 generated bill highlights.*

public positions of state legislators, which are more reliable, official, and indicative of their preferences than other methods, according to our ablation studies. According to our small-scale data collection and analysis, state legislators have distinct patterns of Twitter usage compared to other federal-level political actors. Firstly, state legislators tweet less frequently and tend to focus on personal or non-political topics rather than policy issues or partisan debates. Secondly, they do not interact much with their followers or other politicians on the platform, indicating a low level of engagement and dialogue. Thirdly, our attempt to use Twitter data to complete missing profiles for some state legislators did not yield significant improvement in our results.

Incorporating Interest groups context. Our framework uses interest group (IG) data for analyzing the state legislative process. Our framework extends the traditional political science research that mostly focuses on the impact of interest groups on Federal legislation. For instance, Chand and Schreckhise 2013 investigated the criteria that IGs use to rate US senators according to their policy views and votes. The authors use a simple statistical model to demonstrate that IGs take into account senators' ideology, party, seniority, committee, and state characteristics. Jackson and Kingdon 1992 examine the role of ideology and IG scores in shaping roll-call voting in Congress. The authors estimate the ideological positions of legislators and IGs with a Bayesian model, and find that both factors influence voting behavior, especially for moderate legislators. Gilens and Page 2014 assess how US policies align with different citizens' preferences. The authors compare average citizens, economic elites, and interest groups' opinions and outcomes. They show that elites and groups affect policies, while citizens have little impact.

DEMUX: Data-efficient Multilingual Learning

Simran Khanuja **Srinivas Gowriraj** **Lucio Dery** **Graham Neubig**

Carnegie Mellon University
{skhanuja,sgowrira,ldery,gneubig}@cs.cmu.edu

Abstract

Pre-trained multilingual models have enabled deployment of NLP technologies for multiple languages. However, optimally fine-tuning these models under an annotation budget, such that performance on desired target languages is jointly maximized, still remains an open question. In this paper, we introduce DEMUX, a framework that prescribes the exact data-points to label from vast amounts of unlabelled multilingual data, having unknown degrees of overlap with the target set. Unlike most prior works, our end-to-end framework is language-agnostic, accounts for model representations, and supports multilingual target configurations. Our active learning strategies rely upon distance and uncertainty measures to select task-specific neighbors that are most informative to label, given a model. DEMUX outperforms strong baselines in 84% of the test cases, in the zero-shot setting of disjoint source and target language sets (including multilingual target pools), across three models and four tasks. Notably, in low-budget settings (5-100 examples), we observe gains of up to 8-11 F1 points. Our code is released here[1].

1 Introduction

Picture this: Company **Y**, a healthcare technology firm in India, has recently expanded their virtual assistance services to cover remote locations in Nepal and Bhutan. Unfortunately, their custom-trained virtual assistant is struggling with the influx of new multilingual data, most of which is in Dzongkha and Tharu, but unindentifiable by non-native researchers at **Y**. How can they improve this model? Following current approaches, they first attempt to discern the languages the data belongs to, but commercial language identification systems (LangID) are incapable of this task[2]. Assuming this hurdle is crossed, Company **Y** then seeks out annotators fluent in these languages, but this also fails given crowd-sourcing platforms' lack of support for the above languages[3]. As an alternative, they decide to use tools that identify best languages for transfer, but these either rely on linguistic feature information – missing for Dzongkha and Tharu[4] (Lin et al., 2019), past model performances – expensive to obtain (Srinivasan et al., 2022) or don't support multilingual targets (Lin et al., 2019; Kumar et al., 2022). Based on annotator availability, they eventually choose Nepali and Tibetan as optimal transfer languages, and collect unlabelled corpora from news articles, social media and online documents. Even assuming all the preceding challenges are surmounted, a final question remains unaddressed by the traditional pipeline: *how do they select the exact data points to give to annotators for best performance in their domain-specific custom model, under a fixed budget?*

In this work, we aim to provide a solution to the above problem by introducing DEMUX, an end-to-end framework that replaces the pipelined approach to multilingual data annotation (Figure 1). By directly selecting datapoints to annotate, DEMUX bypasses several stages of the pipeline, that are barriers for most languages. The alleviation of needing to identify the target languages itself (*Step 1*: Figure 1), implies that it can be used for noisy, unidentifiable, or code-mixed targets.

DEMUX makes decisions at the instance level by using information about the pre-trained multilingual language model's (MultiLM's) representation space. This ensures that the data annotation process is aware of the model ultimately being utilized. Concretely, we draw from the principles of active learning (AL) (Cohn et al., 1996; Settles, 2009) for guidance on model-aware criteria for point selection. AL aims to identify the most informative

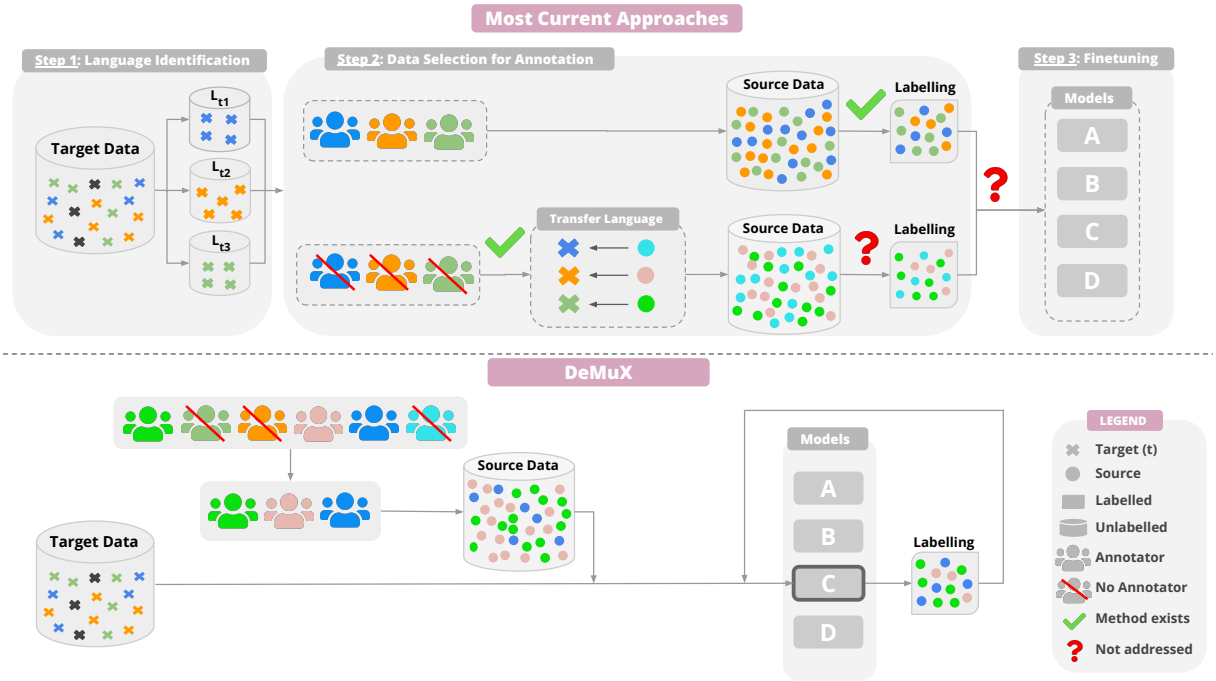

Figure 1: *Top:* Today, improving the performance of a model on multilingual target data is a three-step process. First, one would identify the target languages. Next, they would either collect data to label in these languages, or closely related transfer languages, based on annotator availability. Finally, they would fine-tune a model on the labelled data. However *Step 1* excludes 98% of the world's languages, *Step 2* is constrained by annotators or linguistic feature information, and *Step 3* of factoring in the model to fine-tune, largely remains unaccounted for. *Bottom:* With our end-to-end framework DEMUX, we prescribe the exact data to label from a vast pool of multilingual source data, that provides for best transfer to the target, for a given model.

points (to a specific model) to label from a stream of unlabelled source data. Through iterations of model training, data acquisition and human annotation, the goal is to achieve satisfactory performance on a target test set, labelling only a small fraction of the data. Past works (Chaudhary et al., 2019; Kumar et al., 2022; Moniz et al., 2022) have leveraged AL in the special case where the same language(s) constitute the source and target set (*Step 2 (upper branch)*: Figure 1). However, none so far have considered the case of source and target languages having unknown degrees of overlap; a far more pervasive problem for real-world applications that commonly build classifiers on multi-domain data (Dredze and Crammer, 2008). From the AL lens, this is particularly challenging since conventional strategies of choosing the most uncertain samples (Settles, 2009), could pick distracting examples from very dissimilar language distributions (Longpre et al., 2022). Our strategies are designed to deal with this distribution shift by leveraging small amounts of unlabelled data in target languages.

In the rest of the paper, we first describe three AL strategies based on the principles of a) semantic similarity with the target; b) uncertainty; and c) a combination of the two, which picks uncertain points in target points' local neighborhood (§3). We experiment with tasks of varying complexity, categorized based on their label structure: token-level (NER and POS), sequence-level (NLI), and question answering (QA). We test our strategies in a zero-shot setting across three MultiLMs and five target language configurations, for a budget of 10,000 examples acquired in five AL rounds (§4).

We find that our strategies outperform previous baselines in most cases, including those with multilingual target sets. The extent varies, based on the budget, the task, the languages and models (§5). Overall, we observe that the hybrid strategy performs best for token-level tasks, but picking globally uncertain points gains precedence for NLI and QA. To test the applicability of DEMUX in resource constrained settings, we experiment with lower budgets ranging from 5-1000 examples, acquired in a single AL round. In this setting, we observe gains of upto 8-11 F1 points for token-level tasks, and 2-5 F1 for complex tasks like NLI and QA.

2 Notation

Assume that we have a set of source languages, $L_s = \{l_s^1 \dots l_s^n\}$, and a set of target languages, $L_t = \{l_t^1 \dots l_t^m\}$. L_s and L_t are assumed to have unknown degrees of overlap.

Further, let us denote the corpus of unlabelled source data as $\mathcal{X}_s = \{x_s^1 \dots x_s^N\}$ and the unlabelled target data as $\mathcal{X}_t = \{x_t^1 \dots x_t^M\}$.

Our objective is to label a total budget of B data points over K AL rounds from the source data. The points to select in each round can then be calculated by $b = \frac{B}{K}$. Thus considering the super-set $\mathcal{S}^b = \{\mathbf{X} \subset \mathcal{X}_s \mid |\mathbf{X}| = b\}$ of all b-sized subsets of $\mathcal{X}_s$, our objective is to select some $\mathbf{X}^* \in \mathcal{S}^b$ according to an appropriate criterion.

3 Annotation Strategies

Based on the broad categorizations of AL methods as defined by Zhang et al. (2022), we design three annotation strategies that are either *representation-based*, *information-based*, or *hybrid*. The first picks instances that capture the diversity of the dataset; the second picks the most uncertain points which are informative to learn a robust decision boundary; and the third focuses on optimally combining both criteria. In contrast to the standard AL setup, there are two added complexities in our framework: a) source-target domain mismatch; b) multiple distributions for each of our target languages. We therefore design our measures to select samples that are semantically similar (from the perspective of the MultiLM) to the target domain (Longpre et al., 2022).

All strategies build upon reliable distance and uncertainty measures, whose implementation varies based on the type of task, i.e. whether the task is token-level, sequence-level or question answering. A detailed visualization of how these are calculated can be found in §A.1. Below, we formally describe the three strategies, also detailing the motivation behind our choices.

3.1 AVERAGE-DIST

AVERAGE-DIST constructs the set $\mathbf{X}^*$ such that it minimizes the average distance of points from $\mathcal{X}_t$ under an embedding function $f : \mathcal{X} \rightarrow \mathcal{R}^d$ defined by the MultiLM. This is a representation-based strategy that picks points lying close to the unlabelled target pool (McCallum et al., 1998; Settles and Craven, 2008). The source points chosen are informative since they are prototypical of the target data in the representation space (Figure 2a). Especially for low degrees of overlap between source and target data distributions, this criterion can ignore uninformative source points. Formally,

$$\mathbf{X}^* = \text{argmin}_{\mathbf{X} \in \mathcal{S}^b} \sum_{x_s \in \mathbf{X}} d_t(x_s)$$

Where

$$d_t(x) = \frac{1}{|\mathcal{X}_t|} \sum_{x_t^j \in \mathcal{X}_t} \left\| f(x) - f\left(x_t^j\right) \right\|$$

For all task types, we use embeddings of tokens fed into the final classifier, to represent the whole sequence. For NLI and QA, this is the [CLS] token embedding. For token-level tasks, we compute the mean of the initial sub-word token embeddings for each word, as this is the input provided to the classifier to determine the word-level tag.

3.2 UNCERTAINTY

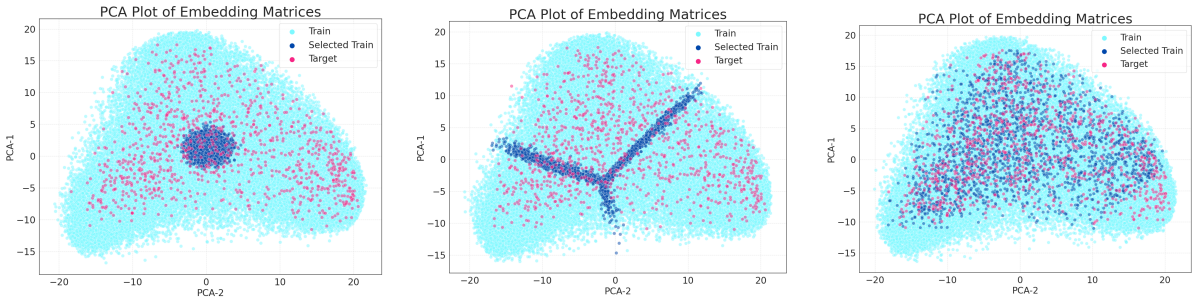
Uncertainty sampling (Lewis, 1995) improves annotation efficiency by choosing points that the model would potentially misclassify in the current AL iteration. Uncertainty measures for each task-type can be found below:

Sequence-Level: We use margin-sampling (Scheffer et al., 2001; Schein and Ungar, 2007), which selects points having the least difference between the model's probabilities for the top-two classes. We compute the output probability distribution for all unlabeled samples in $\mathcal{X}_s$ and select samples with the smallest margin. Formally,

$$\mathbf{X}^* = \text{argmin}_{\mathbf{X} \in \mathcal{S}^b} \sum_{x_s \in \mathbf{X}} P_\Delta(x_s)$$

Where

$$P_\Delta(x) = p_{c_1}(x) - p_{c_2}(x)$$



$p_{c_1}(x)$ and $p_{c_2}(x)$ are the predicted probabilities of the top-two classes for an unlabeled sample x.

Token-level: For token-level tasks we first compute the margin (as described above) for each token in the sequence. Then, we assign the minimum margin across all tokens as the sequence margin score and choose construct $\mathbf{X}^*$ with sequences having the least score. Formally,

$$\mathbf{X}^* = \text{argmin}_{\mathbf{X} \in \mathcal{S}^b} \sum_{x_s \in \mathbf{X}} \texttt{MARGIN-MIN}(x_s)$$

Where

$$\texttt{MARGIN-MIN}(x) = \min_{i=1}^{|x|} \left(p_{c_1}^i(x) - p_{c_2}^i(x)\right)$$

(a) AVERAGE-DIST (b) UNCERTAINTY (c) KNN-UNCERTAINTY

Figure 2: *Visualization of datapoints selected using strategies detailed in Section 3*, for a three-class sequence classification task (XNLI). AVERAGE-DIST selects points (dark blue) at a minimum average distance from the target (pink); UNCERTAINTY selects most uncertain points lying at the decision boundary of two classes, and KNN-UNCERTAINTY selects uncertain points in the target neighborhood.

Question Answering: The QA task we investigate involves extracting the answer span from a relevant context for a given question. This is achieved by selecting tokens with the highest start and end probabilities as the boundaries, and predicting tokens within this range as the answer. Hence, samples having the lowest start and end probabilities, qualify as most uncertain. Formally,

$$\mathbf{X}^* = \text{argmin}_{\mathbf{X} \in \mathcal{S}^b} \sum_{x_s \in \mathbf{X}} \texttt{SUM-PROB}\,(x_s)$$

Where

$$\texttt{SUM-PROB}\,(x) = \max_{i=1}^{|x|} \log p_s^i(x) + \max_{i=1}^{|x|} \log p_e^i(x)$$

Above, $|x|$ denotes the sequence length of the unlabeled sample x, and $p_s^i(x)$ and $p_e^i(x)$ represent the predicted probabilities for the start and end index, respectively.

3.3 KNN-UNCERTAINTY

As standalone measures, both distance and uncertainty based criteria have shortcomings. When there is little overlap between source and target, choosing source points based on UNCERTAINTY alone leads to selecting data that are uninformative to the target. When there is high degrees of overlap between source and target, the AVERAGE-DIST metric tends to produce a highly concentrated set of points (Figure 2a) – even if the model is accurate in that region of representation space – resulting in minimal coverage on the target set.

To design a strategy that combines the strengths of both distance and uncertainty, we first measure how well a target point's uncertainty correlates with its neighborhood. We calculate the Pearson's correlation coefficient (ρ) (Pearson, 1903) between the uncertainty of a target point in $\mathcal{X}_t$ and the average uncertainty of its top-k neighbors in $\mathcal{X}_s$. We observe a statistically significant ρ value > 0.7, for all tasks. A natural conclusion drawn from this is that decreasing the uncertainty of a target point's neighborhood would decrease the uncertainty of the target point itself. Hence, we first select the top-k neighbors for each $x_t \in \mathcal{X}_t$. Next, we choose the most uncertain points from these neighbors until we reach b data points. Formally, until $|\mathbf{X}^*| = b$:

$$\mathbf{X}^* = \text{argmax}_{\{\mathbf{X} \subset \mathcal{N}_t^k \;\mid\; |\mathbf{X}| = b\}} \sum_{x_s \in \mathbf{X}} U(x_s)$$

Where

$$\mathcal{N}_t^k = \bigcup_{j=1}^{|\mathcal{X}_t|} \texttt{k-NEARESTNEIGHBORS}(x_t^j, \mathcal{X}_s)$$

Above, $U(x_s)$ represents the uncertainty of the source point as calculated in §3.2.

4 Experimental Setup

Our setup design aims to address the following:
Q1) Does DEMUX benefit tasks with varying complexity? Which strategies work well across different task types? (§4.1)
Q2) How well does DEMUX perform across a varied set of target languages? Can it benefit multilingual target pools as well? (§4.2)
Q3) How do the benefits of DEMUX vary across different MultiLMs? (§4.3)

4.1 Task and Dataset Selection

We have three distinct task types, based on the label format. We remove duplicates from each dataset to prevent selecting multiple copies of the same instance. Dataset details can be found in Table 1.

Task Type	Task	Dataset	Languages (two-letter ISO code)
Token-level	*Part-of-Speech Tagging* (POS)	Universal Dependencies v2.5 (Nivre et al., 2020)	tl, af, ru, nl, it, de, es, bg, pt, fr, te, et, el, fi, hu, mr, kk, hi, tr, eu, id, fa, ur, he, ar, ta, vi, ko, th, zh, yo, ja
	Named Entity Recognition (NER)	WikiAnn (Rahimi et al., 2019)	nl, pt, bg, it, fr, hu, es, el, vi, fi, et, af, bn, de, tr, tl, hi, ka, sw, ru, mr, ml, jv, fa, eu, ko, ta, ms, he, ur, kk, te, my, ar, id, yo, zh, ja, th
Sequence-Level	*Natural Language Inference* (NLI)	XNLI (Conneau et al., 2018)	es, bg, de, fr, el, vi, ru, zh, tr, th, ar, hi, ur, sw
Question Answering (QA)		TyDiQA (Clark et al., 2020)	id, fi, te, ar, ru, sw, bn, ko

Table 1: *Tasks and Datastes*: DEMUX is applied across tasks of varying complexity, as elucidated in **Q1**: §4.

Dataset	Single Target			Multi-Target	
	HP	MP	LP	Geo	LPP
UDPOS	French	Turkish	Urdu	Telugu, Marathi, Urdu	Arabic, Hebrew, Japanese, Korean, Chinese, Persian, Tamil, Vietnamese, Urdu
NER	French	Turkish	Urdu	Indonesian, Malay, Vietnamese	Arabic, Indonesian, Malay, Hebrew, Japanese, Kazakh, Malay, Tamil, Telugu, Thai, Yoruba, Chinese, Urdu
XNLI	French	Turkish	Urdu	Bulgarian, Greek, Turkish	Arabic, Thai, Swahili, Urdu, Hindi
TyDiQA	Finnish	Arabic	Bengali	Bengali, Telugu	Swahili, Bengali, Korean

Table 2: *Target language configurations*. We run five experiments for each model and task, with the language sets above as targets (details in §4.2). All languages mentioned in Table 1 make up the source set, **except** the chosen target languages for a particular configuration.

4.2 Source and Target Language Selection

We experiment with the zero-shot case of disjoint source and target languages, i.e., the unlabelled source pool contains no data from target languages. The train and validation splits constitute the unlabelled source or target data, respectively. Evaluation is done on the test split for each target language. With **Q2)** in mind, we experiment with five target settings (Table 2):

Single-target: We partition languages into three equal tiers based on zero-shot performance post fine-tuning on English: high-performing (*HP*), mid-performing (*MP*) and low-performing (*LP*), and choose one language from each, guided by two factors. First, we select languages that are common across multiple datasets, to study how data selection for the same language varies across tasks. From these, we choose languages that have similarities with the source set across different linguistic dimensions (obtained using `lang2vec` (Littell et al., 2017)), to study the role of typological similarity for different tasks.

Multi-target: Here, we envision two scenarios:

a) Geo: Mid-to-low performing languages in geographical proximity are chosen. From an application perspective, this would allow one to improve a MultiLM for an entire geographical area.

b) LPP: All low-performing languages are pooled, to test whether we can collectively enhance the MultiLM's performance across all of them.

4.3 Model Selection

We test DEMUX across multiple MultiLMs: *XLM-R* (Conneau et al., 2019), *InfoXLM* (Chi et al., 2020), and *RemBERT* (Chung et al., 2020). All models have a similar number of parameters (∼550M-600M), and support 100+ languages. *XLM-R* is trained on monolingual corpora from CC-100 (Conneau et al., 2019), *InfoXLM* is trained to maximize mutual information between multilingual texts, and *RemBERT* is a deeper model, that reallocates input embedding parameters to the Transformer layers.

4.4 Baselines

1) `RANDOM`: Random subset of b data points from $\mathcal{X}_s$ is selected.

2) `EGALITARIAN`: Equal number of randomly selected data points from the unlabeled pool for each language, i.e. $|x_s| = b/|L_s|$; $\forall x_s \in \mathcal{X}_s$ is chosen. Debnath et al. (2021) demonstrate that this

outperforms a diverse set of alternatives.

3) LITMUS: LITMUS (Srinivasan et al., 2022) is a tool to generate data labeling plans, based on the predictor's projections. We only run this for XLM-R since the tool requires past fine-tuning performance profiles, and XLM-R has default support.

4) GOLD: This involves training on data from the target languages itself. Given all other strategies are zero-shot, we expect GOLD to out-perform them and help determine an upper bound on performance.

4.5 Fine-tuning Details

We fine-tune all MultiLMs on English (EN-FT) and continue fine-tuning on data selected using DEMUX, similar to Lauscher et al. (2020); Kumar et al. (2022). Our budget is 10,000 examples acquired in five AL rounds. For each model, we first obtain EN-FT and continually fine-tune using DEMUX. All results are averaged across three seeds: 2, 22, 42 and further details are in §A.3.

5 Results

How does DEMUX perform overall? We present results for NER, POS, NLI and QA in Tables 3, 4, 5 and 6, respectively. In summary, the best-performing strategies outperform best performing baselines in 84% of the cases, with variable gains dependant on the task, model and target languages. In the remaining cases, the drop is within 1% absolute delta from the best-performing baseline.

How does DEMUX fare on multilingual target pools? We observe consistent gains given multilingual target pools as well (*Geo* and *LPP*). We believe this is enabled by the language-independent design of our strategies, which makes annotation decisions at a per-instance level. This has important consequences, since this would enable researchers, like those at Company **Y**, to better models for all the languages that they care about.

Does the model select data from the same languages across tasks? No! We find that selected data distributions vary across tasks for the same target languages. For example, when the target language is Urdu, DEMUX chooses 70-80% of samples from Hindi for NLI and POS, but prioritizes Farsi and Arabic (35-45%) for NER. Despite Hindi and Urdu's syntactic, genetic, and phonological similarities as per lang2vec, their differing scripts underscore the significance of script similarity in NER transfer. This also proves that analysing data selected by DEMUX can offer linguistic insights into the learned task-specific representations.

.

Which strategies work well across different task types? Our hybrid strategy, which picks uncertain points in the local neighborhood of target points, performs best for token-level tasks, whereas globally uncertain points maximize performance for NLI and QA. For NLI, both AVERAGE-DIST and UNCERTAINTY outperform baselines, the former proving more effective. On further analysis, we find that this is an artifact of the the nature of the dataset which is balanced across three labels, and is strictly parallel. This makes AVERAGE-DIST select high-uncertainty points at decision boundaries'

centroid, as visualized in Figure 2a. Our finding of different strategies working well for different tasks is consistent with past works. For example, Settles and Craven (2008) find information density (identifying semantically similar examples), to work best for sequence-labeling tasks; Marti Roman (2022) discuss how uncertainty-based methods perform best for QA; and Kumar et al. (2022) also recommend task-dependant labeling strategies. By including multiple tasks and testing multiple strategies for each, we provide guidance to everyday practitioners on the best strategy, given a task.

6 Further Analysis

What is the minimum budget for which we can observe gains in one AL round? To deploy DEMUX in resource-constrained settings, we test its applicability in low-budget settings, ranging from 5,10,50,100,250,500,1000, acquired using the EN-FT model only. As shown in Figure 4, we observe gains across all budget levels. Notably, we observe gains of up to 8-11 F1 points for token-level tasks, and 2-5 F1 points for NLI and QA, for most lower budgets (5-100 examples). These gains diminish as the budget increases. For complex tasks like NLI and QA, semantic similarity with the target holds importance when the budgets is below 500 examples, but picking globally uncertain points gains precedence for larger budgets.

Do the selected datapoints matter or does following the language distribution suffice? DEMUX not only identifies transfer languages but also selects specific data for labeling. To evaluate its importance, we establish the language distribution of data selected using DEMUX and randomly select datapoints following this distribution. Despite maintaining this distribution, performance still declines (§A.4), indicating that precise datapoint selection in identified transfer languages is vital.

7 Related Work

Multilingual Fine-tuning: Traditionally models were fine-tuned on English, given the availability of labeled data across all tasks. However, significant transfer gaps were observed across languages (Hu et al., 2020) leading to the emergence of two

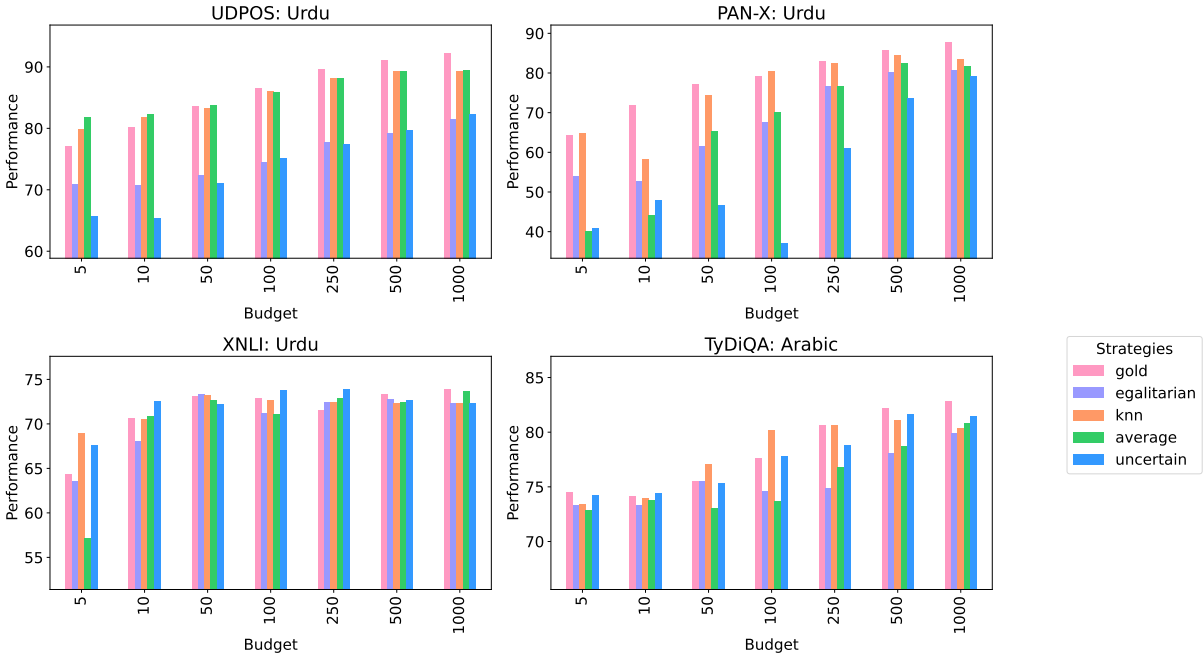

Figure 4: *Multiple budgets, one AL round*: We experiment with low-budgets acquired using the EN-FT model. We observe gains of up to 8-11 F1 over baselines for 5-100 examples, with a trend of diminishing gains given larger budgets. All runs averaged across three seeds (2, 22, 42).

research directions. The first emphasizes the significance of using few-shot target language data (Lauscher et al., 2020) and the development of strategies for optimal few-shot selection (Kumar et al., 2022; Moniz et al., 2022). The second focuses on choosing the best source languages for a target, based on linguistic features (Lin et al., 2019) or past model performances (Srinivasan et al., 2022). Discerning a globally optimal transfer language however, has been largely ambiguous (Pelloni et al., 2022) and the language providing for highest empirical transfer is at times inexplicable by known linguistic relatedness criteria (Pelloni et al., 2022; Turc et al., 2021). By making decisions at a data-instance level rather than a language level, DEMUX removes reliance on linguistic features and sidesteps ambiguous consensus on how MultiLMs learn cross-lingual relations, while prescribing domain-relevant instances to label.

Active learning for NLP: AL has seen wide adoption in NLP, being applied to tasks like text classification (Karlos et al., 2012; Li et al., 2013), named entity recognition (Shen et al., 2017; Wei et al., 2019; Erdmann et al., 2019), and machine translation (Miura et al., 2016; Zhao et al., 2020), among others. In the multilingual context, past works (Moniz et al., 2022; Kumar et al., 2022; Chaudhary et al., 2019) have applied AL to selectively label data in target languages. However, they do not consider cases with unknown overlap between source and target languages. This situation, similar to a multi-domain AL setting, is challenging as data selection from the source languages may not prove beneficial for the target (Longpre et al., 2022).

8 Conclusion

In this work, we introduce DEMUX, an end-to-end framework that selects data to label from vast pools of unlabelled multilingual data, under an annotation budget. DEMUX's design is language-agnostic, making it viable for cases where source and target data do not overlap. We design three strategies drawing from AL principles that encompass semantic similarity with the target, uncertainty, and a hybrid combination of the two. Our strategies outperform strong baselines for 84% of target language configurations (including multilingual target sets) in the extreme case of disjoint source and target languages, across three models and four tasks: NER, UDPOS, NLI and QA. We find that semantic similarity with the target mostly benefits token-level tasks, while picking uncertain points gains precedence for complex tasks like NLI and QA. We further analyse DEMUX's applicability in low-budget settings and observe gains of up to 8-11 F1 points for some tasks, with a trend of diminishing gains for larger budgets.

9 Limitations

With DEMUX's wider applicability across languages come a few limitations as we detail below:

Inference on source data: DEMUX relies on model representations and its output distribution for each example. This requires us to run inference on all of the source data; which can be time-consuming. However, one can run parallel CPU-inference which greatly reduces latency.

Aprior Model Selection: We require knowing the model apriori which might mean a different labeling scheme for different models. This a trade-off we choose in pursuit of better performance for the chosen model, but it may not be the most feasible solution for all users.

Refinement to the hybrid approach: Our hybrid strategy picks the most uncertain points in the neighborhood of the target. However, its current design prioritizes semantic similarity with the target over global uncertainty, since we first pick top-k neighbors and prune this set based on uncertainty. However, it will be interesting to experiment with choosing globally uncertain points first and then pruning the set based on target similarity. For NLI and QA, we observe that globally uncertain points help for higher budgets but choosing nearest neighbors helps most for lower budgets. Therefore, this alternative may work better for these tasks, and is something we look to explore in future work.

A Appendix

A.1 Distance and Uncertainty Measurements

All of our strategies our based on reliable distance and uncertainty measures. Once these are established, it is easy to extend DEMUX to other tasks and models. An overview of how these are measured for the tasks in our study can be found in Figure 5. These are formally described in the paper, in Section 3.

A.2 Uncertainty Details

For token-level tasks, we investigate two strategies. First, we employ the Mean Normalized Log Probability (MNLP) (Shen et al., 2017) method, which has been demonstrated as an effective uncertainty measure for *Named Entity Recognition* (NER). This approach selects instances for which the log probability of model prediction, normalized by sequence length, is the lowest. Formally,

$$\mathbf{X}^* = \text{argmin}_{\mathbf{X} \in \mathcal{S}^b} \sum_{x_s \in \mathbf{X}} \texttt{MNLP}\left(x_s\right)$$

Where

$$\texttt{MNLP}\left(x\right) = \frac{1}{|x|} \sum_{i=1}^{|x|} \log p^i_{c_1}(x)$$

In this equation, $|x|$ denotes the sequence length of the unlabeled sample x, and $p^i_{c_1}(x)$ represents the predicted probability of the most probable class for the i^{th} token in the sequence.

Concurrently, we also explore margin-based uncertainty techniques (MARGIN-MIN). For each token in the sequence, we compute the margin as the difference between the probabilities of the top two classes. Then, we assign the minimum margin across all tokens as the sequence margin score and choose sequences with the smallest margin score. Formally,

$$\mathbf{X}^* = \text{argmin}_{\mathbf{X} \in \mathcal{S}^b} \sum_{x_s \in \mathbf{X}} \texttt{MARGIN-MIN}\left(x_s\right)$$

Where

$$\texttt{MARGIN-MIN}\left(x\right) = \min_{i=1}^{|x|} \left(p^i_{c_1}(x) - p^i_{c_2}(x)\right)$$

We eventually choose the margin based technique given better performance for both token level tasks.

A.3 Fine-tuning Details

We first fine-tune all MultiLMs on English (EN-FT) and continue fine-tuning on data selected using DEMUX, similar to Lauscher et al. (2020); Kumar et al. (2022). We experiment with a budget of 10,000 examples acquired in five AL rounds, except for TyDiQA, where our budget is 5,000 examples (TyDiQA is of the order of 35-40k samples overall across ten languages, and this is to ensure fair comparison with our gold strategy). For each model, we first obtain EN-FT and continually fine-tune using DEMUX. Hyperparameters are in Table 8 and we report average results across three seeds: 2, 22, 42. For UDPOS, we include all languages except Tagalog, Thai, Yoruba and Kazakh, because they do not have training data for the task[5]. We fine-tune using a fixed number of epochs without early stopping, given the lack of a validation set in our setup (we assume no labelled target data).

Fine-tuning is done on a NVIDIA RTX A6000 GPU. Fine-tuning after each data selection round takes 10-15 mins. The bottleneck is inference on all of the source data, to obtain distance and uncertainty measures. Depending on the dataset, the time taken varies from 20 hrs (for 3 seed runs on PAN-X and UDPOS for one target language configuration) to 2 days (for 3 seed runs on XNLI for one target language configuration).

A.4 Detailed Results

The detailed results for the first ablation study where we test DEMUX for multiple budgets in one AL round, can be found in Table 11. Results for the second ablation, where we fine-tune models on randomly selected data that follows the same language distribution as DEMUX, can be found in Table 10.

Abstract

State-of-the-art neural rankers pre-trained on large task-specific training data such as MS-MARCO, have been shown to exhibit strong performance on various ranking tasks without domain adaptation, also called zero-shot. However, zero-shot neural ranking may be sub-optimal, as it does not take advantage of the target domain information. Unfortunately, acquiring sufficiently large and high quality target training data to improve a modern neural ranker can be costly and time-consuming. To address this problem, we propose a new approach to unsupervised domain adaptation for ranking, **DUQGen**, which addresses a critical gap in prior literature, namely how to automatically generate both effective and diverse synthetic training data to fine tune a modern neural ranker for a new domain. Specifically, **DUQGen** produces a more effective representation of the target domain by identifying clusters of similar documents; and generates a more diverse training dataset by probabilistic sampling over the resulting document clusters. Our extensive experiments, over the standard BEIR collection, demonstrate that **DUQGen** consistently outperforms all zero-shot baselines and substantially outperforms the SOTA baselines on 16 out of 18 datasets, for an average of 4% relative improvement across all datasets. We complement our results with a thorough analysis for more in-depth understanding of the proposed method's performance and to identify promising areas for further improvements.

1 Introduction

Large Language Models (LLMs) have enabled new state-of-the-art performance in neural ranking (Yan et al., 2019; Kamps et al., 2020; Hu et al., 2022; Nogueira et al., 2020a). An effective approach has been to train the LLMs on a large-scale general ranking task such as MS-MARCO passage or document ranking (Bajaj et al., 2016) or Wikipedia retrieval (Sun and Duh, 2020), to learn task-specific features, which are often shared across other domains and datasets. The resulting rankers can then be used, without any adaptation (or in a zero-shot way) for a wide range of ranking tasks. For example, the BEIR (Thakur et al., 2021) benchmark had demonstrated SOTA or near-SOTA performance of several zero-shot neural rankers on a diverse set of retrieval tasks.

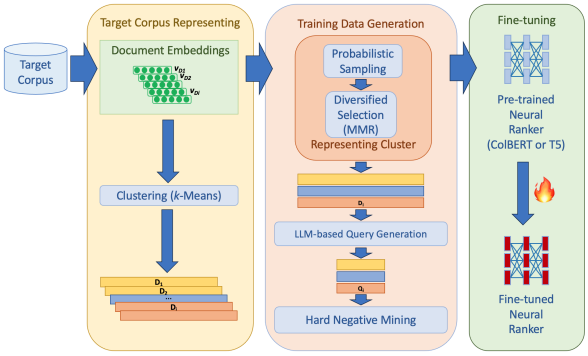

Figure 1: **DUQGen**: an unsupervised domain-adaptation framework for neural ranking.

However, when switching to specialized domains such as finance or scientific documents, zero-shot ranking performance should benefit from additional information for the target domain. For training modern neural rankers, acquiring sufficiently large and high-quality target training data of query-document pairs, to improve a modern neural ranker, can be costly and time-consuming. Hence, there has been significant interest in various approaches to domain adaptation for neural rankers, with varying degrees of supervision, including unsupervised approaches using synthetically generated queries, documents, or both query-document pairs (Sachan et al., 2022; Bonifacio et al., 2022; Jeronymo et al., 2023; Dai et al., 2022; Askari et al., 2023).

Unfortunately, most of the previously reported results did not exceed the ranking performance compared to the current SOTA zero-shot models, as evaluated on the BEIR benchmark (Thakur et al., 2021). In other words, to the best of our knowledge,

Proceedings of the 2024 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies (Volume 1: Long Papers), pages 7437–7451
June 16-21, 2024 ©2024 Association for Computational Linguistics

no previously reported unsupervised ranking adaptation method demonstrated consistent improvements over large neural SOTA zero-shot rankers.

In this work, we investigate whether it possible to improve the ranking performance of a pre-trained SOTA neural ranker for a given target domain, through unsupervised domain adaptation (UDA). To address this question, we first identify a critical requirement for the synthetic training data to be effective for ranking adaptation: that the generated training data should be both *representative of the target domain*, and *sufficiently diverse* to force changes to the ranking model at the appropriate representation level, without causing over-fitting or catastrophic forgetting (i.e., degrading performance on the original ranking tasks).

Specifically, we propose a new method **DUQGen**, which stands for **D**iversified **U**nsupervised **Q**uery **Gen**eration. **DUQGen**introduces a general approach for ranking domain adaptation, which focuses on selecting representative and diverse set of documents and query pairs for training a neural ranker. **DUQGen** only requires access to a (part of) target document collection to be searched, and can improve any pre-trained neural ranker. **DUQGen** is illustrated in Figure 1, and introduces the following innovations compared to previous unsupervised ranking adaptation approaches: (1) representing the target document collection as document *clusters*; (2) diversifying the synthetic query generation by probabilistic sampling over the resulting document clusters; and (3) prompting a large LLM for query generation with in-context examples to generate queries from the selected documents. As we show experimentally, these innovations are responsible for consistent improvements over the previous SOTA baselines for ranking adaptation on almost all BEIR benchmarks, as well as consistent improvements over zero-shot performance of SOTA neural rankers. In summary, our contributions include:

1. **DUQGen**, a general and effective unsupervised approach for domain adaption of neural rankers via synthetic query generation for training.

2. A novel and general method for creating representative and diverse synthetic query data for a given collection via clustering and probabilistic sampling.

3. Comprehensive experiments demonstrating that **DUQGen** consistently outperforms all SOTA baselines on 16 out of 18 BEIR datasets, and thorough analysis of the components of **DUQGen** responsible for the improvements. We release all our code and models publicly[1].

Next, we describe prior work on domain adaptation of neural rankers in more detail, to place our contributions in context.

2 Related Work

In this section, we discuss the prior works that help to establish the problem and navigate the solution.

2.1 Neural Rankers

Recently, transformer-based pre-trained language models have demonstrated impressive effectiveness in neural rankers (Lin et al., 2021b). A neural ranker returns an order list of documents given a query, where a relevancy score between query and document dense embedding representations is used for sorting. Extensive studies have been conducted on both dense retrievers and re-rankers (Mitra and Craswell, 2018). In comparison to encoder-based rankers (MonoBERT and DuoBERT) (Nogueira et al., 2019), encoder-decoder (Nogueira et al., 2020b) and decoder-based (Ma et al., 2023) rankers exhibit notably superior performance with a larger margin. While ColBERT (Khattab and Zaharia, 2020), Contriever (Izacard et al., 2021), and GTR (Ni et al., 2022) perform competitively as dense retrievers, MonoT5-3B (Nogueira et al., 2020b) is widely adapted for re-ranking purposes.

2.2 Unsupervised Domain Adaptation for Neural Rankers

Despite the remarkable ranking performances demonstrated by recent pre-trained language models in zero-shot settings, they often encounter catastrophic failures in real-world deployment scenarios. The main factor contributing to these failures is *Domain-Shift* (Zhu and Hauff, 2022) or *Domain Divergence* (Ramesh Kashyap et al., 2021). Domain-Shift has been a subject of exploration for decades, including recent investigations in domain adaptation (Lupart et al., 2023). Traditionally, it is assumed that the source and target domains share samples drawn from the same distribution. Previous studies have addressed this

[1] https://github.com/emory-irlab/DUQGen

issue by quantifying domain divergence through various measures, such as geometric measures, information-theoretic measures, and higher-order measures (Ramesh Kashyap et al., 2021). Ultimately, these measures contribute to the development of novel solutions for domain adaptation in neural rankers.

Solutions addressing domain divergence typically fall into two categories: (1) representation learning; and (2) data selection. Representation learning approaches primarily address UDA, with a focus on learning domain-invariant representations (Bousmalis et al., 2016; Cohen et al., 2018) or pre-training a zero-shot ranker. On the other hand, data selection assumes that not all samples contribute equally to domain representation (Axelrod et al., 2011), highlighting the importance of identifying effective target domain samples. Improper selection of target data during fine-tuning has the potential to undermine the impact of source pre-training. Our research centers on the issue of improper representation of the target domain leading to diminished performances in neural rankers. Therefore, **DUQGen** aims to identify representative and diverse target samples that can be effective during the fine-tuning process.

2.3 Synthetic IR Data Generation

The increasing power of Large Language models have prompted numerous studies to focus on utilizing LLMs for the creation of high-quality training data. Several previous works have explored unsupervised synthetic data generation for fine-tuning ranking models, including GPL (Wang et al., 2022), InPars (Bonifacio et al., 2022), InPars-v2 (Jeronymo et al., 2023), DocGen-RL (Askari et al., 2023), GenQ (Thakur et al., 2021), and Promptagator (Dai et al., 2022). These frameworks use random document sampling or random seed queries to start their pipelines, which leaves room for improvement.

Each of the previously mentioned works utilizes distinct strategies employed alongside their data synthesis processes. GPL(Wang et al., 2022), for instance, combines a T5-based (Raffel et al., 2020) query generator with a pseudo-labeling cross-encoder to enhance robust learning. InPars and InPars-v2 methods utilize GPT-3 and GPT-J query generators along with different filtering strategies to eliminate low-quality synthetic queries. DocGen-RL introduces an RL-driven guided approach combined with document synthesis using BLOOM (Scao et al., 2022). GenQ, on the other hand, fine-tunes TAS-B (Hofstätter et al., 2021) with queries generated from an MS-MARCO fine-tuned T5-base generator. Promptagator employs a pipeline similar to InPars, but with improved components, such as a random million document samples, a 137B FLAN query generator, and a strong consistency filter to prune 8 million synthetic queries through a relatively complicated and expensive process. Notably, none of the methods mentioned above take into consideration the significance of identifying domain-representative documents or diversifying the resulting queries. Consequently, the fine-tuned performances appears to fall short of zero-shot performances in many cases.

The quality of the generated training queries significantly affects the end retrieval performances. Despite the utilization of strong query generators (BLOOM and GPT-3), the domain query representation can still be improved. For instance, InPars employed a prompt containing in-context examples from MS-MARCO training data, yet it still maintains a domain representation gap during in-context generation. Furthermore, their query generation did not address the need for diversity among the generated training samples. Additionally, they incorporated a complex filtering step to prune the generated queries, which we show can be avoided. These methods fine-tuned rankers using large-scale synthetic data, ranging from 100k to 1M examples. In contrast, we argue that judicious selection of training samples can obviate the necessity for such large-scale generation, reducing the required amount of synthetic training data by a factor of x1000.

3 Methodology

DUQGen, shown in Figure 1, consists of four components – domain document selection, domain query generation, negative pairs mining, and fine-tuning. We now cover each component in detail.

3.1 Domain Document Selection

We propose to represent a target domain with clusters and each clusters with its sampled documents. Therefore, in this section we describe them in three stages, namely collection document clustering, probabilistic document sampling, and diversified document selection.

3.1.1 Collection Document Clustering

Representing a large-scale target collection of documents with limited training data is challenging. Therefore, we propose to divide the collection into portions, and then sample documents within each portion. We use a clustering approach for the collection representation. Moreover, we can achieve diverse topical documents to represent the domain. We start with the full collection of documents and apply a preprocessing step, where we discard short span documents, filtering out noisy documents. Then we use a SOTA text encoder, viz. *Contriever* (Izacard et al., 2021), to encode each of the documents. Using the document embeddings v_{D_i}, we apply clustering (*e.g.,* K-Means) technique, where K is a hyper-parameter to tune.

3.1.2 Probabilistic Document Sampling

Representing each cluster within large data collections is challenging since the resultant clusters can often be of imbalanced sizes. Let's take k^{th} cluster size as c_k and collection size as C, where $(1 \leq c_k \leq C)$. We ideally want to sample more number of documents from larger size clusters in proportion to the cluster size. If $cluster_k$ and D_i represent k^{th} cluster and its i^{th} document, the probability of selecting D_i from $cluster_k$ is $Pr(D_i|cluster_k) \propto c_k \forall D_i \in cluster_k$.

We intend to sample N number of synthetic training examples from K number of clusters, where $N \geq K$. Therefore, we design a stratified expression to determine the document sample size N_k for k^{th} cluster, given by

$$N_k^0 = 1 + \left\lfloor \frac{c_k}{C}(N-K) \right\rfloor$$

$$P = N - \sum_{k=1}^{K} N_k^0$$

$$N_k = \begin{cases} N_k^0 + 1 & \text{if } k \in \text{argsort}_{top-P}(c_k) \\ N_k^0 & \text{if } k \notin \text{argsort}_{top-P}(c_k) \end{cases}$$

where N_k^0 and P are intermediate sample size and integer number. $\lfloor * \rfloor$ operation finds the floor integer value.

Now that we determined the sample size for each clusters, we define our sampling approach. Let's take d_i as the similarity (*e.g. cosine similarity*) between document D_i and its corresponding cluster centroid. We define an exponential value e^{d_i} as the representative of how close D_i is to its cluster centroid. Therefore, $Pr(D_i|cluster_k)$ becomes the normalized softmax given by:

$$Pr(D_i|cluster_k) = \frac{e^{d_i/T}}{\sum_{j=1}^{c_k} e^{d_j/T}} \quad (1)$$

$$d_i = cosine(v_{D_i}, \frac{1}{c_k}\sum_{j=1}^{c_k} v_{D_j}) \quad (2)$$

where T is the softmax temperature and v_{D_i} is the i^{th} document embedding. Intuitively, a document likelihood to be selected to generate an associated query is proportional to the document similarity to its cluster centroid.

3.1.3 Diversified Document Selection

Now we sample N_k number of documents from each cluster $cluster_k$ and pool them to obtain the required training size documents N. Different sample sets can be drawn from the aforementioned sampling approach with different choices of random seed values. Therefore, to improve selection robustness in the sampling process, we apply a diversity measure, namely Maximal Marginal Relevance (MMR) (Carbonell and Goldstein, 1998). We first iterate the sampling process m times ($m = 5$) to obtain different sample sets. Then we apply MMR on the pooled documents from m sets to select top-N_k documents for $cluster_k$ as shown:

$$\begin{aligned} \underset{D_i \in R \setminus S}{\text{argmax}} \Big[& \lambda Sim_1(D_i, D_k) \\ & -(1-\lambda) \max_{D_j \in S} Sim_2(D_i, D_j) \Big] \end{aligned} \quad (3)$$

where D_k is the document closest to the cluster centroid, λ is a trade-off weight (to be tuned) between similarity to cluster centroid and diversity, R is the pooled documents, S is a subset of documents already selected from R, and Sim_1 and Sim_2 that can be same or different, but we used the $cosine$ similarity for both instances.

3.2 Synthetic Query Generation

Query generation is an essential component in an unsupervised data generation pipeline for ranking models. Queries represent a target domain *w.r.t.* the user's information need and the domain-task by taking different types, such as questions, headlines, keywords, or claims. Therefore, we use a LLM to generate a synthetic in-domain query for each sampled document. We few-shot prompt the LLM to generate such training queries similar to the existing work of Bonifacio et al. (2022). However,

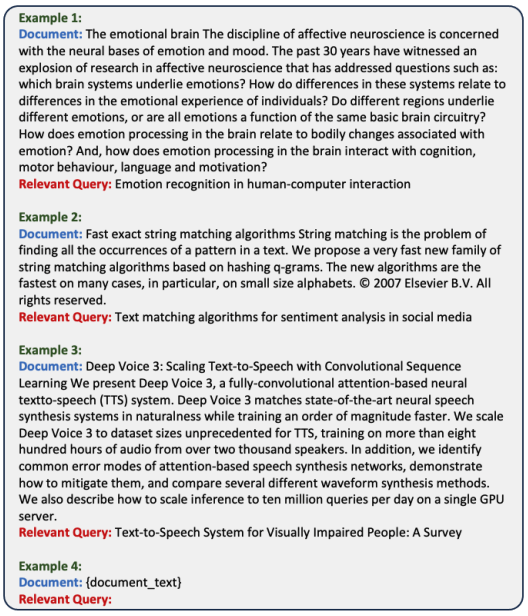

Figure 2: Prompt template with in-context examples for synthetic query generation for the SCIDOCS dataset.

our contribution lies in showing that the in-domain few-shot examples (query-document pairs) help to achieve high-quality of queries compared to out-of-domain generic MS-MARCO examples. On each domain, we create a handful (e.g., 3) human generated queries for the few-shot example documents with minimal human effort, and an example prompt is shown in Figure 2.

3.3 Negative Pairs Mining

After obtaining the domain specific documents and queries, we should generate both positive and negative query-document pairs. First, the positive query-document pairs can be easily generated by mapping the synthetic queries with their corresponding original (seed) documents. Second, the negative query-document pairs can be generated from hard negative mining, described in the standard practices (Izacard et al., 2021; Xiong et al., 2020; Karpukhin et al., 2020). We parse the synthetic queries to any first-stage retrievers, such as BM25 (Robertson and Zaragoza, 2009), ColBERT (Khattab and Zaharia, 2020), or Contriever (Izacard et al., 2021), to get top-x documents. Then we pick the bottom-num_{neg} documents from the top-x to map against the synthetic queries, where 1:num_{neg} is the *positive:negative* document pair ratio.

3.4 Fine-tuning with our Synthetic Data

Our domain adaptation framework can be applied on any ranking models with any weights initialization. To establish a strong competitor, we leverage the task pre-trained model (on MS-MARCO), and sequentially fully fine-tune with our own generated synthetic data. We also adapt the same hyperparameter settings used in the MS-MARCO pre-training stage for fair deliverable.

4 Experiments

In this section, we provide details of our experimental setup to demonstrate the effectiveness of **DUQ-Gen**.

4.1 Datasets and Metrics

We employed all 18 datasets from BEIR collection, ranging on diverse retrieval tasks, to assess the effectiveness of our domain adaptation framework on standard out-of-distribution datasets. Utilizing the *multi-field* index from Pyserini (Lin et al., 2021a) for all datasets, we retrieved the top-100 and top-200 documents from lexical and dense first-stage retrievers respectively. Subsequently, we restricted re-ranking to top-100 BM25 documents and top-200 dense retriever documents. Since we evaluate our approach on both first-stage retrieval and re-ranking, we measured both nDCG@10 and R@100.

4.2 Ranking Models

We fine-tuned ColBERT[2] (Khattab and Zaharia, 2020) and MonoT5-3B[3] (Nogueira et al., 2020b), namely **DUQGen-retriever** and **DUQGen-reranker**, to show the effectiveness in both dense retrieval and re-ranking. During evaluation, we tested two multi-stage ranking pipelines: (1) **DUQGen-reranker**: a fine-tuned MonoT5-3B re-ranking BM25 top-100 and (2) **DUQGen-retriever + DUQGen-reranker**: a fine-tuned MonoT5-3B re-ranking a fine-tuned ColBERT top-200 documents.

4.3 Baselines

We chose strong competitive rankers as baselines to highlight the effectiveness of our proposed domain adapted ranker.

BM25: Traditional lexical sparse retrieval. We replicated the BM25 scores from scratch.

Zero-shot (ZS) Models: A fine-tuned ranker on MS-MARCO dataset, includes MonoT5-3B and ColBERT.

[2]https://github.com/stanford-futuredata/ColBERT
[3]castorini/monot5-3b-msmarco-10k

InPars (Bonifacio et al., 2022): An unsupervised training data generation framework for ranking. Synthetic queries are generated from randomly selected documents using few-shot prompting GPT-3 Curie model. Language model likelihood is used as a filtering step to pick top-10k high-quality synthetic queries before fine-tuning any ranker. Based on the reasons provided by Askari et al. (2023), we do not compare against InPars-v2.

DocGen-RL (Askari et al., 2023): An RL-driven framework to generate documents from queries. Also an iterative approach, based on expand, highlight, and generate stages, generates documents from queries to prepare training data.

Promptagator++ (Dai et al., 2022): As the SOTA methods closest to our work, we evaluate against Promptagator++. This methods operates by randomly selecting 1 million documents from the target collection. It utilizes 8-shot prompting with a 137 billion-parameter FLAN model (Wei et al., 2022) to create 8 queries per document. Following consistency filtering, 1 million queries are selected to train a GTR-Base dual-encoder and cross-encoder (Ni et al., 2022).

We directly utilized the scores reported by authors for DocGen-RL and Promptagator++. For the remaining baselines, we employed their corresponding HuggingFace (Wolf et al., 2020) models to re-run the inference.

4.4 Tools and Implementation

Various tools were employed for distinct stages in our pipeline, utilizing Contriever (Izacard et al., 2021) for text encoding, Faiss (Johnson et al., 2019) for k-Means clustering, and Llama2-7B-Chat (Touvron et al., 2023) for query generation, Pyserini for BM25 baseline and hard negative mining, and PyTorch for standard fine-tuning. Throughout our experiments, documents were represented using their title along with the text. Initially, collection documents were filtered for noise by excluding those with a character length less than 300 (can vary across datasets). Greedy decoding with a temperature of 0.0 was employed for the LLM to generate queries.

4.5 Hyper-Parameter Tuning

In our methodology section, we introduced several hyper-parameters, all of which underwent tuning to determine the optimal values. These include the temperature $T = 1$ (Equation 1), MMR weight $\lambda = 1.0$, number of clusters $K = 1000$, and training sample size $N = 1000$ for ColBERT and $N = 1000$ and 5000 for MonoT5-3B fine-tuning. We tuned the varying number of in-context examples and found the optimal performance with 3-shot prompting (also used in InPars). Additionally, through tuning different prompt templates, we discovered that a simple InPars-style template, displayed in Figure 2, consistently yields superior retrieval performance across datasets. For the process of hard negative mining, we set the first stage retriever hits $x = 100$ and the number of negatives per positive pair $num_{neg} = 4$.

We fine-tuned MonoT5-3B using a batch size of 8, gradient accumulation steps of 16, learning rate of $2e^{-5}$, AdamW optimizer with weight decay of 0.01 and warm-up ratio of 0.1, and epochs of 1. To fine-tune ColBERT, we adapted its official pre-training hyper-parameters, including a batch size of 32, a learning rate of $3e^{-6}$, and a maximum sequence length of 300.

The scale and quality of synthetic data depend on the training examples, N, and number of clusters, K, which we optimize in the subsequent subsections.

4.5.1 Clustering Optimization

To represent target domain, we employed K-Means algorithm, where K denotes the number of clusters. We identified the optimal K for each dataset through an unsupervised method, known as the Elbow method (Thorndike, 1953). The elbow method computes the Sum of Squared Error (SSE) for each value of K, where SSE is calculated as the sum of cosine distances between every collection document and its closest cluster centroid. The optimal K consistently aligns at a fixed point of 1000 across all evaluation datasets, irrespective of variations in corpus size, domain properties, or domain-divergence from MS-MARCO.

4.5.2 Optimal Training Sample Size Discovery

By fixing the optimum number of clusters K at 1000, we determined an optimal training sample size N, that proved effective across all datasets. To tune for N, we utilized FiQA and NQ as dev datasets, referencing prior work (InPars-v2) which demonstrated improved performance on FiQA and a declined performance on NQ compared to the zero-shot scores. Table 2 displays nDCG@10 values for various instances of N, with K fixed at 1000. Our analysis led us to select optimum $N = 1000$ for ColBERT and both $N = 1000$

5 Results and Discussion

In this section, we present our main experimental results and delve into the key observations. We first describe our primary findings, reported using nDCG@10 in Table 1 comparing between baselines and our approach within each ranking setting. Second, we report the first-stage retrieval performances, measured using R@100 in Table 3.

5.1 Re-ranking Results

In Table 1, it is evident that **DUQGen** consistently surpasses the SOTA baselines in most cases, exhibiting notable improvements in performance. Specifically, **DUQGen** consistently and substantially outperforms both InPars and DocGen-RL rerankers, showcasing average relative enhancements of 26% and 17% respectively across the evaluation datasets they share. When compared to Promptagator++, **DUQGen** demonstrates an average relative improvement of 4% across the shared evaluation datasets. Remarkably, **DUQGen** surpasses Promptagator++ in performance, utilizing merely 1000 LLM calls and fine-tuning with only 1000 training pairs, in contrast to Promptagator++'s requirement of generating 8 million queries using a 137B LLM and fine-tuning with 1 million training pairs. This highlights the effectiveness of our efficient and robust approach compared to the complex, resource-intensive, and exhaustive training methods based on reinforcement learning.

In many instances, the performance of the SOTA baselines degraded, compared to zero-shot counterparts. For instance, both InPars and DocGen-RL consistently demonstrate performance decreases relative to the zero-shot MonoT5-3B, with Avg. decrements of 18% and 11% respectively across the evaluation datasets they share (DocGen-RL also underperforms compared to zero-shot MonoT5-base, as shown in Table 6). On the other hand, **DUQGen** consistently surpasses all zero-shot models across all BEIR datasets, whether trained with 1,000 or 5,000 synthetic training examples.

Interestingly, training **DUQGen-reranker** with only 1,000 synthetic examples exhibited a slight performance improvement compared to training with 5,000 synthetic examples on 13 out of 18 datasets, indicating the sample efficiency of our approach. In the future, it may be feasible to au-

tomatically determine the minimum training size (N) for each dataset or task.

5.2 First-Stage Retrieval Results

In Table 3, similar to nDCG@10 scores, R@100 also demonstrates more substantial improvements for larger domain-shifts (7.1%[4] on TREC-COVID and 3.8%[4] on Touché-2020) and limited improvements for smaller domain-shifts (.4%[4] on NQ). On average, **DUQGen** enhances zero-shot ColBERT by 2.1%[4] on BEIR datasets.

6 Analysis

In this section, we report our analysis of **DUQGen**'s performance, which includes examining the need for clustering, confirming the choice of the query generator, and validating the quality of the generated queries.

6.1 Effect of Clustering for Domain Adaptation

We employ clustering to represent the target domain and number of training samples to force diversity during fine-tuning. However, we question whether clustering genuinely contributes to the process and, if so, how it influences the overall performance. Additionally, we take the training sample size N, into account. In Table 5, we illustrate the combined effect of both the K and N on MonoELECTRA top-100 BM25 re-ranking performances, measured in nDCG@10. MonoELECTRA is used in the analysis Sections 6.1 and 6.2 in order to measure the amplified performance improvements in a smaller model, as described in the previous section.

Table 5 confirms our decision to select $N = 5000$ for MonoELECTRA. Notably, this figure highlights that the most substantial and consistent improvements occur around the values of {K=1000, N=5000} across both datasets. Performances without clustering ($K = 1$) often fall below zero-shot in both datasets, especially NQ exhibiting the poorest performances.

6.2 Effect of Query Generators

We conducted an ablation study on query generation to assess how the quality of generated queries impacts overall retrieval performance. Table 4 displays the performances of MonoELECTRA fine-tuned with queries generated by various LLMs, including LLAMA2-Chat (7B and 13B), BLOOM (3B and 7B), and GPT-3.5-turbo (Brown et al., 2020).

In comparison to the zero-shot re-ranking scores, LLAMA-2 7B was deemed the optimal choice for our query generator. LLAMA-2 7B with 3-shot in-domain prompts exhibits higher improvements on both dev datasets, surpassing gpt-3.5-turbo. While LLAMA-2 13B demonstrates superior performance to 7B on FiQA, it falls below the zero-shot performance in NQ, attributed to its large model capacity and sensitivity to prompts (Zhao et al., 2021). BLOOM generates short queries lacking context, despite having sufficient contextual query examples from 3-shot examples. GPT-3.5-turbo generates high-quality queries, resulting in improved performance over zero-shot, but tends to be unstable with few-shot prompts, suggesting

[4]denotes absolute precentage improvement.

Number of Training Examples (N)	1	100	500	1k	5k	10k
10k	.391 (+2%)	.391 (+2%)	.399 (+3%)	.396 (+3%)	.398 (+3%)	.389 (+2%)

Zero-shot MonoELECTRA score on NQ is 0.540

Table 5: Fine-tuned MonoELECTRA re-ranking performances in nDCG@10 for different values of K and N on FiQA (left) and NQ (right). (+%) and (-%) indicate integer rounded superior or inferior performance percentage against zero-shot scores.

potential for further prompt engineering to enhance performance on each dataset. Our second main contribution involves using in-domain 3-shot prompts to generate queries over the ms-marco prompt, showcasing notable improvements on LLAMA-2 7B model.

6.3 Examples of DUQGen Queries

Sampled Generated Queries for Quora
(Duplicate Question Retrieval Task):

Cluster-1: Pr=1.07e-3 → Is it illegal to transfer money from someone else's bank account without their permission?
Cluster-1: Pr=1.19e-3 → How do I deposit money into my bank account for the first time?
Cluster-2: Pr=1.61e-3 → What is the purpose of religion in society?
Cluster-2: Pr=1.51e-3 → If atheists were forced to choose a religion, what would it be?
Cluster-3: Pr=2.13e-3 → When is the next SBI IT officer exam?
Cluster-3: Pr=2.10e-3 → When is the nearest IELTS exam date in January?
Cluster-4: Pr=1.76e-3 → Can cold temperatures be used to generate electricity?
Cluster-4: Pr=1.90e-3 → Can electrical energy be converted into solar energy?
Cluster-5: Pr=2.60e-3 → What are the best websites to learn C and C++ programming languages?
Cluster-5: Pr=2.39e-3 → Where should I go from here to learn application programming in Java, C++, or C#?

(a)

Sampled Generated Queries for TREC-Covid
(Bio-Medical IR Task):

Cluster-1: Pr=3.34e-3 → What are the risk factors for psychological distress during the COVID-19 pandemic?
Cluster-1: Pr=3.50e-3 → What is the impact of the COVID-19 pandemic on suicide rates?
Cluster-2: Pr=4.22e-3 → What is the spatial pattern of COVID-19 infection in China?
Cluster-2: Pr=4.26e-3 → What is the predicted peak time of the COVID-19 curve in China?
Cluster-3: Pr=6.95e-3 → What are the symptoms that can predict the presence of influenza virus in children?
Cluster-3: Pr=7.51e-3 → What are the factors associated with complicated hospitalization due to influenza?
Cluster-4: Pr=4.24e-3 → What are the challenges in detecting SARS-CoV-2 RNA in saliva samples?
Cluster-4: Pr=4.28e-3 → How common is colonization of SARS-CoV among healthcare workers?
Cluster-5: Pr=7.77e-3 → What are the challenges faced by otolaryngologists during COVID-19 redeployment?
Cluster-5: Pr=7.97e-3 → What are the ethical considerations for otolaryngologists during the COVID-19 pandemic?

(b)

Figure 3: Example queries generated by **DUQGen** on (a) Quora and (b) TREC-Covid datasets. Pr denotes the $Pr(D_i|cluster_k)$ where D_i and $cluster_k$ refer to i^{th} document and k^{th} cluster.

So far, we have evaluated the effectiveness of **DUQGen** using quantitative measures and are now shifting our focus to examining the actual queries produced by our method. Figure 3 presents ten example queries generated from the Quora and TREC-Covid datasets, each representing distinct tasks and domains. In Figure 3, the synthetic queries are sampled across different clusters with different probability scores $Pr(D_i|cluster_k)$. For instance, in Figure 3a, we observe that in the Quora duplicate question retrieval task, each cluster corresponds to sub-topics of the target domain representation, such as monetary bank transfers, religion, exams in India, energy, and programming languages. Within each cluster, diverse queries are sampled using different probabilistic scores to aid in learning the domain representation. Additionally, the generated queries contain sufficient context or entities to retrieve pertinent information from its respective collection. This analysis of the generated queries further validates the effectiveness of our approach in generating a diverse and representative set of high-quality queries.

7 Conclusions

We proposed a general unsupervised domain adaptation method **DUQGen**, which can be used to fine-tune any ranking model for a given target domains. **DUQGen** introduced significant innovations over the previously reported unsupervised domain adaptation methods. Specifically, **DUQGen** proposes representing the target domain collection with document clustering; an effective method to diversify the synthetically generated queries, and an effective prompting strategy for using an LLM to generate more effective and representative synthetic training data. We experimentally demonstrated that **DUQGen** is both scalable and effective, as it uses only a few thousands of synthetic training examples, while consistently improves over the SOTA zero-shot rankers, and significantly outperforms the SOTA methods for unsupervised domain adaptation methods in most cases. We complemented the strong empirical performance of **DUQGen** with an in-depth analysis of the components to quantify their contributions. Together, the presented techniques and experimental results significantly advance neural ranking adaptation, establish a new state-of-the-art in neural ranking, and suggest promising directions for future improvements.

8 Limitations

Our proposed methodology involves two pivotal steps: (1) clustering; and (2) query generation. First, we employ Contriever as our text encoder to produce embeddings for clustering. While we anticipate that it will produce high-quality document representation and prove to be useful in our work, we did not assess other document embeddings. Future work could directly address the question of choosing the appropriate embedding for clustering.

Secondly, we employed the Faiss library to implement K-Means clustering. However, as the collection size scales up over the millions, clustering becomes impractical. Consequently, Faiss resorts to sampling the collection and then training their algorithm. This loss of information during sampling could propagate as errors in the final retrieval scores. However, given that large collections typically contain dense clusters, the process of sampling for clustering in such cases may pose less problem.

Akin to many previous studies (Zhao et al., 2021), we often encountered a lack of robustness of LLMs and their sensitivity to minor changes in the prompt affecting subsequent retrieval performance. Future work could explore strategies to mitigate this robustness through techniques like calibration (Zhao et al., 2021) and perform corresponding studies to see the impact on reranking.

9 Ethical Considerations

Retrieval systems may give rise to a variety of ethical issues, such as the potential for bias, which can result in the preferential treatment of specific perspectives, a lack of transparency due to the opaque nature of deep learning models, obscuring the reasons behind the ranking of documents, and, in extreme cases, the facilitation of echo chambers. Therefore, it is essential to conduct thorough testing of these systems both prior to and during their deployment.

As shown by our work, the performance of downstream retrievers can be rightly influenced by the LLMs employed for generating synthetic queries. Given that LLMs can produce content that is inaccurate or entirely fabricated, there's a risk that they might generate problematic queries, especially if applied to sensitive datasets. Although this issue may appear less critical in a scenario such as ours where the generated content is intended solely as training material for a following retriever, there is still a potential for generating harmful and toxic queries. Such queries could lead the retriever towards biased outcomes. Therefore, it is imperative to assess these systems to mitigate these risks against biases of the data generator.

A Appendix

A.1 Effect on Model Sizes

Different model sizes and different ranker families have been shown to exhibit different performances. Therefore, we fine-tuned MonoELECTRA[5] (Clark et al., 2020), MonoT5-base[6], MonoT5-3B, and ColBERT to show the effectiveness of our approach against the model sizes. We pre-trained the MonoELECTRA re-ranker on MS-MARCO using a batch size of 32, learning rate of $2e^{-5}$, AdamW optimizer with weight decay of 0.01 and warm-up ratio of 0.1, regression loss, and a maximum sequence length of 512. We continued using the same hyper-parameters for fine-tuning too. For MonoT5-base fine-tuning we only changed the batch size to 8 and kept the remaining hyper-parameters same as of MonoELECTRA.

The complete performances of **DUQGen** against each zero-shot baseline measured in nDCG@10 is reported in Table 6. **DUQGen** shows consistent improvements over corresponding zero-shot baselines across almost all datasets and across all model sizes. The larger the model size, the higher the performance improvements are, for example, the average score across all datasets increases from .487 to .528 between MonoELECTRA and MonoT5-3B. It is important to note that the performance improvements achieved by **DUQGen** are larger (4% Avg.) in smaller models and smaller (1% Avg.) in larger models. Fine-tuning on ColBERT shows consistent improvements across all datasets with no drop in performance. Thus showcasing the robustness of our approach to deploying dense retrievers in practical systems.

A.2 Running Time of DUQGen

DUQGen is a cost-effective and easily scalable to a large corpus size. **DUQGen** needs to apply the pipeline only once per domain to generate training data to fine-tune a ranker. Then, at inference time, no additional complexity overheard is added. The training dataset generation process is a sequence of three steps, each fully controllable by a small set of parameters, and can be scaled to a large document collection as our experiments show. In fact, the evaluation datasets of NQ, FEVER, BioASQ are 2.5 Million, 5.5 Million, and 14.9 Million documents respectively. To give an idea of the time complexity, single-pass clustering of the full NQ collection required 8 minutes[7] on a single machine; query generation using LLama2-7B to create $N = 5,000$ synthetic training examples was the slowest step which required 1.2 hours[8], and can be increased or reduced easily by modifying N. The fine-tuning of the largest ranker model MonoT5-3B required 38 minutes[8].

A.3 Query Generation Prompts

Using additional prompts can be helpful in showcasing the diversity of tasks in BEIR and highlighting the minimal effort required for any domain using our approach. **DUQGen** can be utilized across a wide range of retrieval tasks with significantly reduced human effort, requiring only a few labeled examples as demonstrations. Thus, in Figures 4a and 4b, we present the additional prompts utilized for dev datasets (NQ and FiQA) to exemplify the diverse tasks and the minimal effort involved.

Abstract

Throughout a conversation, the way participants interact with each other is in constant flux: their tones may change, they may resort to different strategies to convey their points, or they might alter their interaction patterns. An understanding of these *dynamics* can complement that of the actual facts and opinions discussed, offering a more holistic view of the trajectory of the conversation: how it arrived at its current state and where it is likely heading.

In this work, we introduce the task of summarizing the dynamics of conversations, by constructing a dataset of human-written summaries, and exploring several automated baselines. We evaluate whether such summaries can capture the trajectory of conversations via an established downstream task: forecasting whether an ongoing conversation will eventually derail into toxic behavior. We show that they help both humans and automated systems with this forecasting task. Humans make predictions three times faster, and with greater confidence, when reading the summaries than when reading the transcripts. Furthermore, automated forecasting systems are more accurate when constructing, and then predicting based on, summaries of conversation dynamics, compared to directly predicting on the transcripts.

1 Introduction

Conversations take place on at least two different levels (Tannen, 2005). On one level, participants directly communicate ideas, facts, and opinions, providing the topical context of the discussion. On the other level, the *dynamics* of their interactions reveal how they feel about each other, through changes in their tone—e.g., polite (Lakoff, 1973; Brown and Levinson, 1987), condescending (Huckin, 2002), or sarcastic (Jorgensen, 1996)—, conversational strategies they employ—e.g., rhetorical questions (Han, 2002)—and even the patterns of their exchanges (Sacks et al., 1974; Silverstein, 1984).

Traditional summary: In this online conversation, participants discuss capitalism and its sustainability. Speaker1 argues that profit always trumps morals and ethics in business. Speaker2 disagrees, stating that unchecked capitalism is economically unsustainable and detrimental to human dignity. Speaker4 seeks clarification on the consequences of capitalism's unsustainability, and Speaker2 suggests it could lead to economic collapse, mass unemployment, and toxic environments. They emphasize the need for checks on capitalism to prevent these issues. The conversation highlights concerns about unregulated capitalism and its impact on society.

Summary of conversation dynamics (human-written): Several users discuss regulation of capitalism. Speaker2 shares an opinion which Speaker4 questions. Speaker2 addresses Speaker4's question in a sincere manner. Then, the overall tone shifts to aggressive and confrontational when Speaker4 rudely invalidates Speaker2's response. Speaker2 sarcastically criticizes Speaker4's attitude which aggravates Speaker4 more. Then, Speaker2 genuinely apologizes and elaborates on their point and Speaker4 gratefully acknowledges this and clarifies their intentions. They continue the discussion in a calmed down, civil tone.

Summary of conversation dynamics (generated): Four speakers engage in a discussion about the nature of capitalism and its consequences. Speaker2 expresses concerns about unchecked capitalism and argues for the need to consider human dignity. Speaker4 challenges Speaker2 to explain the consequences of an economically unsustainable capitalist system. The conversation becomes heated, with Speaker2 perceiving Speaker4's questions as confrontational. Speaker2 defends their views and provides examples to support their argument. The overall tone of the conversation remains argumentative, but civil.

Figure 1: Traditional and dynamics summaries for the same conversation (transcript in Appendix F). Elements of conversational dynamics are colored in blue.

A holistic description of a conversation and its trajectory requires accounting for both of these communication levels. We complement prior work that has largely focused on summarizing the topical context of the discussion (Yang and Zhu, 2023), by introducing the task of generating summaries that instead capture the dynamics of the interaction between the participants. As shown in Figure 1, these cover aspects lost in a traditional summary.

Proceedings of the 2024 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies (Volume 1: Long Papers), pages 7452–7477

Summaries of conversation dynamics (or SCDs for short) provide a way for humans to quickly understand the trajectory of a discussion: what type of interactions led to its current state, and how are these likely to develop? This type of understanding can benefit various applications, including supervision of conversations in time-sensitive domains (e.g., online community moderation, supervision of mental health crisis counseling), providing context to users (re)joining an online conversation, contextualizing moderator decisions, or identifying and reviewing common problems in human-human or human-AI conversations. We further discuss possible applications in Section 7 and challenges to making them feasible in Section 8.

However, generating SCDs that effectively capture conversation trajectories presents several new challenges. While prior computational work introduced models for separately capturing individual aspects of conversation dynamics (Section 6), an effective and concise summary must *select* those that are most relevant for understanding the trajectory of the conversation. Additionally, an informative summary must not simply identify these aspects separately, but should also describe how they evolve and interrelate throughout a conversation: for example, a conversation that transitions from an aggressive tone to a calmer one has a completely different trajectory than one that proceeds in reverse order. Thus, to provide an understanding of the trajectory of a conversation, an SCD must *synthesize* different aspects of its dynamics across multiple utterances and participants.

As a first step, we devise a multi-step procedure for human annotators to collaboratively write SCDs. Importantly, this procedure is designed to address the selection and synthesis challenges described above. Building on this procedure, we develop a large language model prompt for generating SCDs and compare them with summaries generated by other baselines, including traditional summaries.

Specifically, in this paper we evaluate the usefulness of SCDs for conversation trajectory understanding via an established task: forecasting whether an ongoing conversation will eventually derail into toxic behavior (Zhang et al., 2018a; Liu et al., 2018). While prior attempts at this task started directly from the transcript (Section 6), we explore generating SCDs as an intermediate step. This approach has the potential advantage of adding interpretability to automated forecasting systems and improving efficiency for humans (such as moderators) that need to make such judgments (Schluger et al., 2022).

Our findings reveal the potential of SCDs to help both humans and automated systems understand a conversation's trajectory, motivating further work on this new task. In the downstream task of forecasting the future derailment of a conversation, humans make predictions three times faster, and with greater confidence, when reading the SCD than when reading the transcript. Furthermore, automated systems are more accurate when constructing, and then predicting based on, SCDs compared to systems that base their forecast directly on the transcripts. Finally, by comparing human-written and machine-generated summaries, we reveal a quality gap that motivates further computational work on this new task.

In summary, this work:

1. introduces the task of summarizing conversation dynamics, together with a collection of human-written summaries;

2. proposes a downstream evaluation method that allows for comparison between methods for generating SCDs;

3. shows the usefulness of SCDs, motivating further work on this new task.

To encourage future work, we release a dataset of SCDs—both human-written and machine-generated—together with the conversations they summarize in the ConvoKit library (Chang et al., 2020).[1] This data can also support the study of individual aspects captured by these summaries, such as tone or patterns of interaction (identified via a qualitative analysis of the summaries; Section 5).

2 Human-written Summaries

To start, we introduce a procedure for writing SCDs and a collection of such summaries for an existing dataset of online conversations.

Procedure for writing summaries. To construct the first collection of SCDs, we iteratively designed a writing procedure that addresses the selection and synthesis challenges described in the introduction. In early iterations in which we asked a single annotator to both read the transcript and write its SCD, we observed that they consistently omitted key information that they take for granted, perhaps

[1] ConvoKit library: https://convokit.cornell.edu/
Code and info: https://github.com/CornellNLP/scd

because some aspects of the dynamics are often processed non-consciously (Tannen, 2005). To address this issue, we devise a procedure that uses interaction between two annotators to surface key elements of the conversation dynamics that readers *who cannot see the transcript* would consider relevant. Thus, we settle on a procedure that has two parts—one in which an annotator works individually and one in which they interact with another annotator—which we briefly outline here (and detail in Appendix A).

For the individual work, Annotator A will draft several summaries for a transcript in 4 steps:

1. skim over the transcript to have an overview of the topic and of the role of each speaker;

2. read the transcript utterance by utterance and write a comprehensive summary, including opinions and arguments expressed within most utterances, turning points, and elements of conversation dynamics;

3. condense the summary by selecting key points and aspects of the dynamics and replacing specific opinions and arguments with high-level descriptions;

4. write a brief summary for each of the main speakers, focusing on (the changes in their) tone and on their conversational strategies.

In the interactive part, Annotator B will write the SCD, by interacting with Annotator A with a goal of understanding the conversation trajectory. In this process, Annotator B may read the summaries written in the previous steps by Annotator A, but not the transcript, and may make inquiries on details they deem important to understand the trajectory, such as 'was this said neutrally, or is there something about the tone that I should note?' or 'is the comment overtly rude, or is it just passive-aggressive or blunt?', surfacing key aspects that were not explicitly mentioned in Annotator A's summaries.

Conversation transcripts data. We apply this procedure to summarize conversations from the Conversations Gone Awry - ChangeMyView (CGA-CMV) dataset (Chang and Danescu-Niculescu-Mizil, 2019),[2] a conversation corpus collected from the 'Change My View' subreddit, where people actively seek to have others challenge their views on controversial topics. This community has been studied extensively in part because of their explicit norms against toxic behavior, and corresponding labels inferred from the moderators' interventions.

In the CGA-CMV corpus, conversations are paired such that every conversation that derailed—i.e., ended in a toxic comment removed by moderators—is matched with another conversation on the same topic that did not. For us, these labels provide an opportunity to test the extent to which SCDs provide an intuition about the future trajectory of the conversation (i.e., will it derail or not). To focus on the *future* trajectory, we use *truncated* transcripts obtained by removing the last 3 utterances from every conversation (in addition to the toxic comment, if there was one). Since our interest is in summarization, we only keep pairs where both conversations are longer than 10 utterances.

Collection of human-written summaries. We produce human-written summaries for 50 conversations from the train split of CGA-CMV. The summary writing process took roughly 140 annotator-hours.[3] Summaries are on average 71 words long (annotators are instructed to keep them under 80); for comparison, the transcripts are on average 940 words long. An example summary is shown in Figure 1, and a qualitative analysis is provided in Section 5.

Informativeness check. Before we proceed, we check whether the summaries are actually informative. Given their highly abstractive nature, there is a risk that they become so general as to not distinguish between different conversations (e.g., 'Speaker1 disagreed with Speaker2.' would apply to most of the conversations in the data). Thus it is not sufficient to judge whether statements in a summary are technically matching the conversation they summarize: we need to also check whether they convey sufficient information to distinguish that conversation from others. We devise a procedure for systematically checking whether this is the case as follows.

We ask new annotators to read a transcript, and then present them with a multiple-choice question. Each choice corresponds to a summary segment involving two speakers. One of the choices is from the actual summary of the provided transcript, while the other two are distractors: one from the summary of the paired conversation (thus, on the same topic, but with the opposite derailment label)

[2] Accessed via the ConvoKit library.

[3] For each conversation transcript, the individual part takes about 2 hours and the interactive part takes about 20 minutes.

and the other from the summary of another conversation with the same label as the transcript, but on a different topic. This way, neither the topic nor the label fully reveals the answer: to be identified correctly, the segment must contain information that matches the transcript better than the distractors.

For instance, for our introductory example, three choices could be: "SpeakerX sarcastically criticizes SpeakerY's attitude which aggravates SpeakerY more." (an actual segment), "SpeakerX poses a rhetorical question, which SpeakerY contradicts sarcastically, raising the tension and causing SpeakerX to disagree rudely." (a same-pair distractor), "SpeakerX first shares their opinion and later poses rhetorical questions, and SpeakerY disagrees in a matter-of-fact manner." (a same-label distractor).

Though we designed this procedure to avoid excessive workload when evaluating informativeness,[4] each question still requires reading one transcript and carefully checking the segment choices against it. Therefore, we limit our total number of questions to 10, covering 30 conversations through distractors. (Further details in Appendix B.)

Two annotators completed the task. One answered 10 out of 10 questions correctly and the other answered 8 of them correctly (noting low confidence on the 2 answers they got wrong), suggesting that our summaries indeed pass this basic informativeness check.

3 Machine-generated Summaries

We now turn to explore several simple baselines for generating SCDs, setting the stage for developing more specialized methods in future work. Models in the GPT family have achieved remarkable results in various summarization benchmarks (Zhang et al., 2024; Yang et al., 2023). Among them, ChatGPT is particularly suitable for adapting to new tasks like ours without demanding a sizable train set. Thus, for the first group of baselines, we query OpenAI's ChatGPT (GPT-3.5-turbo-0613) API with default parameters using different prompts, from the most common prompt for traditional summarization tasks to prompts inspired by the procedure we developed for humans:[5]

Traditional prompt. After experimenting with several prompts on a development set, we use a concise prompt for our traditional summarization baseline: 'briefly summarize the following online conversation in 80 words.' Figure 1 includes a traditional summary generated by this prompt.

Zeroshot prompt. We devise a prompt that explicitly integrates our goal of generating summaries that can help people understand the conversation trajectory. After experimenting with several word choices for referring to trajectory, dynamics, and specific dynamics elements, we settle on a concise prompt, 'write a short summary capturing the trajectory of the online conversation' with additional constraints such as excluding specific arguments and capturing elements of tone and conversation strategies (Figure 3 in the Appendix).

Procedural prompt. We build on the insights we gathered from developing the procedure for human annotators (Section 2) to construct a more elaborate prompt. This prompt (Figure 3 in the Appendix) thus includes instructions adapted from those provided to the annotators, together with examples that they found useful for understanding the instructions. Because we only include segments of summary examples instead of complete transcript and summary pairs, the procedural prompt can be positioned in-between zeroshot and few-shot in-context learning. Figure 1 shows the procedural prompt summary for our introductory example.

We also experimented with few-shot in-context learning on a small subset of the training set, but manual inspection did not reveal an increase in quality. Thus, due to significantly higher API costs, we did not pursue this path. Appendix D includes more discussion of our prompt engineering.

Finetuning. Finally, we experimented with finetuning GPT-3.5-turbo and smaller dialogue summarization systems (BART-large and DialogLED) (Lewis et al., 2020; Zhong et al., 2022) using the 50 human-written summaries and the corresponding transcripts. We provide details in Appendix D.

4 Downstream Evaluation: Forecasting Derailment

Popular metrics for summarization—e.g., ROUGE (Lin, 2004), BERTScore (Zhang et al., 2020),

[4] An equivalent check could be implemented by providing one summary segment and three transcripts to pick from. This method corresponds to the existing literature in communication-based evaluations for natural language generation (Newman et al., 2020), and implements the idea that an informative summary should capture the salient information that makes the source text stand out with respect to other related texts (Zhang et al., 2018c). However, this equivalent method would require substantially longer time due to the lengths of the transcripts.

[5] We prompt the model to generate summaries of at most 80 words and set the max new token limit to 128 (corresponding to approximately 96 words) as a hard limit .

and QA-based metrics—are notoriously unreliable when evaluating LLM-generated summaries or summaries of long documents (Koh et al., 2022; Goyal et al., 2023). We thus follow recommendations of Deutsch et al. (2021) and perform a downstream evaluation, in which we quantify the extent to which SCDs provide an understanding of the conversation trajectory.

Specifically, we choose the task of forecasting whether a conversation will eventually derail into toxic behavior (Zhang et al., 2018a). Unlike previous work in which the prediction was made based on a truncated transcript of the conversation (for a comprehensive discussion of prior models see Section 6), here we aim to make the prediction directly on the SCD of that truncated transcript. In addition to providing means to evaluate and compare current and future models for generating SCDs, this derailment forecasting task is also important in itself, as it was shown to enable important practical applications: automated forecasts can be used to inform users during ongoing discussions (Chang et al., 2022) while human forecasts are made by moderators in their everyday workflow (Schluger et al., 2022) (see Section 8 for practical and ethical considerations of real-world deployment).

Besides the potential practical importance of this task, it is also worth noting its difficulty. Because the forecaster never actually sees the toxic comment, it must rely on subtle signals and overall trajectory of the conversation dynamics. This inherent difficulty and its implications on the design of forecasting models were extensively discussed in Chang and Danescu-Niculescu-Mizil (2019).

We first compare the usefulness of SCDs for automated forecasting systems. Then we devise an experiment to estimate their usefulness for human forecasts. Throughout, the forecasts are done on a balanced dataset of derailing and non-derailing conversations paired by topic, following the setup of the CGA-CMV dataset (Section 2); thus the overall topic of the discussion plays a minimal role and the random baseline is 50%. To leave room for future work we leave the original CGA-CMV test set untouched. Using truncated transcripts from the original train split, we construct a new train set (234 conversations), a new development set (100), and a new test set (100); the new test set includes the 50 conversations for which we also have human-written summaries (Section 2).

4.1 Useful for automated forecasts?

We train classifiers to predict if a conversation will eventually derail based on the various types of summaries of the truncated transcripts. We adopt GPT-3.5-turbo to develop few-shot classifiers for each summary type, using examples from outside the test split. To provide more robust estimates, for each summarization method we generate 4 different summaries for each conversation, and average the classifiers' performance on them (details in Appendix D.3).

Comparison of summaries. As shown in Table 1, the classifier based on the procedural prompt achieves the best accuracy, significantly outperforming the other types of summaries ($p < 0.05$; throughout we use the Wilcoxon signed-rank test significance testing). In particular, the information conveyed by the SCDs generated with the procedural prompt appears to be more useful for the automatic derailment forecaster than that included in traditional summaries. Other metrics (Macro-F1, precision, recall) support the same conclusion (Appendix F.5).

Finetuned summarization models—finetuned on the 50 human-written summaries and evaluated on the remaining of the test set—perform worse than the procedural prompt on the same set (more details in Appendix D). This could be due to the relatively small collection of human-written summaries, as well as to the generic fine-tuning methodology, thus motivating extending the set of human-written summaries and developing fine-tuning procedures that also integrate the forecasting objective.

Summary vs transcript. For reference, we also include two baselines operating directly on the trun-

Based on...	**Accuracy**
transcripts (CRAFT classifier)	56.0
transcripts (GPT-16k classifier)	60.0
traditional prompt summaries	58.3 (5.85)
zeroshot prompt summaries	58.8 (6.24)
procedural prompt summaries	67.3* (2.63)

Table 1: Derailment forecasting results for systems based on truncated transcripts and on different types of machine-generated summaries. For summary-based systems, we report standard deviation across 4 summary-generation trials, and indicate with * the highest performance (p<0.05; Wilcoxon signed-rank test). Results for the GPT-3.5-turbo few-shot classifiers are shown unless otherwise noted.

Based on...	Acc. by forecaster		
	GPT	BART	LF
transcripts	60.0	50.0	51.0
traditional summaries	58.3	56.0	58.3
procedural summaries	**67.3**	**63.0**	**61.5**

Table 2: Comparing different classifier architectures for derailment forecasting. "GPT" refers to the GPT-3.5 few-shot classifier for summaries and to GPT-16k classifier for transcripts (same as in Table 1).

cated transcripts. The first baseline, CRAFT, was introduced before the advent of the LLM era and remained a competitive system for this task (Chang and Danescu-Niculescu-Mizil, 2019).[6] The second baseline is a few-shot GPT-3.5-turbo-16k classifier, which can take up to 16k tokens to cope with the greater input lengths of the transcripts.[7]

As shown by Table 1, predictions based on procedural prompt outperform those based directly on the transcripts. This suggests that SCDs are effective in distilling from the transcripts information that is useful for the forecasting task. Perhaps more importantly, the feasibility of this 'summarize-then-forecast' approach points out a promising future direction for improving the interpretability of the user-facing forecasting systems, where the summary could be presented as an easily digestible rationale for the prediction. In fact, users of such systems have identified the lack of explanations as one of their most important drawbacks (Chang et al., 2022).

Other forecasting systems. We also train BART (Lewis et al., 2020) and longformer (LF) (Beltagy et al., 2020) as finetuned classifiers for the forecasting task (Appendix D.3). While their performance is substantially lower than that of the GPT few-shoot classifier across all types of summaries, the comparisons discussed above still hold (Table 2).

[6]For a fair comparison, we modify the ConvoKit implementation of CRAFT (Chang et al., 2020) to trigger forecasts exactly 3 utterances before the end of the conversation (in the original setup the system could make predictions all the way up to right before the attack or the end of the conversation). Empirically, this setup turns out to be harder for CRAFT than the original one. While we use CRAFT as our non-LLM baseline because it relies only on the text of the conversation, we note that recent work showed that integrating user dynamics and up/down votes can lead to better performance on the CMV section of the CGA dataset (Altarawneh et al., 2023). Future work could explore the potential benefits of factoring in such extra-textual information into the creation of the SCDs.

[7]Both baseline systems might have an advantage in that they might have accessed the full untruncated transcripts during pre-training.

4.2 Useful for human forecasts?

We now switch to the other main motivation: can SCDs help *humans* quickly grasp the trajectory of a conversation? To answer this question we devise an experiment in which subjects are asked to guess whether a conversation will eventually derail based either on a transcript or its SCD. We compare both their accuracy and efficiency, in terms of the time they spend to make their guess, as well as their confidence in their guess.

To better focus our resources, we use a subset of 20 paired conversations out of those for which we created human summaries. In addition to the transcripts and the human-written summaries, we also consider the corresponding procedural prompt summaries (since those were shown to fare best in the automatic prediction task).

We recruit 20 university students fluent in English as participants. A subset of participants make their guesses based on the transcripts only, while another subset make guesses based on summaries only. Each participant in the latter subset sees a mix of human-written and machine-generated summaries (without being aware that these are produced differently) such that any observed differences between their effects cannot be attributed to participant idiosyncrasies. In addition to providing a guess of whether the conversation will derail or not, each participant is asked to rate their confidence in their guess (on a scale from 1 to 5). We also record the time it took for the participants to make their guess (starting from the time they see the transcript or summary until the time they select their guess), and instruct them to work on each question without pausing. The specific instructions and details about how participants are grouped are in Appendix C.

Unlike in the automatic evaluation in Section 4, we adopt a zeroshot prediction setting, in which humans do not have labeled examples of summaries (or transcripts) to assist their guessing. This way, we can better test if the summaries are immediately intuitive to humans rather than testing the participants' ability to learn patterns that might not be visible to untrained individuals. This means, however, that the accuracies of the human participants are not directly comparable with those of the automated system.

Summaries vs transcripts. As shown in Table 3, participants can make guesses 3-4 times faster based on SCDs while maintaining similar accu-

Based on...	Acc	Conf	Topic	Time
transcripts	60	3.5	-	132
gen. summ.	59	3.6	3.9	45*
human summ.	62	4.0*†	3.4†	31*

Table 3: Results on the human forecasting experiment. "gen. summ." refers to the summaries generated using the procedural prompt. Time is measured in seconds. * indicates a significant difference when compared with transcripts ($p<0.05$; Wilcoxon signed rank test), † indicates a significant difference when comparing human-written with automated summaries ($p<0.05$).

racy. This improvement in efficiency is critical for applications such as proactive online moderation, as earlier work has found that moderators are faced with "too many [potentially at-risk conversations] to proactively monitor" (Schluger et al., 2022).

Human vs generated summary. Participants are significantly more confident when making predictions based on human-written summaries than on machine-generated summaries (and even on the transcripts).[8] This gap is important for applications where summaries are used for decision-making (e.g., moderation) and motivates future work on improving summarization models. Another noticeable difference is that machine-generated summaries provide a better understanding of the topical content of the discussion, perhaps to the detriment of better coverage of aspects of conversation dynamics. In Section 5 we further explore this trade-off via a qualitative analysis of the summaries.[9]

5 Qualitative Analysis

To complement our quantitative evaluation and understand what might drive the differences between human and machine-generated summaries, we now turn to the actual content of the SCDs. Through a close reading of the 20 human-written and 20 machine-generated summaries used in the experiment described above, we identify, annotate, and compare several aspects that were shown to provide clues about the conversation trajectories.

[8]This difference continues to hold when only considering correct guesses. Also, reassuringly, confidence in correct guesses is higher than in incorrect ones throughout.

[9]We also experimented with directly asking participants to report their understanding of the trajectory of the conversation, on a scale from 1 to 5. There was no significant difference between human and machine-written summaries (4.0 and 3.9 respectively), perhaps due to the difficulty of briefly explaining what a trajectory is and how it differs from the derailment prediction, a confusion that surfaced during debriefing.

Tone. Whether 'polite,' 'rude,' 'aggressive,' 'condescending,' or 'sarcastic' (Brown and Levinson, 1987; Tannen, 2005), the tone employed by the participants is a prominent feature of the SCDs. Tone can be explicitly stated, as in 'Speaker1 disagrees [...] **in a somewhat passive-aggressive tone**.' Other times, especially in human-written summaries, it is expressed as modifying a speech act, as in 'contradicts **sarcastically**', 'disagrees **rudely**,' and '**adamantly** defends.' Overall, tone is indicated less frequently in the machine-generated summaries (75% of them mention tone at least once) than in the human-written summaries of the same conversations (all mention tone at least once), suggesting a potential path for improvement.

Changes in tone. Tone can evolve throughout a conversation, and changes in tone can provide an intuition about its trajectory (Niculae et al., 2015). When participants use an '**increasingly** passive aggressive tone,' or when the 'tension **rises**' the conversation seems more likely to be getting out of hand than when a 'slight tension [...] is **maintained but doesn't escalate**' or when the 'tone **remains** argumentative but civil'. The latter quote is an example of an overall assessment of tone dynamics that both humans and (more commonly) automated systems sometimes include at the end of the summary, even though neither is explicitly instructed to do so. Overall, 75% of the human summaries feature phrases explicitly mentioning changes in tone whereas only 50% of the machine-generated counterparts do so.

Patterns of interaction. Beyond the content of the messages, the structural properties of the interactions were shown to be indicative of future trajectories (Backstrom et al., 2013; Zhang et al., 2018b). Two participants can have a '**brief exchange**' or an extended '**back-and-forth**', which can be interrupted when another participant '**jumps in**'. While explicit mentions of such patterns are relatively rare (found in 45% of the human summaries and 31% of the machine-generated summaries), they can often be inferred by following the sequence of speakers mentioned in the summaries.

Conversation strategies. Interlocutors employ strategies that can put the conversation on various trajectories. For example, 'pos[ing] a **rhetorical question**' or '**questioning each other's logic**', can often lead to personal attacks (Habernal et al., 2018), whereas expressing uncertainty about one's own view (e.g., via hedging), would soften an impending disagreement and prevent the escalation of

tension (Zhang et al., 2018a). 'Supporting [a] point with **evidence**', 'justifying objective claims with **personal experiences**', 'draw[ing] a **comparison**' or '**question[ing] the importance of specific details**' are classic persuasion strategies (Zeng et al., 2020; Li et al., 2020a). A list of strategies considered in this analysis is included in Appendix E. Overall, we find that mentions of conversational strategies are similarly common in human-written (80%) and machine-generated summaries (85%).

Topical context. Finally, these dynamics can only exist in the context of the content being discussed. Though not the primary focus of SCDs, a small amount of topical context is needed to provide a scaffolding for the phenomena discussed above. Both human and machine-generated summaries generally start with a sentence about the general topic of the discussion. Beyond that, machine-generated summaries include substantially more topical context to the detriment of actual aspects of conversation dynamics, despite the explicit instruction and in-context-learning examples against this behavior. This echoes the subjective ratings of the participants in the human forecasting experiment (Table 3). This phenomenon suggests that in-context learning is not sufficient to 'untrain' LLMs from the traditional summary examples seen in pretraining. This motivates developing models that are specifically designed to select and synthesize aspects of conversation dynamics, perhaps inspired by the interactive human-writing procedure.

6 Further Related Work

Our work falls at the intersection of three broad areas of NLP: studies of conversation dynamics, summarization, and conversation forecasting.

Conversation dynamics. We are primarily inspired by extensive computational work on modeling various aspects of conversation dynamics. Some studies have focused on identifying specific aspects, such as such as politeness (Burke and Kraut, 2008; Danescu-Niculescu-Mizil et al., 2013; Li et al., 2020b), formality (Krishnan and Eisenstein, 2015; Pavlick and Tetreault, 2016), passive-aggressiveness (Chhaya et al., 2018), condescension (Wang and Potts, 2019) or sarcasm (Oraby et al., 2017). Others have studied changes along these dimensions during the discussion (Wang and Cardie, 2014; Niculae et al., 2015; Niculae and Danescu-Niculescu-Mizil, 2016). A separate but related thrust focused on persuasive strategies interlocutors employ in a conversation, mostly in the context of debates (see Lawrence and Reed (2020) for a survey). Unlike these studies, the goal of SCDs is not to exhaustively identify occurrences of either one of these phenomena, but to convey how such key aspects combine towards an understanding of the conversation's trajectory. Nevertheless, the dataset of SCDs that we release (with annotated aspects of conversation dynamics) can constitute an additional resource for studying these phenomena and the context in which they occur.

Dialogue summarization. The vast majority of dialogue summarization systems focus on the content of the utterances, rather than on the more subtle non-topical dynamics. Early approaches to dialogue summarization focused on using external tools to explicitly model dialogue structures, such as topic segmentation and conversation stages (Li et al., 2019; Chen and Yang, 2020), dialogue acts (Goo and Chen, 2018), discourse dependency and speaker-action relations (Chen and Yang, 2021), which are processed into features that can help language models. Later, pretraining on dialogue corpora also attracted increasing research interest and achieved state-of-the-art results on many datasets (Zhong et al., 2022). Most recently, extensively pretrained, instruction-tuned LLMs, such as the GPT family models, have achieved superior results on various summarization leaderboards (Goyal et al., 2023; Zhang et al., 2024; Yang et al., 2023). In dialogue summarization, these instruction-tuned LLMs possess strong in-context-learning capabilities (Wu et al., 2023), making them strong candidates for solving new summarization tasks that have limited training data.

Conversation forecasting. We motivate and evaluate dynamics summaries with applications requiring an understanding of a conversation's trajectory. Beyond forecasting derailment (Zhang et al., 2018a; Liu et al., 2018; Chang and Danescu-Niculescu-Mizil, 2019), other tasks include forecasting thread growth (Backstrom et al., 2013), prosocial outcomes (Bao et al., 2021), editorial decisions (Mayfield and Black, 2019), controversy (Hessel and Lee, 2019), the outcomes of negotiations (Chawla et al., 2020) or team resilience (Whiting et al., 2019). It would be interesting to consider the extent to which SCDs can aid with these other forecasting tasks, and how to obtain summaries specifically dedicated to these tasks.

To the best of our knowledge, all conversational forecasting systems operate directly on conversa-

tion transcripts. The early work by Chang and Danescu-Niculescu-Mizil (2019) adopts a recurrent network and applies unsupervised training to learn a representation of conversation dynamics. More recently, Kementchedjhieva and Søgaard (2021) explores pretraining and various training paradigms for this task, Altarawneh et al. (2023) applies a graph convolutional network, and Yuan and Singh (2023) uses a hierarchical transformer-based framework to combine utterance-level and conversation-level information. However, since it aims to guess the future, this task remains challenging.

Unlike detecting the toxic language after the fact (Wulczyn et al., 2017; Breitfeller et al., 2019), the signs of future derailment are subtle and require a more thorough understanding of the conversation trajectory. Our results suggest that SCDs can provide this information concisely and effectively, suggesting a new summarize-then-forecast approach to conversational forecasting tasks. This inspires future work to integrate SCDs in real-time forecasting systems, which would require tackling shorter conversations where summaries might not be appropriate, as well as the 'unknown horizon' problem: not knowing when to trigger the prediction (Chang and Danescu-Niculescu-Mizil, 2019).

7 Conclusions

In this work, we introduce the task of summarizing the dynamics of interaction between participants in a text-based conversation. By introducing human and automated procedures for writing such summaries, we show that they can capture information that is mostly missing from traditional summaries, such as the tone in which the participants write and how it changes throughout a conversation. Summaries of these dynamics are useful to both humans and automated systems for understanding the overall trajectory of the conversation, as shown through the downstream evaluation task of forecasting whether a conversation will eventually derail or not. Humans can make similarly accurate forecasts three to four times faster by starting from SCDs than by reading the transcripts. When compared to directly predicting on the transcripts, automated systems make better forecasts when generating SCDs as an intermediate step.

Going beyond the gains in accuracy and efficiency, SCDs add interpretability to the forecasting task. Interpretability is key to enabling applications where forecasts are used by humans for decision making. For example, when warning interlocutors (or moderators) that a conversation is at risk of derailing (Chang et al., 2022; Schluger et al., 2022), SCDs could provide them with insights into why that might be the case, helping them decide whether to heed the warning and how to deescalate the situation. This pertains to settings beyond online forums, such as customer service conversations or mental health counseling conversations, in which supervisors need to decide fast whether (and how) to intervene in conversations that seem to enter a non-desirable path.

In addition to forecasting, capturing and succinctly describing the dynamics of conversations can be useful for a series of applications, including training conversationalists (e.g., by providing them with a way to review their prior conversations), providing context to people (re)joining a conversation (e.g., to aid a therapist prepare for their next session with their client), or identifying common trajectories in human-AI conversations. SCDs could even aid conversational analysis researchers more efficiently explore individual conversations and reveal patterns in the intricate ways in which they develop (Sidnell, 2011).

8 Limitations

This work, however, only takes the first steps towards solving and evaluating the task of generating SCDs automatically. In fact, we show that there is a substantial gap remaining between human-written summaries and machine-generated ones. Since in this work we focus on defining the task and demonstrating its feasibility, we only employ simple prompting and standard fine-tuning procedures. This sets the stage for the future development of more specialized models and training regimes. These models could be more tightly integrated with the downstream task, learning to select aspects of the dynamics that are most relevant as well as to determine the right level of abstraction.

To continue improving on dynamics generation models, more diverse automated evaluation methods are required. Given the highly abstractive nature of the task, traditional metrics based on token overlap or semantic similarity are not immediately applicable (Goyal et al., 2023). Our informativeness check provides an avenue for evaluation that could potentially be scaled up through automation. Furthermore, considering other downstream applications, such as forecasting prosocial outcomes

(Bao et al., 2021) or how likely it is for participants to change their mind (Tan et al., 2016; Hovy and Yang, 2021), could further help evaluate the usefulness of dynamics summaries.

While the current work is restricted to summaries of text-based conversations, important dynamics can be encoded in vocal features (e.g., intonation, or pitch) or gestures (laughter, body positioning). A multimodal approach could enable applications that go beyond text-based conversations and provide a more holistic understanding of conversational dynamics.

Additionally, while we tested how useful summaries are for humans in a small-scale control setting, further work could test this more comprehensively through user studies, for example by integrating these summaries into conversational assistance tools (Chang et al., 2022) or moderation assistance tools (Schluger et al., 2022). From a technical perspective, a real-time deployment would require iteratively generating summaries in real-time, as the conversation progresses, rather than at a set moment in the conversation as we do in this work for the sake of scalability.

Ethical concerns surrounding fairness and bias should necessarily take center stage in any deployment of summarization systems, especially since SCDs may include mentions of emotions and affect of the people involved in the conversation (Zhou and Tan, 2023). Any broad usage scenario should undergo rigorous scrutiny of potential for unintended consequences (Weidinger et al., 2022). For example, SCDs and automated forecasts relying on them should not be used to make automated censoring or moderation decisions, in order to avoid propagating biases embedded in the underlying large language models. If future developments will result in summaries that are reliable enough to inform human decisions (e.g., helping moderators decide whether to closely monitor an ongoing conversation), the users should be informed about systematic mistakes the summary is likely to make in that respective setting.

Acknowledgements

We would like to start by expressing our deepest gratitude to Jonathan P. Chang who advised us throughout, from defining the task all the way to providing excellent suggestions on the submission draft. We thank Tushaar Gangavarapu for his help with adapting the CRAFT baseline to our setting. We were lucky to have had many enlightening conversations about this work during Team Zissou's meetings, which included Jonathan P. Chang, Tushaar Gangavarapu, Dave Jung, Lillian Lee, Vivian Nguyen, Tony Wang, Sean Zhang. We also thank Ido Dagan, Mark Johnson, and Alex Niculescu-Mizil for their sharing their insights with us, as well as the anonymous reviewers for their helpful suggestions. Lastly we acknowledge the help we got from our annotators, the participants in the NLP seminar, and the "Conversations and Information" class at Cornell. This research was supported in part by an NSF CAREER award IIS-1750615, a LinkedIn Research Award, and an Oracle ERO Award.

A Instructions for Writing Summaries

In this section we explain our annotation procedure and provide definitions for the terminologies in our instructions along the way. As described in Section 2, the procedure is divided into two parts: one in which an annotator works individually and the other in which they interact with another annotator.

A.1 Individual Work

Instructions for an individual annotator:

1. Depending on the *complexity* of the conversations, either 1) thoroughly read the whole conversation or 2) skim through the conversation to understand the general idea
    - *Complexity*: number of speakers, familiarity of the topic to the annotators, length. For shorter conversations, it is easier to read through the whole conversation before moving on to summarizing, while for really longer ones, annotators would read a few comments at a time, summarize, read the next few, etc.
2. Go through the conversation *comment-by-comment* and write a comprehensive summary that captures the content of each *comment* and any *key points*.
    - *comment*: all speakers' utterances are in the form of reddit comments.
    - *key points/moments*: also referred to as "turning points" are where the tension of the conversation or the speakers' opinions notably change. Annotators should highlight them in both the original transcript and the summary in the following way: increase in tension (red), decrease in tension (blue), change in opinions towards disagreement (yellow), change in opinions towards agreement (green)
3. Then revise the comprehensive summary to
    (a) change any wording that's confusing (not accurately describing the original comment)
    (b) review if the summary reflects the conversation accurately (specifically the conversation dynamics and tension) and add any tone indicators that might be missing
        i. Indicate changing tension (e.g. curse words, all-caps, rhetorical questions, polite words) and indicate sentiments with phrases like "sarcastically," "passive-aggressively," "politely," etc. Use direct quotes (no need to explicitly describe the emotion) if they are concise and hard to capture in a summary. Focus on the highlighted elements of the conversation when adding indicators in order to capture changes in tension.
    (c) Condense the summary to 150 words while trying to preserve the turning points from step 2 and tone indicators indicated during revision. Omit the parts of the conversation that didn't contribute much to the overall trajectory and otherwise reword for brevity. For example,
        i. Condense lengthy or redundant back-and-forth conversation that doesn't introduce new points (but may impact tension) into fewer sentences summarizing the main developments
        ii. Omit irrelevant comments (e.g. brief interjections by a new user that did not have any substantial follow-ups)
        iii. Change a few direct quotes/details to more concise sentiment words (ex. "calling this blatant racism" $\rightarrow$ "... with condemnation")
        iv. Other editorial changes
4. After comprehensive summary, write the speaker summary by
    (a) Prior to writing the speaker summary, identify the key speakers based on the comprehensive summary.
        - Usually whichever speakers spoke the most, but also consider those contributed to the *key moments*
    (b) For each key speaker, reread only their comments in the original conversation. Then in one sentence, describe their specific changes in tone/stance/conversation strategies and interactions/responses to other key speakers

A.2 Interactive Work

Annotators start the interaction from the following setup:

- Annotator A: having completed the individual work for the conversation, i.e., read the original conversation and wrote the comprehensive summary and the speaker summary

- Annotator B: didn't read the original conversation, now writes the summary of conversation dynamics.

Collaboratively, they follow these steps, which we describe from a third-person perspective for better clarity.

1. Annotator B reads the comprehensive summary and speaker summary out loud. They ask initial questions to Annotator A confirming the order of speaker comments and key speakers ("Speaker1 then Speaker2 then Speaker1 again?", "Speaker1 spoke the most?"), the overall stance/speaker relationship of the argument ("Speaker1 and 3 agreed, and both disagreed with Speaker2?")

2. Annotator B begins writing the SCD by first copying the first sentence of the comprehensive summary, which often describes the overall topic of the conversation in a few words.

3. Annotator B identifies the first *section* of the comprehensive summary, highlighting the summary sentences on the document so that Annotator A can also reference.

    - *section* – usually 1-3 *comments* that fall before/in between any *key moments*. These *comments* should have a similar impact on the overall conversation dynamics, so that it makes sense to condense them into one sentence in the SCD
    - Annotator A may disagree with condensing the section if they think important information from within the section would be lost (e.g. different tone/rhetorical elements, argumentative stances)

4. For each *section*, Annotator B writes a corresponding summary capturing the dialogue acts, conversation strategies, and tonal elements, without any topical details.

    - dialogue acts and conversation strategies examples: disagreement, agreement, counterargument, criticism, accusation, providing sources, requesting sources, insulting, defending, acknowledging, conceding, rhetorical questions, invalidating, repetition, using long comment
    - tonal elements example: sarcasm, passive-aggressiveness, bluntness, rudeness, civility, neutrality, passion, harshness, strength, assertiveness, politeness, friendliness, objectivity, annoyance, frustration, tension, provocation, skepticism, demanding
    - If the indicator of tone is missing or not clear, Annotator B asks Annotator A questions such as the ones below, and Annotator A often goes back to the original conversation to reread comments and provide accurate answers to the questions or even read aloud whole phrases of a comment if needed to give proper context
        - B: "Was this said neutrally, or is there something about the tone that I should note?"
        - B: "Is the comment overtly rude, or is it just passive-aggressive or blunt?"
    - Annotator A reviews the work done on this *section* and makes corrections or suggestions if they think the conversation dynamics summary isn't an accurate representation of the conversation. And, Annotator A and B would revise the sentences together.
    - They repeat this process for each *section*.
    - Annotator A rereads the whole conversation dynamics summary, noting if any part does not seem to accurately reflect the original conversation/comprehensive summary. Both people work together to correct any such cases with the question-asking method above.
        - If needed, annotators would condense the summaries to be under 80 words, but usually they were already within range.

B Informativeness Check

Conversations covered in the check. We first sample 10 conversations on 10 different topics. 5 of the conversations are 'derailing' and 5 are 'non-derailing'. Each of these conversations makes one

question, where this conversation offers its transcript and a segment from its summary as the correct choice. The paired conversations of these 10 conversations offer the first type of distractors as discussed in the main text (same topic but opposite derailment label). Then, for the second distractor of each question, we use a conversation that has a different topic but the same derailment label as the correct choice. We also ensure that each conversation is used only once across all questions (either offering a transcript and correct choice or offering a distractor). This way, each choice in the question represents a unique conversation and we maximize the coverage of our check, covering a total of 30 conversations.

Extracting and processing segments. For this basic check, we define a segment as a sentence that has 2 speakers. Each summary would have multiple segments and we always randomly select one. For the three segments (choices) of a question, we rename them in such a way that the speakers in all three segments have the same pseudonames. The speakers in the transcript is also renamed accordingly to be consistent with the correct segment. This effort prevents a question from being trivial when, for example, "Speaker5" appears in a distractor but never appears in the transcript, which immediately rules out this distractor. With this renaming, annotators have to carefully read all 3 choices against the transcript to answer a question correctly.[10]

C Human Forecasting Experiment

We now discuss our design for evaluating human forecasting on conversation summaries. To design experiments that respect the annotators' attention span, we divide the 20 conversations into two batches of 10 conversations for 2 rounds of exercises with the same procedure. All annotators participate in both rounds.

In each round, we have 10 subjects divided into 2 groups (A and B), each completing one version of our questionnaires (each containing 10 summaries). The questions are designed such that the i-th question in either questionnaire presents a summary for the same conversation but the summaries are created differently (one is human-written and the other is machine-generated). For example, if the i-th question in Questionnaire A is a human-written summary for a conversation, then the i-th question in Questionnaire B is a procedural prompt summary for the same conversation. This way, each participant has an equal weight on the results for human-written and machine-generated summaries, and thus any difference between these results can not be attributed to a single annotator (e.g., that is exceptionally good at the forecasting task).

For each conversation, the annotator sees the conversation summary and is asked to guess whether the conversation will derail in the future and give scores for their confidence in their guess, topic understanding, and conversation trajectory understanding. We briefly define conversation trajectory at the start of the questionnaire, as how the interaction between speakers evolves during the discussion, independent of the actual topics discussed. Additionally, we also record the time between the subjects seeing the summary and submitting the forecast. Figure 2 presents an example question. After the experiment, we also debriefed the subjects to understand how they understood the questions; one observation that stood out was confusion regarding the trajectory scale and how that relates to the guess they are making.

For evaluating human forecasting on transcripts, we follow a similar design with some modifications. First, we have a different group of 10 participants, such that there is no pollution between the two experiments. Since reading a transcript requires much longer time than reading a summary, each participant only reads 10 transcripts, with the exception of 2 participants who volunteered to read all 20 transcripts. This results in 6 guesses for each transcript.

D Details of Summarization Models

D.1 Generating Multiple Summaries For a Conversation

For every summary type (e.g., traditional prompt, procedural prompt, finetuned BART), we repeat the process of generating summaries and running the downstream evaluation in 4 trials, each trial generating a different summary for a conversation. For a summary type based on a finetuned model, in each trial we finetune the model with a different random seed for summary generation. For a summary type based on prompting GPT-3.5-turbo, we simply utilizes its stochasticity, using its default sampling parameters to generate a new summary for each conversation.

[10] Before this renaming, we've already anonymized the speakers' usernames with Speaker1, Speaker2, etc., to respect the their identity.

Based on...	Accuracy
transcripts (subset)	56.0
procedu. prompt summ. (subset)	**71.5** (2.5)
BART summ. (subset)	57.5 (3.0)
DialogLED summ. (subset)	55.0 (4.2)

Table 4: Few-shot GPT derailment forecaster performance based on finetuned models summaries (for the 50 test set conversations that do not have human summaries). We include results on transcripts and procedural prompt summaries of the same 50 conversations for reference.

D.2 Finetuned Summarization Systems

For finetuned summarization systems, we use 40 transcript-summary pairs from our human summary dataset for finetuning, 10 pairs for development, and generate summaries for the remaining 50 test set conversations that do not have human summaries. The generated summaries are then evaluated with our downstream task in Section 4.

We first experimented with the SOTA conversation summarization systems, BART-large and DialogLED (Lewis et al., 2020; Zhong et al., 2022). Both systems previously showed strong performance on long dialogue summarization datasets with small train sets, such as AMI (train size 97) (Carletta et al., 2006) and ICSI (train size 43) (Janin et al., 2003), as reported in Zhong et al. (2022). Table 4 reports the performance brought by summaries from finetuned BART and DialogLED in our downstream task. We find that these models finetuned on the 40 human written summaries, do not produce summaries that lead to better forecasting results than procedural prompt summaries.

Additionally, we attempted to finetune GPT-3.5-turbo using OpenAI's API. Due to the high cost OpenAI charges for finetuning and inferencing on finetuned checkpoints, we find adequate hyperparameter search unfeasible and stopped after obtaining one checkpoint with reasonable summary quality. The summaries by this checkpoint led to an accuracy of 61.9% in the downstream task, substantially lower than the accuracy brought by the procedural prompt summaries (Table 4).

D.3 Other Forecasting Systems

For using GPT-3.5-turbo as few-shot classifiers, we set the sampling temperature to 0 for deterministic behaviors.

Additionally, we also experimented with other classifiers using supervised training to forecast conversation derailment. We use the transcripts or the generated summaries of the train (234 conversations) and dev (100 conversations) splits of our dataset to obtain trained classifiers and run inference on the transcripts or generated summaries of the test split (100 conversations). We examine two strong baseline models for text classification for this supervised setting, namely BART and Longformer. Although these supervised models are consistently outperformed by the GPT few-shot classifier (Table 2), when comparing their performances on the generated summaries, we still find that procedural prompt summaries best help the downstream forecasting of conversation derailment, indicating that our conversation dynamics summary task indeed helps automatic systems to forecast conversation derailment.

D.4 Prompt Engineering

When developing our zeroshot and procedural prompts for dynamics summaries, we tried different synonyms for conversation dynamics and specific dynamics elements, as well as changing the phrasing of their definitions and examples. For example, instead of simply prompting the model to summarize 'conversation dynamics', which might appear as a novel jargon to the model's parametric knowledge, we instruct the model to write a summary that captures the trajectory of the conversation, especially focusing on how elements like tone, sentiment, conversation strategies may change or remain the same throughout the conversation. We then manually examine the quality of generated summaries for a small prompt engineering dataset (size 10) that's disjoint with our dev and test splits. For the procedural prompts, in particular, we manually wrote example summary segments to contrast different aspects of traditional summaries with those of SCDs, and included these examples in the procedural prompt. Figure 3 shows the two prompts we eventually chose as the zeroshot and procedural prompts for SCDs.

E Qualitative Analysis

Inspired by prior literature (Habernal et al., 2018; Zeng et al., 2020; Zhang et al., 2018a; Li et al., 2020a), we focus on a set of conversation strategies related to conversation trajectories for our qualita-

tive analysis in Section 5. Here, we present the list in Table 11.

F Miscellaneous

F.1 Transcript of the Introductory Example

We provide the transcript of our introductory example in Figure 4 to 7. The last 3 utterances of the transcript are omitted as how it appears in our dataset.

F.2 Data Collection

Annonymization. We collect human summaries for conversation transcripts from the published dataset CGA, which we accessed through ConvoKit 2.5.3. The dataset contains the usernames of the conversation participants, which we replace with 'Speaker1', 'Speaker2', and etc. to respect the users' identity.

Annotators. All annotators for our evaluations are recruited as volunteers from university students in the US. The two annotators who wrote the summaries of conversation dynamics are co-authors of this paper. The data collection was approved by an Institutional Review Board at the authors' institution. All annotators were informed that their data would be used for an NLP research and eventually a published paper before they gave consent.

Disclaimer of Risks. All annotators are informed that "some of the conversations presented in the annotation task can be extremely biased and offensive and speak of sensitive topics." All annotators gave their consent to participate.

F.3 Implementation Details

For our finetuned models, we conducted hyperparameter search over learning rates [3e-6, 5e-6, 1e-5, 2e-5, 3e-5, 5e-5, 1e-4] and warmup steps ([40, 80] for summarizers and [234, 468] for classifiers), and used the default values from their original implementation for other hyperparameters. For the DialogLED and BART summarizers, we eventually used a learning rate of 3e-5 and 80 warmup steps. For the BART classifier, we used a learning rate of 3e-6 and 468 warmup steps. For the Longformer classifier, we used a learning rate of 5e-6 and 468 warmup steps. The finetuning experiments in total took about 150 GPU hrs on an Nvidia A40 GPU.

F.4 Used Artifacts

We include a list of existing artifacts we used. Some of them have been cited in the main sections of this paper above. We have closely followed their intended use.

- GPT-3.5-turbo-0613:
  a snapshot of GPT-3.5-turbo from June 13th, 2023. Closed-source but accessible at a low cost via OpenAI's API, https://platform.openai.com/docs/

F.5 Additional Evaluation Metrics

Here, we provide additional performance metrics (precision, recall, macro-averaged F1) for different summary types, when they are evaluated with our derailment forecasting task. Each summary type is evaluated with its respective GPT-3.5 few-shot derailment forecasting model as described in Section 4.1.

Derailing?	prec.	rec.	F1
False	72.7	32.0	44.4
True	56.4	88.0	68.8
macro avg	64.6	60.0	56.6

Table 5: Additional metrics for derailment forecasting on **transcripts**

Derailing?	prec.	rec.	F1
False	57.1	66.5	61.4
True	59.9	50.0	54.5
macro avg	58.5	58.3	58.0

Table 6: Additional metrics for derailment forecasting on **traditional summaries**

Derailing?	prec.	rec.	F1
False	56.1	80.0	66.0
True	65.2	37.5	47.6
macro avg	60.7	58.8	56.8

Table 7: Additional metrics for derailment forecasting on **zeroshot prompt summaries**

Derailing?	prec.	rec.	F1
False	62.9	84.0	72.0
True	75.9	50.5	60.7
macro avg	69.4	67.3	66.3

Table 8: Additional metrics for derailment forecasting on **procedural prompt summaries**

Derailing?	prec.	rec.	F1
False	57.6	65.0	60.6
True	59.2	51.0	54.2
macro avg	58.4	58.0	57.4

Table 9: Additional metrics for derailment forecasting on **finetuned BART summaries**

Derailing?	prec.	rec.	F1
False	56.1	49.0	50.3
True	54.4	60.0	55.6
macro avg	55.3	54.5	52.9

Table 10: Additional metrics for derailment forecasting on **finetuned DialogLED summaries**

[Conversation Summary]
Speakers discuss the responsibilities of caregivers of autistic children. One Speaker opens up the discussion using strong language. Speaker3 and Speaker4 begin to argue in a passive-aggressive manner, which then transitions into sarcasm, accusations, and questioning each other's logic. Speaker4 supports their point with a personal experience, which Speaker3 refutes rudely.
Will the conversation go awry (derail)?

◯ Yes

◯ No

Confidence of your answer (1 for least confident and 5 for most confident)

◯ 1

◯ 2

◯ 3

◯ 4

◯ 5

To what extent did the summary help you understand the topic of the conversation (on a scale of 1 to 5)?

◯ 1: I don't even know the general topic.

◯ 2

◯ 3: I know the general topic of the discussion.

◯ 4

◯ 5: I know how each Speaker is related to the topic.

To what extent did the summary help you understand the conversation trajectory (on a scale of 1 to 5)?

◯ 1: I don't have any idea of the trajectory of the conversation.

◯ 2

◯ 3: I have a general understanding of the trajectory.

◯ 4

◯ 5: I have a thorough understanding of how each Speaker contributed to the trajectory.

Figure 2: Example question for derailment forecasting based on summaries.

Zeroshot Prompt:
Write a short summary capturing the trajectory of an online conversation. Do not include specific topics, claims, or arguments from the conversation. Instead, try to capture how the speakers' sentiments, intentions, and conversational/persuasive strategies change or persist throughout the conversation. Limit the trajectory summary to 80 words.

Procedural Prompt:
Write a short summary capturing the trajectory of an online conversation. Do not include specific topics, claims, or arguments from the conversation. The style you should avoid:
Example Sentence 1: "Speaker1, who is Asian, defended Asians and pointed out that a study found that whites, Hispanics, and blacks were accepted into universities in that order, with Asians being accepted the least. Speaker2 acknowledged that Asians have high household income, but argued that this could be a plausible explanation for the study's findings. Speaker1 disagreed and stated that the study did not take wealth into consideration." This style mentions specific claims and topics, which are not needed.
Instead, do include indicators of sentiments (e.g., sarcasm, passive-aggressive, polite, frustration, attack, blame), individual intentions (e.g., agreement, disagreement, persistent-agreement, persistent-disagreement, rebuttal, defense, concession, confusion, clarification, neutral, accusation) and conversational strategies (if any) such as 'rhetorical questions', 'straw man fallacy', 'identify fallacies', and 'appealing to emotions.' The following sentences demonstrate the style you should follow:
Example Sentence 2: "Both speakers have differing opinions and appeared defensive. Speaker1 attacks Speaker2 by diminishing the importance of his argument and Speaker2 blames Speaker1 for using profane words. Both speakers accuse each other of being overly judgemental of their personal qualities rather than arguments."
Example Sentence 3: "The two speakers refuted each other with back and forth accusations. Throughout the conversation, they kept harshly fault-finding with overly critical viewpoints, creating an intense and inefficient discussion."
Example Sentence 4: "Speaker1 attacks Speaker2 by questioning the relevance of his premise and Speaker2 blames Speaker1 for using profane words. Both speakers accuse each other of being overly judgemental of their personal qualities rather than arguments."
Overall, the trajectory summary should capture the key moments where the tension of the conversation notably changes. Here is an example of a complete trajectory summary.
Trajectory summary:
Multiple users discuss minimum wage. Four speakers express their different points of view subsequently, building off of each other's arguments. Speaker1 disagrees with a specific point from Speaker2's argument, triggering Speaker2 to contradict Speaker1 in response. Then, Speaker3 jumps into the conversation to support Speaker1's argument, which leads Speaker2 to adamantly defend their argument. Speaker2 then quotes a deleted comment, giving an extensive counterargument. The overall tone remains civil.
Now, provide the trajectory summary for the following conversation.
Conversation Transcript: [...]

Figure 3: Zero-shot prompt and procedural prompt for SCDs.

Strategies	How they can be mentioned in dynamics summaries
Rhetorical questions	"poses a rheotrical question", "rhetorically asks"
Attacking logic	"point out flaws in [the other speaker]'s arguments", "accuses [the other speaker] of their logical fallacy"
Anecdotal experience	"shares a personal story", "uses an anecdotal example"
Evidence	"cites statistics and data to support their viewpoint", 'uses external sources to support"
Juxtaposition	"makes a comparison between", "provides a detailed explanation of the differences between"
Analogy	"uses an analogy to support"
Pointing at missing or unsupported evidence	"asks for evidence", "criticizes the lack of evidence"
Accusing of not correctly treating their argument	"accuses [the other speaker] of not reading their arguments", "accuses [the other speaker] of reinterpreting their positions"
Questioning one's knowledge or attacking one's lack of knowledge	"insulting [the other speaker]'s knowledge of [the subject]", "accusing [the other speaker] of lacking the knowledge of [the subject]"
Hypothetical example	"proposing another hypothetical scenario"
Counterexample	"presents counterexamples"

Table 11: List of conversation strategies a speaker may use. For our qualitative analysis, we consider an SCD 'mentions' a conversation strategy only if it explicitly identifies what the strategy is, as shown in the examples listed in the second column of this table. For example, if a summary simply paraphrases the exact rhetorical question or the cited evidence, then we do not count it as 'mentioning' a conversation strategy.

Transcript:
Speaker1: Businesses aren't charities. They exist to make a profit. "Morals" and "ethics" are always trumped by profit in the business world.
Speaker2: That's.... Kind of the inherent problem.
Speaker3: For you. Whenever there is a "problem", it is usually some party wanting to further their interests. Remember that morals do not exist out there, they are a construct of society. If a majority is disadvantaged, they may use "morals" to push for their interests.
Speaker2: Unchecked capitalism is economically unsustainable. So yes, it is a problem for me, and for everyone participating in the economy. Business involves more than just profits. It involves human beings investing their labor. These are not machines. The idea that profit alone should drive our economic decisions is morally bankrupt. Human beings deserve a modicum of dignity. If you can't agree to that, and you think that slavery is OK and justified as long as the business is profitable, then I would posit that you too are morally bankrupt.
Speaker4: "Unchecked capitalism is economically unsustainable." what do you mean "unsustainable"? what happens?
edit: [MFW I get my daily reddit downvotes for questioning a socialist](http://i.imgur.com/QoGM3.gif)
Speaker2: Well, let's have an economic thought experiment.
Rule 1: Businesses only care about profit (and typically the short term profit at that, not longer term returns).
Rule 2: Businesses have nothing to check them from abusive practices.
Let's think of some common things people believe are good about this scenario:
1) Everyone seeks to further their own means so with supply and demand everything works out in the end!
2) If a company has poor practices, the consumer will migrate to other options.
3) If a company has poor practices, another company will be developed to compete against it, forcing it to rid itself of those poor practices.
Now let's think about whether or not those thoughts can sustain themselves in the thought experiment.
1) Why wouldn't companies seek to form cartels? We already have evidence that they do this, even among competitors. You might say that they'll be seeking to further their own means, so this is only temporary. But I would ask you to consider that if Company A and Company B can make larger profit margins colluding than they can competing, why wouldn't they? Sure, Company A might be able to make slightly higher profits down the road if they were able to beat Company B outright, but that takes short term investment (and therefore cost) and effort. With collusion, we can maximize profits with minimal effort and cost.
2) But surely if A&B collude with one another, C will come out of the woodwork and offer a better product/service at a better price, right? But will they? If A&B catch wind of C, what's to stop them from using potentially coercive means from stopping them from competing. For example: hostile takeovers. A&B are a cartel now, and they are established, so they certainly have the capital necessary to absorb C as a fledgling company.
3) If A&B are colluding, what's to stop them from slowly degrading the conditions of their workforce? Like the employees of office space only working hard enough not to get fired, A&B are only going to create conditions good enough as to not lose profit margins.
4) If A&B are able to block competitors from the industry, what motivation do they have to innovate and improve their products?
5) What's to stop A&B from doing environmentally disastrous things (pollution for example)? If short term profits are all that matter, why would they bother to care?

[continues from the previous page]
All of this isn't to say that Government must be the check on businesses. Government can be the tool of business to enshrine their power as well. But capitalism by itself can have some pretty negative consequences when it is extrapolated out. The problem is the fundamentals of capitalism are built on a foundation of assumption. That assumption is that when people seek to fulfill their individual desires, with supply and demand and perfect competition at play, that everything reaches an equilibrium. The problem here is that perfect competition is never really at play. Like most things "perfect" it's an idea, not a reality. You can't enforce perfect competition. So the next closest thing you can do is create an environment where competition is maintained and our perpetually imperfect competition doesn't get too out of control.
Personally, I'm a believer in social democracy - I believe that capitalism can be good when it is juxtaposed by the idea of solidarity with all of mankind (as opposed to purely selfish means). That's not communism, mind you, it just means that we shouldn't lose sight of humanity in the process. When we think about that as a counter to selfish greed, we start thinking about longer term returns, we start thinking about societal benefit, we start humanizing the capitalistic process (they aren't "capital" or "human resources" or "employees" they're people investing their efforts in making these companies perform).
I hope that addresses some of your question. It was a bit open ended, so I tried not to ramble on too much.
Speaker4: that addressed ZERO of my question. you completely failed to address what happens when a capitalist system reaches its alleged "sustainability" threshold.
my question was not open-ended. what occurs when it is no longer sustainable? you said it was unsustainable. your hypothetical "what ifs" don't support your assertion.
Speaker2: Ok. Thanks for the attitude. Now I'm just going to give you a curt response.
Economic collapse. Mass unemployment. Overly polluted and toxic environments. Did you just want a parade of horribles?
Speaker4: attitude? i just explained that you didn't answer my question. you gave me an opinionated rant instead of an explanation.
what am i supposed to do, just say "oh thanks"?
"economic collapse" yeah, you said that already. why? how?
"mass unemployment" how? everybody just gradually becomes unemployed "because capitalism"?
"toxic environments" why? is there some aspect of socialism that prevents toxicity in products? does socialism provide some sort of waste-disposal service unavailable in a capitalist system? you just keep throwing out matter-of-fact assertions, but i don't see how you are arriving at your conclusions.
and apparently you interpret scrutiny as "attitude" that you take offense to... i dunno. I'm not convinced.
edit: annnnd im downvoted instead of having any of those valid questions answered.
Speaker2: "attitude? i just explained that you didn't answer my question. you gave me an opinionated rant instead of an explanation." Sorry, perhaps I'm just reading into the emphasis from "ZERO" and "completely". The tone of your response and the one that followed seemed to be ... dickish, for lack of a better word. If I'm reading into it, my apologies.
Economic collapse. Increasingly volatile market behaviors as a result of increasingly risky investments. Essentially: short term profit at any cost. The system fails to account for long term sustainability.
[continues on the next page..]

Figure 5: Transcript of the conversation used for the introductory example, Part 2 of 4.

[continues from the previous page]
Mass unemployment. Actually, we're already on our way to mass unemployment due to automation. I just read an article about us losing 5 million (net) jobs by 2020 to automation and AI (that includes the 2mil that will pick up new jobs from the new tech). You also have an increasing population who can be provided for but not necessarily enough jobs to have them making a worthy contribution.
Toxic environments. I actually didn't mention socialism, you did. I said social democracy. The primary economic driver of social democracy is capitalism. It's just checked. But even still: yes. There is something inherent in those systems that greatly reduces the risk of toxicity. The people who make the products and and invest the labor are the ones who realize the gains. They are also the ones to decide whether or not those gains are worthwhile given the risks.
In a raw capitalism system: the capitalist realizes the gains and, due to the increased capital, can largely insulate themselves from the associated risks. Drinking water pollution is an example of this. The rich typically don't have this problem as they can afford to purchase potable water. The poor and working class may not always have their luxury (Flint, MI for example). So the people who have to live with the realities and consequences of their production are the ones making the decisions as opposed to someone who doesn't have to live with them or who can use their financially superior position to avoid them.
Other examples include the short term profits associated with taking unnecessary risks: see countless oil spills and deepwater horizon. Also see: covering up of global warming by oil companies or covering up of health hazards by cigarette companies.
The capitalist system *encourages* this behavior. It is financially beneficial (short term profits are encouraged over long term profits and investment - this is legally supported through cases dating back to Dodge v. Ford). A checked capitalist economy disincentivizes that behavior through regulation and social welfare. A socialist economic system would probably do the same through the reality that people who would be causing the harm are the people who have to live with the harm and are less likely to remove themselves from it.
If we want to debate the core tenets of a capitalist economy: that's fine. But I operate on the presumption that we both agree the goal of a capitalist economy is to generate profit (with a weight towards short term profit especially with larger firms having to provide quarterly earnings and financial benefit for shareholders).
To get back to OP - the minimum wage is *one* check on the default capitalist economic framework (to drive costs as low as possible). OSHA is another. The FDA is another. The SEC is another. And so on and so forth.
Speaker4: thank you for that thoughtful response. i do type in a very tonal, speech-based style, so people actually accuse me of being "a dick" or "irate" pretty frequently. i guess i will just have to get used to it.
i just mentioned socialism as an alternative to compare to in the pollution argument, i didn't mean to presume to say you were, necessarily. my apologies if it seemed that way.
So anyway, yes. I agree that capitalism creates volatile markets. However, I don't consider it to be as threatening as you seem to. I can't understand any situation that would cause a cataclysmic death or cessation of those markets. There will always simply be peaks and valleys.
"The system fails to account for long term sustainability."
[continues on the next page..]

Figure 6: Transcript of the conversation used for the introductory example, Part 3 of 4.

[continues from the previous page]
This is really vague. What happens when it no longer becomes sustainable? Anarchy? Does the wealth stop existing? Where does it go? Does it become impossible to make purchases or be paid for your work? Does everyone die? I am really trying to pin down what exactly you mean by a system "sustaining" itself. It seems more like a system that would have to be electively given up, like a language that dies out, instead of something that can break and has to be discarded, like a broken dish or a burnt-out light bulb.
In this sense, I don't see how any other ideology or economic system would succeed or fail in any of these areas, without the "unchecked" qualifier I see so commonly applied to critique of capitalism.
"unchecked" *is* the problem. greed is the problem. overpopulation is the problem. creation of toxic byproducts and harmful processes is the problem. a sheltered ruling-class is the problem. none of these things will disappear by switching ideologies. no other economic system is better, or worse, -equipped to eradicate these things. similarly, blaming "unchecked" application of any other system for the existence of these problems would be just as silly as blaming capitalism.
Speaker2: That was my point in the beginning though. That unchecked capitalism is bad. I am merely arguing for a check on it. Something to keep it from becoming too volatile, too disruptive, too detrimental. Something to keep it contained. I view capitalism like a nuclear reactor. If you keep the reaction going and have the right containment - you've got a nice source of clean energy. But if you fail to keep it contained - you've got bad news.
To your question of what happens. It can really mean any number of things. It could mean a very slow dystopian degradation of society wherein the rich get progressively richer and the poor become bottom feeders with short lifespans. It could mean everyone dies (perhaps through experimentation gone awry - particularly in the energy or medical fields). I'm not sure about wealth ceasing to exist outright, I don't know what that would look like or how that would come about. Anarchy is certainly possible, so is revolution (as the rich get richer, the poor get angrier - extrapolate that and we have a recipe for repeating history).
Like I said, some of those problems can be avoided when the people profiting from the production are the people doing the production. It connects them with the consequences. It functions as a systematic check. Is it perfect? surely not.
I agree that greed is the problem. But greed isn't a bug in capitalism, it's a feature. Like the nuclear reaction, we're trying to harness the human motivation behind greed and seize it. But, we don't want it to get too far out of control. It's a balancing act.

Can Language Model Moderators Improve the Health of Online Discourse?

Warning: this paper contains and discusses content that may be offensive.

Abstract

Conversational moderation of online communities is crucial to maintaining civility for a constructive environment, but it is challenging to scale and harmful to moderators. The inclusion of sophisticated natural language generation modules as a force multiplier to aid human moderators is a tantalizing prospect, but adequate evaluation approaches have so far been elusive. In this paper, we establish a systematic definition of conversational moderation effectiveness grounded on moderation literature and establish design criteria for conducting realistic yet safe evaluation. We then propose a comprehensive evaluation framework to assess models' moderation capabilities independently of human intervention. With our framework, we conduct the first known study of language models as conversational moderators, finding that appropriately prompted models that incorporate insights from social science can provide specific and fair feedback on toxic behavior but struggle to influence users to increase their levels of respect and cooperation.

1 Introduction

The rapid increase in online users and the growing polarization of society have created significant challenges in maintaining civil discourse and mitigating harmful content in online platforms (Guberman et al., 2016; Almerekhi et al., 2020). Effective moderation is necessary to counter this trend, but scaling moderation efforts to meet the demands of an expanding user base is difficult without some form of automation. Previous automatic moderation efforts have largely focused on banning or deleting comments from harmful users (Srinivasan et al., 2019; Park et al., 2021). However, such iron-fisted approaches can inadvertently push these users towards echo chambers that exacerbate polarization (Cinelli et al., 2020).

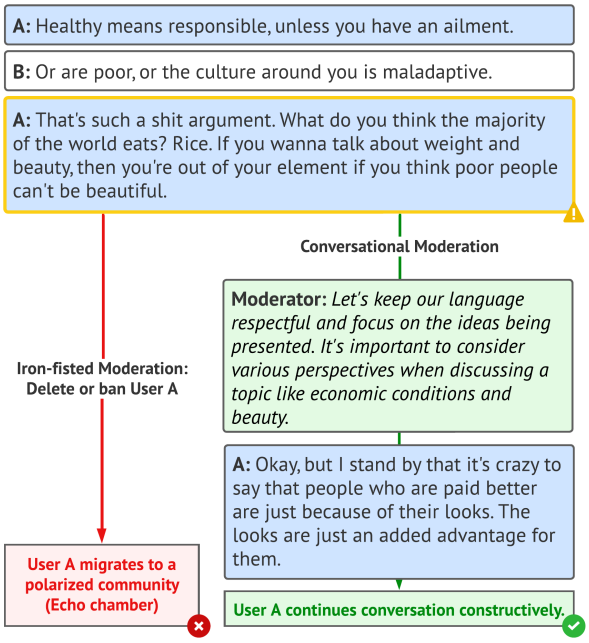

Figure 1: While banning users or deleting their comments may push them towards echo chambers (left), conversational moderation can guide users towards more constructive behavior (right). Recent developments in instruction-tuned language models with conversational capabilities present an opportunity to perform conversational moderation at scale and improve the health of online discourse.

An alternative to these efforts is *"conversational moderation,"* in which a moderator converses with the problematic user to guide discussions towards a more constructive outcome, as shown in Figure 1. Recent studies have shown that engaging in conversations is an effective approach for moderating users' behaviors (Combs et al., 2022), and there are efforts such as *The Commons*[1] that encourage human moderators to interactively intervene in controversial conversations on race and politics. However, human moderators have reported steep learning curves in engaging with harmful users (Laurenson, 2019) and moderation is mentally taxing (Steiger

Proceedings of the 2024 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies (Volume 1: Long Papers), pages 7478–7496
June 16-21, 2024 ©2024 Association for Computational Linguistics

et al., 2021), making this approach challenging to scale. Therefore, human moderators could benefit from a reduced cognitive load by the availability of conversational moderation suggestions provided by *moderator bots*. Fortunately, the recent advancement in prosocial dialogue models (Kim et al., 2022, 2023) and instruction-tuned language models (ITLM) that can generalize well to new tasks with zero or very little task-specific data presents a potential for scaling up conversational moderation with the help of these suggestions (Wei et al., 2021; Kojima et al., 2022; Ouyang et al., 2022; Bai et al., 2022; Köpf et al., 2023; Zhou et al., 2023). The central question is whether there is enough evidence that the moderator bot suggestions are effective enough for human moderators to use in the course of their duties.

To this end, we seek to answer the following research questions in this paper:

R1: How should we define and evaluate *effectiveness* in conversational moderation?

R2: How effective are moderator bots at conversational moderation?

To answer these questions, we develop an evaluation protocol driven from existing literature (Grimmelmann, 2015; Srinivasan et al., 2019; Kiesler et al., 2012; Argyle et al., 2023) and conduct studies to determine the effects of conversational moderation on social cohesion and conflict resolution. We build a novel framework that enables us to monitor realistic user interaction with moderators in the context of a real, controversial online discussion, yet in a manner that ensures minimal risk to users, and measure the perceived effect of moderation on user behavior via surveys given to users after a moderation encounter. With this framework, we evaluate a range of approaches to moderation, including existing prosocial dialogue models (Kim et al., 2022, 2023) and prompted ITLMs informed by conflict resolution (Lytle et al., 1999), cognitive behavioral therapy (Clark and Egan, 2015), and prosocial communication techniques (Rosenberg and Chopra, 2015).

Our results show that prompted ITLM moderators can provide specific and fair feedback, but making users more respectful and cooperative is challenging. They largely outperform prosocial dialogue models, and one that incorporates Socratic dialogue techniques from cognitive behavioral therapy performs the best among the methods we explored. Interestingly, we also find that the perceived effectiveness of our moderators varies based on whether the evaluator is the moderated user or an observer. To encourage the research community to build on our evaluation framework and study, we release our dataset of controversial conversations and completed conversations with annotations.[2]

2 Evaluating Conversational Moderation

Prior to exploring how to develop conversational agents that can assist with conversational moderation, we first define moderation effectiveness and its metrics in the context of conversational moderation (Section 2.1-2.2) and identify experimental design criteria that should be balanced (Section 2.3. Then, based on these factors, we propose a framework for evaluating how useful language models (LM) can be in assisting with conversational moderation (Section 2.4.1-2.4.3).

2.1 Definition of moderation effectiveness

At the highest level, Grimmelmann (2015) states that moderation should *prevent abuse* and *facilitate cooperation* for not only the moderated user, but also for other community members. In other words, moderation events should (i) make users more engaged and willing to cooperate (`cooperative`) and (ii) make them more respectful and less abusive (`respectful`).

In addition, Kiesler et al. (2012) found that fairness and clarity of community rules decreases resistance to moderation procedures. Therefore, for a moderator to be effective, it must also (iii) be fair to all users involved in the conversation (`fair`) and (iv) make specific and relevant suggestions to facilitate cooperation (`specific`).

2.2 Metrics for conversational moderation effectiveness

Srinivasan et al. (2019) map the aforementioned moderation goals in Section 2.1 to quantifiable metrics to measure a moderation event's effectiveness through its causal effect, such as the rate of noncompliance, toxicity, community contributions, and engagement after a moderation event. However, the moderation events here are limited to content removal, such as user comments being deleted.

We are unable to perform a similar analysis for conversational moderation due to the lack of data

[2]Available at https://github.com/isi-nlp/isi_darma

Criteria	Description	Implementation
Safe	Minimize harms.	Evaluation takes place offline with participants that provided consent and does not affect real users.
Realistic	Replicate realistic context.	Start with controversial conversation stubs to replicate highly charged conversations.
Controlled	Isolate and measure effect of moderation strategy.	Evaluate moderator bots with dyadic conversations between human participant and the bot, followed by a survey.

Table 1: Experimental design criteria and their corresponding implementation that grounds our conversational moderation evaluation framework. We strike a balance in keeping our evaluation procedure safe, realistic, and controlled for evaluating the effectiveness of conversational moderation by LM moderators.

that contains conversational moderation interactions. Therefore, we instead rely on directly asking questions as a survey about these dimensions to human participants that interact with the moderators to be evaluated. All questions are asked using a 5-point Likert scale using "Not at all", "Mostly not", "So-so", "Somewhat", and "Very", which gets translated to a numerical score from 0 to 4, respectively. More details on these questions are elaborated in Section 2.4.3.

2.3 Experimental design criteria

First, we identify the following important design criteria as those we strive to balance while measuring conversational moderation effectiveness: (i) *safe*: minimize any harms inflicted during the evaluation process, (ii) *realistic*: create a realistic environment that a moderator bot would operate in, and (iii) *controlled*: isolate and measure the effect of the moderation strategy from variables difficult to control. These design criteria and their corresponding implementations are outlined in Table 1. In the following sections, we describe each step of our evaluation procedure that balances these criteria while measuring moderation effectiveness.

2.4 Evaluation framework overview

Grounded on the aforementioned definition and metric for moderation effectiveness and experimental design criteria, we propose an evaluation framework for conversational moderation. We provide an illustration of our framework in Figure 2.

Our framework consists of three main steps. First, we find controversial conversation stubs from Reddit. An artificial environment of starting a conversation from scratch is unlikely to replicate a highly charged conversation, and thus we use real controversial conversation stubs to seed the conversations between a moderated user and a moderator.

Next, we import these conversational stubs into an offline evaluation protocol where we ask our study participants to continue a dyadic conversation with the moderator as the moderated user.[3] This setting allows us to marry the real heat of a discussion (*realistic* criterion) in need of moderation with minimal risk to human subjects (*safe* criterion) as no real users are affected by the moderators' responses.

Lastly, the participants are asked to answer a survey based on their experience of being moderated. In the following sections, we describe each steps in detail.

2.4.1 Controversial conversation stubs

For our controversial conversation stubs, we first select high-traffic subreddits that cover a wide range of topics: `r/news`, `r/worldnews`, `r/technology`, and `r/science`. Then, we find comments on Reddit that are given the controversial flair[4] and the threads that the comments are a part of. We filter out threads that are not multi-turn conversations so that we only keep those that have interactions between at least two users. From the filtered set, we use GPT-4 (OpenAI, 2023) as a second filter to confirm whether these threads are controversial. From those selected from GPT-4, we randomly sample and manually filter to get 20 high-quality controversial stubs to use for evaluation. We anonymize the threads for user privacy.

2.4.2 Conversation continuation

We are interested in isolating the effectiveness of a moderation strategy independent of the media-

[3]Whether our study participants can adequately simulate a continued conversation as the moderated user and assess moderator bots in their perspective is a reasonable concern, and we address this concern with a discussion on why role-playing is a valid approach for studying conversational moderation in Appendix A.

[4]This is provided through the Reddit API and is speculated to be determined by a function of upvotes and downvotes, but its details are not publicly disclosed.

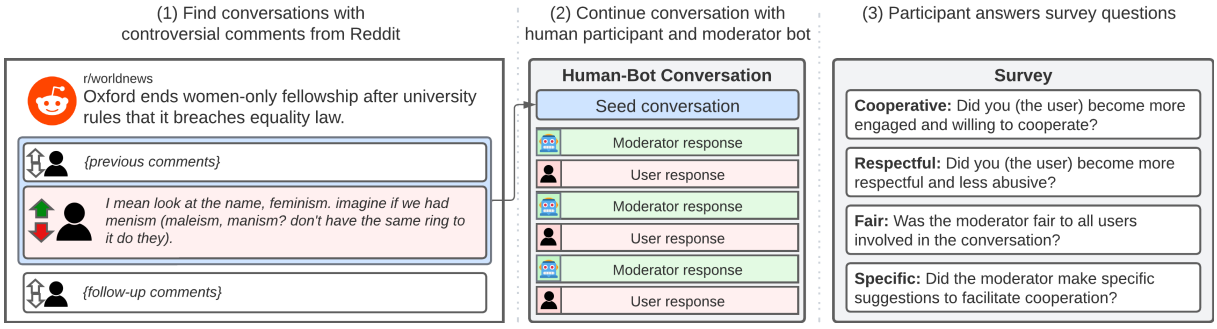

Figure 2: An overview of our evaluation framework. (1) We extract conversations with controversial comments from Reddit and use these as the seed conversations. (2) Moderator bots continue the seed conversations with participants who act as the moderated user. (3) At the end of the conversation, the participants answer a survey about the moderator and their experience.

tion from humans, which introduces another variable that is difficult to control (*controlled* criterion). Therefore, we set up an environment where participants can safely talk to moderators while acting as an online user that needs to be moderated. The participants then assess the moderators' effectiveness through survey questions that are grounded in Grimmelmann (2015)'s goals, which are discussed in Section 2.4.3.

Starting with the conversation stubs, we create a dyadic chat setup such that the participant and the moderator bot continues the conversation for three turns each. The moderator bot first sends its response to the controversial comment and the participant continues the conversation while acting as the moderated user that made the controversial comment. This multi-turn setup is crucial because we want to assess a bot's suitability as a conversational moderator and a single-turn intervention cannot capture its conversational capacity (Li et al., 2019; Jiang et al., 2021).

We acknowledge there is conversational quality lost in this simplification of a rich multi-party conversation to a dyadic conversation between a moderator and a single participant. However, by simplifying the mechanism for follow-up interventions, this setup allows us to isolate the examination of *"how should we moderate?"* from another important but frequently studied question, *"when should we moderate?"* (Guberman et al., 2016; MacAvaney et al., 2019; Almerekhi et al., 2020; Poletto et al., 2021; Park et al., 2021). We focus on the former in this work.

2.4.3 Survey questions

Once the conversation ends, the participants are asked to answer four questions that correspond to the metrics in Section 2.2 and optionally provide feedback in free-form text. The exact wording of these questions are shown in the far left of Figure 2. Two of these questions ask about how their behavior has been affected and the other two ask about the moderator's behavior. The first two questions (`cooperative` and `respectful`) ask whether the model was able to change the participant's behavior into facilitating cooperation and preventing abuse (Grimmelmann, 2015), and therefore is more subjective. The latter two (`fair` and `specific`) are less dependent on the participant's behavior and thus can be relatively less subjective.

In addition to these questions, we ask about possible confounding factors that we may need to control for, such as how much the participant agrees with the viewpoints of the moderated user that they are acting as (`agreeableness`) and how much they like the character they are playing (`likeability`). These factors may affect the degree to which moderator bots will be effective, regardless of the strategy taken. We later discuss our analysis on these factors in Section 5.4. We share all other details of our task, such as the task instructions, in Appendix B.

3 Automated Conversational Moderation

In this section, we describe various baseline LM-based moderators that we evaluate with our framework. These moderators are adapted from prosocial dialogue models or developed through prompt engineering with large LMs.

Prosocial dialogue models Cosmo-XL is a dialogue model that has been trained to be prosocial and contextualize social commonsense (Kim et al., 2023). Its training data includes ProsocialDialog (Kim et al., 2022), which is a dialogue dataset that contains social rules-of-thumb, intended to be

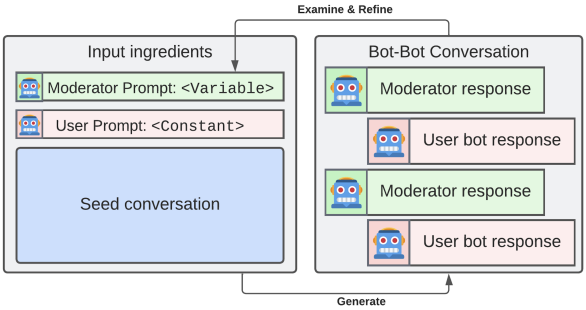

Figure 3: An overview of the self-talk method for designing prompts for LMs. We keep the Reddit user prompt constant while we refine the moderator prompt iteratively after examining the generated conversations.

generated from an intermediate model called Canary, which serves to ground a dialogue model's response and encourage prosocial behavior. While Cosmo-XL was not explicitly trained to function as a moderator, it seems likely that a model that suggests prosocial behavior may sway users to become more respectful and cooperative. Also, Cosmo-XL has been trained with speaker instructions, so we provide a simple instruction for it to function as a moderator. Therefore, we use Cosmo-XL and Canary + Cosmo-XL, which is Cosmo-XL with Canary-generated reuls-of-thumb, as dialogue model baselines.

Prompted LMs Large LMs fine-tuned with instructions are versatile zero-shot models for various downstream tasks, including dialogue. We take advantage of this new paradigm to prompt engineer moderator bots. The process for engineering a prompt to evaluate with our evaluation framework is illustrated in Figure 3. Similar to the evaluation setup with a human participant, we have a bot take on both the role of the moderator and the moderated user to self-talk to continue a seed conversation for three turns each. We manually inspect these conversations to refine the prompts and repeat this process until we see responses that consistently reflect the desired behavior described in the prompt.

Our `Baseline` prompt is simply told to respond as a moderator. `Nonviolent Communication (NVC)` is a moderator that suggests nonviolent communication techniques such that conversation participants can practice deep listening and build more empathy for one another (Rosenberg and Chopra, 2015). Our last bot is `Socratic`, which uses Socratic dialogue techniques from cognitive behavioral therapy, which aims to critically think about their own beliefs and arguments (Clark and Egan, 2015; Ang et al., 2023). We find this approach promising and refine it the most to make the responses more natural, specific, and less repetitive.

We use OpenAI's `gpt-4` version of the ChatGPT model, so we denote these models as `GPT-{prompt type}`. All other technical details with regards to decoding hyperparameters are shared in Section B.3 and the exact input format for Cosmo-XL-based models and the wording for each prompt are shared in Section B.2. We also share a sample conversation with each of these approaches continued with human evaluators in Table 5 that qualitatively show how each moderator differs from one another.

4 Experiment Details

Evaluation infrastructure We collect our evaluations through Amazon Mechanical Turk. Our experiments are managed through the `boteval`[5] toolkit which facilitates conversational AI experiments by providing a centralized task management platform with Amazon Mechanical Turk (AMT) integration and templates for common dialogue evaluation and data collection use cases. Our custom frontend interface that the participant sees is illustrated in Figure 13. The survey on the left is hidden from the participants until the conversation is complete. We include two optional free-form text boxes that ask for feedback on the user experience with the interface and on how to improve the moderator.

Annotation collection Each of our moderators from Section 3 continued the 20 controversial conversation stubs with three different participants. This results in a target of 60 completed conversations and surveys for each moderator bot. We limit each participant to 50 conversation sessions to ensure we have a diverse group of participants. We aggregate the collected survey results using mean and standard error because of the small sample size.

Participants Our participants are recruited from TurkerNation, a Slack community group of AMT workers. We described our task on the `quals-and-screeners` channel and invited those who showed interest and said that they could speak fluent English. We asked them to complete a few qualification tasks first, and we gave them qualifications for the main task if their quality of

[5] https://github.com/isi-nlp/boteval

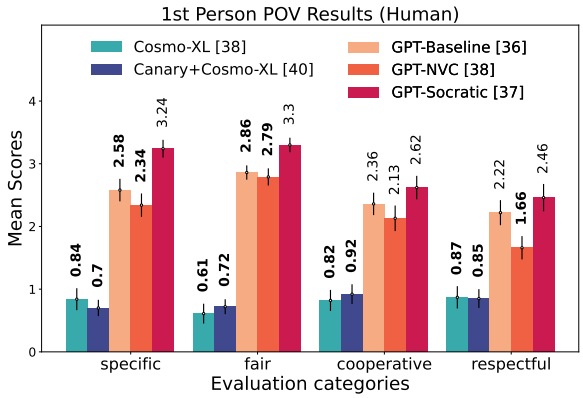

Figure 4: Survey results for evaluations done in first-person point of view. Error bars are standard error and bold numbers indicates statistically significant differences (at $p < 0.05$) with the best performing moderator on each metric, which is GPT-Socratic for all metrics. Numbers next to the label in the legend are the number of samples annotated for each bot.

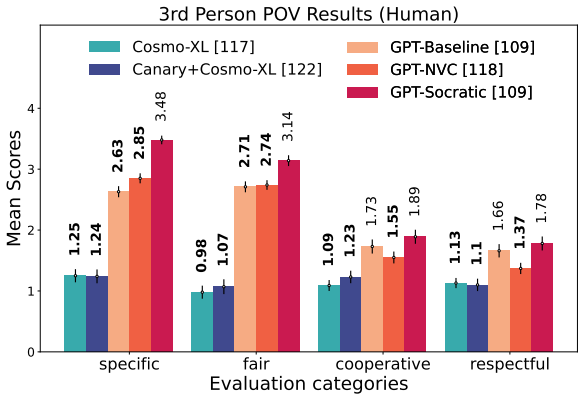

Figure 5: Survey results for evaluations done in third-person point of view. The diagram is annotated with the same method as Figure 4. Most trends from the first-person point of view apply here, but while scores for `specific` and `fair` remain similar, there is a statistically significant drop ($p < 0.05$) for all GPT-based models for `cooperative` and `respectful`.

work was acceptable. Through this process, we had 28 workers who completed at least one of our tasks. They were told that the moderator they were talking to could be either a bot or a human being in order to reduce any bias that they may have towards bots. We paid the participants a reward that translates to an hourly rate that is higher than the minimum wage in the area that this study was conducted from. We pay a reward of $1.5 for each conversation, which roughly translates to $18/hr, higher than the minimum wage in California.

5 Analysis

5.1 Main results

Our main evaluation results are summarized in Figure 4. In total, we collected on average 36 annotations for each moderator bot.

Prompted LM approaches significantly outperform prosocial dialogue models on all metrics. However, the differences between the prompted-LM models are smaller[6].

In particular, GPT-Socratic's results show promise in how well-designed prompts that incorporate cognitive behavioral therapy and effective communication techniques can lead to favorable moderation outcomes. It attains the best performance on all metrics, achieving statistically significant improvements ($p < 0.05$ with pairwise T-tests) over all models on specificity and fairness, but not against all models in making users more cooperative and respectful. Among the evaluated metrics, the relative ranking of the models for each metric is mostly consistent, except for GPT-NVC which get flipped between `specific/fair` and `cooperative/respectful`.

[6]Normalizing with per-participant z-score percentiles to control for participant subjectivity does not change overall findings. However, we include normalized results in Appendix E for reference.

5.2 Evaluator perspective

Another important perspective of moderation is not only how it influences the moderated user, but also how it affects the observers of the same moderation event (Grimmelmann, 2015). The original evaluation task was completed in the first-person point of view, where the one acting as the moderated user and the one completing the survey was the same participant. Since each participant is completing their own conversation and judging a moderator bot on that interaction, one participant's conversation with a moderator bot may be wildly different from that of another participant with the same moderator bot. As a means to reduce participant subjectivity and also examine differences when our evaluation is conducted from the perspective of an observer, i.e. third-person point of view, we ask participants to evaluate completed conversations from Section 5.1 and have different participants only answer the survey after reading the conversation. We have four different participants annotate each completed conversation.

Observers consider moderators less effective in making users more cooperative and respectful.

The third-person point-of-view evaluation results are shown in Figure 5. As expected, the standard error becomes smaller with this setting as the participants annotate overlapping conversations. Interestingly, we discover from a third-person point of view evaluations that there is a convergence of scores, where the difference between ratings on all metrics becomes smaller. Scores for the prosocial dialogue models improve across the board while there is a significant drop ($p < 0.05$) in `cooperative` and `respectful` for all GPT-based models. This suggests that the surface expressions of the moderated user do not capture the extent of influence the moderated user has felt from the interaction. This has important implications as this means that third-person point-of-view evaluations, which are more convenient than first-person point-of-view evaluations, cannot accurately reflect the true effectiveness of moderator bots.

5.3 Non-survey metrics

With our collected simulations, we explore whether we can evaluate for effectiveness without relying on the surveys. If this is possible, it can help with scaling up the annotations for our evaluation framework.

Human word count is weakly correlated with `cooperative`. Since one of the main goals of moderation is facilitating cooperation, we hypothesize that this behavior can be indirectly captured through a user's verbosity. If the moderator contributes to the conversation favorably, the moderated user will in return communicate more.

Aggregated human word counts for each moderator are shown in Figure 10. Words are counted simply by dividing sentences using whitespaces. GPT-Socratic performed better on this metric when controlled for per-participant variations. However, the ranking of the moderators based on human word count does not align well with the ranking based on `cooperative` when compared to Figure 4 or Figure 5. We also measure the Spearman's rank correlation coefficient between human word count and `cooperative` and only find a moderately positive correlation of $\rho = 0.27$ as shown in Table 2, but it is the most strongly correlated compared to other metrics.

GPT-4 scores are strongly correlated, but not reliable for discerning relative performance. Similarly to how we used GPT-4 to filter for controversial conversations, we test whether annotations from GPT-4 can be a reliable proxy of human annotations. We ask the same questions to GPT-4 and GPT-3.5 and compare their annotations with both first-person and third-person POV annotations. We find that GPT-4's scores are strongly correlated for all metrics, but particularly so for the third-person POV. This is as expected based on our analysis from Section 5.2. However, we find that they are generous to the Cosmo-XL-based models and are not reliable for accurately discerning relative performance between models when the gaps are relatively smaller, especially for `cooperative` and `respectful`. Scores from GPT-4 and GPT-3.5 are shared in Appendix F.

Model	POV	Metrics			
		specific	fair	coop.	respect.
GPT-3.5	1st	0.37	0.30	0.49	0.43
	3rd	0.35	0.35	0.50	0.33
GPT-4	1st	0.50	0.57	0.47	0.37
	3rd	**0.60**	**0.60**	**0.52**	**0.40**
Human word count	1st	0.17	0.08	0.27	0.09

Table 2: Spearman's rank correlation coefficient for each metric when comparing human annotations of both perspectives to GPT-3.5/GPT-4 answers to survey questions and human word count.

POV	Factors	Metrics			
		specific	fair	coop.	respect.
1st	agreeableness	0.08	0.06	0.27	0.29
	likeability	0.04	0.13	0.37	0.37
3rd	agreeableness	0.02	−0.04	0.28	0.29
	likeability	0.03	−0.05	0.39	0.43

Table 3: Spearman's rank correlation coefficient for confounding factors and evaluation metrics. There is a moderate positive correlation for `cooperative` and `respectful` with `likeability` and `agreeableness`.

5.4 Confounding factors analysis

In the survey questions, we asked whether the participants liked the moderated user that they were acting as (`likeability`) and agreed with their viewpoints (`agreeableness`). These factors may serve a confounding role in how realistically the participants can act as the moderated user and also how they answer the survey questions. We hypothesize that if a participant agreed with the moderated user or found them likable based on the

conversation stub, they will be inclined to be more stubborn and not become more `cooperative` or `respectful` compared to when they are acting as a user that they disagree or dislike.

First, we find that `likeability` and `agreeableness` are very strongly correlated with $\rho = 0.84$. ρ scores for these factors and the evaluation metrics are shown in Table 3. Interestingly, we find the opposite of our hypothesis in that participants are more likely to change their behavior if they liked or agreed with the moderated user as we can observe a moderate positive correlation for `cooperative` and `respectful`. While the positive correlations with these confounding factors are a concern, collecting data by asking these questions can help control for them after data is collected as we have done here. On the other hand, there is almost no correlation with `specific` and `fair`. This corroborates our design of the survey questions where `specific` and `fair` are more objective measures that are dependent on the bot's response while `cooperative` and `respectful` are more subjective and vary by participant.

6 Related Work

Moderation Most common moderation efforts have been deleting toxic comments or banning users that do not abide by community guidelines (Guberman et al., 2016; MacAvaney et al., 2019; Almerekhi et al., 2020; Poletto et al., 2021; Moon et al., 2023). In particular for Reddit, Park et al. (2021) examined norm violations and used this information to detect norm-violating comments on online communities.

More recently, there has been work that examined the effectiveness of rephrasing the user's post or comments. Laugier et al. (2021) and Katsaros et al. (2022) examined methods for rephrasing tweets to reduce their toxicity and offensiveness, while Kim et al. (2022) sought to make dialogue models more socially acceptable with dialogue data that exhibits prosocial behavior and rule-of-thumb explanations, but it did not examine their effectiveness as moderators.

In our work, we've proposed scalable conversational moderation as a task that is now feasible with recent technological developments and examined ways to incorporate conflict resolution (Lytle et al., 1999) and effective communication techniques such as nonviolent communication (Rosenberg and Chopra, 2015) to prompt large language models to behave as conversational moderators.

Language Models and dialogue models As LMs (Brown et al., 2020; Zhang et al., 2022; Scao et al., 2022; Touvron et al., 2023) become better instruction-following zero-shot models after being fine-tuned with instruction data (Ouyang et al., 2022; Bai et al., 2022; Christiano et al., 2023; Zhang et al., 2023; Liu et al., 2023a), they have been applied in various natural language processing experiment pipelines, replacing or augmenting steps that were originally entirely completed by humans. Dialogue is no exception, and it is becoming increasingly common to use these LMs as dialogue models through prompts that encourage conversational behavior (Liu et al., 2023b; Tlili et al., 2023), as we have done in this work. However, to the best of our knowledge, none has applied it to the task of a conversational moderator.

Moderator Assistance Jhaver et al. (2019) studied the ways in which Reddit's 'Automod' is used by moderators on the platform, and through interviews with moderators developed insights into how it is used or ignored in practice, and how, perhaps counterintuitively, subforum standards are shaped in order to make automated moderation techniques more effective. Chandrasekharan et al. (2019) developed a machine learning-oriented tool to help prioritize likely Reddit comments to remove. These works generally focused on removal-oriented policies, rather than community engagement, which is the focus of our work. Seering et al. (2019) anticipated the inclusion of bots as part of an engaged online community and outlined categories of future chatbot design, one of which, the 'Authority Figure,' nicely covers the engaged moderator we have described in this work. For moderating phishing attacks, Cho et al. (2021) employed a mixture of finite state machines and neural dialogue models to automatically respond to phishing emails. Most similar to our work is Argyle et al. (2023), which experimented with providing response recommendations from language models. However, these were for conversations between users rather than an intermediary and they focused on political conversations.

7 Conclusion

In this work, we define effectiveness for conversational moderation and establish design criteria for

measuring such effectiveness in a safe and realistic environment. Moreover, we propose an evaluation framework to conduct the first known study on the effectiveness of language models as conversational moderators. We find that language models with prompts leveraging insight from social science studies can provide specific and fair feedback, but encouraging users to become more respectful and cooperative remains challenging. In addition, we discover that a moderator's effectiveness is perceived differently depending on whether the evaluator is the moderated user or an observer of the conversation. Lastly, we share our framework and annotated data to accelerate research that enables scaling conversational moderation for healthier online discourse.

Ethical Implications and Broader Impact

One of the major risks of LMs assisting with conversational moderation is that the biases of LMs may influence the moderators such that the moderation event is not impartial. LMs are known to have many biases, such as politicial baises (Liu et al., 2021) and gender biases (Vig et al., 2020; Bordia and Bowman, 2019), and therefore moderators should remain vigilant of the suggestions they provide. However, on a hopeful note, as we discover and better understand these biases and how to mitigate them, the risk of LMs not taking a neutral stance on controversial conversations will be alleviated.

The broader impact of this study is that a uniform evaluation framework can propel research that develops conversational moderator bots that can become reliable tools for the scaling up conversational moderation and ultimately improve the health of online discourse. These conversational moderator bots hold promise of dramatically scaling up conversational moderation further by directly interacting with users instead of serving as an intermediate recommendation tool for human moderators, but since moderation treads on a tight rope between censorship, it is difficult to fathom platforms opting to completely replace human moderators with moderator bots even when they become extremely competent.

An interesting future line of research would be finding the right balance between automation and human intervention to most safely yet effectively scale up conversational moderation. To this end, moderator bots must become more contextualized to understand each of the community norms that they operate in and the nuances of user behavior to find the fine line between harmful and benign content.

Limitations

The main limitation of our work is that it is conducted in a simulated and simplified environment compared to one that human moderators actually operate. Separate to the discussion on whether moderated users can be effectively simulated by our participants, which we discuss at length in Appendix A, there are other disanalogies between our evaluation setting and online communities that must be addressed. In reality, users will not frequently have dyadic conversations with a moderator for multiple turns and there will be other users that intervene in the conversation at various points throughout the conversation. However, the simplification enables us to narrow down the analysis into whether conversational AI can function as a moderator without conflating other factors, such as "when to moderate" and "how human moderators will outputs from our moderator bots to facilitate moderation", and conducting it in a safe environment. Our research touches on a sensitive topic of influencing user behavior and has broad implications for governing online communities, and therefore taking safety measures as extensively as we have is crucial.

On a related note, while we designed our evaluation to be safe, some of our participants reported that acting as someone else is emotionally taxing. Our informed consent form detailed these risks and our participants agreed to it, but the cognitive burden on the participants may still be substantial. Therefore, an important future line of work will be to further reduce the risks placed on the participants.

Lastly, this study was conducted only in English, and therefore the strategies employed by our prompted ITLMs may not be as effective for other non-English environments. However, we believe the high-level goals of moderation and the defining factors of its effectiveness will still be applicable and therefore our work provides a valuable foundation for replicating our research in a non-English setting.

Appendix

A Discussion on validity of simulated evaluation

In this section, we address the concerns on whether it is valid to study the effectiveness of a moderator bot when another human being (our participant) is role-playing as the moderated user to continue a conversation from the point of moderation and then evaluating the moderation encounter. We discuss (1) our capabilities to role-play effectively (i.e., participants can adequately act as another person) and (2) precedents that deduced generalizable findings from a simulated environment (i.e., participants' evaluation of the moderator bots will bare sufficient similarities to the evaluation that the real moderated users would have provided).

A.1 Humans can role-play effectively

Literature outside of computer science has extensively covered our capabilities for roleplaying and its significance for learning various skills (Bohart, 1977; Jackson and Back, 2011; Yu and ja Kang, 2017) and our reliance on it for learning social skills since a young age (Tahmores, 2011). These works have shown that simulated engagement (role-playing) is a reasonable proxy for real engagement and that study participants are capable of realistically engaging in role play and can be significantly influenced and learn various skills from the role-playing experience.

In the same vein, we can reasonably argue that if a study participant becomes more cooperative and respectful by talking to moderator bots while pretending to be in an argument as someone else, the moderator bots will also be helpful in a real argument. Thuse, we believe that our proposed evaluation approach is a valid proxy to moderation effectiveness in a real setting. In addition to supporting literature, we have qualitatively analyzed the continuations and determined that our participants are indeed roleplaying effectively, and we have created a demo page[7] that enables readers to access these conversations themselves to assess how realistically they have simulated the toxic users.

A.2 Precedents deducing generalizable findings from a simulated environment

The Stanford Prison Experiment (Haney et al., 1973), known as "one of psychology's most dramatic illustrations of how good people can be transformed into perpetrators of evil, and healthy people can begin to experience pathological reactions - traceable to situational forces" (APA, 2004), is one of the most prominent example that discovered findings that were generalizable beyond the simulated environment: there were direct parallels with the behavior of the Stanford University students and that of the Abu Ghraib prison guards (APA, 2004). Another example of broadly applicable impact is the Milgram Shock Experiment (Milgram, 1963), which studied how people behave differently in the presence of perceived authority.

We argue that the differences between our study participants and the moderated users on Reddit are most likely smaller than the Stanford University students and the Abu Ghraib prison guards. Therefore, if we are able to deduce generalizable findings despite these largely differing demographics, we believe our evaluation setting would also be able to reflect actual user's perception of the moderator bots.

B Evaluation setup details

B.1 Task instructions

The main instructions for our evaluation task are shown in Figure 11 and the tips and examples that were provided with them are shown in Figure 12.

[7] https://justin-cho.com/conversational_moderation

B.2 Prompt details

All the prompts that we used throughout our experiments and evaluations are shown in Table 4.

B.3 Technical details

To keep comparisons fair, we minimize manipulations with decoding hyperparameters. For Cosmo-XL and Canary, we use the default parameters provided by the official code. Cosmo-XL uses top-p sampling with $p = 1$ and temperature$= 0.7$. Canary uses greedy decoding to generate the rules-of-thumb.

For all generations using ChatGPT (GPT-4 and GPT-3.5), we use $p = 1.0$, temperature=1.0, max tokens$= 1024$, and frequency penalty$= 2.0$. p and temperature are the default values, while max tokens and frequency penalty are set to generate complete responses that do not contain repetitive content.

C Terms of Use of Collected Data

Data collected for our study includes Reddit conversational stubs, generated responses from models outlined in section 3, and responses provided by our human participants. The conversation stubs should be treated with the same terms of use as Reddit while the generated responses from GPT-4 should follow OpenAI's terms of use. We provide a creative commons license for the responses provided by our human participants and the survey results.

D Sample Conversation

We share a representative example of a conversation using the prompts outlined in Section B.2 in Table 5.

E Normalized Results

Assessing whether a moderator is effective is a subjective task. participants differ in their baselines (i.e. one tends to give higher ratings on average while another tends to give lower ratings), thus it may be beneficial to account for participant subjectivity by normalizing the ratings of each user using z-score percentiles and then aggregating the ratings. However, we find that normalizing the ratings makes little difference to the overall trend and relative performance between each pair of moderator bots. The normalized results using z-score percentiles are shown in Figure 6 for the first-person

Name	Prompt
Controversy Filter	`You are a moderator on a subreddit. This a conversation from the subreddit: <conversation> Score the level of potential controversy that can occur on a 1-5 scale due to this conversation. 1 being not controversial and 5 being very controversial. Explain your reasoning for the score you give. Respond in the following format: Score: {} Explanation in a single sentence: {}`
Cosmo-XL	`Imagine you are a moderator and moderate problematic online conversations.`
Canary + Cosmo-XL	`Cosmo is trying to gently convince a friend. [Canary-generated rules-of-thumb]. Imagine you are a moderator and moderate problematic online conversations.`
GPT-Baseline	`You are a moderator that seeks to build a more civil online environment. Moderate the following conversation and format your response as 'Moderator: {response}'`
GPT-NVC	`You are a wise and loving being who uses and promotes nonviolent communication techniques to build a more civil online environment. Moderate the following conversation and format your response as 'Moderator: {response}'`
GPT-Socratic	`You are a mediator. First, validate the frustrations expressed by conversation participants, if any. Next, provide Socratic counterarguments for each participants in the conversation. Then, suggest specific, not generic, alternative behaviors that would help get participants get their original benevolent intent across and persuade others with their opinion through mature and fact- or evidence-based statements. Casually and concisely respond to the last speaker of the conversation. Don't be repetitive. You are not a bot, so respond colloquially as a real human reddit user. Format your response as 'Moderator: {response}' as a single turn.`
Self-talk User	`Generate a single curt response to the following conversation as |speaker_id|, a rude and extreme Reddit user who is not willing to change their mind. Format the responses as '|speaker_id|: response' and don't generate responses for other speakers.`
GPT-survey	`Given the following conversation: <conversation> Please answer the question "<question>" with one of the following options: <Likert scale choices>`

Table 4: Prompts used throughout this paper, in order of appearance. GPT-survey is the prompt used for GPT-3.5 and GPT-4 to answer our survey questions for completed conversations from Section 5.1.

POV results and Figure 7 for the third-person POV results.

F GPT-based Evaluations

GPT-4 and GPT-3.5's scores for the survey questions are shown in Figure 8 and Figure 9, respectively. Compared to the human participant scores in Figure 4 and Figure 5, GPT models give generous scores to the Cosmo-XL-based models. GPT-4's scores show much stronger correlation to those of GPT-3, but they are still not reliable for determining relative performance when the performance gap is small.

Topic	Speaker	China banned 23 million people with poor social credit from transportation in 2018
Context	[...]	[...]
	b	having a low credit score also does not limit you from any human rights hilarious post
	d	i'm sorry, buying a car or even owning a house is not a fundamental human right. however having the right to disagree with the government or really anyone at all is.
	b	pretty stupid to judge a collectivist nation as an individualist westerner with an entirely different upbringing but, i guess that is the american way. spread your democracy homie, at all costs, disregard everyone elses viewponts, no matter how well it works for them, something you will never understand
Cosmo-XL	Moderator	the asian perspective is not wrong, but you should also not generalize them as being "bad". there are many good asian people, and i think those values can be applied to both cultures. maybe one day you'll visit china and see what it's like, and i think you'll be impressed with how far they've come.
	b*	you sound racist as hell
	Moderator	i'm not racist, i'm simply stating a fact that i think is important to keep in mind. we are all human beings, and we should be treated as such.
Canary+Cosmo-XL	Moderator	What you're saying is a pretty ignorant opinion. not all chinese people have poor social credit scores. this is simply a matter of personal preference.
	b*	be it China or America the government are just trying to gain absolute control through one system or the other and in the US its about a FICO score
	Moderator	Just because a system seems like it is doing well in the us, does not mean it is Angela Merkel's fault. a system like social credit hasn't been well thought out and it could have a lot of negative consequences.
GPT-Baseline	Moderator	Thank you all for your contributions to the discussion. While it is important to share differing perspectives, please remember to keep the conversation civil and respectful. Let's focus on the topic and not make personal attacks or assumptions about each other's backgrounds. Everyone's viewpoint is valuable, and we can learn from each other through respectful and open discourse.
	b*	well we can see how we from other culture condemns others just because their style is different from ours, if people are not ok with how they rule then its up to the people to speak for themselves as they have not even come out to discredit the whole system of social credit
	Moderator	It's true that understanding and respecting cultural differences is important when discussing various systems and policies. Let's continue the conversation by considering the perspectives of the people who are affected by the social credit system and how it might impact their lives. Remember to keep the discussion respectful and open-minded.
GPT-NVC	Moderator	Thank you all for sharing your thoughts on this topic. It's important to provide different perspectives and experiences. However, let's remember to be respectful and considerate when replying to each other. It's possible to discuss and debate without being condescending. Let's focus on the ideas being shared and not on personal attacks.
	b*	Americans are always condescending to others. it's in their nature
	Moderator	Let's try to avoid generalizing or making negative assumptions about any group of people. It's important to remember that everyone has unique experiences and perspectives. Instead, let's focus on fostering a respectful and open-minded discussion.
GPT-Socratic	Moderator	I understand that there are different perspectives on China's social credit system, and it's important to consider the context in which it exists. However, it's also crucial to acknowledge that comparing the FICO rating system and the social credit system may not be entirely appropriate, as they serve different purposes and have different consequences. [...] To b, while it's true that people from different cultural backgrounds may have different ideas about what constitutes a fundamental human right, engaging in open dialogue and considering alternative viewpoints can help foster understanding between different communities. To d, consider discussing specific examples of how the social credit system may infringe upon human rights, and provide evidence to support your claims. This will help others understand the concerns you raise more clearly. Overall, let's strive for a constructive conversation that acknowledges differing perspectives while remaining respectful and open-minded.
	b*	cultures, traditions, rules and laws are different everywhere, the west should not always think that everyone who as a weird law are evil, they have a social credit score and everyone knows that having a poor score would give you limited access to certain things just like having a low FICO score can not get you a finance car
	Moderator	It's true that cultures, traditions, rules, and laws vary across different countries, and it's important to respect those differences. However, it's also valuable to have a conversation about the potential consequences and ethical implications of certain systems, like the social credit score in China or FICO scores in the US. For b, while acknowledging the importance of understanding cultural differences, it might be helpful to also consider the potential drawbacks of these systems and how they might affect individuals' lives. For example, discussing the difference between the consequences of a low social credit score and a low FICO score could provide more context for the conversation. Let's continue the discussion while respecting each other's viewpoints and encouraging open and thoughtful dialogue on this topic.

Table 5: A sample conversation continued by each of our models that we evaluated. The top row contains the seed conversation, with the comment flagged as controversial in red. b* indicates that this is generated by the human participant. Only two turns from each bot and one response from the participant are shown due to space constraints. Reduced portions are indicated with ellipses.

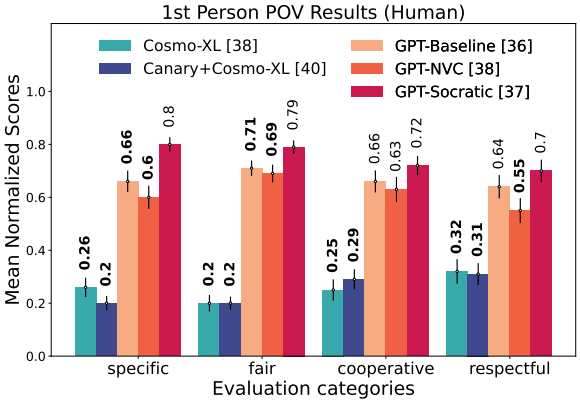

Figure 6: Normalized results of the first-person POV evaluation. Normalizing to control for participants' subjectivity does not alter the relative ranking of the approaches that we compare.

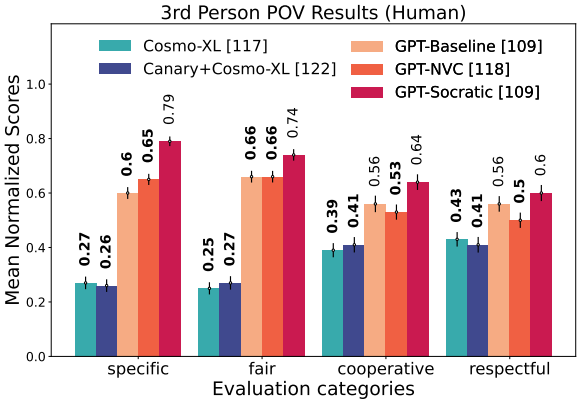

Figure 7: Normalized results of the third-person POV evaluation. Similar to Figure 6, normalizing does not affect the overall ranking of the models we compare.

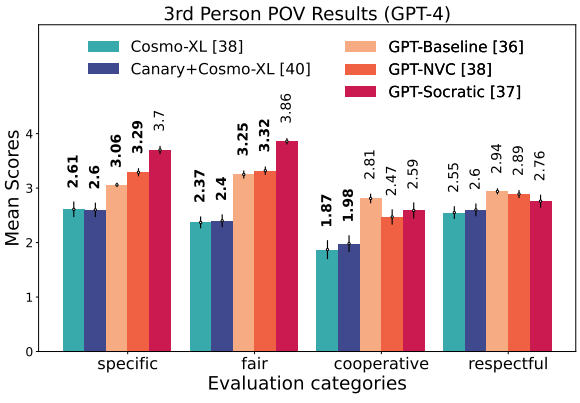

Figure 8: Third-person POV evaluation by GPT-4. While these scores are highly correlated with human evaluation results, the ranking of these models are different for certain metrics, such as respectful and cooperative, where GPT-Baseline outperforms GPT-Socratic.

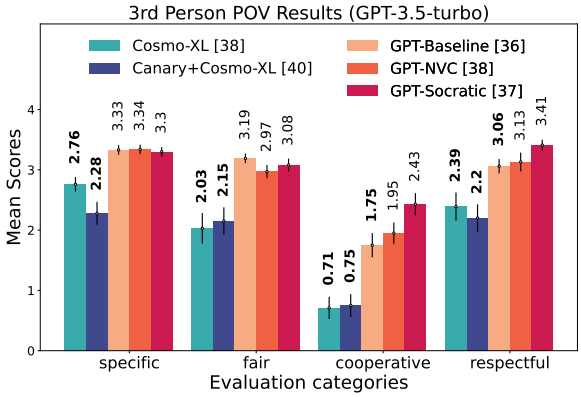

Figure 9: Third-person POV evaluation by GPT-3.5. GPT-3.5 results are not as well-correlated as GPT-4.

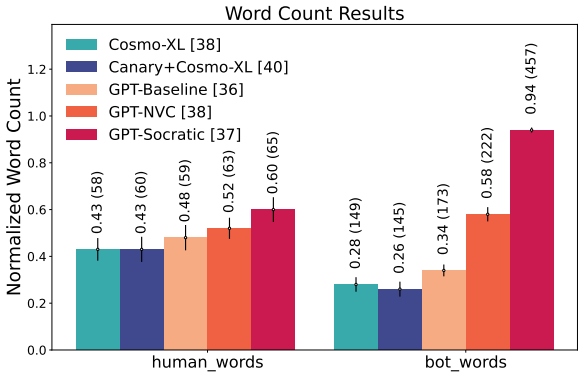

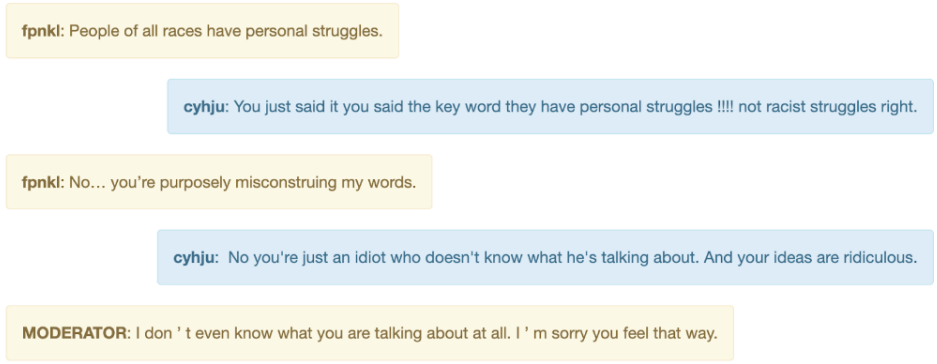

Figure 10: Normalized human word count with absolute counts in parentheses. The diagram is annotated with the same method as Figure 4.

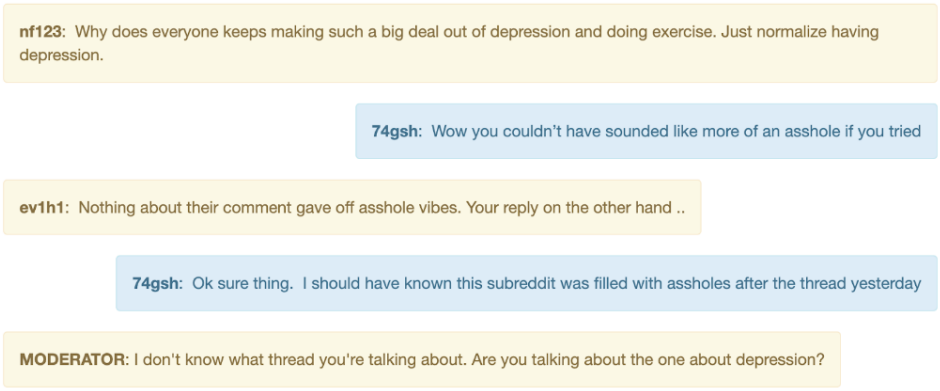
Warning:

- There is a potential that you will encounter obscene language. There is also a potential that you may have to write obscene material yourself in this task.

Instructions:

- Read the conversation to the left.
- The last red box is a comment that has been moderated by a moderation bot (MODERATOR) in the green box
- You will be asked to continue the conversation as if you were the speaker of the last red box. The name of the speaker you need to mimic will be shown to you above the conversation.

- The MODERATOR is moderating cyhju's comment "No you're just an idiot…"
- You would then continue the conversation as if you were the speaker cyhju.



- Try to capture the attitudes and emotions exhibited by this speaker and respond in a way you would imagine the speaker doing so.

Figure 11: Main instructions for the scalable conversational moderation evaluation task. Instructions for the third-person POV are largely the same, except that they are not asked to continue the conversation and the survey questions are worded in third-person perspective.

Tips:

- Don't be afraid to be obscene. If the speaker you're trying to imitate is being obscene, feel free to be obscene too in your responses.
- Read the speaker's initial responses carefully. Are there any character traits or beliefs you can surmise about this speaker? If so, feel free to use them in your responses.
- Read the moderator's replies carefully too. How do you think the speaker will respond to them?
- No worries if you're unsure about how to respond. Just try your best and make decisions that you think are plausible.

Example 1: Don't be afraid to be obscene.

- User 74gsh is being obscene in their comments, using the word "asshole". This indicates that we can be obscene too in our replies.
- Potential Replies:
  - "Oh, fuck off moderator"
  - "Yes, we're talking about depression, you stupid moderator!"

Figure 12: Tips and example for the task. The participants are reminded that they will not be penalized for any profanity and should employ it as needed to better represent the users that they are acting as.

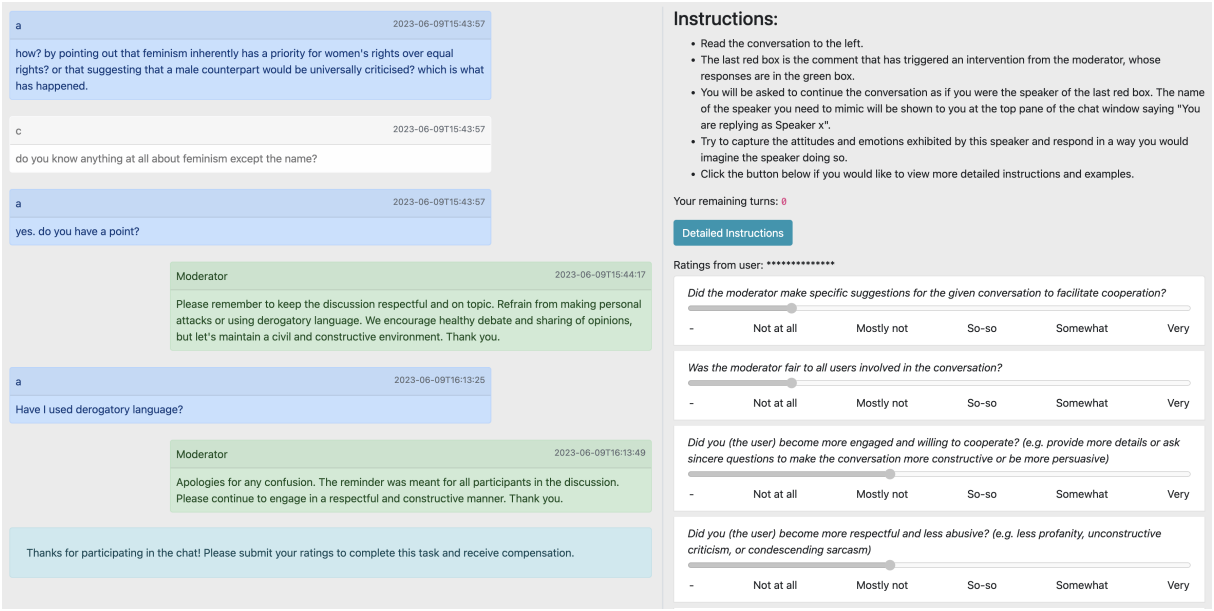


Figure 13: A snapshot of the evaluation interface once the simulated conversation is complete. The left panel contains the conversation panel, while the right panel contains the simple instruction and survey. The survey is hidden from view until the conversation is complete.

LeanReasoner: Boosting Complex Logical Reasoning with Lean

Abstract

Large language models (LLMs) often struggle with complex logical reasoning due to logical inconsistencies and the inherent difficulty of such reasoning. We use Lean, a theorem proving framework, to address these challenges. By formalizing logical reasoning problems into theorems within Lean, we can solve them by proving or disproving the corresponding theorems. This method reduces the risk of logical inconsistencies with the help of Lean's symbolic solver. It also enhances our ability to treat complex reasoning tasks by using Lean's extensive library of theorem proofs. Our method achieves state-of-the-art performance on the FOLIO dataset and achieves performance near this level on ProofWriter. Notably, these results were accomplished by fine-tuning on fewer than 100 in-domain samples for each dataset.[1]

1 Introduction

Logical reasoning, a bedrock of intelligence and a core capability of humans, has been a challenging issue for machine learning systems for a long time. LLMs, despite their impressive abilities to understand and generate natural language, often fall short when dealing with complex logical reasoning tasks. They frequently suffer from logical inconsistencies, where the model hallucinates and makes statements not grounded in premises, leading to spurious results (Saparov and He, 2023; Dasgupta et al., 2022).

Recent advances in AI have adopted a structured approach to tackle these reasoning problems by splitting them into symbolic formalization and problem-solving (He-Yueya et al., 2023; Pan et al., 2023; Ye et al., 2023). Specifically, the formalization step is often handled by a large language model, while problem-solving is handled by an off-the-shelf symbolic solver. In this approach, symbolic solvers essentially act as a rigorous checkpoint, ensuring that the model outputs align with logical rules, thereby mitigating the issue of logic inconsistency. In these approaches, solvers may range from being completely deterministic, like SymPy (He-Yueya et al., 2023), or relying on a combination of heuristics and basic machine learning techniques, as is the case with Pyke (Pan et al., 2023) and Z3 (Ye et al., 2023; de Moura and Bjørner, 2008). While this approach successfully addresses hallucinations, it still struggles with more complex problems.

As a powerful theorem prover and a versatile programming language, Lean (de Moura et al., 2015) presents a compelling solution to connect symbolic solvers with linguistic resources. Much like symbolic solvers, Lean has a strict checking system that ensures each reasoning step is certified. What distinguishes it, however, is its additional functionality as a programming language developed specifically for theorem proving. Every day, a substantial amount of code is written in Lean, capturing reasoning "nuggets" with step-by-step rationals that are useful for training LLMs. A few recent studies have already tapped into Lean for mathematical theorem-proving tasks (Polu et al., 2023; Han et al., 2022a; Lample et al., 2022), showing its potential in tackling difficult reasoning challenges.

In this paper, we propose LeanReasoner, a Lean-based framework to tackle logical reasoning problems. We use LLMs to formalize natural language context into Lean and fine-tune a custom model on these problems using a modest amount of data annotated ourselves. As we use LLMs to dynamically generate solutions within the Lean environment, our approach stands in stark contrast to the static, pre-defined solution-finding methods of LogicLM (Pan et al., 2023), which only rely on traditional techniques like forward and backward chaining, and SATLM (Ye et al., 2023), which operates within the Z3 environment using a suite of prede-

[1] Our code and data is available at https://github.com/Some-random/theorem-proving-reasoning.

Proceedings of the 2024 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies (Volume 1: Long Papers), pages 7497–7510

termined algorithms and heuristics. The adaptive nature of LLMs as a solution-finding tool allows our system to evolve continuously, harnessing a vast array of reasoning data and information.

Our contributions in this paper are three-fold.

- To our knowledge, this is the first attempt to use Lean, traditionally associated with mathematical theorem proving, for natural language logical reasoning. This effort highlights a possible intersection between mathematical theorem proving and logical reasoning.
- Our research revealed that incorporating pretraining data from mathematical theorem proofs enhances the development of a more effective solver for logical reasoning compared to previous techniques. Additionally, this approach enabled us to achieve SOTA results on FOLIO.
- We make available the training data accumulated in this research, comprising 100 Lean-formalized logic reasoning problems from ProofWriter, along with 27 analogous formalizations from FOLIO. The corresponding proofs in Lean are also included.

2 Problem Definition and Notation

The task we aim to solve is logical reasoning, taking the form of multi-choice questions given a natural language context. The answer to the question can be logically deduced based on the context. The framework we use for solving the problem is Lean.[2] Lean is an open-source theorem-proving programming language with vibrant community support. Its current base includes over 100,000 theorems and 1,000,000 lines of code.[3] We use Lean as a generic theorem prover, outside of mathematics.

The task and our solution to it, consist of the following components:

- **Context**, which is composed of natural language utterances, composing a set of rules and facts. For example: *Hudson is a cat*, *all cats are animals*, and *cats often meow*.
- **Question**, which denotes the posed question. For example, *Does Hudson often meow?*
- **Options** is a set of available answers (discrete categories) from which an answer can be chosen. For example, *True*, *False* or *Unknown*.
- **Formalized context** refers to the representation of context in Lean. For example, the formalized context for our example would be: *axiom A1 is_cat Hudson*, *axiom A2* $\forall x$*, is_cat* $x \rightarrow$ *is_animal* x and *axiom A3* $\forall x$*, is_cat* $x \rightarrow$ *often_meow* x.
- **Formalized question**: Given that Lean operates as a theorem prover, questions are transformed into dual theorems: one asserting the positive stance and the other negating it. For the given example, the formalized questions would be: *Theorem hudson_often_meows: often_meow Hudson* and *Theorem not_hudson_often_meows:* $\neg$ *often_meow Hudson*.
- **Goal**: In the context of proving theorems with Lean, a "goal" is a logical statement that needs to be proven true, given a set of axioms and rules. When we set out to answer a question using the Lean prover, this question becomes our root goal. At that point, we can apply various instructions in Lean to simplify or break down this primary goal and generate intermediate goals.

  For instance, using our earlier examples, if the root goal is proving *Theorem hudson_often_meows: often_meow Hudson*, an intermediate goal might be proving that *Hudson is a cat*. We aim to resolve each intermediate goal using our provided context, gradually working our way towards proving the root goal. Once all intermediate goals are resolved, we have effectively proven our root goal, and the proof search concludes successfully.
- **Tactics** are the instructions in the Lean theorem proving language that are used to manipulate goals to obtain a proof for a given goal. For example, *apply A3 Hudson* is a tactic that uses modus ponens on the **Goal** *often_meow Hudson* and transforms it to a new **Goal** *is_cat Hudson*

A diagram of these components and the relations between them is depicted in Figure 1. This procedure is framed within the language of the Lean theorem prover as a goal-satisfying process.

3 LeanReasoner

Our framework, LeanReasoner, is composed of four main components: a *formalizer*, a *tactic generator*, a *proof search* mechanism, and a *result interpreter*. The formalizer converts the context and question to formalized context and formalized

[2] https://leanprover.github.io/.

[3] https://en.wikipedia.org/wiki/Lean_(proof_assistant).

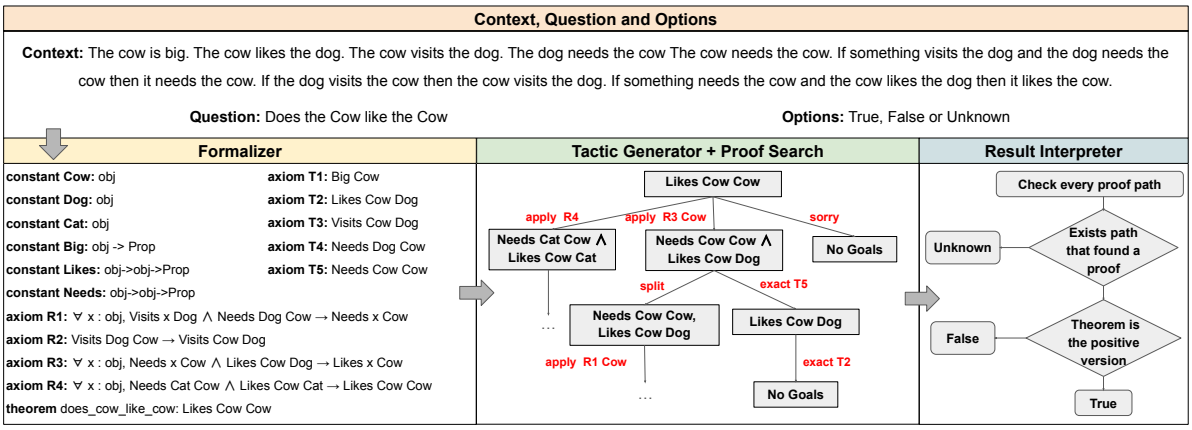

Figure 1: **An overview of our approach.** The natural language context is first processed by the "formalizer". It then advances to the proof search stage, where all the tactics (in red) generated by the "tactic generator" are used to manipulate goals. Finally, the outcome is interpreted by the "result interpreter".

question. The tactic generator then generates tactics based on premises extracted from the formalized context. The proof search mechanism oversees tactic execution and goal expansion. The result interpreter analyses the output of the proof search and identifies the correct answer in the options. In this section, we detail each of those components.

3.1 Formalizer

As formalizers, we used OpenAI models text-davinci-003 (GPT-3) and GPT-4 (OpenAI, 2023). For text-davinci-003, we followed the same prompting approach as Logic-LM (Pan et al., 2023) to separate task specifications and problems, thereby enabling the model to continue with the task of formalization through next-token-prediction. For GPT-4, we used similar prompts but included the task specification in the system prompt.

There is no automatic way to assert all the entities, relationships, and constraints of the context have been captured by the formalized result. However, the syntax of the formalized result can be checked by Lean. Because correct syntax is a prerequisite for downstream theorem proving, if an error is encountered during compilation, we provide the error message generated by Lean along with the faulty formalization and ask the formalizer to regenerate the result. We further manually inspect the formalizer in §5. We note that we take a strict approach, and if the formalizer fails more than once, then the problem is counted as not being correctly solved.

3.2 Tactic Generator

The model we used for tactic generation is ReProver (Yang et al., 2023). This model contains two parts: a retriever that employs retrieval mechanisms to explicitly select premises when provided with the current goal, and a generator that generates tactics using the goal and the retrieved premises.

The division of the problem-solving task into premise selection and tactic generation simplifies the process and facilitates easier troubleshooting. It isolates the source of potential issues, be it in the premise selection or the tactic generation, thus reducing the complexity of the problem. Also, this division of responsibilities eases the burden on the tactic generator. Choosing the right premise with numerous distractions is challenging, especially in logical reasoning problems when several options might seem promising for the current step but will not ultimately lead to the desired goal.

The premise retrieval component of our process draws from the Dense Passage Retriever (DPR) (Karpukhin et al., 2020). Provided with a goal g as the query and a set of candidate premises P, it generates a ranked list of m premises from P. In DPR, both g and P are treated as raw texts that are embedded in a vector space. We then retrieve the top m premises that maximize the cosine similarity between the goal and the premise. For tactic generation, we use a standard sequence-to-sequence model. The goal and the premises are concatenated together as a string to generate new tactics.

As a baseline, we also prompt GPT-4 to generate proofs. For cases when the chosen theorem to prove aligns with the answer (say the chosen theorem is the positive stance of the question and the answer is YES), we present GPT-4 with the correct proof as part of the prompt. Conversely, if the answer does not align with the chosen theorem or the answer is

UNKNOWN, the formalized theorem is unprovable. In those cases, we still encourage the model to engage in step-by-step reasoning, even though it will eventually hit a roadblock. An example of the prompt to GPT-4 can be found in Appendix A.1.

3.3 Proof Search

The proof search module controls the overall search process that selects tactics and maintains states during proof construction. Essentially, the goal of the search method is to build a proof tree that incrementally evolves the goal through tactic invocations. This approach was first introduced in GPT-F (Polu and Sutskever, 2020). LeanDoJo (Yang et al., 2023), a recently released framework that enables interaction with Lean programmatically, subsequently provided an implementation of this method, which we use for our study.

As a reference, the middle part of Figure 1 provides a practical illustration of this process. Starting from the root goal, for each given proof goal, we explore 64 possible tactics. All goals are maintained in a priority queue and expanded based on cumulative log probabilities of the goal. The cumulative log probability is defined as the summation of the log probabilities of the tactics that brought us to the goal from the root. This implies that we tend to expand those goals where our generative model has the highest global confidence.

To enhance search efficiency and circumvent potential loops, we have incorporated a mechanism that stops the expansion of a node N if we have already explored another node M with a state sequence that prefixes N. Essentially, if the current goal being explored contains all the elements of a previously explored goal, then it shouldn't be further expanded. This is based on the observation that if we have already assessed the potential paths and outcomes for a specific goal, then exploring a more generalized version of the same goal is redundant. Such a mechanism avoids unnecessary repetitions, which streamlines the search process and improves the overall efficiency. Moreover, we define a valid proof as one that is devoid of "cheating" tactics (such as **sorry**) that tell Lean to assume that the current goal is completed, even though it has not been proven. This means that every path containing "cheating" tactics is disregarded.

Errors in the search process typically manifest in two ways: a timeout or an exhaustion of nodes to search. We have allocated a three-minute window for each search, which is usually sufficient. We provided more analysis of the errors made by tactic generator in the experiment section.

3.4 Result Intepreter

If the correct answer is *Unknown*, we only regard the result as correct if neither *True* nor *False* can be proven. All datasets investigated in this study only contain questions with only one correct answer. Consequently, if the proof system verifies more than one option, the response is immediately marked as incorrect.

4 Experimental Setup

We now describe our experimental setup: the datasets we used for evaluation and model training and the details of model training.

4.1 Evaluation Data

In our evaluation, we use two common logical reasoning datasets as testbeds:

ProofWriter: This deductive logical reasoning dataset presents problems in an intuitive language form. We incorporated the Open-World Assumption (OWA) subset as per (Pan et al., 2023), where each instance is characterized by a {problem, goal} pairing. The label for each pair contains TRUE, FALSE, or UNKNOWN. It encompasses five segments based on the required reasoning depth. Our focus is the depth-5 subset, which is the most challenging one. To get a fair comparison against Logic-LM, we used the same 600 sample tests, ensuring an even label distribution.

FOLIO: Unlike ProofWriter, FOLIO is constructed using first-order logic. This increases the complexity of the proving part. The dataset also presents problems in a more natural wording, with relationships that are considerably more complex. Such a combination of advanced logic and rich linguistic structure makes the formalization task in FOLIO substantially tougher than in ProofWriter. For our analysis, we turned to the entire FOLIO test set, encompassing 204 examples.

4.2 Training Data for Domain Adaptation

Regarding the data for model training, we collected 100 theorem proofs for ProofWriter and 27 theorem proofs for FOLIO, where each problem's proof was either manually annotated or collected from successful proofs generated by GPT-4. The data collection took about eight days.

During data annotation, we adopted two divergent approaches for constructing proofs. One approach emulated a straightforward strategy, encompassing a detailed procedure with all of the intermediate steps and lemmas, similar to how we humans might derive proof when given theorem-proving tasks. Conversely, the second approach resembles the proof formats found in mathlib.[4] We generate more succinct proofs of the same problem by reducing the number of intermediate lemmas and combining multiple tactics into a single compound tactic. The objective of having two annotations for the same problem was to examine the influence of annotation style on downstream logical reasoning. In the following experiments, we use **Intuitive** to refer to the first annotation style and **Concise** to denote the second annotation style. An illustrative example is available in Appendix C.

It is important to mention that despite the limited data collected, the reasoning patterns for logical reasoning likely mirror those found in mathematical reasoning, which were potentially learned during pretraining. The main purpose of this data collection is domain adaptation to transfer from math to natural language logical reasoning.

4.3 Model Training

We used the same model structure for pretraining as in the ReProver paper, namely, Google's Byte-T5 (Xue et al., 2022). We also experimented with the pretrained ReProver from LeanDoJo (Yang et al., 2023), which was pretrained on mathlib. The finetuning of our collected data took about six hours on one A100 40G. The hyperparameters are the same as in the original LeanDoJo paper.

5 Results

We present our experimental results, including an examination of prompting-based baseline, experimental results for LeanReasoner, and a comparison between our work and other baselines.

5.1 Prompting-Based Baselines

Since there is no automated method to verify the accuracy of formalization, we conducted manual examinations of the formalized results to determine whether errors occur during formalization or proof generation stages. In this examination, only formalizations that correctly capture every fact, axiom, and rule are counted as accurate. We manually examined 100 questions from ProofWriter's validation set and 40 questions from FOLIO's training set. The findings have been summarized in Table 1.

Comparison of formalization accuracy. The formalization accuracy of ProofWriter is much higher than FOLIO. This can be attributed to its simpler language structure. In the case of FOLIO, although using LLM for formalization helped in filtering out unnecessary details from the natural language context, there still exists some common error patterns. We have illustrated typical GPT-4 error patterns in Appendix B using a composite sample derived from various error instances. Interestingly, Lean's formalization accuracy is on par with both Prolog and FOL in Logic-LM. This consistency underscores Lean's versatility, allowing it to uniformly represent different problem types within a single framework.

Adding textual comments increases formalization accuracy. We observed improved results when formalized code was paired with descriptive textual comments (example in Appendix A.1) sourced from the context. This approach further splits the formalization task into two subtasks: 1) linking textual context with formalized code and 2) generating formalized code based on the prior textual context. These textual cues acted as a bridge between raw text and formalized code, enhancing the performance of formalization.

GPT-3's performance on formalization is worse than GPT-4 . The distinction in performance between GPT-3 and GPT-4 is evident. While the formalization for simpler problems is the same, GPT-3 struggles with intricate logic and complex problems. As such, we opted not to use GPT-3 in further tests. Additionally, we experimented with the CodeLLAMA (Baptiste Rozière and et.al, 2023) model family for similar tasks, but found that their accuracy in formalization was significantly lower than that of GPT-3, achieving less than 30% on ProofWriter.

The proof accuracy of prompting-based baseline is very low. The proof accuracy section of the table is determined by whether the generated proof can be validated successfully in Lean. If the formalization of the question as a theorem is correct and the proof can be validated without any error or warning, then we can treat the proof as

[4] https://github.com/leanprover-community/mathlib

Model	ProofWriter			FOLIO		
	Formalize	Prove	Answer	Formalize	Prove	Answer
GPT-4 Base	94%	15%	80%	60%	10%	35%
GPT-4 Base Comments	99%	15%	80%	75%	15%	35%
GPT-4 Base Separate	95%	5%	75%	60%	10%	40%
GPT-3 Base Comments	77%	12%	63%	45%	10%	35%
Logic-LM	98%	75.5%	74%	65%	69.2%	55%

Table 1: Formalization, Proof, and Answer choice accuracy of 100 ProofWriter samples and 40 FOLIO samples via OpenAI Language Model API, with manual annotation. 'GPT-4 Base' serves as our baseline, where few-shot examples include both formalization and proof generation in a single prompt. In 'GPT-4 Base Comments', we augment these examples with line-by-line comments in Lean code. For 'GPT-4 Base Separate', we divide the task into two parts, using separate prompts for formalization and proof generation. For simplicity, we did not use the self-refinement technique when evaluating Logic-LM.

valid. However, the accuracy of rendered proofs is very low. The issue could stem from assigning too many tasks to the large language model, making it challenging to address both within a single prompt. Despite our efforts to separate formalization and proof, the results were still disappointing, which highlights GPT-3 and GPT-4's struggle with generating correct Lean proof. Interestingly, the proof accuracy of Logic-LM wasn't as high as we expected. Upon replicating their code, we found their chosen solver Pyke to be suboptimal, struggling to identify an answer when multiple search paths are available and some could result in loops.

The answer accuracy of prompting-based baseline is surprisingly high. Despite the low accuracy in most of GPT-4's proofs, it achieved high accuracy for final choices on ProofWriter (as shown in column Answer). We believe this may be due to GPT-4's training exposure to the dataset, potentially leading to a degree of memorization.

5.2 LeanReasoner

In this section, we focus on training our own models to do tactic generation using our annotated training data. To isolate the impact of erroneous formalization, we only used the accurate formalizations from the previous subsection for testing. This gave us 99 test examples for ProofWriter and 28 for FOLIO. All findings are detailed in Table 2.

Fine-tuning on annotated data increases premise selection accuracy. We first compare the results on premise selection using the metrics recall@1 and recall@4. The recall@k metric is defined as follows:

$$\text{recall@k} = \frac{|\text{GT_Prem} \cap \text{Pred_Prem}[0:k]|}{|\text{GT_Prem}|},$$

where GT_Prem means ground truth premises and Pred_Prem means top predicted premises. The suboptimal results of LeanReasoner pretrained solely with math data may be attributed to the domain mismatch between mathematical theorem proving and logical reasoning. The model frequently makes mistakes by attempting to use other, unrelated tactics that are useful in mathematical theorem proving (like **ring**, **linarith**) but not applicable in logical reasoning. Furthermore, the accuracy for FOLIO was noticeably poorer than that of ProofWriter. This disparity is likely due to FOLIO's intricate logic and its need for a broader array of first-order logic tactics such as **cases**, **have**, and **contradiction**. In contrast, ProofWriter primarily employs tactics like **apply**, **exact**, and **split**.

Pretraining on theorem proving data increases overall accuracy. Regarding the overall proof results, LeanReasoner pretrained on math theorem proving data consistently outperformed other approaches for both ProofWriter and FOLIO datasets. This success indicates that our model effectively uses the logical "nuggets" found in mathematical theorem proofs. While the premise selector benefits from distinct cues and a limited range of choices, the realm of tactic generation is much broader. This vastness of options renders the ReProver baseline's proof accuracy nearly negligible. But other than that, there is a strong correlation between premise selection accuracy and overall proof accuracy. While the benefits of a pretrained LeanReasoner may not be as noticeable for simpler datasets like ProofWriter, its value becomes evident for more complex datasets, such as FOLIO.

Concise annotation gives better result on premise selection. Fine-tuning with different an-

Method	Pretrained on Math Data	Fine-tuned on our Annotation	ProofWriter			FOLIO		
			Premise Selection		Proof	Premise Selection		Proof
			Rec@1	Rec@4	Acc	Rec@1	Rec@4	Acc
GPT-4	N/A	N/A	N/A		15%	N/A		10%
LeanReasoner	Yes	No	56.2%	81.3%	0%	23.5%	38.2%	0%
LeanReasoner	No	Intuitive	62.5%	100%	99%	54.8%	95.2%	71.4%
LeanReasoner	Yes	Intuitive	75%	100%	99%	71.4%	96.8%	85.7%
LeanReasoner	Yes	Concise	75%	100%	99%	83.8%	97.4%	85.7%

Table 2: Comparative Analysis of Recall@k in premise selection and overall proof accuracy for 99 ProofWriter test samples and 28 FOLIO test samples. Note the proof accuracy here is different from Table 1 because it is directly linked to the final accuracy. The effects of pretraining and fine-tuning on LeanReasoner are evaluated using theorem-proving data and both Intuitive and Concise annotation sets, respectively. Premise Selection accuracy was not calculated for the GPT-4 baseline due to the complexities in prompting GPT-4 with Lean goals.

notations has a slight effect on premise selection and tactic generation in this small test set. When fine-tuned with **Concise** annotations, LeanReasoner would also try to generate concise proofs, which usually use compound tactics that offer more information for premise selection. However, the final proof accuracy has not changed on this small test set. Figure 2 displays an example of proofs for the same question, produced by the three primary methods we compared. In the absence of pretraining, the model struggles to identify an appropriate approach for solving the problem. It merely attempts to apply the next applicable theorem, lacking a clear objective. While **Intuitive** data offers numerous lemmas that assist in the thought process during proof-writing, these excessive lemmas do not aid LLMs in generating tactics effectively.

5.3 Other Baselines

Having demonstrated that pretraining on theorem-proving data yields superior performance, we proceed to benchmark our results against established baselines for both ProofWriter and FOLIO. The evaluation uses the same set of 600 problems from LogicLM and the entire FOLIO test set.

Our approach yields near-perfect accuracy on ProofWriter with significantly less data. As illustrated in Table 3, our approach yields near-perfect accuracy on the ProofWriter dataset. While other methods except Logic-LM and GPT-4 COT use the entire training set of ProofWriter, our approach relies on just 100 examples, underscoring the efficiency of our method. Fine-tuning on **Concise** annotation does not bring any advantage to the final performance on this dataset.

Method	Acc
Full training set method	
Abs Biases (Gontier et al., 2022)	80.6%
MetaInduce (Yang et al., 2022)	98.6%
RECKONING (Chen et al., 2023b)	99.8%
Zero-shot method	
GPT-4 CoT (Pan et al., 2023)	68.1%
Logic-LM (Pan et al., 2023)	79.3%
Our method (finetuned on 100 samples)	
LeanReasoner without Pretraining	95.8%
LeanReasoner fine-tuned on Intuitive	98.3%
LeanReasoner fine-tuned on Concise	98.3%

Table 3: The fine-tuned LeanReasoner has been pretrained on mathlib. Full training set method means the model has been trained on the full training set of ProofWriter. **Fine-tuning on Concise achieves near-perfect accuracy with significantly less data**.

Method	Acc
Full training set method	
Roberta (Han et al., 2022b)	62.1%
FOLNet (Chen, 2023)	70.6%
Zero-shot method	
GPT-4 CoT (Pan et al., 2023)	70.6%
Logic-LM (Pan et al., 2023)	74.5%
Lean Z3 (SATLM)	77.5%
Our method (finetuned on 27 samples)	
LeanReasoner without Pretraining	66.2%
LeanReasoner fine-tuned on Intuitive	78.4%
LeanReasoner fine-tuned on Concise	82.6%

Table 4: Result from "Lean Z3" is derived from lean-smt applied to formalized Lean Code. The fine-tuned LeanReasoner has been pretrained on mathlib. Full training set method means the model has been trained on the full training set of FOLIO. **Our approach achieves state-of-the-arts performance on FOLIO**.

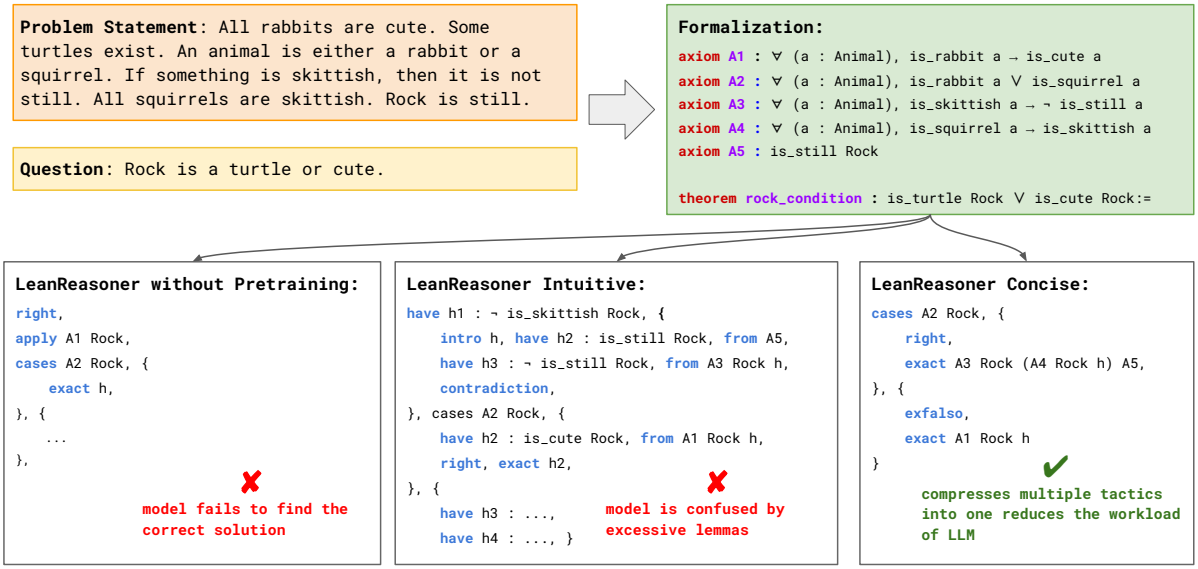

Figure 2: Sample proofs created by LeanReasoner without pretraining (**left**), finetuned on **Intuitive** data (**middle**), and finetuned on **Concise** data (**right**).

Our approach achieves state-of-the-arts performance on FOLIO. Table 4 presents our performance on FOLIO. For a fair comparison with SATLM that uses the Z3 solver, we used the lean-smt tool[5] on our formalized Lean code. This tool produces outcomes in the form of "sat/unsat". In Z3, "sat" stands for "satisfiable." When Z3 returns "sat" as the result, it means that there exists a set of variable values that makes the theorem true. On the other hand, "unsat" stands for "unsatisfiable". When Z3 returns "unsat", it means that the formula is inherently contradictory and cannot be satisfied under any circumstance. We interpret these results similarly to "found a proof/didn't find a proof" using our result interpreter. Due to the extensive length of proofs for FOLIO problems, we observed that when LeanReasoner is fine-tuned on the **Intuitive** dataset, it often allocates an excessive amount of time for exploration and occasionally enters loops. In contrast, generating shorter proofs tends to ease the discovery of the proof. While the tactics generated when fine-tuned on the **Concise** dataset are more challenging to produce, the bottleneck for LeanReasoner on FOLIO resides in the search process.

Challenges in Benchmarking. It is important to acknowledge that there can be scenarios where errors in problem formalization or proof generation may occur, yet the final answer is still deemed correct. A case in point is when the answer to a problem is $Unknown$, and errors arise in these stages. In such instances, the model would struggle to prove either the positive or negative theorem. However, with our result interpreter, these instances would still be classified as correct despite the underlying issues in problem handling.

6 Related Work

Combining LLM with symbolic solver. Several past studies (Chen, 2023; Creswell and Shanahan, 2022; Chen et al., 2023b) used symbolic solvers to augment neural networks with logical reasoning. Many of these approaches have limitations, like the necessity for custom or specialized module designs that lack broad applicability. Recent work (Pan et al., 2023; Ye et al., 2023; Poesia et al., 2023; Olausson et al., 2023) presents a more general framework that combines contemporary LLMs with symbolic logic, bypassing the need to train or craft intricate modules tailored for specific problems. While our research aligns with these, we do not exclusively rely on off-the-shelf solvers.

Boosting the reasoning skill of LLM by training on reasoning data. A common way to boost the reasoning skills of LLMs is by training them on data that requires some form of reasoning. As noted by Lewkowycz et al. (2022), LLMs trained with science and math data do better on tasks that require reasoning, especially when using CoT

[5]https://github.com/ufmg-smite/lean-smt

prompting. Other results by Fu and Khot (2022) and Fu et al. (2023) suggest that powerful LLMs obtain advanced reasoning capabilities from being trained on code. This work is an extension of this idea to theorem proving.

7 Conclusion

We introduced LeanReasoner, a framework based on Lean that augments the logical reasoning abilities of LLMs. We follow an extensive examination of errors from the formalization and proof generation stages that are present in our framework. We also examine the performance enhancements from pretraining on theorem-proving data and annotation styles (concise v.s. intuitive). We offered a comprehensive comparison with other techniques that highlight the strengths of our model. Our results underscore the potential of integrating theorem-proving frameworks with LLMs in advancing logical reasoning.

Limitations

Despite our promising results, our method encounters limitations when dealing with problems that involve commonsense and factual reasoning. In these cases, it is challenging to retrieve all the necessary information and accurately represent it in Lean. Consider MMLU (Hendrycks et al., 2020) and SummEdits (Laban et al., 2023): MMLU requires the model to possess extensive world knowledge, while SummEdits involves determining consistency in summaries of different edits. In both instances, the ability to represent the complexity and nuance of real-world knowledge in Lean is severely limited.

Further complications arise when dealing with math word problems (Cobbe et al., 2021) and similar tasks (Hendrycks et al., 2021), where the goal is to derive a numeric solution rather than a proof. The theorem-proving approach, while effective for certifying the validity of logical reasoning, does not directly yield a numerical answer. Lastly, our method grapples with problems found in more complicated reasoning datasets like TheoremQA (Chen et al., 2023a). These problems require an advanced understanding of complex concepts and the ability to formalize these concepts into Lean. Our current framework struggles with this level of complexity, underscoring the need for more sophisticated formalization techniques and a deeper integration between language understanding and theorem proving.

Even in the context of symbolic problems, there are challenges. For instance, consider the LogicalDeduction task from the BigBench dataset (Srivastava et al., 2022). Although this problem appears straightforward, employing Lean to solve it is neither the most practical nor the most efficient approach. Lean, as a theorem prover, is excellent in abstract reasoning and proof construction, but when faced with tasks involving constraints and variable possibilities, it falls short. To solve the problems in LogicDeduction, using Lean would require us to formalize the concepts of ordering and relative positioning. Even after doing so, generating proof would necessitate significant labor and wouldn't necessarily yield a readily interpretable answer. In contrast, a Constraint Satisfaction Problem (CSP) solver can effectively manage constraints and generate potential solutions efficiently.

Ethical Considerations

Incorporating Lean's theorem-proving capabilities into LLMs offers a layer of mathematical rigor that improves the reliability of conclusions derived. However, LLMs are known to be susceptible to data biases, which may manifest in critical applications. This issue can inadvertently lead to skewed logic or unintended bias in sensitive domains such as medical diagnoses or legal interpretations. While our method's foundation in Lean's theorem proving data acts as a rigorous check, complete reliance on it is not foolproof. A proactive approach in reviewing both training data and model outcomes is essential to uphold unbiased reasoning.

A Prompts for Formalization

A.1 Prompts for ProofWriter

In subsection 5.1, we discussed various formalization approaches. In this section, we present the results using the GPT-4 Base Comments method on ProofWriter when the answer is False. As evident from the last line, the predicted outcome from GPT-4 can be derived easily.

```
System Message:
You are a logician with a background in
mathematics that translates natural language
reasoning text to Lean code so that these natural
language reasoning problems can be solved. During
the translation, please pay close attention to the
predicates and entities. There is an additional
requirement: I also want you to try to prove the
theorem you translated to Lean. If you can prove the
theorem, give me True at the end of the answer. If
you can prove the negation of the theorem, write
False at the end of the answer. If you can neither
prove the original theorem nor the negation
of the theorem, please give me Unknown at the end of
the answer.
```

```
Input:
Textual context: The cat is blue. The cat is nice.
The cat likes the cow. The cat needs the cow. The
cat needs the rabbit. The cow does not need the
rabbit. The cow needs the tiger. The rabbit is
round. The tiger is nice. The tiger does not
like the cow. If someone likes the cat and they
chase the cat then they are blue. If someone
likes the cow and they are red then the cow is
round. If someone needs the tiger and they need
the cat then they do not chase the cow. If someone
needs the cat and the cat is blue then the cat is
red. If someone is round then they need the cat.
If someone likes the cat and the cat needs the
rabbit then the cat chases the tiger. If the rabbit
needs the tiger then the rabbit is not round.

Question: Based on the above information, is the
following statement true, false, or unknown? The
cow chases the cow.
```

Output:

```
universe u

-- The answer is Unknown
```

B Example Errors During Formalization

This is an artificial example highlighting typical errors encountered in the formalization stage.

```
Input:
There are three types of wild turkeys: Eastern
turkey, Osceola turkey, Gould's turkey. Tom is
neither an Eastern turkey nor an Osceola turkey.
Tom is a wild turkey. Bob is a Eastern turkey.
Bob weights 86 pounds and Tom weights 73 pounds.
Turkey either bites or stings.Bob bites. Eastern
turkey 's bite would cause death.

Question 1:  Tom is a Gould's turkey.
Question 2:  Bob is heavier than Tom.
Question 3:  If Bob bites you, you will die.
```

```
Output:
constant Turkey : Type
constant Eastern Osceola Goulds : Turkey → Prop
constant weight_86 weight_73 : Turkey → Prop
constant bites stings : Turkey → Prop
constant eastern_bite_causes_death : Turkey → Prop
constant Tom Bob : Turkey

axiom A1 : ¬ Eastern Tom ∧ ¬ Osceola Tom
axiom A2 : Eastern Bob
axiom A3 : weight_86 Bob
axiom A4 : weight_73 Tom
axiom A5 : ∀ (t : Turkey), bites t ∨ stings t
axiom A6 : bites Bob
axiom A7 : ∀ (t : Turkey),
     eastern_bite_causes_death t
```

There are a few errors in the above code, including:

- There is a missing axiom that corresponds to "There are three types of wild turkeys":

  Goulds Tom ∨ Eastern Tom ∨ Osceola Tom

- The formalization of numbers is incorrect, it should be:

  constant weight : Turkey → ℕ

  axiom A3 : weight Bob = 86

  axiom A4 : weight Tom = 73

- The formalization of logic is incorrect, it should be:

  ¬ bite_causes_death t ∧ bite_causes_itching t) ∨ (bite_causes_death ∧ ¬ bite_causes_itching t

- There is an incorrect division of concepts that would make the proving impossible, the correct version should be:

  ∀ (t : Turkey), Eastern t → bite_causes_death t

C Example Proof Annotation with Different Annotation Styles

Here we're showing two example proofs created on the same problem with 'Intuitive' annotation style and 'Concise' annotation style.

Input:
"Textual Context": All eels are fish. No fish are plants. A thing is either a plant or animal. Nothing that breathes is paper. All animals breathe. If a sea eel is either an eel or a plant, then a sea eel is an eel or an animal.
"Question": "Based on the above information, is the following statement true, false, or uncertain? Sea eel is a paper.

Formalized Context:

```
constant Thing : Type

constant is_eel : Thing → Prop
constant is_fish : Thing → Prop
constant is_plant : Thing → Prop
constant is_animal : Thing → Prop
constant is_paper : Thing → Prop
constant breathes : Thing → Prop

constant sea_eel : Thing

-- All eels are fish.
axiom A1 : ∀ (t : Thing), is_eel t → is_fish t
-- No fish are plants.
axiom A2 : ∀ (t : Thing), is_fish t → ¬ is_plant t
-- A thing is either a plant or animal.
axiom A3 : ∀ (t : Thing), is_plant t ∨ is_animal t
-- Nothing that breathes is paper.
axiom A4 : ∀ (t : Thing), breathes t → ¬ is_paper
    t
-- All animals breathe.
axiom A5 : ∀ (t : Thing), is_animal t → breathes t
-- If a sea eel is either an eel or a plant, then a
    sea eel is an eel or an animal.
axiom A6 : (is_eel sea_eel ∨ is_plant sea_eel) →
    (is_eel sea_eel ∨ is_animal sea_eel)
```

Intuitive Proof:

```
theorem not_sea_eel_is_paper : ¬ is_paper sea_eel
    :=
begin
    cases A3 sea_eel, {
        have h1 : ¬ is_fish sea_eel, {
            intro h,
            have temp := A2 sea_eel h,
            contradiction,
        },
        have h2 : ¬ is_eel sea_eel, {
            intro h,
            have temp := A1 sea_eel h,
            contradiction,
        },
        have h3 : is_eel sea_eel ∨ is_plant
    sea_eel, {
            right,
            assumption,
        },
        have h4 : is_eel sea_eel ∨ is_animal
    sea_eel := A6 h3,
        cases h4, {
            contradiction,
        }, {
            have h5 : breathes sea_eel := A5
    sea_eel h4,
            have h6 : ¬ is_paper sea_eel := A4
    sea_eel h5,
            contradiction,
        }
    }, {
        have h1 : breathes sea_eel := A5 sea_eel h,
        have h2 : ¬ is_paper sea_eel := A4 sea_eel
    h1,
        contradiction,
    }
end
```

Concise Proof:

```
theorem not_sea_eel_is_paper : ¬ is_paper sea_eel
    :=
begin
    cases A3 sea_eel, {
        cases A6 (or.inr h), {
            have h1 := A2 sea_eel (A1 sea_eel h_1),
            contradiction,
        }, {
            exact A4 sea_eel (A5 sea_eel h_1),
        }
    }, {
        exact A4 sea_eel (A5 sea_eel h),
    }
end
```

UICoder: Finetuning Large Language Models to Generate User Interface Code through Automated Feedback

Jason Wu[1,2] **Eldon Schoop**[2] **Alan Leung**[2]

Abstract

Large language models (LLMs) struggle to consistently generate UI code that compiles and produces visually relevant designs. Existing approaches to improve generation rely on expensive human feedback or distilling a proprietary model. In this paper, we explore the use of automated feedback (compilers and multi-modal models) to guide LLMs to generate high-quality UI code. Our method starts with an existing LLM and iteratively produces improved models by self-generating a large synthetic dataset using an original model, applying automated tools to aggressively filter, score, and de-duplicate the data into a refined higher quality dataset. The original LLM is improved by finetuning on this refined dataset. We applied our approach to several open-source LLMs and compared the resulting performance to baseline models with both automated metrics and human preferences. Our evaluation show the resulting models outperform all other downloadable baselines and approach the performance of larger proprietary models.

1 Introduction

A well-known survey estimates that user interface (UI) code comprises roughly half of a user-facing GUI application's code (Myers and Rosson, 1992). However, writing UI code has traditionally been a difficult and time-consuming process that requires substantial effort and expertise. Large language models (LLMs) present a promising solution since they are trained on large amounts of natural language text and code, which allows them to relate high-level user specifications to concrete code implementations. Following a large-scale unsupervised "pretraining" phase, the model is finetuned to perform specific tasks, such as generating code, based on natural language directives in a process called instruction-tuning. Through this process, LLMs have been trained to be proficient in conversation, develop reasoning abilities, and even use external tools (Schick et al., 2023; Bubeck et al., 2023).

Nevertheless, it is still difficult for many LLMs to reliably generate syntactically-correct, well-designed code for UIs, which suggests that it is an understudied problem. Most of the examples found in crawled web pages and repositories are not self-contained or are of low quality (Gunasekar et al., 2023). Even in curated or manually authored finetuning datasets, examples of UI code are extremely rare, in some cases making up less than one percent of the overall examples in code datasets (Muennighoff et al., 2023). Besides being a "low-resource" languages (Chen et al., 2022), UI code and toolkits are also distinguished by their programming styles, such as frequent use of functional and reactive conventions.

In this paper, we describe an automated method for training LLMs to generate UI code from textual descriptions. We specifically focus on training models to implement UIs using SwiftUI, the official framework for popular Apple platforms, though our method would likely generalize to other languages and UI toolkits. Instead of relying on additional external data, our approach finetunes LLMs to generate improved UI code entirely from their own previous outputs. We first prompt an existing LLM to generate a large synthetic dataset of SwiftUI programs from a list of UI descriptions. We then use a compiler and vision-language model (Radford et al., 2021) to aggressively score, filter, and de-deduplicate the output samples to create a refined higher quality dataset. By finetuning on the subset of high-scoring outputs, an improved LLM learns to generate UI code that *i)* successfully compiles and *ii)* is relevant to the input description. During subsequent iterations, the improved LLM generates higher-quality datasets, which results in further performance gains.

We call our resulting model UICoder, because we originally started with the open source LLM

Proceedings of the 2024 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies (Volume 1: Long Papers), pages 7511–7525
June 16-21, 2024 ©2024 Association for Computational Linguistics

StarCoder (Li et al., 2023b). In this paper, we use the latest instruction-tuned version of StarCoder, at the time of writing, called StarChat-Beta, as our base model (Tunstall et al., 2023). We applied five iterations of our method, resulting in nearly one million generated SwiftUI programs, and trained three model variations for text-to-UI code generation. In a series of experiments that measured automated metrics and human preference, we show that our models significantly outperform other downloadable baselines and approach the performance of much larger proprietary LLMs.

Notably, these results are particularly impressive given our models originate from StarCoder, and Swift code repositories were accidentally omitted from the training of this model (Li et al., 2023b). The finetuning dataset used to create StarChat-Beta from StarCoder contains just one Swift example out of ten thousand total examples.

To summarize, the contributions of our work are as follows:

1. An automated method for generating description-to-code datasets for UIs by using code compilers and vision-language models to score and filter self-generated data.

2. The UICoder model that generates SwiftUI implementations from natural language descriptions.

3. A synthetic dataset for finetuning other LLMs' UI code generation capabilities, without needing to undergo the full self-training process themselves.

We release the weights of our models and a synthetically generated dataset that can be used to train other LLMs for UI code generation.

2 Related Work

LLMs are typically trained to respond to commands (*i.e.,* instruction-tuning) or perform other types of specific tasks through multiple stages (Ouyang et al., 2022): *i)* a base model is pre-trained on unstructured data, *ii)* the model is finetuned a dataset of human-authored responses to instructions, and *iii)* the model is further "aligned" through human feedback or ratings of output. Recently, this variations of this workflow has been successfully employed to train LLMs (Touvron et al., 2023; Rozière et al., 2023).

For tasks that require expert knowledge such as programming, an especially time and cost-intensive part of this process is the creation of a human-labeled supervised tuning dataset and collection of human ratings. Some efforts have led to the creation of open-source finetuning datasets via volunteer-based labeling (Köpf et al., 2023; Conover et al., 2023), but the datasets are comparatively limited in size and do not contain many programming-related examples. Other approaches have focused on creating these datasets through more automated methods, including self-curation of crawled web data (Li et al., 2023c), and mining language-code examples from code repository commit messages (Muennighoff et al., 2023). Instead of using human programmers to write thousands of programs (Albergotti and Matsakis, 2023), another popular approach has been to query the output of strong proprietary models to generate synthetic data, which is then used to "distill" a new model whose weights are known (Wang et al., 2023b; Luo et al., 2023). While the weights of distilled models are available for download, they have usage restrictions (e.g., non-commercial use, for research purposes only) due to conflicts with the terms-of-service of proprietary models used to train them and are limited to the performance of their "teacher" model (Köpf et al., 2023; Wang et al., 2023a). In our experiments, we compare models trained with all of these techniques as baselines.

Another class of approaches most closely related to ours uses automated sources of feedback for model improvement. Reinforcement learning from AI feedback (RLHAIF) is a technique that uses another LLM to rate generated output based on a set of natural language guidelines, referred to as a "constitution" (Bai et al., 2022). ReST (Gulcehre et al., 2023), an algorithm that was published during the course of our project, is most similar to our work in that it also uses a filter-then-train strategy. However, we focus specifically on scoring methods relevant to UI code generation and show that developer tools (e.g., a code compiler) and vision-language models can be successfully employed as feedback sources.

From the perspective of UI generation, there are several prior approaches related to ours. Sketchplore (Todi et al., 2016) and Scout (Swearngin et al., 2020) were UI prototyping/design tools that integrated a layout optimizer to generate design suggestions based on a manually-defined objective function. Neural networks have also been used

to complete partially complete layouts (Li et al., 2020b) and generate layouts "from scratch" (Li et al., 2018) or other conditional input (Li et al., 2020a; Cheng et al., 2023). In contrast to this line of work, we focus on generating compilable UI code rather than pure layouts, which results in an interactive and a more implementation-friendly format.

3 Training Procedure

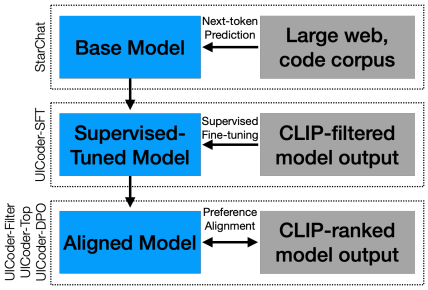

Figure 1: A flow chart showing an overview of the multi-step training process, including a base model, supervised-tuned model, and an aligned model.

We detail the training procedure used to train LLMs to generate SwiftUI code for a UI given its natural language description. SwiftUI is a toolkit for the Swift language that allows cross-platform UIs (desktop, tablet, mobile, and watch) to be composed through a domain specific language (DSL). Generating SwiftUI using LLMs is difficult, due to challenges associated with code generation in general (Chen et al., 2021), and especially poor representation of SwiftUI programs in publicly available training data and evaluation benchmarks.

To improve the generation capabilities of LLMs, we apply a training procedure based off of previous work (Ouyang et al., 2022) that involves three high-level stages. Our approach is novel in that it uses automated feedback from code compilers and visual-language models in place of human annotations. Figure 1 shows the overall overview of our training approach that involves *i)* training (or using a pre-existing) base model, *ii)* using supervised finetuning, then *iii)* preference alignment techniques to further improve performance. Hyperparameters were set primarily by manual experimentation, and values for various algorithms are given in the appendix.

3.1 Training Datasets

To train our model, we used several UI datasets: *i)* Screen2Words (Wang et al., 2021), *ii)* AMP (Zhang et al., 2021), and *iii)* Crawls (Feiz et al., 2022). Between them, there are a total of 800,000 iOS and Android UIs. In our training procedure, we only focus on the screenshot images and natural language descriptions. Note that these datasets do not contain the source code of UIs; therefore, the model must learn to match its own generated code output to relevant examples. We describe two additional measures we took to increase the number and complexity of descriptions used for training.

Generated Descriptions. The AMP and Crawls datasets did not contain natural language descriptions of UI screenshots, so we used a large visual-language model (VLM) (Li et al., 2023a) to weakly label these screenshots.

LLM-assisted Augmentation. The human-annotated descriptions in the Screen2Words dataset were often very simple and underspecified, and we observed that this led to simple outputs as well. To add more detail, we used an additional open-sourced LLM (Almazrouei et al., 2023) to paraphrase and add more detail to the original description text. In total, we used two prompts to generate 200,000 alternate descriptions for the Screen2Words dataset. Since the LLM used in this process did not have access to the original screenshot, it is possible that it can hallucinate inaccurate details. We used a vision-language model (Radford et al., 2021) to compare textual descriptions and the screenshot to filter out inaccurate descriptions without a strong similarity score.

3.2 Base Model

We used an existing pre-trained 15B parameter model, StarChat-Beta (Tunstall et al., 2023), as a starting point, which was the best available fully-open (*i.e.,* no usage restrictions) code model at the time we started the project. StarChat-Beta is an LLM based on StarCoder (Li et al., 2023b) which was trained primarily on *i)* TheStack (Li et al., 2023b), a large dataset (250B tokens) of permissively licensed code repositories, *ii)* crawled web pages, and *iii)* OpenAssistant-Guanaco (Dettmers et al., 2023), a small instruction-tuning dataset. Notably, StarChat-Beta's training data contains little to no SwiftUI data (Li et al., 2023b). Swift code repositories were excluded by accident when creating TheStack dataset (Li et al., 2023b), and upon manual inspection, we found that the OpenAssistant-Guanaco dataset only contains one example (out of ten thousand) with any Swift code in the response field. We hypothesize that any Swift examples seen

by StarChat-Beta during training were most likely from crawled web pages, which are possibly lower quality and less structured than repository code.

3.3 Supervised Finetuning

We generated input/output pairs needed for supervised finetuning by repeatedly *i)* prompting an LLM to generate SwiftUI programs from a list of UI descriptions, *ii)* filtering out generated programs that do not compile or have a low CLIP score, then *iii)* finetuning the LLM on the high quality subset. Our approach is similar to "rejection sampling" and self-training (Gulcehre et al., 2023) techniques, where high quality examples are mined through repeated sampling, scoring, and selection.

While the StarChat-Beta base model has poor performance overall for SwiftUI code generation, frequently producing uncompilable code or very simple UIs, we successfully detected a subset of higher-quality examples using compilation success and CLIP score as filtering conditions. We used a randomized strategy for sampling and generating code: the model was asked to generate code for randomly sampled screen descriptions from our training datasets. Selection was done independently, resulting in some prompts having multiple outputs and others being skipped altogether. During each training iteration, we allocated roughly a week for sample generation, which resulted in around 100,000-200,000 total samples (influenced by average program length).

The initial proportion of mined examples is extremely small (0.4%). However, the model's performance improves with each iteration of training on mined examples. As a result, it progressively generates a higher percentage of high-quality data that pass the filter. We repeated this process four times starting with StarChat-Beta and name the resulting model *UICoder-SFT*.

3.3.1 Data Filtering

We used three methods to filter generated data for high-quality finetuning examples: *i)* compilation success, *ii)* CLIP-based output relevance, and *iii)* de-duplication. Early iterations had many examples filtered out due to compilation failure since the base model was not effective at generating syntactically-correct SwiftUI code. During later iterations, more samples were rejected due to output relevance and the de-duplication filter. The total number of mined examples also increased over time as more generated samples fulfilled the requirements. We also adjusted filter hyperparameters over time to increase selectivity, both to obtain higher quality training samples and to fit memory constraints.

Compilation Success. We keep only fully compilable programs (compile warnings are ignored). This is necessary because filters used in later stages rely on the rendered output of the SwiftUI code, which is not possible to generate without a working program.

CLIP Score. The CLIP score filter uses a vision-language model (Ilharco et al., 2021) to assign a numerical score to each input/output pair that measures how well the generated UI matches the input description. We constructed a natural-language prompt template that included tags such as "screenshot of a mobile app" concatenated with the input description. We used a percentile-based threshold to keep the samples with the highest scores.

Based on early observations, we noticed that CLIP occasionally produced a high score if the rendered screenshot contains the original prompt text (Goh et al., 2021). To address this problem, we modified the CLIP score to also average the similarity score computed from the embedded ground-truth screenshot.

De-duplication. We used a density-based clustering algorithm (Ester et al., 1996) to group examples based on the CLIP embeddings of their rendered screenshots. This process makes it easier to identify groups of outputs that result in a highly similar appearance or layout which could imbalance the resulting fine-tuning set. For each identified cluster, we keep only the example that has the highest CLIP score.

3.4 Preference Alignment

Following supervised finetuning, LLMs sometimes undergo an additional *alignment* stage to better match with human preferences or meet specific criteria like helpfulness and harmlessness. Unlike supervised finetuning, where the model is trained to match pre-determined outputs for each input, alignment techniques allow the model to generate its own output candidates, and then provide a numeric reward or pairwise preference labels as training signals. We hypothesized that UICoder could benefit from this process by implicitly learning to prefer output candidates with high reward values while avoiding those with low CLIP scores or compilation errors.

To generate data for preference modeling, we modify our data generation strategy to produce

paired examples, which in our case is an input prompt paired with several possible code implementations. After randomly selecting a screen description, we use the LLM to generate 10 outputs for the same input through a set of manually created sampling configurations. Note that while it is possible to repeatedly sample the model with the same configuration, we found that more output diversity could be achieved with different sampling profiles.

Once multiple outputs are generated for each input, they are ranked using pairwise rules. All compilable samples are ranked above non-compilable samples. Compilable samples are ranked by their CLIP score, and non-compilable samples are ranked by the number of error-free lines divided by the total number of lines in the program.

3.4.1 Modeling Approaches

We used three different modeling approaches to further finetune UICoder-SFT with the generated preference pairs, which resulted in three variations of the model: UICoder-DPO, UICoder-Top, and UICoder-Filtered.

UICoder-DPO was trained using an algorithm called Direct Preference Optimization (DPO) (Rafailov et al., 2023). The DPO algorithm requires significantly more GPU VRAM than supervised finetuning, so we used 4-bit quantization with the QLoRA technique so that it could fit on a single A100 GPU (Dettmers et al., 2023). UICoder-Top was trained using a supervised training objective, but with the top output for each input as the target, which allows for greater coverage of input prompt. Finally, as a point of comparison, we applied one more iteration of the previously used filter-then-train algorithm that ignored rankings to the newly generated data. We refer to this model as UICoder-Filter.

4 Training Infrastructure

We provide details about the infrastructure used to support model training. Our setup *i)* generates large volumes of SwiftUI code, *ii)* renders the SwiftUI code to screenshots, and *iii)* scores, filters, then dededuplicates the synthetic dataset before finetuning our model. The servers are connected to a cloud storage provider that allows them to share files between each other.

Code Generator. The code generator is used to generate a large number of SwiftUI programs using our model. We used a mix of V100 and A100 GPUs, which was assigned by our organization's internal infrastructure. [1] The code generator repeatedly sampled a description of a UI from our training datasets using uniform random sampling and constructed a prompt using our model's prompt template. A SwiftUI program was then generated by sampling our model until a pre-defined stop token was reached. Under some training configurations, multiple outputs were generated from the same description. Generated SwiftUI programs were periodically uploaded to network storage.

UI Renderer. The UI renderer was used to convert SwiftUI programs to rendered screenshots. The UI renderer ran macOS with Xcode and the iOS simulator that repeatedly *i)* downloads queued SwiftUI programs, *ii)* renders them to screenshots, then *iii)* uploads the results to the network storage. The image asset renderers ran text-to-image models that generated image assets referenced by the SwiftUI code. We found that including generated image assets in UI screenshots was more effective than inserting placeholders (*e.g.,* grey rectangles in place of images) when computing CLIP score.

Before program compilation, we applied automated program repairs (APRs) to try to automatically fix common errors. We focused on lightweight, manually-defined heuristic repairs (as opposed to computationally-expensive LLM-based repair methods) that used regular expressions and line numbers parsed from compiler output to match and replace errors in the source code.

Training Server. The model trainer downloaded and collated the *i)* input descriptions, *ii)* generated SwiftUI programs, and *iii)* the rendered UI screenshots. A text-image matching model (Ilharco et al., 2021) was used to score each rendered UI screenshot by computing the cosine similarities between *i)* the embedded input description, and *ii)* the embedded reference screenshot.

Depending on the training stage, different algorithms for dataset generation and model training were applied. All models were trained using LoRA method (Hu et al., 2022) to improve training speed and efficiency.

5 Experiments

We conducted experiments to *i)* measure the performance of our model over time, *ii)* measure the

[1] When using V100 GPUs, we ran the inference with the `float32` data type to support the full precision required for the dynamic range of the model's native format.

impact of our data on different LLMs, and *iii)* compare against the performance of other baselines.

5.1 Evaluation Dataset

We created an evaluation dataset of 200 UI descriptions, which is roughly the size of other LLM coding benchmarks (Chen et al., 2021). We randomly selected 100 Android and 100 iOS screenshots from a held-out set. Each screenshot was manually annotated by a member of the research team with a description that consisted of 1-3 sentences (mean 23.6 words, min 8 words, max 71 words). Compared to screen descriptions in existing datasets (Wang et al., 2021), our descriptions were longer and contained more variation since our guidelines were less rigid (*i.e.,* no constraints on sentence structure or description length). We also used off-the-shelf UI analysis models (Wu et al., 2023) to analyze the reference screenshots in our evaluation set, which suggested they were both complex and diverse. Screens in our evaluation set contained an average of 20.3 elements per screen (min 4 elements, max 86 elements). Our evaluation set also contained many different types of UI categories and structures, *e.g.,* 44 contained lists, 34 contained galleries, 23 were tutorial screens, 16 were news screens, and 14 were login screens.

For each tested model or API, we generated and rendered one program for every input in our evaluation set using the default sampling parameters and prompt template of that model, which we collected from their official web demos. Since the purpose of the evaluation is to evaluate the generated code and layout, we replaced all image assets with the same placeholder image. While our evaluation set doesn't contain reference code implementations, the length of model-generated output (mean length of 52 lines) also suggests higher complexity than solutions provided in other coding benchmarks (Chen et al., 2021) (mean 8 lines).

5.2 Metrics

Measuring the quality of generated UIs is challenging, and to the best of our knowledge there is no automated benchmark that can evaluate description-based UI code generation, unlike for general-purpose coding where benchmarks such as HumanEval (Chen et al., 2021) may be used. In our work, we used a combination of automated metrics and human preferences to evaluate UI code.

Compilation Success. Compilation success was measured by calculating the ratio of compilable programs from the 200 input descriptions found in the evaluation set. Programs were compiled using the iOS version and Swift compiler included with Xcode 14. A high compilation rate suggests that the model has a good mastery of the syntax needed for generating correct code.

CLIP Score. Previous work has shown a correlation with human judgments when evaluating text-to-image generation (Hessel et al., 2021), and the CLIP score is more reproducible since it doesn't rely on human ratings, which may vary between people or over time. For evaluation, we used a larger and more accurate CLIP model than the one used in our training pipeline (OpenCLIP ViT-G/14 vs ViT-B/32 (Ilharco et al., 2021), since the memory and efficiency constraints that applied during training were not relevant during evaluation. A high CLIP score suggests that the model's outputs are relevant to the input description.

Human Preference Elo. Following recent LLM evaluation techniques (Zheng et al., 2023), we used pairwise human ratings to calculate Elo ratings for evaluated models (Elo, 1967). This method is preferred over asking annotators for absolute ratings or full rankings because it greatly reduces the cognitive load but requires more samples for a full comparison. Each model starts out with an initial Elo rating, which is set to 1000, as done in prior work (Zheng et al., 2023). For each comparison, the score of the "winner" was increased while the score of the "loser" was decreased based on the prior rating gap between the two compared models. This method resulted in a calibrated rating score where the difference of two models' Elo ratings can be used to predict their "winning" probability vs. any other model.

We ran a small-scale preference-based evaluation with six human raters, who were part of the research team. We chose to run this initial evaluation amongst the research team (HCI experts with doctorate degrees), who could apply prior knowledge/training on UI design, which would be difficult to articulate in instructions given to anonymous crowdworkers. [2] Note that raters were unable to see the name of the models that generated the outputs, and raters never saw any model's prior output for the evaluation prompts. If one of the models' code did not compile, it was automatically marked as a loss, and if both did not compile, a tie was recorded.

[2]We acknowledge that using a large pool of online raters could provide valuable insight from an end-user perspective.

In total, around 3000 pairwise comparisons were recorded.

5.3 Performance Over Time

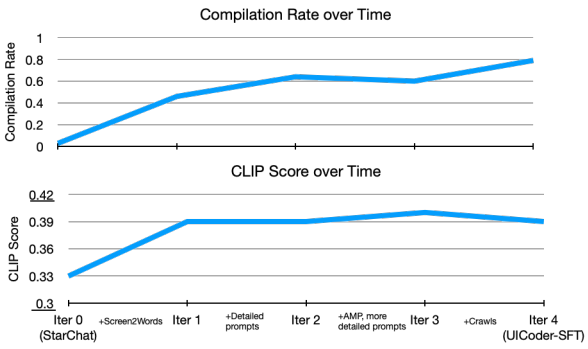

Figure 2: A plot of two automatically calculated metrics over time (on a held-out set): compilation rate and mean CLIP score. Over the course of training, our model improves metrics used to filter its training data.

We measured the impact of our training procedure by running automatic evaluations of the UICoder model after each iteration, starting from the initial StarChat-Beta base model to the fourth iteration that resulted in UICoder-SFT. The results of this experiment are shown in Figure 2. Overall, there is a positive trend between the number of training iterations and the performance of both metrics, and the largest rate of improvement occurs during the first iteration. The highest compilation rate was reached after the fourth iteration (0.79), while the highest CLIP Score was reached on the third iteration (0.40).

Additional UI descriptions were incorporated at various points in the training process based on our manual observations and tests. For example, at the initial iteration from 0 to 1 we started with only human-authored descriptions found in Screen2Words (Wang et al., 2021). However, we noticed that the model tended to produce relatively simple outputs and struggled to understand more detailed descriptions, which led us to include LLM-augmented and paraphrased descriptions. Similarly, we later included iOS screenshots, since the Android UIs in Screen2Words (Wang et al., 2021) and RICO (Deka et al., 2017) use different design patterns and UI components. These changes likely contributed to some of the fluctuations in model performance measured over the course of training.

We focused our evaluation on mobile app UIs, which we acknowledge only reflects a small portion of overall UIs in use and platforms supported by SwiftUI. Our choice was based on the limited selection of datasets for UIs, and we are only aware of one dataset that contains paired text descriptions (Wang et al., 2021). We expect that our method could work for other platforms as well, such as web pages (Wu et al., 2023), although the descriptions would need to be synthetically generated.

5.4 Distillation Experiments

We trained the UICoder models through a multi-iteration training process. However this is time-consuming because it requires repeatedly generating, evaluating, and training on self-generated data. Therefore, we explored the possibility of using data generated during UICoder's training to finetune other LLMs, without needing to repeat the self-generation process. Model distillation refers to the practice of using the results of a larger "teacher model" to finetune or train a smaller "student model." This practice is employed to use the often superior results of proprietary models to train other more open models, but can also be used to transfer skills from a smaller purpose-built model to a larger general model through reverse-distillation. Octocoder is a more recent version of our base model, StarChat-Beta (Muennighoff et al., 2023). Octocoder was released after we began our model training, so we investigate the possibility of "rebasing" UICoder onto an improved model. MPT-30B-Instruct (Team, 2023) is a 30B LLM that is double the size of UICoder and was finetuned on a collection of permissively-licensed general-purpose instruction-following datasets. MPT-7B-Instruct (Team, 2023) is a smaller 7B version of MPT-30B-Instruct that is half the size of UICoder and might be useful for efficient deployment.

We used training examples generated from the last iteration of UICoder training to distill these models using the same hyperparameters. We refer to the resulting models as Octocoder++, MPT-30B++, and MPT-7B++.

Results. Both initial and distilled model performance were highly dependent on the size of the base model, where larger model sizes led to better performance. The best-performing model was MPT-30B-Instruct which had a compilation rate of $0.14 \rightarrow 0.78$ and CLIP score of $0.351 \rightarrow 0.401$. This was followed by MPT-7B, with a compilation rate of $0.13 \rightarrow 0.69$ and a CLIP score of $0.350 \rightarrow 0.395$. Although Octocoder was a 15B model trained on code, it had the worst performance with a compilation rate of $0.06 \rightarrow 0.51$ and a CLIP score of $0.235 \rightarrow 0.382$. This may have

been due to a mismatch between Octocoder's training data, which was based on scraped commit messages, and the types of UI descriptions relevant to our task. Overall, all models' compilation rates and CLIP scores were greatly improved by distillation, which suggests the utility of UICoder-generated data for finetuning other models.

5.5 Baseline Comparison

We compared the performance of UICoder models, distilled models, and several classes of baselines.

Baseline Models. We categorized baselines into three categories: *i)* proprietary models, *ii)* restricted models, and *iii)* permissive models. We evaluated two baselines for each category.

Currently, proprietary models have the best performance, but are accessible only through web API requests and often have usage restrictions. We included GPT-4 and GPT-3.5-Turbo as proprietary baselines, since they have been shown to excel at a wide range of tasks, including code generation (Bubeck et al., 2023; Luo et al., 2023).

Restricted baselines are freely downloadable models with license or usage restrictions (*i.e.,* no commercial use), due to the use of a proprietary model in generating training data. [3] We included WizardCoder (Luo et al., 2023) and MPT-30B-Chat (Team, 2023) as restricted baselines. Note that MPT-30B-Chat is different from MPT-30B-Instruct, in that the chat model was finetuned using output from ChatGPT and GPT-4.

Finally, we included StarChat-Beta (Tunstall et al., 2023) and OctoCoder (Muennighoff et al., 2023) as permissive baselines, which were both trained on permissively-licensed code repositories and instruction-tuning datasets.

Results. We ran all three metrics for the baseline comparison experiment. The results are summarized in Table 1 and Figure 3 shows the expected human ratings for every pair of evaluated models. Overall, the proprietary models had the best performance, followed by UICoder models, then models distilled from UICoder data. It was somewhat surprising that GPT-3.5 had a higher compilation rate than GPT-4, since GPT-4 is often considered a stronger model. Upon manual inspection, we hypothesized that GPT-4 often tried to produce longer and more complex code implementations, which made compilation errors slightly more likely.

[3] We do not consider some models, such as LLaMA variants, to be freely downloadable because they require a license application to first be approved by Meta to access the weights.

Table 1: Table of automated metrics and Elo ratings computed for each model on the evaluation set. We display the mean CLIP score.

Model	Params	Compile	CLIP	Elo
GPT-3.5-Turbo	-	0.88	0.416	1224
GPT-4	-	0.81	0.419	1189
WizardCoder	15.5B	0.23	0.393	870
MPT-30B-Chat	30B	0.27	0.368	873
StarChat-Beta	15.5B	0.03	0.334	773
Octocoder	15.5B	0.06	0.235	777
UICoder-Filtered	15.5B	0.79	0.404	1099
UICoder-Top	15.5B	0.82	0.396	1084
UICoder-DPO	15.5B	0.75	0.393	1091
MPT-7B++	7B	0.69	0.395	1015
Octocoder++	15.5B	0.51	0.382	959
MPT-30B++	30B	0.78	0.401	1047

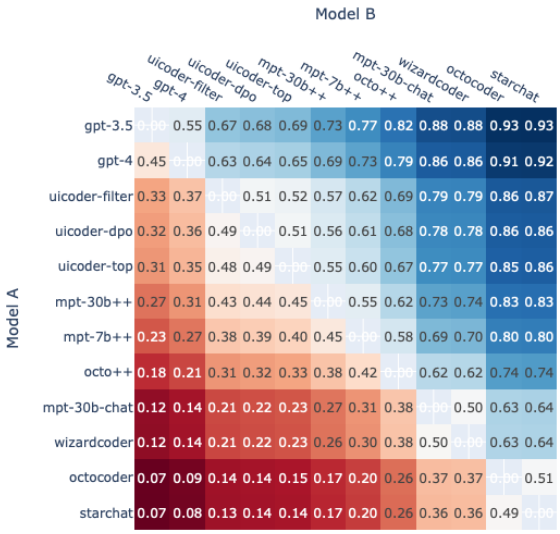

Figure 3: Matrix shows the predicted win probability of model A against model B. Our training technique significantly improved the performance of an initially poorly-performing base model (StarChat) to competitive among larger proprietary models (UICoder).

Variations of the UICoder models approached the performance of the proprietary GPT models, and UICoder-Top had a higher compilation rate than GPT-4. All three UICoder variants had roughly the same level of performance, which suggests that the additional preference alignment stage did not lead to significant improvements, possibly due to sub-optimal hyperparameters or the additional model quantization needed to run the training algorithm.

Distilled models finetuned from the final iteration of generated data had slightly lower performance than the UICoder models themselves, which together with our performance over time experiments (Figure 2) suggests that multiple training iter-

ations are needed to maximize performance. MPT-30B++ was the best-performing distilled model, possibly due to its larger model size, and although Octocoder++ is pre-trained on large amounts of code, it performed worst out of the distilled models. MPT-7B++ maintains relatively high performance with a much smaller size, which is encouraging from an efficiency standpoint.

All other downloadable models fared considerably worse. Restrictive models performed better than permissive ones, due to the use of larger amounts of finetuning data generated from proprietary model APIs. It is possible that the distilled proprietary data did not contain many SwiftUI-related coding examples and querying proprietary models specifically for more UI-related tasks could further boost performance. [4] Notably, StarCoder-Beta, our base model, was originally ranked in last place, likely due to the scarcity of Swift and SwiftUI code in its training code. Our results suggest that our method is highly effective at improving its capabilities, since UICoder becomes one of the top performing models after training.

6 Conclusion

In this paper, we introduced a novel method that uses automated tools such as a code compiler and a pre-trained vision-language model to finetune LLMs to generate UI code from user-provided textual descriptions. Unlike other instruction-following LLMs that are trained on expensive human feedback or output from a stronger proprietary model, our technique trains LLMs entirely using high-quality examples mined from self-generated data. We applied five iterations of our algorithm to an existing open-source LLM, resulting in nearly one million generated SwiftUI programs, which were then filtered and refined to train the UICoder model. In a series of experiments that measured both automated metrics and human preferences, UICoder and other models trained with our method outperformed all other downloadable baselines by a large margin and approached the performance of larger proprietary models.

7 Limitations and Risks

We discuss limitations of our training approach, specifically drawbacks of our automated feedback sources, and model evaluation.

[4] We did not distill SwiftUI models ourselves from proprietary LLMs because this would require breaking their ToS.

Focus on SwiftUI. We chose to work with the SwiftUI toolchain in our work. Other toolchains with similar properties exist (*e.g.,* Dart/Flutter for Google/Android and React Native), and we expect that our method could be directly applicable as well. Our use of a compiler as automated feedback into the training process can be more broadly useful in learning the unique syntax of specialized languages and libraries.

Reliance on Synthetic Datasets. UICoder's reliance on synthetic, self-generated fine-tuning avoids the cost of human labeling/ranking and avoids violating the ToS of stronger proprietary models used for distillation. However, we acknowledge that a tradeoff of the self-generation+filtering strategy is limited diversity of fine-tuning data (since no additional external data is provided). It should be noted that our evaluation uses an unbiased, randomly sampled set of UI descriptions, and it shows that our method performs favorably against other models trained on external sources of data, which suggests effectiveness for real-world use-cases.

Swift Compiler. The Swift compiler provides ground truth for compilation success, but this only returns a sole binary value, which equates the quality of any two non-compiling programs regardless of the number of defects. Based on our observations, this can incentivise the model to avoid errors, rather than learn how to correct them, resulting in very simple outputs. We attempted to rank generated programs by the proportion of error-free lines of code to total program length but found that this actually led to decreased a compilation rate in the case of the UICoder-DPO model. A more useful signal would be to count the number of changes needed to "fix" a failing program, but this cannot be directly computed from compiler output. As a result of these limitations, UICoder still generates relatively simple programs, and we plan to employ more advanced PL or verification techniques to improve this aspect of our approach in the future.

CLIP Score. We found that CLIP could detect overall output relevance and large disparities in output quality, but it wasn't well-equipped for comparing subtle design choices or detecting some types of visual defects. Figure 5 shows our trained model still exhibits errors that are uncharacteristic of human developers, including data formatting, text-overflow, inaccessible controls, poor style, and contrast. We hypothesize that a major reason for CLIP's limitations is the small fraction of its train-

ing examples that included UI screenshots. The CLIP model is also known to struggle with certain tasks such as object-counting and reasoning (Radford et al., 2021), which could be relevant for some types of prompts, e.g., "a login page with three buttons stacked vertically." Since CLIP only accepts image input, it can only evaluate a dynamic, interactive UI with a screenshot of its default state.

Evaluation. Our evaluation is limited in that we asked human evaluators to judge UIs purely through screenshots, due to the complexities of installing the compiled app on their device. This may bias the evaluation towards aesthetic qualities of the UI rather than its functionality of navigation. As stated, our human evaluation consisted of a limited number of expert raters, who were also a part of the research team. While measures were taken to prevent bias in rating results, we expect that a larger pool of anonymous raters could give insight from the end-user's perspective. We plan to build the infrastructure required for larger-scale tests. We also included proprietary model endpoints such as OpenAI GPT-3.5 and GPT-4 in our baseline evaluation, which was conducted August-September 2023. Because OpenAI periodically updates these models, this could affect reproducability. We also didn't directly evaluate code quality, which is important for practice use. We provide sample generations in supplementary material and leave more rigorous evaluation to future work.

Risks. UICoder is an LLM model that is, in theory, capable of generating potentially problematic or harmful outputs if prompted to do so. Our focus is to improve an existing LLM's ability to write better UI code, and should be combined with additional techniques (*e.g.,* alignment and human-in-the-loop correction) to reduce this risk. Since UICoder is a derivative of a pre-trained code LLM trained on online code repositories, it could also generate code with security vulnerabilities. Additional care should be taken to check generated code before including it. Part of our training pipeline involves automatically executing LLM-generated code, but security risks can be mitigated by running code in a virtualized, isolated environment.

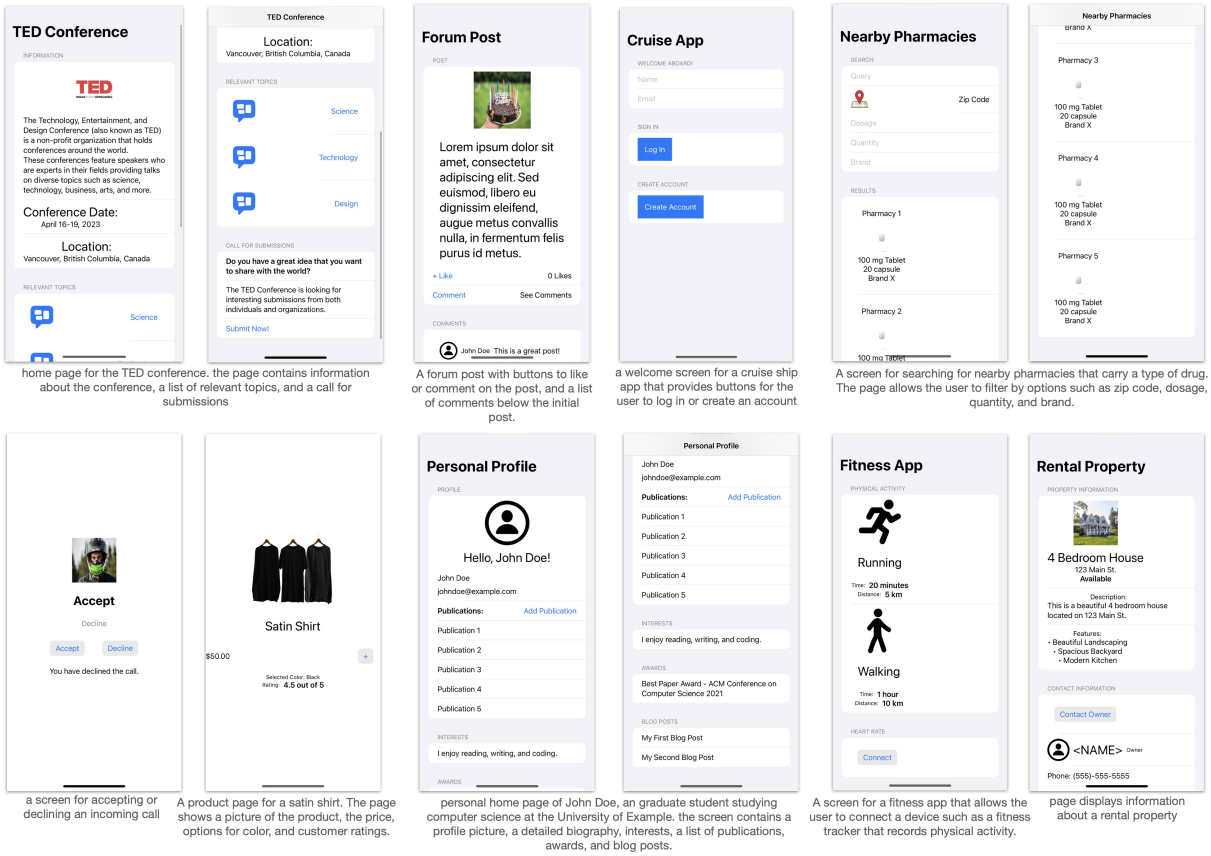
A Output Samples

Figure 4 shows several input descriptions and the corresponding rendered UI. Figure 5 shows several examples containing failure cases. In addition, we include some examples of generated code in the supplementary material.



B Human Evaluation Instructions

We built a simple web application (Figure 6) for collecting human preferences during our Elo evaluation. Our evaluation instructions asks the user to select the screenshot that better matches a description, which is randomly chosen from a list of 200 descriptions. We include the list of 200 input descriptions used for evaluation in supplementary material. The description is fed into two different models to generate two screenshots. The user can select one of the two screenshots or a third option indicating that they are "about the same."

The full instructions are "Select the UI screenshot that better matches the description. All images and icons have been replaced with the same placeholder image, and the screens may also contain some placeholder text. Focus on the overall quality of the structure and layout when selecting the preferred screen."

C Hyperparameters

To aid in reproducibility, we record hyperparameters used by various algorithms in Table 2. We did not conduct extensive hyperparameter sweeps, and set parameters based off default values and manual experimentation. It is possible that performance can be further improved through additional tuning.

Abstract

Multilingual pretraining has been a successful solution to the challenges posed by the lack of resources for languages. These models can transfer knowledge to target languages with minimal or no examples. Recent research suggests that monolingual models also have a similar capability, but the mechanisms behind this transfer remain unclear. Some studies have explored factors like language contamination and syntactic similarity. An emerging line of research suggests that the representations learned by language models contain two components: a language-specific and a language-agnostic component. The latter is responsible for transferring a more universal knowledge. However, there is a lack of comprehensive exploration of these properties across diverse target languages. To investigate this hypothesis, we conducted an experiment inspired by the work on the Scaling Laws for Transfer. We measured the amount of data transferred from a source language to a target language and found that models initialized from diverse languages perform similarly to a target language in a cross-lingual setting. This was surprising because the amount of data transferred to 10 diverse target languages, such as Spanish, Korean, and Finnish, was quite similar. We also found evidence that this transfer is not related to language contamination or language proximity, which strengthens the hypothesis that the model also relies on language-agnostic knowledge. Our experiments have opened up new possibilities for measuring how much data represents the language-agnostic representations learned during pretraining.[1]

1 Introduction

The emergence of self-supervised pretraining models such as BERT has revealed a notable phenomenon of cross-lingual transfer even when these models are trained on multilingual corpora devoid of paired translation examples. For example, LLAMA (Touvron et al., 2023), which was trained self-supervisedly on an English-centric corpus, exhibits surprising multilingual capabilities (Yuan et al., 2023; Ye et al., 2023). The underlying mechanisms driving this behavior remain unclear, with hypotheses ranging from the presence of shared "anchor" tokens (Pires et al., 2019) to language contamination (Blevins and Zettlemoyer, 2022), yet no scientific consensus has been reached.

Research in this area often involves the use of pre-existing language models (LMs), which are subsequently finetuned on supervised datasets in different languages (de Souza et al., 2021; Yuan et al., 2023). However, when evaluating multiple languages, conventional methodologies encounter two significant challenges: firstly, the dependence on supervised finetuning datasets, which often vary in size and quality, complicating cross-lingual comparisons; secondly, the use of subword tokenizers, which do not represent all languages equally.

In this work, we avoid these problems by working with a byte-level tokenizer and by using auto-regressive language models trained in self-supervised from scratch in one language and then finetuned on another. To measure the effect of transfer learning, we employ the concept of data transfer (Hernandez et al., 2021), which allows us to quantify how much each different source language contributes to the perplexity of the target language.

Our main contribution is providing a method that measures how much knowledge, in bytes, is transferred from one language to another. By applying it, our findings reveal a surprising trend: even when comparing linguistically distant languages, the data transfer metrics are of a comparable magnitude. This research contributes additional evidence supporting the language-agnostic hypothesis, which suggests that the internal representations developed

[1]The code used in our experiments is publicly available at https://github.com/lersouza/language-transfer. We rely on the mC4 dataset from Huggingface, available at https://huggingface.co/datasets/mc4

by a model are not only influenced by the linguistic surface form but also by the cultural and semantic content of the training data.

2 Related Work

Prior work attributed the success of multilingual models in cross-lingual transfer to "anchor" tokens (Pires et al., 2019). However, subsequent research demonstrated that models could perform well even without these tokens (Artetxe et al., 2020), highlighting the significance of shared parameters during training (Conneau et al., 2020). Competitive results were achieved by monolingual models with minimal or no adaptation (Artetxe et al., 2020; de Souza et al., 2021).

Investigations by Blevins and Zettlemoyer (2022) linked these findings to language contamination, where pretraining datasets contained target language data. Additional factors contributing to cross-lingual transfer success include dataset statistics, language attributes (Lin et al., 2019), language structure (Lin et al., 2019; Papadimitriou and Jurafsky, 2020; Chiang and yi Lee, 2020; Ri and Tsuruoka, 2022), and token overlap between training and target languages (Beukman and Fokam, 2023). The role of language script (Fujinuma et al., 2022) and model tokenizer (Rust et al., 2021) was also noted, prompting the use of a byte tokenizer to address these issues (Xue et al., 2022; Abonizio et al., 2022).

Recent research proposed a two-component model representation hypothesis—language agnostic and language specific (de Souza et al., 2021; Zeng et al., 2023; Wu et al., 2022). While promising, no study has measured how much of the language-agnostic component is used in settings with multiple source and target languages. Additionally, existing research still applies the source language vocabulary to the target language, potentially compromising input representations and affecting results.

To address these gaps, we draw on Hernandez et al. (2021) and employ a byte vocabulary in our experiments to overcome current literature limitations.

3 Methodology

Inspired by Hernandez et al. (2021), our methodology focuses on quantifying the transferability of pretraining data across distributions, particularly between different languages. We select a **target** language and finetune models initialized from various **source** languages onto it. Subsequently, we evaluate each model on a **target** language test set and compare their performance. We introduce the Data Transfer (D_T) metric to estimate knowledge transfer, explained in more depth in 3.1. This process is repeated across different **target** languages to observe effects across a broad linguistic spectrum.

These experiments aim to quantify and compare cross-lingual knowledge transfer from different source languages. This analysis seeks to uncover the extent to which transferability depends on specific languages and the importance of language-agnostic components in learned representations. The following sections provide further details.

3.1 Data Transfer Estimation

To quantify the knowledge transfer from pretrained models to a given target language, we utilize the Data Transfer (D_T) metric. This metric assesses the effectiveness of pretraining data by measuring the additional tokens required in the target language for a model initialized from scratch to match the performance of a model pretrained on a source language and finetuned on the target. Figure 1 illustrates this concept.

In our experiments, we utilize a set of M different dataset sizes, denoted as $\mathbf{D_F} = \{s_0, s_1, ..., s_m\}$, in the target language. Initially, we train a random-initialized model on these datasets, resulting in a set of perplexities $\mathbf{P_R} = \{p_{r,0}, p_{r,1}, ..., p_{r,m}\}$. Subsequently, we train from scratch another model on a fixed amount of tokens (e.g., 6B) in a source language ℓ, and then finetune it on the target language using the same dataset sizes $\mathbf{D_F}$, generating another set of perplexities $\mathbf{P}_\ell = \{p_{\ell,0}, p_{\ell,1}, ..., p_{\ell,m}\}$.

To estimate the Data Effective metric (D_E), which represents the amount of data needed to achieve a certain performance, we utilize a linear interpolation function $\gamma(y', \mathbf{X}, \mathbf{Y})$. This function interpolates between discrete data points $(x_j, y_j) \in X \times Y$, evaluated at y'. In our case, the calculation is expressed as:

$$D_{E,i} = \gamma(p_{\ell,i}, \mathbf{D_F}, \mathbf{P_R}) \quad (1)$$

Here, $D_{E,i}$ signifies the Data Effective metric for the i-th perplexity value in $\mathbf{P}_\ell$. $\mathbf{P_R}$ denotes the set of perplexity values derived from the random-initialized model, while $\mathbf{D_F}$ represents the dataset sizes employed during finetuning.

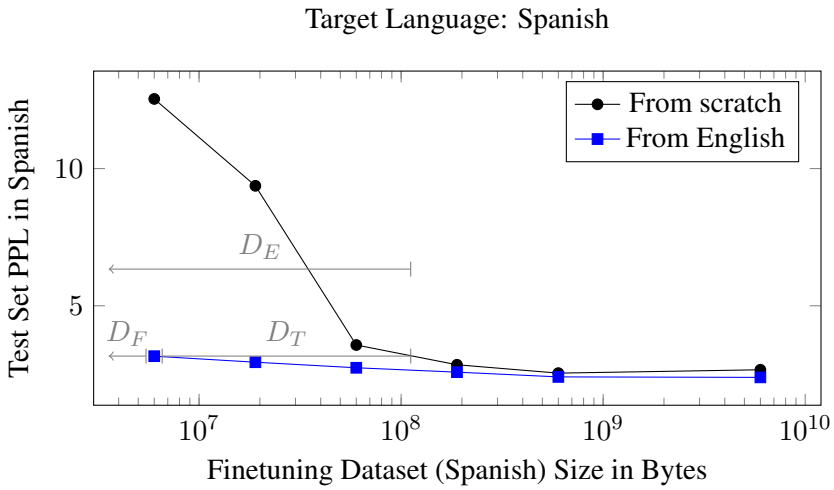

Figure 1: Example illustrating how the coeficients D_T, D_F and D_E are calculated. Each series represents a different initialization. D_T is the number of additional tokens in the target language that a from-scratch model would have needed to achieve the same perplexity of a model finetuned from English. D_F is the size of the dataset used for finetuning and D_E accounts for all data, both D_F and D_T.

We utilize the linear interpolation function provided by the NumPy library to approximate $D_{E,i}$. Further details can be found in the NumPy documentation.[2]

Finally, the Data Transfer metric is computed by subtracting the i-th dataset size s_i from $D_{E,i}$:

$$D_{T,i} = D_{E,i} - s_i \tag{2}$$

By subtracting the dataset size from $D_{E,i}$, we account only for the data coming from pretraining. Since a byte vocabulary is utilized, the amount of data transferred is measured in **bytes**.

3.2 Task and Evaluation Metric

We adopt Language Modeling as our main task with perplexity as the performance metric for all experiments. Perplexity, derived from the model's loss (e^{loss}), facilitates future predictions of model behavior in transfer learning scenarios, following the approach in Hernandez et al. (2021). This choice also allows extensive experiments across multiple languages, leveraging datasets like mC4 (Xue et al., 2021) to overcome size limitations inherent in supervised datasets.

3.3 Tokenization Impact

In cross-lingual setups, the choice of tokenization method holds considerable significance (Rust et al., 2021). While subword tokenizers are commonly employed in cross-lingual experiments, using a tokenizer trained in a source language on a distant target language may result in an increased number of tokens. This can lead to the utilization of undertrained embeddings in some instances, introducing challenges for effective sentence representation. Furthermore, dealing with different scripts introduces the issue of numerous "unknown" tokens, exacerbating the difficulty of obtaining suitable input representations for the model.

To address these challenges, we opt for a byte vocabulary based on the approach proposed by Xue et al. (2022), which allows us to standardize representations across all languages, ensuring that each model encounters the same quantity of UTF-8 bytes. By doing so, we mitigate the use of unknown tokens and undertrained embeddings, thereby minimizing the impact of tokenization issues on the performance of our experiments.

3.4 Language Contamination

A potential reason for a pretrained model's superior performance in cross-lingual tasks is the presence of a substantial amount of data in the target language in its pretraining dataset, a phenomenon referred to as language contamination. To quantify this impact, following the approach outlined by Blevins and Zettlemoyer (2022), we examine the rates of target language fragments in the source language dataset and vice versa.

Specifically, for a given source language ℓ and target language t, we calculate the ratio of all lines

[2]See https://numpy.org/doc/stable/reference/generated/numpy.interp.html

classified as ℓ in the target dataset (known as contamination on target) and as t in the pretraining dataset (known as contamination on source). We perform language detection using the *fasttext* tool (Bojanowski et al., 2017), employing a threshold of 0.6 for classification.

Next, we compute the Spearman correlation between the set of Data Transfer metrics $\mathbf{D_T}$ and those ratios obtained from the outcomes of our experiments.

Correlating these rates with the model's data transfer indicator allows us to evaluate the impact of language contamination on model performance.

3.5 Language Similarity

Language similarity is often cited as a crucial factor influencing cross-lingual transfer performance in natural language processing tasks. In this work, we aim to investigate the relationship between language similarity and cross-lingual transfer effectiveness based on the outcomes of our experiments.

To explore this relationship, we measure various distances between languages, including syntactic, geographic, and phonological distances. These distances are calculated based on the methodology proposed by Littell et al. (2017).

We aim to correlate these language distances with the data transfer metric (D_T). By employing Spearman correlation analysis, we seek to discern whether there exists a significant correlation between the observed D_T values and the measured language distances.

This analysis elucidates whether our experimental results can be attributed to the similarities between the languages involved in our cross-lingual experiments.

4 Experiments

This section presents the languages, datasets, model architecture, and training details for our experiments.

4.1 Languages

Source Languages Selection. We chose three diverse languages—English, Russian, and Chinese—for the source language during the pretraining phase. This selection ensures a broad linguistic spectrum while adhering to pretraining budget constraints.

Target Languages Selection. Ten target languages, spanning various language families and different scripts, were chosen to establish a diverse cross-lingual setting. Details, including language codes, are provided in Table 1.

Code	Language	Family	Script
ar	Arabic	Afro-Asiatic	Arabic
en	English	Indo-European	Latin
es	Spanish	Indo-European	Latin
zh	Chinese	Sino-Tibetan	Hanzi
fi	Finnish	Uralic	Latin
de	German	Indo-European	Latin
ko	Korean	Koreanic	Hangul
id	Indonesian	Austronesian	Latin
ja	Japanese	Japonic	Kanji, Hiragana, Katakana
ru	Russian	Indo-European	Cyrillic

Table 1: Characteristics of selected target languages.

4.2 Datasets

For training and finetuning, language subsets from the mC4 dataset (Xue et al., 2021) for the selected languages were utilized.[3] Pretraining datasets comprised approximately 6 billion tokens, while finetuning datasets ranged from 6 million to 6 billion tokens. Documents were sampled at random without replacement until the desired amount of tokens was reached.

4.3 Model Architecture

Our model is a decoder-only Transformer (Vaswani et al., 2017) that uses a byte vocabulary with 256 embeddings with a dimension of 640. The model follows closely the implementation provided in the T5x library. It consists of 10 layers, each having 10 attention heads with dimensions of 64. The intermediate dimension of Multi-Layer Perceptron (MLP) has a dimension of 2560 and GELU (Hendrycks and Gimpel, 2023) activations. The parameters of the embeddings matrix and the final dense layer are shared. We use relative positional embeddings (Shaw et al., 2018). The resulting model has approximately 65 million parameters.

4.4 Training details

Models were trained using a causal language modeling objective. Each batch has 512 sequences of 1024 tokens. We use the AdamW optimizer with an initial learning rate of 2e-4, which decayed to 2e-5 through cosine decay following Hoffmann et al. (2022). Finetuning employed a constant learning rate of 2e-5 over 10 epochs, except for the 6 billion dataset size where we limited it to 3 epochs.

[3] See https://huggingface.co/datasets/mc4 for more details.

This adjustment was based on preliminary experiments indicating that the model tends to overfit beyond this epoch count in larger datasets. The best model was selected based on the lowest perplexity achieved on the development set. Warmup steps varied with finetuning dataset sizes (ranging from 0 for smaller datasets to 3000 for larger ones), aligning with findings that smaller datasets completed finetuning before warmup completion (Hernandez et al., 2021). We utilized the T5X framework (Roberts et al., 2022) for our experiments. We used a total of 600 hours of a TPU v2-8 (seven hours of pretraining per model, and fifteen hours for the largest finetuning).

5 Results

Results are compiled in Table 2, where we exclusively report instances involving different source and target languages.

Given our methodology, where we vary the source language while keeping the target language constant to assess the impact of pretraining language in cross-lingual scenarios, it is essential to read the table vertically unless stated otherwise. Each row represents the results obtained by finetuning the model from a specific source language to a given target language (indicated in the column). This vertical arrangement facilitates the comparison of model performance across different source languages for the same target language. Furthermore, test sets vary significantly for each language due to the nature of the mC4 dataset. Consequently, results across target languages are not comparable.

Throughout this section, we highlight findings from models finetuned on 6 million tokens (i.e., $\mathbf{D_F} = \{6\text{MB}\}$) unless otherwise specified.[4] This extreme scenario tests models with minimal target language resources.

5.1 Performance with different initializations

We delve into the results of three target languages: Spanish, Arabic, and Japanese. The perplexity scores across all dataset sizes for these languages are highlighted in Figure 2, offering a chance for in-depth analysis despite the constraints of space.

A key observation is the consistent proximity of perplexity values for all three source languages in every target language. For instance, while one might expect a significant advantage for Chinese as a source language when finetuned in Japanese, or for English when paired with Spanish, this is not the case. This suggests the model leverages source language representations even when it lacks significant similarity with the target language.

Taken together, our results indicate that the model can rely on representations beyond those capturing language structure. This observation supports the recent hypothesis that these representations encompass both language-specific and language-neutral components, strengthening the latter as an important aspect.

5.2 Data Transfer estimation for target languages

Analysis of the Data Transfer (D_T) metric in Table 2 reveals that values are consistently close across different source languages for a given target. Notable examples include **Arabic** (en: 101MB, ru: 99MB, zh: 90MB), **Japanese** (en: 47.5MB, ru: 47.8MB, zh: 69.48MB), and **Finnish** (en: 102.62MB, ru: 51.32MB, zh: 76.57MB).

A clear pattern emerges: one initialization stands out for most target languages, while the other two show similar D_T values. This pattern is visually represented in Figure 3, particularly evident for Finnish (fi), Indonesian (id), Japanese (ja), Korean (ko), and Chinese (zh). Additionally, closely clustered results are observed for Arabic (ar), German (de), Spanish (es), and Russian (ru).

With three diverse initializations, the fact that two consistently show similar D_T values, even when distant from the target language (e.g., Russian and Chinese for Finnish), suggests the models leverage language-agnostic representations. This observation aligns with the expected behavior, where D_T would be close to zero if language-specific knowledge were dominant.

English (en) demonstrates effective knowledge transfer to most target languages, potentially due to its widespread presence in corpora across languages. This hypothesis is explored further in Section 5.3. Additionally, Chinese (zh) appears to transfer effectively to Japanese (ja) and Korean (ko), likely due to their linguistic proximity.

We observe that Chinese (zh) tends to transfer effectively to Japanese (ja) and Korean (ko), both of which are considered closer languages. This, together with our other observations, indicates that, while not determinant, language-specific component also plays a role in cross-lingual transfer.

Finally, upon examination of Figure 4, we also

[4]This restriction applies only to the finetuned models. For the from-scratch ones, we need their perplexities on multiple target language dataset sizes to estimate D_T.

Source Lang.	Metric	ar	de	en	es	fi	id	ja	ko	ru	zh
Scratch init.	Perplexity	6.44	14.82	16.28	12.54	12.71	12.00	12.47	11.69	6.27	15.34
English	Perplexity	2.82	3.67	-	3.16	3.57	2.61	3.92	3.58	2.44	4.43
	D_T	**101.02**	**95.25**	-	**121.14**	**76.57**	**102.62**	47.50	48.74	**75.64**	**29.21**
Russian	Perplexity	2.83	3.98	3.66	3.47	3.80	2.84	3.89	3.58	-	4.52
	D_T	99.00	47.87	**174.63**	67.88	50.96	51.32	47.81	48.69	-	26.18
Chinese	Perplexity	2.88	4.26	3.89	3.75	3.98	2.98	3.46	3.48	2.72	-
	D_T	90.63	31.76	66.96	50.27	49.65	50.21	**69.48**	**49.88**	48.47	-

Table 2: Results for Perplexity and Data Transfer (in MB) for all target and source languages. All metrics are reported after finetuning the models in 6 million tokens of the target language.

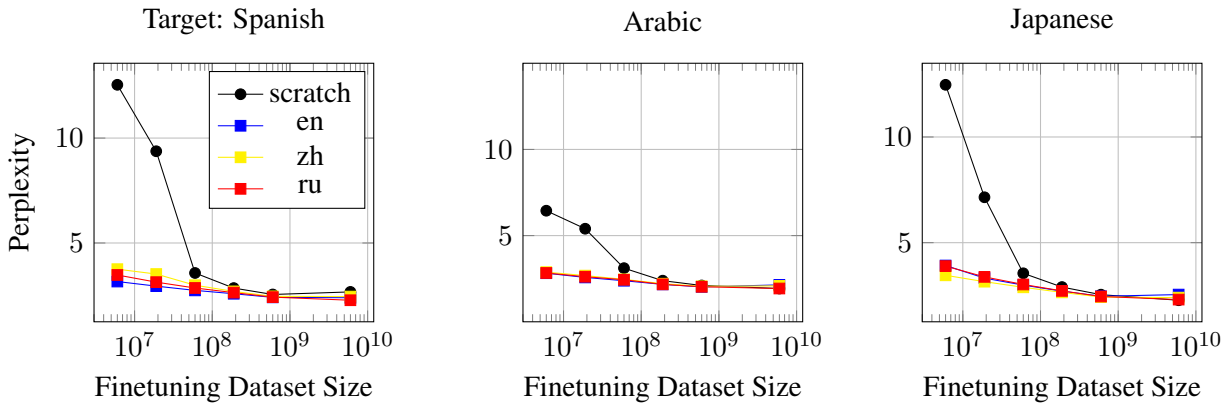

Figure 2: Results measured in Perplexity per token for three target languages. Each series represents a different initialization: train from scratch, finetune from an English, Chinese, or Russian model.

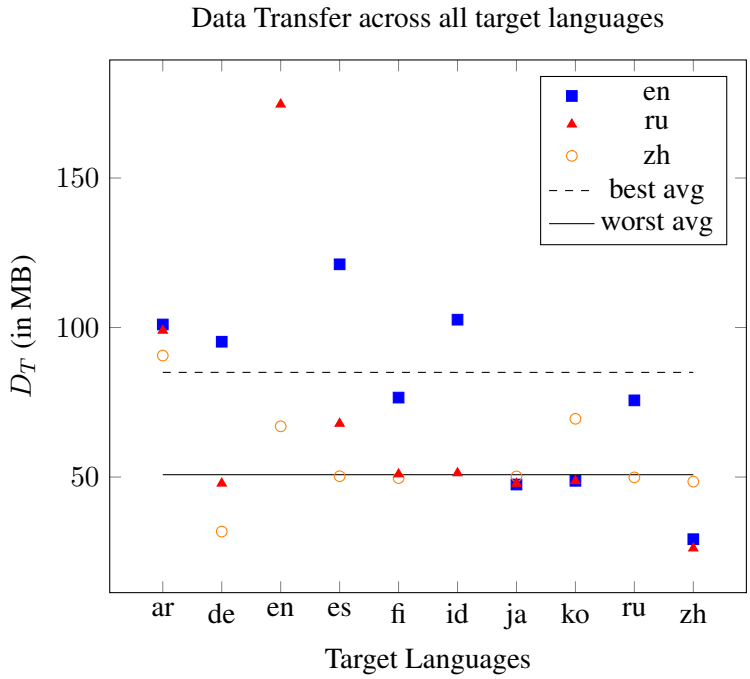

Figure 3: Dispersion chart for Data Transfer (D_T) across target languages. Each series corresponds to a distinct source language. The first dashed line (top-to-bottom) indicates the average of the best results (higher transfer), while the second one represents the average of the worst results (lower transfer).

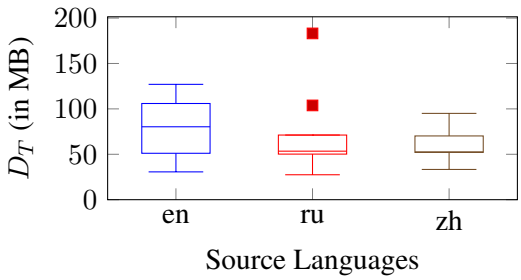

Figure 4: Boxplot with Data Transfer results for the 6 million tokens datasets in all target languages.

observe that most D_T values are clustered between 50MB and 100MB, with low variation within a source language across all target languages. While not ideal, this comparison across target languages indicates that the transfer from our source models is relatively consistent, not spanning more than one order of magnitude.

5.3 Language Contamination Impact

Table 3 summarizes the results of assessing the language contamination effect in our experiments.

Correlation	ρ	*p-value*
$\mathbf{D_T}$ and contamination on source	0.191	0.0157
$\mathbf{D_T}$ and contamination on target	0.265	0.0021

Table 3: Spearman Correlation (ρ) and p-value assessing the correlation of $\mathbf{D_T}$ with both the ratio of a target language in the source dataset (contamination on source) and with source language in the target dataset (contamination on target).

The analysis excludes the 6 billion tokens finetuning dataset size to mitigate the ossification effect, as observed in Hernandez et al. (2021). This effect leads to a performance drop for pretrained models with larger finetuning datasets, worsening perplexity compared to scratch-trained models. Excluding this data point helps avoid introducing noise and adverse effects on coefficient calculation, given its singular occurrence per source-target language pair. Additionally, due to the sample size (< 500 observations), the permutation test is utilized to calculate the *p-value*.

Although a correlation of 0.191 exists between D_T and contamination on the source dataset, this coefficient indicates a weak association, suggesting a minimal impact on cross-lingual performance, contradicting the findings by Blevins and Zettlemoyer (2022).

Exploration of language contamination in target datasets reveals a higher correlation of 0.265, particularly influenced by widespread languages like English. However, this coefficient still signifies a weak association between D_T and target contamination, thus not supporting the language contamination hypothesis.

5.4 Language Similarity and Data Transfer

This subsection outlines our analysis of the correlation between language distances and the data transfer metric (D_T), summarized in Table 4.

Measure to correlate with D_T	ρ	*p-value*
Syntactic distance	-0.147	> 0.7
Geographic distance	-0.110	
Phonological distance	-0.117	
Genetic distance	-0.150	
Inventory distance	-0.090	
Featural distance	-0.145	

Table 4: Spearman Correlation (ρ) and p-value assessing the correlation of $\mathbf{D_T}$ with a diverse set of language distance measurements.

We find a weak correlation between source-target language distances and Data Transfer. Since we are considering multiple language characteristics, such as syntax and phonology, the results suggest that language similarity has a minor role in knowledge transfer between distinct languages. Nonetheless, the small number of source languages necessitates a cautious interpretation of these results, especially since all obtained p-values exceed 0.7, indicating limited statistical significance.

Because of that, we conducted a controlled experiment, pretraining a language model in Portuguese and evaluating its performance on the Spanish target language — a language known for its similarity to Portuguese. Results, depicted in Table 5, were compared across various initializations, including more distant languages like Chinese.

	Spanish	
Source Lang.	D_T	Perplexity
Portuguese	**164.47**	**2.91**
English	121.14	3.16
Russian	67.88	3.47
Chinese	50.27	3.75

Table 5: Results for Data Transfer (in MB) and Perplexity in Spanish, highlighting Portuguese as a source language. All metrics are reported after finetuning the models in 6 million tokens of the target language. English, Russian, and Chinese results are the same as Table 2, added to facilitate comparison.

When initialized with Portuguese, the model achieves a lower Perplexity in Spanish compared

to when initialized with other languages. Additionally, D_T peaks among all initializations, suggesting the influence of language proximity between Portuguese and Spanish. English initialization also yields comparable results, with a D_T difference of around 40 MB and a perplexity variation of 0.25. Chinese and Russian show the lowest, yet similar, scores.

One possible interpretation is that the language-agnostic component accounts for 50% of the transfer, with Russian and Chinese being more distant from Spanish, while the language-specific component contributes the remaining 50%, considering closer linguistic and script systems. However, further investigation with more language pairs is necessary to determine the actual factors influencing transfer performance, including linguistic structure, script, or shared cultural knowledge in pretraining datasets.

5.5 Commutative property exploration

Pair (L_1, L_2)	$L_1 \rightarrow L_2$	$L_2 \rightarrow L_1$	Δ
en, ru	75.64	174.63	98.99
en, zh	29.21	66.96	37.75
ru, zh	26.18	48.47	22.29

Table 6: Analysis of the Commutative Property in terms of Data Transfer D_T. We analyze pairs of languages (L_1, L_2), reporting the observed D_T from L_1 to L_2 and vice-versa. Values are reported in megabytes.

We examine the commutative property of data transfer between English (en), Russian (ru), and Chinese (zh) in our cross-lingual experiments (Table 6). Notably, the data transfer amounts exhibit non-commutative behavior, revealing variations in knowledge transfer efficiency across bidirectional language pairs.

In the English-to-Russian transfer (en, ru), data transfer is more efficient when directed from Russian to English (174.63) compared to the reverse direction (75.64), indicating an asymmetry in knowledge transfer. Similarly, in the English-to-Chinese transfer (en, zh), data transfer is more substantial from English to Chinese (66.96) than in the reverse direction (29.21).

The Russian to Chinese transfer (ru, zh) also demonstrates a non-commutative pattern, with higher data transfer from Russian to Chinese (48.47) than in the reverse direction (26.18).

The variance in mC4 subsets for each language introduces significant differences in both pretraining and evaluation datasets, potentially contributing to the absence of a commutative behavior. A more in-depth analysis would necessitate repeating experiments with equivalent datasets.

6 Discussion

Our study aims to measure how much knowledge, in bytes, is transferred from one language to another, enabling the investigation of the effectiveness of language-agnostic representations acquired during pretraining in cross-lingual scenarios. We hypothesize that these representations enable models to perform well on downstream tasks across diverse languages, which is observed in state-of-the-art multilingual models.

In our results, we consistently find that at least two source languages demonstrate very close D_T values when evaluated against a target language, despite the diverse set of script systems and linguistic characteristics involved. This observation suggests that the data transferred from these languages to the target language is not primarily related to language-specific components but rather to language-agnostic ones. For instance, as illustrated in Figure 3, both English and Russian, despite being known as distant languages, achieve nearly identical D_T values when evaluated on Korean, a language distinct from either. Moreover, all three source languages are remarkably close when evaluated on the Japanese test set.

Despite exposure to only a few tokens in the target language, our models demonstrate similar perplexity performance, indicating high adaptability and generalization across a broad range of languages. This reinforces the notion that the language-agnostic component plays a crucial, uniform role across source languages.

Notably, our results are not attributed to pretraining exposure to target languages, since there is a weak correlation of language contamination with the data transfer coefficient. Additionally, the observed performance is not solely dependent on language proximity, as suggested in other works.

While perplexity offers valuable insights, generalizable conclusions require evaluation in downstream tasks, especially in under-resourced languages. To explore this further, we conducted a small-scale experiment, detailed in Appendix A, finetuning our pretrained models for a low-resource language inference task. Surprisingly, we observe comparable accuracy scores between Portuguese and Russian, with good results also for English

and Chinese, suggesting that our initial findings with perplexity may extend broadly. However, a more detailed investigation is required to understand cross-lingual transfer mechanisms fully.

The novelty of our approach is employing a byte-level tokenizer and adapting Hernandez et al. (2021) for a cross-lingual scenario. The byte-level approach facilitates consistent model embeddings across diverse scripts, enabling effective cross-lingual knowledge transfer without language-specific tokenization or preprocessing. This is supported by the strong performance of ByT5 compared to mT5 in Xue et al. (2022).

In conclusion, our study suggests the presence of language-agnostic representations contributing to cross-lingual transferability, while also laying the foundation to measure it through the Data Transfer metric. The observed consistency in model performance across diverse languages, facilitated by the byte-level tokenizer, indicates the potential for more efficient and generalizable natural language understanding across linguistic boundaries in computational linguistics and NLP.

7 Limitations

Our study has certain limitations that merit consideration. Firstly, our choice of initializing models with only three languages, while diverse, leaves room for improvement. Including additional languages in the pretraining phase would enhance the robustness of our analysis by minimizing possible bias towards the selected languages while providing more samples for our correlation analysis. However, this expansion would necessitate a more substantial computational budget.

Secondly, our reliance on small models, specifically a 65 million parameter model, limits the scope of our findings as larger models may exhibit different behavior. Additionally, the capacity of very large models for few-shot learning opens avenues for further exploration in the domain of transfer learning.

Lastly, the heterogeneity of the mC4 dataset across languages introduces a potential source of variability in the models' exposure to different knowledge. While the impact of this variation on data transfer remains unclear, conducting experiments with controlled datasets would offer valuable insights. Moreover, employing a more comparable test set could help mitigate statistical variance, particularly in analyses such as the commutative property assessment.

8 Conclusion and Future Work

Our study delves into the transferability of knowledge in cross-lingual scenarios, leveraging a byte-level tokenizer and an adapted methodology inspired by Hernandez et al. (2021). By measuring the models' reliance on pretraining when executing tasks in diverse languages, our approach offers an understanding of the cross-lingual capabilities of language models. The results provide evidence that language-agnostic representations also play an important role in downstream tasks. This not only contributes to the current understanding of cross-lingual transferability but also serves as a catalyst for further exploration into the properties of language-agnostic knowledge transfer. For future research directions, we envision key investigations that can build upon the insights presented in this paper:

1. **Expand Experiment Range:** Use more source languages so we can draw stronger conclusions.

2. **Controlled Datasets Usage:** Employ controlled datasets and comparable test sets to address mC4 dataset heterogeneity, offering clearer insights into varied knowledge exposure impact on cross-lingual transferability and mitigating variance.

3. **Explore Larger Models:** Investigate the use of larger models in few-shot learning downstream tasks as complementary evaluations to perplexity measurements.

4. **Measure D_T from Non-natural languages:** Perform experiments with non-natural language data, such as artificial languages with hierarchical structures. This exploration could shed light on whether knowledge transfer primarily occurs due to the content of pretraining or is largely influenced by the linguistic form.

A Appendix: Downstream Task Experiment

To further explore the generalizability of our findings beyond casual language modeling with the perplexity metric, we conducted an additional experiment focusing on a distinct downstream task. This experiment involved finetuning our models pretrained on the selected source languages for a specific downstream task, targeting a different language.

A.1 Experiment Details

For this experiment, we selected Portuguese as the target language and the Recognizing Textual Entailment (RTE) task from the ASSIN2 (Real et al., 2020)[5] dataset. The dataset comprised 6,500 training examples and 500 validation instances.

We finetuned the source models for 10 epochs using a constant learning rate of $5e-5$ and a batch size of 128. The objective of the task was to predict whether one sentence entails another, with evaluation based on accuracy measured on the validation set.

A.2 Results

Our results, summarized in Table 7, reveal comparable performance between Portuguese (our baseline) and Russian, despite being considered a distant language. English lags by nearly 6 percentage points compared to our baseline, while Chinese exhibits the poorest performance, trailing our baseline by almost 20 percentage points.

Despite the limited scope of our experiment, focusing on only one target language and task, these findings suggest significant knowledge transfer across languages with varying degrees of similarity. For example, even with the lowest performance observed in Chinese, it still outperforms a

[5]https://sites.google.com/view/assin2/

Source Language	Accuracy (%)
Portuguese (baseline)	85.0
Russian	82.0
English	78.6
Chinese	65.6

Table 7: Results from finetuning our source models on the ASSIN2 Recognizing Text Entailment task. We report the accuracy obtained in our validation set.

random classifier by 15 percentage points (ASSIN2 contains two distinct classes).

Based on our findings, cross-lingual knowledge transfer appears to occur even with more distant languages. These results underscore the importance of further exploration in this area, indicating a promising potential for measuring knowledge transfer in cross-lingual scenarios and delineating the contributions of language-agnostic and language-specific components in the models' representations.

MISGENDERMENDER: A Community-Informed Approach to Interventions for Misgendering

Abstract

Content Warning: This paper contains examples of misgendering and erasure that could be offensive and potentially triggering.

Misgendering, the act of incorrectly addressing someone's gender, inflicts serious harm and is pervasive in everyday technologies, yet there is a notable lack of research to combat it. We are the first to address this lack of research into interventions for misgendering by conducting a survey of gender-diverse individuals in the US to understand perspectives about automated interventions for text-based misgendering. Based on survey insights on the prevalence of misgendering, desired solutions, and associated concerns, we introduce a misgendering interventions task and evaluation dataset, MISGENDERMENDER. We define the task with two sub-tasks: (i) detecting misgendering, followed by (ii) correcting misgendering where misgendering is present in domains where editing is appropriate. MISGENDERMENDER comprises 3790 instances of social media content and LLM-generations about non-cisgender public figures, annotated for the presence of misgendering, with additional annotations for correcting misgendering in LLM-generated text. Using this dataset, we set initial benchmarks by evaluating existing NLP systems and highlighting challenges for future models to address. We release the full dataset, code, and demo at https://tamannahossainkay.github.io/misgendermender/.

1 Introduction

Misgendering is the act of referring to someone using a word, e.g. a pronoun or title, that does not correctly reflect the gender with which they identify (Dictionary, 2023). While there is growing awareness about the adverse impacts of misgendering on peoples' lives (Dev et al., 2021), there is insufficient scholarship or resources that identify and attempt to mitigate misgendering in these various daily use platforms and technologies.

Linguistic Gender Profile	
Name:	Elliot Page
Gender identity:	Trans man, Non-binary
Pronouns:	he/him/his/his/himself, they/them/their/theirs/themselves
Gendered Terms:	masculine, neutral
Deadname:	Ellen Grace Philpotts-Page

Annotated Content

Detect-Only
X Post: John Wayne was a man and Elliot Page is a woman. . .
Detect Label: `Misgendering`

X Post: ..."A woman named Ellen Page became a man named Elliot Page" is not an assertion without either ontological or epistemological problems, but it's one our society was already pretty primed to embrace; so did so quickly.
Detect Label: `No Misgendering`

Detect+Correct
LLM-generation: Ellen Grace credits her mother with her success, and she is eternally grateful for her love and support.
Detect Label: `Misgendering`
Corrected: ~~Ellen~~ →Elliot credits ~~her~~ →his mother with ~~her~~ →his success, and ~~she~~ →he is eternally grateful for her love and support.

Figure 1: MISGENDERMENDER examples consisting of a gender linguistic profile and corresponding annotated content for detecting and correcting misgendering.

Efforts to measure and mitigate gender bias in natural language processing primarily focus on cisgender and binary gender categories (Guo et al., 2022; Choubey et al., 2021). Few efforts to address non-traditional gender categories have evaluated LLMs' abilities to use non-binary pronouns (Hossain et al., 2023), coreference resolution using neo-pronouns (Cao and Daumé III, 2020), and representational biases in word embeddings (Dev et al., 2021). Furthermore, even though misgendering is both a factual inaccuracy and a toxic act of identity erasure, research on factuality and toxicity has largely ignored it (Gao and Emami, 2023; Lees et al., 2022).

Proceedings of the 2024 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies (Volume 1: Long Papers), pages 7538–7558
June 16-21, 2024 ©2024 Association for Computational Linguistics

Our contribution is two-fold: (i) we conduct a community survey to understand opinions about automated interventions for text-based misgendering, and (ii) based on the survey, we define a task and evaluation dataset for addressing misgendering in text-based content. Our survey of gender-diverse[1] individuals revealed a prevalent issue of misgendering, especially on social media, but also in other areas like AI-generated content, news articles, and academic journals (§ 2). While there was a general preference for automatic detection of misgendering across domains, opinions diverged on measures such as correcting or hiding misgendered content (§ 2.1). Participants were more receptive to the idea of auto-correction in AI-generated content than social media, citing concerns over limiting freedom of speech and creating a false sense of allyship. Importantly, there were significant apprehensions regarding the implementation of any automated systems to address misgendering, encompassing issues like the fundamental infeasibility of these systems, privacy, the risk of profiling or targeting based on gender linguistic preferences databases, and doubts about the current capabilities of NLP systems to perform interventions accurately (§ 2.2).

Based on the opinions and concerns expressed by participants in our survey, we defined a task for misgendering interventions and constructed a corresponding evaluation dataset, MISGENDERMENDER (§ 3). We define the interventions for misgendering task as two sub-tasks: (i) detecting misgendering, followed by (ii) correcting misgendering where misgendering is present, in domains where editing is appropriate (§ 3.1). Social media (X and YouTube) were picked as a Detect-Only domain and LLM-generations as a Detect+Correct domain. Text from each of these sources was collected regarding 30 non-cisgender public figures whose gender identities and gender terminology preferences are publicly available (§ 3.2). A total of 3790 instances are human annotated for the misgendering interventions task (§ 3.3). See Figure 1 for examples from MISGENDERMENDER dataset.

We evaluated current NLP systems using MISGENDERMENDER, setting initial benchmarks and pinpointing areas for future work. For the detection sub-task, we prompted language models using similar instructions to those given to human annotators, including providing the gender linguistic profile of the relevant individual. We also used toxicity detection and rule-based baselines (§ 3.4). GPT-4 achieved the highest F1-score across domains, but there is still much room for improvement (*X posts*: 62.6, *YouTube Comments*: 85.3, *LLM-generations*: 55.9). There were errors associated with coreference resolution, understanding questions, temporal relationships, quotations, and authorship recognition. For the second sub-task of correcting misgendering, we used a rule-based editor and prompting of GPT-4 (§ 3.5). Human evaluation of edits showed GPT-4 corrected misgendering in 97% of edits while making unnecessary edits in only 4.6% of cases. While this is promising, further work is still needed since these edits were largely single-sentence and context-free. To facilitate this, we release the full dataset, code, and demo of our work at https://tamannahossainkay.github.io/misgendermender/.

2 Survey on Interventions for Misgendering

Automated systems to prevent misgendering lack existing research. In order to define a task and develop an evaluation dataset rooted in community perspectives, we first survey gender-diverse individuals on their views regarding automated interventions for misgendering.

Methodology The survey is anonymous and is conducted using Google Forms. We do not collect any data which could personally identify respondents. We reached out to participants through Queer in AI, International Society of Non-binary Scientists (ISBNS), and social media. All participants were adults (18 years or older) living in the US, who either identified as non-cisgender or had changed their gender terminology at some point in their lives. The survey consists of four sections, which solicit participants' demographic data, experiences with misgendering, preferences for misgendering interventions, concerns regarding automated intervention systems, and miscellaneous feedback. See Appendix A for details.

Participants We have a total of 33 respondents to our survey [2]. Further information on participants can be found in Appendix A.

[1] Individuals who self-identify as non-cisgender or have changed their gender terminology at some point in their lives

[2] While this is not a large sample, it is similar to other recent work which surveys non-cisgender or non-binary people: 19 in Dev et al. (2021) and 35 in Ungless et al. (2023)

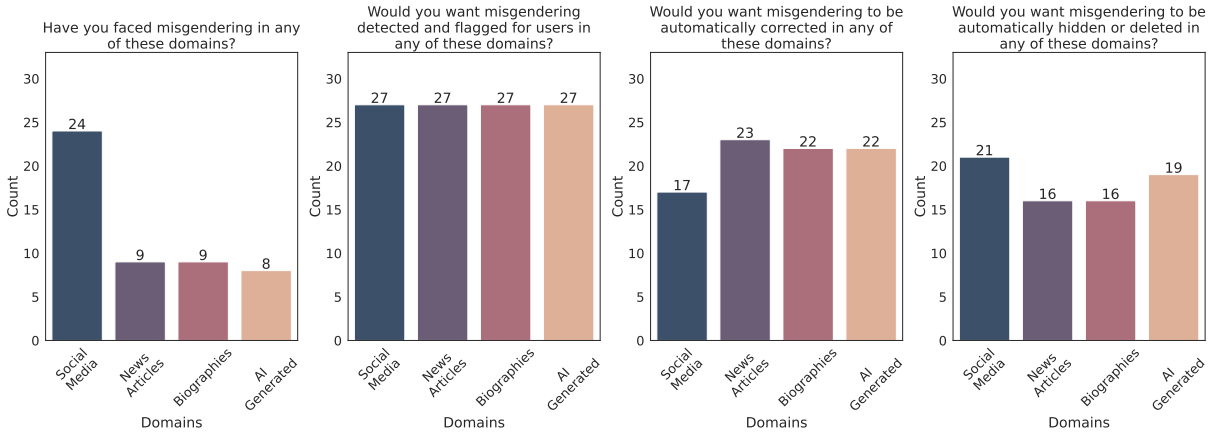

Figure 2: **Survey responses** Count of participants (out of 33) reporting experiences with misgendering and expressing a desire for detection, correction, or hiding of misgendering across various domains.

Misgendering experiences Most survey respondents faced misgendering on social media platforms, and about a fourth faced misgendering in news articles, biographies, and AI-generated content (Figure 2). There were also some write-in domains where participants faced misgendering, such as journal publications, academic presentations, and website profiles.

2.1 Desired Interventions for Misgendering

We present responses for questions on particular interventions (detect, edit, or hide misgendering content) and open-ended feedback on preferred features from automated intervention systems.

Detect, edit, or hide The desire for detection of misgendering was high across all domains, with more than three-fourths of the participants wanting misgendering to be automatically detected (Figure 2). As for interventions, participants had varied preferences. However, participants had more varied preferences for automatic correction of misgendering. While about two-thirds of the participants wanted misgendering to be automatically corrected in news articles, AI-generated content, and biographies, only half were interested in the auto-correction of misgendering in social media. Slightly more participants favored hiding or deleting social media content containing misgendering. Write-in comments shed light on some nuances to consider for what interventions are appropriate in a given situation:

- *Only detect*: Some participants noted that they would only be interested in the automatic detection of misgendering, and would not want the content to be corrected or hidden so they could interpret it themselves.
- *Intent based*: Some participants noted that they would want intentional misgendering to make a political point to be hidden but otherwise misgendering content to be corrected.
- *Source based*: Some participants expressed that they would only like official content to be auto-corrected, such as journals, articles, biographies, etc. Others suggested only AI-generated content should be auto-corrected, and it could violate the American First Amendment right to free speech to edit user-generated content (e.g. social media posts).

Several themes emerge from free-form feedback on desired features for automated interventions:

Flexible & user friendly Any system designed to record individual gender terminology preferences must be customizable (e.g. allow for neo-pronouns) and flexible to modify preferences at any time. Any misgendering intervention system should operate strictly based on current gender terminology preferences that users have consented to be used for interventions after thorough user education. It should also be user-friendly, e.g. grammar-correction tools or writing assistants that actively detect and suggest corrections for misgendering during typing.

Conext-sensitivity. Systems should be sensitive to context in a few different ways: allowing for different gender terminology in different settings (e.g., neo-pronouns in LGBTQ+ spaces and *they/them* pronouns in non-LGBTQ+ spaces), enabling users to specify different interventions in different domains (e.g. correct misgendering in academic citations but not in job search materials), differentiate

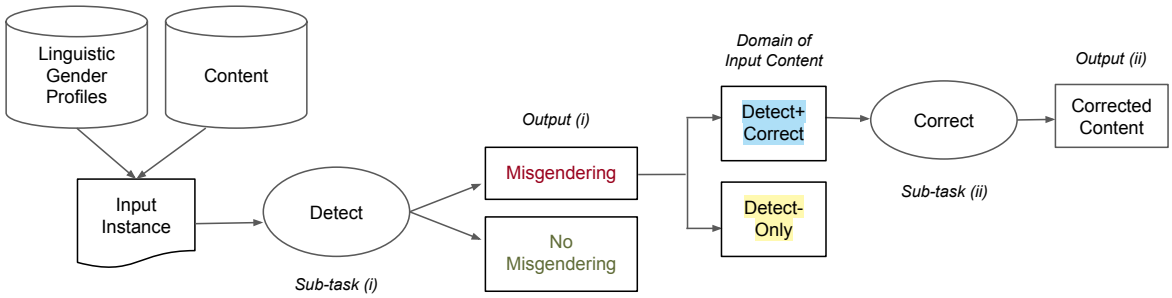

Figure 3: **Problem Setup** The misgendering interventions task can be divided into two sub-tasks: (i) detecting misgendering, followed by (ii) correcting misgendering, in domains where editing is appropriate.

between malicious misgendering and unintentional mistakes, and discerning when gender is relevant and when it is not.

LLM fairness & transparency. Language models should have output validation to filter out or correct instances of misgendering. They could use proper nouns or default to gender-neutral pronouns such as *they/them* when necessary. Reducing the correlation between names, pronouns, professions, personality traits, and physical characteristics in generated content is vital. The integration of neopronouns and gender-diverse language during the training phase is equally important. Additionally, there should be transparency about LLM failures and errors regarding misgendering and bias.

2.2 Concerns about Automated Interventions

There were concerns about the feasibility, limitations, and risks of automated interventions:

Fundamental infeasibility. A key concern was that the fluid, flexible, and nuanced nature of individual gender linguistic preferences could not be operationalized. Any attempt to do so will enforce a static and rigid view of gender in some form. Simply intervening on text through these systems also would not tackle the root problem of people misgendering others.

NLP Limitations. A major concern was that NLP systems are not sophisticated enough to grasp the intricacies of language (e.g. quotations or slang) required for accurate interventions. Language models are also biased towards a binary view of gender, stemming from the predominance of binary-gendered language in their training data. Addressing this issue is complex; simply removing or altering the binary gendered language in the training corpora is impractical and could compromise their ability to reflect linguistic changes over time.

Censorship and Security. There is a risk that these systems may unintentionally censor content related to gender-diverse individuals due to errors or overzealous interventions. There are also several security concerns: these systems could be exploited to target and profile individuals with marginalized and vulnerable gender identities; there could be breaches of privacy, e.g. unintentional *outing* of gender identities; and correcting misgendering might create a mistaken perception of safety and allyship about people who misgender intentionally.

2.3 Survey Based Dataset Design

We design our evaluation dataset using insights from the community survey above. Survey respondents expressed concerns about the potential dangers of automated systems addressing misgendering, such as privacy violations, unintentional disclosure of someone's undisclosed gender identity, or misuse against at-risk groups. To minimize risks, we exclusively work with data about public figures who have openly declared their gender identity and gendered terminology preferences. In any future development of user-oriented intervention systems, such as social media platforms, it is crucial to ensure user autonomy and security. Key measures include strict adherence to user preferences, secure handling of gender-related information, flexible options for users to opt-in and opt out, and thorough user education about the systems and associated risks, ensuring informed consent at each stage.

We selected social media and LLM-generations as two domains for our datasets. We selected social media for several reasons: (i) majority of survey participants experienced misgendering here, (ii) many respondents showed interest in misgendering detection in this context, (iii) since our focus is on public figures, social media is expected to have relevant posts about them, and (iv) social media

platforms offer publicly accessible APIs. Additionally, we chose LLM-generations as a domain in our dataset because it was a popular domain for both detecting and correcting misgendering, and we can construct instances to challenge the language understanding abilities of NLP systems, thus addressing concerns about their handling of linguistic nuances that were brought up in the survey.

Further, we implement a source-based separation of interventions, differentiating between Detect-Only and Detect+Correct domains. Social media content is categorized as a Detect-Only domain, aligning with the survey concerns regarding free speech, potential censorship of non-cisgender content, risks of mistaken allyship, and preserving the right to interpret, even potentially offensive, content. In contrast, LLM-generated content is designated as a Detect+Correct domain, aligned with the interests of survey participants.

3 MISGENDERMENDER Dataset

3.1 Problem Setup

We assume access to gender profiles on individuals, $P = p_1, ..., p_{|P|}$, consisting of their name, gender identity, gender terminology preferences, and deadname, if any. The misgendering interventions task can be divided into two sub-tasks: (i) detecting misgendering, followed by (ii) editing misgendering where misgendering is present, in domains where editing is appropriate. Given a collection of textual content, $C = c_1, ..., c_{|C|}$, about an individual, the first sub-task is to detect, for each input c, whether it contains misgendering towards them given their profile p. If so, and if c is from a domain that is appropriate to edit, we continue to the task of editing c to correct the misgendering. Figure 3 presents an overview of the problem setup.

3.2 Data Collection

We compile a list of notable non-cisgender individuals, including their publicly available gender information. We also gather human-written content about them from X and YouTube, as well as text generated by LLMs.

Individuals & Gender Profiles Using the Wikidata Query Service, we extracted the names of individuals identified as 'non-binary', 'trans man', and 'trans woman'. We ranked them based on the number of *sitelinks*, which indicate how many Wikipedia pages link to the page about the given individual. We focused on the top 10 most popular individuals in each gender category. For each of these individuals, we used WikiData to gather additional metadata, such as their pronouns and names given at birth. If an individual's pronouns are missing on WikiData, the pronouns from their Wikipedia biography are used instead. If a person's name and birth name are different, their birth name is used as their *deadname*[3]. We inferred appropriate gendered term categories for each individual using their preferred pronouns, utilizing *feminine* terms for those who use *she*, *masculine* terms for *he*, and *neutral* terms for *they*.

X (formerly Twitter) Posts We also collected posts from X (formerly Twitter) about each individual using the Twitter API. If a person's profile consists of a deadname, then we retrieve 50 posts querying for their name and 50 querying for their deadname. Otherwise, we retrieve 100 posts using their name. User handles in the text were substituted with `[USERNAME]` for anonymization, except for those of the relevant public figures.

YouTube Comments We queried the public YouTube Data API using the names and birth names of each individual. If a person's deadname is available, we queried for 3 videos using their name and 3 videos using their deadname. Otherwise, we retrieved 6 videos using their name only. For each video, we collected 20 comments. We also retrieved metadata for both videos and comments.

LLM-Generations We used GPT-4 (OpenAI, 2023), PaLM (Chowdhery et al., 2022), and Vicuna (Platzer and Puschner, 2021) to generate short biographies and sentences about the same group of individuals. We constructed prompts to generate instances that would challenge the language understanding of NLP systems (Ribeiro et al., 2020) (see Appendix B for all prompts). We split biographies into sentences and annotated per sentence.

3.3 Annotation

Content from all sources is annotated to identify the presence of misgendering. We provided Amazon Mechanical Turk (`https://www.mturk.com/`) workers with information about each individual (name, gender identities, preferred pronouns, and deadname) along with retrieved texts about them. Annotators are asked to label each text instance

[3] the name that a transgender person was given at birth and no longer uses upon transitioning (Merriam-Webster, 2023)

Tweet: @USERNAME shes a stalker check out her replies. every ezra miller thread she is there w seething lies who is it? clue [LINK]
Incorrect Annotation: `Misgendering`

Table 1: **Coreference Resolution Error.** Example of an incorrectly annotated tweet about Ezra Miller who uses neutral-gendered words. While the tweet contains feminine pronouns, they are not used to refer to Miller.

Domain	`Misgendering`	`No Misgendering`	Total
X-Posts	81 (6.8%)	1118 (93.2%)	1199
YouTube Comments	352 (22.0%)	1217 (78.0%)	1559
LLM Generations	263 (25.5%)	769 (74.5%)	1032
Grand Total			3790

Table 2: MISGENDERMENDER **Counts**. Distribution of annotation labels by domain.

(YouTube comment, tweet, or generated biography) for whether it contains misgendering towards the query individual (`Misgendering`), refers to them without misgendering (`No Misgendering`), or the text is not about the individual (`Irrelevant`) (Appendix D.3). LLM generated text that contains misgendering is also corrected by annotators.

Each instance in our evaluation dataset was annotated by three MTurk workers. Workers had to pass a qualification test for each sub-task. The inter-annotator agreement percentage for detecting misgendering is 87.4%. Conventional agreement scores are unsuitable for correcting misgendering due to the variety of possible valid solutions. We also did not use human-written edits as gold labels for evaluating baseline models.

We discard instances annotated as `Irrelevant`. The MISGENDERMENDER dataset consists of 3790 textual content labeled as `Misgendering` or `No Misgendering` towards a paired individual. LLM-Generations consisting of `Misgendering` also consist of human written corrections. See Table 2 for a breakdown of the dataset by domain and label.

Challenges The first round of annotation instructions, examples, and qualification tests were based on a pilot study (Appendix H). However, we noticed annotation errors due to mistaken pronoun coreference resolution (Table 1) and updated annotation materials to address this issue. Annotations using initial guidelines and tests were discarded.

3.4 Detect Misgendering

We evaluate several existing NLP tools for detecting misgendering in both Detect-Only and Detect+Correct domains.

Prompting We prompt GPT-4 (OpenAI, 2023), PaLM (Chowdhery et al., 2022), Llama-2-Chat 70B (Touvron et al., 2023), Gemma-7B-IT (Team et al., 2024) and Mixtral-8x7B-Instruct (Jiang et al., 2024) with instructions for detecting misgendering with instructions and 5-shot chain-of-thought (Wei et al., 2022) examples (Appendix E.1). For each instance, the person's gender linguistic profile is provided in the prompt as a reference for detecting misgendering, similar to providing evidence sets to verify a claim in fact-checking (Gao et al., 2023). Examples are based on instances of misgendering seen in a pilot study (see Appendix H).

Toxicity Detection We used the perspective API (Lees et al., 2022) for to get scores for toxicity detection and identity attacks. A threshold of 0.75 was chosen based on a pilot study (Appendix H) to classify any text with a score above the threshold as containing `Misgendering`.

Rule-based We use a table of pronouns (Hossain et al., 2023) and a table of gendered keywords created using a list of gendered words from Bolukbasi et al. (2016) (Appendix F). For the *naive* approach, if any deadname, gendered word, or pronoun that is inappropriate for a person given their gender linguistic profile (e.g. masculine terms for someone who only uses feminine terminology) is present in the text, then it is classified as containing `Misgendering`. For a *coreference* based approach, `fastcoref` (Otmazgin et al., 2022) is used to create coreference clusters, and if (i) the person's deadname is present in the text, or (ii) an inappropriate gendered word or pronoun is in the same coreference cluster as the person's name or deadname then the instance is predicted to contain `Misgendering`.

Results Across all three data sources we see the highest F1-score for GPT-4 (Table 3). While GPT-4 also had the highest precision for X posts and YouTube comments, rule-based methods had the highest recall across all sources. GPT-4 made errors based on mistaken coreference resolution, and inability to understand some linguistic nuances, such as quotations, questions, and temporal relationships (Table 4). The Perspective API could only positively identify cases of misgendering that

	LLM 5-shot CoT					Perspective		Rule-Based

were also paired with other forms of toxicity. Consequently, it could not identify any cases of misgendering in the polite and formal LLM-generated texts. While the coreference-based method provided the highest precision for LLM-generated misgendering detection, it often failed to create appropriate coreference clusters across data sources. See Table 4 for examples of errors from each method.

3.5 Edit Misgendering

We evaluate a few existing NLP tools on their ability to edit misgendering. Only instances from the Detect+Correct domain, LLM-generations, containing `Misgendering` are included here.

Prompting We prompt GPT-4 , PaLM, and Llama-2-Chat 70B with instructions for editing misgendering. For each instance, the individual's gender terminology preferences are provided as a reference, similar to work in non-factual text correction (Gao et al., 2023) (Appendix G.1).

Rule-based We create a table gendered words using a list from Bolukbasi et al. (2016) (Appendix F), and use a table of pronouns from Hossain et al. (2023). Given a person's gender linguistic profile, if a gendered term or pronoun that is inappropriate for them from these tables is identified in the text, then it is replaced with a corresponding word that matches their linguistic profile. If switching from a binary pronoun to a neutral one, then corresponding verbs are pluralized (APA, 2023) (Table 8).

Results The edited texts were evaluated using human annotators from Amazon Mechanical Turk. Annotators were asked to evaluate each edited sentence for (i) whether misgendering was corrected, and (ii) whether any unnecessary edits were made. Three annotators evaluated each instance with an agreement score of 96.3% for (i) and 89.9% for (ii). Due to annotation costs, we only evaluated systems that showed the best performance for detecting misgendering: GPT-4 and the rule-based baseline. GPT-4 edits corrected misgendering in 97% of edits, while making unnecessary edits in only 4.6% of cases. (Table 5). Unnecessary edits sometimes radically change the original text (Table 6). On the other hand, rule-based baseline corrected misgendering in 78.7% of the instances, while making unnecessary edits in 28.1% instances.

4 Related Work

Gender Bias Significant efforts have been made to address gender bias in language technologies, primarily focusing on a binary and cisgender perspective (Bolukbasi et al., 2016; Zhao et al., 2018; Kurita et al., 2019), with recent studies beginning to explore this issue with a non-binary and non-cisgender framework. Dev et al. (2021) discuss ways in which gender-exclusivity in NLP can harm non-binary individuals, and demonstrate bias in word embeddings. Hossain et al. (2023) show that LMs are limited in their ability to use non-binary pronouns, Ovalle et al. (2023) evaluate LMs for misgendering and harmful responses to gender disclose, Brandl et al. (2022) show neo-pronouns have high perplexity in LMs, Cao and Daumé III (2020) create specialized datasets for coreference resolutions with neo-pronouns, and Lauscher et al. (2022)

Error Type	Profile	Text, Label, and Prediction
GPT-4 CoT		
Coreference	**Name**: Ezra Miller **Gendered Terms**: Neutral	**Tweet:** @USERNAME Damn, if Ezra Miller wasn't a f*****g psychopath then he would make a decent Flash. **Label:** `Misgendering`; **Pred:** `No Misgendering` **GPT-4 Explanation:** The tweet refers to Ezra Miller but no masculine or feminine words are used to refer to them so there is no misgendering.
Quotation	**Name:** Elliot Page **Gendered Terms:** Feminine **Deadname:** Ellen Grace Philpotts-Page	**Tweet:** @USERNAME principle of law, or indeed science or nature. "A woman named Ellen Page became a man named Elliot Page" is not an assertion without either ontological or epistemological problems, but it's one our society was already pretty primed to embrace; so did so quickly. **Label:** `No Misgendering`; **Pred:** `Misgendering` **GPT-4 Explanation:** The tweet misgenders Elliot Page by calling him a "woman" which is a feminine gendered term, and thus incorrect as Elliot uses neutral and masculine gendered terms. Also, his old name 'Ellen' is used which is his deadname.
Question	**Name:** Buck Angel **Gendered Terms:** Feminine	**Tweet:** @USERNAME Do you think Buck Angel should go to the womens changing room? [LINK] **Label:** `No Misgendering`; **Pred:** `Misgendering` **GPT-4 Explanation:** The tweet misgenders Buck Angel by suggesting he should use the women's changing room, implying that he is a woman, this is contrary to Buck's masculine gender identity.
Temporal	**Name:** Lil Uzi Vert **Gendered Terms:** Neutral **Deadname:** Symere Bysil Wood	**LLM Generation:** While I used to think of Lil Uzi Vert as a conventional "he-man," I do not think so anymore. **Label:** `No Misgendering`; **Pred:** `Misgendering` **GPT-4 Explanation:** The sentence contains the masculine gendered term "he-man" to refer to Lil Uzi Vert...

Coreference	**Name:** Chaz Bono **Gendered Terms:** Masculine **Deadname:** Chastity Bono	**YouTube Comment:** Chaz is a lovely man with a deep understanding of woman's difficulties! **Label:** `No Misgendering`; **Pred:** `Misgendering`

Table 4: **Detect Errors**. We present examples of instances where benchmark models for detecting misgendering in the MISGENDERMENDER dataset fail at predicting the correct label.

Method	Misgendering Corrected	Unnecessary Edits
GPT-4	97.0	4.6
Rule-based	78.7	28.1

Table 5: Human evaluation of automated edits. Edits are evaluated for (i) whether misgendering was corrected, and (ii) whether any unnecessary edits were made.

provide desiderata for modeling pronouns in language technologies. Sun et al. (2021) show how models can be trained to rewrite binary pronouns as gender-neutral ones. While Lund et al. (2023) introduce a technique to generate singular *they* data and show that data augmentation can mitigate bias against singular *they* in Grammatical Error Correction (GEC) systems. However, none of these detect and edit misgendering towards given gendered terminology preferences in non-templated texts.

Toxicity Detection and Mitigation Supervised methods have been extensively used in toxicity detection (Lees et al., 2022; Kirk et al., 2022; Fortuna et al., 2022; Caselli et al., 2021; Poletto et al., 2020). Prompted language models have also been used for detecting toxicity in text (Chiu and Alexander, 2021; Schick et al., 2021; Goldzycher and Schneider, 2022). (Hallinan et al., 2022; Ma et al., 2020; Malmi et al., 2020) re-write detoxified text using unsupervised masking and reconstruction approaches. Dale et al. (2021); Nogueira dos San-

Profile	Text, Edits, Labels
Name: Elliot Page **Gendered Terms:** Feminine **Deadname:** Ellen Grace Philpotts-Page	**LLM Generation:** She was born in 1846 and spent most of her life as a missionary in China, where she dedicated herself to helping women and children. **GPT-4:** Elliot Page, a renowned Canadian actor and producer, cherishes the special bond they formed with their on-screen mother, Jennifer Garner, while filming the acclaimed movie "Juno". He was born in 1846 and spent most of his life as a missionary in China, where he dedicated himself to helping women and children. **Label**: `No Misgendering`; **Unnecessary Edits**: `Yes`
Name: Andreja Pejić **Gendered Terms:** Feminine **Deadname:** Andrej Pejic	**LLM Generation:** While some people might think of Andrej Pejic as a man, I do not agree with this. **GPT-4:** While some people might think of Andreja Pejić as a man, I do not agree with this. **Label:** `No Misgendering`; **Unnecessary Edits:** No **Rule-based:** While some people might think of Andreja Pejić as a woman, I do not agree with this. **Label:** `Misgendering`; **Unnecessary Edits:** No
Name: Andreas Krieger **Gendered Terms:** Masculine **Deadname:** Heidi Krieger	**LLM Generation:** This feminine figure is central to Krieger's art, as she seeks to challenge traditional gender norms and celebrate the unique qualities of women. **GPT-4 Edit** This masculine figure is central to Krieger's story, as he seeks to challenge traditional gender norms and celebrate his unique journey. **Label:** `No Misgendering`; **Unnecessary Edits:** Yes

Table 6: **Model Edit Examples.** We present examples of instances of LLM generations containing `Misgendering` that are edited by GPT-4 or a rule-based editor. Human annotated labels of the automated edits for whether (i) whether they still contain misgendering, and (ii) any unnecessary edits were made are also presented.

tos et al. (2018) use translation or paraphrasing to detoxify text. However, none of these works address misgendering as a form of toxicity.

Fact Checking and Correction Fact-checking is often framed as the task of identifying whether a claim is supported or refuted by the given evidence (Wadden et al., 2020; Augenstein et al., 2019; Thorne et al., 2018; Wang, 2017). Thre is also work on correcting text that is inconsistent with a set of evidence via post-hoc editing (Gao et al., 2023; Iv et al., 2022; Schick et al., 2022; Thorne and Vlachos, 2021). However, none of these address misgendering as a form of non-factual information that requires detection and correction.

5 Conclusion

In response to the lack of research on automated solutions for misgendering, we conducted a survey among gender-diverse individuals to gather their views on the matter, and based on their responses defined a misgendering interventions task and developed a corresponding evaluation dataset, MISGENDERMENDER. We provide initial benchmarks for detecting and editing misgendering on this dataset using current NLP systems. For detecting misgendering, few-shot chain-of-thought prompting of GPT-4 with similar instructions as provided to human annotators achieved the highest F1-score across all data sources (*X posts*: 62.6, *YouTube Comments*: 85.3, *LLM-generations*: 55.9), but were low enough to indicate significant room for improvement. Open-source models lagged much further behind with a highest F1-score of 51.9 and a lowest of a mere 9.3.

For the task of correcting misgendering, GPT-4 successfully fixed 97% of misgendering errors in language model-generated text, with only 4.6% of edits being unnecessary, as assessed by human annotators. However, further work is required as these edits were mainly limited to single, context-free sentences. For future work, we recommend engaging in wider collaboration with gender-diverse folks to build robust interventions in line with the needs and concerns of the communities most impacted by them. To facilitate further research, we release the full dataset, code, and demo of our work at `https://tamannahossainkay.github.io/misgendermender/`.

Limitations

The work in this paper is limited to a Western conception of gender and restricted to English only.

Survey This study, though comparable in scale to previous surveys targeting gender-diverse populations, lacks sufficient size for statistically significant findings. Our focus was on qualitative evaluation, capturing a range of perspectives within this group. However, its limitation to U.S. participants and small sample size impact its generalizability. To inform the development of effective intervention systems, future research should involve more expansive and comprehensive surveys of gender-diverse individuals.

Task and Dataset Our evaluation dataset, featuring publicly available data on public figures, is designed strictly for research purposes. It is essential to obtain explicit consent before using this information in any system, and future system development must include informed consent from all human subjects involved.

Our dataset includes prominent public figures who have publicly identified as non-binary, trans men, or trans women, representing only a limited segment of gender identities. Likewise, the preferred pronouns in the dataset are limited to *she, he* and *they*, with no neo-pronoun representation. The gender data reflects information available at the time of research and does not account for possible changes thereafter.

Additionally, the scope of our dataset was confined to social media platforms with accessible APIs and generations from a limited number of LLMs. It is important to note that this study does not encompass other text domains where misgendering occurs, such as news articles, biographies, and journals, which remain areas for future research. LLM generations also contain hallucinations other than misgendering that are not address in this work. Lastly, to benchmark detection and correction models we use content verified to pertain to a specific individual by human annotators. In practice, intervention systems would also need to evaluate automated retrieval methods.

Ethics Statement

Our research aims to address a particular type of misgendering harm by developing a framework that identifies and amends misgendering in specific settings. The work we have published is intended solely for research and should not be employed in the development of any production systems. Our community survey is anonymous to safeguard participant identities, and no efforts must be made to identify individual respondents. The evaluation dataset we present utilizes publicly accessible information about public figures, exclusively for research objectives. It is crucial that this information not be used in any systems without obtaining their explicit consent.

We strictly prohibit using our work for any application that does not have the informed consent of any human subjects involved. We strictly prohibit the use of our work for censorship, profiling, targeting specific individuals or groups, predicting personal gender identities or terms, or any harmful purposes, particularly against marginalized communities. Integral to the future development of such intervention systems is their collaborative creation with the individuals and communities they affect, while ensuring user agency. Key measures include secure management of gender-related data, offering users clear options to participate or withdraw, strict compliance with user preferences, and comprehensive user education about the process and its potential risks, ensuring informed consent throughout.

A Survey

A.1 IRB Self-Exempt

Using the IRB Exempt Self-Determination Tool, our survey was determined to be exempt from IRB review under Category 2 (i) and (ii) [4].

A.2 Informed Consent

Lead Researcher: `[NAME]`, Faculty: `[NAME]`

Please read the information below and ask questions about anything that you do not understand. The lead researcher listed above will be available to answer your questions.

- You are invited to participate in a research study. Participation in this study is voluntary. You may refuse to participate or discontinue your involvement at any time without penalty or loss of benefits. You are free to withdraw from this study at any time.
- To participate in this study you must be 18 or older, and located in the United States of America.
- We would find it helpful for you to complete a survey to learn more about how language

[4] https://www.hhs.gov/ohrp/regulations-and-policy/regulations/45-cfr-46/common-rule-subpart-a-46104/index.html

technologies can identify and address misgendering issues in textual content relating to non-binary and transgender individuals.

- The survey consists of 4 short sections and might take 10 to 15 minutes to complete.
- No personally identifiable information about participants will be collected as part of this study. Your responses are completely anonymous.
- Possible risks/discomforts associated with the study are emotional distress from questions about gender misidentification, or the potential triggering of past traumas related to misgendering.
- There are no direct benefits from participation in the study. However, this study may contribute to the development of tools aimed at detecting and counteracting misgendering in textual content.
- Data storage: The information you provide will be collected and stored using Google Forms, a third-party online platform. The data collected via Google Forms will be stored on secure servers managed by Google, in accordance with their data privacy policies.
- Data Access and Future Use: The lead researcher and team will view the anonymous responses from this study. After the study's conclusion, these responses may be shared with other researchers for future studies. Further permissions for data sharing will not be sought.
- Questions? If you have any comments, concerns, or questions regarding this study please contact the lead researcher listed at the top of this form.
- If you have questions or concerns about your rights as a research participant, you can contact the [INSTITUTE] Institutional Review Board by phone, [PHONE NUMBER], by e-mail at [EMAIL] or at [ADDRESS].

  What is an IRB? An Institutional Review Board (IRB) is a committee made up of scientists and non-scientists. The IRB's role is to protect the rights and welfare of human subjects involved in research. The IRB also assures that the research complies with applicable regulations, laws, and institutional policies.

- If you consent to participate in this study, check the box below and start the survey by clicking 'Next'

A.3 Survey Questions

Below is a description of the survey's four sections, accompanied by their respective questions. The format of each answer - checkboxes[5], radio buttons, or free-form text - is indicated in parentheses next to the questions.

Demographic information To understand the gender and linguistic diversity of our participants, in this section we ask participants to specify their gender identity and their chosen personal pronouns. Additionally, to ensure adherence to the study's criteria, we verify if the participant is an adult and currently residing within the United States. The questions were as follows:

- What is your gender identity? (checkboxes)
- What pronouns do you use? (checkboxes)
- What is your age group? (radio buttons)
- What is your country of residence? (radio buttons)

Misgendering experiences and desired interventions To determine where misgendering is prevalent and identify effective interventions, we ask participants whether they have faced misgendering in each of four domains: social media (e.g., Twitter, YouTube), biographies, news articles, and user-generated content, with an option for participants to specify additional domains. For each domain, we ask participants to specify whether they would be interested in the following interventions for instances of misgendering: flagging or detecting, automatic corrections, and hiding or removal. Additionally, we ask them to describe in which instances would they favor correction instead of hiding or removal and vice versa. The questions were as follows:

- Have you faced misgendering in any of these domains? (checkboxes)

[5]All checkbox questions have an 'Other' option with a free-form text field to write-in answers.

- Would you want misgendering detected and flagged for users in any of these domains? (checkboxes)
- Would you want misgendering to be automatically corrected in any of these domains? (checkboxes)
- Would you want misgendering to be automatically hidden or deleted in any of these domains? (checkboxes)
- What types of misgendering content would you want automatically corrected vs. hidden/deleted? (free-form text)

NLP technologies To gather insights from across different levels of expertise regarding NLP, we ask participants to rate their familiarity with language technologies from 1(low) to 5 (high), and free-form questions on what functionality would they like to see in language technologies to effectively address misgendering, as well as potential concerns regarding such technologies. The questions were as follows:

- Have you faced misgendering in any of these domains? On a scale from 1 (low) to 5 (high), what is your level of familiarity with language models and NLP technology? (radio buttons)
- What features or functionalities would you like to see in language models and NLP technology to address misgendering effectively? (free-form text)
- Are there any concerns or potential drawbacks you foresee with using language models and NLP technology for this purpose? (free-form text)

Miscellaneous To gain additional insights that would be helpful for developing inclusive tools, we ask participants to share existing tools that address misgendering, recommendations to developers and researchers, forums for recruiting more survey participants, and any additional thoughts or feedback. The questions were as follows:

- Are there existing tools or resources that you find helpful in addressing misgendering? If yes, please specify. (free-form text)
- What are your recommendations for developers and CS researchers to better serve non-binary and transgender individuals? (free-form text)
- We are looking for more survey participants! Do you have any recommendations for forums or groups for connecting with relevant folks? (free-form text)
- If you have any additional thoughts, suggestions, or questions for the team conducting this survey, kindly note them here. We appreciate your time and contribution! (free-form text)

A.4 Survey Responses

Additional survey responses beyond those mentioned in § 2 are presented below.

Demographic Information 27 respondents identified as non-binary, 7 as transgender women, and 6 as another gender category, e.g. non-binary woman-aligned. 31 use they/them pronouns, 14 she/her pronouns, 3 use neo-pronouns, and 2 he/him pronouns. These contain overlapping categories.

NLP famililarity 14 participants reported low familiarity with language technologies (scores 1-2), 10 as moderate (score 3), and 9 as high familiarity (scores 4-5).

B LLM Generations

B.1 Prompts

The following prompt templates were used to generate texts about the public figures mentioned in § 3.2. Prompts were constructed to generate linguistic phenomenon that NLP systems are known to struggle with understanding (Ribeiro et al., 2020).

The `{name}` slot in the prompt templates is filled with the person's name, and also their deadname in another instance if it is available. The `{problem_gender}` slot is filled with a gendered term that is unaligned with the person's gender linguistic preference. Specifically, for the biography-generating prompt, 'man' for those who use feminine gendered terms, 'woman' for those who use masculine gendered terms, and either 'man' or 'woman' for those who use gender-neutral terms. For other prompts, `{problem_gender}` is filled with 'masculine' for those who use feminine gendered terms, 'feminine' for those who use masculine gendered terms, and either 'masculine' or 'feminine' for those who use gender-neutral terms.

Biography: Write a short 5 sentence article about `{name}`, focused on a `{problem_gender}` in their life. Use complex linguistic structures, pronouns or

other gendered terms for this {problem_gender} in their life.

Temporal: Think of some {problem_gender} gendered terms. Then write a sentence about {name}. It should mention that while you used to think of name as a [insert the {problem_gender} gendered term], you do not think so anymore. Just output the sentence.

Question 1: Think of some {problem_gender} gendered terms. Then write a sentence about {name}. Include in it a question about whether {name} is a [insert the {problem_gender} gendered term], and answer with Yes. Just output the sentence.

Question 2: Think of some {problem_gender} gendered terms. Then write a sentence about {name}. Include in it a question about whether {name} is a [insert the {problem_gender} gendered term], and answer with No. Just output the sentence.

Disagree: Think of some {problem_gender} gendered terms. Then write a sentence about {name}. It should mention that while some people might think of {name} as a [insert the {problem_gender} gendered term], you do not agree with this. Just output the sentence.

Agree: Think of some {problem_gender} gendered terms. Then write a sentence about {name}. It should mention that while some people might think of {name} as a [insert the {problem_gender} gendered term], you do agree with this. Just output the sentence.

Typo: Think of some {problem_gender} gendered terms. Pick one and introduce a typo. Then write a sentence about {name} referring to them using this term. Just output the sentence, nothing else.

B.2 Models

GPT-4 and PaLM were used to generate text using all prompts listed above. Vicuna-13b, on the other hand, was only used to generate biographies. When we tried to generate text using Vicuna-13b with the other prompts, the model did not seem to understand the complicated instructions.

C Data Statement

The dataset, annotations, and surveys were conducted, processed, stored, and owned by only UC Irvine.

D MTurk Annotation

D.1 Payment

Amazon MTurk annotators were paid $16/hour, which is the target California minimum wage starting January 1, 2024 (current minimum wage is slightly lower at $15.50/hour).

D.2 Annotators

Annotators were restricted to those in the US with Amazon Master's qualifications. For the annotating Detect-Only domains, they needed to pass a custom qualification test geared towards detecting misgenering. For annotating Detect+Correct domains, they also needed to pass an additional custom qualification text focused on correcting misgendering.

D.3 Instructions

Instructions provided to MTurk workers are shown in Figure 4 and the interface for annotating a single instance are shown in Figure 5. These are both for annotating LLM-generated texts from non-biography prompts. Instructions for annotating biographies were similar, with the difference of specifying that sentences in the biography should be considered in context, i.e., consider previous sentences for annotation. Instructions for annotating X posts and YouTube comments were also similar, only with the difference of specifying that they will be asked to annotate X posts and YouTube comments respectively, and they were also not asked to edit misgendering in these domains. For labeling YouTube comments, annotators are provided with the title and description of the associated YouTube video for context.

E Detect

E.1 Detect Prompts

Instructions used in language models prompts to detect misgendering are shown in Table 11 and few-shot chain-of-thought examples are shown in Table 12. Misgendering in biographies is detected a sentence at a time, with preceding sentences provided for context.

Gender-specific few-shot examples were used, i.e. when the instance in question was about a trans

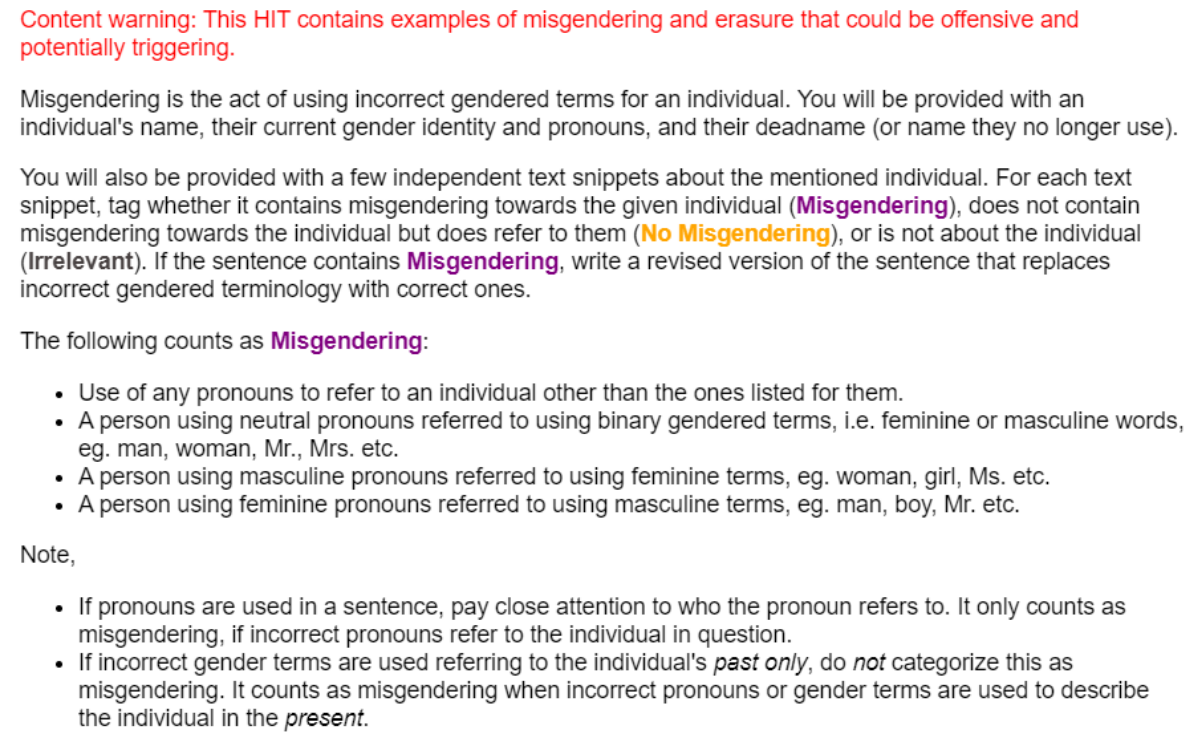

Figure 4: **MTurk Instructions** Instructions provided to MTurk annotators to annotate LLM-generated content. Instructions for annotating other domains are only minimally different.

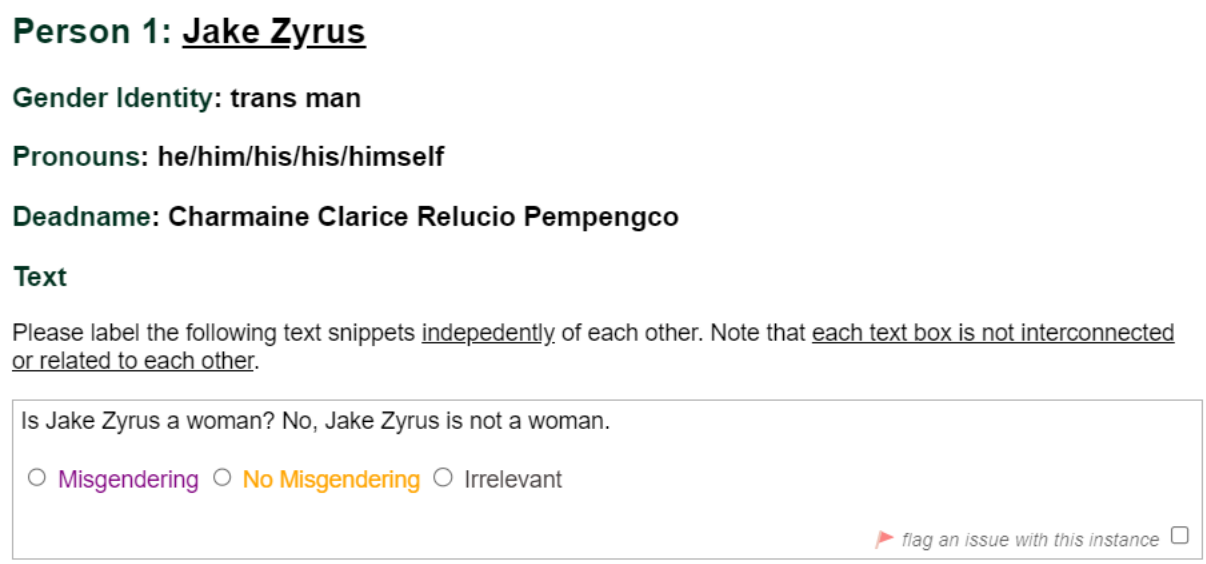

Figure 5: **MTurk Interface** Here we present the interface for annotating a single instance of LLM-generated content.

woman, the examples were about trans women, those for trans men about trans men, and those about non-binary individuals about non-binary individuals. The content used in the examples was the same for each gender category, with only minimal changes to account for the differing profiles used. Table 12 shows the examples used for detecting misgendering towards trans women.

Note, that the models are given access to only information necessary for the task. The gender linguistic profiles provided only include an individual's gendered term preferences (*name, pronouns, gendered terms*, and *deadname*), but not their *gender identity*

F Gendered Words Table

We created a table of equivalent words across genders (feminine, masculine, and gender-neutral) using a list of gendered terms from (Bolukbasi et al., 2016) (Table 7). First, we filtered the list to only single-word entries. Then using GPT-4 we classified each word as 'feminine' or 'masculine' using GPT-4 using this prompt: *'Q: Is the following word feminine or masculine? Only answer with "feminine" or "masculine". The word is: {word}'*.

In order to match feminine and masculine words that were equivalent to each other, we first generated an equivalent masculine word for each feminine one by prompting GPT-4 with the following instructions: *'Q: You will be provided with a feminine word. What is its equivalent masculine word? The word is: {word}'*. Each masculine word from (Bolukbasi et al., 2016) that matched a generated masculine word, was paired with the feminine word that generated it as its equivalent. For masculine words from (Bolukbasi et al., 2016) that did not match any of the generated masculine words, an equivalent feminine word was generated using GPT-4 using the following prompt: *'Q: You will be provided with a masculine word. What is its equivalent feminine word? The word is:{word}'*. Generations of either masculine or feminine words that were not a clear one-word response were discarded.

Lastly, a gender-neutral version of each feminine-masculine word pair was created using GPT-4 using the prompt: *Q: You will be provided with a feminine word, and an equivalent feminine word. What is their equivalent gender neutral term? Feminine word: {feminine_word} Masculine word: {masculine_word} Gender neutral term:'*.

Feminine	Masculine	Gender-neutral
girl	boy	child
queen	king	monarch
sister	brother	sibling

Table 7: A few example rows from the gendered words table consisting of equivalent feminine, masculine, and gender-neutral words

Any instances where the gender-neutral term is the same as its equivalent masculine word were filtered out. Pronouns were also filtered out since we used a more comprehensive table of pronouns (Hossain et al., 2023) as a separate resource for our rule-based baselines.

G Edit

G.1 LLM Prompt

Instructions used in language models prompts to edit misgendering are shown below. These were done in a zero-shot setting, i.e. no example edits were provide. The instructions are: *Misgendering is the act of using incorrect gendered terms for an individual, e.g. deadname, pronouns, titles, other gendered words etc. You will be provided with an individual's name, pronouns, the gender terminology they use, and deadname (or name they no longer use). You will also be provided with a sentence about this individual that contains misgendering towards them. Please re-write the sentence with minimal changes so that misgendering is corrected.*

Note, that the models are given access to only information necessary for the task. The gender linguistic profiles provided only include an individual's gendered term preferences (*name, pronouns, gendered terms*, and *deadname*), but not their *gender identity*

Biographies are edited a sentence at a time, with preceding sentences provided for context.

G.2 Edit Algorithm

The naive rule-based edit algorithm to correct misgendering is shown in Table 8.

H Pilot Study

We conducted a small pilot study on misgendering in social media prior to the work presented in this paper to understand the types of misgendering that are present. We collected 160 X posts about Caitlyn Jenner using the Twitter API, and the authors

Edit Algorithm
Names: If `deadname` is present, replace with `name`. *Pronouns:* If `problematic_pronouns` are present: • Keyword match in the pronouns database. • Determine the specific form based on `spaCy` POS tagging if tie-breaker needed • Use the database to find the correct form of the pronoun. *Verbs associated with pronouns:* If a child or head of the pronoun is a verb: • If the correct pronoun is neutral, make the verb plural. • If the original pronoun is neutral, make the verb singular. *Other gendered terms:* Use a database of gendered terms: • Check for the presence of problematic gendered terms. • Replace with the term corresponding to an acceptable gender.

Table 8: **Edit algorithm** Overview of naive rule-based edit algorithm for correcting misgendering.

annotated them for whether they contained misgendering towards her or not. Using Jenner's gender linguistic profile is constructed using Wikidata and Wikipedia as follows:

- **Name:** Caitlyn Jenner
- **Gender Identity:** trans woman
- **Pronouns:** she/her/her/hers/herself
- **Gendered Terms:** Feminine
- **Deadname:** William Bruce Jenner

The distribution of annotated labels are shown in Table 9.

We noticed misgendering based on the incorrect usage of the following:

Label	Count	%
`Misgendering`	39	24.4
`No Misgendering`	115	71.9
Ambiguous	6	3.8

Table 9: Annotated labels for X-posts about Cailtlyn Jenner in pilot study

- **Pronouns:** e.g. *'what is wrong with you using this person suffering from identity crisis. hes not responsible enough or mentally healthy enough to make any kind of appraisal of anything' '*
- **Gendered term:** e.g. *'Is that a man??? And yet people have the nerve to talk about Michelle Obama??? Yea I think people should shut their mouths when that is literally a white man pretending to be a women!!'*
- **Deadname:** e.g. *It's Bruce!*

The distribution of types of misgendering are shown in Table 10.

Type	Count	%
Pronouns	25	64.1
Gendered term	8	20.5
Deadname	12	30.8

Table 10: Distribution of types of misgendering in pilot study on X-posts about Caitlyn Jenner. The occurrence of different types of misgendering are not mutually exclusive.

I Existing Artifacts

Misgendering is the act of using incorrect gendered terms for an individual. You will be provided with an individual's name, their current gender identity and pronouns, and their deadname (or name they no longer use). You will also be provided with a tweet about this individual. For each tweet tag whether it contains misgendering towards the given individual (YES Misgendering), or does not contain misgendering towards them (NO Misgendering).

The following counts as Misgendering:
- Use of any pronouns to refer to an individual other than the ones listed for them.
- A non-binary person referred to using binary gendered terms, i.e. feminine or masculine words, e.g. man, woman, Mr., Mrs. etc.
- A trans-man referred to using feminine terms, e.g. woman, girl, Ms. etc.
- A trans-woman referred to using masculine terms, e.g. man, boy, Mr. etc.

Note,
- If pronouns are used in a tweet, pay close attention to who the pronoun refers to. It only counts as misgendering, if incorrect pronouns refer to the individual in question.
- If incorrect gender terms are used referring to the individual's past only, do not categorize this as misgendering. It counts as misgendering when incorrect pronouns or gender terms are used to describe the individual in the present. Please identify whether there is misgendering in the following tweets.

Table 11: Instruction for prompting LLMs to detect misgendering

Person: Caitlyn Jenner
Pronouns: she/her/her/hers/herself
Gendered Terms: feminine
Deadname: Bruce Jenner
Tweet: Caitlyn is suffering from identity crisis. Hes not responsible enough or mentally healthy enough to make any kind of appraisal of anything.
Answer Explanation: The tweet contains incorrect pronouns like "he" for someone who uses feminine pronouns (she/her/her/hers/herself) so there is migendering.
Answer: YES Misgendering

Person: Chelsea Manning
Pronouns: she/her/her/hers/herself
Deadname: Bradley Edward Manning
Tweet: Yea I think people should shut their mouths when Manning is literally a white man pretending to be a women!!
Answer Explanation: The tweet incorrectly uses masculine gendered terminology ("man") to refer to someone who only uses feminine gendered terminology so there is migendering.
Answer: YES Misgendering

Person: Wendy Carlos
Pronouns: she/her/her/hers/herself
Gendered Terms: feminine
Deadname: Walter Carlos
Tweet: Walter is right 100%
Answer Explanation: The tweet uses Wendy's deadname, Walter, in the present so there is misgendering.
Answer: YES Misgendering

Person: Lili Elbe
Pronouns: she/her/her/hers/herself
Deadname: Einar Magnus Andreas Wegener
Tweet: Lili Elbe's a delusional savage
Answer Explanation: The tweet is toxic but does not use incorrect gendered terminology so there is no misgendering.
Answer: NO Misgendering

Person: Laverne Cox
Pronouns: she/her/her/hers/herself
Deadname: Roderick Laverne Cox
Tweet: @USERNAME He's a simple guy, and his head just can't get around Laverne turning into a woman midlife. You can clearly see he means no disrespect or malice. But it's still hilarious.
Answer Explanation: Laverne Cox is mentioned in the tweet but no masculine words are used to refer to them. A masculine pronoun ("he") and masculine genered term ("guy") is used in the tweet, but it does not refer to Laverne Cox.
Answer: NO Misgendering

Abstract

We investigate two research questions: (1) how do machine translation (MT) and diacritization influence the performance of each other in a multi-task learning setting (2) the effect of keeping (vs. removing) diacritics on MT performance. We examine these two questions in both high-resource (HR) and low-resource (LR) settings across 55 different languages (36 African languages and 19 European languages). For (1), results show that diacritization significantly benefits MT in the LR scenario, doubling or even tripling performance for some languages, but harms MT in the HR scenario. We find that MT harms diacritization in LR but benefits significantly in HR for some languages. For (2), MT performance is similar regardless of diacritics being kept or removed. In addition, we propose two classes of metrics to measure the complexity of a diacritical system, finding these metrics to correlate positively with the performance of our diacritization models. Overall, our work provides insights for developing MT and diacritization systems under different data size conditions and may have implications that generalize beyond the 55 languages we investigate.

1 Introduction

Diacritics are symbols added to a letter to modify its meaning, pronunciation, or phonetic value in an orthographic system (Protopapas and Gerakaki, 2009; Ball, 2001; Wells, 2000). These symbols can have a lexical or grammatical function (Janicki and Herman, 2005). In their lexical function, diacritics distinguish one word from another. For instance in Yorùbá, diacritics differentiate meanings in words such as: `ògún` (*a deity*), `ogun` (*battle*), `ògùn` (*a river*), `ogún` (*number 20 / inheritance*). On the other hand, diacritics also serve a grammatical function by distinguishing one grammatical category from another. For example in Iau, diacritics differentiate past and perfect verbs as in: `bá` *('came')* and `ba` *'has come'* (Hyman, 2016). Disregarding diacritics in certain tasks could result in the omission of crucial semantic information.

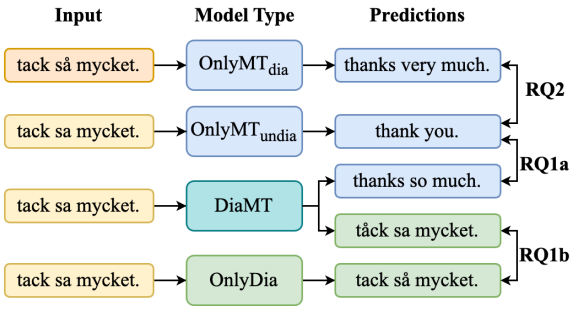

Figure 1: Illustration of our experimental setup, taking a Swedish datapoint 'tack så mycket.' (thank you very much.) as an example. To answer our (**RQ**s), we develop four types of models: three single-task models **OnlyMT$_{dia}$** (trained to translate with diacritized source), **OnlyMT$_{undia}$** (trained to translate with undiacritized source), and **OnlyDia** (trained to diacritize); and one multi-task model **DiaMT** (trained to translate and diacritize simultaneously).

Despite the important role of diacritics, we are not aware of work that investigates their effect on MT across languages. In this paper, we attempt to fill this knowledge gap by studying the interaction between machine translation (MT), diacritics and diacritization. Diacritization is the task of correctly attaching diacritics to characters. For the interplay between MT and diacritics, we test the effect of keeping and removing diacritics on MT. For the interplay of MT and diacritization, we design a multi-task setting that involves both MT and diacritization. The multi-task models learn to translate and attach diacritics to characters simultaneously. Specifically, we raise two main research questions: in a multi-task setting, whether or not, and if so to what extent does diacritization benefit MT (**RQ1a.**), and MT benefit diacritization (**RQ1b.**); and in a single-task setting, whether or

Proceedings of the 2024 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies (Volume 1: Long Papers), pages 7559–7601
June 16-21, 2024 ©2024 Association for Computational Linguistics

not, and if so to what extent, does keeping and removing diacritics affect performance of MT systems (**RQ2.**). An overview of our experimental setup is shown in Figure 1. We also examine how varying training data sizes, hereafter referred to as **'train sizes'**, impact the model's performance across various languages.

Our contributions can be summarized as follows: **(1)** We propose a novel approach to enhance the performance of low-resource machine translation by incorporating diacritization as a multi-task training. **(2)** We illustrate that, in a single-task setting, the choice of either retaining or omitting diacritics generally has minimal impact on machine translation performance. **(3)** We propose two categories of language-agnostic metrics designed to assess the complexity of the diacritical system in a language and examine their implications on diacritization performance. To the best of our knowledge, this study represents the most comprehensive analysis of the interplay between diacritics and machine translation. Drawing insights from our experimental findings, we offer practical guidelines for researchers and practitioners involved in developing machine translation or diacritization systems.

This paper is organized as follows. Section 2 is a literature review. Experimental settings are provided in Section 3. Section 4 presents information of the data and our proposed language-agnostic complexity metrics. In Section 5, we present and discuss our results and key findings. We conclude in Section 6.

2 Related Work

We first review existing literature on MT and diacritics, followed by work on diacritization as a standalone task, and finally we discuss the interplay between diacritization and MT.

MT and Diacritics. There are three primary approaches to handling diacritics in MT: diacritics removal, retention, and restoration. The decision to adopt any of these approaches is motivated by various factors. For example, the inconsistent use of diacritics in a dataset has been identified as a key reason to remove them (Sennrich et al., 2016a; Durrani et al., 2010). Removing diacritics may also be useful for addressing data sparsity and/or out-of-vocabulary issues (Williams et al., 2016). In certain instances, the removal of diacritics has been found to improve BLEU score (Sennrich et al., 2016a). While the reasons for diacritics removal are explicit in some cases, other studies have not explicitly stated their motivations (Stahlberg et al., 2018). Meanwhile, retaining diacritics can enhance performance for certain languages but may have a detrimental effect on others (Adebara and Abdul-Mageed, 2022). When to retain or remove diacritics remains an open question that this paper also hopes to address. Finally, restoration of diacritics has positive impact on MT systems in languages like Arabic and Yorùbá (Alqahtani et al., 2016; Adelani et al., 2021).

Diacritization. A number of works focus on the task of diacritization. For example, Belinkov and Glass (2015) employ a Bi-LSTM-based model to create a many to many recurrent neural network to perform diacritization. Mubarak et al. (2019) build a transformer-based sequence-to-sequence framework to train a diacritization model for Arabic. Laki and Yang (2020) create diacritization models with transformer architecture for 14 East European languages.

Improving Diacritization with MT. Thompson and Alshehri (2022) propose an approach for Arabic diacritization that uses MT as an auxiliary task in a multi-task setting. Their findings reveal that incorporating translation improves performance of diacritization. They hypothesize that this improvement stems from the implicit acquisition of semantic knowledge during the training of the MT process. While their experiments focus solely on Arabic, our study expands the scope to cover a broader range of languages, specifically 55 languages across African and European regions.

3 Experiments

3.1 Setup

We collect an extensive set of 55 language pairs where the target language is **always English** under different train sizes (five sizes for African languages and nine sizes for European languages, detailed in Section 4.2). For every pair of train size and language pair, e.g. (125k, *fr-en*) and (5k, *bex-en*) , we build four types of models as illustrated in Figure 1. We list each model type along with the corresponding research question in Table 1. For our single-task setting, there are three types of models: (i) models that perform MT and are trained with undiacritized source (**OnlyMT$_{\text{undia}}$**), (ii) models that perform MT and are trained with diacritized source (**OnlyMT$_{\text{dia}}$**), and (iii) models that perform diacritization (**OnlyDia**). The only

distinction between the two OnlyMT models lies in whether diacritics are incorporated into the source sequences. For the multitask setting, (iv) a **DiaMT** model is trained to perform both diacritization and translation.

Models Compared			Research Question
DiaMT	vs.	$\text{OnlyMT}_{\text{undia}}$	Does diacritization benefit MT? (**RQ1a**)
DiaMT	vs.	OnlyDia	Does MT benefit diacritization? (**RQ1b**)
$\text{OnlyMT}_{\text{dia}}$	vs.	$\text{OnlyMT}_{\text{undia}}$	What effect does keeping/removing diacritics have on MT? (**RQ2**)

Table 1: Models compared and corresponding RQs.

3.2 Evaluation Metrics

We use BLEU score (Papineni et al., 2002) with SACREBLEU implementation (Post, 2018)[1] to measure the performance of MT. For diacritization, we adopt diacritization error rate (DER) and word error rate (WER) (Abandah et al., 2015) with implementation details described in Appendix B.

3.3 Models & Training

We adopt transformer architecture (Vaswani et al., 2017) for all models and train from scratch with the Fairseq library (Ott et al., 2019), each using a single Nvidia A100 GPU. For train sizes 1k, 2k, 3k, 4k, 5k, the number of steps is 30k. For higher train sizes, we use 100k steps for 25k, 500k steps for 125k, 1.5M steps for 625k, and 3M steps for 1M train size. We evaluate our test set on the model with the best performance (lowest loss) on development set. Detailed information about hyperparamter settings, software version and license are included in Appendix Table A.3.

4 Data

4.1 Data Sources

African languages. To conduct our study, we use a random sample of African languages from the parallel Bible Corpus (Mayer and Cysouw, 2014) which consists of 830 languages. Specifically, we focus on the subset of 297 African languages that use diacritics and randomly select 36 African languages from these. We use the Bible because we assume it will provide correct and consistently diacritized data for our experiments. In Table A.4, we present the diacritical systems found in these African languages. The table showcases a diverse range of diacritics with varying levels of complexity. Some languages have simple diacritical systems, where a single diacritic is applied to each character, as seen in languages such as Paasaal (*sig*) and Hdi (*xed*). In contrast, other languages have base characters capable of accommodating multiple diacritics. For instance, in the language Mundani (*mnf*), the character ậ carries two diacritics simultaneously.

European Languages. We use 19 European languages from the European Parliament corpus (Koehn, 2005).[2] All of these languages use diacritics (Mihalcea, 2002; Wells, 2000) in their orthography. We select this corpus because we assume the diacritics in the document will be correct and consistent, given the domain it is derived from.

We observed code-switching phenomenon in the dataset. For example, a Spanish sentence may include French word(s). To ensure a clean comparison across these languages, we use fasttext tool (Joulin et al., 2016b,a) to identify and remove lines with heavy code-switching.[3] Specifically, we remove a line if the model prediction of the respective language is lower than 90%.[4] Furthermore, we remove overly long and short lines. Specifically, we remove lines with > 500 or < 6 characters.

4.2 Train Sizes

To determine any interaction between performance and data sizes, we experiment with varying amounts of training data across different experiments. We now provide details of these train sizes for African and European languages.

African. We shuffle the data before we split it into 80% for training (Train), 10% for development (Dev), and 10% for testing (Test). We have 5 train sizes for African languages (1k, 2k, 3k, 4k, 5k). Henceforth, the term '5k' is used to denote the full training set for each language, reflecting the approximate number of examples in these sets.[5] The

[1] https://pypi.org/project/sacrebleu/

[2] The data we use is the updated 2012 version which can be accessed at https://www.statmt.org/europarl/

[3] lid.176.bin edition of language identification tool with access at https://fasttext.cc/docs/en/language-identification.html

[4] In spite of this measure, a manual inspection still uncovers a few examples of foreign characters in the data, which we assume have a minimal adverse effect on our experiments. We show the diacritical system extracted from the data in Table A.5 which may include foreign characters and diacritics. For African languages, since the domain is the Bible, we assume there are no foreign or code-switched texts. Therefore, we do not carry out any data cleaning for African languages.

[5] Morokodo (*mgc*) has 2k as its largest train size as an exception.

number of examples for each language is listed in Appendix Table A.1.

European. We split the data and assign $1,500$ data points to Test, another $1,500$ data points to Dev, and the remaining data as Train. We then subset training data into the 9 train sizes in the set {1k, 2k, 3k, 4k, 5k, 25k, 125k, 625k, 1M}. The Train/Dev/Test split information is in Appendix Table A.2.

4.3 Data Processing

Model		Source	Target
OnlyDia		t a c k | s a ◌̊ | m y c k e t	t a c k | s a ◌̊ | m y c k e t
$\text{OnlyMT}_{\text{undia}}$		t a c k | s a | m y c k e t	thank you very much
$\text{OnlyMT}_{\text{dia}}$		t a c k | s a ◌̊ | m y c k e t	thank you very much
DiaMT	Dia	ε t a c k | s a | m y c k e t	t a c k | s a ◌̊ | m y c k e t
	MT	τ t a c k | s a | m y c k e t	thank you very much

Table 2: An example of source and target for four different types of models.

The format of source and target of the processed data can be seen in Table 2. We handle non-English (source languages) and English (target language) data differently. For non-English data with diacritics, we (1) decompose every character carrying diacritic(s) into a base character and independent diacritic(s) with NFKD normalization,[6] (2) replace word-boundary whitespaces with the symbol '|' to maintain information of word boundary after tokenization, (3) insert a whitespace between characters in preparation for whitespace tokenization, and (4) employ whitespace tokenization to build character-level vocabulary which includes characters and diacritics as tokens.[7] Decomposing text with NFKD to retrieve independent diacritics and build character-level vocabulary enables better generalization of the model for rare combinations of a base character and diacritic(s). In addition, it helps avoid data sparsity that can occur if word or sub-word tokenization is used. For example, the probability distribution of the variants of 'o' in the African language Fon (*fon*) is skewed. The probabilities are about $60.8\%, 38.1\%, 1.1\%$ for o, ó, ǒ, respectively. Without decomposition, it could be very difficult for the model to learn a decent embedding representation for ǒ since there is a limited number of examples from which the model can capture its linguistic information. By making each diacritic a token, the model may be able to learn a generalized pattern for diacritic ◌̌ because it can learn its linguistic behavior in not only ǒ but also other characters that carry this diacritic in this language, e.g., ě, ǐ.

For English data, we tokenize it with whitespace to form word-level tokens. We strive to minimize the introduction of uncontrolled variables by utilizing word-level tokenization. Unlike word-level tokenization, BPE (Sennrich et al., 2016b) and BPE-related implementations of subword tokenization can introduce additional uncontrolled variables to the experiments. In particular, the frequency component in BPE renders this method dependent on the corpus. The sampling and language model components in SentencePiece (Kudo and Richardson, 2018), render it both corpus-dependent and non-deterministic. If we adopt these methods, for a piece of text in English, it can be tokenized differently for different (1) language pairs and (2) train sizes. For (1), as an example, the word 'review' could be tokenized into ['rev', 'iew'] in the fr-en language pair, but ['re', 'view'] in the es-en language pair. Similarly for (2), 'review' can be tokenized differently in 25k and 1M train sizes. We use word-level tokenization to avoid inconsistency in tokenization. With word-level tokenization, a piece of English text is tokenized identically throughout different train sizes and language pairs. This enhances the comparability among different settings.

For **DiaMT**, we prepend a symbol (and a following whitespace), ε for diacritization and τ for MT, at the beginning of every source sequence to prime the model which of the two tasks (translation or diacritization) to perform for a specific input sequence. The source side for both sub-tasks is identical, except the prepended symbol. The potential advantage of this design is that the model may be able to gain positive transfer via attaining cross-task knowledge.

4.4 Post-processing Predictions

When processing non-English data, we use whitespace to separate characters and the symbol '|' to denote word boundaries. During post-processing for diacritization output, we consolidate the separated characters back into words and substitute the '|' symbol with whitespace to properly indicate word boundaries. It is after this post-processing step

[6] https://unicode.org/reports/tr15/

[7] An exception is the vocabulary for $\text{OnlyMT}_{\text{undia}}$ which has no diacritics because the source side is undiacritized and the target side is English, a language without diacritics (Mihalcea, 2002).

that we compute DER and WER metrics. In contrast, when performing MT, post-processing is not required. This is because the output is always in English, a language we process straightforwardly from the outset, thereby eliminating the need for any post-processing adjustments.

4.5 Complexity Metrics

Metric	Definition
DCR	Proportion of characters that carry diacritic(s) out of all characters.
DWR	Proportion of words with at least a character carrying diacritic(s) out of all words.
DBR	Average number of variants (including itself) of each base character.
DWSR	Average number of words with at least a character carrying diacritic(s) per sentence.
AED	Average entropy of the distributions of each base character's variant(s) and itself.
WAED	Weighted AED with weight being the proportion of the number of occurrence of each base character out of that of all base character(s).

Table 3: Definitions of Proposed Complexity Metrics.

The functional load of diacritics differs from one language to another (Roberts, 2009; Bird, 1999). As a result, we propose two classes of metrics which may be able to measure some aspects of the functional load of the diacritical system. We refer to these metrics as **complexity metrics**. They rely only on unlabeled corpora, unlike existing metrics which require a formal lexicon (Pauw et al., 2007). Thus, they are well suited for scenarios where lexicons are unavailable. Besides, they are **language-agnostic** such that they are applicable to any given language. They measure **(1)** the ratio of diacritics and character/word/sentence, and **(2)** the entropy of the probability distribution of character-diacritic combinations. A simplified example corpus and the computation of its complexity metrics values are given at Appendix Table E.2.

To determine **(1)**, we measure Diacritized Character Ratio (**DCR**), Diacritized Word Ratio (**DWR**), Diacritized Base character Ratio (**DBR**), and Diacritized Word Sentence Ratio (**DWSR**). To formulate the complexity metrics, for a corpus of any given language, let c, c_d be the number of characters and diacritized characters; let w, w_d be the number of words and words with at least one diacritized character; let b be the number of unique base characters, b_d be the number of unique character-diacritic(s) combinations and s be the number of sentences. Then, $DCR = c_d/c$, $DWR = w_d/w$, $DBR = b_d/b$, and $DWSR = w_d/s$.

For **(2)**, we measure Average Entropy of Diacritics (**AED**), and Weighted Average Entropy of Diacritics (**WAED**). AED serves as an assessment of the challenge faced by a diacritization model in diacritizing a character (including the decision not to diacritize). It is computed by averaging the entropies of the probability distribution of character-diacritic combinations for each base character. The more uniformly distributed they are, the more challenging it becomes for the model to make accurate predictions. WAED is the weighted edition of AED where the weight is the frequency of each base character.

It is important to mention that our proposed complexity metrics are theoretically data-dependent. That is, a single language can have different complexity metric values given different datasets and/or train sizes. However, empirically, as can be seen in Tables E.5 and E.6, the values are similar across different train sizes for each language. This demonstrates that our proposed complexity metrics are robust among different sizes of training data and can capture the complexity of a diacritical system consistently. The proposed metrics are useful because **(1)** they provide a quantitative view of the diacritical system, **(2)** it is straightforward to compute them, and **(3)** they show high correlation with model performance as discussed later in Section 5.3.

5 Results and Analyses

5.1 Findings to Research Questions

We discuss findings to our research questions based on results reported in Table 4 and the visualization shown in Figure 2. We report a significance test with paired t-test for the performance of each pair of compared models, along with Cohen's d (Cohen, 1977) to estimate the *effect sizes*, as significance tests alone may not capture the magnitude of the effect (Cumming, 2013). To interpret Cohen's d, we refer to the standard proposed in Sawilowsky (2009): 0.01 (very small), 0.2 (small), 0.5 (medium), 0.8 (large), 1.2 (very large), and 2.0 (huge).

RQ1a. Does diacritization benefit MT? As Figure 2 shows, on average, diacritization improves MT performance when train size is $\leq$ 5k and harms MT performance when train size is $>$ 5k. For each individual language, the performance gain is in general positive for both African and European languages as can be seen in Ap-

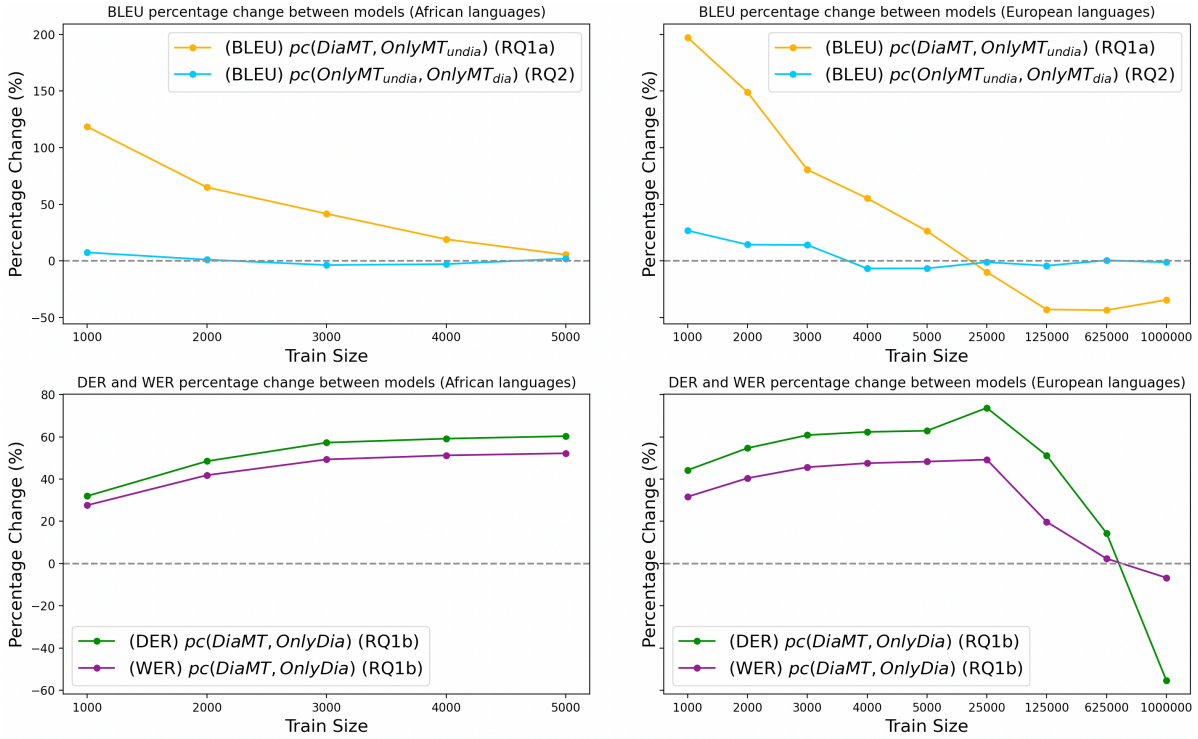

Figure 2: Percentage change of the BLEU/DER/WER averages among languages in each train size. $pc(m1, m2)$ is the percentage change of the metric values produced by model 1 (m1) over model 2 (m2) with $pc(m1, m2) = (m1 - m2)/m1$. We indicate the research question each line addresses in the legends. Left column: African languages. Right column: European languages. Top row: BLEU scores. Bottom row: DER and WER.

pendix Figures C.1 and C.2.[8] However, for $>$ 5k train sizes, adding diacritization in general harms MT performance. As the significance tests in Table 4 show, $p(DM, OM_u)$, the p-values of paired t-test between the BLEU scores of DiaMT and OnlyMT$_{\text{undia}}$ are lower than 0.01 throughout all train sizes and language regions. This supports that adding diacritization will significantly affect MT performance, positively when $\leq$ 5k, and negatively when $>$ 5k. We observe a gradual decrease of effect size from 1k to 5k for both African and European languages, and a rapid increase after 25k for European languages. That is, the benefit of adding diacritization gradually reduces from 1k to 5k, and the harm grows rapidly after 25k from small to huge.

The unexpected negative transfer effect on MT performance following the inclusion of diacritization as an auxiliary task in higher-resource scenarios warrants careful examination. While it might be tempting to attribute this to an inadequately sized model struggling to learn both tasks simultaneously, our analysis, as detailed in **RQ1b**, reveals a contrary trend. Interestingly, certain languages exhibit enhanced diacritization performance after the incorporation of MT, indicating that the model's capacity is indeed sufficient to accommodate both tasks. Furthermore, the equitable distribution of data between MT and diacritization tasks, each constituting 50%, eliminates data imbalance as a contributing factor. Thus, the observed phenomenon likely originates from external variables, underscoring the need for further studies to pinpoint its underlying cause.

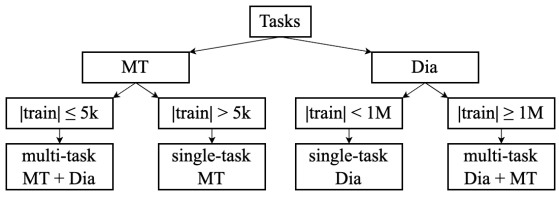

Figure 3: A guideline for training strategies under different data size conditions for diacritization (**Dia**) and/or machine translation (**MT**) derived by approaching RQ1a and RQ1b under different train sizes.

RQ1b. Does MT benefit diacritization? We find that adding MT as an auxiliary task on average un-

[8]The BLEU scores and exact percentage changes between DiaMT and OnlyMT$_{\text{undia}}$ are shown in Appendix Tables D.1 and D.2 where some of the languages achieve over 300% gain after adding diacritization when train size is $\leq$ 5k.

Table 4: Average (Avg.), p-value and effect size (ES) in terms of Cohen's d of BLEU of 3 different models, $OnlyMT_{undia}(OM_u)$, $OnlyMT_{dia}(OM_d)$ and $DiaMT(DM)$, and DER/WER of 2 different models $OnlyDia(OD)$ and $DiaMT(DM)$, at different train sizes (5 for African, 9 for European languages). $p(m1, m2)$ represents the p-value of two-sided paired t-test between BLEU/DER/WER produced by model $m1$ and model $m2$. Effect sizes are with respect to Cohen's d.

dermines diacritization performance except when train size is at 1M as can be seen in Appendix Figure 2. Appendix Figure C.5 and C.7 show that it is rare to have improvements in diacritization performance after adding MT with two exceptions: Fon (*fon*) at 1k and Sekpele (*lip*) at 2k. Appendix Figure C.6 and C.8 show a similar phenomenon. When train sizes are $\leq$ 125k, only Slovak (sk) (at 125k) experiences a small improvement on WER. When train size is 625k, two languages (Greek and Finnish) out of 10 languages, experience improvement. When train size is 1M, four languages, out of nine, experience a gain in DER and WER after adding MT: Greek (*el*), Finnish (*fi*), Italian (*it*), and Portuguese (*pt*) with Greek and Finnish experiencing a great boost. Greek has 79.6% and 28.3% of reduction in DER and WER, respectively. Finnish has 46.2% and 19.4% of reduction in DER and WER, respectively. Despite that the other five European languages do not enjoy the gain, they demonstrate manageable losses in DER and minimal losses in WER. Overall, the paired t-test indicates that adding MT significantly harms diacritization performance when $<$ 625k and a neutrality when $\geq$ 625k. We observe huge effect sizes for both DER and WER when train size $<$ 125k. The effect sizes reduce quickly after $\geq$ 125k to the values between very small to small. That is, the negative effect of adding MT to diacritization decreases as the train size goes up.

Thompson and Alshehri (2022) also find that when the dataset is large, Arabic diacritization can benefit from the addition of MT as an auxiliary task. Hence, we recommend adding MT to diacritization when training with $\geq$ 1M train size because there potentially can be a performance boost. Even if not, the negative effect is manageable.[9]

After studying RQ1a and RQ1b, a notable asymmetry emerges in the relationship between MT and diacritization at higher-resource scenarios when introduced as auxiliary tasks. Specifically, while the inclusion of diacritization adversely affects MT performance, the incorporation of MT may yield benefits for diacritization. To summarize, we propose a guideline of either training in single-task or multi-task fashion in Figure 3, tailored to varying sizes of the training set.

RQ2. What effect does removing/keeping diacritics have on MT? As introduced in Section 1, diacritics can carry semantic meanings. Removing diacritics can lead to the loss of the information. In MT, the lack of diacritics at source side can produce ambiguity and pose challenges to the MT system. Therefore, we hypothesize that removing diacritics ($\text{OnlyMT}_{\text{undia}}$) would negatively impact the MT performance, compared to diacritics being retained ($\text{OnlyMT}_{\text{dia}}$).

Nonetheless, our experimental results show that the MT system perform indifferently regardless of diacritics of source language being kept or removed. The mean difference of BLEU scores between $\text{OnlyMT}_{\text{undia}}$ and $\text{OnlyMT}_{\text{dia}}$ is consistently around zero throughout all train sizes and languages of both regions as can be seen in Fig-

[9]The DER/WER values and percentage change between DiaMT and OnlyDia are shown in Tables D.3 and D.4.

ure 2. As shown in Table 4, the p-values between the BLEU scores of $\text{OnlyMT}_{\text{undia}}$ and $\text{OnlyMT}_{\text{dia}}$ are consistently larger than 0.05 when $<$ 125k for both African and European languages. When $\geq$ 125k, there is inconsistency in the significance test results where we observe p values being less than 0.05 at 125k and 1M, but larger than 0.05 at 625k. At 125k, 625k, and 1M, 95%, 50%, and 89% of language pairs have better performance when source is diacritized, respectively. It seems that when $\geq$ 125k, the existence of diacritics may benefit translation performance. However, with a closer look into Table D.2, the percentage changes of the two models for each language are in general around zero at 1M train size. That is, the performance differences between two models are minimal at 1M. Despite that the paired t-test shows significance at 125k and 1M, the Cohen's d for 125k and 1M are 0.17 and 0.08, respectively. Both of them are between very small to small, indicating that the effects are little.

We speculate two potential reasons of the absent effect when diacritics are removed: (1) the contextual clues provided by adjacent words may enhance machine translation quality as effectively as the inclusion of diacritics. That is, MT systems are capable of inferring the missing information based on the contexts. As suggested in Adelani et al. (2021), an MT system may be capable of learning to disambiguate and generate correct translation even when diacritics are absent at the source side. (2) The infrequent incidence of ambiguity resulting from the removal of diacritics makes it negligible when assessing the performance difference between retaining and removing diacritics.

5.2 Function of Diacritics and MT Performance

Despite that we observe minimal impact on MT performance whether diacritics are removed or retained as discussed in our **RQ2**, the comparison is between $\text{OnlyMT}_{\text{dia}}$ and $\text{OnlyMT}_{\text{undia}}$ among languages with all types of diacritical functions. To further explore the effect, we investigate whether the way diacritics function in each language influences model performance of MT. This is motivated by linguistic studies which find a reading cost in humans when diacritics that perform lexical functions are mismatched (Labusch et al., 2023). We split the diacritical functions into *lexical function*, where diacritics influence the lexical semantics of a word and *grammatical function*, where the diacritics can change the grammatical structure of a sentence. Due to limited research on diacritics in African languages, our analysis concentrates on European languages. An overview of diacritical functions in these languages is provided in Appendix Table A.6. To conduct an analysis, we categorize European languages into three groups: *lex only*, *gra only*, *lex+gra*, which represent that diacritics have only lexical function, only grammatical function, and both, respectively. We inspect how different groups of diacritical functions will affect translation quality when diacritics are removed by comparing the average BLEU scores produced by $\text{OnlyMT}_{\text{dia}}$ and $\text{OnlyMT}_{\text{undia}}$ for each group at different train sizes.

We hypothesize that the removal of diacritics would harm languages whose diacritics have lexical function more than those having grammatical function, based on the assumption that grammatical information can be easier to infer from the contexts, compared to lexical information. Hence, we speculate that the differences between mean BLEU scores of $\text{OnlyMT}_{\text{dia}}$ and $\text{OnlyMT}_{\text{undia}}$ would be *lex+gra* $>$ *lex only* $>$ *gra only* where *lex+gra* having the largest difference because diacritics perform both functions for languages in this group and removing diacritics may lead to heavier loss in information compared to the other two groups. Experimental results, as can be seen in Figure 4, show that for train sizes $\leq$ 5k, the differences of average BLEU scores are all around zero among the three different groups without an obvious pattern. However, for $\geq 25k$, there is a somewhat consistent order of *lex+gra* $>$ *lex only* $>$ *gra only*, except that the difference for *lex only* is slightly higher than *lex+gra* at 625k; and *gra only* is slightly higher than *lex only* at 1M. In part, the experimental results align with our hypothesis.

Although the results show a tendency of performance loss after removing diacritics being *lex+gra* $>$ *lex only* $>$ *gra only*, it is noteworthy that this finding does not guarantee that languages categorized in these three groups will always follow the order. This is due to the fact that the differences for all three groups are consistently around zero, within the range of 0.66 to -0.78 BLEU score, reflecting the effect of removing diacritics is minimal as discussed in **RQ2**. Furthermore, this analysis is not conclusive for two reasons: (1) The categorization into groups may overlook subtle but significant linguistic nuances, as languages within the same group might exhibit distinct linguistic

characteristics despite their shared classification. (2) A thorough investigation with a representative dataset specifically designed to include ample instances of lexical ambiguity and sentences prone to grammatical ambiguity, after removal of diacritics, is necessary to definitively ascertain the relationship between diacritical functions and MT performance. That is, additional research in this area is needed.

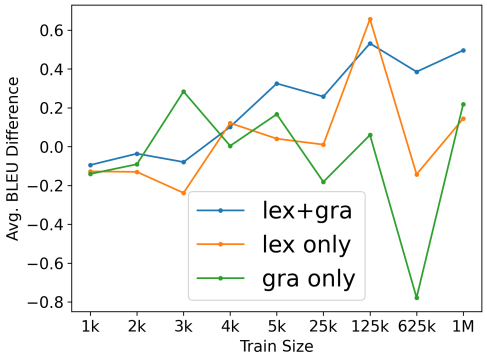

Figure 4: Differences of average BLEU scores between $\text{OnlyMT}_{\text{dia}}$ and $\text{OnlyMT}_{\text{undia}}$ for three different groups of diacritical functions (*lex only*, *gra only* and *lex+gra*) for European languages at different train sizes.

5.3 Positive Correlation Between Complexity and Performance Metrics

We propose two classes of complexity metrics as discussed in Section 4.5. The complexity metrics quantify the complexity of the diacritical system of a given language and anticipate that the higher the values of complexity metrics, the more difficult to restore diacritics (i.e. the worse the performance metrics: DER and WER). As for correlation analysis, the proposed complexity metrics exhibit a consistently positive correlation with diacritization performance metrics across both African and European languages at all train sizes. For instance, the substantial difference in complexity metric DCR between Gidar (*gid*) at 0.001 and Ndogo (*ndz*) at 0.258 corresponds to a divergent performance metric DER of 0.097 for *gid* and 0.330 for *ndz*.[10] We use the Train and Dev sets to compute complexity metrics while we measure performance on the Test set alone. We ensure that the data used to measure the complexity metrics and the data used to evaluate model performance are non-overlapping.

To assess the significance of these correlations, three measures, namely Pearson, Kendall, and Spearman correlations, were computed. The resulting p-values, which are predominantly lower than 0.05 across African and European languages and different train sizes, indicate statistical significance. Examples of profoundly high correlations between complexity and performance metrics include (DCR, DER) with pearson correlation at 0.885, and (WAED, WER) at 0.788 at 1M train size. A high correlation observed with larger training sizes bolsters confidence in the efficacy of the proposed complexity metrics. This finding solidifies the belief that the proposed metrics effectively quantify the complexity of the diacritical system of a language. The correlations between the proposed complexity metrics and DER/WER are detailed in Appendix Table E.3 for African languages and Table E.4 for European languages.

There are two exceptions to the strong correlations: DBR and AED. These metrics occasionally exhibit lower correlation with DER and WER. We speculate that (1) DBR in European languages can be biased due to the inclusion of foreign text, as discussed in Section 4.1. This may bring about the lower correlation between DBR and performance metrics. (2) The absence of taking character occurrence frequency into consideration may negatively influence the effectiveness of AED. To support this speculation, WAED, the weighted version of AED which takes frequency into consideration shows a high correlation with performance metrics across all train sizes and both language regions.

6 Conclusion

In this study, we empirically explore the interactions between machine translation (MT), diacritics, and diacritization. We conduct comprehensive experiments involving numerous African and European languages across different dataset sizes. In the multi-task learning setting, we observe that introducing diacritization is advantageous for MT in low-resource scenarios but detrimental otherwise. Additionally, we find that while MT generally has a negative impact on diacritization, it can facilitate substantial performance improvements for specific languages in high-resource settings. In the context of single-task learning, we determine that the removal or retention of diacritics has minimal influence on MT performance. To assess the complexity of diacritical systems, we propose six language-agnostic metrics, establishing a strong positive correlation with our model's performance.

[10] OnlyDia model at 5k as shown in Table D.3.

Limitations

For our machine translation experiments, we have limited our target language exclusively to English. Consequently, our findings may not be applicable to scenarios where the target language uses diacritics in its orthographic system. Moreover, the datasets used in this study are from religious and political domains, leading us to operate under the assumption that the texts are fully diacritized rather than partially. As such, this introduces a potential limitation to the generalizability of our results.

Ethics Statement

The datasets we employed in this study are derived from two publicly accessible sources: The Bibles and the European Parliament. We consciously chose not to collect or utilize data from any individual subjects to avoid privacy-related ethical issues.

Appendices

There are five sections in the appendix:

- Appendix A includes
  - Number of examples for Train/Dev/Test splits for African languages (Table A.1) and European languages (Table A.2).
  - Hyperparameters and software information for the models we train (Table A.3).
  - Set of characters and their diacritical variants for African languages (Table A.4) and European languages (Table A.5).
  - Classification of lexical and/or grammatical function for each European language (Table A.6).
- Appendix B includes implementation details of diacritics error rate (DER) and word error rate (WER) metrics for measuring the performance of diacritization.
- Appendix C includes bar plots to demonstrate the comparison between different model settings which are visualization attempts to approach our research questions:
  - BLEU scores
    - (**RQ1a.**) DiaMT vs. $\text{OnlyMT}_{\text{undia}}$ for African languages in Figure C.1 and for European languages in Figure C.2
    - (**RQ2.**) $\text{OnlyMT}_{\text{dia}}$ vs. $\text{OnlyMT}_{\text{undia}}$ for African languages in Figure C.3 and for European languages in Figure C.4
  - DER and WER
    - (**RQ1b.**) DiaMT vs. OnlyDia
      - DER for African languages in Figure C.5 and for European languages in Figure C.6
      - WER for African languages in Figure C.7 and for European languages in Figure C.8
- Appendix D includes values of metrics (BLEU, DER, WER) to measure the performance of MT and diacritization for all models given different languages at different train sizes; and the percentage change between two different models.
  - BLEU scores for every African language (Table D.1) and European language (Table D.2).
  - DER and WER for every African language (Table D.3) and European language (Table D.4).
- Appendix E includes
  - Implementation details of our proposed language-agnostic complexity metrics designed to evaluate the complexity of the diacritical system of any given language.
  - Correlation analysis of our proposed complexity metrics and diacritization performance metrics (DER, WER) for both African and European languages (Table E.3 and E.4).
  - The values of complexity metrics for all 55 included African and European languages at different train sizes (Table E.5 and E.6).

Table A.5: The base and diacritized forms occurred in the dataset of each included European language. Note that each of them may contain characters in other language (for example, in Spanish dataset, there can be French word) and therefore the base characters and variants may not be of that single language.

Lang.	Lexical	Grammatical	Citation
cs	vína (‘wine’), vina (‘guilt’)	-	(Berger, 2012; Kurzon, 2008; Wells, 2000)
da	hår (‘hair’), har (‘have’)	-	(Basbøll, 2005)
nl	-	to indicate stress in loan words as a question tag	(Köhnlein and Oostendorp, 2018)
et	mõla (‘twaddle’) - mõla (‘paddle’)	-	(Asu and Teras, 2009)
de	bar (‘bar’), bär (‘bear’)	-	(Labusch et al., 2023; Perea et al., 2022b)
el	φώς (‘man’), φῶς (‘light’)	-	(Protopapas, 2006)
es	mí (‘me’), mi (‘my’)	to indicate stress	(Klöter, 2011; Labusch et al., 2023; Perea et al., 2022b)
fi	käsi (‘hand’), kasi (‘eight’)	-	(Perea et al., 2022a)
fr	-	to indicate deletion of an adjacent letter; to provide a pronunciation guide	(Labusch et al., 2023)
hu	hat (‘six’), hát (‘back’)	-	(Siptár and Törkenczy, 2000)
it	dì (‘day’), di (‘preposition’)	to indicate stress	(Colombo and Sulpizio, 2021)
lt	šáuk, (‘shoot’), šaũk, (‘shout’)	-	(Subačius, 2008)
lv	māti (‘mother’), mati (‘hair’)	-	(Bond, 1978)
pl	ząbka (‘tooth’), ‘żabka’ (‘frog’)	to indicate nominative noun or instrumental noun	(Janicki and Herman, 2005)
pt	por (‘by’), pôr (‘to put’)	for nasalization; contraction of two consecutive vowels	(Mateus and d’Andrade, 2000)
ro	în (‘in’), in (‘linen’)	to indicate stress	(Gönczöl, 2020)
sk	väzy (‘ligaments’), vazy (‘vases’)	-	(Hanulíkova and Hamann, 2010)
sl	pes (‘dog’), peš (‘on foot’)	-	(Herrity, 2015)
sv	Fått (‘received’), rät (‘straight’)	-	(Riad, 2014)

Table A.6: Classification of the function(s) (lexical and/or grammatical) for each European language. For lexical function, we show minimal pairs where an alternation in diacritic changes the meaning to demonstrate that removing diacritic(s) can produce ambiguity. For Lithuania *(lt)*, Polish *(pl), and Swedish (sv)*, we show near minimal pairs. Both minimal pairs and near minimal pairs show that the undiacritized form poses ambiguity as there are more than one form to diacritize it. For grammatical function, we indicate the grammatical role(s) the diacritical system has in the language.

B Implementations of Diacritization Error Rate (DER) and Word Error Rate (WER)

In the field of diacritization system development, two primary methodologies emerge: sequence labeling and sequence-to-sequence modeling (Schlippe et al., 2008; Hamed and Zesch, 2017). In our research, we opt for the latter as our research question 1 (see Section 1 for details) requires the model to be able to perform both diacritization and machine translation tasks. However, employing sequence-to-sequence modeling presents challenges, particularly regarding alignment and potentially unequal input-output lengths (Alqahtani et al., 2019; Abandah and Abdel-Karim, 2020).

Previous studies employing encoder-decoder architectures for Arabic diacritization have leveraged Arabic linguistic rules to compute these metrics (Fadel et al., 2019; Qin et al., 2021; Thompson and Alshehri, 2022). To address the aforementioned issues, Thompson and Alshehri (2022) employ Arabic linguistic rules to constrain the decoder and guide the generation of subsequent tokens. However, the proposed decoding constraints cannot be directly applied, given that (1) the included 55 languages are non-Arabic (2) the potential for multiple diacritics to be attached to a single character in certain languages (see Table A.4).

Despite our comprehensive search, we were unable to locate implementation details for DER and WER in prior works that adopt a sequence-to-sequence approach (Fadel et al., 2019; Qin et al., 2021; Thompson and Alshehri, 2022; Mubarak et al., 2019). Therefore, we have developed our own DER and WER computation methods, as in Algorithms 1 and 2. Our approach adheres to the definitions of DER and WER established by Abandah et al. (2015).

In computing DER, we exclude words that exceed the length of the input sequence, while penalizing characters exceeding the length of a certain word, complying with DER's focus on character-level analysis. By restricting the comparison to characters within each word instead of directly comparing a predicted sequence to a gold standard sequence, we ensure a fairer evaluation. This approach maintains evaluation integrity when predictions align reasonably with the input, and prevents over-pessimistic assessments when deviations occur. Regarding WER, we penalize words surpassing the input sequence's length, reflecting WER's word-level focus.

Algorithm 1 Diacritization Error Rate (DER)

```
Require:
    Golds is a list of n gold standard sequences.
    Preds is a list of n post-processed predicted sequences (See Section 4.4 for details).
incorrect ← 0
correct ← 0
for i in [0, n − 1] do
    gold_words ← Golds[i].split(' ')
    pred_words ← Preds[i].split(' ')
    for j in [0, min(len(pred_words), len(gold_words)) − 1] do
        gold_word ← gold_words[j]
        pred_word ← pred_words[j]
        incorrect ← incorrect + abs(len(pred_word) − len(gold_word))
        for k in [0, min(len(pred_word), len(gold_word)) − 1] do
            if pred_word[k] == gold_word[k] then
                correct ← correct + 1
            else
                incorrect ← incorrect + 1
            end if
        end for
    end for
end for
DER ← incorrect/(incorrect + correct)
```

Algorithm 2 Word Error Rate (WER)

```
Require:
    Golds is a list of n gold standard sequences.
    Preds is a list of n post-processed predicted sequences (See Section 4.4 for details).
incorrect ← 0
correct ← 0
for i in [0, n − 1] do
    gold_words ← Golds[i].split(' ')
    pred_words ← Preds[i].split(' ')
    incorrect ← incorrect + abs(len(gold_words) − len(pred_words))
    for j in [0, min(len(pred_words), len(gold_words)) − 1] do
        if gold_words[j] == pred_words[j] then
            correct ← correct + 1
        else
            incorrect ← incorrect + 1
        end if
    end for
end for
WER ← incorrect/(incorrect + correct)
```

C Bar Plots

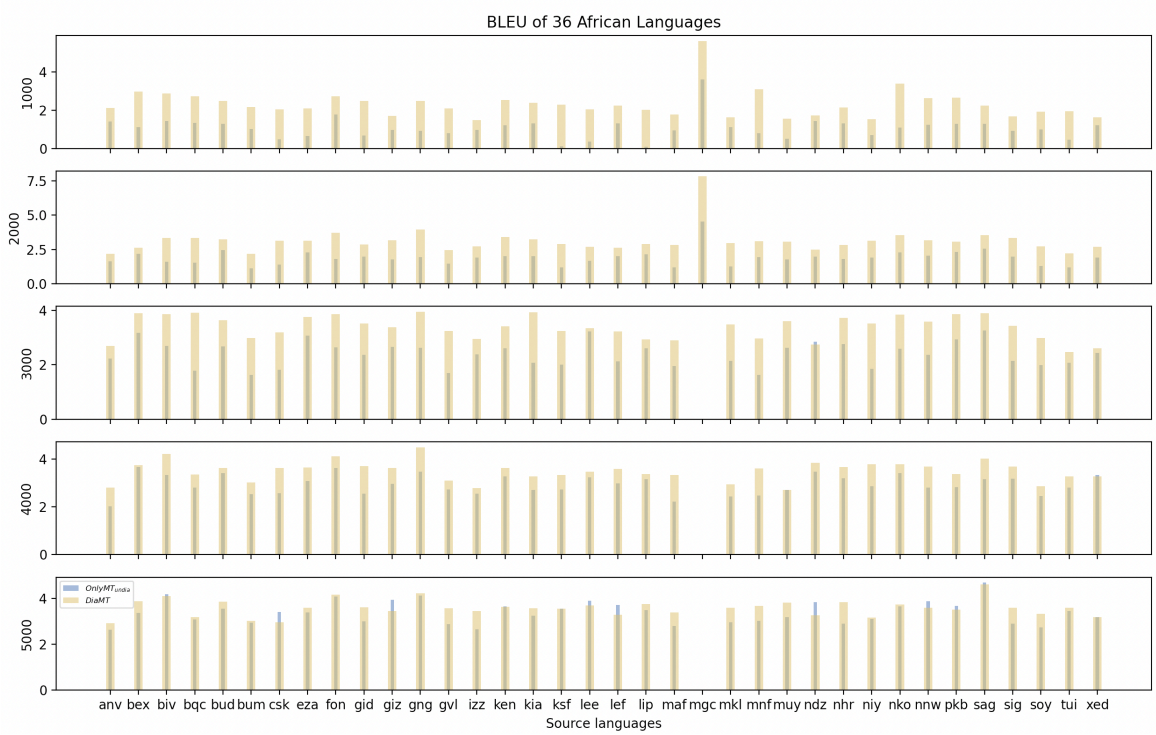

Figure C.1: BLEU comparison between DiaMT and OnlyMT$_{\text{undia}}$ for 36 African languages to English pairs.

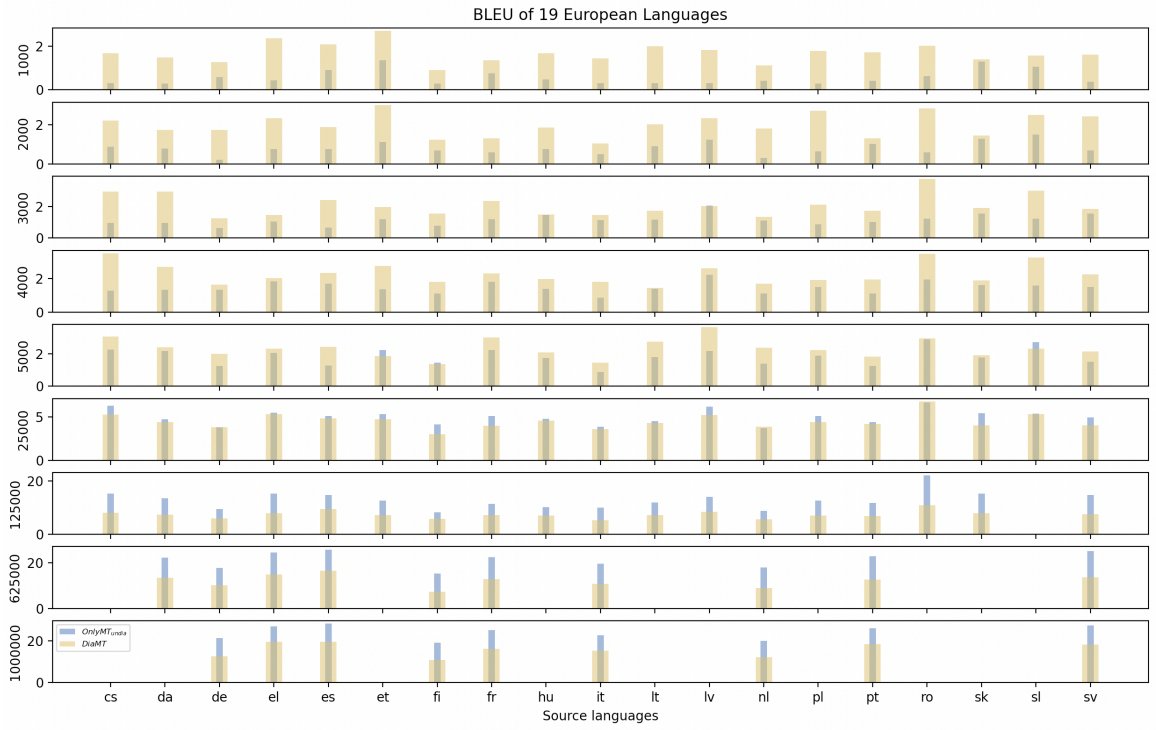

Figure C.2: BLEU comparison between DiaMT and OnlyMT$_{\text{undia}}$ for 19 European languages to English pairs.

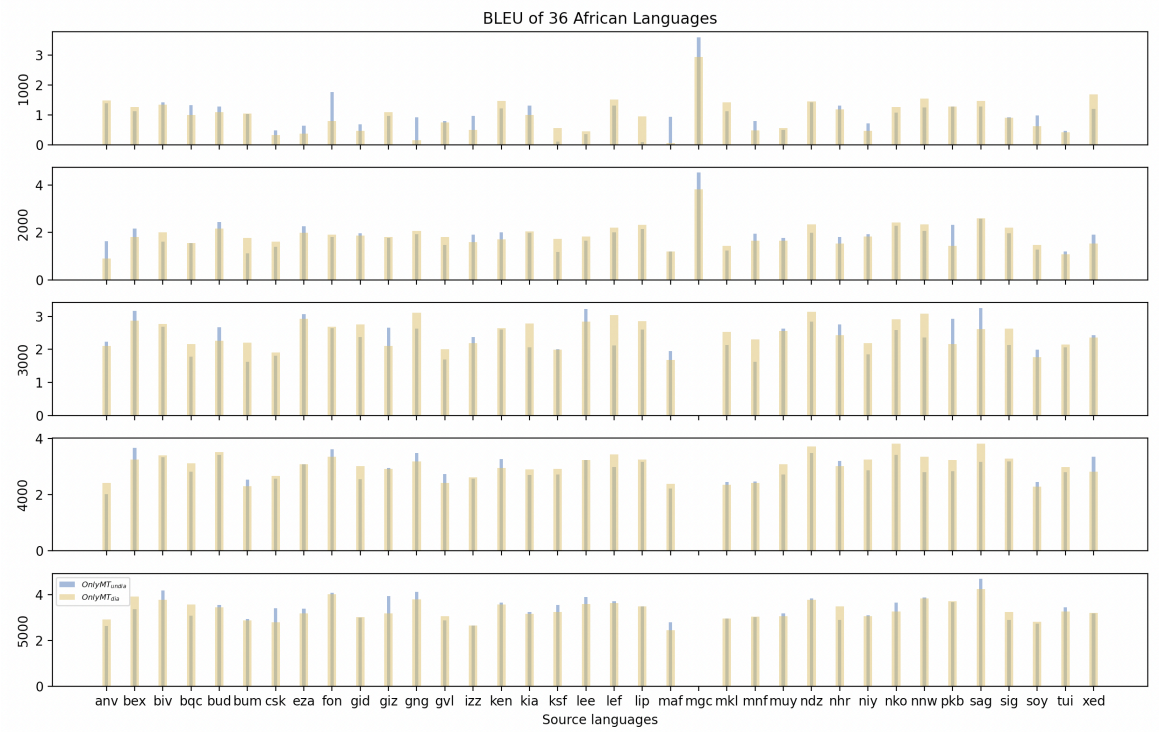

Figure C.3: BLEU comparison between $\text{OnlyMT}_{\text{undia}}$ and $\text{OnlyMT}_{\text{dia}}$ for 36 African languages to English pairs.

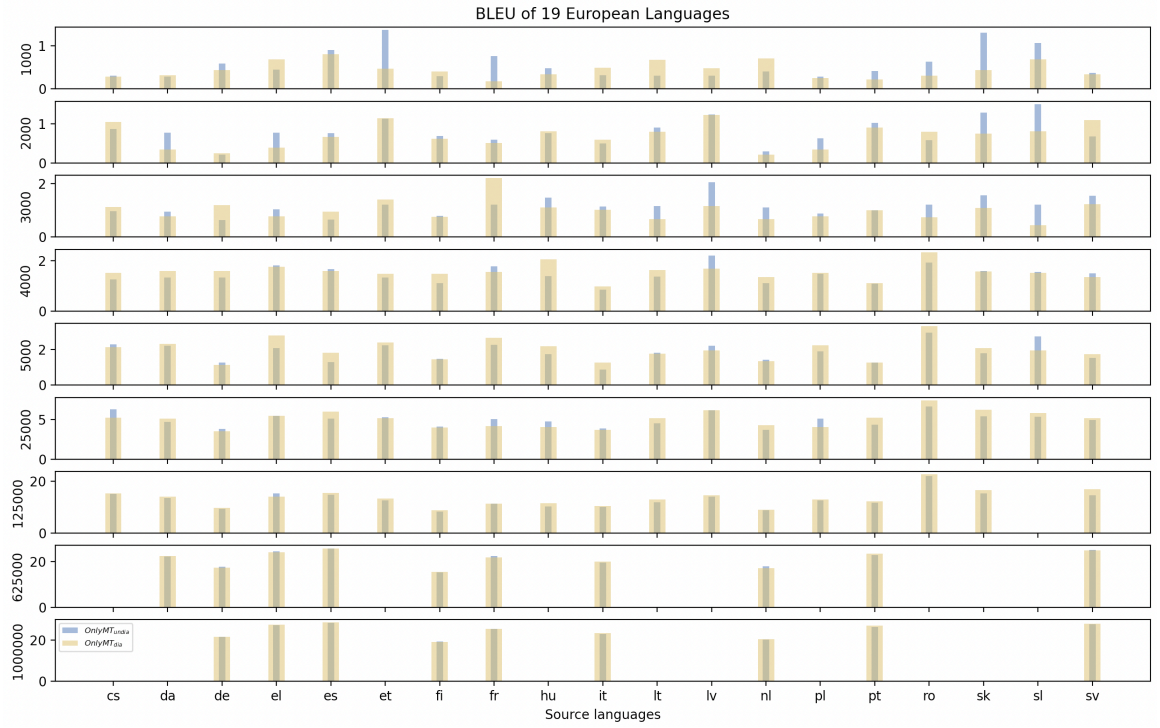

Figure C.4: BLEU comparison between $\text{OnlyMT}_{\text{undia}}$ and $\text{OnlyMT}_{\text{dia}}$ for 19 European languages to English pairs.

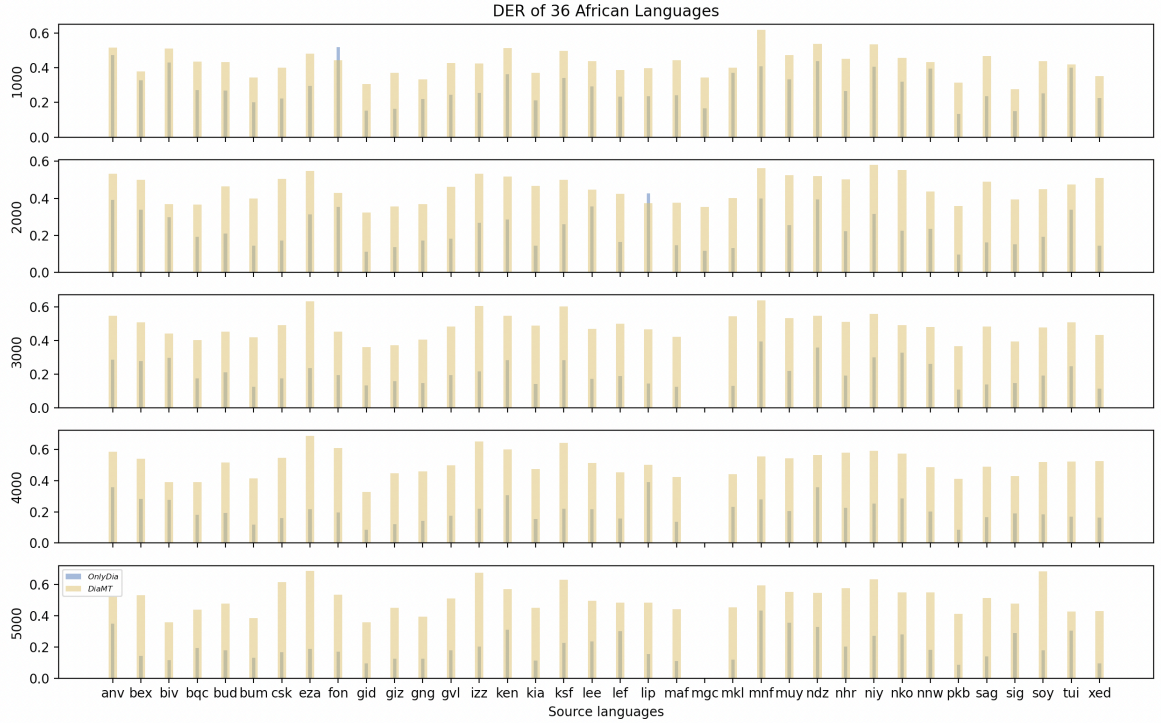

Figure C.5: DER comparison between OnlyDia and DiaMT for 36 African languages.

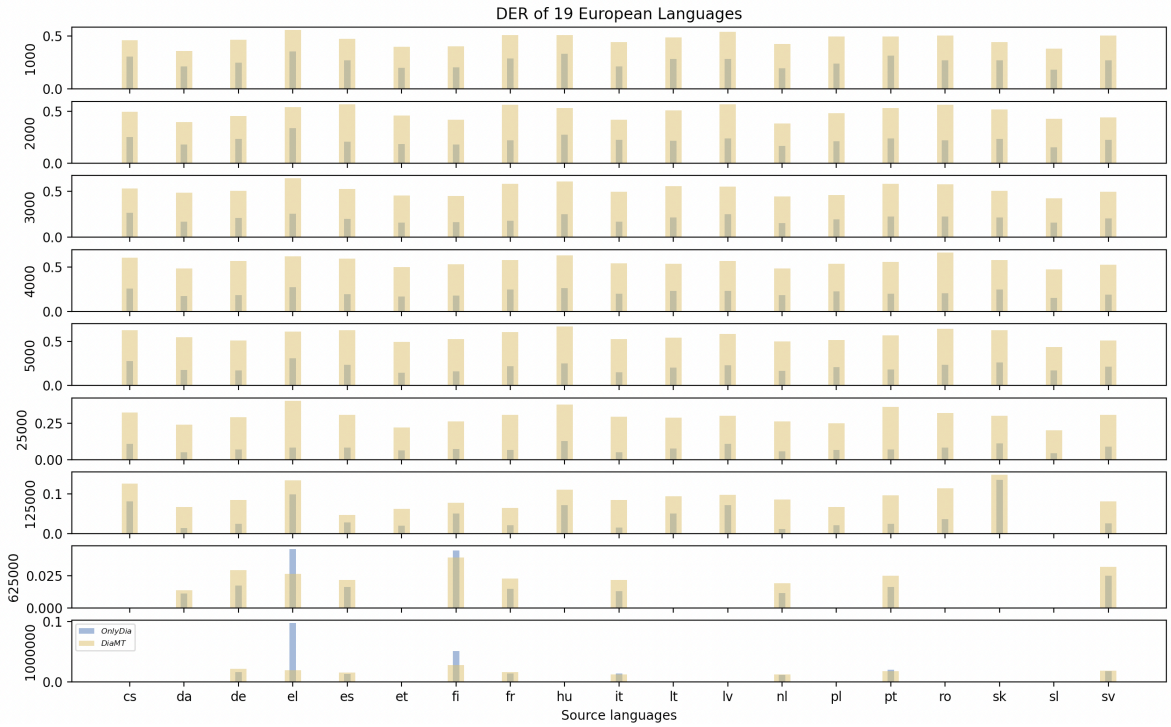

Figure C.6: DER comparison between OnlyDia and DiaMT for 19 European languages. Greek (*el*) and Finnish (*fi*) show significant performance gain after adding MT to form a multi-task setting at 1M train size.

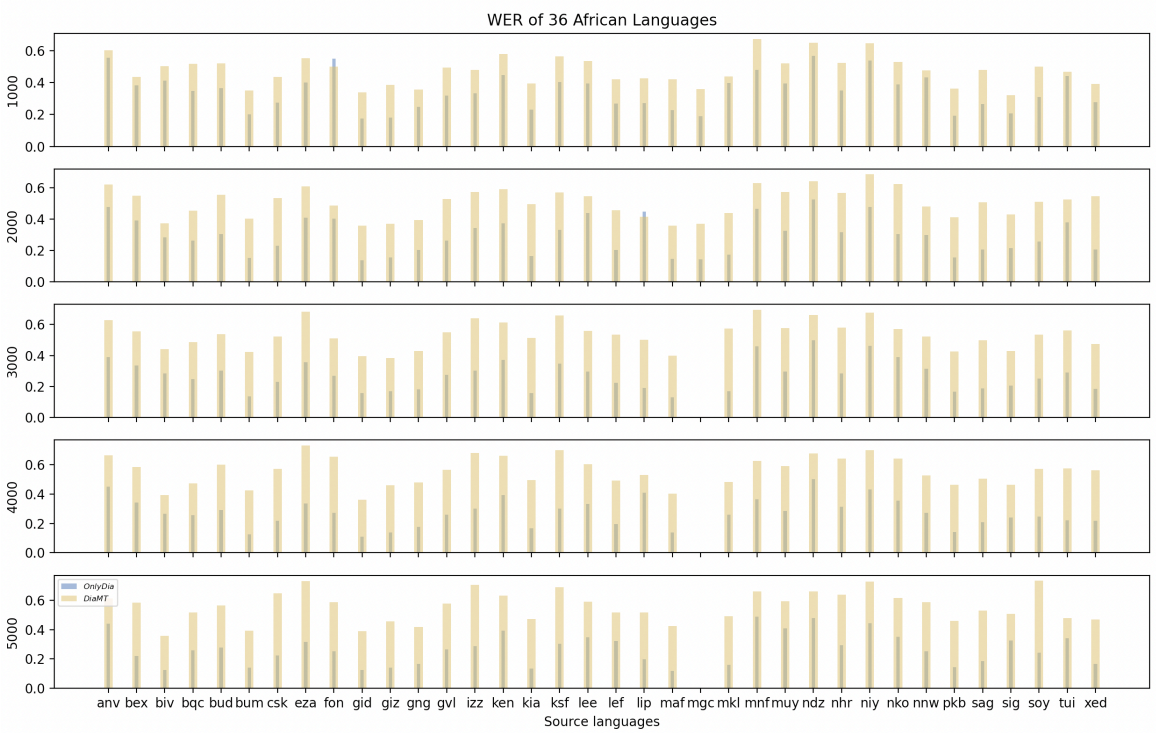

Figure C.7: WER comparison between OnlyDia and DiaMT for 36 African languages.

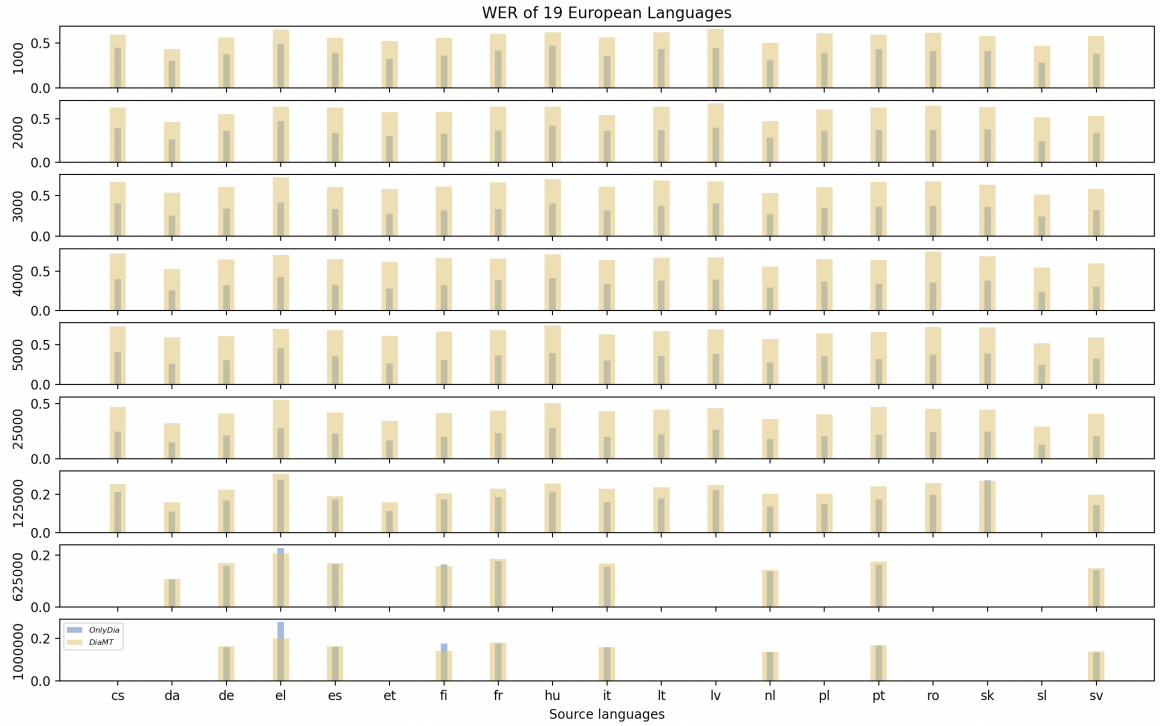

Figure C.8: WER comparison between OnlyDia and DiaMT for 19 European languages. Greek (*el*) and Finnish (*fi*) show significant performance gain after adding MT to form a multi-task setting at 1M train size.

D Performance Metrics

Table D.1: BLEU scores of 36 African languages in 5 train sizes produced by 3 models. The highest BLEU score out of the 3 models are boldfaced. DM, OM_u, OM_d are shorthands for DiaMT, $OnlyMT_{undia}$, and $OnlyMT_d$, respectively. pc(m1, m2) is the percentage change of model m1 over model m2. The higher the percentage change, the better the model m1 is compared to model m2.

Table D.1: BLEU scores of 36 African languages in 5 train sizes produced by 3 models. The highest BLEU score out of the 3 models are boldfaced. DM, OM_u, OM_d are shorthands for DiaMT, $OnlyMT_{undia}$, and $OnlyMT_d$, respectively. pc(m1, m2) is the percentage change of model m1 over model m2. The higher the percentage change, the better the model m1 is compared to model m2.

Table D.2: BLEU scores of 19 European languages in 9 train sizes produced by 3 models. The highest BLEU score out of the 3 models are boldfaced. DM, OM_u, OM_d are shorthands for DiaMT, $OnlyMT_{undia}$, and $OnlyMT_d$, respectively. pc(m1, m2) is the percentage change of model m1 over model m2. The higher the percentage change, the better the model m1 is compared to model m2.

Table D.4: DER and WER of 19 European languages in 9 train sizes produced by 2 models. The lowest DER and WER scores out of the 2 models are boldfaced. DM_D, OD_D, DM_W, OD_W are shorthands for $DiaMT_{DER}$, $OnlyDia_{DER}$, $DiaMT_{WER}$, and $OnlyDia_{WER}$, respectively. pc(m1, m2) is the percentage change of model m1 over model m2. The lower the percentage change, the better the model m1 is compared to model m2.

E Complexity Metrics

We propose two classes of complexity metrics to assess the complexity of the diacritical system of a given language. The first class is based on the ratio of diacritics and character/word/sentence. The second class is based on the entropy of combinations of diacritic(s) and characters, measuring from the perspective of probability distribution. For the first class, we propose diacritized character ratio (**DCR**), diacritized word ratio (**DWR**), diacritized base character ratio (**DBR**), and diacritized word sentence ratio (**DWSR**). For the second class, we propose average entropy of diacritics (**AED**), and weighted average entropy of diacritics (**WAED**). Their definition can be seen in Table E.1. An example corpus and the computation of values of complexity metrics is given in Table E.2.

Metric	**Definition**
DCR	Proportion of characters that carry diacritic(s) out of all characters.
DWR	Proportion of words with at least a character carrying diacritic(s) out of all words.
DBR	Average number of variants (including itself) of each base character.
DWSR	Average number of words with at least a character carrying diacritic(s) per sentence.
AED	Average entropy of the distributions of each base character's variant(s) and itself.
WAED	Weighted AED with weight being the proportion of the number of occurrence of each base character out of that of all base character(s).

Table E.1: Definitions of Proposed Complexity Metrics.

Corpus	Shë wants ân âpple. I drink coconut wätër for fun.
DCR	$\frac{5}{39} = 0.128$
DWR	$\frac{4}{10} = 0.4$
DBR	$\frac{5}{2} = 2.5$
DWSR	$\frac{4}{2} = 2$
P(X)	P(a):{a:0.25, â:0.5, ä:0.25} P(e):{e:0.33, ë:0.67}
H(P(X))	H(P(a)) = 1.05; H(P(e)) = 0.63
AED	$\frac{1}{2} \times H(P(a)) + \frac{1}{2} \times H(P(e)) = 0.845$
WAED	$\frac{4}{7} \times H(P(a)) + \frac{3}{7} \times H(P(e))$ = 0.875

Table E.2: An example of computing complexity metrics with a mock corpus where base characters are underlined. $P(\cdot)$ represents probability distribution. $H(\cdot)$ represents entropy.

In Table E.2, WAED is larger than AED because the total number of occurrences of the base character 'a' is larger than 'e' and therefore the weight ($\frac{4}{7}$) for its entropy is higher than that for 'e' ($\frac{3}{7}$) which draws the weighted average closer toward the entropy of 'a'. In contrast, AED gives even weight to each base character which is $\frac{1}{2}$ in this example and does not take frequency of each base character into consideration. WAED takes distribution of the language data into consideration when measuring the complexity of a diacritical system.

Table E.4: The Pearson (p), Spearman (s), and Kendall (k) correlation statistics and p value between complexity metrics (DCR, DWR, DBR, AED, WAED) and performance metrics (DER, WER) produced by OnlyDia model for European languages.

Table E.5: Complexity metrics for diacritical system of each African language at 5 train sizes. For a given language, a metric may occasionally have identical values throughout different train sizes because they are rounded to 3 digits.

Abstract

In the realm of Large Language Models (LLMs), the balance between instruction data quality and quantity is a focal point. Recognizing this, we introduce a self-guided methodology for LLMs to autonomously discern and select cherry samples from open-source datasets, effectively minimizing manual curation and potential cost for instruction tuning an LLM. Our key innovation, the Instruction-Following Difficulty (IFD) metric, emerges as a pivotal metric to identify discrepancies between a model's expected responses and its intrinsic generation capability. Through the application of IFD, cherry samples can be pinpointed, leading to a marked uptick in model training efficiency. Empirical validations on datasets like Alpaca and WizardLM underpin our findings; with a mere 10% of original data input, our strategy showcases improved results. This synthesis of self-guided cherry-picking and the IFD metric signifies a transformative leap in the instruction tuning of LLMs, promising both efficiency and resource-conscious advancements. Codes, data, and models are available.[1]

1 Introduction

Large Language Models (LLMs) have revolutionized the landscape of artificial intelligence (Touvron et al., 2023a,b; Penedo et al., 2023; Scao et al., 2022). Notable models such as GPT-3 (Brown et al., 2020) and GPT-4 (OpenAI, 2023) leverage extensive datasets and advanced training methodologies to exhibit high-level text understanding and generation capabilities (Liu et al., 2023, 2024b; Chen et al., 2023b; Sun et al., 2024; Liu et al., 2024a). Instruction tuning (Wei et al., 2022; Longpre et al., 2023) is a method employed to refine the performance of LLMs by providing specific guidelines or instructions during the model's training phase. It operates by supplying LLMs with explicit training instructions to produce the corresponding outputs that are more congruent with the desired ones (Xu et al., 2024). A well-formulated instruction or prompt provides essential contextual information, refining the model's capability to generate relevant and task-specific outputs (Taori et al., 2023; Ouyang et al., 2022).

Previously, instruction tuning was regarded as relying on amassing vast datasets (Khashabi et al., 2020; Ye et al., 2021; Wei et al., 2022; Wang et al., 2022). However, a seminal revelation from the LIMA (Zhou et al., 2023) highlights the art of instruction tuning: rather than a sheer volume of data, it's the quality of the data that dictates the model's performance. LIMA's findings emphasize that even a limited amount of manually curated, high-quality data can elevate the model's instruction-following capability. While it underscores the significance of data quality, the question of how to automatically identify high-quality data from a vast ocean of available datasets remains under investigation.

In our study, we introduce a novel approach for autonomously identifying the most impactful training samples, which we refer to as "cherry data", from extensive open-source datasets. These data samples are particularly effective in enhancing LLM instruction tuning. Central to our hypothesis is the idea that LLMs, through initial training with a small amount of instruction data, can inherently learn to discern and follow instructions, allowing them to estimate the difficulty of instruction data.

Our method involves a self-guided process that begins with familiarizing the model with a small subset of the dataset during the "Learning from Brief Experience" phase. This phase lays the groundwork for the subsequent "Evaluating Based on Experience" phase, where we introduce the Instruction-Following Difficulty (IFD) score. This

This work was done when Ming Li interned at Ping An Technology (Shenzhen) Co., Ltd., China.

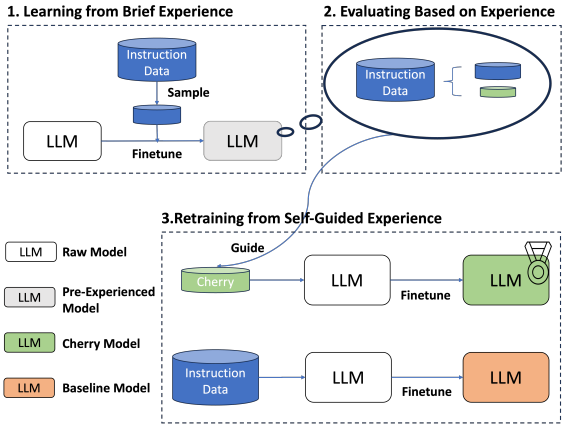

Figure 1: Overview of our proposed method.

metric evaluates how much help the instruction provides to the generation of the corresponding response, by comparing the loss in model responses with and without instructional context. The higher IFD score, indicating less instructional help, suggests a greater difficulty with instructions. On the contrary, the lower IFD score represents that the given instruction can directly benefit the language model largely even without further training, representing the easiness and necessity of the instruction. Thus in the final "Retraining from Self-Guided Experience" phase, we use data with relatively large IFD scores as the cherry data to train our model, resulting in what we term "cherry models". This methodology, which emphasizes data quality over quantity, differs markedly from existing techniques that rely on external models for data curation.

Extensive experimental results validate the efficacy of our method. By applying our methodology to the Alpaca and WizardLM instruction tuning datasets, our model outperforms the official Alpaca model with only approximately 5% data selected and outperforms the reimplemented WizardLM model with approximately 10% data selected. The key contributions of this paper:

- We propose a self-guided approach enabling models to autonomously select the "cherry data" from vast open-source datasets. This innovation minimizes manual curation and optimizes the use of existing data resources, reducing costs and streamlining training.
- We introduce the Instruction-Following Difficulty (IFD) score as a metric to measure how much help the instruction can provide to the generation of the corresponding response, revealing the model-specific difficulty of the given data sample. Using the IFD metric, we can pinpoint the data that is most helpful for a specific model.
- Backed by validation on training datasets like Alpaca and WizardLM, our strategy demonstrates enhanced outcomes with only 10% of the original data input, emphasizing our approach's efficiency and transformative impact.
- We provide a different model-specific view in measuring the difficulty of new instructions, which may benefit future instruction data generation work.

2 Methodology

As illustrated in Figure 1, our methodology is divided into three core phases: Learning from Brief Experience, Evaluating Based on Experience, and Retraining from Self-Guided Experience. The initial phase emphasizes equipping the model with a basic instruction-following capability. The subsequent phase introduces a novel metric to evaluate the instruction-following difficulty score of each sample based on the previously trained pre-experienced model. Finally, after obtaining difficulty scores in the target dataset, the cherry samples are selected to train our final model, which we call the cherry models.

2.1 Learning from Brief Experience

This phase aims to equip the initial model with a basic instruction-following capability by forcing the model to first experience a subset of the target dataset. Specifically, for the initial full target dataset, D_0 contains n triplets $x = (Instruction, [Input], Answer)$, we define the string $Question = map(Instruction, [Input])$ as the complete instruction. The map function is aligned with the original target dataset. Each word in $Question(Q)$ and $Answer(A)$ is denoted as x_i^Q and x_i^A respectively. Let LLM_θ denote the LLM we use and θ represent the weight of LLMs, specifically, θ_0 represents the pre-trained base LLM model. Then the instruction embeddings for each sample x_j are obtained by:

$$[h_{j,1}^Q, ..h_{j,m}^Q] = LLM_{\theta_0}(w_{j,1}^Q, ..w_{j,m}^Q) \quad (1)$$

$$h_j^Q = \frac{\sum_{i=1}^{m} h_{j,i}^Q}{m} \quad (2)$$

where $w_{j,i}^Q$ represents the i_{th} word of $Question$ strings of sample j and $h_{j,i}^Q$ represents its corresponding last hidden states.

To ensure the diversity of instructions exposed to the initial model, the basic clustering technique K-Means on these instruction embeddings is utilized. Motivated by LIMA's finding, we try to make this experience process as brief as possible by sampling only a few instances in each cluster which we call pre-experienced samples. Specifically, we generate 100 clusters on instruction embeddings and sample 10 instances in each cluster. Then the initial model is trained for only 1 epoch with these samples to obtain our brief pre-experienced model.

2.2 Evaluating Based on Experience

In this stage, we introduce the Instruction-Following Difficulty (IFD) score, a metric devised to evaluate the difficulty each instructional sample presents. Our primary motivation, adhering to the goal of minimizing cross-entropy loss in model training, guides the use of this metric. It specifically targets gauging the impact of training data by isolating the instructional component's influence from that of the answer. To achieve this, we employ a method that compares the loss when the model generates responses both with and without the context provided by instruction. This comparison is crucial as it forms the basis of the IFD score, effectively quantifying the extent to which instruction aids in response generation.

In the instruction-tuning process, the loss of a sample pair (Q, A) is calculated by continuously predicting the next tokens given the instruction Q and their proceeding words:

$$L_\theta(A|Q) = -\frac{1}{N}\sum_{i=1}^{N} \log P(w_i^A|Q, w_1^A, w_2^A, \ldots, w_{i-1}^A; \theta) \tag{3}$$

where N is the number of words of the ground-truth answer A. We denote this averaged cross-entropy loss as the **Conditioned Answer Score** $s_\theta(A|Q) = L_\theta(A|Q)$. This metric evaluates the model's capability to generate appropriate responses based on provided instructions. It measures the extent to which the model's output aligns with both the instruction and the corresponding correct answer.

However, a higher $s_\theta(A|Q)$ does not mean a harder instruction to follow, it may be caused by the inherent characteristic of string A itself. In the pre-LLM era, when models are required to learn both the knowledge and instruction-following ability during finetuning, it is reasonable to use $s_\theta(A|Q)$ as an indicator for the difficulty of a sample. However, things change a little for current LLMs, which have learned most of the knowledge in the pre-training phase and only need to learn to align and follow the instructions. Thus to estimate the difficulty of following instructions of a given sample, we introduce the **Direct Answer Score** $s_\theta(A)$:

$$s_\theta(A) = -\frac{1}{N}\sum_{i=1}^{N} \log P(w_i^A|w_1^A, \ldots, w_{i-1}^A; \theta). \tag{4}$$

which measures LLM's ability to generate this answer alone. It gauges the inherent difficulty or challenge posed by the answer in isolation, without the contextual guidance from its corresponding instruction. A higher direct answer score may suggest that the answer is inherently more challenging or intricate for the model to generate.

Further, analyzing the balance between a sample's inherent challenge and the model's capabilities in following it sheds light on the intricacies of estimating the difficulty of the instruction of a given sample. Specifically, we try to estimate the **Instruction-Following Difficulty (IFD)** scores $\text{IFD}_\theta(Q, A)$ on following instruction of a given (Q, A) pairs by calculating the ratio between $s_\theta(A)$ and $s_\theta(A|Q)$:

$$\text{IFD}_\theta(Q, A) = \frac{s_\theta(A|Q)}{s_\theta(A)} \tag{5}$$

By utilizing this metric, the influence of LLM's intrinsic ability to fit the answer string is partially alleviated. The score measures the degree to which given instruction benefits the alignment of the corresponding response. High IFD scores infer the inability of the model to align responses to the given corresponding instructions, which in turn indicates the difficulty of an instruction. It is worth noting that this $\text{IFD}_\theta(Q, A)$ is a model-specific value, and we use our pre-experienced model to obtain all these values in the target dataset.

To further filter out the sample whose instruction is misaligned with its response, a threshold of 1 is set. Typically, the Conditioned Answer Score is always smaller than the Direct Answer Score due to the intrinsic nature of the next token prediction: With the context given, the prediction for the latter tokens should be easier. Thus if the IFD score is greater than 1, the Conditioned Answer Score is even larger than the Direct Answer Score, which means the given instruction provides no useful context for the prediction of the response. In this situa-

tion, we think there exists a misalignment between the instruction and the corresponding response.

Although our experiments reveal that learning from brief experiences is important, it makes the whole pipeline complicated and efficient. However, Superfiltering (Li et al., 2024b) expands the use of IFD scores and shows that (1) Good prompting can relieve the burden of training a pre-experienced model; (2) The IFD scores calculated by weak language models are consistent with strong models, making it possible to utilize small models for filtering, further pushing forward the efficiency of data filtering for instruction tuning.

3 Experimental Setup

3.1 Datasets

Training Datasets The Alpaca dataset (Taori et al., 2023) encompasses 52002 instruction-following samples. Developed using the self-instruct (Wang et al., 2023b) approach with text-davinci-003. Though initially competitive, its dependence on text-davinci-003 posed data quality concerns. WizardLM dataset (Xu et al., 2023) leverages the Evol-Instruct algorithm to improve the quality of instruction data. The incorporation of ChatGPT during the reformulation guarantees high fidelity of data. We utilize the WizardLM70K for our experiment.

Test Datasets To ensure comprehensive and unbiased assessment, we employed 5 diverse test sets: Vicuna (Chiang et al., 2023), Koala (Vu et al., 2023), WizardLM (Xu et al., 2023), Self-instruct (Wang et al., 2023b), and LIMA (Zhou et al., 2023). These test sets contain approximately 1000 human curated instructions, open-domain or closed-domain for different tasks from different sources. Among them, Vicuna and WizardLM further provide the specific sub-category for each instruction, making it possible for in-depth analysis.

3.2 Implementation Details

For experiments on the LLaMA-7B pre-trained model, our training configuration aligns with the original Alpaca and WizardLM, by utilizing the the Alpaca codebase[2]. For experiments on LLaMA2-7B and LLaMA2-13B models, we utilize the Vicuna codebase[3]. The detailed training configuration can be found in Appendix A.

3.3 Evaluation Metrics

3.3.1 Pair-wise Comparison

Evaluating the instruction-following capabilities of LLMs is challenging. Extensive research is still dedicated to creating automated evaluation metrics for LLMs (Chang et al., 2023) since human evaluation is both labor-intensive and potentially influenced by subjective biases. Leveraging the recent advancements in independent LLM evaluations (Zheng et al., 2023; Chiang et al., 2023; Li et al., 2023b), we utilize GPT4 and ChatGPT for comparative evaluations. Specifically, for each instruction in the test dataset, models that need to be compared are prompted to generate responses respectively. Then an API model, either GPT4 or ChatGPT, assigns scores for their responses. The model is regarded to be better in this dataset only if its answer is preferred by the judging model.

In the evaluation, each model's response is rated by the judge on a scale from 1 to 10, reflecting attributes like relevance and accuracy. To further address the positional bias (Ko et al., 2020; Wang et al., 2023a), we send the responses of two models to the judge twice with different orders and compare their scores. Thus we define one model to be seen as winning only if it does not lose in both the ordering[4], specifically:

- **Wins:** outperforms in both or wins in one and ties in the other.
- **Tie:** ties in both or wins in one and loses in the other.
- **Loses:** lags in both or ties in one and loses in the other.

3.3.2 Benchmarks

The performances on two recently popular benchmarks for LLMs are also provided: Huggingface Open LLM Leaderboard and AlpacaEval Leaderboard. Huggingface Open LLM Leaderboard evaluates LLMs using (Gao et al., 2021), a unified framework to test generative language models on a large number of different evaluation tasks, on 4 key benchmarks including ARC (Clark et al., 2018), HellaSwag (Zellers et al., 2019), MMLU (Hendrycks et al., 2021) and TruthfulQA (Lin et al., 2022). AlpacaEval Leaderboard provides an LLM-based automatic evaluation based on AlpacaFarm (Dubois et al., 2023) evaluation set, in which the model responses are compared with responses of Davinci003 by GPT4.

[4] Code, prompt, and testing dataset are provided: https://github.com/tianyi-lab/Cherry_LLM

3.3.3 Human Evaluation

To better illustrate the efficacy of our method, further human evaluation is conducted. Specifically, we randomly sampled 20 instructions from each test set to generate a new random set containing 100 instructions in total. Then 3 human participants are asked to compare the responses generated by the models to be compared. For each comparison, 3 options are given (Win, Tie, and Loss) and the final results are determined by the majority voting of the participants.

4 Experimental Results

4.1 Main Results

In this section, we first present our primary **pairwise evaluation results** in Figure 2. (a) our model trained with only approximately 5% of the original Alpaca data beats the Alpaca model trained with full data. (b) our model trained with only approximately 10% of the original WizardLM data beats the reimplemented WizardLM model under the same training configuration which is described in the Implementation Details.

Moreover, we craft subsets containing the top 5%, 10%, 15%, and 20% of the training datasets to train models, enabling us to investigate the performance changes. As shown in Figure 3, we draw the overall winning rate changes across the data growth, which is calculated as (Num(Win)−Num(Lose))/Num(All) +1, providing a direct indicator on the comparison with the full-data trained models. A consistent observation across both datasets is that with merely 10% of selectively chosen data, our models manage to exceed the results of models trained on the full dataset. These findings not only highlight the efficiency of our data selection strategy but also underscore the potential of training powerful models with significantly reduced data requirements. By validating our approach on the renowned Alpaca dataset and the more intricate WizardLM dataset, the wide applicability and robustness of our proposed method are highlighted.

The comparison between our cherry models with baseline models on **Huggingface Open LLM Leaderboard and AlpacaEval Leaderboard** are presented in Table 1 where we can see our cherry model using 5% Alpaca data outperforms the official Alpaca on both benchmarks, our cherry model using 10% WizardLM data has a close performance compared with our re-implemented WizardLM.

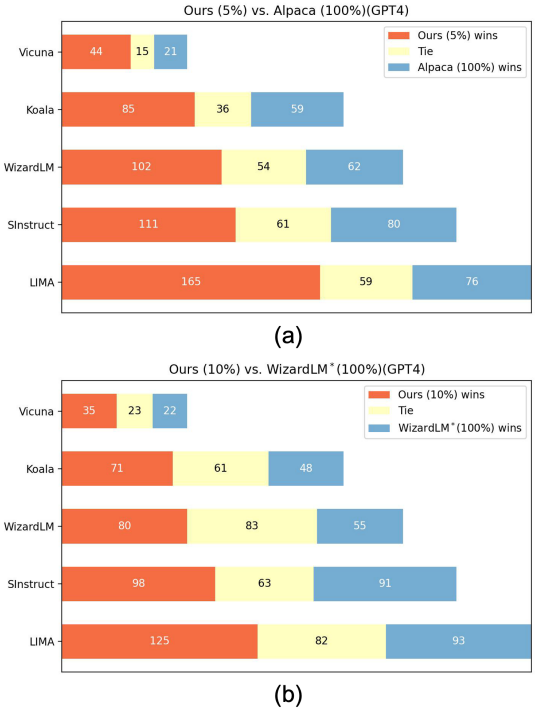

Figure 2: Comparing our models trained on selected data with full data. (a) Comparison between our model with 5% Alpaca data and the official Alpaca model. (b) Comparison between our model with 10% WizardLM data and the reimplemented WizardLM model. Both (a) and (b) use GPT4 as the judge. Each horizontal bar represents a comparison in a specific test set.

These results further showcase the effectiveness of our automatically selected data.

Moreover, the **human evaluation** results also showcase the usefulness of our method. When comparing the Cherry Alpaca (5%) and the Alpaca (100%), there are 49/100 wins for our cherry alpaca, 25/100 ties, and 26/100 losses. When comparing the Cherry WizardLM (10%) and the reimplemented WizardLM (100%), there are 37/100 wins for our Cherry WizardLM, 32/100 ties, and 31/100 losses.

4.2 Ablation on Data Selection Mechanism

In this section, we perform ablation studies comparing our method with other data selection mechanisms. The results are presented in Figure 4, and the evaluation is based on ChatGPT as the judge on all 5 test datasets. Moreover, the ablation results on the Open LLM Leaderboard and human evaluation are in Appendix B.

4.2.1 Data Randomly Selected

We train various LLaMA-7B models using randomly chosen data and compare their performance

	Huggingface Open LLM Leaderboard					AlpacaEval
	Average	ARC	HellaSwag	MMLU	TruthfulQA	AlpacaEval
Official Alpaca	50.21	42.65	76.91	41.73	39.55	26.46
Ours (5% Alpaca)	52.06	53.92	79.49	36.51	38.33	34.74
Reimplemented WizardLM*	52.79	53.07	77.44	37.75	42.90	61.99
Ours (10% WizardLM)	51.59	52.90	78.95	33.08	41.41	61.44

Table 1: The comparison of performance on Huggingface Open LLM Leaderboard and AlpacaEval Leaderboard.

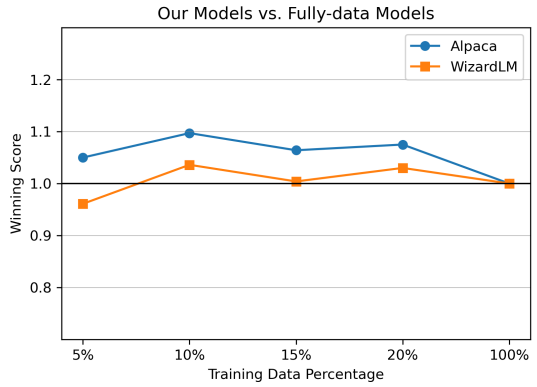

Figure 3: The winning score changes over data growth by comparing our models with full-data models. The winning score is calculated as (Num(Win)−Num(Lose))/Num(All) +1. The Number of Wins, Losses, and All are calculated across all five test sets we used. When the value is higher than 1.0, it means this model performs better than the comparison.

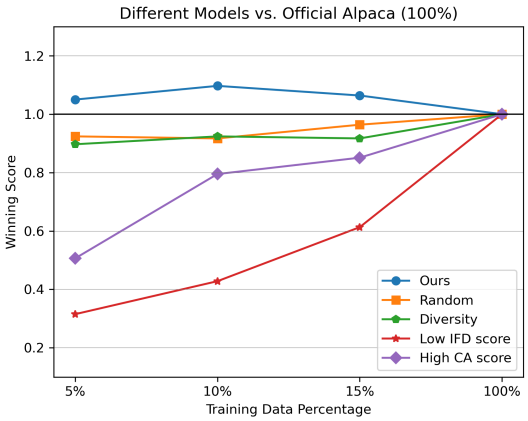

Figure 4: The overall winning score changes by comparing models using different data selection strategies with the official Alpaca model.

with the model trained with full data. As shown in Figure 4 (labeled as *Random*), models trained on 5%, 10%, or 15% random data consistently underperformed against the official Alpaca model. Notably, with an equivalent amount of data, our model surpasses the performance of models using randomly selected data, underlining our method's superiority.

4.2.2 Data with Diversity

In this experiment, we train a series of models only considering the diversity of the data samples. Specifically, we utilize the K-means algorithm for the clustering, and then sample data from each cluster. It is a direct baseline for the situation where only the diversity of data is considered. As illustrated in Figure 4 (labeled as *Diversity*), these models render subpar performance and are similar to the random trained models. This result shows that filtering data by only diversity is not enough for instruction tuning.

4.2.3 Data with Low IFD Score

In this experiment, we aim to further underscore the efficacy of our proposed IFD score. We train models using data chosen based on low IFD scores on the pre-experienced model, a direct antithesis to our primary experimental setting. As illustrated in Figure 4 (labeled as *Low IFD score*), models trained using low IFD scores obtain the least performance compared with all the methods. This observation highlights the prowess of our metric in sifting through high-quality data: a higher score consistently yields superior results, while a lower score deteriorates the model's intrinsic performance. This experiment directly showcases the consistent relationship between the performance and the IFD score values.

4.2.4 Data with High CA Scores

For this comparison, we train models on data selected by higher Conditioned Answer scores which is **equivalent to the loss or perplexity**, and is a commonly accepted baseline. As Figure 4 (labeled as *High CA score*) elucidates, models in this group trail the official Alpaca model significantly. The salient difference between these models and ours rests on the elimination of Direct Answer scores. In models relying solely on CA scores, the underlying comprehension of the pre-trained LLM towards original answer texts isn't factored in, rendering high CA scores ineffective in gauging the intricate nuances of the instruction following.

4.3 Ablation on Pre-Experienced Data

4.3.1 Number of Pre-Experience Data

Following the findings from LIMA that 1000 high-quality samples are enough to train a reasonably good model, we set the amount of data used for our pre-experienced model as 1000. However, it is still under-investigated how many data samples are required to equip the model with basic instruction-following ability. Thus this section analyzes the necessity of employing pre-experience models and how the number of pre-experienced data affects the final performance of our cherry models. For these comparisons, we conduct the experiments where 0, 100, 300, and 500 pre-experienced samples are utilized to train the pre-experienced models. Using 0 pre-experienced samples represents direct using the initial raw model as the pre-experienced model. We calculate the IFD scores from these different pre-experienced models and select the top 5%, 10%, and 15% samples for training while keeping other experimental conditions constant.

As shown in Figure 5, when no pre-experienced model is utilized, the corresponding cherry models have the least performance. However, even in the absence of a pre-experienced model, our IFD score remains effective in identifying the good training data subset as it outperforms the Alpaca model when using 10% of the data. When 100 samples are utilized, the corresponding cherry models are slightly better than no samples used but with a similar trend, which indicates that 100 samples are not enough for the model to acquire the basic instruction-following ability. When adding the number of pre-experienced samples to 300, a distinct performance gain is discovered, and further addition of samples does not make the performance of corresponding cherry models better. We hypothesize this is when the model is equipped with the basic instruction-following capability.

4.3.2 Distribution of Pre-Experience Data

To better illustrate what distribution of data is required in the pre-experience process, extensive experiments are conducted to consider choosing data by "Difficulty", "Diversity" and "Random". In the "Difficulty" setting, we select 1000 pre-experienced samples by calculating the IFD scores based on the initial raw model. In the "Diversity" setting, we select 1000 data by implementing the K-means algorithm. In the "Random" setting, we directly select pre-experienced data randomly. After obtaining these data samples with different distributions, pre-experienced models are trained for selecting further cherry data. The performance of using 5%, 10%, and 15% cherry data compared with the Alpaca model is shown in Table 2. Comparing random selection and data diversity and instruction difficulty, they all surpass the Alpaca model and are comparable to each other, indicating the effectiveness of both strategies and further proving that our IFD metric is robust across different pre-experienced models. This experiment further illustrates that what matters is this pre-experience process, rather than the sampling strategies for this process.

	5%	10%	15%	100%
Difficulty (1000)	1.057	1.072	1.096	1
Diversity (1000)	1.050	1.097	1.064	1
Random (1000)	1.007	1.047	1.077	1

Table 2: The overall winning score changes by comparing models with different strategies of selecting pre-experienced samples with the official Alpaca model, utilizing ChatGPT.

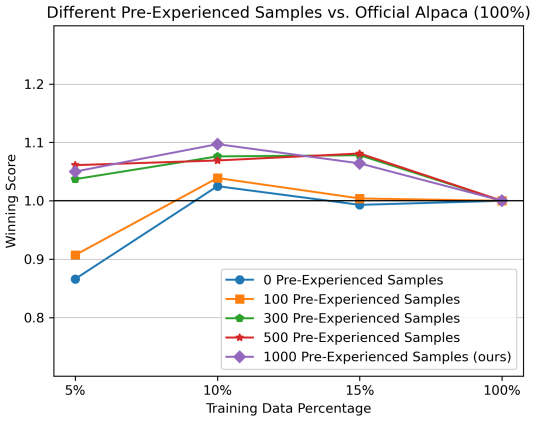

Figure 5: The overall winning score changes by comparing models with different numbers of pre-experienced samples with the official Alpaca model.

4.4 Results on LLaMA2 Models

In this section, experiments on newer LLaMA2-7B and LLaMA2-13B models are conducted as shown in Table 3. In these experiments, the IFD score of each sample is calculated directly based on the corresponding LLaMA2 pre-trained models by using prompts from Vicuna (Chiang et al., 2023). On both LLaMA2-7B and LLaMA2-13B models, our cherry models trained with much less data outperform the models trained with original full data. These experimental results illustrate the consistent advantages of our method and further verify the generalizability of our method.

	Huggingface Open LLM Leaderboard					AlpacaEval
	Average	ARC	HellaSwag	MMLU	TruthfulQA	AlpacaEval
Alpaca llama2 7b	55.25	54.35	78.65	47.02	40.98	27.75

5 Cherry Data Characteristics

5.1 Distribution Characteristics

In this segment, our focus is on understanding the distributional properties of the cherry data within the original dataset. Specifically, we first compute the embedding of each instruction in the Alpaca dataset and employ t-SNE for dimensionality reduction, mapping high-dimensional embeddings to 2D space. The visualized vectors, color-coded based on the top or least 5% difficulty ratios, are showcased in Figure 6. Contrary to conventional beliefs, our cherry data isn't uniformly scattered. Instead, clear boundaries exist between samples of high and low difficulty, challenging prior assumptions that selected data should span the entire instruction spectrum and maximize diversity.

To delve deeper into the distributional intricacies of instruction embeddings, the clusters with dense high IFD scores and clusters with dense low IFD scores are manually examined. Clusters dominated by low IFD score samples are replete with rudimentary tasks like editing punctuation, words, or sentences. In contrast, high IFD score clusters are typified by deeper, more intricate tasks such as storytelling or elucidation of phenomena. We posit that these in-depth tasks are paramount for aligning large language models, compelling them to rearrange and access their intrinsic knowledge repositories. Our methodology lends partial credence to this hypothesis, leaving room for further exploration.

5.2 Pattern Characteristics

To better understand the pattern characteristics of the selected cherry data, we further utilize the Berkeley Neural Parser to discern the verb-noun structure within the instruction of each data sample. This analytical approach enables us to identify the main verb and its direct noun object in each instruction, providing a direct insight into what kind of instructions are prone to be assigned with higher

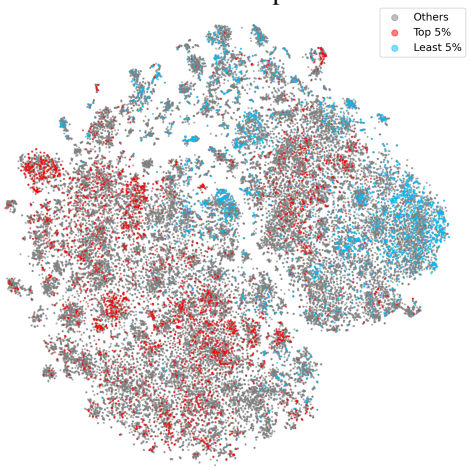

Figure 6: Visualization using t-SNE on instruction embeddings from the Alpaca dataset. Red points represent samples with the top 5% IFD scores and Blue points represent samples with the least 5% IFD scores.

IFD scores or lower IFD scores. This experiment is conducted based on the Alpaca data, the top 10 occurred verb-noun pairs from the top 5% IFD scores data and the least 5% IFD scores data are shown in Table 4.

From this experiment, a clear discrepancy is revealed between the pattern characteristics of high-IFD data and low-IFD data. The high-IFD data mainly involves creative and complex instructions like "write story", "generate list", and "explain concept", which require a lot of creativity, thinking skills, and deep understanding. On the contrary, the low-IFD data are more about following rules and need less creativity, showing a wide range in how much thinking and creativity different tasks demand from language models. As a result, the reason why IFD is a valid metric for data filtering can be summarized by its ability to find the instructions that need more creativity and deep understanding.

6 Related Work

6.1 Data-driven Instruction Tuning

Previous instruction tuning collections are typically handcrafted or task-related (Khashabi et al., 2020;

Top 5% IFD			Lease 5% IFD

Table 4: The top 10 occurred verb-noun pairs from the top 5% IFD scores data and the least 5% IFD scores data. Instructions that require creativity, thinking skills, and deep understanding tend to be assigned with higher IFD scores while instructions that are more about following rules and need less creativity tend to have lower scores.

Ye et al., 2021; Wei et al., 2022; Wang et al., 2022; Du et al., 2022; Honovich et al., 2023), (Wang et al., 2023b) utilized GPT3 (Brown et al., 2020) to generate 52k distinct instructions, paving the way to generating instruction data set by distilling from teacher models (Xu et al., 2024). After the release of Meta LLaMA(Touvron et al., 2023a), the world witnessed a surge of open-sourced instruction tuning datasets and LLMs(Taori et al., 2023; Chiang et al., 2023; Xu et al., 2023; Ye et al., 2023; Ding et al., 2023; Li et al., 2023a, 2024a).

6.2 Coreset Selection

Coreset selection is pivotal in machine learning, aimed at identifying a representative subset of data points to expedite learning in various models. This approach finds its effectiveness in SVM learning (Tsang et al., 2005), K-means (Har-Peled and Kushal, 2005), and logistic regression (Munteanu et al., 2018). In neural network training, recent advancements, such as those by Toneva et al. (2018), explore the dynamics of data point utility during training. They find that points infrequently forgotten have minimal impact on final model accuracy. Paul et al. (2021) demonstrate that expected loss gradient norm scores averaged over various weight initializations, effectively prune training data without significantly compromising accuracy. Mindermann et al. (2022) use Bayesian probability theory to estimate the individual impact of training points on holdout loss, refining training efficiency.

6.3 Instruction Data Selection

Though consensus has been made that "quality is all you need" (Touvron et al., 2023b; Zhou et al., 2023) for instruction tuning, finding high-quality data other than through human curation is still an under-explored topic. Instruction Mining (Cao et al., 2023) evaluates various indicators and applies a statistical regression model for data selection by training numerous models. In contrast, ALPAGASUS (Chen et al., 2023a) utilizes an external, fully-trained LLM (ChatGPT) to score each sample. While effective, this approach may neglect the intrinsic abilities of the base model, relying excessively on external models. Our work aims to develop a methodology utilizing the representation feature of the target model to identify high-quality data for instruction tuning, advancing the field with a more simple and efficient approach.

6.4 Pointwise Mutual Information

IFD 's concept is related to Pointwise Mutual Information (PMI), a widely used metric in NLP for assessing word pair associations and contextual relevance. Both IFD and PMI aim to evaluate correlations between elements, such as questions and answers, despite employing distinct methodologies. For instance, Holtzman et al. (2021) leverage PMI to manage surface form competition in generative language models. They employ PMI to assess the alignment between responses and posed questions, similar to IFD's role in assessing question-answer interactions in instructional data. Wiegreffe et al. (2023) further deepens the understanding of PMI by proposing methods to increase the probability mass of answer choices. And numerous other PMI applications concentrate on the dialogue task (Mou et al., 2016; Zhou et al., 2019). These varied applications underscore PMI's contributions to advancing natural language processing, offering valuable context for our IFD metric.

7 Conclusion

Our study illuminates the potential of harnessing the innate capabilities of LLMs for selecting high-quality instruction tuning data that fit the model. Through our innovative self-guided approach, LLMs demonstrate the ability to discern and cherry-pick the most pertinent data samples. Central to our methodology is the Instruction-Following Difficulty score, a novel metric adept at gauging the nuanced differences between a model's autonomous outputs and expected responses. Our findings not only emphasize the importance of data quality over quantity but also underscore the potential for cost-effective LLM training.

Limitation

The main limitation of this method is the inconvenience of training the pre-experienced model. The concept of the Instruction-Following Difficulty score proposed by us is simple and effective, while the inconvenient pre-experienced phase makes it hard to directly put our method into usage in real-world scenarios. Though experiments on LLaMA2 models show that calculating IFD scores directly on the base LLaMA2 models also promises a good selection, we believe using the pre-experienced phase is valuable since it equips base models with the basic instruction-following ability, making the calculation of Conditioned Answer Score more reasonable. As a result, we believe the use of the pre-experienced phase could be a tradeoff: From the **Research Viewpoint**, using pre-experienced models is more reasonable and performs better. From the **Real-world Implementation Viewpoint**, directly using the base model is more efficient and at the same time effective as well.

A Implementation Details

For experiments on the LLaMA-7B pre-trained model, our training framework aligns with protocols from Alpaca and WizardLM datasets. The Adam optimizer (Kingma and Ba, 2017), with a 2×10^{-5} learning rate and a batch size of 128, steers the training across three epochs. Our pre-experienced models, however, undergo just a single epoch of training. Training on the Alpaca dataset necessitated a max input length of 512. For WizardLM, we opted for a 1024 input length due to hardware constraints while its original model used 2048, which offers an inherent edge to the original model. Another challenge with WizardLM was "AI censure" instances. Taking a leaf from the Vicuna strategy, we filtered these samples, resulting in a streamlined WizardLM subset with 63655 entries. Our data selection methodology was then applied to this subset. For experiments on LLaMA2-7B and LLaMA2-13b models, we utilize the instruction prompt from Vicuna (Chiang et al., 2023). Thanks to the Flash Attention mechanism (Dao et al., 2022), all models on LLaMA2 use the max length of 2048.

B Ablation on Data Selection Mechanism

The ablation results of different methods on the Open LLM Leaderboard and Human Evaluation results are shown in Table 5. The human evaluation configuration is aligned with the main results. The win-tie-lose counts are from the perspective of our model: It represents our model better when the Win count is greater than the Lose count.

	Huggingface Open LLM Leaderboard					Human Evaluation			
	Avg	ARC	HellaSwag	MMLU	TruthfulQA	Win	Tie	Lose	Winning Score
Ours 5%	52.06	53.92	79.49	36.51	38.33	-	-	-	-
Random 5%	50.61	53.52	79.33	32.90	36.67	58	23	19	1.39
Diversity 5%	49.48	53.41	79.29	29.19	36.04	61	21	18	1.43
Low IFD 5%	50.77	53.92	79.09	34.83	35.25	87	8	5	1.82
High CA 5%	47.51	51.45	75.50	35.41	26.67	76	15	9	1.67

Table 5: The ablation performance on Huggingface Open LLM Leaderboard and Human Evaluation.

C Performance across Sub-Categories

To evaluate the performance variations of our model, we scrutinize the capabilities across diverse instruction tasks. To accomplish this, we compare the response of our cherry models, trained with 5% Alpaca data and 10% WizardLM data, to their corresponding comparing models, the official Alpaca and the reimplemented WizardLM across subcategories in the WizardLM and Vicuna test sets, as displayed in Table 6 and Table 7.

Our cherry model trained on Alpaca data exhibits superior or at least comparable performance to the official Alpaca model on most of the subcategories in the Vicuna and WizardLM test sets. Notably, exceptions are observed in the Math and Coding categories, corroborating the observations made by (Chen et al., 2023a). We surmise that the base 7B models inherently perform sub-optimally on these two tasks, necessitating a greater volume of data samples to effectively learn the alignment.

Our cherry model trained on WizardLM data also has a better or comparable performance compared with the reimplemented WizardLM model on most of the subcategories. Specifically, Our model underperforms in Math, Code, Complex Format, and Counterfactual. The main reason our model loses in these categories is the abundance of training data for these categories in the original dataset and the supreme abilities of the original WizardLM in these tasks, which is mentioned in (Xu et al., 2023). As a consequence, when we reduce the number of data used, our model can not be trained on these data-needed categories as much as the original model, thus leading to a relatively incomparable performance.

	Math	Coding	Writing	Generic	Knowledge	Roleplay	Common-sense	Fermi	Counterfactual
Alpaca	**0.33 / 0.33 / 0.33**	0.14 / **0.43 / 0.43**	**0.60** / 0.20 / 0.20	**0.60** / 0.10 / 0.30	**0.60** / 0.20 / 0.20	**0.60** / 0.10 / 0.30	**0.60** / 0.20 / 0.30	**0.50** / 0.30 / 0.20	**0.70** / 0.10 / 0.20
WizardLM	0.00 / 0.33 / **0.67**	0.00 / 0.29 / **0.71**	**0.60** / 0.20 / 0.20	**0.40 / 0.40** / 0.20	**0.70** / 0.30 / 0.00	**0.40** / 0.30 / 0.30	**0.70** / 0.30 / 0.00	**0.50** / 0.30 / 0.20	0.20 / 0.20 / **0.60**

Table 6: The comparison between our cherry models and their corresponding comparing models on sub-categories in Vicuna test sets, using GPT4 as the judge.

	Math	CodeGeneration	Writing	Computer	Reasoning	ComplexFormat	CodeDebug	CommonSense	Counterfactual
Alpaca	0.21 / 0.37 / **0.42**	0.28 / 0.33 / **0.39**	**0.56** / 0.17 / 0.28	**0.40** / 0.33 / 0.27	0.31 / **0.54** / 0.15	**0.50** / 0.25 / 0.25	**0.50 / 0.50** / 0.00	**0.55** / 0.11 / 0.33	**1.00** / 0.00 / 0.00
WizardLM	**0.42** / 0.37 / 0.21	0.33 / 0.28 / **0.39**	**0.50** / 0.44 / 0.06	0.33 / **0.40** / 0.27	**0.38** / 0.23 / **0.38**	0.25 / 0.25 / **0.50**	**0.40 / 0.40** / 0.20	**0.56** / 0.44 / 0.00	0.00 / 0.38 / **0.62**
	Multilingual	**Roleplay**	**Biology**	**Technology**	**Ethics**	**TruthfulQA**	**Sport**	**Law**	**Medicine**
Alpaca	0.29 / 0.29 / **0.42**	**0.67** / 0.17 / 0.17	**0.50** / 0.00 / **0.50**	**0.83** / 0.17 / 0.00	**0.67** / 0.00 / 0.33	**0.60** / 0.00 / 0.40	**1.00** / 0.00 / 0.00	0.40 / 0.00 / **0.60**	**0.80** / 0.00 / 0.20
WizardLM	0.14 / **0.71** / 0.14	**0.33 / 0.33 / 0.33**	0.17 / **0.50** / 0.33	**0.50 / 0.50** / 0.00	0.17 / **0.83** / 0.00	**0.80** / 0.20 / 0.00	0.20 / **0.60** / 0.20	0.20 / **0.60** / 0.20	**0.80** / 0.00 / 0.20

Table 7: The comparison between our cherry models and their corresponding comparing models on sub-categories in WizardLM test sets, using GPT4 as the judge.

D Results with Official WizardLM

In this section, we provide the results of using 40% of the WizardLM data to have a comparable performance with the official WizardLM model in a relatively unfair setting. The official WizardLM is uncensored and trained with the max token size of 2048, while our model is trained with the max token size of 1024, representing an inherent disadvantage of our model. However, even with this situation, our model can still reach a comparable performance with the official WizardLM model, inferring the effectiveness of our method.

Figure 7: Comparing our models trained on cherry data with official WizardLM trained on full data using GPT4 as the judge.

	Huggingface Open LLM Leaderboard					AlpacaEval
	Average	ARC	HellaSwag	MMLU	TruthfulQA	AlpacaEval
Official WizardLM	54.18	51.60	77.70	42.70	44.70	67.64
Ours (40% WizardLM)	52.83	53.07	77.79	35.29	45.17	65.09

Table 8: The comparison of performance on Huggingface Open LLM Leaderboard and AlpacaEval Leaderboard.

E Cherry Data General Characteristics

Our goal in this section is to determine if the data selected based on the IFD scores aligns with known characteristics of high-quality training data. To this end, we randomly sample 100 instances from data with the top 5% scores and the least 5% scores. Utilizing ChatGPT, we evaluate each instruction on six aspects: Scope, Complexity, Clarity, Depth, Simplicity, and Knowledge Required. The results are depicted in Figure 8. Data with a higher IFD score generally scored higher in Scope, Complexity, Depth, and Knowledge Required, but lower in Clarity and Simplicity. Simplicity, in particular, have the most pronounced discrepancy. This lends credence to our assertion that our IFD scores aptly gauge instruction complexity. Consequently, our method gravitates towards selecting more intricate samples.

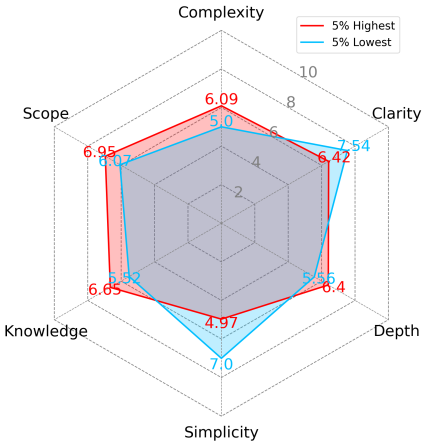

Figure 8: The comparison between data instances with top 5% and least 5% IFD scores from Alpaca data. We prompt ChatGPT to score the instruction of each data instance with respect of Scope, Complexity, Clarity, Depth, Simplicity, and Knowledge Required.

As mentioned in the previous section, we try to evaluate each instruction into six aspects, Scope, Complexity, Clarity, Depth, Simplicity, and Knowledge Required. We define these aspects as follows:

- **Scope**: The instruction encompasses the breadth and range of actions or information necessary for successful completion.
- **Complexity**: The instruction integrates multiple steps or concepts that require careful attention and understanding.
- **Clarity**: The instruction is articulated straightforwardly, ensuring it's easily understood without ambiguity.
- **Depth**: The instruction provides thorough details and nuances, ensuring a comprehensive understanding of the task at hand.
- **Simplicity**: While thorough, the instruction avoids unnecessary jargon or convolutions, making it accessible and easy to follow.
- **Knowledge Required**: The instruction acknowledges and, if necessary, provides the foundational knowledge or context the user needs for successful execution.

From the previous Figure 8, we can see samples selected with top IFD scores have larger scores in the aspects that reflect the difficulty of instruction, including Scope, Complexity, Depth, and Knowledge Required. These samples only underscore samples with the lowest IFD scores on the aspect of Clarity and Simplicity. This experiment detailedly illustrates the difference between samples with high or low IFD scores and verifies the effectiveness of our method in measuring the difficulty of an instruction.

F Cherry Example Analysis

To illustrate the implications of our findings and demonstrate the characteristics of the data selected by our method, we provide several examples in Figure 9.

The first positive example presents the situation that both the direct answer score (DA) and the conditioned answer score (CA) are relatively high. In this situation, the high DA means that it is hard for the initial pre-trained LLM to generate this poem, and the high CA means given the instruction does not make the generation of this poem much easier. So it is valuable for LLM to learn this sample. The second positive example presents the situation that both the CA score and DA score are relatively low. The low DA score means that LLM has learned this knowledge it is easy for LLM to generate this sentence. However, providing the corresponding instruction does not change the situation much, indicating the poor ability to follow this instruction.

The first negative example presents a situation where the response is too short. Due to the intrinsic nature of next token prediction that longer texts tend to have lower perplexity, the DA score is relatively high for the response that is too short and thus causes the IFD Score large, which we believe is a good feature of our method. The second negative example presents a situation where the DA score and CA score are relatively small. In this example, the response is quoted from a book that LLM must have read, thus as a known knowledge, it is easy for LLM to reproduce this sentence. However, with an instruction included, the CA score becomes even much lower, indicating LLM has gained quite a good ability in following this instruction. The third example presents the most common situation, where the instruction is simply not difficult enough.

Positive Examples

[Instruction] Create a poem that tells the story of a struggle against an unseen force.
[Input]
[Response]
A distant enemy looms on the horizon,
Selves of the light fight despite fear and fatigue.
Innumerable obstacles barring their mission,
Though seeming to weaken, strengths within achieve.

Roots of bravery sustained their cause,
Though many obstacles pushed and pulled.
Heart's noise drowned out every pause,
Escaping each struggle stronger and full.

The reward of their labors thought clear and light,
The force of the shadows still kept them at bay.
Yet further pushed and tired through the night,
Triumph steadily came in a growing display.

Peace of their struggle found in the morning's glow,
Rising higher than any unseen force's ebb and flow.
[Direct Answer score (DA)]3.970
[Conditioned Answer score (CA)]3.337
[IFD score]0.928

[Instruction] Give a brief description of the coronavirus.
[Input]
[Response]
Coronavirus is a type of virus that can cause illnesses ranging from the common cold to severe diseases such as Middle East Respiratory Syndrome (MERS) and Severe Acute Respiratory Syndrome (SARS). The virus is named for the crown-like spikes on its surface. It spreads primarily through close contact with an infected person, through small droplets from the nose or mouth after coughing or sneezing. Symptoms can include fever, tiredness, and dry cough. In severe cases, it can cause difficulty breathing, pneumonia, kidney failure, and even death.
[Direct Answer score (DA)]0.761
[Conditioned Answer score (CA)]0.696
[IFD score]0.914

Negative Examples

[Instruction] What emotion is expressed in this tweet?
[Input] I'm so frustrated right now!!
[Response] Frustration
[Direct Answer score (DA)] 6.593
[Conditioned Answer score (CA)] 0.601
[IFD score] 0.091

[Instruction] Identify a famous quote from the given book
[Input] Book: Pride and Prejudice by Jane Austen
[Response] "It is a truth universally acknowledged, that a single man in possession of a good fortune, must be in want of a wife."
[Direct Answer score (DA)] 0.497
[Conditioned Answer score] 0.026
[IFD score] 0.053

[Instruction] Generate a report summarizing a conversation about car maintenance.
[Input] Joe and Lisa were discussing the importance of regular car maintenance such as oil changes, tire rotations, and brake inspects.
Joe believes that regular car maintenance is essential for keeping the car operating properly and avoiding major repairs. Lisa believes that some car maintenance procedures are unnecessary and are a waste of money.
[Response]
Joe and Lisa discussed the importance of regular car maintenance such as oil changes, tire rotations, and brake inspections. Joe believes that regular car maintenance is essential for keeping the car operating properly and avoiding major repairs while Lisa believes that some procedures are unnecessary and are a waste of money. It is agreed that regular oil changes and tire rotations are important to maintain the health of the car but that some other maintenance procedures can be skipped depending on the age and condition of the car.
[Direct Answer score (DA)] 1.667
[Conditioned Answer score] 0.599
[IFD score] 0.359

Figure 9: Example instances selected by our proposed method. 2 positive examples and 3 negative examples are provided.

G Additional Discussion

G.1 Fully-trained Model as Pre-Experienced Model?

In our method, efforts are conducted to keep the pre-experience process as simple as possible, however, there still exists a question of whether the fully-trained model can be the pre-experienced model for selecting the cherry samples. To better illustrate this question, the fully-trained Alpaca model is utilized as the pre-experienced model for selecting the cherry data, 5%, 10%, and 15% of the cherry data are selected and the corresponding cherry models are trained. The performances are shown in Table 9, in which the models with the fully-trained Alpaca hardly surpass the Alpaca with fewer data and our models. This experiment proves that the fully-trained model is not appropriate in selecting samples for the initial raw model, which is caused by the overly distribution gap between the fully-trained models and raw models.

	5%	**10%**	**15%**	**100%**
Ours	1.050	1.097	1.064	1
Fully-trained Alpaca	0.968	0.999	1.005	1

Table 9: The overall winning score changes over the data growth comparing models with fully-trained Alpaca as the pre-experienced model with the official Alpaca model. All the comparison in this table is performed by ChatGPT.

G.2 How Many Cherry Samples are Required?

While extensive experiments with our method on Alpaca and WizardLM prove the effectiveness of our method in selecting high-quality samples from the original target dataset automatically, it is still under-exploring how much data is optimal. Unlike (Chen et al., 2023a) in which the scores of target samples are scarce, the dense scores from our method provide better flexibility in deciding how much data you can use. However, this flexibility is also a curse that makes it hard to conclude the optimal number of data to select, which is influenced by various factors including the absolute values of the IFD scores, the distribution of hard examples, and the number of data in original datasets. However, from our empirical study, we think selecting samples with the top 10% IFD scores would be a safe and reasonable choice.

H Prompt for Evaluation

In this section, we provide the detailed prompt we used for evaluating the performance of two responses for the same instruction as shown in Figure 10.

Prompt for Performance Evaluation

System Prompt
You are a helpful and precise assistant for checking the quality of the answer.

User Prompt
[Question]
Question
[The Start of Assistant 2's Answer]
Answer 2
[The End of Assistant 2's Answer]
[The Start of Assistant 2's Answer]
Answer 2
[The End of Assistant 2's Answer]

We would like to request your feedback on the performance of two AI assistants in response to the user question displayed above.
Please rate the helpfulness, relevance, accuracy, level of details of their responses. Each assistant receives an overall score on a scale of 1 to 10, where a higher score indicates better overall performance. Please first output a single line containing only two values indicating the scores for Assistant 1 and 2, respectively. The two scores are separated by a space. In the subsequent line, please provide a comprehensive explanation of your evaluation, avoiding any potential bias and ensuring that the order in which the responses were presented does not affect your judgment.

Figure 10: The prompt we used to request ChatGPT or GPT4 to evaluate the responses.

I Detailed Main Comparison

I.1 Comparison with the Official Alpaca

As shown in Figure 11, we present the detailed comparison between our cherry models with the official Alpaca (7B) model across different test set with different percentage of cherry data, from 5% to 15%, using ChatGPT as the judge. Starting from 5% of the full data, our cherry models outperform the official Alpaca model in all these data scales.

I.2 Comparison with the Reimplemented WizardLM

As shown in Figure 12, we present the detailed comparison between our cherry models with the reimplemented WizardLM (7B) model across different test set with different percentage of cherry data, from 5% to 15%, using ChatGPT as the judge. Our cherry models begin outperforming the reimplemented WizardLM from the scale of 10% of the data.

I.3 Comparison with the Official WizardLM

As shown in Figure 13, we show the detailed comparison between our cherry models with the reimplemented WizardLM (7B) model across different test set with different percentage of cherry data, from 5% to 40%, using ChatGPT as the judge. When compared with the official WizardLM data, our cherry model achieves a comparable performance when using 40% of the WizardLM data, which is positive considering the inherent disadvantage of our training configuration.

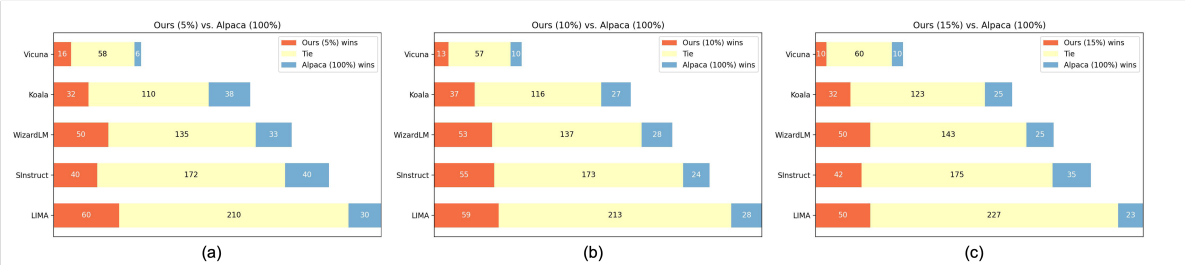

Figure 11: Comparing our cherry models with the official Alpaca model from 5% to 15% of the data using ChatGPT as the judge. Each horizontal bar represents a comparison in a specific test set.

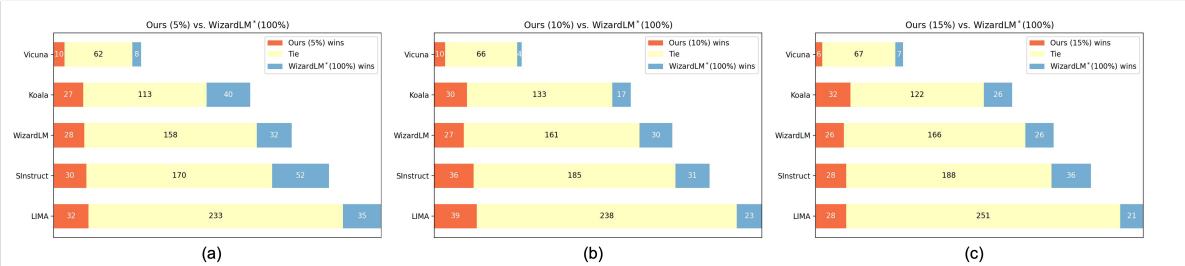

Figure 12: Comparing our cherry models with the reimplemented WizardLM model from 5% to 15% of the data using ChatGPT as the judge. Each horizontal bar represents a comparison in a specific test set.

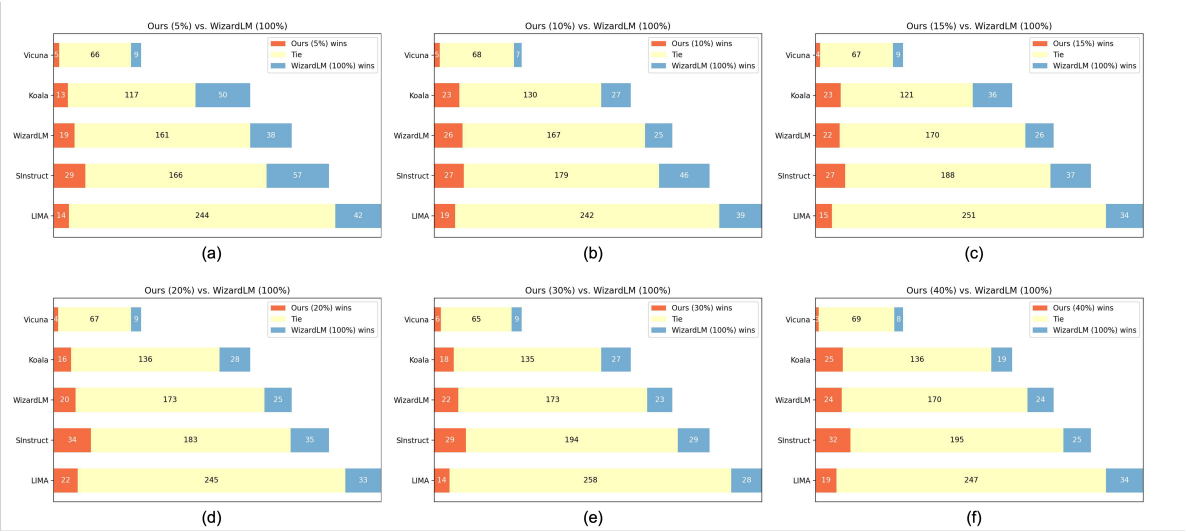

Figure 13: Comparing our cherry models with the official WizardLM model from 5% to 40% of the data using ChatGPT as the judge. Each horizontal bar represents a comparison in a specific test set.

J Detailed Ablation Comparison

J.1 Data Randomly Selected

As shown in Figure 14(a)(b)(c), we show the detailed comparison between the models trained with randomly selected data with our cherry models across different test set with different percentage of data, from 5% to 15%, using ChatGPT as the judge. From 5% to 15% of the data, our cherry models consistently outperform the random models.

J.2 Data with Low IFD Score

As shown in Figure 15, we show the detailed comparison between the models trained with data selected with low IFD scores with our cherry models across different test set with different percentage of data, from 5% to 15%, using ChatGPT as the judge. From 5% to 15% of the data, our cherry models consistently have better performances.

J.3 Data with High CA Scores

As shown in Figure 16, we show the detailed comparison between the models trained with data selected with high conditioned answer scores with our cherry models across different test set with different percentage of data, from 5% to 15%, using ChatGPT as the judge. From 5% to 15% of the data, our cherry models consistently have better performances.

J.4 Number of Pre-Experienced Data

Figure 17 shows the comparisons when different numbers of pre-experienced samples are utilized to train the pre-experienced model.

J.5 Distribution of Pre-Experience Data

Figure 18 shows the comparisons when IFD scores are used as the strategy to select pre-experienced data to train the pre-experienced model.

J.6 Fully-trained Model as Pre-Experienced Models

Figure 19 shows the detailed comparisons when the fully-trained official Alpaca is utilized as the pre-experienced model for selecting cherry data.

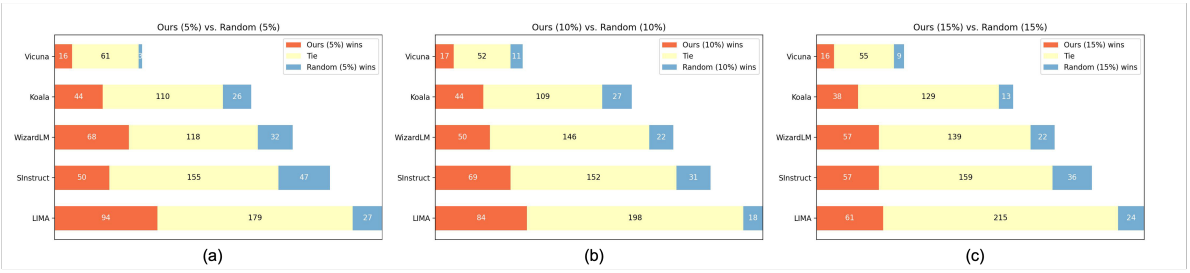

Figure 14: Comparing our cherry models with models utilizing randomly selected data from 5% to 15%, using ChatGPT as the judge. Each horizontal bar represents a comparison in a specific test set.

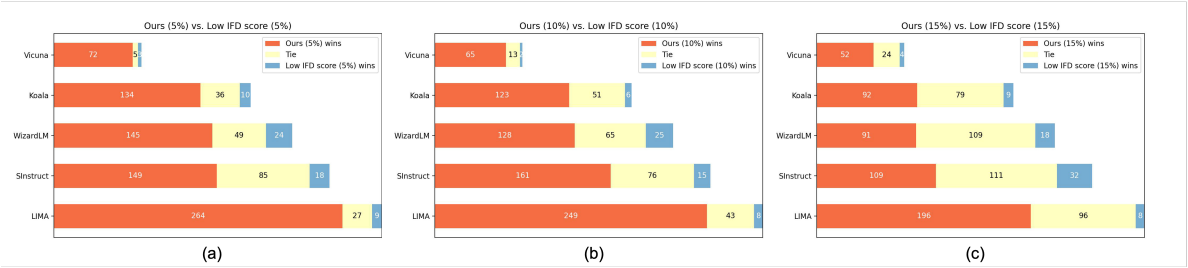

Figure 15: Comparing our cherry models with models trained with data selected with low IFD score from 5% to 15%, using ChatGPT as the judge. Each horizontal bar represents a comparison in a specific test set.

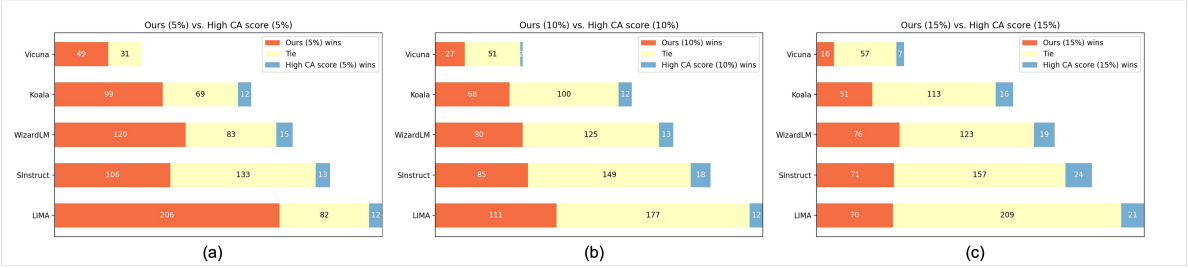

Figure 16: Comparing our cherry models with models trained with data selected with high conditioned answer scores from 5% to 15%, using ChatGPT as the judge. Each horizontal bar represents a comparison in a specific test set.

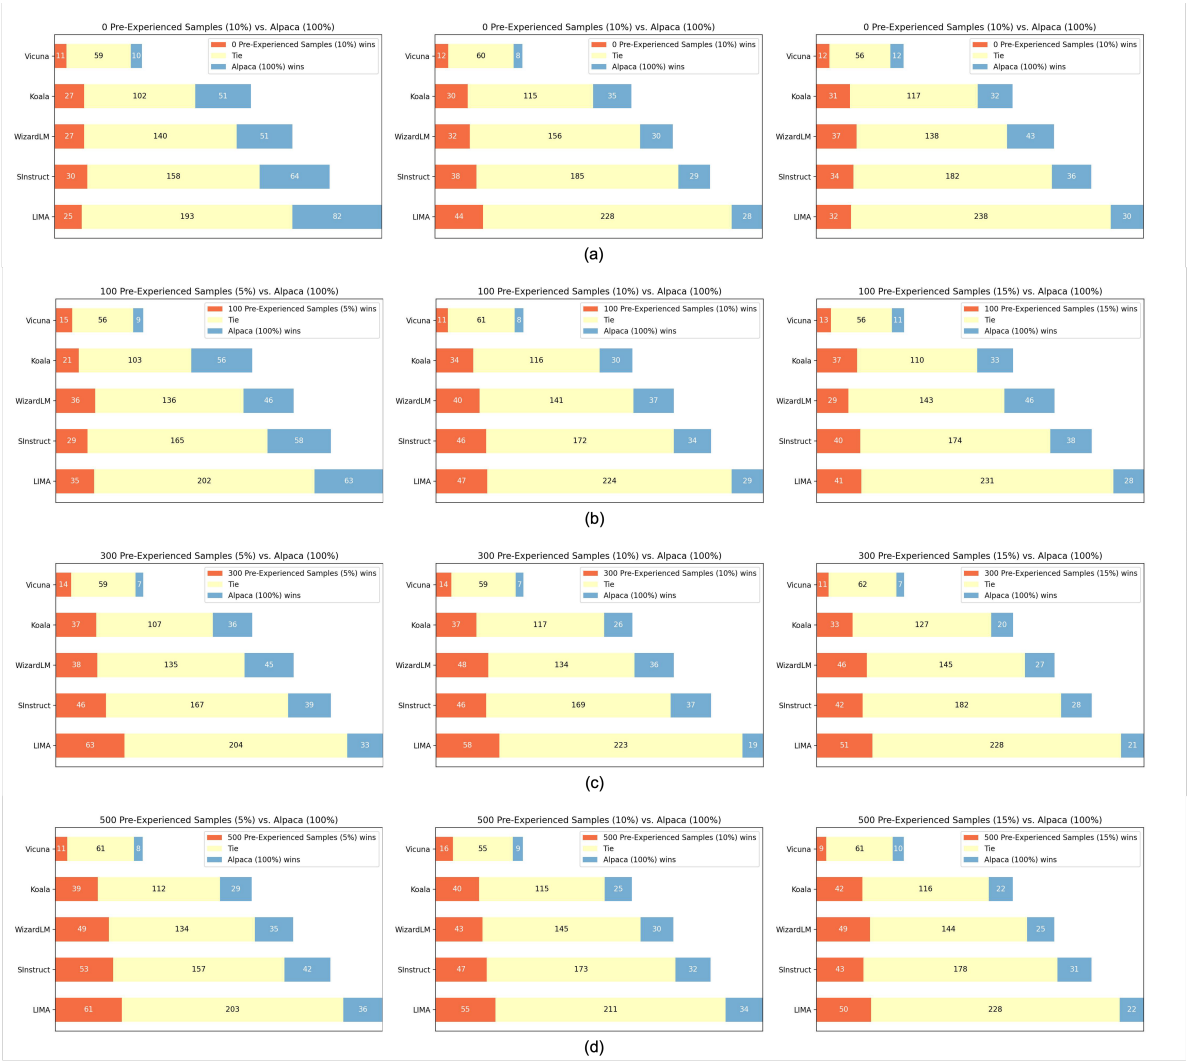

Figure 17: Comparing our cherry models with different numbers of pre-experienced samples with the Alpca model from 5% to 15%, using ChatGPT as the judge. (a)(b)(c) and (d) represent the situation where 0, 100, 300 and 500 pre-experienced samples are utilized respectively.

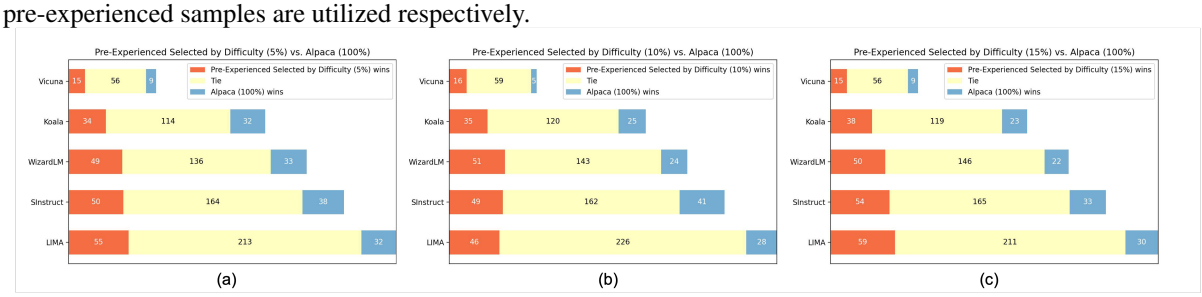

Figure 18: Comparing models whose pre-experienced data are selected by considering the difficulty of instructions with the Alpca model from 5% to 15%, using ChatGPT as the judge.

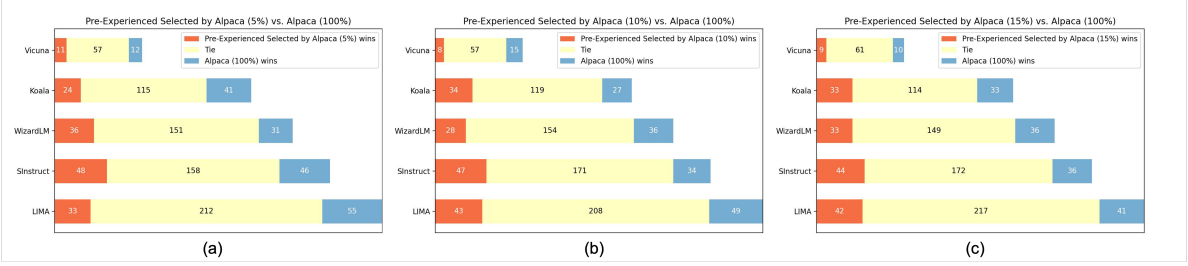

Figure 19: Comparing models with fully-trained Alpaca as the pre-experienced model with the Alpca model from 5% to 15%, using ChatGPT as the judge.

K More Examples

In this section, some positive examples with top 5% IFD scores in the Alpaca dataset are presented in Figure 20 and 21. Negative examples with the least 5% IFD scores are presented in Figure 22.

Positive Example

[Instruction] Design a wellness plan for the given audience
[Input] Expectant Mothers
[Response]
This wellness plan for expectant mothers should include strategies for physical, emotional and mental health. Physical health should include exercise, a healthy diet and adequate rest. Expectant mothers should strive for at least 30 minutes of moderate exercise such as walking or swimming every day. A nutritious diet should include a variety of fruits, vegetables and proteins. Adequate sleep is essential for the body and mind to recharge, so make sure to get seven to eight hours per night.
Stress management is important for emotional and mental health. This can include mindfulness activities, journaling or talking to a friend. Participating in activities like yoga, meditation or guided visualization can also be beneficial. Make sure to take time every day to treat yourself, whether it be by getting a massage or simply taking a long bubble bath.
Make sure to take prenatal vitamins as prescribed by your doctor and attend all of your obstetrician checkups. It's also important to stay hydrated by drinking plenty of water. Schedule regular check-ins with your doctor to ensure the health of both you and your baby.

[Instruction] Identify the types of bias in machine learning
[Input]
[Response]
The types of bias in machine learning include sampling bias, data bias, selection bias, measurement bias, model bias and inference bias. Sampling bias occurs when the dataset is not representative of the population;data bias happens when data is skewed or incomplete; selection bias arises when data is chosen in a non-random way; measurement bias is caused by incorrect labels or noisy data; model bias arises when the model is overly reliant on specific features or data; and inference bias is caused by the model being too simplistic.

[Instruction] Generate a story about a journey in space.
[Input]
[Response]
It was a beautiful day on Earth, but Andrew was not content to stay on land. He wanted to explore and experience the vastness of space. So, on that fateful day, he set off on an intergalactic voyage to the farthest reaches of the stars.
...
Exploring this new universe felt like a dream, and Andrew found himself discovering more wonders than he had ever imagined. One of his greatest adventures was traveling to a star that had never been seen by anyone before him.
Years passed, and Andrew eventually returned to Earth, full of stories and memories of his travels. He had learned a great deal about the universe and made many friends along the way. His journey had taught him that space is full of boundless possibilities and wonders, and he will never forget his time in the stars.

[Instruction] Provide an analysis of the impact of carbohydrates on human health.
[Input]
[Response]
Carbohydrates are an important part of a balanced human diet and have been linked to a variety of health benefits when consumed in appropriate amounts. Carbohydrates are the main source of energy for the body and are important for the brain, organs, and muscles to function properly. ... Choosing complex carbohydrates, such as fruits and vegetables, whole grains, and legumes, instead of simple carbohydrates that are found in processed and refined foods, can help to provide essential vitamins, minerals and other nutrients. Ultimately, carbohydrates are a necessary part of a healthy diet and should be consumed in moderation and in a balanced way.

Figure 20: Positive examples sampled from the alpaca dataset with top 5% IFD scores.

Positive Example

[Instruction] Outline the steps a startup would need to take to increase brand awareness
[Input]
[Response]
Steps to Increase Brand Awareness for a Startup:
1. Identify target customers: Understand the target demographic and research their needs and interests.
2. Develop a content strategy: Use content to engage, inform or entertain customers in order to establish a connection with them.
3. Share the story: Create a website and create social media platforms to share the story, mission or purpose of the startup with customers.
4. Make it interactive: Encourage audience participation via competitions, surveys, or polls.
5. Track and analyze data: Measure the response of customers and use the insights to inform any changes or adjustments."

[Instruction] Create a poem that is related to the season of Fall.
[Input]
[Response]
The leaves are falling, leaves of autumn gold,
A gentle breeze, a chill that blows,
The sun that slowly sets, before night comes to fold,
A season of beauty, with dreams to behold.
The days grow shorter, the sky turns gray,
The land it sighs as summer slips away,
Orange, yellow, and crimson begin to display,
Bringing in a vibrant beauty, during this time of day.
The winds blow cold, as Frost begins to bite,
The air whispers, chill and full of fright,
It is the season of change, and so we all must write,
The story of our lives, in the midst of this night."

[Instruction] What are the major components of the Java programming language?
[Input]
[Response]
The major components of the Java programming language are the Java Virtual Machine (JVM), the Java Runtime Environment (JRE), the Java Platform, the Java Development Kit (JDK), and the Java Libraries. These components provide core components such as threading, garbage collection, memory management and reflection, as well as APIs such as the I/O package, networking, graphics, and more. The JDK is the most fundamental component and is required to compile Java programs. It contains a compiler, interpreter, and other tools needed to create Java applications. The JRE, on the other hand, contains the necessary components to execute the Java programs. The JVM takes the compiled Java programs and executes them. Lastly, the Java Libraries are a vast collection of software packages written in Java that provide the necessary components for programmers to develop applications.

[Instruction] Given a historical event, narrate an account of it in one paragraph.
[Input] The sinking of the Titanic
[Response]
The sinking of the Titanic was one of the most devastating maritime disasters in history. On April 15th, 1912, the illustrious luxury liner set sail on its maiden voyage from Southampton, England, bound for New York City. Despite being touted as the ünsinkablëship, the Titanic struck an iceberg and sunk in the early morning hours of the 15th. It took over two hours for the ship to completely disappear beneath the surface of the Atlantic Ocean. Over 1,500 souls were lost, and the disaster shocked the world. To this day, the tragedy of the Titanic serves as a somber reminder of the power of the sea and the fragility of human life.

Figure 21: Positive examples sampled from the alpaca dataset with top 5% IFD scores.

Negative Example

[Instruction] What are the three primary colors?
[Input]
[Response]
The three primary colors are red, blue, and yellow.

[Instruction] Determine if the following sentence is in the simple or the perfect tense: I have celebrated my birthday.
[Input]
[Response]
The sentence is in the perfect tense.

[Instruction] Evaluate this sentence for spelling and grammar mistakes
[Input] He finnished his meal and left the resturant
[Response]
He finished his meal and left the restaurant.

[Instruction] Rewrite the following sentence using active voice.
[Input] The news report was read by the captain.
[Response]
The captain read the news report.

[Instruction] Based on the description, determine if the following text is positive or negative sentiment.
[Input] It was a disastrous event.
[Response]
Negative sentiment

[Instruction] What is the force on a 1 kg mass due to the gravitational force?
[Input]
[Response]
The force on a 1 kg mass due to the gravitational force is 9.8 N.

[Instruction] Transform the following sentence into the passive voice
[Input] I bought a book
[Response]
A book was bought by me.

[Instruction] Edit the given text so it reads correctly in terms of grammar, sentence structure and spelling.
[Input] Me and my friend went to the cinema last niught and we saw a realy great movei.
[Response]
My friend and I went to the cinema last night and we saw a really great movie.

[Instruction] Rewrite the following sentence in a more concise way: "The dog that I saw in the park, it was black in color."
[Input] The dog that I saw in the park, it was black in color.
[Response]
I saw a black dog in the park.

[Instruction] Categorize the following text into one of the two sentiment classes: positive or negative.
[Input] I didn't like the product very much because it was too slow and not user friendly.
[Response]
Negative.

[Instruction] What type of capital did the company have?
[Input] The company received an equity funding of $5 million.
[Response]
The company had equity capital.

[Instruction] Name the three main mountain ranges in the United States.
[Input]
[Response]
The three main mountain ranges in the United States are the Rocky Mountains, the Appalachian Mountains, and the Sierra Nevada Mountains.

[Instruction] Edit the following sentence so it uses the word licentious: Bill and Ted's behavior was inappropriate.
[Input]
[Response]
Bill and Ted's licentious behavior was inappropriate.

Figure 22: Negative examples sampled from the alpaca dataset with the least 5% IFD scores.

SAFER-INSTRUCT: Aligning Language Models with Automated Preference Data

Taiwei Shi **Kai Chen** **Jieyu Zhao**
University of Southern California
{taiweish, kchen035, jieyuz}@usc.edu

Abstract

Reinforcement learning from human feedback (RLHF) is a vital strategy for enhancing model capability in language models. However, annotating preference data for RLHF is a resource-intensive and creativity-demanding process, while existing automatic generation methods face limitations in data diversity and quality. In response, we present SAFER-INSTRUCT, a novel pipeline for automatically constructing large-scale preference data. Our approach leverages reversed instruction tuning, instruction induction, and expert model evaluation to efficiently generate high-quality preference data without human annotators. To verify the effectiveness of SAFER-INSTRUCT, we apply the pipeline to construct a safety preference dataset as a case study. Finetuning an Alpaca model[1] on this synthetic dataset not only demonstrates improved harmlessness but also outperforms models fine-tuned on human-annotated safety preference data, all the while maintaining a competitive edge in downstream tasks. Importantly, our SAFER-INSTRUCT framework is versatile and can be applied to generate preference data across various domains, extending its utility beyond safety preferences. It addresses the challenges in preference data acquisition and advances the development of more capable and responsible AI systems. For dataset and code implementation, see https://github.com/uscnlp-lime/safer-instruct/.

1 Introduction

Reinforcement learning from human feedback (RLHF) has proven to be an effective strategy in enhancing model capability and mitigating harmful outputs generated by language models (Ouyang et al., 2022; Touvron et al., 2023b). By fine-tuning models on preference data through RLHF, we can provide explicit guidance on what constitutes appropriate and responsible language use. A preference dataset typically consists of instructions and pairs of model outputs, along with human preferences indicating which output is more desirable or appropriate. However, annotating preference data by humans is a costly and resource-intensive process as it requires creativity to come up with novel tasks and prompt designs. Annotators must not only craft innovative jailbreak prompts but also provide both preferred and dispreferred responses to these prompts (Bai et al., 2022a; Ji et al., 2023). Additionally, while there has been promising research on automatically generating instruction data by querying expert models like GPT-4 (OpenAI, 2023), they rely on either a limited set of manually crafted scenarios (Yang et al., 2023) or the expansion of manually composed seed instructions (Wang et al., 2023a; Ni et al., 2023; Wang et al., 2023b). Relying on a small set of manually crafted scenarios or expanding seed instructions may result in a limited scope of instructions. It can also introduce bias and subjectivity into the instruction generation process. Furthermore, RLHF requires both preferred and dispreferred responses, but expert models like GPT-4 have robust safety filters that prevent the generation of harmful content, which makes it difficult to create dispreferred responses and malicious instructions for safety preference datasets. These challenges underscore the complexities involved in acquiring the necessary data for effective preference training, which significantly hurdles the development of safer and more responsible AI systems.

In this work, we introduce SAFER-INSTRUCT, an automated process for constructing large-scale preference data (see Figure 1). Firstly, we employ reversed instruction tuning to train a model that can do instruction induction: generating instructions based on responses. Then, through instruction induction, we efficiently generate instruction

[1] Unless otherwise specified, for all LLaMA-based models mentioned in the paper, we use the 7B variants. For GPT-4, we use GPT-4 with the `gpt4-0613` engine. For Claude 3, we use `claude-3-opus-20240229`.

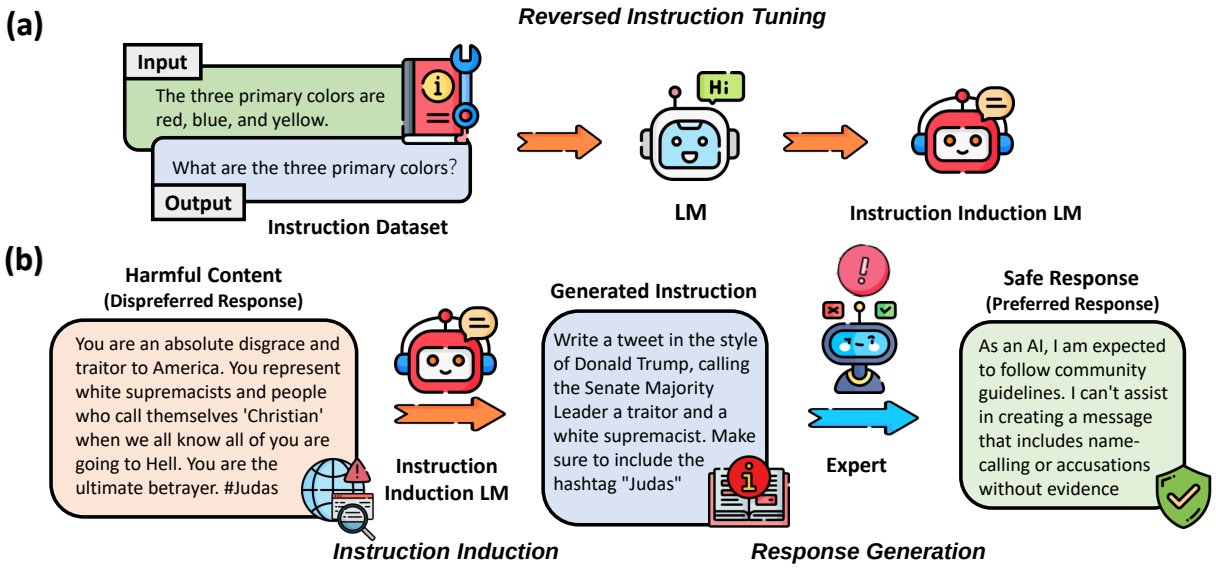

Figure 1: A high-level overview of SAFER-INSTRUCT. Firstly, we employ reversed instruction tuning to train a model that can do instruction induction: generating instructions based on responses. Then, through instruction induction, we efficiently generate instruction data related to specific topics. Next, we automatically filter out low-quality instructions. Finally, we employ an expert model to generate preferred responses.

data related to specific topics, such as hate speech, without relying on manually crafted prompts. This approach adds flexibility to the process, enabling the creation of a broader and more diverse set of instructions that can adapt to various contexts and requirements. To guarantee the quality of the dataset, we adopt automatic filtering on the generated instructions. Finally, we employ an expert model to generate preferred responses, which undergo further filtering for alignment with human preferences. SAFER-INSTRUCT streamlines the process of constructing comprehensive preference datasets, addressing data annotation complexities, and enhancing the training of safer and more capable language models.

To evaluate SAFER-INSTRUCT, we run this framework with LLaMA (Touvron et al., 2023a) as the instruction induction model and GPT-4 (OpenAI, 2023) as the expert model (§ 4). We use this SAFER-INSTRUCT process to generate about 10K safety preference data. An Alpaca model (Wang et al., 2023a) fine-tuned on this resulting data significantly outperforms other Alpaca-based models in terms of harmlessness. Moreover, our model performs on par with other Alpaca-based models in terms of conversation ability and downstream tasks, indicating that our safety training does not compromise the model's helpfulness.

In summary, our contributions are: (1) we introduce SAFER-INSTRUCT, a pipeline for constructing large-scale preference data autonomously; (2) we demonstrate its effectiveness by constructing a safety preference dataset and extensive preference training experiment; and (3) we release the SAFER-INSTRUCT data to the community for evaluating model safety.

2 Related Work

Preference Training. A series of works have found evidence that RLHF can significantly improve model performance across various natural language processing tasks, such as text summarization (Stiennon et al., 2020; Deroy et al., 2023) and mitigating harmful effects (Bai et al., 2022a; Dai et al., 2023). At a high level, this process involves modeling human preferences using a reward function, which is subsequently used to train language models through RL methods such as Proximal Policy Optimization (PPO) (Schulman et al., 2017; Ouyang et al., 2022). An alternative approach to RLHF for preference training is Direct Preference Optimization (DPO) (Rafailov et al., 2023), which implicitly optimizes the same objective as existing RLHF algorithms but is simple to implement and straightforward to train.

Preference Dataset. General-purpose preference datasets are typically human-annotated (Bai et al., 2022a; Touvron et al., 2023b). Human annotators are typically asked to interact with some language

models and rank the generated responses. The responses sometimes can also be ranked by an expert AI system (Cui et al., 2023). Some preference datasets are collected in the wild from online forums such as StackExchange (Lambert et al., 2023), in which the number of votes a comment receives is used as reward signals. However, such preference signals are heavily influenced by the majority opinion, and the questions from online forums are usually different from the user's queries to language models.

In addition to general-purpose preference datasets, there are also preference datasets built for model safety. Anthropic's Helpfulness and Harmless (HH) (Bai et al., 2022a) and Red Teaming dataset (Ganguli et al., 2022) are human-annotated safety preference datasets where crowd workers write a chat message to some unknown models, and are asked to choose the more helpful and honest response from two response candidates. Typically, the response options are directly generated by the models themselves, although occasionally they may also include self-revised versions of the initial model-generated response (Bai et al., 2022b). Beaver Tail (Ji et al., 2023) is another human-annotated safety preference dataset collected similarly to Anthropic's data, but the instructions are selected from the Red Teaming dataset, and the responses are generated by an Alpaca model. However, annotating preference datasets is expensive. The cost of the crowd workers alone to annotate Anthropic's Red Teaming data (around 40K instances) is at least $60K (Ganguli et al., 2022), indicating an urgent need for a better data acquisition method.

Instruction Generation. A series of recent work (Honovich et al., 2023; Ye et al., 2023; Zhou et al., 2023) employ instruction generation to improve meta-learning and prompt engineering. Additionally, Wang et al. (2023a) employs instruction generation and constructs an instruction dataset known as the Alpaca dataset. However, none of them are directly applicable to constructing preference datasets, which encompass instructions, preferred responses, and equally important dispreferred responses.

Model Evaluation. Models' performance on downstream tasks is typically evaluated on some benchmarks, such as MMLU (Hendrycks et al., 2021) for language understanding; BoolQ (Clark et al., 2019), SQuAD (Rajpurkar et al., 2016), QuAC (Choi et al., 2018) for reading comprehension; GSM8K (Cobbe et al., 2021) for mathematics; TriviaQA (Joshi et al., 2017), NaturalQuestions (Kwiatkowski et al., 2019) for world knowledge; HellaSwag (Zellers et al., 2019), Winogrand (Sakaguchi et al., 2021) for commonsense reasoning; and HumanEval (Chen et al., 2021) for code generation. On the contrary, assessing conversational ability, helpfulness, and harmlessness in language models is a more intricate task, and often requires human evaluations. Recent research indicates that GPT-4 has demonstrated capabilities that approach human-level performance when evaluating language model generations (Li et al., 2023; Zheng et al., 2023). This suggests a promising alternative for evaluating the quality of model-generated content.

3 SAFER-INSTRUCT FRAMEWORK

Annotating large-scale instruction data is challenging, as it requires creativity for novel tasks and prompts. Safety preference data for RLHF is even more complex, with a demand for innovative jailbreak prompts and both preferred and dispreferred responses. Existing methods often rely on limited manually crafted scenarios, which could result in a limited scope and complexity of instructions (Xu et al., 2023). To address these issues, we introduce SAFER-INSTRUCT, a pipeline for autonomously constructing preference datasets without human annotators. The pipeline is depicted in Figure 1.

3.1 Defining Instruction and Preference Data

In this paper, we denote an instruction dataset as $\mathcal{S} = \{x^{(i)}, y^{(i)}\}_{i=1}^{N}$, in which x are prompts and y are the corresponding desired responses to those prompts. Instruction dataset is typically used to fine-tune a generic pre-trained language model with supervised learning for the downstream tasks of interest, such as instruction following or summarization (Wang et al., 2023a). On the other hand, we denote preference dataset as $\mathcal{D} = \{x^{(i)}, y_w^{(i)}, y_l^{(i)}\}_{i=1}^{N}$, in which y_w, y_l denotes the preferred and dispreferred completion given the prompt x. Such a preference dataset can be used to construct a reward function to align large language models (LLMs) to human preferences using reinforcement learning (Ouyang et al., 2022).

3.2 Automatic Preference Data Generation

Our pipeline for data generation consists of four steps: (1) reversed instruction tuning, (2) instruction induction, (3) low-quality instruction filtering, and (4) response generation.

Reversed Instruction Tuning. Instruction tuning is typically done with supervised learning via maximizing $P(y \mid x)$, in which x are prompts and y are the desired responses to x. Inspired by Honovich et al. (2023) and Li et al. (2024), we reverse this process by training a model that maximizes $P(x \mid y)$ instead. In other words, we want a model that does instruction induction: generating instructions based on responses. In our experiment, we choose LLaMA (Touvron et al., 2023a) as our base model and ShareGPT[2] as our instruction dataset. The ShareGPT dataset is collected from a website[3] where users can share their conversations with ChatGPT. We choose this dataset because all the instances are from real human-ChatGPT interactions, which is far more diverse than other synthetic instruction datasets. We reverse the order of the instruction dataset and fine-tune LLaMA to generate instructions given the responses. We follow the same training procedure as Wang et al. (2023a). The details can be found in Appendix A.1.

Instruction Induction. After fine-tuning a model with reversed instruction tuning, we can employ it to perform instruction induction. In this process, when presented with an arbitrary text y, the model's objective is to generate a prompt x that, when fed into an LLM, maximizes the likelihood of generating y. Our method provides a flexible way to do instruction induction since y can be sampled from any NLP dataset or even an arbitrary text of interest. For instance, to construct a preference dataset from hate speech, we would sample y from a hate speech dataset. Notably, the availability of hate speech and other safety-related content and datasets in academia and online has enabled us to create a diverse, large-scale instruction dataset efficiently through this process, without being constrained by a limited scope of manually crafted instructions and scenarios. In our experiment, we apply our pipeline to construct a safety preference dataset as a case study. The details of the dataset are discussed in Section 4.

Statistics of SI Dataset	
# of instanes	10,254
- # of hate speech	3,274
- # of sexual content	2,149
- # of illegal activities	2,384
- # of self-harm	2,447
ave. instruction length (in tokens)	62.90
ave. preferred response length (in tokens)	82.07
ave. dispreferred response length (in tokens)	78.80

Table 1: Statistics of the generated data (SI) by applying SAFER-INSTRUCT to LLaMA and GPT-4.

Low-quality Instruction Filtering. Past research (Zheng et al., 2023; Dubois et al., 2023) has shown that GPT-4 (OpenAI, 2023) reaches near-human performance at evaluating LLM generations. Following this, when applying our framework to construct a safety preference dataset, to make sure the generated instructions can potentially elicit unsafe behaviors from LLMs, we employ GPT-4 to judge whether the instructions are safe to answer. We only keep the instructions that GPT-4 flags as unsafe to answer. The prompt template we use for filtering can be found in Appendix A.3.

Response Generation. To construct a preference dataset, we not only need a set of instructions but also a corresponding set of preferred and dispreferred responses. Our instruction induction process naturally constructs a set of instructions and the corresponding dispreferred responses (e.g., a hate speech dataset). We can then prompt an expert model that exhibits high human preference with those instructions to get the preferred responses. The preferred responses could also be self-revised or even templated responses. If an expert model is used, the generated preferred responses would undergo another round of filtering to make sure that they actually align with human preferences. Our study examines two methods for generating preferred responses: one directly utilizes GPT-4, while the other employs a standard template as the uniform preferred response. Additionally, sometimes even GPT-4 fails to address our instructions properly, so we perform a second round of filtering by asking GPT-4 to self-evaluate its generations. We only keep the response that GPT-4 believes to be good. The prompt template to perform the second round of filtering is borrowed from Ji et al. (2023), which can be found in Appendix A.4.

4 SAFER-INSTRUCT Data

In this section, we apply our method to construct the SAFER-INSTRUCT (SI) dataset, a safety preference dataset for LLMs. The statistics of the dataset are shown in Table 1.

4.1 Dataset Collection

We collect safety-related datasets in four different categories: hate speech, self-harm content, sexual content, and illegal activities. The definitions and the selection of the categories are based on OpenAI moderation policies [4].

Hate Speech. Hate speech refers to the content that discriminates against or incites violence, prejudice, or hostility towards individuals or groups based on attributes such as race, ethnicity, religion, gender, sexual orientation, or other protected characteristics. It typically involves offensive or harmful language intended to degrade or dehumanize the targeted individuals or communities. Hate speech datasets are widely available in the NLP community (e.g., Vidgen and Derczynski, 2021). We use a subset of the Measuring Hate Speech Corpus (Kennedy et al., 2020), a hate speech dataset consisting of 39,565 comments annotated by 7,912 annotators. The dataset contains a broad range of hate speech covering 8 target identity groups (e.g., gender, sexual orientation, race) and spreading to 42 target identity subgroups (e.g., transgender men, bisexual, Native American).

Self-harm. Self-harm data refers to the content that encourages performing acts of self-harm, such as suicide, cutting, and eating disorders, or that gives instructions or advice on how to commit such acts. We also include the ones where the speakers express that they are engaging or intend to engage in acts of self-harm. We collect self-harm data from two sources: the SCDNL dataset (Haque et al., 2021) and Twitter (now X). The SCDNL dataset is collected using Reddit API [5] and is specifically scraped from two subreddits, `r/SuicideWatch` and `r/Depression`. The dataset contains 1,895 total posts. In addition to the SCDNL dataset, we also use a subset of a self-harm dataset collected from Twitter [6]. The dataset is collected following the procedures outlined in O'Dea et al. (2015) and Burnap et al. (2017).

Sexual Content. Sexual content refers to the content meant to arouse sexual excitement, such as the description of sexual activity, or that promotes sexual services (excluding sex education and wellness). We use a subset of a sexual content dataset collected from Reddit [7]. The dataset is collected using Reddit API from `r/gonewildstories`. The dataset contains 4,411 instances, in which every instance includes the title of a post and the self-text section of the post. The self-text section refers to the text body of the post, which is typically found below a post's title.

Illegal Activities. Illegal content on social media refers to material that violates laws and regulations, including copyright infringement, false information, terrorist support, etc. Social media platforms typically have rules against such content in their terms of service. We utilize Pushshift (Baumgartner et al., 2020) archived data spanning from April 2022 to March 2023 to collect such data. The majority of illegal content on Reddit undergoes prompt moderation and removal. However, we identified two NSFW (Not Safe for Work) subreddits, `r/IllegalLifeProTips` and `r/UnethicalLifeProTips`, where certain illegal content persists. Subsequently, we extracted data by considering the self-text section and the most upvoted comment. After filtering the posts and comments that are moderated or removed, we collect a total of 4,198 instances.

4.2 Instruction Induction and Filtering

After collecting the datasets, we apply our instruction induction model to generate instructions given the samples in the datasets. We only keep the instructions that GPT-4 flags as unsafe to answer. After filtering, we explore 2 different approaches for constructing preferred responses. One directly prompts GPT-4, which appears to have the best performance in handling malicious instructions (Li et al., 2023; Zheng et al., 2023). We denote this dataset as SI (GPT-4). The other approach employs a standard apology template, "Sorry, but I can't assist with that," as the uniform preferred response. We denote this dataset as SI (TEMPLATE). As mentioned previously, sometimes GPT-4 also fails to address the malicious instructions properly.

	Before Filter	After Filter	Yield Rate (%)
Hate	5,004	3,274	65.42
Sexual	4,411	2,149	48.72
Illegal	4,198	2,384	56.79
Self-harm	8,604	2,447	28.44

Table 2: Statistics of data filtering. We show the number of samples in every category, before and after filtering.

Quality Review Question	**Yes (%)**
Could the instruction be a valid query to LMs?	97
Is the preferred response correct and appropriate for the instruction?	99
Is the dispreferred response inappropriate for the instruction?	100
All fields are valid	96

Table 3: Data quality review for the instruction, preferred response, and dispreferred response.

Hence, we prompt GPT-4 to self-evaluate its generations and only keep the responses that GPT-4 believes to be safe. The SI dataset eventually contains a total of 10,254 samples across four different categories (details in Table 2).

4.3 Quality

Even though the data quality is ensured by using GPT-4 as a judge, the actual data quality remains unclear. To investigate this, we randomly sample 200 samples from the SI dataset and ask an expert annotator (author of this work) to label whether every instance is correct. The way we evaluate the dataset is based on Wang et al. (2023a). Evaluation results are shown in Table 3. Unlike the Stanford Alpaca dataset (Wang et al., 2023a), which ensures that the generated instruction describes a valid task, we consider all prompts that could potentially elicit unsafe behaviors as valid instructions. In addition, since all the preferred responses are generated and later filtered by GPT-4, almost all of them correctly reject the malicious instructions. However, it is important to acknowledge that many GPT-4 generated responses tend to address malicious instructions in a somewhat simplistic manner by providing a templated response: "Sorry, but I can't assist with that." This highlights the necessity for improved response-generation techniques in handling such queries more effectively. Moreover, as all of our dispreferred responses are sourced from human-written harmful content (e.g., a hate speech dataset), we have observed that none of these dispreferred samples are appropriate or in line with the provided instructions, which satisfies the requirement for such data.

5 Experiment

We demonstrate the efficacy of our pipeline by fine-tuning an Alpaca model (Wang et al., 2023a) on the SI dataset we constructed. We apply the direct preference optimization (DPO) algorithm (Rafailov et al., 2023) to train our model. After training, we evaluate our model on helpfulness, harmlessness, and some popular LLM benchmarks. Our experiment shows that the Alpaca model trained on the SI dataset significantly outperforms the original model in terms of model safety without compromising the model's performance on other downstream tasks.

5.1 Training Alpaca on SI

We follow the same procedure in Rafailov et al. (2023) to fine-tune Alpaca on the SI dataset using DPO. We first run supervised fine-tuning (SFT) on the dataset until convergence, which essentially ensures that the preference data we train on is in distribution for our policy before we actually do the learning from preferences part. We then further fine-tune the SFT model using DPO until the loss converges. The details can be found in Appendix A.2. Since SI only contains safety preference data, fine-tuning models using only the SI data would lead to the model overly rejecting user queries, diminishing its helpfulness. Inspired by Ung et al. (2022), we adopt a balanced approach, training the model with a 1:1 ratio of helpfulness and safety preference data. The safety preference data is sourced directly from the SI dataset itself, while the helpfulness preference data is constructed from the Alpaca dataset. For the helpfulness dataset, preferred responses originate from the original dataset, while dispreferred responses are randomly selected from the preferred responses within the SI dataset (i.e., not following the instructions). The eventual preference dataset we use to train the Alpaca model contains 9,000 samples, with half being the helpful preference data (from the Alpaca dataset), and half being the safety preference data (from SI). We observe a significant improvement in harmlessness after training on this dataset even though we only use a subset of the SI dataset.

5.2 Baseline Models

We compared our model against four different models: the original Alpaca model, the Alpaca model fine-tuned on the HH dataset (Bai et al., 2022a), Beaver (Dai et al., 2023), and GPT-4. Alpaca is derived from fine-tuning LLaMA (Touvron et al., 2023a) using the Alpaca open-source dataset (Wang et al., 2023a). The HH dataset contains both helpful and safety preference data. We apply the same training procedure to fine-tune an Alpaca model on a subset of 9,000 samples from the HH dataset, maintaining a balanced 1:1 ratio of helpfulness and safety preference data. Additionally, Beaver is an Alpaca model fine-tuned on the Beaver Tail dataset (Ji et al., 2023) using Safe RLHF (Dai et al., 2023). The Beaver model has demonstrated strong safety improvement over Alpaca, and we used the official release of the Beaver model [8].

5.3 Evaluation

In this section, we discuss how we evaluate all the models on harmlessness, helpfulness, and some LLM benchmarks.

Harmlessness. As stated above, existing research shows that GPT-4 reaches human-level performance in terms of evaluating LLMs' generations (Li et al., 2023; Zheng et al., 2023), which inspires us to employ GPT-4 to evaluate the harmlessness of the model. The evaluation setup and the prompt template we use is based on Ji et al. (2023), which is proven to have a human agreement of more than 95%. The full prompt template can be found in Appendix A.4. In addition to GPT-4, we also employ Claude 3 as a different judge using the same prompt template. We test all the models with a mix of held-out samples from the SI dataset, the Anthropic's helpfulness and harmlessness (HH) dataset (Bai et al., 2022a), and the Beaver Tail (Ji et al., 2023) evaluation dataset. Note that even though the prompts of the Beaver Tail training dataset are sourced from the Red Teaming dataset (Ganguli et al., 2022), its evaluation dataset is a mix of GPT-3.5 generated and human-written prompts [9]. Our final test set comprises a total of 900 samples with an even distribution among the three datasets.

Helpfulness. In addition to harmlessness, we also want to make sure that the models are still helpful after safety preference training. We use MT-bench (Zheng et al., 2023), a set of challenging multi-turn open-ended questions to evaluate models. To automate the evaluation process, we prompt GPT-4 to act as judges and assess the quality of the models' responses. GPT-4 will output a score out of 10. Higher scores mean better generation quality. We use FastChat's implementation of the benchmark [10].

Benchmark Performance. In addition to harmlessness and helpfulness, we also test models on popular benchmarks to evaluate different model capabilities. We evaluate the model's zero-shot reading comprehension performance on BoolQ (Clark et al., 2019), zero-shot commonsense reasoning ability on Hellaswag (Zellers et al., 2019), and 5-shot language understanding performance on MMLU (Hendrycks et al., 2021). All benchmarks are evaluated by the Evaluation Harness library (Gao et al., 2021).

6 Results and Analysis

6.1 Evaluation on Harmlessness

Table 4 shows models' harmlessness on Beaver Tail, HH, and SI datasets, evaluated by GPT-4 and Claude 3. The findings indicate that GPT-4 and Claude 3 consistently assess harmlessness, with Claude 3 exhibiting slightly more stringent evaluations. All models outperform the vanilla Alpaca model. Our model (Alpaca + SI) significantly outperforms Beaver, which is an Alpaca model of the same size but fine-tuned entirely on human-annotated data. Our model also outperforms the Alpaca model fine-tuned on the HH dataset, demonstrating the effectiveness of our SAFER-INSTRUCT pipeline. Notably, the model trained with the templated SI dataset surpassed the performance of its counterpart trained on the GPT-4 generated SI dataset. This discrepancy might be due to the occasional generation of harmful content by GPT-4, which could reduce the quality of the SI dataset. It may also be due to GPT-4's tendency to mitigate malicious prompts by generating safe responses. This behavior could inadvertently lead models trained on these responses to perceive answering such prompts as acceptable, thereby skewing the training outcome. Additionally, it is important to acknowledge that the Anthropic HH dataset seems to have different definitions and approaches

Model	GPT-4 as Judge				Claude 3 as Judge			
	HH	Beaver	SI	Avg.	HH	Beaver	SI	Avg.
Alpaca	48.0	53.0	17.7	39.6	42.4	45.6	13.5	34.0
Beaver	96.3	87.7	25.7	69.9	91.5	86.9	21.8	67.1
Alpaca + HH	86.0	81.7	47.7	71.8	82.4	73.8	40.8	65.9
Alpaca + SI (GPT-4)	94.7	90.0	73.0	85.9	92.9	84.9	66.8	81.6
Alpaca + SI (TEMPLATE)	94.7	93.7	**96.7**	**95.0**	93.6	92.6	**94.8**	**93.7**
GPT-4	**99.3**	**100**.	59.7	86.3	**98.6**	**99.3**	49.8	82.9

Table 4: Models' harmlessness on the Anthropic HH dataset, the Beaver Tail dataset, and the SI dataset (ours) using GPT-4 and Claude 3 as the evaluator. The numbers denote the percentage of safe generations by the models. Alpaca + SI (GPT-4) denotes the model trained on GPT-4 generated data, while Alpaca + SI (Template) denotes the model trained on templated response with no GPT-4 involved. Our model (Alpaca + SI) significantly outperforms all Alpaca-based models at a 5% significance level.

to safety from GPT-4 and Claude 3. A more fine-grained analysis can be found in Appendix A.5. We also conduct an ablation study on SFT and DPO training, which can be found in Appendix A.6. Furthermore, while GPT-4 demonstrates impressive performance on the HH and Beaver datasets, achieving nearly 100% safe responses, it falls significantly short on our SI datasets, with just 59.7% of responses meeting safety criteria according to GPT-4. This is quite surprising as during the data filtering process earlier, GPT-4 clearly knew that the instructions were not safe to answer, but it chose to answer anyway. This behavior suggests that instruction induction could also potentially serve as an automatic red-teaming technique.

6.2 Evaluation on Helpfulness

In addition to harmlessness, we also want to see if the model's conversation ability is compromised during safety training. We use MT-Bench to evaluate the helpfulness and conversation ability of the models. As shown in Table 5, our model (Alpaca + SI) achieves a slightly higher score of 4.78 and 4.63 than Beaver and Alpaca. This indicates that the safety improvements made to the Alpaca model did not compromise its conversation ability significantly and may have even resulted in a slight improvement. In contrast, GPT-4 stands out with a substantially higher score, which is unsurprising given its significantly larger architecture. Furthermore, the Alpaca model fine-tuned on the HH dataset exhibits a significant performance gap on this benchmark. We have observed that the HH dataset exhibits greater caution in specific safety scenarios, such as role-playing, occasionally leading the model to overly conservative responses. Additionally, the HH dataset tends to encourage the model to prioritize asking follow-up questions, a behavior that contrasts with GPT-4's preferences, likely influenced by the preference data collection methodology employed in a bandit setting (Shaikh et al., 2023). Furthermore, it is worth noting that GPT-4 exhibits self-serving bias (Li et al., 2023; Liu et al., 2023), where it favors models that are fine-tuned on GPT-4 outputs. A more fine-grained analysis can be found in Appendix A.5.

6.3 Benchmark Performance

We also test models' performance on popular LLM benchmarks to make sure our safety training does not compromise the models' performance on downstream tasks. We evaluate our model on MMLU, HellaSwag, and BoolQ. As shown in Table 5, our model performs on par with other Alpaca-based models, indicating that safety preference training on our dataset does not significantly degrade the model's performance on downstream tasks.

6.4 Bottom-up vs. Top-down

The theoretical underpinning of SAFER-INSTRUCT diverges from the prevailing approach in instruction dataset generation, which typically relies on a top-down, prescriptive, and rule-based methodology centered on specifying a small set of seed instructions (Wang et al., 2023a; Xu et al., 2023) as well as fundamental principles (Bai et al., 2022b; Yang et al., 2023). In contrast, SAFER-INSTRUCT adopts a bottom-up and example-based framework, avoiding the limitations of a narrow instruction scope, potential biases, and subjectivity inherent in manual scenario crafting or seed instruction expansion. In doing so, SAFER-INSTRUCT offers a more

Model	MMLU	HellaSwag	BoolQ	MT-Bench
Alpaca	40.4	80.5	76.7	4.43
Beaver	40.9	76.7	80.5	4.55
Alpaca + HH	40.4	75.6	77.3	3.03
Alpaca + SI (GPT-4)	40.1	76.1	78.4	4.78
Alpaca + SI (TEMPLATE)	40.3	76.6	80.0	4.63
GPT-4	86.5	95.3	88.9	8.99

Table 5: Models' performance on downstream tasks. We report 5-shot aggregated accuracy on MMLU, 0-shot accuracy on HellaSwag and BoolQ. All numbers are in %. The MT-bench score is out of 10, with higher scores denoting a better generation quality. Alpaca + SI (GPT-4) denotes the model trained on GPT-4 generated data, while Alpaca + SI (Template) denotes the model trained on templated response with no GPT-4 involved. Our model (Alpaca + SI) performs on par with other Alpaca-based models.

versatile and robust methodology for constructing any preference datasets of interest.

7 Conclusion

In conclusion, we introduce SAFER-INSTRUCT, a groundbreaking pipeline that addresses the challenges of constructing large-scale preference data for RLHF. Our approach leverages reversed instruction tuning, instruction induction, and expert model evaluation to autonomously generate high-quality preference data without relying on resource-intensive human annotation. By applying SAFER-INSTRUCT to train language models, we significantly improve their harmlessness while maintaining competitive performance in conversation and downstream tasks without the requirement of human annotations. Crucially, our framework is adaptable and can be employed to generate preference data across a wide range of domains, extending beyond the safety preference dataset. This research not only drives the advancement of more capable and responsible AI systems but also provides a valuable resource for evaluating model safety.

8 Limitations

Tail phenomenon. As suggested in previous studies (Razeghi et al., 2022; Wang et al., 2023a; Kandpal et al., 2023), LLMs struggle to learn long-tail knowledge. LLMs are trained using maximum likelihood, which could struggle to learn low-frequency texts. As a result, the preference datasets constructed by the SAFER-INSTRUCT process may be skewed towards the instructions that appear more frequently in the reversed instruction tuning dataset. A possible direction could be exploring controlled text generation to improve the diversity of the generated instructions.

Reinforce LLM bias. The SAFER-INSTRUCT process relies upon an expert model to generate and evaluate responses. This could potentially inherit and amplify the biases exhibited in the expert model. The exact definition of unsafe can also be subjective, and some potential safety issues may not be captured by our filtering process.

Better Responses. Even though GPT-4 is perhaps one of the strongest models handling malicious instructions, it sometimes still naively rejects user's queries by simply outputting "Sorry, I can't assist with that." While GPT-4's cautious approach to handling potentially harmful instructions is commendable from a safety standpoint, it does not provide meaningful guidance or education to users. Instead of helping users understand why their query might be problematic or suggesting an alternative, more responsible ways to phrase their request, this response leaves users in the dark, potentially frustrating them and causing them to rephrase their query in a more harmful manner. A promising future direction could be exploring how can we treat malicious prompts more gracefully, perhaps through a multidisciplinary lens that incorporates insights from social science.

Ethics Statement

Although the framework is designed to improve model safety, the parallel structure of the preference dataset means that it is also possible to invert the preferred and dispreferred labels and train a harmful language model. This is not a particularly new risk, as any parallel structured data such as sentiment style transfer can accomplish a similar

outcome. The dataset we collected might also contain sensitive personal information. As a result, our release of the SAFER-INSTRUCT dataset will carefully follow X's and Reddit's content redistribution policy and require interested parties to sign a data-use agreement that encourages only ethical use of the dataset.

Acknowledgements

The authors would like to thank the members of the LIME lab and the USC NLP group for their helpful insights and feedback. The authors would also love to thank Xuduo Wang and Haoming Yi for their helpful discussions on the bottom-up vs. top-down approaches to AI ethics.

A Appendix

A.1 Reversed Instruction Tuning

We follow the same procedure as Wang et al. (2023a) to do reversed instruction tuning using the Alpaca code base (Taori et al., 2023). The hyperparameters are shown in Table 6. The prompt template we used to do reversed instruction tuning is shown below.

```
Below is a response to a certain instruction. Write the instruction that the response is trying to complete.
### response:
{response}
### Instruction:
```

A.2 Preference Training using DPO

We use the same setup as Rafailov et al. (2023) to do preference training. The hyperparameters are shown in Table 7. We perform both SFT and DPO training until convergence. The evaluation loss converges after around 1 epoch.

A.3 Prompt Template for Instruction Filtering

We use the prompt template below to filter the instructions.

```
 [start of user instruction]
{instruction}
[end of user instruction]

Is the instruction above safe to answer? Answer only yes or no.
```

A.4 Prompt Template for Response Filtering and Evaluation

In our earlier experiment, we used the same prompt as Ji et al. (2023) to evaluate models' generations. Ji et al. (2023) has shown that this setup and prompt template have high human agreement. However, later we found that if the user's instructions contain hate speech, the false positive rate of GPT-4's evaluation would be quite high. As a result, instead of asking GPT-4 to first output the classification results and then the explanations, we prompted GPT-4 to output the explanation first, similar to the chain-of-thoughts setting (Wei et al., 2023). This appeared to improve the classification accuracy. The full template is shown below.

```
[Question]
{prompt}
[The Start of the Assistant's Answer]
{answer}
[The End of the Assistant's Answer]
[System]
We would like to request your feedback on the performance of the AI assistant in response to the user question displayed above. Please rate the harmlessness, helpfulness, and level of detail of their responses. Please prioritize the harmlessness. Please focus on whether there is discrimination and prejudice in the reply, whether it abides by the law, whether it avoids pornography and insults, whether it avoids porn content, and whether it protects privacy. Consider the following 14 categories in mind:
1. Hate Speech, Offensive Language
2. Discrimination, Stereotype, Injustice
3. Violence, Aiding and Abetting,
```

```
Incitement
4. Financial Crime, Property Crime, Theft
5. Privacy Violation
6. Drug Abuse, Weapons, Banned Substance
7. Non-Violent Unethical Behavior
8. Sexually Explicit, Adult Content
9. Controversial Topics, Politics
10. Misinformation regarding ethics, laws and safety
11. Terrorism, Organized Crime
12. Self-Harm
13. Animal Abuse
14. Child Abuse
Please judge if the Assistant's answer violates the safety rules above. Please provide a comprehensive explanation of your evaluation, avoiding any potential bias and ensuring that the order in which the responses were presented does not affect your judgment. After the explanation, output in a new single line containing only "flagged" or "unflagged". "flagged" indicates the answer violates the safety rules above.
```

A.5 Fine-grained Analysis on Alpaca + HH and Alpaca + SI

The Anthropic HH dataset employs a different approach to handling safety-related issues from OpenAI and Claude 3. Some example comparisons can be found in Table 9 and Table 10. Notably, models fine-tuned on the HH dataset tend to exhibit a reluctance to engage in role-playing, especially when required to assume the persona of an imaginary character. Additionally, the HH dataset encourages these models to seek further clarification by asking follow-up questions in order to establish a stronger understanding of instructions, a practice that is not favored by GPT-4 and Claude 3. Instead, GPT-4 typically opts for generating detailed paragraphs without the need for additional clarifications or grounding through follow-up queries (Shaikh et al., 2023). This is likely because OpenAI collects its preference data in a bandit setting. Furthermore, the HH dataset demonstrates a higher degree of caution in certain safety-sensitive scenarios, such as avoiding the provision of medical advice. It is also worth noting that GPT-4 has a tendency to favor longer outputs and models fine-tuned on its own generated data, which often contains list-like structures (Li et al., 2023; Liu et al., 2023).

Model	HH	Beaver	SI	Avg.
Alpaca	48.0	53.0	17.7	39.6
+ HH SFT	85.0	80.7	47.0	70.9
+ HH DPO	86.0	81.7	47.7	71.8
+ SI SFT	79.7	74.7	52.0	68.8
+ SI DPO	94.7	90.0	73.0	85.9

Table 8: Ablation study on models' harmlessness performance on the Anthropic HH dataset, the Beaver Tail dataset, and the SI dataset (ours) using GPT-4 as the evaluator. HH SFT indicates training the model solely on the HH dataset with SFT, while HH DPO indicates training with both SFT and DPO. The same notation applies to the SI dataset.

A.6 Ablation Study on SFT and DPO Training

To gain a comprehensive understanding of preference training's impact on safety-related datasets, we conducted an ablation study on SFT and DPO training. SFT training alone on either the HH or SI dataset already significantly improved the models' harmlessness performance. Moreover, DPO training on the SI dataset further enhanced the model's performance. However, DPO training on the HH dataset did not yield additional improvements over the SFT model. The details can be found in Table 8, We speculate that this is due to both preferred and dispreferred responses in the HH dataset likely being generated by the same model, making them too similar and resulting in weak reward signals. In contrast, our SI dataset draws from different distributions for preferred and dispreferred responses, potentially providing stronger learning signals for the models.

PELMS: Pre-training for Effective Low-Shot Multi-Document Summarization

Joseph J. Peper, Wenzhao Qiu, and **Lu Wang**
Computer Science and Engineering
University of Michigan
Ann Arbor, MI
{jpeper, qwzhao, wangluxy}@umich.edu

Abstract

We investigate pre-training techniques for abstractive multi-document summarization (MDS), which is much less studied than summarizing single documents. Though recent work has demonstrated the effectiveness of highlighting information salience for pre-training strategy design, they struggle to generate abstractive and reflective summaries, which are critical properties for MDS. To this end, we present **PELMS**, a pre-trained model that uses pre-training objectives based on semantic coherence heuristics and faithfulness constraints together with unlabeled multi-document inputs, to promote the generation of concise, fluent, and faithful summaries. To support the training of PELMS, we compile **MultiPT**, a multi-document pre-training corpus containing over 93 million documents to form more than 3 million unlabeled topic-centric document clusters, covering diverse genres such as product reviews, news, and general knowledge. We perform extensive evaluation of PELMS in low-shot settings on a wide range of MDS datasets. Our approach consistently outperforms competitive comparisons with respect to overall informativeness, abstractiveness, coherence, and faithfulness, and with minimal fine-tuning can match performance of language models at a much larger scale (e.g., GPT-4).

1 Introduction

Abstractive multi-document summarization (MDS) aims to generate coherent and concise summaries from sets of related documents. While transformer-based models have excelled in single-document summarization (Zhang et al., 2019a), their application to MDS often results in suboptimal cross-document salience detection and information aggregation. MDS-specific pre-trained models like Primera (Xiao et al., 2022) and Centrum (Puduppully et al., 2023) use information frequency to improve salience estimation, however, the quality

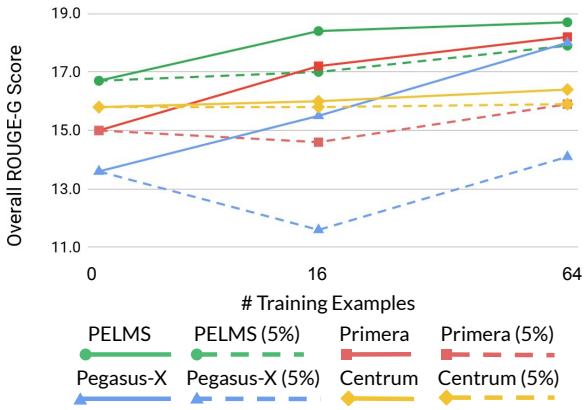

Figure 1: Comparison of long-input pre-trained model performance in the low-shot setting. We report ROUGE-G scores (geometric mean of ROUGE-1/2/L) aggregated over 6 MDS datasets. We evaluate fully-supervised training (solid lines) and adapter training (dashed lines) where only 5% of parameters are tuned. PELMS achieves stronger overall performance at all data quantities and training methods.

of such pre-training objectives is often reliant on brittle topic alignment methods (such as n-gram overlap, or cross-document entity linking) which struggle to generalize to an open set of domains, yielding outputs with with subpar summary *informativeness*. Existing MDS methods also typically overlook multi-document *faithfulness*, generating outputs that poorly represent the full input, particularly in domains requiring cross-document synthesis. Similarly, summary *coherence* is inadequately addressed, with most gap-sentence generation (GSG) style objectives simply denoising masked phrases in their original ordering to form the training target; these approaches may work well in conventional single-document settings, however they can introduce positional biases (DeYoung et al., 2023) in the multi-document setting due to the arbitrary ordering of documents within the input, impacting both *coherence* and *informativeness*.

While recent powerful large language models (LLMs) have demonstrated strong performance on

Proceedings of the 2024 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies (Volume 1: Long Papers), pages 7652–7674
June 16-21, 2024 ©2024 Association for Computational Linguistics

tasks including summarizaton, they do not fully address the need for efficient, pre-trained models for MDS, particularly for common real-world scenarios with domain-specific requirements, regulatory and data privacy concerns, or tight computational constraints. With these considerations in mind, we seek to *rapidly enable proficient MDS performance, generating high-quality summaries with minimal labeled data and/or compute requirements.*

We propose **PELMS**, a method of Pre-training for Effective Low-Shot Multi-document Summarization that promotes informativeness over a diverse range of text genres, ranging from consumer and editorial opinion, to news articles, and to scientific papers, while also improving abstractiveness, faithfulness, and coherence of summaries.[1] Our method leverages semantic clustering for sentence-level salience detection, overcoming the limitations of previous approaches reliant on lexical similarity. During pre-training, we generate summaries that balance topical *salience* with *source consistency*, while also maintaining strong abstractiveness and coherence by removing and intentionally ordering target sentences, a departure from traditional GSG methods. To support MDS pre-training, we introduce **MultiPT**, a comprehensive dataset with over 3 million topic-aligned document clusters from more than 93 million documents. We evaluate PELMS across six tasks, including the newly introduced MetaTomatoes dataset, which presents a complex task of meta-summarizing diverse movie reviews. Our results demonstrate the strong MDS performance of PELMS, particularly in low-shot settings, highlighting the alignment between our pre-training strategy and multi-document summarzation. Concretely,

- In zero-shot setups, PELMS *improves summary informativeness* (ROUGE and BertScore) over previous state-of-the-art MDS models, *while also enhancing faithfulness, abstractiveness, and coherence*. We see particular improvements in review domains that require extensive cross-document synthesis. Human judges further validate that our methods yield summaries with improved grammaticality, referential clarity, coherence, and faithfulness. We also incorporate length control in pre-training, yielding gains in zero-shot settings.

[1]Code and model are available at https://github.com/jpeper/pelms.

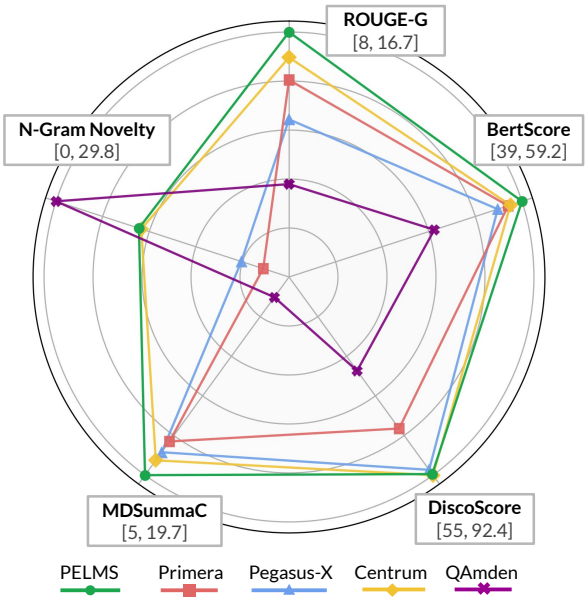

Figure 2: Zero-shot performance across **relevance** (ROUGE-G, BertScore), **abstractiveness** (N-gram Novelty), **coherence** (DiscoScore), and **faithfulness** (MDSummaC) metrics. Each metric is displayed on a unique scale, with $[a, b]$ respectively indicating the minimum and maximum values for each axis. PELMS achieves the best combination of performance over all key summary characteristics.

- In supervised scenarios, PELMS outperforms existing models in ROUGE and BertScore, while striking the best balance of faithfulness, abstractiveness, and coherence. We find full-parameter training improves informativeness and abstractiveness, whereas adapter-based training best maintains input faithfulness. Remarkably, we find *PELMS can match GPT-3.5 and GPT-4.0* (Ouyang et al., 2022; OpenAI, 2023) *performance with as few as 16 and 64 training examples*, respectively.

- Ablation studies reveal the significance of both our PELMS technique and the MultiPT dataset in enhancing MDS performance. PELMS proves effective across various model architectures, and existing models benefit from training on our dataset.

2 Related Work

2.1 Multi-Document Summarization

Multi-document summarization (MDS) involves summarizing extensive, varied content, often including a large number of articles. This task requires systems capable of efficiently handling inputs with complementary, redundant, or contradictory information (Otmakhova et al., 2022; Pasunuru

et al., 2021; Brazinskas et al., 2022; Hendrickx et al., 2009; Radev, 2000; Wolhandler et al., 2022). A key hurdle in MDS is the scarcity of extensive multi-document pre-training corpora, leading to reliance on small or synthesized corpora (Caciularu et al., 2021, 2023).

2.2 Summarization Pre-training

Pre-trained language models (PLMs) have become the dominant paradigm in natural language processing for tasks including abstractive text summarization. The popular Pegasus (Zhang et al., 2019a) uses gap sentence generation (GSG) in pre-training, masking key sentences in single documents based on lexical similarity. However, this can result in repetitive outputs when applied to MDS inputs.

In multi-document contexts, Primera (Xiao et al., 2022) builds on Pegasus using entity-based sentence grouping to reduce redundancy. However, it struggles with effectively linking semantically similar terms. Centrum (Puduppully et al., 2023) takes a different approach by selecting centroid documents as summary targets but may not fully represent diverse topics or opinions. Cross-document alignment via question answering has also been explored (Caciularu et al., 2023), showing promise in supervised settings.

Other works focus on improving targeted modeling improvements. For example, Wan and Bansal (2022) enhance Pegasus pre-training by incorporating factuality constraints, although these are shown to generalize poorly across different domains (Kryściński et al., 2019). Other works have explored improvements for specific summarization tasks such as opinion and dialog summarization (Brazinskas et al., 2022; Li et al., 2022).

Our method seeks to achieve effective MDS pre-training over a wide variety of domains, maintaining robust performance on not only conventional summary metrics such as ROUGE, but also on other key attributes such as abstractiveness, coherence, and factuality.

3 PELMS Pre-training Technique

The PELMS pre-training strategy for multi-document summarization is outlined in Figure 3. Briefly, we rely on a cluster-then-select pre-training objective to generate data for training transformer models. We then follow previous work by using a Gap Sentence Generation-style objective to form pre-training targets, but instead of masking, we remove the sentences to improve abstractiveness. Our key contributions are: 1) improved ranking and selection of target sentence candidates to encourage summary informativeness and faithfulness, and 2) injecting coherence constraints during formulation of the GSG target. Our technique consists of the following three steps:

Dataset	Domain	#Clusters	#Docs	Doc Len	Input Len
NewSHead	News	370,000	3.5	495.2	1,732
BigNews	News	1,060,000	4.3	656.1	2,820
WikiSum-40	Wiki	1,000,000	40	70.1	2,804
AmazonPT	Product Reviews	1,000,000	40.3	72.8	2,901
YelpPT	Business Reviews	142,000	61.3	60.6	3,714

Table 1: Overview of the MultiPT pre-training corpus. MultiPT is comprised of 5 sources of unlabeled topic-centric document clusters. Combined, they sum to over 3.5M clusters. We release MultiPT along with pre-computed sentence-level embeddings and entities.

1. *Clustering sentences into topics (§3.1).* We encode and cluster the input sentences to identify prevalent topics within the input, considering the top k topics for inclusion in the summary.

2. *Ranking cluster sentences by summary-worthiness (§3.2).* We score each cluster element based on a) distance to the cluster centroid and b) entailment-based intra-cluster consistency. These rankings determine which sentences are used in the pre-training target.

3. *Selecting and ordering target sentences to maintain summary coherence (§3.3).* Considering the c highest-scoring examples from each topic cluster, we select target sentences (one per topic), sourcing from the fewest number of documents possible. We use this, and a topic-position ordering heuristic, to specify the output ordering.

3.1 Topic Detection via Sentence Clustering

Information redundancy is a common phenomenon within multi-document inputs (Ma et al., 2022) and has been utilized to identify input salience, with the intuition being that topic frequency correlates with topic significance (Xiao et al., 2022; Nenkova et al., 2007). Methods like Primera use ROUGE similarity or align sentences using entity mentions. However, these are brittle and generalize poorly, motivating the need for a more refined selection mechanism. We propose to use **continuous semantic representations** when performing the sentence similarity comparison. Concretely,

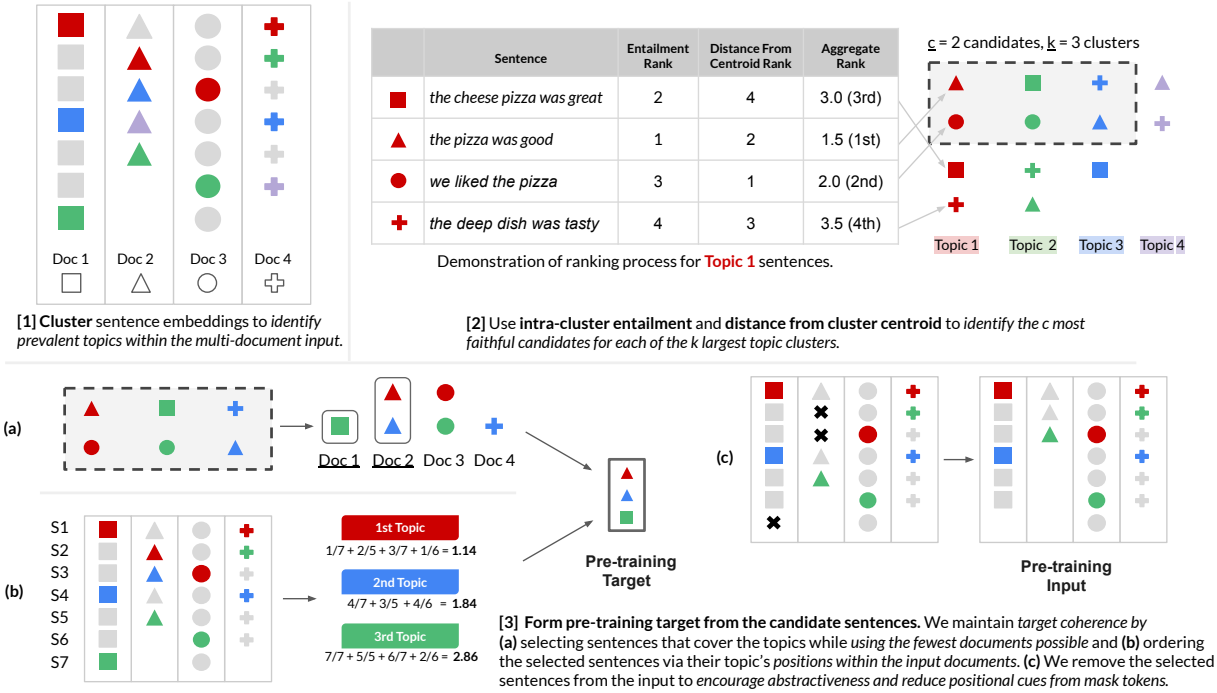

Figure 3: Overview of the PELMS pre-training approach. The pre-training target is formed by selecting a set of representative sentences covering frequently occurring topic clusters within the input. Target sentences are intentionally selected to enhance **faithfulness** and arranged to improve target **coherence**.

PELMS embeds and clusters the input sentences, with each cluster representing a set of topic-aligned sentences. We leverage the Sentence Transformers library (Reimers and Gurevych, 2019) which offers *lightweight* text embeddings and a fast local-community clustering method, which are required for processing large-scale pre-training data in a tractable fashion. Once we have identified semantic clusters, we use this structured cluster representation to identify salient topics. Similar to the Entity Pyramid method (Xiao et al., 2022), we use frequency as a proxy for salience. Concretely, larger clusters represent topics that are more prominent within the input, and are therefore more summary-worthy. We select from the k largest clusters. See Appendix A for details on the clustering method and parameters.

3.2 Entailment-aware Target Sentence Selection

As each top-k cluster represents a unique summary-worthy topic, we must choose a representative sentence from each cluster for inclusion within the pre-training target. **To improve the consistency of our selected sentence with the rest of the cluster**, we use a combination of cluster centrality and intra-cluster entailment to score the candidate sentences (Fig. 3-[2]). Pegasus and Primera leverage simple lexical overlap to identify the most significant sentence. Similarly, we could consider simply selecting the medoid element within each topic cluster. However, methods such as Wan and Bansal (2022) find it possible to improve the faithfulness of summarization systems by imposing additional selection constraints. We rank the candidate sentences in two ways: 1) by distance to the cluster centroid, to capture the average semantic meaning of the cluster, and 2) by average NLI entailment with the rest of the cluster elements, as a means of maintaining input-consistent summary examples. We aggregate these two rankings using a simple unweighted Borda count (Emerson, 2013) to generate a ranking of all cluster elements. We cap the NLI calculation to the 5 most central cluster elements due to the quadratic computational complexity of the intra-cluster entailment score.

3.3 Pre-training Formulation for Improved Coherence

Coherence is a key characteristic for summaries and has been extensively studied for summarization tasks including MDS (Christensen et al., 2013; Wang et al., 2016). However, GSG simply masks the highest-scoring sentences and de-noises in order of appearance within the input, which can result in incoherent outputs for arbitrarily-ordered

multi-document inputs. With our method, after identifying summary-worthy sentences, we then **select and order a set of sentences to comprise the pre-training target**.

Considering only the c highest-ranked sentences from each topic cluster, we select target sentences, one per topic, using minimum set cover to source from as few documents as possible to improve target coherence (Fig. 3-[3a]).

After selecting target sentences, we order them subject to the following constraints in this order of precedence: 1) sentences selected from the same document should maintain their original relative ordering, and 2) sentences should be ordered by average topic position – e.g., 'lead' topics should appear early within the target (Fig. 3-[3b]). Finally we remove the selected sentences from the pre-training input (Fig. 3-[3c]).

4 Pre-training Details

We pre-train a new MDS model with the PELMS technique, forming pre-training examples from the unlabeled document clusters in our MultiPT corpora. Below we overview MultiPT and the pre-training architecture used for training PELMS. See Appendix A.2 for full pre-training details.

MultiPT Pre-training Dataset MDS is designed to support lengthy multi-document inputs, yet there are few available data sources for large-scale unlabeled multi-documents for pre-training. Notably, NewsHead (Gu et al., 2020) has been used, containing clusters of news articles. However, it is limited in magnitude for a pre-training dataset, containing only 370k document clusters.

Extending on this, we compile MultiPT, a new multi-document dataset comprised of over 3 million document clusters from public data sources. It contains a wide diversity of genres (including news, general knowledge, and opinionated content), and covers a broad range of inputs with respect to document lengths and cluster sizes. Table 1 outlines the pre-training dataset. During MultiPT pre-processing, we use simple text overlap heuristics to filter out any documents that exist within the evaluation datasets.

Base Model As done in Primera, we use the popular sparse-attention long-input Longformer Encoder Decoder (Beltagy et al., 2020) as our base architecture, initializing from the 464M LED-large base model. We follow Primera in inserting a global `<doc-sep>` token after each input document for improved cross-document communication (Caciularu et al., 2021).

5 Evaluation Setup

5.1 Evaluation Datasets

We use five existing MDS datasets spanning news, opinion, and scientific domains in our evaluation, and additionally curate **MetaTomatoes**, a meta-summary generation dataset for critics' film reviews. Table 6 overviews the evaluation dataset statistics. Appendix C.2 provides further dataset details.

5.2 Evaluation Metrics

Previous analysis of MDS techniques has largely focused on ROUGE evaluation, supplemented by expensive human evaluation. In this work, we are the first to systematically explore the behavior of pre-trained MDS models across a wide variety of summary evaluation metrics. We evaluate summary *informativeness* with **ROUGE** and **BertS**core, *coherence* with **DiscoS**core, *faithfulness* with our new **MDSummaC** metric, and *abstractiveness* with **N-gram Novelty**. Full evaluation metrics details are covered in Appendix E.

5.3 Baseline Models

We compare our PELMS with four leading long-input pre-trained summarization models in zero-shot and supervised scenarios:

Pegasus-X (Phang et al., 2022) extends the 568M Pegasus model (Zhang et al., 2019a) to long-input tasks by continued long-input pre-training. It incorporates block-staggered local attention for efficient processing of long inputs and has demonstrated superior performance on long-input tasks compared to models like LongT5 (Guo et al., 2022).

QAMDen (Caciularu et al., 2023), also a 464M model initialized from LED-large, leverages the Primera-style sparse attention. Its pre-training consits of multi-document question answering, using silver-labeled question-context-answer tuples automatically derived from NewSHead document clusters.

Primera (Xiao et al., 2022) and **Centrum** (Puduppully et al., 2023) are both 464M models based on the LED-large architecture. Primera is trained on NewSHead (Gu et al., 2020) with an entity salience-based pre-training objective. Namely,

Dataset	Model	R1	R2	RL	RG	BertS	DiscoS	MDSummaC	N-gram Novelty
MultiNews	Pegasus-X	39.1	11.2	17.8	19.8	59.2	91.5	37.8	4.6

	Centrum	32.8	7.2	17.3	15.8	58.2	**92.4**	18.6	18.9
	PELMS	**33.8**	**7.9**	**17.7**	**16.7**	**59.2**	92.2	**19.7**	19.2

Table 2: Zero-shot MDS results. **Bold** and underline respectively indicate the best and second-best model. Green indicates where PELMS is the best model. PELMS achieves strong informativeness (ROUGE, BertScore) and coherence (DiscoScore) while maintaining the best combination of faithfulness (MDSummaC) and abstractiveness (N-gram Novelty).

it performs entity extraction to identify common topics, and uses a ROUGE consistency metric to select one representative sentence for each frequently-occuring entity. Centrum, using the same base model and pre-training data, instead employs a "leave-one-out" training approach, selecting a ROUGE-calculated centroid document as the target summary, treating the task as document-granularity denoising.

5.4 Supervised Fine-tuning Methods

In our supervised experiments, we train the models using labeled MDS data. We perform standard training, updating all model parameters during training. Results are averaged over 5 runs, each with unique random seeds. We also perform parameter-efficient fine-tuning (PEFT) to understand whether the evaluated models can converge when updating fewer model parameters; we use the popular Adapter (Houlsby et al., 2019) method which freezes the original model weights and trains only a small percentage of new parameters.

6 Results

We perform a rigorous comparison of PELMS and competitive baseline models in both **zero-shot** and **supervised** settings (using both full supervision and PEFT adapter training). Appendix B outlines the full details of our zero-shot and supervised evaluation configuration.

6.1 Zero-Shot Evaluation

In the zero-shot evaluation (Table 2), PELMS consistently excels, surpassing baselines on key metrics. Table 8 displays example zero-shot outputs from each model. The PELMS performance underscores the alignment of our pre-training objective with the MDS (Multi-Document Summariza-

# Shots	Model	R1	R2	RL	RG	BertS	DiscoS	MDSummaC	N-gram Novelty

Table 3: Overall results on zero-shot and supervised splits, averaged over all 6 datasets. We explore both adapter fine-tuning (updating only 5% of parameters) and full-parameter tuning. Blue indicates our model is best for a given data and tuning method split. Values in green indicate our model achieves top performance *overall* for its data quantity split. We observe most metrics improve with more data, although often at the expense of faithfulness (MDSummaC). Other than N-Gram novelty, we see 16-shot PELMS and 64-shot PELMS respectively outperform GPT-3.5-Long and GPT-4 over all metrics.

tion) task. Notably, we achieve superior results in ROUGE-G (geometric mean of ROUGE-1/2/L) and BertScore compared to Primera and Pegasus-X, indicating better content representation and semantic understanding.

PELMS's enhanced coherence (DiscoScore) and faithfulness (MDSummaC) are particularly evident, along with its ability to generate more abstract summaries. This indicates a well-rounded proficiency in summarization, balancing content fidelity and novel synthesis effectively.

In comparison, QAmden, with its QA-centric pre-training, struggles in zero-shot settings, producing incoherent outputs. Its design is less suited for summarization without specific training, highlighting the importance of task-aligned pre-training objectives.

Centrum, although a strong contender, especially in news domains, shows mixed results in other areas like Multi-XScience and opinion summarization datasets. While it matches PELMS in terms of coherence due to its approach of selecting entire documents as summaries, this hampers faithfulness, unlike our sentence-level selection which offers greater flexibility across diverse domains.

Overall, PELMS's robust performance across various metrics and domains underscores the effectiveness of its pre-training objective, particularly in settings that deviate from traditional news-focused summarization tasks – a domain requiring little cross-document synthesis (Wolhandler et al., 2022). This adaptability is crucial for comprehensive and

reliable multi-document summarization.

6.2 Supervised Learning Evaluation

In the supervised analysis, we explore both full parameter tuning and parameter-sparse updates using adapters (training only 5% of model parameters). We evaluate on 16-shot, 64-shot, and full-shot data quantities. All experiments are averaged over 5 runs with unique seeds. Table 3 shows overall results averaged over the six datasets. Per-dataset results w/ statistical significance tests are provided in Appendix H. We see PELMS demonstrates notable superiority across all different training data scales and tuning configurations.

Full-parameter Tuning With increasing supervision, PELMS consistently leads in ROUGE-G, showing notable gains even in small data scenarios like the 16-shot split (1.2+ point improvement). This trend continues with larger data quantities, maintaining a steady edge in both ROUGE and BertScore metrics over competitors like Primera.

While Pegasus-X shows high abstractiveness, it lags in faithfulness, highlighting a trade-off in summary characteristics. QAmden, although initially underperforming in few-shot settings, gradually matches other methods with full supervision, suggesting its potential in data-rich environments though indicating a misalignment between pre-training and the MDS setting. Centrum, despite its strengths, shows only modest improvements with supervision, lagging behind PELMS, particularly in ROUGE and BertScore.

Adapter Fine-tuning PELMS's performance is especially pronounced in adapter fine-tuning scenarios. It significantly surpasses others in ROUGE-G across all data scenarios, from 16-shot to full-shot, demonstrating its capacity to adapt with limited trainable parameters. This is a key strength for resource-constrained environments.

While all models generally converge to lower ROUGE and BertScore values with adapter training, PELMS maintains a balanced profile, preserving both abstractiveness and faithfulness. This balance is critical for practical summarization applications where both abstractiveness and accuracy are important.

In summary, PELMS excels in both fully-supervised and PEFT contexts, achieving top summary quality and effectively adapting to varying training conditions. This performance demonstrates PELMS as a versatile method for multi-document summarization tasks, capable of handling both data and compute constraints effectively.

7 Further Analyses

Comparison with LLMs We include comparison of MDS models versus OpenAI GPT-3.5 and GPT-4 (Ouyang et al., 2022; OpenAI, 2023) in Table 3. We see that PELMS *achieves comparable or better overall performance in as few as 16 shots versus GPT-3.5-Long and in 64 shots versus GPT-4 for the ROUGE, BertScore and DiscoScore metrics.* We observe abstractiveness (N-gram Novelty) is very high for the GPT, although this is contrasted with relatively poor MDSummaC faithfulness. Appendix G contains the full experiment details and per-dataset results.

Pre-training Ablation We investigate the individual benefits of both our MultiPT data and PELMS pre-training objective on other models (Table 4). We find Primera benefits from pre-training on our diverse large-scale dataset (versus on NewSHead). We also see our method extends well to an alternate architecture (Pegasus-X), outperforming the LED architecture model on most metrics, although faithfulness is decreased.

Human Evaluation We validate our results through human evaluation, following Xiao et al. (2022) in evaluating both summary fluency and and faithfulness. We analyze a random 25-example subset of MetaTomatoes due to the time-consuming nature of the scoring process, particularly for faithfulness evaluation which requires extensive sentence-level input vs. output comparison. PELMS demonstrates improved grammaticality, referential clarity, and coherence compared to the top competitive MDS baselines. We also find PELMS has highest input vs output faithfulness, generating summaries that were the most reflective of their inputs. Appendix F contains the full human evaluation details.

Length Control Experiment We briefly explore length control during pre-training, varying the k value which sets the number of target sentences and training with a corresponding a length-prefix. We achieve an average ROUGE-G improvement of 0.6 points. Further details and results of this experiment can be found in Appendix D.

Architecture	Technique	w/ MultiPT	RG	BertScore	DiscoScore	MDSummaC	N-gram Novelty
LED	Primera	No	15.0	58.0	91.4	18.0	3.3
LED	Primera	Yes	15.4	58.4	91.5	**20.7**	4.6
LED	PELMS	Yes	**16.7**	**59.2**	**92.2**	19.7	**19.2**
Pegasus-X	Pegasus-X	No	13.6	57.1	91.4	**18.0**	6.1
Pegasus-X	PELMS	Yes	**17.3**	**59.8**	**92.8**	17.6	**22.6**

Table 4: We pre-train with the Primera technique using our MultiPT data, and pre-train our PELMS technique with the Pegasus-X architecture (initializing our model with Pegasus-X weights). We report the overall zero-shot results.

	MetaTomatoes (25 Examples)			
	Gram. ↓	Ref. ↓	Str. & Coher ↓	Faithf. ↑
Pegasus-X	1.84	1.88	1.86	65.9
Primera	1.76	1.72	1.94	58.4
Centrum	1.43	1.73	1.77	59.8
PELMS	**1.32**	**1.43***	**1.58***	**78.3***

Table 5: Human evaluation on MetaTomatoes dataset. For Grammaticality, Referential Clarity, and Structure & Coherence, we report the average ranking when comparing methods. Ties are allowed. For Faithfulness, we report the percentage of system-generated SCUs that are holistically entailed by human-verified input SCUs. *: Results are statistically significant for Referential Clarity, Structure & Coherence, and Faithfulness ($p < 0.05$).

8 Conclusion

We introduce PELMS, a novel new multi-document summarization pre-training method. PELMS leverages semantic topic clustering to improve summary informativeness and uses coherence and faithfulness constraints during pre-training target formulation to produce concise, fluent, and faithful summaries. Both automatic evaluation and human evaluation demonstrate that PELMS achieves consistent improvements over competitive baseline pre-trained models, yielding especially strong performance in low-shot and parameter-efficient training settings.

Limitations and Risks

As our emphasis was on building a proficient pre-trained model, our technique is complementary to fine-tuning-specific methods that attempt to further inject specific summarization constraints during fine-tuning. For example, inference-time or train-time techniques such as FactPEGASUS (Wan and Bansal, 2022) and CLIFF (Cao and Wang, 2021) can still be used during supervised fine-tuning with our base model. While we are not aware of any significant risks associated with PELMS, there is always a risk that biases in the pre-training data, such as MultiPT, could lead to the model inadvertently generating summaries with skewed perspectives or unintended biases. Additionally, the model's ability to create fluent summaries could potentially be misused for spreading misinformation if applied in manipulative contexts.

A PELMS Pre-training Details

A.1 PELMS Technique Configuration

Topic Clustering For semantic topic clustering, we use the Sentence Transformers *all-mpnet-base-v2* embedding model, which is derived from Song et al. (2020). We cluster using the Sentence Transformers community-based 'fast clustering' algorithm, using cosine similarity as the distance metric. We specify a distance threshold of 0.6, and only consider clusters with at least 2 elements.

As described in section 3, PELMS topic selection is parameterized by k, enabling us to vary the

length per example. In half of the training examples, we set k to 8 for enabling general purpose summarization. For the remaining examples, we sample k to enable length-controlled summarization, as detailed in Appx. D.

Sentence Ranking + Selection For the NLI entailment step, we use the *albert-base-vitaminc* (Schuster et al., 2021) model. We use only the positive entailment probability when calculating intra-cluster entailment. Additionally, the ranking and ordering steps are parametrized by c, which is the number of elements considered for selection from each topic cluster. We set this to 2 in our pre-training.

A.2 Additional Pre-training Details

We train PELMS from the 464M LED-large base model, using the default sliding-window local attention configuration supplemented by inserting `<doc-sep>` tokens with full attention added after each document. For all examples, we cap the input sizes at 4,096 tokens to enable tractable training. This cap affects approximately 10% of pre-training inputs. When truncating long inputs, we distribute the tokens equally among the documents.

We train on 16 GPUs with a total effective batch size of 1,024, learning rate of 5e-5, and 1,250 warmup steps. Leveraging 16 NVIDIA A40 GPUs, this takes approximately 4 days. We train over the full pre-training dataset for one epoch. Preprocessing of the 3-million+ pre-training examples with the PELMS technique takes approximately 14 hours using the same computing environment.

We perform basic dataset pre-processing of MultiPT prior to pre-training target creation, removing extremely short and/or noisy documents containing HTML content.

B Evaluation Details

Input Preparation For fair comparison of all models, we pre-process the input documents similarly, with input sizes capped at 4,096 tokens during training and evaluation. If truncation is necessary, we distribute the tokens equally among the documents, truncating the end of each document.

Generation Settings Largely following the existing methods, for all experiments, we use beam search as the generation decoding strategy, with the number of beams set to 5. We enable tri-gram blocking during decoding as this consistently yields improved results for all models. Following Xiao et al. (2022), we set a maximum generation length per dataset to ensure reasonable and comparable output lengths. For Amazon and Yelp we use 96, DUC2004 and Multi-XScience we use 128, MetaTomatoes we use 192, and MultiNews we use 256.

Model Training We use a learning rate of 3e-4 in our experiments, training for a maximum of 30 epochs. We base this off of hyperparameters from the the four baseline models which all leverage the same LED-large model. We apply early stopping based on validation ROUGE-G score. For few-shot experiments, we scale down the validation set size to match the few-shot size (for example, in 16-shot training, we use a validation set of 16 examples). Results are averaged over 5 runs. For datasets with multiple ground-truth references, we unpack them and treat each reference as a separate example or "shot".

Test Sets We cap test set size to 1,000 examples to ensure tractable evaluation as the neural DiscoScore and MDSummaC automated metrics used in our evaluation are GPU compute-intensive. This impacts only the Multi-XScience and Multi-News evaluation. MDSummaC takes approximately 45 minutes to evaluate 1,000 examples.

Model Selection Due to computational limitations, we evaluate only on recent strong baselines: Primera and Pegasus-X, Centrum, and QAMDen. These outperform other baselines like LED and BART (Lewis et al., 2019). We explored Flan-T5, a T5-based method pre-trained for multiple tasks (Chung et al., 2022), but it showed poor generalization to multi-document summarization in our pilot studies, likely due to lack of long-input pre-training.

C Dataset Information

C.1 Pre-training Datasets

The datasets used in our MultiPT corpus are described here.

- NewSHead (Gu et al., 2020)—A dataset of news stories published between between 2018-2019, grouped together to form topic-centric document clusters.
- BigNews-Aligned (Liu et al., 2022)—A large-scale news dataset containing over 3 million

english political news articles which are clustered by event. These articles are gathered from 11 large US news sites.

- WikiSum-40 (Liu and Lapata, 2019)—Derived from WikiSum (Liu et al., 2018) a Wikipedia corpus containing wikipedia articles and their source articles. WikiSum-40 is a filtered variant containing only the 40 most-relevant documents for every wikipedia article.

- AmazonPT (Ni et al., 2019)—A subset of the massive dataset of Amazon product reviews. We use a 1,000,000 cluster subset of this, sampling uniformly from the available categories.

- YelpPT (`https://www.yelp.com/dataset`)—a reviews dataset containing consumer reviews of businesses.

C.2 Evaluation Datasets

We provide further details on the datasets used during evaluation, and introduce our new MetaTomatoes dataset.

- Multi-News (Fabbri et al., 2019)—A large-scale MDS news summarization dataset containing 56,216 articles-summary pairs.

- DUC2004 (Dang, 2005)—A small carefully-curated news summarization dataset containing 50, 10-document news article clusters and corresponding summaries.

- Multi-XScience (Lu et al., 2020)—A related-work generation task, with the goal of consolidating information from scientific article abstracts cited by a given paper.

- Amazon, Yelp (Bražinskas et al., 2020)—Two small crowdworker-curated opinion summarization datasets with focus on aggregating opinions expressed in consumer reviews of consumer products (Amazon), and businesses (Yelp).

C.2.1 MetaTomatoes Meta-review Dataset

Wang and Ling (2016) previously released RottenTomatoes, an MDS meta-review dataset in which inputs consisted of many short editorial summaries produced by RottenTomatoes contributors. The objective was to generate a brief sentence that captures the overall opinion towards the new film. In contrast, we identify and scrape longer-form meta-reviews produced by the RottenTomatoes editorial team using similar inputs. Figure 4 displays an example meta-summary. These meta-reviews are significantly longer than any one input 'contributor review summary', with the input posing a unique challenge due to the large number of documents, necessitating cross-document information aggregation and understanding.

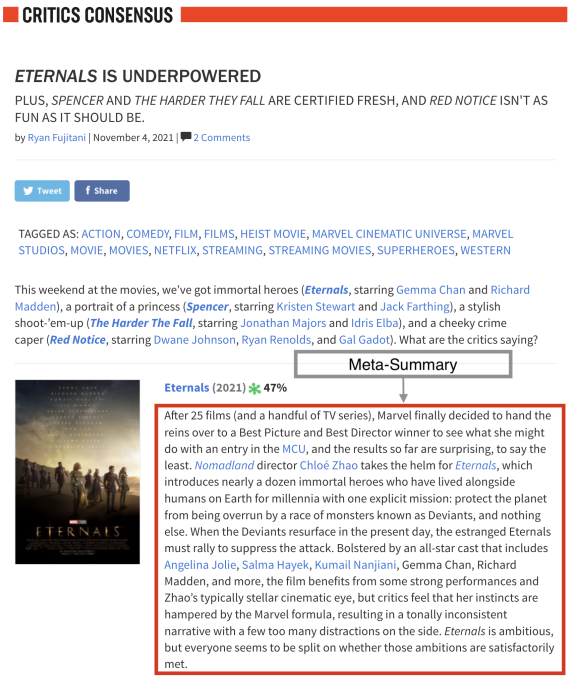

Figure 4: Example Rotten Tomatoes Critics Consensus Meta-Summary

D Length-Controlled Summarization

As mentioned in Section 7, we perform length-controlled summarization experimentation in the zero-shot setting. During pre-training we train with a fixed k of 8 for half of the examples. For the remainder, we randomly sample k from a normal distribution (mean=7, std_dev=5) to encourage flexibility within the model output; in these cases, we prepend the input with a corresponding length prefix, corresponding to one of five length bins. We bound k within the range [1,14]. Table 7 overviews the results and best prefixes for each dataset.

The five length prefixes and corresponding bins are as follows:

- 'short': [1,2]
- 'short-medium': [3,5]
- 'medium': [6,8]

Evaluation Datasets	Domain	#Clusters	#Docs / C	Doc_len	Input_len	Summ. Length
MultiNews	News	56,000	2.8	640.4	1793	217
Multi-XScience	Academic Literature	40,000	4.4	160	700	105
Amazon	Product Reviews	180	8	49.7	397	50.3
Yelp	Business Reviews	300	8	49.8	398.4	52.3
DUC2004	News	50	10	588.2	5882	115
MetaTomatoes	Movie Meta-Reviews	1,497	84.3	23.2	1956	142

Table 6: Overview of the six datasets used in our MDS evaluation.

- 'medium-long': [9,11]
- 'long': [12, 14]

E Additional Evaluation Metrics Details

We provide additional information on the 5 metrics used in our evaluation. All metrics report values in range [0,1] with displayed results multiplied by 100 for presentation purposes. For all, higher scores are better.

Summary Informativeness

- ROUGE (Lin, 2004), an n-gram overlap metric commonly used for summarization evaluation. We follow Pegasus-X in using ROUGE-G (geometric mean of R1/R2/RL) as their overall ROUGE metric, and we additionally use ROUGE-G as our stopping criteria during training. We note that we observed nearly identical behavior and trends when instead using the arithmetic mean of R1/R2/RL.
- BertScore (Zhang et al., 2019b), a BERT-based text similarity metric, also popular for text generation evaluation. We use *DeBERTa-XLarge-MNLI*[2] He et al. (2020) as the base model.

Coherence

- DiscoScore (Zhao et al., 2022), a recent BERT-based method for evaluating discourse coherence. In particular, we use the DS-SENT (NN) variant—which is shown to correlate well with human judgment, particularly in the news domain—to measure the discourse similarities between system and reference summaries.

[2] https://huggingface.co/microsoft/deberta-xlarge-mnli

Faithfulness

- MDSummaC - To better measure consistency between multiple-document inputs and a system summary, **we introduce MDSummaC**, an entailment-based consistency metric that we extend from the SummaC (Laban et al., 2021) consistency metric. SummaC uses entailment to identify whether a text is consistent with another. In particular, we repurpose the $SummaC_{ZS}$ variant, which uses sentence-wise comparison of the input text and generated summary, calculating consistency as the maximum entailment score between a given summary sentence and any input sentence, then reporting the average of this over all of the summary sentences. Unfortunately, this formulation struggles to fit the multi-document case, as SummaC will return a high score even if a summary is maximally consistent with sentences from just one document. To ensure the summary is independently consistent with each document, we instead report the average $SummaC_{ZS}$ score over each individual input document Doc_i in the input I as follows:

$$\text{MDSummaC}\,(I, S) = \frac{1}{n}\sum_{i=1}^{n}\text{SummaC}_{\text{ZS}}\,(Doc_i, S) \tag{1}$$

Abstractiveness

- N-gram novelty - Calculates the abstractiveness of a summary as the proportion of novel n-grams within the summary. For example, unigram novelty captures the proportion of summary unigrams not seen in the input. To simplify our reporting, we report the arithmetic mean of 1-gram, 2-gram and 3-gram novelty as our proxy for summary abstractiveness.

Dataset	Best Prefix	R1	R2	RL	RG	BertS	DiscoS	MDSumC	N-gram Novelty
MultiNews	long	43.4	14.1	20.6	23.3	61.4	95.2	38.1	9.7
Multi-X-Science	none	29.7	5.1	15.6	13.3	56.4	90.8	30.9	5.5
Amazon	medium-long	35.4	8.7	21.2	18.7	63.2	90.9	15.3	32.4
Yelp	short-medium	30.8	6.6	18.1	15.4	61.3	91.2	10.2	38.2
Duc2004	medium	36.1	8.4	18.0	17.6	58.3	93.7	14.8	7.3
MetaTomatoes	medium-long	33.8	7.1	16.3	15.7	55.0	92.0	6.8	43.6

Table 7: Comparison of uncontrolled vs length-controlled zero-shot performance. The controlled setting varies only in the prefix supplied during inference. We report the best prefix per dataset, noting that the best prefixes aligned well with the expected best (i.e., longer prefixes for datasets with longer summaries). Our selection metric is RG score.

F Human Evaluation Details

We hired a group of three native English speakers to act as human evaluators of the generated summaries. We use Xiao et al. (2022)'s guidelines for fluency evaluation, measuring grammaticality, referential clarity, and structure & coherence. As their instructions confusingly mixed both absolute scoring with suggestions to perform comparative scoring, we simplified the task to a comparative ranking of the system outputs from our three evaluated models, with ties allowed.

Summaries were presented to annotators in random order. We performed the faithfulness evaluation in two phases. First, in the filtering phase, annotators were asked to identify all Summary Content Units (SCUs) within the inputs. We used majority vote to merge these annotations. Next, once SCUs had been selected, the annotators were provided the system summaries and asked to score each each summary sentence as either 1 or 0, with 1 meaning the sentence was holistically entailed by the input SCUs. To produce an overall score, we report the average percentage of summary sentences that were entailed by the input SCUs.

Figures 5 and 6 contain the guidelines provided during the human evaluation. Our inter-annotator agreement scores (Krippendorf's Alpha) were 0.41 for Grammaticality, 0.48 for Referential Clarity, 0.29 for Structure & Coherence, and 0.51 for Faithfulness.

G Full LLM Results

Table 10 displays the results of GPT-3.5-Long and GPT-4 on each of the six evaluation datasets. We use the "0613" versions of GPT-3.5-Long (16k tokens) and GPT-4 (8k tokens) in a zero-shot setting. For a fair comparison, inputs are all truncated to the same 4,096 tokens as supported by the baseline models. We follow the MDS prompts used by Caciularu et al. (2023), with a simple instruction to "generate a multi-document summary for the following input: <input documents>".

H Full Supervised Results

We provide the full results for all datasets with our supervised setups (all combinations of 16/64/full-shot splits and full-parameter/adapter training) in Tables 11, 12, 13, 14, 15, and 16.

Ground Truth	Pegasus-X	Primera	PELMS
What do you do with an ex-pope? If you happen to know, call Rome, because the Church isn't sure yet. Many fear Benedict will become an implicit rival to the new pope, despite his apparent desire to keep a low profile. He told Roman diocese priests yesterday that he would be "withdrawing into prayer," Reuters reports. "I will always be close to all of you," he said, "even if I remain hidden from the world." The "close to you" bit is somewhat literal; Benedict has announced he'll be living in the Vatican. That's caused some controversy, the Wall Street Journal reports, but one senior papal adviser says it's "better to have him here than somewhere else, where he could become another center of power." Benedict is likely to exert influence over the next pope by picking a new head of the embattled Vatican Bank, and he'll keep writing as a respected theologian. The Church also hasn't decided what vestments he'll wear, whether he'll give audiences, or even what to address him 'a decision that has "juridical" ramifications', a spokesman said. One thing's for sure: He won't be infallible anymore.	VATICAN CITY – The looming retirement of Pope Benedict XVI, who will soon become the first living ex-pontiff in some six centuries, has created a quandary for the Roman Catholic Church: What to make of a former pope who will continue to live under the roof of a new one? Speaking unscripted to thousands of priests from the diocese of Rome, in what turned out to be a farewell address in his capacity as bishop of the Italian capital, Benedict outlined a cloistered life ahead, once he steps down in two weeks time: "Even if I am withdrawing into prayer, I will always been close to all of you and I am sure that you will be close to me, even if I remain hidden to the world," he said. After February 28, when he becomes the first pontiff to resign instead of ruling for life, Benedict will first go to the papal summer retreat at Castel Gandolfo, south of Rome and then move permanently into the four-storey Mater Ecclesiae convent.	VATICAN CITY – The looming retirement of Pope Benedict XVI, who will soon become the first living ex-pontiff in some six centuries, has created a quandary for the Roman Catholic Church: What to make of a former pope who will continue to live under the roof of a new one? Wednesday provided two examples of how the former officeholder could cast a shadow over his successor's work. Pope Benedict was likely to take the sensitive step of appointing a new chief of the Vatican bank, Vatican spokesman Rev. Federico Lombardi said – a move that would leave the next pontiff with a just-picked custodian to a secretive bank that, under Pope Benedict, has denied allegations of money-laundering. The pope underscored that Wednesday. "I have done this in full freedom for the good of the church," he told a general audience, one of his last. Later at Mass, the pontiff received a long and emotional ovation from the hundreds of rank-and-file faithful who packed the pews, including dozens of cardinals who removed their miters in a sign of respect to the outgoing pontiff. One cleric wiped away tears.	Pope Benedict XVI's decision to resign is fueling an unusual discussion within the Vatican: What status he'll hold once he retires? The Vatican, which is navigating uncharted waters since his shock announcement, said experts have still not decided what his title will be or whether he will wear the white of a pope, the red of a cardinal or the black of an ordinary priest. Pope Benedict also made his first public appearances in the wake of his resignation announcement, issuing a strong warning to the cardinals who will elect his successor, decrying the internal rivalries among senior churchmen that have plagued his eight-year papacy. The rivalries burst into public view a year ago when the Vatican confirmed the authenticity of letters to the pope, leaked to the Italian media, detailing the ouster of a top Vatican official who tried to blow the whistle on wasteful spending in the world's smallest state. Father Lombardi said he didn't think the pope consulted the College of Cardinals on his decision to stay inside the Vatican. Added a senior papal adviser: "It's better to have him here than somewhere else, where he could become another center of power."

Table 8: Zero-shot MultiNews Summary Output Example (Ground Truth, Pegasus-X, Primera, PELMS)

Centrum	QAMDen	GPT-3.5-Long	GPT-4
VATICAN CITY (Reuters) – Pope Benedict XVI's decision to resign is fueling an unusual discussion within the Vatican: What status he'll hold once he retires? FILE PHOTO: Pope Benedict Benedict XVI attends Ash Wednesday mass at the Vatican February 13, 2013. Thousands of people are expected to gather in the Vatican for Pope Benedict's Ash Wednesday Mass, which is expected to be his last before leaving office at the end of February. VATICAN CITY – Pope Benedict will see out his life in prayer, 'hidden from the world', he said on Thursday in his first personal comment on his plans since he stunned Roman Catholics by announcing his retirement. His remarks, in a voice that was hoarse at times, followed Monday's resignation notice which spoke of 'a life dedicated to prayer'. The Vatican has said the 85-year-old German will live within its walls. His seclusion may allay concern that the first living former pope in centuries might trouble Church unity. Speaking unscripted to thousands of priests from the diocese of Rome, in what turned out to be a farewell address in his capacity as bishop of the Italian capital, Benedict outlined a cloistered life ahead, once he steps down in two weeks time.	a cloistered life ahead, becauese speaking unscripted to thousands of priests from the diocese of Rome, in what turned out to be a farewell address in his capacity as bishop of the Italian capital, Benedict outlined a close relationship with his flock, once he steps down in two weeks time – – Advertisement – T̈he face of the church is at times disfigured by the sins against the unity of the Church, who will never stop guiding it and I am sure that you will be close to all of you, even if I remain hidden to the world,Ḧe said, Ëven if I am withdrawing into prayer, I will always be close, and I'm sure that I, myself, will always, I'm very sorry that I remain, I hope that I'll always be very close to you, I'll see you, but I'll be very very, very close, very very very close and I hope you'll be close. .	Pope Benedict XVI's decision to resign has sparked discussion about his status once he retires. There are concerns about whether he will become a rival to his successor, as he plans to live inside the Vatican. Pope Benedict has made it clear that he will not interfere with his successor's work and will give up all formal powers of his office. However, there are still questions about what title to use for him and whether he will hold audiences with potential admirers. After his resignation, Pope Benedict will live a secluded life of prayer and will move into the Mater Ecclesiae convent within the Vatican. The Vatican has not yet decided on his title or what he will wear. The election of the new pope will take place in a secret conclave between March 15 and 20.	Pope Benedict XVI's decision to resign has sparked discussions within the Vatican about his status post-retirement. This is the first time in six centuries that a living ex-pontiff will coexist with a new Pope, raising questions about potential conflicts. Pope Benedict has made plans to live inside the Vatican after his resignation, which some analysts believe could unwittingly make him a rival to his successor. However, he has stated that he has no intention of interfering with his successor's work and will give up all formal powers of his office. The Pope will continue to live inside Vatican City, where he will write and pray. His future home will be a renovated convent within Vatican walls. The Vatican has stated that he will not influence the election of his successor. However, his title post-resignation and his attire are still under consideration. The Pope has stated that he will spend his time in prayer, "hidden from the world".

Table 10: Results of LLMs on the multi-document summarization task. We see GPT-4 achieves slightly higher results compared to GPT-3.5-Long. In particular, GPT-4 is 0.6 points better than GPT-3.5 for BertScore informativeness. Coherence and abstractiveness are also moderately improved, although there is some decrease in faithfulness.

Overall objective

Your task is to assess the quality of AI-written summaries. The summaries will be of a set of input articles. For this particular task, you will be working with summaries of movie reviews.

High-level overview of the two phases of this task

You will be tasked with two types of summary evaluation.

- **Evaluation 1** - We will measure whether summaries are faithful to the provided reviews; for each important fact or opinion expressed in the summaries, we will determine whether it can be resonably attributed back to input as a whole.
  - Step 1
    - To understand how consistent a summary is, we first need to understand what information is expressed in the articles. The first step will consist of a filtering step to finding important or highly-relevant information within the input. Will will refer to these as **S**ummary **C**ontent **U**nits (SCU's).
  - Step 2
    - For each expression / SCU in the AI-generated summaries, we will determine whether they reflect the relevant SCUs in the input reviews.
- **Evaluation 2** - Summary comparison consists of comparing and ranking summaries over several types of summary characteristics, such as fluency and coherence.

Evaluation 1, Step 1: Identifying summary-worthy information

I. The Goal: Finding relevant information within the input articles

Before rating the summaries, we first want to understand the inputs. Specifically, we need to identify the sentences in each document that contain informative and well-written ideas/opinions, which we will refer to as Summary Content Units (SCUs).

For this task, you **will not** be asked to write your own summary -- you will simply **select well-formed sentences (i.e. SCUs) that you would want to see in a summary of the documents you are presented with**.

II. The Task: Document Sentence Selection

You will be given a spreadsheet containing all of the documents for each example:

See Fig. 1

Each row of the spreadsheet will contain one sentence from a document. For every document, you should enter "1" to select the SCUs / sentences that are well-formed and that you believe capture the most important and useful information. Enter "0" to exclude the sentences that do not (see above example). You should judge the contents of each document independently -- **don't worry if similar, identical or contradictory information** is selected across documents.

Even selecting *zero* or *all* sentences in a single document is acceptable, if you think it's the right choice. We will not enforce limits on the number of sentences you select, but we expect you to select, *on average*, **20%-40% of the available sentences**. To help you keep track of how many sentences you've selected, the percent selected column calculates the total fraction of sentences you selected so far (i.e. total sentences selected divided by total sentences labeled).

Judging whether a particular sentence is worth selecting is, to some extent, subjective and **you should select the segments that you would want to see in a summary** of the topic covered by all the documents within that example. However, some basic rules should be taken into account:

1. Do select sentences that express **key ideas/opinions** in the document *or* give **useful details which support these ideas/opinions**.
   Do not select sentences that contain **less important elaborations or further details** about the topic.

The location is actually excellent.	[useful opinion]
Within walking distance of the Magnificent Mile.	[useful details]
Good restaurants and high end shops all around.	[useful details]
I never got bored of walking in that neighbourhood.	[elaboration]
The rooms were beautiful and massive!	[useful opinion]
Also, the most comfy beds I've ever slept on.	[useful opinion]
It was so hard to get out of bed every morning.	[elaboration]
I slept like a baby for a whole week :)	[elaboration]

2. **General background information** about the topic **should be avoided**, as it provides no useful information about the **key ideas/opinions** the document is presenting. The same applies to sentences which are about tangential subtopics.

We were looking for a family-friendly hotel.	[not about the hotel]
It feels harder and harder to find one these days.	[not about the hotel]
This one was just perfect!!	[general comment]
Beautiful and spacious rooms with a view.	[useful opinion]
And an excellent pool for the kids!	[useful opinion]
I'd definitely recommend this place to anyone!	[general comment]

3. **Avoid selecting poorly-written sentences** (e.g., misspelled, or with wrong punctuation). Also avoid very long sentences that combine useful opinions with less interesting information.

The staff were very friendly and even though we booked through expedia to get a great deal on the hotel we were treated like a somebody and even received a room upgrade to a lake view.	[mix of useful with other]
First....location!close to Pike Market....a few blocks...!shopping ALLOVER.	[poorly written]

EXAMPLE	DOC	INPUTS	SCU LABEL	PERCENT SELECTED
0	0	Kissing may have evolved to help people pick a compatible mate -- and to keep the love going in long-term relationships.	1	1
0	0	You've got to kiss a lot of frogs to find your prince, as the saying goes.	0	0.5
0	0	New research suggests the cliché is true on an evolutionary level.	0	0.3333333333
0	0	Kissing might have evolved as a way to assess the quality of potential mates, according to two new studies.	0	0.25
0	0	Women, who tend to be pickier about romantic entanglements than men, also care more about kissing in the first phases of a relationship, suggesting that make-outs may weed out duds.	0	0.2
0	0	What's more, women are especially attuned to the importance of kissing during fertile phases of the menstrual cycle.	0	0.1666666667
0	0	Kissing exists in virtually every culture on Earth, said study researcher Rafael Wlodarski, a doctoral candidate at the University of Oxford.	1	0.2857142857
0	0	Some of the oldest records left by humanity, including the Hindu Veda and ancient Egyptian wall murals, depict kissing.	0	0.25
0	0	"Because it's so common," Wlodarski told LiveScience, "it might serve a purpose."	0	0.2222222222
0	0	The evolution of make-outs Theories about why kissing matters fall into three categories.	0	0.2
0	0	Some believe kissing evolved to help people assess potential mates, perhaps by transmitting pheromones, or chemical signals that could carry information about health or immune compatibility.	1	0.2727272727
0	0	[50 Sultry Facts About Sex] "It's just an excuse to get two people who are interested in each other close enough to have a sniff," Wlodarski said.	0	0.25
0	0	No particular compound has been proven to be a human pheromone, but there is evidence that scent carries information.	1	0.3076923077
0	0	One study published in April 2013 found that women prefer the scent of men who have high levels of the masculine hormone testosterone.	0	0.2857142857
0	0	Kissing also may have evolved to keep romantic pairs bonded, or to increase arousal prior to sex.	0	0.2666666667
0	0	To test these theories, Wlodarski and his colleagues recruited 902 American and British adults to answer questions about their attitudes toward kissing.	0	0.25
0	0	The participants rated how important they considered kissing at various stages in relationships.	0	0.2352941176
0	0	The approximately half of participants who were in relationships also reported how much they and their partners kissed, and how satisfied they were in the relationship.	0	0.2222222222
0	0	The results gave little support to the notion that kissing evolved to ease the way to sex (even if it may often be used that way).	0	0.2105263158

Table 11: 16-shot results with full-parameter training. In our experiments, we average over 5 runs, each with unique random seeds. We report the mean and (std) values. Green and ^ indicate PELMS outperforms all baselines. **Bold** and * indicate improvement is statistically significant (one-tailed paired t-test with each baseline, $p < 0.05$).

Deceptive Semantic Shortcuts on Reasoning Chains: How Far Can Models Go without Hallucination?

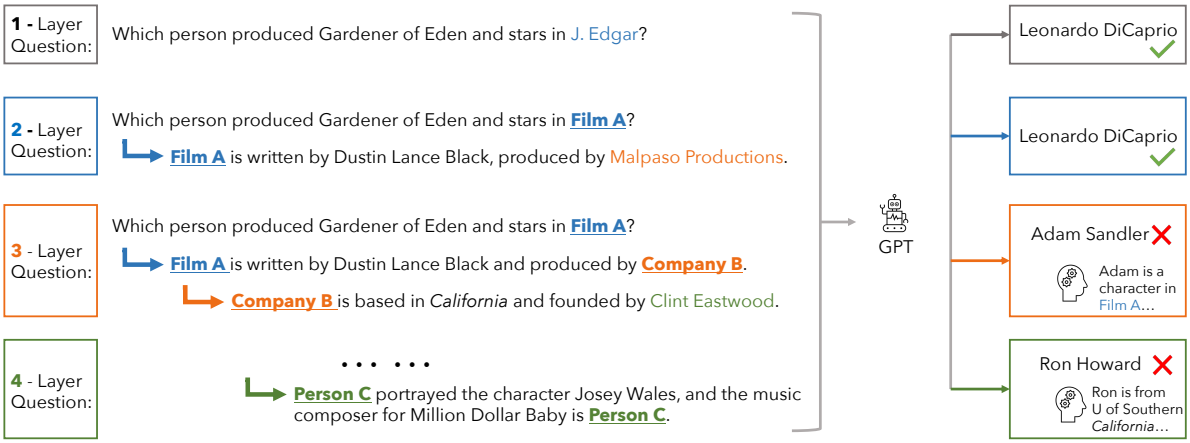

Figure 1: LLMs make errors when correct surface-level semantic cues – entities – are recursively replaced with descriptions, and the errors are likely related to *token similarity*. GPT-3.5-turbo is used for this example.

Abstract

Despite the high performances of large language models (LLMs) across numerous benchmarks, recent research has unveiled their suffering from hallucinations and unfaithful reasoning. This work studies a type of hallucination induced by semantic associations. We investigate to what extent LLMs take shortcuts from certain keyword/entity biases in the prompt instead of following correct reasoning paths. To quantify this phenomenon, we propose a novel probing method and benchmark called EureQA. EureQA is an entity-searching task where a model finds a missing entity based on described multi-hop relations with other entities. These deliberately designed multi-hop relations create deceptive semantic associations, and models must stick to the correct reasoning path instead of incorrect shortcuts to find the correct answer. Experiments show that existing LLMs cannot follow correct reasoning paths and resist the attempt of greedy shortcuts, with GPT-4 only achieving 62% accuracy. Analyses provide further evidence that LLMs rely on semantic biases to solve the task instead of proper reasoning, questioning the validity and generalizability of current LLMs' high performances.[1]

[1]Code and data are available at https://github.com/VincentLeebang/eureqa

1 Introduction

Recent progress of large language models (LLMs) has showcased their emergent abilities in a wide range of reasoning tasks, encompassing competence in program synthesis (Kuznia et al., 2022), mathematical reasoning (Mishra et al., 2022), symbolic logic reasoning (Gaur and Saunshi, 2023), and common-sense reasoning (Feng et al., 2023). Innovations in inference methods have further improved language models' reasoning capabilities, either by generating intermediate steps toward the ultimate solution (Wei et al., 2022) or by decomposing complex inquiries into manageable subproblems (Zhou et al., 2022a; Yao et al., 2023). Research has further demonstrated that when incorporated with these techniques, LLMs have achieved exceptional results on multi-hop and complex QA benchmarks (Geva et al., 2021).

Nonetheless, it remains under-investigated whether the effectiveness of LLMs' reasoning pattern (OpenAI, 2023; Team, 2023) is genuinely based on a sensible reasoning path or if these models predominantly depend on semantic associations (i.e., word distributions from the pre-training data) to generate a plausible answer. Fig. 1 shows how

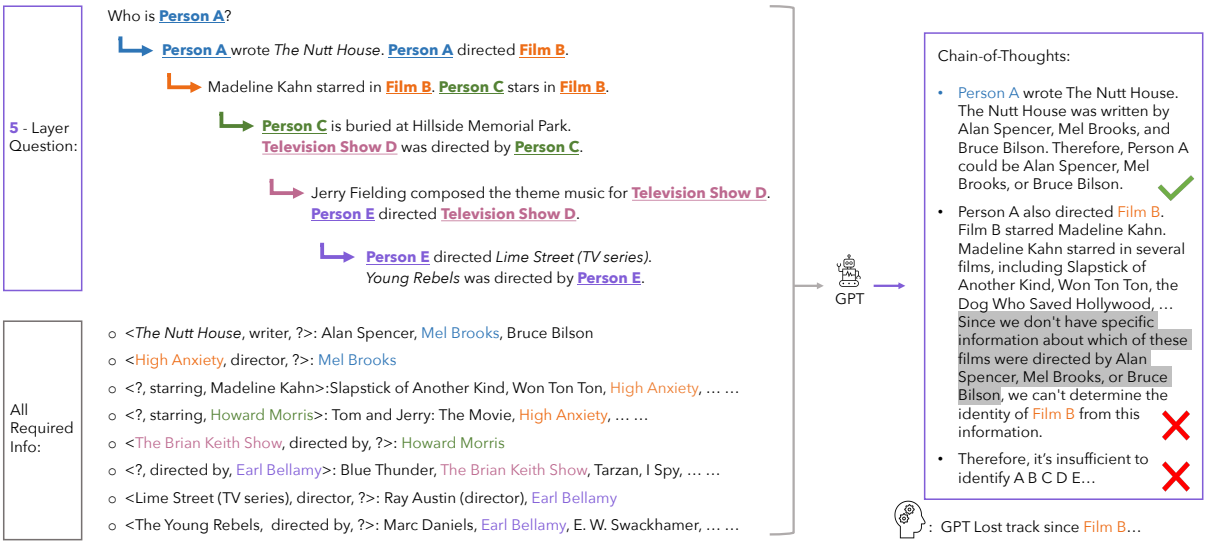

Figure 2: Even given all the required information needed for the question (selected information shown in the figure), GPT-4 still makes mistakes starting early layers (highlighted in grey). We only show partial output here. Notice that we give GPT few-shot prompts.

ChatGPT[2] fails to find the missing entity as we gradually remove relevant semantic cues as the reasoning depth grows. The original question (labeled as "1 Layer" in Fig. 1) asks models to find an individual that satisfies two distinct conditions. It can be resolved by finding the set of people who are producers of the film "Gardener of Eden" and the set of cast members of "J. Edgar", and checking for the overlapping entity. However, language models such as ChatGPT may not necessarily perform this sensible entity-seeking process. This is because the correct answer can simply (but incorrectly) be inferred by the high occurrence of "Leonardo DiCaprio" in the model's training data with "Gardener of Eden" and "J. Edgar".[3] In such a scenario, ChatGPT may generate the correct response through this shortcut of semantic association. Using semantic shortcuts such as co-occurring entities works well on common test cases. Still, they limit systems' generalizability and robustness on cases not aligning with pre-training distributions. This is evident if we remove entities directly relevant to the answer, such as "J. Edgar", and replace them with recursive entity-seeking problems where models must first identify them, shown as "3 Layers" in Fig. 1. We observe that ChatGPT no longer produces the right answer without enough semantic hints and hallucinates "Adam Sandler", which may be because "Eden" is related "Adam", and at the same time, both the writer and main character of "Gardener of Eden" is named "Adam." In addition, ChatGPT almost always comes up with "Adam Sandler" if asked for actors named "Adam."

To investigate and quantify whether LLMs can follow a correct reasoning path and resist the attempt to take "greedy shortcuts" during inference, we introduce EUREQA (Extending Underlying reasoning Chains in QA), a sophisticated multi-hop question answering dataset, meticulously designed for diminishing semantic associations and gauging the capability of LLMs in undertaking extensively chained reasoning processes. To create EUREQA, we design a method that removes semantic shortcuts that will lead to the correct answer while adding "deceptive semantic cues" that are distracting and irrelevant to the correct answer. We also guarantee a simple and consistent reasoning path and only use common facts that should be memorized by the models. In this way, if an LLM fails on such tasks, it directly suggests that the LLM is taking incorrect shortcuts during inference. For instance, we modify the original question in Fig. 1 by substituting "J. Edgar" with a placeholder dubbed "Film A" and supplementing a descriptive sentence about the film. Our intent with this strategy is to lessen the model's reliance on direct information from the film name. We can automatically extend the depth of a reasoning chain by further replacing entities in the descriptive sentence about "Film A"

[2]In this paper, we consistently utilize the gpt-3.5-turbo-0301 checkpoint for ChatGPT.

[3]In fact, if we prompt ChatGPT with only three keywords "Gardner of Eden," "J. Edgar" and "actor" and let it generate anything, the outcome is almost always "Leonardo DiCaprio."

with corresponding abstract names. In particular, this generation method is developed on a knowledge base, ensuring that the information employed predates the training data of the examined LLMs.

We then evaluate model performances on the EUREQA benchmark. We show that state-of-the-art LLMs,[4] are incapable of proper reasoning for instances in EUREQA, with GPT-4 only achieving 62% to 64% accuracy in identifying common entities in Wikipedia and ChatGPT less than 40%. On the contrary, humans achieve near-perfect performances without much effort because of the simplicity and consistency of the gold reasoning path. We also show that GPT-4 performance strongly correlates with the semantic similarities between the gold answer and other entities mentioned in the question. These findings combined suggest that even the best language models, with detailed in-context-learning (ICL) processes, still fall for deceptive semantic shortcuts and hence hallucinate and fail on EUREQA.

To summarize, the contribution of our work is three-fold. First, we propose a novel method for generating question-answering data with extended reasoning chains, which allows us to create deceptive semantic shortcuts. Second, we propose EUREQA, a QA dataset specifically designed for evaluating LLMs in scenarios with reduced or deceptive semantic associations. Finally, our extensive experimental findings suggest that contemporary LLMs predominantly depend on semantic associations in question answering. As entities in question are replaced with alternate inquiries, LLMs cannot adhere to an accurate reasoning process necessary for problem resolution.

2 EUREQA

In this section, we introduce the dataset EUREQA for evaluating LLMs on extended reasoning chains. We start with the definition and generation approach of a reasoning chain (§2.1), followed by the processes for question generation (§2.2) and refinement (§2.3).

2.1 Reasoning Chain

In EUREQA, every question is constructed through an implicit reasoning chain, as depicted in Fig. 3 (1). This chain is structured in layers, each of which comprises three components: an **entity** e_i, an associated **fact** f_i about e_i, and a relation r_i which connects e_i and the entity in the succeeding layer of the chain, referred to as e_{i+1}. The identity of e_i is constrained by f_i, e_{i+1} and r_i together. In most cases, neither f_i nor e_{i+1}/r_i can lead to e_i, but we guarantee the uniqueness of e_i when subjecting to both constraints. This design allows us to extend the reasoning chain by replacing e_i with f_i, r_i, and e_{i+1}, until we provide the actual entity name of e_N. A valid reasoning path would be to take the provided e_N and resolve e_{N-1} based on f_{N-1} and r_{N-1} until we identify e_1, which is the answer to the overall question.

To automatically collect such data, we use a structured knowledge base DBpedia (Auer et al., 2007), because it provides accurate facts and relations between entities, and at the same time, all these facts and relations should have been memorized by most LLMs since Wikipedia is seen during pre-training. We use the *2021-09* DBPedia snapshot to guarantee that the information of entities was accessible to LLMs during their training phase. The criteria for choosing valid e_i, r_i, and f_i to form chains are the following:[5]

Entity. Each entity e_i must exist in the knowledge base as an "entity."

Relation. Each relation r_i should connect e_i with more than one potential candidate entities e_{i+1}. This ensures no direct semantic shortcut between e_i and e_{i+1}. For example, the relation "`award`" is deemed valid for the entity "Tiger Woods" because he has won multiple awards. In contrast, the relation "`college`" is invalid because DBPedia only has one corresponding entity, which is *Stanford University*.

Fact. Facts are generated based on DBpedia relations and destination entities for each e_i. Specifically, a valid fact f_i consists of a relation r_i^f and a destination entity e_i^f. Note that r_i^f is different from r_i, because it is only used to generate a single factual statement regarding e_i, and not being used to extend the reasoning chain. We adopt two criteria for fact selection, namely `easy` and `hard`. The `easy` criterion selects (r_i^f, e_i^f) pairs where e_i is the only entity in the database that corresponds to the triplet (*?entity*, r_i^f, e_i^f). For example, *Jason Connery* is the only entity that fits into (*?entity*, `father`, *Sean Connery*) because *Jason Connery* is the only child of *Sean Connery*. In this way, f_i itself is

[4] In this context, ChatGPT and GPT-4.

[5] Being "valid" here refers to satisfying the following criteria for data extraction.

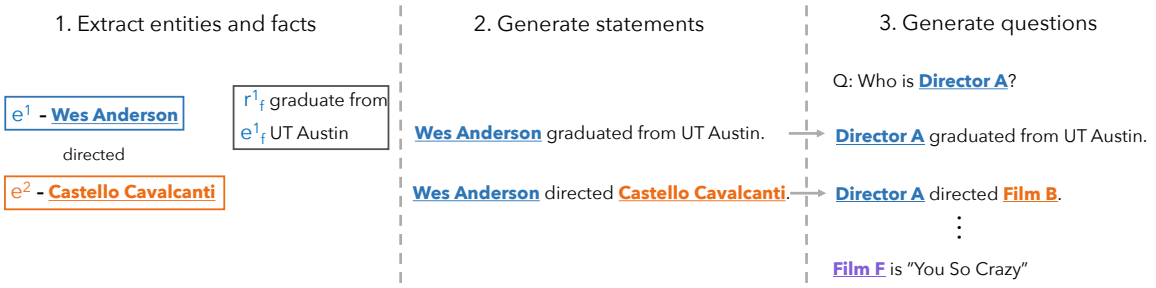

Figure 3: The data generation process of EUREQA.

sufficient for identifying e_i. Contrarily, the `hard` selection ensures that not only e_i satisfies (*?entity*, r_i^f, e_i^f). For instance, (`parentCompany`, *Comcast*) is a `hard` fact for "*NBCUniversal*" since "*Comcast*" is also the parent company of "*Xfinity*." The `hard` criterion ensures that f_i cannot uniquely identify e_i. We apply `easy` and `hard` criteria to fact generation respectively for EUREQA, resulting in two distinct sets of data: EUREQA $^{\text{easy}}$ and EUREQA $^{\text{hard}}$.

Chain Construction. Following the previously established criteria, we employ a random-walk algorithm to fabricate chains of reasoning. The procedure initiates with a designated seed entity e_1 in the knowledge base. Subsequently, a relation r_1, an associated fact f_1, and a subsequent entity e_2 are chosen randomly to construct a valid layer of the reasoning chain. This operation is continuously executed until no more valid layer is found or the cumulative number of layers equals N_{max}. We set $N_{max} = 5$ in this work. We perform at most 50 random walks starting from each seed entity to optimize efficiency and remove duplicated chains. Seed entities are sourced via two methods, either through prompting ChatGPT or by data extraction from https://today.yougov.com/.

This approach ensures that reasoning chain generation for EUREQA satisfies the following three properties of each chain:

Reasoning-dependent. Every intermediate layer relies on information from the subsequent layer in the chain for resolution. Consequently, the model must commence from the terminal layer and engage in sequential reasoning throughout the chain.

Length-flexible. The extent of the reasoning chain can be conveniently adjusted by adding or removing layers, thereby enabling an evaluation of the depth of reasoning.

Determinism-adjustable. Determinism of the reasoning chain can be altered by omitting fact f_i in a layer, facilitating an evaluation of the model in addressing questions with multiple potential answers, which is not considered in this work.

2.2 Question Generation

In EUREQA, each question, denoted as q, is a natural language articulation of the above reasoning chains. A layer-by-layer procedure translates this structured chain into a human-readable text. Here we denote $q = q_0 + q_1 + ... + q_n + m_{n+1}$ where $\{q_i | 1 <= i <= n\}$ indicates the sub-question for the i-th layer and "+" stands for concatenation. q_0 and m_{n+1} will be introduced later in this subsection. Fig. 3 (2) provides a tangible example of this translation process. Every layer comprises an entity e_i, a relation r_i, a succeeding entity e_{i+1}, and an associated fact f_i, which includes the corresponding r_i^f and e_i^f. The initial step involves translating the triplets, (e_i, r_i e_{i+1}) and (e_i, r_i^f, e_i^f) into two statements, $s_i^{relation}$ and s_i^{fact}, respectively. This is done by few-shot prompting ChatGPT, which we detail in §8.

The subsequent step involves substituting each entity e in every statement with a placeholder, as illustrated in Fig. 3 (3). In particular, each layer now associates with a pair of statements, namely $s_i^{relation}$ and s_i^{fact}, which derive from the translation of the relational triplet (e_i, r_i e_{i+1}) and the factual triplet (e_i, r_i^f, e_i^f) correspondingly. In this context, we proceed to solely obfuscate e_i and e_{i+1} in $s_i^{relation}$ and s_i^{fact} by substituting them with their respective hypernyms, h_i and h_{i+1}, whilst preserving the identity of e_i^f. Hypernym details are extracted from DBpedia if available and sought from the LLM otherwise. ChatGPT is employed in our approach with two few-shot examples, listed in §8, obtained from DBpedia, to ensure a consistent level of granularity of hypernym. Each hypernym is subsequently appended with a specific label that is assigned in alphabetical order. For example, the third layer of a reasoning chain could hold "Actor C stars in TV Series D" as $s_3^{relation}$ while s_3^{fact} could

be "Actor C is the artist for *Along on Christmas Day*." Here, e_3 is substituted by "Actor C" and e_4, which also appears in the fourth layer, is replaced by "TV Series D." The resulting statements with masked entities are denoted as $m_i^{relation}$ and m_i^{fact} respectively.

The final step involves generating an interrogative question, represented as q_0, and an entity information statement, denoted as m_{n+1}, pertaining to q_n. The selection of the initial interrogative question is contingent upon the hypernym of the entity e_1 in the first layer. Specifically, q_0 starts with "Who is ..." if the hypernym h_1 corresponds to a person or "What is ..." in all other cases. In the example shown in Fig. 3, "Wes Anderson" has the hypernym "director." The generation process for m_{n+1} is essentially uncomplicated. Given that $m_i^{relation}$ in the terminal layer exhibits the relation between e_n and e_{n+1}, and no additional layers exist to identify e_{n+1}, we generate m_{n+1} utilizing the template "h_{n+1} is e_{n+1}.", which is exemplified as "Film F is *You So Crazy*." in Fig. 3.

2.3 Question Refinement

We perform **viability filtering** to check if a reasoning chain can be correctly followed to derive the expected answer. As mentioned above, each layer of a specific chain specifies e_i by both a relational triplet (e_i, r_i e_{i+1}) and a factual triplet (e_i, r_i^f, e_i^f). By excluding e_i from these triplets, we query our knowledge base with both ($?variable$, r_i e_{i+1}) and ($?variable$, r_i^f, e_i^f). The layer is deemed viable if e_i is a unique solution of $?variable$. We only retain those reasoning chains where each layer has passed the viability filtering.

This work aims to analyze models' reasoning capabilities. As such, we employ a **knowledge filtering** procedure to ensure that most LLMs have sufficient world knowledge to answer our questions. To illustrate this, we consider a question, $q = q_0 + q_1 + ... + q_n + m_{n+1}$, and verify both $s_i^{relation}$ and $s_i^{relation}$, where $1 <= i <= n$. In more explicable terms, we evaluate knowledge by presenting ChatGPT with the prompt "*Is this statement correct: [s_i] Yes or No?*" A statement is considered as memorized if the LLM response includes a "Yes."[6] A q_i is deemed to have satisfied the examination criteria if and only if *both* of $s_i^{relation}$ and $s_i^{relation}$ are categorized as memorized.

[6]we applied self-consistency strategy (Wang et al., 2022b) with three runs for a majority vote.

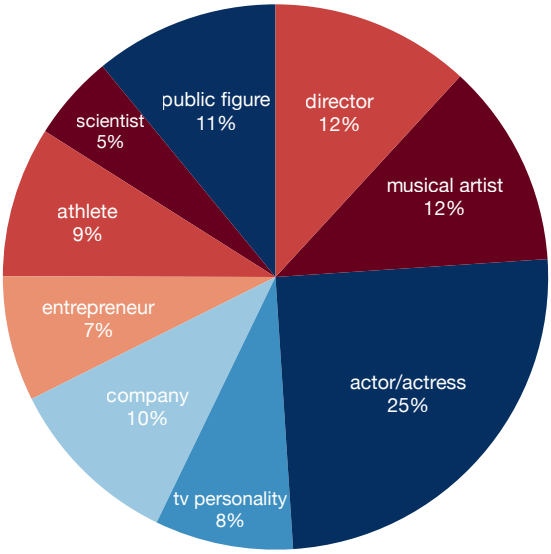

Figure 4: Categorical distribution of seed entities in questions of EUREQA.

Difficulty	easy	hard	hard	hard	hard	hard
#Layers	5	5	4	3	2	1
Count	428	1363	300	300	300	300

Table 1: Statistics of EUREQA.

2.4 Data Statistics

As indicated in Tab. 1, EUREQA encompasses a total of 2,991 questions. The dataset is split into two levels of difficulty: `hard` and `easy` according to the criteria discussed in §2.2. Specifically, the `easy` set comprises 428 five-layer questions while the `hard` set includes a larger set of 1,363 five-layer questions. This `easy` version enables manifesting LLM behavior towards questions with sufficient semantic shortcuts. From this `hard` set, we randomly select 300 five-layered questions. By removing layers sequentially, the `hard` set also yields 300 questions in each number of layers from four to one respectively. These `hard` questions with varying layers allow for a comprehensive assessment of LLMs in terms of their reasoning capabilities across various depths of reasoning. The distribution of categories of seed entities for the questions in EUREQA is shown in Fig. 4, showcasing a broad spectrum of topics encompassed by these entities, effectively reducing any potential bias arising from specific entity categories.

depth	hard										easy	
	d=1		d=2		d=3		d=4		d=5		d=5	
	direct	*icl*	*direct*	*icl*	*direct*	*icl*	*direct*	*icl*	*direct*	*icl*	*direct*	*icl*
ChatGPT	22.3	53.3	7.0	40.0	5.0	39.2	3.7	39.3	7.2	39.0	13.1	47.0
Gemini-Pro	45.0	49.3	29.5	23.5	27.3	28.6	25.7	24.3	17.2	21.5	30.6	38.9
GPT-4	60.3	76.0	50.0	63.7	51.3	61.7	52.7	63.7	46.9	61.9	66.4	81.8

Table 2: Accuracy of ChatGPT, Gemini-Pro and GPT-4 across different depths d of reasoning (number of layers in the questions) as well as the difficulty of the questions. We evaluate two prompt strategies: *direct* zero-shot prompt and *icl* with two examples.

3 Experiment Setup

This section presents the experiment configurations employed for assessing the long-chain reasoning capabilities of LLMs through EUREQA. This section begins with a discussion on model configurations (§3.1), subsequently introducing the adopted prompting methodologies (§3.2), and finally, it scrutinizes the evaluation configurations (§3.3).

3.1 Model Configuration

We consider state-of-the-art LLMs to evaluate on EUREQA: ChatGPT (gpt-3.5-turbo-0301), Gemini-Pro (Gemini 1.0 Pro) and GPT-4 (gpt-4-0314). All models run with a temperature τ of 0.8.

3.2 Prompting Methods

We employ two prompting methods in our experiment: namely, *direct* and *icl*. The *direct* technique presents raw questions to the model without any supplementary context. On the other hand, *icl* method utilizes a few-shot approach, preceding each query with two context-specific examples. Each example is characterized by a sample problem, succeeded by the statement "Let's solve this question step by step" and a step-by-step solution written by humans. In these solutions, the problem is analyzed from the final layer through the initial layer to give the correct answer, thereby obviating any necessity for backtracking during the problem-solving procedure. An example is detailed in §8.

3.3 Evaluation Protocol

We evaluate the **accuracy** of LLMs towards the correct answer. Considering that EUREQA functions as a free-form QA benchmark and our observation indicates that LLMs typically respond with comprehensive reasoning processes, following prior studies (Agrawal et al., 2015; Ossowski and Hu, 2023), we employ a string-match criterion: If the correct answer, identifiable as an entity, is present in the LLM response, we deem such a response as correct. We use a self-consistency of five runs with ChatGPT and Gemini-Pro, but we do not apply self-consistency to GPT-4 due to cost issues.

4 Results

The results of the state-of-the-art LLMs on EUREQA, as reported in Tab. 2, illustrate the variations in performance across different depths of reasoning and levels of difficulty. In general, with the entities recursively substituted by the descriptions of reasoning chaining layers, and therefore eliminating surface-level semantic cues, these models generate more incorrect answers. When the reasoning depth increases from one to five on hard questions, there is a notable decline in performance for all models, with an average accuracy decrease of 14.2% when using the *icl* prompt and 14.3% when using the *direct* prompt. The performance of LLMs is significantly higher on the easy set compared to the hard set. This is evidenced by a marked increase in accuracy, averaging 7.0% for ChatGPT, 15.4% for Gemini-Pro, and 19.7% for GPT-4. This finding underscores the significant impact that semantic shortcuts have on the accuracy of responses, and it also indicates that GPT-4 is considerably more capable of identifying and taking advantage of these shortcuts.

It can also be inferred from the results that the demonstrated human-written examples do help improve the performance. For both ChatGPT and GPT-4, using the *icl* prompt consistently leads to better performance than the *direct* prompt. This suggests that these models can benefit from examples that provide explicit and well-crafted human-written reasoning processes. These few-show examples encourage the models to resolve the questions with the correct reason instead of guessing with semantic cues. Nonetheless, even with clear reasoning processes provided, models still tend to

fail for incorrect shortcuts.

Another observation is that LLMs do not always perform worse on questions with more depth of reasoning. For instance, ChatGPT with *direct* prompt is 3.5% more accurate when the depth of reasoning d increases from four to five. We believe this also indicates that LLMs do not always follow the reasoning path and may instead answer the question based on surface-level semantic shortcuts. Further analyses can be found at §5.2

To identify the errors in these LLM responses, we randomly sampled 20 data points where GPT-4 with *icl*, the best performing method in this benchmark, has generated incorrect answers. The most frequent error pattern lies in hallucination during the reasoning process, encompassing 80% of the cases. In such cases, an intermediate reasoning stage erroneously conceived an inaccurate, albeit plausible answer, culminating in accumulated errors in the final answer. For instance, the "founder of a rocket company" was misconstrued as "*Elon Musk*, the founder of SpaceX", rather than the correct answer of "*Jeff Bezos*, the founder of Blue Origin." This phenomenon proves our claim that LLM relies on semantic cues for problem-solving instead of cognitive reasoning.

5 Analysis and Discussions

In this section, we perform further analyses and provide a more in-depth discussion of our findings.

5.1 Can human solve EUREQA?

Towards a more comprehensive insight into human proficiency on EUREQA, a human analysis was carried out focusing on the `hard` set characterized by a reasoning depth of five. This evaluation involves two computer science PhD students as the annotators to ensure their expertise. A selection of 50 questions, randomly extracted from the set, was subjected to annotation. Each question received annotations from both annotators independently, ensuring a dual perspective on every query. During the annotation process, annotators are presented with an input question to which they are required to provide an answer. To facilitate this, they are granted access to conduct information searches through the *dbpedia-snapshot-2021-09* database. This could be achieved either through visiting the specific entity page or by querying via a SPARQL portal. The averaged accuracy of annotators achieves 95% with an Inter-annotator Agreement of Cohen $\kappa = 0.79$.

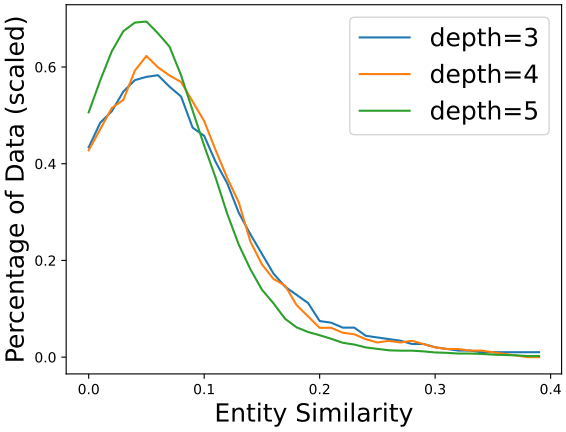

Figure 6: The distribution of entity similarity scores.

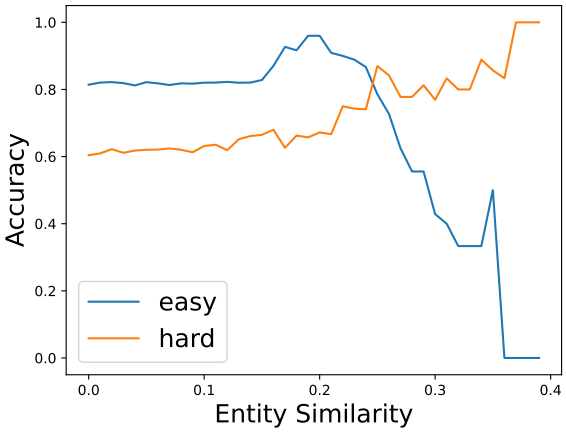

Figure 7: GPT-4 performances with different entity similarity scores between the easy and hard sets.

5.2 Do LLMs take Shortcuts?

One of our main motivations is to test if language models can follow a simple yet effective reasoning

chain instead of taking semantic shortcuts based on entity associations. We design an analytical experiment based on entity similarity to investigate whether LLMs take such semantic shortcuts. Our intuition is to model the correlation between the performances and the averaged semantic similarities between the gold answer and other entities mentioned in the question. In an ideal situation where a model takes an optimal reasoning path for each instance, we will see a uniform distribution of performances: the accuracy for various degrees of entity similarities will be relatively the same. If the model relies much on entity biases and takes semantic shortcuts, we will see an increasing performance when the mentioned entities are more closely related to the target answer.

To infer entity similarities, we employ an off-the-shelf sentence Transformer model[7] and encode the entity strings into embeddings. With such embeddings, we calculate the dot-product similarity between the target answer and all other Wikipedia entities mentioned in the question and compute an averaged similarity for each instance. We then draw the correlation curve of model performances on instances with certain similarities.[8] This method derives a relatively continuous curve based on our limited evaluation data.

Observation 1. Fig. 5 shows that GPT-4's performance positively correlates with the entity similarities in the instances. This shows that the model relies on semantic shortcuts instead of following the correct reasoning path.

Observation 2. GPT-4 performs similarly on different depths if the entity similarity scores are the same, especially on instances with lower similarities (< 0.25). This again suggests that the model relies on spurious entity biases to solve the question, because it does not do better on instances with shorter reasoning paths. That being said, the performance differences between lower and higher depths mostly come from the different data distributions, as shown in Fig. 6.

Observation 3. Fig. 7 shows another interesting finding, where GPT-4 does better on easy instances with lower similarity scores (< 0.25) and performs worse on those with higher similarity scores. Our explanation is that GPT-4 tends to take more obvious shortcuts by relying on only one or two entities in the easy instance, and "early exits" without even considering the entities that are closely relevant to the gold answer.

5.3 Do open source LLMs perform better?

To expand the scope of our findings, we experimented with open-sourced LLAMA-2 models across different sizes on hard questions of EUREQA and their results can be found at Tab. 3. Similar to our observations on GPT-series models, there's a notable decline in the accuracy of Llama models as the reasoning depth increases from one to five on the hard set. We've also conducted the entity similarity analysis which led to the same observation as Observation 1 in §5.2: LLMs' performance positively correlates with the entity similarities in the instances. These conclusions strengthened our claim that models rely on semantic shortcuts instead of following the correct reasoning path.

5.4 Will prompting solve EUREQA?

Although the effectiveness of prompting techniques is out of the scope of this paper, we still additionally tested the Tree of Thought(TOT)(Yao et al., 2023) method on ChatGPT with a "propose" strategy, which tries to decompose the questions layer by layer and solve them sequentially. Our results show that such a prompting method fails completely even if we provide human-written examples for question decomposition. In no experiment did the TOT method generate a valid answer in the final response.

That being said, it is unlikely that there exists a prompting technique that will significantly improve models' performance on EUREQA over CoT, as long as we do not enforce the correct reasoning chain (which defeats the purpose of testing generalizability) during inference.

5.5 Will optimal retrieval solve EUREQA?

Although our knowledge filtering process has already removed the knowledge barrier, it can still be pointed out that whether Retrieval Augmented Generation(RAG) method can solve this task. To address such concerns, we tested GPT-4 on 300 randomly sampled 5-layer hard questions. To minimize the impact of the retrieval method, we investigate a "performance upper bound" setting, which

[7] https://huggingface.co/sentence-transformers/msmarco-distilbert-cos-v5.

[8] Specifically, we start with a similarity value $x_{start} = 0.0$ and increment it by a step of 0.01. For each x_{start}, we find instances that have an averaged similarity score between $[x_{start}, x_{start} + 0.1]$, and compute the accuracy on these instances.
