directly injects the retrieval result of the visible entities and relations in the input question from DBpedia. To be specific, statements like "`Storm Warning (1951 film) stars Actor D`" will have "`<Storm Warning (1951 film), starring, ?>: Ginger Rogers, Steve Cochran, Ronald Reagan, Doris Day`" prepended to the input question. The retrieved knowledge will obtain at most 20 candidate entities and the correct entity is guaranteed to be included. A complete example of a question and retrieved knowledge can be found in Fig. 2. We believe this represents an upper bound of the retrieval result. Additionally, we provide each input with a 1-shot demonstration with the retrieved knowledge, input questions, and human-written reasoning thoughts.

The accuracy of GPT-4 through the above process is 62.0%, which is close to our reported performance of 61.9% in the original setting. We can then hypothesize that simply injecting knowledge into the model can hardly solve the problem and the bottleneck remains at the reasoning/question decomposition ability of LLMs. Moreover, it can be concluded that our knowledge-filtering process can effectively estimate parametric knowledge, and it is also reliable after self-consistency.

6 Related Work

We discuss two topics of works that are highly relevant to this study.

Hallucination. Existing research on analyzing LLMs hallucination mainly focuses on three aspects: input-conflicting hallucination, context-conflicting hallucination, and fact-conflicting hallucination (Zhang et al., 2023). Input-conflicting hallucination happens when the LLMs outputs are divergent from prompts (Maynez et al., 2020). Self-contradictory outputs can occur in long-form or multi-turn answers, implying that LLMs lose track of the core input information during generation (Liu et al., 2023). Factual-based errors – misaligns with established world knowledge – are most widely studied since they can happen in various LLMs to affect multiple tasks' performance (Min et al., 2023; Li et al., 2023). Knowledge conflicts also lead to hallucination when in-context information contradicts what LLMs memorize from pre-raining (Longpre et al., 2021; Zhou et al., 2023; Wang et al., 2023). However, none of these existing works look into hallucination on reasoning-required questions and test whether the models are following the correct reasoning path versus the semantic token bias.

Reasoning capability of LLMs. The success of in-context learning (Brown et al., 2020) and instruction tuning (Wei et al., 2021) have inspired various works to solve reasoning tasks by prompting LLMs. More advanced prompting strategies have been proposed to enhance the reasoning capabilities of LLMs. These investigations take advantage of the heuristic nature of human problem-solving procedures and incorporate them into textual prompts as guidance for the models. An example of this can be seen in chain-of-thought prompting (Wei et al., 2022), a method in which intermediate steps are generated leading up to a final solution. Yao et al. (2023) and Zhou et al. (2022b) proposed to decompose the questions into simpler, manageable sub-problems as a method to facilitate complex reasoning. Researchers also attempted to investigate LLMs' reasoning ability over structured knowledge (Ding et al., 2023) which necessitates reasoning with uncertainty as well as back-tracking. Studies prior to LLMs also propose to generate rationales to improve with more faithful reasoning (Rajani et al., 2019; Wang et al., 2022a). Nonetheless, this work questions the exhibited "reasoning capabilities" of LLMs by distinguishing them from the attempt to take greedy semantic shortcuts during the reasoning process.

7 Conclusion

This paper proposes a novel QA benchmark for probing LLM hallucinations induced by semantic shortcuts on reasoning chains. We introduced a systematic method for generating question-answering data with extended reasoning chains. This dataset enables us to examine the reasoning capabilities of LLMs on extended reasoning paths and our experimental results indicate that LLMs predominantly depend on semantic shortcuts for reasoning and such behavior contributes to its failure. Our analyses questioned the validity of current LLMs and also inspired future studies. The problem-solving or reasoning trajectories of humans could be incorporated into the training or inference phase of current Language Modeling systems for more effective computational models.

Ethical Considerations

Innovations in technology often encounter the moral challenge of dual-use: the same develop-

ment can bring both benefits and risks. With the probing method and benchmark presented in this paper, the line between beneficial and harmful usage largely depends on data. Proper utilization of the technology necessitates the legal and ethical acquisition of input text corpora and other modalities of inputs. Legal frameworks and standards are crucial for ensuring proper data use and for granting individuals the right to remove their data. In the absence of such regulation, the ethical use of data depends on the responsibility of technology users. Additionally, the generated and analysis data may exhibit biases that systematically affect accuracy for less represented groups or in new areas, potentially resulting in performance disparities among sub-populations based on ethnicity, race, gender, and other factors. Moreover, the effectiveness of trained systems diminishes when applied to new data that deviates from their training set. Therefore, issues of generalizability and fairness must be thoroughly examined when implementing the methodologies discussed in this paper. It is crucial to embed ethical considerations as fundamental principles at each stage of system development, ensure high levels of transparency and clarity in data, algorithms, models, and functions within the system, release software under open-source licenses to facilitate public scrutiny and investigate strategies to safeguard at-risk groups.

Limitations

Our work proposes an analytical framework and dataset to evaluate how well language models can take the right reasoning paths instead of deceptive semantic shortcuts. To this end, we identify the following limitations.

Limited Baselines. We only consider two variants of language models as our baselines. With more efforts in the future, we can extend to more families of large language models with different prompting techniques. Although we project that all current systems will be far behind human performances on EUREQA, we may identify specific models and methods that are more resistant to deceptive semantic shortcuts.

Limited Entities. We only consider popular entities in Wikipedia as our target answer. Future works may benefit from considering a wider range of entities and a more general setting of our data extraction processes.

8 Appendices

We present the prompts used in data generation or model evaluation on EUREQA. During the question generation process (§2.2), The Verbalization Prompt in Fig. 8 transforms a triplet, $(e_i, r_i\ e_{i+1})$ or (e_i, r_i^f, e_i^f), into a statement by querying ChatGPT with it. Typing Prompt in Fig. 9 is later used when we try to substitute an entity with its hypernyms in a statement but its hypernym is unavailable from DBpedia. Fig. 10 is one of the two examples we used in the *icl* prompt answering questions with a depth of five. Questions with fewer depths of reasoning adopt two similar examples with corresponding depths. Fig. 11 is an example input of the RAG experiment, as elaborated in §5.5 and illustrated in Fig. 2.

Tab. 3 is the experimental results of the open-sourced Llama-2 models on EUREQA, as discussed in §5.3.

Translate the triplets into a sentence. The second entity is the relationship between the first and third entities in the triplets.

triplet: [Robert_De_Niro, foundedBy, TriBeCa_Productions]

sentence: TriBeCa_Productions is founded by Robert_De_Niro.

triple: [Frederic_L._Smith, almaMater, University_of_Michigan]

sentence: Frederic_L._Smith's alma mater is University_of_Michigan.

triple: [{ent1}, {rel}, {ent2}]

sentence:

Figure 8: Verbalization Prompt: verbalize (*entity*, `relation`, *entity*) into a natural sentence.

Define entities with their hypernyms:

Steven_Spielberg is a director.

General_Motors is a car company.

{entity} is a

Figure 9: Typing Prompt: generate hypernym of an entity when it is unavailable from DBpedia.

Question: Who is Person A? Person A produced Gardener of Eden. Person A starred in Film B. Brian Grazer is the producer of Film B. Company C is the production company of Film B. Invictus (film) was produced by Company C. Person D founded Company C. Person D starred in Every Which Way but Loose. Person D produced Film E. Malpaso Productions produced Film E. Person F stars in Film E. Person F is Brian Dennehy.

Let's solve this question step by step:

Brian Dennehy stars in Film E, which is produced by Malpaso Productions. Among all films starring Brian Dennehy, only The Stars Fell on Henrietta is produced by Malpaso Productions. So Film E is The Stars Fell on Henrietta. Therefore Person D starred in Every Which Way but Loose and produced The Stars Fell on Henrietta. The producers of The Stars Fell on Henrietta include Clint Eastwood and David Valdes. Only Clint Eastwood starred in Every Which Way but Loose, so Person D is Clint Eastwood. Invictus (film) was produced by Company C, which was founded by Clint Eastwood, confirming that Company C is Malpaso Productions. Brian Grazer is the producer of Film B and Malpaso Productions is the production company of film B. Given that the only satifying film is J._Edgar, Film B is identified as J._Edgar. Person A produced Gardener of Eden and starred in J._Edgar. J._Edgar is produced by Brad Simpson and Leonardo DiCaprio. Only Leonardo DiCaprio starred in J._Edgar. So Person A is Leonardo DiCaprio. The answer is Leonardo DiCaprio.

Figure 10: One of the two examples used in *icl* prompt, with depth of five reasoning process.

Knowledge:
<?, music, Craig Safan>: Delivering Milo, Remo Williams: The Adventure Begins, Tag: The Assassination Game, ...
<?, starring, Xander Berkeley>: Deadly Dreams, The Last Full Measure (2004 film), Tag: The Assassination Game, ...

IndiSentiment140: Sentiment Analysis Dataset for Indian Languages with Emphasis on Low-Resource Languages using Machine Translation

Saurabh Kumar, **Sanasam Ranbir Singh**, and **Sukumar Nandi**
Department of Computer Science and Engineering
Indian Institute of Technology Guwahati
{saurabh1003, ranbir, sukumar}@iitg.ac.in

Abstract

Sentiment analysis, a fundamental aspect of Natural Language Processing (NLP), involves the classification of emotions, opinions, and attitudes in text data. In the context of India, with its vast linguistic diversity and low-resource languages, the challenge is to support sentiment analysis in numerous Indian languages. This study explores the use of machine translation to bridge this gap. The investigation examines the feasibility of machine translation for creating sentiment analysis datasets in 22 Indian languages. Google Translate, with its extensive language support, is employed for this purpose in translating the Sentiment140 dataset. The study aims to provide insights into the practicality of using machine translation in the context of India's linguistic diversity for sentiment analysis datasets. Our findings indicate that a dataset generated using Google Translate has the potential to serve as a foundational framework for tackling the low-resource challenges commonly encountered in sentiment analysis for Indian languages.

1 Introduction

Within the domain of natural language processing (NLP) research, a notable challenge is the scarce or limited availability of resources, particularly in the context of Indian languages. This scarcity extends to the field of sentiment analysis as well. As NLP researchers and practitioners continue to explore innovative solutions to bridge the gap between resource-rich languages like English and resource-poor languages in the Indian subcontinent, this study embarks on a critical inquiry into one such challenge: the support for Low-resource languages within the Indian context, specifically in the realm of sentiment analysis.

A fundamental realization emerges – fulfilling the resource requirements for Indian languages necessitates the creation of these resources. This entails manually creating linguistic datasets, including labeled text, grammatical structures, and socio-cultural and language specific sentiment indicators. While this approach is undoubtedly effective, it raises questions about its feasibility, especially when dealing with the extensive linguistic and cultural diversity found in India. Given the multitude of languages spoken in India, manual resource creation for each language becomes a monumental and perhaps unfeasible task. Considering the experience of the NLP researcher in the context of resource constrain, *is it possible to supplement the resource gap by bootstrapping with partially correct English to Indian languages machine translation tools such as Google Translate?* Various machine translation tools and APIs, including Google Translate, DeepL, Microsoft Translator, and OpenAI's Machine Translation, are readily available. According to the documentation available for Google Translate (Bapna et al., 2022), it supports over 1000+ languages, among which 22 are Indian languages.

Motivated by this, and with the objective of assessing the feasibility and efficacy of machine translation in the context of India's linguistic diversity, particularly in the development of sentiment analysis datasets for Indian languages, this paper considers Sentiment140 (Go et al., 2009) which is considered to be one of the largest corpora for sentiment analysis task in general domain curated from Twitter (currently X). Our selection of the Sentiment140 dataset is driven by its reputation as a significant dataset for sentiment analysis in noisy environments. Its substantial size, balanced distribution, and the inherent challenges of tweets make it an ideal choice for evaluating sentiment analysis models in real-world scenarios. By incorporating this dataset into our study, we address resource constraints in Indian languages while benefiting from a well-established benchmark for assessing sentiment analysis models in noisy environments.

Proceedings of the 2024 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies (Volume 1: Long Papers), pages 7689–7698
June 16-21, 2024 ©2024 Association for Computational Linguistics

Leveraging this widely used Sentiment140 dataset, we generate parallel corpora, known as *IndiSentiment140*, by translating it into 22 Indian languages supported by Google Translate. We utilize these generated parallel corpora to investigate their suitability for sentiment analysis by training two foundational neural models: the multi-layer perceptron (MLP) and the Long Short-Term Memory (LSTM) models. Despite the availability of more advanced neural and transformer-based models, our choice of these simpler models is driven by the aim to assess whether the translated dataset preserves both the sentiment characteristics of the original dataset and maintains the underlying sequential structure rather than the model aspect. If the dataset is suitable for these two models, it is likely to be suitable for advanced models.

Considering the socio-cultural and language-specific nuances influencing sentiment, we not only leverage this translated corpus but also utilize a human-translated sentiment dataset, indicSentiment (Doddapaneni et al., 2023), to evaluate the sentiment analysis model trained on the translated corpus, *IndiSentiment140*. Our findings indicate that these translated datasets not only retain the sentiment characteristics of the original dataset but also maintain the sequential structure within the translated text across specific languages. This suggests that these translated datasets have the potential to serve as a foundational framework for addressing the low-resource issue that prevails in Indian languages, offering a promising avenue for further NLP research and development in this context. The *IndiSentiment140* dataset is available on https://www.iitg.ac.in/cseweb/osint/resourcess.php.

Table 1: Performance of Google Translate in terms of BLEU score on different parallel corpora. Here **Lang** column represents the language pair that has been used as the source and the destination language while translating the text. **Flores**, **PMI**, and **Indic** represent the BLEU score of the Google-translated dataset and human-translated dataset taken from Flores-200 dataset (Costa-jussà et al., 2022), PMIndia (Haddow and Kirefu, 2020), and IndicSentiment (Doddapaneni et al., 2023) respectively. The BLEU score in **Google** column is directly taken from the report (Bapna et al., 2022).

2 Related Work

Sentiment analysis in the context of Indian languages presents a unique challenge due to the limited availability of resources. Addressing this low-resource challenge, several studies have introduced sentiment datasets for Indian languages. Most of the existing sentiment analysis datasets are primarily designed for resource-rich languages like Hindi, Bangla, Tamil, Telugu, Malayalam, among a few others. These datasets are typically small in size and rely on human annotations. Here are some of the datasets specifically crafted for sentiment analysis in the context of Indian languages.

A sentiment dataset consists of 8K review sentence in Hindi was introduced by Akhtar et al. (2016). These reviews were sourced from various newspapers, blogs, and e-commerce websites and manually labeled with sentiment. A similar Hindi dataset named BHAAV was introduced by Kumar et al. (2019) , consisting of 20K sentences collected from different short stories.

A manually annotated Telugu dataset, Sentiraama, for sentiment analysis in Telugu, was presented by Gangula and Mamidi (2018). This dataset integrates multiple domain sources to improve sentiment prediction, comprising 1K documents from various domains, including song lyrics, movie reviews, product reviews, and book reviews.

In a similar vein, Md. Rezaul Karim and Cochez (2020) presented a dataset of 320K documents

Table 2: Statistics of the translated dataset. In the table, the columns **Lang**, **#sample**, **#min**, **#max**, **#avg**, **%eng**, **#train**, and **#test** correspond to various attributes of the translated dataset. Specifically, they represent the language of the translated dataset, the total number of text samples, the minimum word count, the maximum word count, and the average word count in a particular dataset, the percentage of English words remaining in the translated dataset, the sample count in the train split, and the sample count in the test split, respectively.

* The percentage of English word is relatively high as Mizo (lus) language is also using Roman script. For all other languages we have used the script based approach to distinguish between English and non-English word and in case of Mizo simple dictionary based approach is applied.

for sentiment analysis in Bengali. These data were gathered from diverse sources like Bengali news articles, TV channel news dumps, books, blogs, sports portals, and manually annotated. SentNoB (Islam et al., 2021) introduced another dataset of 15K instances for analyzing sentiment in Bangla text. This dataset was created by annotating comments on news and videos from different domains.

A dataset, consisting of 15K manually annotated comments for sentiment analysis in Sinhala, is presented by Senevirathne et al. (2020).

More recently, indicSentiment (Doddapaneni et al., 2023) has been introduced for sentiment analysis in 13 Indian languages, including Assamese, Bengali, Bodo, Gujarati, Hindi, Kannada, Malayalam, Marathi, Odia, Punjabi, Tamil, Telugu, and Urdu. This dataset comprises 1K reviews for each language, which were manually translated and annotated from English reviews collected from various e-commerce websites.

3 Proposed Dataset

We have considered Sentiment140 (Go et al., 2009), a publicly available large dataset for sentiment analysis as source dataset. This dataset contains 1.6 million tweets in English extracted using the Twitter API. Each of these tweets has been labeled either with 0 or 4 which represents negative and positive sentiment respectively. As this dataset was collected from Twitter, a microblogging-based social media platform, the text predominantly employs informal and casual language, incorporating slang, fancy acronyms, emojis, URLs, as well as hashtags and keywords. Before translating this dataset to Indian languages URLs, emojis, and special symbols like # and @ have been removed. We have considered 22 Indian languages i.e. Assamese (as), Bengali (bn), Bhojpuri (bho), Dogri(doi), Gujarati (gu), Hindi (hi), Kannada (kn), Konkani (gom), Maithili (mai), Malayalam (ml), Marathi(Mr), Meiteilon

(Manipuri) (mni), Mizo (lus), Nepali (ne), Odia (or), Punjabi(pa), Sanskrit (sa), Sindhi (sd), Sinhala (si), Tamil (ta), Telugu (te), and Urdu (ur) for our study. We have created the dataset for each language listed above after translating the Sentiment140 dataset to corresponding language. The same sentiment labels are kept back after translating it to different Indian languages.

There are many machine translators (and or APIs) available like Google Translate, DeepL, Microsoft Translator, OpenAI's Machine Translation, and many more. We have chosen Google Translate as it supports 1000+ languages (Bapna et al., 2022) out of which 22 are above mentioned Indian languages.

To understand the level of correctness of the translated text, we also evaluate the performance of Google Translate taking different publicly available parallel corpora in Indian languages such as Facebook's Flores-200 dataset (Costa-jussà et al., 2022) that contains parallel corpora of 24 Indian languages out of which 19 languages are found to be relevant for our study, PMIndia dataset (Haddow and Kirefu, 2020) which we have found 12 languages are relevant for our study and IndicSentiment dataset (Doddapaneni et al., 2023). We have chosen 1000 random samples from each of these parallel corpora for evaluating the performance of Google Translate. We have taken the samples in English as the source sample and translated them to different Indian languages available in the particular parallel corpus. After that the BLEU (BiLingual Evaluation Understudy) score has been calculated taking the 4-Gram Overlap and the same is tabulated in Table 1. From this table, it can be observed that the low-resource Indian languages like Assamese (as), Bhjpuri (bho), Dogri (doi), Mizo (lus), Maithali(mai), Manipuri (mni) Sanskrit (sa) and Sinhala (si) are having relativly low BLEU score over other Indian languages. The statistics of the translated dataset for each language is tabulated in Table 2.

4 Model Training on Translated Data

In order to evaluate practicality of using the translated dataset for sentiment analysis, we implement two basic machine-learning models for each language – a simple classifier employing Multi-Layer Perceptron (MLP) and a sequential model-based classifier employing LSTM (Long Short-Term Memory). We have considered the simplest models, as we are interested in investigating usability of the datasets, rather than the model design.

The MLP model is composed of an input layer with dimensions matching the word embeddings, a single hidden layer with 256 nodes, followed by a dropout layer, and concluding with an output layer having 2 nodes for sentiment classification. Similarly, the LSTM-based model is tailored to process sequences, each with a length of 128 tokens. The architecture includes two stacked LSTM layers, each with a hidden size of 64. Subsequently, the model's output is concluded with an output layer having 2 nodes for sentiment classification. The choice of the LSTM model serves the purpose of exploring whether the translated datasets effectively retain sequential information.

To obtain text embeddings, we have used two distinct pre-trained word embedding models: (i) IndicBERT v2 (Doddapaneni et al., 2023), which was trained using the BERT architecture, and (ii) IndiSocialFT (Kumar et al., 2023)– a multilingual fastText (Bojanowski et al., 2017) based embeddings for Indian languges. To obtain the embedding for a specific text(tweet), we have calculated the mean of all the embeddings generated by the pre-trained model for each token. The text embedding generated by the IndicBERT v2 is of size 768 and that of IndiSocialFT is 300. These text embeddings are directly supplied to the input layer of our MLP model.

For each language in our dataset, we have trained separate classifiers, taking into account the embeddings from both IndicBERT v2 and IndiSocialFT individually (for LSTM model only IndicBERT v2 is used). We split each language dataset into an 80% portion for model training and a 20% portion for model testing. The statistics for the train and test splits for each language dataset are summarized in Table 2. During the model training process, we have employed the early-stopping technique to mitigate the risk of overfitting the data, ensuring our model's generalizability and performance.

5 Result and Evalution

We have evaluated the trained model considering two datasets - (i) the test split of the translated dataset mentioned in Table 2, and (ii) IndicSentimet dataset–a human translated and annotated dataset (Doddapaneni et al., 2023).

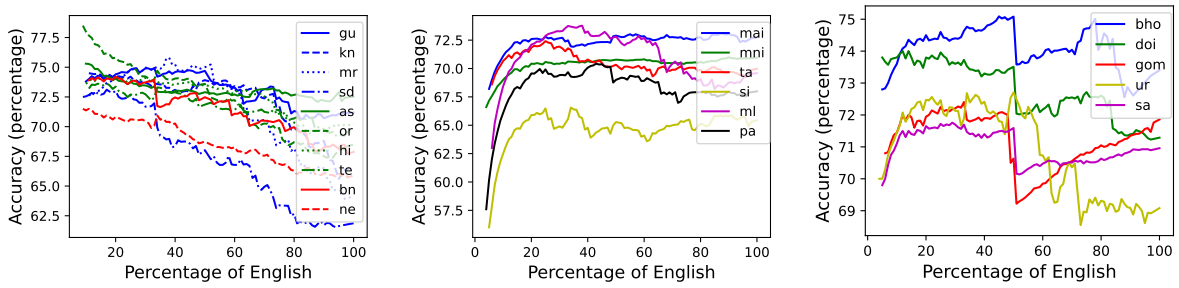
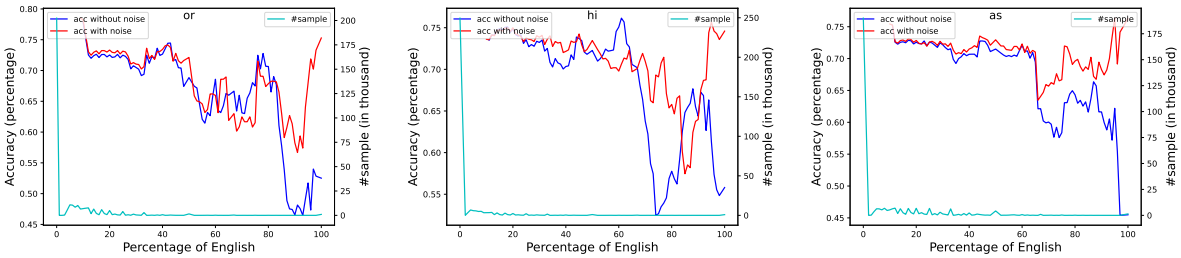
Table 3: Sentiment analysis over the dataset obtained after translating the Sentiment140 dataset using Google Translate. The performance metrics reported as accuracy (**Acc**), micro precision (**Preci**), micro recall (**Recall**) and micro F1 (**F1**) of the model trained using the **IndiSocialFT**, and **indicBert v2**. (**Acc*** is accuracy after removing the untranslated English word).



5.1 Evaluation with Translated Sentimet140

5.1.1 Evaluation with MLP model

We have conducted an evaluation on 20% of the entire Google-translated Sentiment140 dataset for each language to assess the performance of the trained MLP model for sentiment analysis. Similar to the model training phase, we have utilized both fastText and IndicBERT v2 embedding models independently for embedding the test set. The evaluation results, encompassing various performance metrics such as accuracy, micro precision, micro recall, and micro F1, are presented in Table 3.



From the table, it is apparent that when evaluating the fastText-based MLP model, accuracy remains consistently high across all languages, approximately at $75\% \pm 2\%$. Similarly, other performance metrics also exhibit remarkable consistency. When assessing the indicBert-based MLP model, we find a consistent accuracy of $76\% \pm 5\%$ across all languages. This remarkable consistent performance suggests that, despite the lower BLEU scores for low-resource languages, Google Translate effectively preserves the sentiment in the translated text.

Notably, in both setups, the model's performance on the English-language dataset, i.e., the original Sentiment140 dataset, stands out high. We have also observed that IndicBert v2 performs better than the fastText one. We have got the correlation value of 0.738 between the accuracy of model trained over fastText embedding and that of IndicBert v2 embedding. This high correlation value

Table 4: Evaluation of trained model on Translated Sentiment140 using LSTM based model and IndicBert v2. The performance metrics reported are accuracy (**Acc**), micro precision (**Preci**), micro recall (**Recall**) and micro F1 (**F1**).

indicates that both the models perform in same way for all the languages. Only the difference is that they have different embedding space. This difference in performance with different embeddings suggest that the context of sentiment analysis is closely intertwined with the choice of embedding space.

We have also calculated the correlation between the accuracy of both model and the percentage of English remaining in each languages. We have got the correlation value of -0.183 and -0.243 while considering fastText and indicBert v2 embedding respectively. This negative value of the correlation suggests that there is no relation between the Accuracy and the percentage of the English present in the translated text.

For the purpose of comparison, we have also trained the basic MLP model using the original Sentiment140 dataset with three different pre-trained embeddings: fastText, indicBert v2, and bert-base-uncased (Devlin et al., 2018) and the performance of these models is tabulated in Table 3. The performance of these models is found to be similar, with bert-base-uncased exhibiting slightly better results.

For error analysis, we have also generated a graphical representation illustrating the perfor-

The column **corBE** reports the correlations of the BLEU score and the percentage of English words remaining in the Google translated dataset.

mance of the IndiSocialFT-based model in terms of accuracy concerning the percentage of remaining English words in the translated Sentiment140 dataset for various languages. This analysis allows us to delve deeper into the structure of the translated dataset. The corresponding graph is displayed in Fig. 1.

In the Graph presented in Fig. 1.a, we observe a collection of 10 languages, each exhibiting an average negative slope. This pattern indicates that as the percentage of untranslated words increases, the model's performance declines. In contrast, the Graph in Fig. 1.b shows a set of 6 languages where the performance initially improves and then stabilizes as the percentage of untranslated words increases. Finally, in Fig. 1.c, we find the plot of 5 languages for which the relationship between performance and the percentage of untranslated words does not adhere to a consistent pattern. Analyzing these graphs, we can draw a general conclusion that most translated datasets exhibit a common behavior: as the level of noise in the dataset increases, performance tends to decrease. This decline in performance can be attributed to the fact that the embedding space of the noise (in this case, untranslated English words) differs significantly from the embedding space of the words in a particular language.

Further, we have also plotted the graph of accuracy with noise and accuracy after removing the untranslated English word(i.e. noise) over the same sample for some of the languages and the results are shown in Fig. 2. These plots illustrate that the variation of the accuracy remains consistent for most of the sample. Most of the variation is observed for the sample having greater than 70% of the noise and these samples are very few in number. This observation also suggests that this translated dataset has the potential to serve as a foundational framework for tackling the low-resource challenges commonly encountered in sentiment analysis for Indian languages.

5.1.2 Evaluation with LSTM model

We have conducted an evaluation on 20% of the entire Google-translated Sentiment140 dataset for each language to assess the performance of the trained LSTM model for sentiment analysis. while training and testing, we have only utilized the IndicBERT v2 embedding model for text embedding. The results of the evaluation, including various performance metrics such as accuracy, micro precision, micro recall, and micro F1, are presented in Table 4.

Upon comparing the indicBert v2 column of Table 3 with Table 4, we observe a notable improvement in results following the utilization of the sequential model, i.e., LSTM. This significant performance enhancement suggests that Google Translate adequately preserves the sequence in the translated text across all languages.

5.2 Performance with IndicSentiment Dataset

Taking into account the socio-cultural and language-specific intricacies that impact sentiment, we go beyond merely employing the translated corpus. We also integrate a human-translated sentiment dataset, indicSentiment (Doddapaneni et al., 2023), into our evaluation of the sentiment analysis model trained on the translated corpus, *IndiSentiment140*. IndicSentiment dataset consists of the text available in 13 Indian languages which have been manually translated to these different languages from same English source text (Doddapaneni et al., 2023). Out of these 13 languages only 12 languages dataset are found to be relevant for our study. For each languages we have considered the 1000 sample for the evaluation purpose. Each of these samples is having either positive or negative sentiment label.

While considering this IndicSentiment dataset for evaluating the trained MLP model we have considered two setup. In first setup we have considered the provided human translated text as testing dataset and in another setup we have used the Google Translate to translate the provided English text to the different Indian languages available in this parallel corpus. Then this Google translated version of IndicSentiment is also used for further evaluation. A detailed statistics of IndicSentimet dataset both the Human Translated version and the Google Translated version is tabulated in Table 5. In the Table we have also mentioned the correlations of the BLEU score and the percentage of English word remaining in the translated text. Most of these correlation values are either negative or near to zero that suggests there is no link of BLEU score with the percentage of English word remains in the translated dataset.

The performance of the trained MLP sentiment classifier model in term of different performance metrics i.e. accuracy, micro precision, micro recall and micro F1 considering both pre-trained embedding models over the manually (human) translated version of IndicSentiment is reported in Table 6 and that of Google translated version is in Table 7. In these tables also all performance metrics remain consistent.

Readings from the Table 6 suggest that the model trained over the translated dataset for each language is efficient enough for predicting the sentiment for the manually translated (naturally written) data. Here also we find the same trend for both MLP model i.e. based on fastText and the indicBert v2, across all languages. The accuracy of the fastText based model remains consistent, $74\% \pm 3\%$ across all languages, and a consistent accuracy of $87\% \pm 2\%$ across all languages for indicBert v2 based MLP model.

Results in Table 7 also follow the same trend that again suggests that the machine translation (Google Translate) preserves the sentiment of the text.

6 Conclusion and Future Work

In this paper, we have investigated the potential of machine translation as a solution to overcome the low-resource challenge faced by diverse Indian languages, specifically in the context of sentiment analysis. Our approach involved translating the Sentiment-140 dataset into 22 Indian languages using Google Translate and conducting comprehensive experiments to assess the usability of these translated datasets. Our findings reveal that these translated datasets not only retain the sentiment characteristics of the original dataset but also maintain the sequential structure within the translated text across specific languages. This suggests that these translated datasets could serve as a foundational framework to address the low-resource issue prevalent in Indian languages.

As for future work, we plan to further improve our dataset by incorporating more machine translation tools and APIs available for Indian languages. We also plan to add more languages to this dataset.

Limitations

While the translated dataset proposed in this study serves its intended purpose, it is essential to acknowledge certain limitations. One notable limitation is the presence of noise in the form of untranslated English words within the dataset. This factor may limit its applicability for diverse linguistic purposes. Moreover, conducting a direct comparison between the proposed translated dataset and a manually translated dataset—representing the actual translation in the target language—poses a challenge. Unfortunately, as of now, there is no available human-translated dataset for this specific content. Consequently, the absence of such a benchmark hinders a comprehensive assessment of the accuracy and quality of the automated translation.

Abstract

There has been limited success for dense retrieval models in multilingual retrieval, due to uneven and scarce training data available across multiple languages. Synthetic training data generation is promising (e.g., InPars or Promptagator), but has been investigated only for English. Therefore, to study model capabilities across both cross-lingual and monolingual retrieval tasks, we develop **SWIM-IR**, a synthetic retrieval training dataset containing 33 (high to very-low resource) languages for fine-tuning multilingual dense retrievers without requiring any human supervision. To construct SWIM-IR, we propose SAP (*summarize-then-ask prompting*), where the large language model (LLM) generates a textual summary prior to the query generation step. SAP assists the LLM in generating informative queries in the target language. Using SWIM-IR, we explore synthetic fine-tuning of multilingual dense retrieval models and evaluate them robustly on three retrieval benchmarks: XOR-Retrieve (cross-lingual), MIRACL (monolingual) and XTREME-UP (cross-lingual). Our models, called SWIM-X, are competitive with human-supervised dense retrieval models, e.g., mContriever-X, finding that SWIM-IR can cheaply substitute for expensive human-labeled retrieval training data. SWIM-IR dataset and SWIM-X models are available at: https://github.com/google-research-datasets/SWIM-IR.

1 Introduction

Dense retrieval models have demonstrated impressive performance in ad-hoc information retrieval (IR) tasks, e.g., web search, outperforming traditional retrieval systems such as BM25 (Karpukhin et al., 2020; Lin et al., 2021; Ni et al., 2022; Neelakantan et al., 2022, *inter alia*). A major reason for its success lies in the availability of large-scale supervised training datasets in English, such as MS MARCO (Nguyen et al., 2016) or NQ (Kwiatkowski et al., 2019), and coupled with effective training strategies, such as custom hard-negative mining (Xiong et al., 2021; Lin et al., 2023), or teacher distillation (Hofstätter et al., 2021; Ren et al., 2021).

However, there is a limited exploration of dense retrieval models in multilingual retrieval,[1] due to

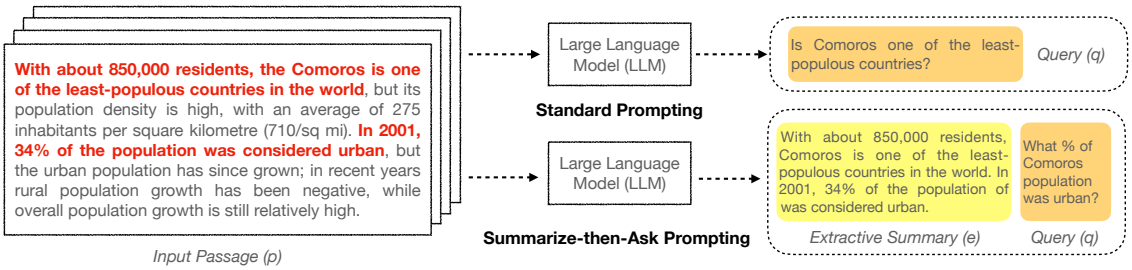

Figure 2: An illustration of SAP (*Summarize-then-Ask Prompting*) versus standard prompting for English query generation on English Wikipedia. SAP assists the LLM in improving the query generation quality (orange box) by identifying the relevant sections of the input passage (highlighted in red) via the extractive summarization (yellow box) as an intermediate reasoning step.

uneven and low distribution of human-supervised training data for other languages apart from English (Reimers and Gurevych, 2020; Feng et al., 2022; Wieting et al., 2023). Collecting human annotations for training data generation is not scalable, as it is cumbersome to search and hire native speakers, check their language proficiency, and teach them. Additionally, human annotators are expensive, thereby requiring a large annotation budget for generating a sufficient amount of training pairs (cf. Figure 6).

Multilingual query generation is a complex task (Wang et al., 2021). It requires understanding of semantic mappings of words across languages, similar to machine translation (Forcada, 2002; Tan et al., 2019; Zhu et al., 2023). Recently, utilizing LLMs for query generation has been popular in English (Bonifacio et al., 2022; Dai et al., 2023). But as illustrated in Figure 2, standard prompt templates can lead the LLM to generate either extractive or uninformative[2] queries across languages.

To improve the quality of the generated query, we propose SAP (*Summarize-then-Ask Prompting*), where we optimize the prompt to break down the query generation with LLM in two stages: (i) *summary extraction*, which identifies the relevant information from the long input passage and extracts the best representative sentences as the summary, and (ii) *query generation*, which generates a multilingual query relevant for the input passage, using the extracted summary (first stage) as the intermediate step. SAP highlights the relevant information within the passage and produces difficult (i.e., informative) queries in the target language.

In our work, we utilize PaLM 2 (Anil et al., 2023), a recent multilingual LLM (successor of PaLM 540B (Chowdhery et al., 2023)) for query generation. The generated query paired with the original passage from Wikipedia is used to construct the SWIM-IR dataset. SWIM-IR provides synthetic training (query-passage) pairs for improving dense retrieval models without requiring any human supervision. The dataset spans across 33 diverse languages, including both high and very-low resource languages and is one of the largest multilingual synthetic training dataset with 28 million training pairs (cf. Table 1).

We develop synthetic multilingual (both monolingual and cross-lingual) dense retrieval models called SWIM-X, using mT5 (base) (Xue et al., 2021) as the backbone and fine-tune on SWIM-IR. We compare SWIM-X against models fine-tuned with human supervision by changing only the training dataset while keeping other, i.e., model parameters and training settings unchanged. We evaluate on three standard multilingual retrieval benchmarks (two cross-lingual and one monolingual). As shown in Figure 1, on XOR-Retrieve (Asai et al., 2021a), SWIM-X outperforms the best-supervised baseline (mContriever-X) by 7.1 points at Recall@5kt. On MIRACL (Zhang et al., 2023b), a monolingual retrieval benchmark, SWIM-X is inferior to mContriever-X by 9.0 points at nDCG@10, which shows room for future improvement. On XTREME-UP (Ruder et al., 2023), a challenging benchmark containing 20 underrepresented Indo-European languages, SWIM-X outperforms mContriever-X by 11.7 points at MRR@10. We publicly open-source SWIM-IR dataset and SWIM-X models at `https://github.com/google-research-datasets/SWIM-IR`.

2 SWIM-IR Dataset Overview

In our dataset overview, we first describe the SAP design formulation for multilingual query generation (§2.1), data construction details (§2.2), and fi-

lectively denote both cross-language, i.e., cross-lingual and within language, i.e., monolingual retrieval tasks.

[2] *Uninformative* denotes a query that can be easily answered using the first (or last) few words in the passage.

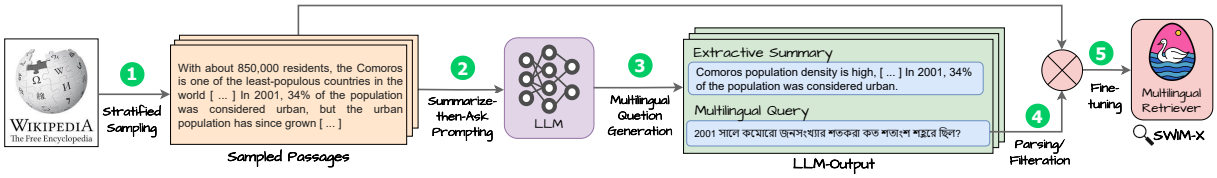

Figure 3: An illustration of the cross-lingual SWIM-IR dataset construction procedure. Steps are as follows: (1) Sample N passages from the English Wikipedia using stratified sampling for each language out of the L languages; (2) Feed a sampled passage along with the few-shot exemplars to the LLM with SAP; (3 & 4) Parse the LLM output to receive the synthetic query in the target language (above in Bengali); (5) Fine-tune a multilingual dense retriever model (SWIM-X) with training pairs combined for all languages, i.e., N×L pairs.

nally discuss about human validation and content filtration (§2.3).

2.1 SAP Design Formulation

Multilingual query generation is not a trivial task as it requires a deep understanding of the passage content and its own translations across different languages (Wang et al., 2021). Also, passages can often be lengthy and contain information on multiple topics. Using the entire passage can potentially cause hallucinations in models by generating non-meaningful queries, which affects the retrieval performance (Gospodinov et al., 2023).

To break down the task complexity of multilingual query generation and improve the query quality, we implement summarize-then-ask prompting (SAP). As shown above in Figure 2, we identify the relevant information within a passage by asking the LLM to generate an extractive summary and use it as an intermediate step for generating informative queries (Wei et al., 2023). The procedure is described in more detail below:

(i) Summary extraction. The LLM constructs an extractive summary e_s of the input passage p_s, where s denotes the source language. The summary captures the highly relevant information contained within the passage p_s (which occasionally may be long) acting as an useful intermediate signal for the LLM to generate a multilingual query in the later stage. We denote the first stage as $e_s = \text{LLM}(p_s; \theta^1, \cdots, \theta^k)$, where $(\theta^1, \cdots, \theta^k)$ denotes the k few-shot prompt exemplars[3] containing the passage, summary in the source language s and the query in the target language t.[4]

(ii) Query generation. Next, the LLM combines the summary e_s generated previously with the original input passage p_s, highlighting the relevant information required for composing the query q_t in the target language t. We denote this stage as $q_t = \text{LLM}(e_s, p_s; \theta^1, \cdots, \theta^k)$, where extractive summary e_s, input passage p_s and k-shot exemplars all appear from the first stage.

2.2 SWIM-IR Dataset Construction

For constructing SWIM-IR, we only require an unlabeled corpus of passages and few-shot exemplars. An overview of the cross-lingual generation procedure is shown in Figure 3. Prompt examples are provided in the Appendix (§C.3).

Cross-lingual. The goal is to generate a query in the target language t using the input passage in English (source language s). We use a stratified sampling algorithm (for more details, refer to §E.4 in the Appendix) to sample a maximum of one million passages for each target language t from the English Wikipedia corpus used in XOR-Retrieve (Clark et al., 2020; Asai et al., 2021a) or XTREME-UP (Ruder et al., 2023). Next, we construct five prompt exemplars and manually construct both the summary and query for the exemplar in English. Further, we use Google Translate[5] to translate the exemplar queries across other languages. Finally, we construct the prompt, where we explain our query generation task as an instruction, include the target language, and the 5-shot exemplars as an input to the LLM with SAP.

Monolingual. The goal is to generate a query in the same language as the input passage ($s = t$). We follow the setting similar to the cross-lingual task. We first sample one million passages (if available) for each language-specific Wikipedia corpus in MIRACL (Zhang et al., 2023b).[6] Next, we carefully select three training pairs as our

[3]Multilingual query generation requires few-shot prompt exemplars. As our experiments show in (§4), zero-shot prompting often generates unparseable outputs with PaLM 2.

[4]In our work, we did not use abstractive summarization, as LLMs have notoriously been shown to hallucinate and generate factual inconsistencies in their output generations (Maynez et al., 2020; Liu et al., 2023).

[5]Google Translate: translate.google.com

[6]For 16 out of the 18 languages, MIRACL contains a training split except for two: German (de) and Yoruba (yo).

Benchmark	Retrieval Task	Evaluation Metric	Query → Passage	# L	ISO	Languages	Train Split # Q	Train Split HNeg.	Dev/Test Split # Q	Dev/Test Split # Passages
XOR-Retrieve (Asai et al., 2021a)	Cross-lingual	Recall@5kt	L → English	7	ar, bn, fi, ja, ko, ru, te	Arabic, Bengali, Finnish, Japanese, Korean, Russian, Telugu	15,250	Yes (1 each)	2,110	18,003,200
MIRACL (Zhang et al., 2023b)	Monolingual	nDCG@10	L → L	18	ar, bn, de, en, es, fa, fi, fr, hi, id, ja, ko, ru, sw, te, th, yo, zh	Arabic, Bengali, German, English, Spanish, Farsi, Finnish, French, Hindi, Indonesian, Japanese, Korean, Russian, Swahili, Telugu, Thai, Yoruba, Chinese	88,288	Yes (max 4)	13,495	106,332,152
XTREME-UP (Ruder et al., 2023)	Cross-lingual	MRR@10	L → English	20	as, bho, brx, gbm, gom, gu, hi, hne, kn, mai, ml, mni, mr, mwr, or, pa, ps, sa, ta, ur	Assamese, Bhojpuri, Boro, Garhwali, Konkani, Gujarati, Hindi, Chhattisgarhi, Kannada, Maithili, Malayalam, Manipuri, Marathi, Marwari, Odia, Punjabi, Pashto, Sanskrit, Tamil, Urdu	13,270	No	5,300	112,426

Table 2: Overview of the multilingual retrieval evaluation benchmarks used in our work: (i) XOR-Retrieve (Dev) (Asai et al., 2021a), (ii) MIRACL (Dev) (Zhang et al., 2023b) and (iii) XTREME-UP (Test) (Ruder et al., 2023); (HNeg.) denotes availability of hard negatives for fine-tuning; (# L) denotes the number of languages covered by the benchmark; (# Q) denotes the number of queries in each dataset split.

Lang. (ISO)	fluency (↑)			adequacy (↑)			language (↑)		
Rating (→)	0	1	2	0	1	2	0	1	2
English (en)	2%	3%	95%	2%	13%	85%	0%	0%	100%
Spanish (es)	1%	10%	89%	14%	12%	74%	1%	0%	99%
Chinese (zh)	7%	19%	74%	7%	30%	63%	0%	0%	100%
Hindi (hi)	12%	5%	83%	6%	19%	75%	0%	0%	100%
Bengali (bn)	6%	4%	90%	10%	14%	76%	1%	0%	99%

Table 3: Human validation statistics on SWIM-IR. Annotators evaluate the quality of the generated query on a three-level rating scale (0/1/2) based on thee factors: (i) fluency, (ii) adequacy and (iii) language.

prompt exemplars.[7] For languages with no training split, we manually construct our prompt exemplars. Further, we use Google Bard[8] to generate exemplar summaries in the target language. Finally, we construct the prompt, where we explain our query generation task as an instruction, and the 5-shot exemplars with SAP.

2.3 Human Validation & Content Filtration

Human validation. The goal of our query generation is to generate an adequate and fluent query according to a given passage (Qiu and Xiong, 2019). To evaluate the intrinsic query quality, we conduct a validation study in SWIM-IR on a subset of five languages.[9] Within the five evaluated languages, three are high-resource, one medium-resource and one low-resource. For each language, we randomly sample a fixed amount of query-passage pairs resulting in a overall sum of 500 evaluation pairs to be human validated across all languages.

We compute the query quality on a three-level rating scheme (0/1/2) based on three evaluation criteria: fluency, adequacy, and language. (i) *fluency*, measures the coherence of the generated query, i.e., whether the query is understandable and readable by the user and contains no spelling or grammatical mistakes. (ii) *adequacy*, measures the relevancy of the query with passage (used for query generation) (iii) *language*, detects the language of the generated query, or whether code-switching occurs in the generated query.

Validation statistics. Table 3 reports the human validation statistics. For fluency, major mistakes are observed in Hindi (12%) and Chinese (7%), where the passage sampled in MIRACL (Zhang et al., 2023b) can be too short (only 2–3 words long), this leads to the exact duplication of the exact text in the query. For adequacy, we observe that in Chinese (30%) of the queries are not relevant to the passage. Similar to fluency, a low adequacy is observed in cases when either query is generated for a short passage or when the query is about a related topic which is not directly referenced within the passage. Finally for language, annotators achieve between 99–100% for all languages indicating PaLM 2 is likely to generate the query in the correct language.

Content filtration. LLMs have been shown to generate undesirable content, particularly under conditions that prime the model with material targeted at drawing out any negative patterns or associations in the training data (Gehman et al., 2020; Bender et al., 2021). To avoid this, we use the Google Cloud Natural Language content classification categories[10] to filter out harmful content present within the SWIM-IR training pairs. We discard samples with a high content classification of either `/Adult` or any of the `/Sensitive Subjects` labels. For more details on content filtration, refer to (§D) in the Appendix.

[7] As language-specific passages consume more tokens, e.g., Telugu, to save computational budget, we rely only on 3-shot exemplars (instead of five) for the monolingual task.

[8] Google Bard: bard.google.com

[9] The authors in the paper are native speakers of the five languages used for evaluation: English (en), Bengali (bn), Spanish (es), Chinese (zh) and Hindi (hi).

3 Experiments

3.1 Datasets and Metrics

We evaluate on three multilingual retrieval benchmarks: (i) **XOR-Retrieve** (Asai et al., 2021a), (ii) **MIRACL** (Zhang et al., 2023b) and (iii) **XTREME-UP** (Ruder et al., 2023). XOR-Retrieve and XTREME-UP are cross-lingual and MIRACL is monolingual. Following prior work, we evaluate models at Recall@5kt on XOR-Retrieve, nDCG@10 on MIRACL and MRR@10 on XTREME-UP. An overview of the evaluation dataset statistics is available in Table 2. For additional details, refer to the Appendix (§F).

3.2 Experimental Methods

Baseline categories. Following common practice across all datasets, we evaluate three range of baselines: (i) *Zero-shot baselines*: where the model denoted by "EN" (model-EN) is fine-tuned using supervised English-only training data such as MS MARCO (Nguyen et al., 2016) or NQ (Kwiatkowski et al., 2019). (ii) *Supervised baselines*: where the model denoted by "X" (model-X) is fine-tuned on human-supervised, i.e., multilingual training data. (iii) *Synthetic baselines*: where the model denoted by "SWIM-X" is fine-tuned without any supervision, relying purely on synthetic multilingual training data. Additionally, we report the amount of synthetic pairs, e.g., SWIM-X (500K) is fine-tuned on 500K training pairs.

Model choices. For our dense retrieval models, we adapt DPR (Karpukhin et al., 2020) to the multilingual setting with the mT5-base (Xue et al., 2021) language model with 580M parameters. Next, we include mContriever (Izacard et al., 2022) which adopts an additional pre-training stage with contrastive loss based on unsupervised data prepared from pairwise sentence cropping in mC4 (Xue et al., 2021). For query generation, we use PaLM 2 (S) (Anil et al., 2023) for efficient generation due to its low-cost and inference latency.

Existing baselines. For XOR-Retrieve, we include Dr. DECR (Li et al., 2022), a cross-lingual ColBERT (Khattab and Zaharia, 2020) fine-tuned on a large amount of supervised data in a computationally expensive setup involving knowledge distillation with English ColBERTv2 (Santhanam et al., 2022). xQG (Zhuang et al., 2023) involves cross-language query generation and concatenating the queries along with the passage representation. We also include two-stage translation baselines, Google Translate and Opus-MT from Asai et al. (2021a). For MIRACL, we include the official BM25, mDPR and Hybrid (combining BM25, mDPR and mColBERT) baselines (Zhang et al., 2023b), and Cohere-API is used as a reranker with top-100 BM25 results (Kamalloo et al., 2023).

3.3 Training Methodology

Zero-shot & supervised baselines. We replicate mContriever and mDPR zero-shot baselines by ini-

Table 5: Experimental results for monolingual retrieval on MIRACL dev (Zhang et al., 2023b). All scores denote **nDCG@10**; (Hyb.) denotes Hybrid retriever with ranked fusion of three retrievers: mDPR, mColBERT and BM25; BM25, mDPR and Hybrid scores taken from (Zhang et al., 2023b); Cohere-API is used as a reranker on top of 100 BM25 results, taken from (Kamalloo et al., 2023). SWIM-X (ours) is fine-tuned on 180K synthetic training pairs.

tializing from an mT5-base checkpoint (Xue et al., 2021) and further fine-tuning on MS MARCO, following a setup similar to Ni et al. (2022). Similarly, mContriever-X and mDPR-X have been additionally fine-tuned on training split available for each dataset. For additional technical details on supervised baselines, refer to the Appendix (§E.2). As mContriever includes an additional pre-training stage, we set the batch size to 8192, learning rate to $1e^{-3}$ and pre-train for 600K steps with mC4 (Xue et al., 2021). For more details on pre-training, refer to the Appendix (§E.1).

Synthetic baselines. For SWIM-X, we pre-train the mT5-base checkpoint on mC4 (Xue et al., 2021) for 600K steps using a contrastive loss function objective, similar to Contriever (Izacard et al., 2022). Next, we fine-tune the pre-trained mT5-base model on SWIM-IR with in-batch negatives and a contrastive loss function (van den Oord et al., 2018). During fine-tuning, we set the batch size to 4096, learning rate to $1e^{-3}$ and fine-tune between 5K to 50K training steps, depending upon the size of the training dataset. For technical details on synthetic baselines, refer to the Appendix (§E.3).

3.4 Experimental Results

XOR-Retrieve. Table 4 shows that SWIM-X (7M), fine-tuned on 7M synthetic pairs (max. of 1M per language) outperforms the best supervised baseline, mContriever-X, by 7.1 points Recall@5kt. Without mC4 pre-training, SWIM-X (7M) performance drops by only 1.6 points. We also evaluate SWIM-X (500K), a limited-budget baseline fine-tuned on 500K training pairs, which outperforms mContriever-X by 3.6 points. Few existing baselines outperform SWIM-X, however, the comparison is not fair. For instance, Dr. DECR is a multilingual ColBERT (Khattab and Zaharia, 2020) model, which is computationally expensive at inference (Thakur et al., 2021). Similarly, Google MT + DPR relies on a Google Translate system for the translation of queries to English.

MIRACL. Table 5 shows that the SWIM-X (180K) model is competitive on MIRACL. SWIM-X (180K) outperforms the best zero-shot model by 6.6 points nDCG@10. However, SWIM-X underperforms mContriever-X on MIRACL, fine-tuned on 90K human-labeled training pairs with up to four hard negatives available in MIRACL by 9.0 points nDCG@10. This highlights the difficulty in the monolingual retrieval task, as models need to rely on human-supervision for improvement. Few existing baselines outperform SWIM-X, however the comparison is not fair. The Hybrid baseline relies on information based on aggregation of three models, and for Cohere-API, the underlying model information is unknown.

XTREME-UP. Table 6 shows the results on XTREME-UP. SWIM-X (120K) is fine-tuned by randomly selecting 5 exemplars from the XTREME-UP training dataset (human-labeled queries) for all languages, whereas the MT variant reuses XOR-Retrieve prompt exemplars with translated summaries and queries for 15 languages.[11] SWIM-X (120K)^{MT} outperforms the best supervised baseline, mContriever-X$^{\heartsuit}$ (fine-tuned without MS MARCO) by a huge margin of 12.6 points MRR@10, but performs minimally worse than the MT version by 0.9 points. Interest-

[11] We were unable to translate our prompt exemplars for 5 languages due to language unavailability in Google Translate: Boro (brx), Garhwali (gbm), Chattisgarhi (hne) and Marwari (mwr). Manipuri (mni) is available in Google Translate in "Meitei" script instead of the "Bengali-Assamese" script present in the XTREME-UP dataset.

Table 6: Experimental results for cross-lingual retrieval on XTREME-UP test (Ruder et al., 2023). ($^{\heartsuit}$) denotes the mContriever-X model fine-tuned without MS MARCO (Nguyen et al., 2016); Two variants of SWIM-X considered, both fine-tuned on 120K synthetic data: (1) SWIM-X (120K)^{MT} fine-tuned using Google Translate, i.e., translated prompt exemplars for 15 languages, whereas (2) SWIM-X (120K) is fine-tuned using prompt exemplars sampled from XTREME-UP training split for all languages.

ingly, none of the evaluated baselines perform well on two extremely low-resource languages, Boro (brx) and Manipuri (mni).

3.5 Effectiveness of Summarization in SAP

In our work, we utilize SAP, where we employ extractive summarization as a rationale for PaLM 2 to generate informative multilingual queries. To evaluate the effectiveness of summarization, we assess both models (i.e., contrasting with and without summarization) on cross-lingual retrieval using Recall@5kt on XOR-Retrieve. We additionally evaluate different PaLM 2 model sizes to observe a correlation between retrieval model performance and changes in LLM size, i.e., model parameters. To ensure consistency, we adopt the experimental setup utilized in SWIM-X (500K) for all models.

Our results are shown in Figure 4 (left). we infer two insights: (i) an increase in the LLM size provides diminishing returns in terms of Recall@5kt on XOR-Retrieve. (ii) SAP outperforms standard prompting by at least 0.6 points consistently with all various PaLM-2 generators on XOR-Retrieve, with a maximum improvement of up to 3.2 points Recall@5kt. We observe that PaLM 2 with large sizes (sizes $>$ S) are inherently able to generate coherent queries, leading to diminishing improvements in SAP versus standard prompting.

3.6 How much Synthetic Data to Generate?

We analyze the optimal amount of synthetic training data required for fine-tuning SWIM-X. Figure 6 depicts the relative improvement in Recall@5kt on XOR-Retrieve. SWIM-X performance (gradually increasing) starts to saturate after 500K synthetic training pairs. The first observation is that with only 2K training pairs, SWIM-X (2K) achieves 49.1 Recall@5kt on XOR-Retrieve, already outperforming the best zero-shot (English-only) baseline. The break-even point occurs at 200K pairs, where SWIM-X (250K) achieves 60.5, outperforming mContriever-X, which achieves a 59.6 Recall@5kt on XOR-Retrieve.

3.7 Indo-European Language Transferability

We investigate the language transfer capabilities of the available Indic split (Indo-European language family) in SWIM-IR. We fine-tune individual SWIM-X models for eight selected languages and evaluate them on XTREME-UP. From Figure 5, we observe that SWIM-X models fine-tuned for Konkani (gom) or Hindi (hi) transfers best on all languages in XTREME-UP (rows 3 and 4), whereas fine-tuning for Tamil (ta) transfers worst overall (row 8). Assamese (as), Konkani (gom), Odia (or), Pashto (pa) and Sanskrit (sa) exhibit the lowest zero-shot capabilities with SWIM-X, thereby highlighting the importance of in-language synthetic data. Hindi (hi), Kannada (kn) and Malayalam (ml) demonstrate good zero-shot transfer capabilities with all Indic languages.

4 Ablation Studies

Optimal value of k-shot exemplars. We investigate the optimal value of few-shot exemplars required by PaLM 2 and the variation in the retrieval performance on XOR-Retrieve.[12] From Figure 4 (right), we observe a linear improvement in Recall@5kt with increase in K. Best Recall@5kt is observed with K = 5. SAP is unable to perform well zero-shot (i.e., K = 0) due to the complex nature of the multilingual query generation task which requires few-shot exemplars to understand and generate a summary and a query.

[12] We limit K = 5 to fit within a context length of 4096 tokens. For additional exemplars, PaLM 2 would need a longer context length increasing the computational cost significantly.

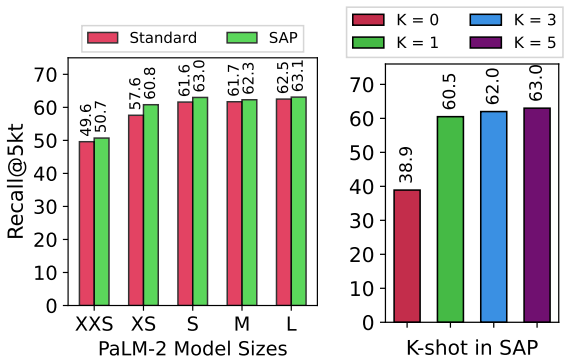

Figure 4: (Left) SAP (*Summarize-then-Ask Prompting*) (green) versus standard prompting (red) for various PaLM 2 model sizes. (Right) Varying K-shot prompt exemplars. SWIM-X is fine-tuned on 500K SWIM-IR training pairs and evaluated on XOR-Retrieve.

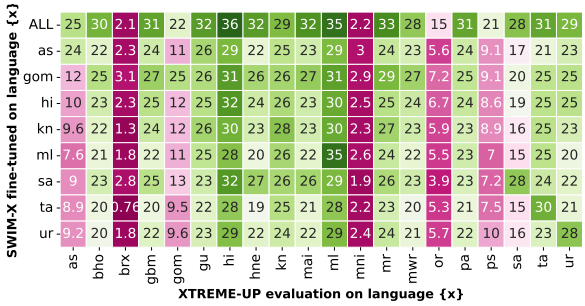

Figure 5: Heatmap showing MRR@10 denoting language-based transfer ability of SWIM-X (120K) across Indo-European languages available in XTREME-UP (Ruder et al., 2023). (ALL) denotes SWIM-X fine-tuned on all XTREME-UP languages.

ByT5 tokenizer. We evaluate whether the poor performance of SWIM-X on low-resource languages in XTREME-UP can be attributed to low-quality language tokenization. We replicate SWIM-X using a ByT5-base model as backbone, which contains a language independent tokenizer extension (Xue et al., 2022). From our results in Table 7, ByT5 models underperform by up to 9.8 points MRR@10 on XTREME-UP, in contrast to mT5-base. Additionally, the performance of SWIM-X on both `mni` and `brx` does not improve with ByT5. We leave it as future work to investigate the low performance on `mni` and `brx`.

Training split query replacement. Next, we evaluate the impact of human-generated versus LLM-generated queries on retrieval performance on XTREME-UP. We replace all human-generated queries in the XTREME-UP training split with only synthetic queries generated using PaLM 2 (S). From Table 7, the performance drops by 2.0 points at MRR@10. This confirms that human-generated queries are of better quality, which correlates with an improvement in MRR@10 on XTREME-UP. However, SWIM-X can be fine-tuned efficiently using few synthetic training pairs, by only marginally dropping in retrieval performance.

5 Cost Comparison

Generating synthetic training data is relatively inexpensive; however, it is not free. The cost is dependent upon the length of the prompt, input, and output generated from the LLM. The costs also linearly increase with each additional language pair. At the time of writing, PaLM 2 and similar LLMs cost about 0.0005 USD for 1000 characters in the input and output text.[13] Our prompts on average contain about 8–9K characters in the prompt input and generate about 1–2K characters in the output. The relative performance improvement associated with annotation cost in XOR-Retrieve is shown in Figure 6. Generating 200K synthetic training pairs in SWIM-IR will roughly cost $1K USD. SWIM-X (200K) performs comparably to the best supervised baseline (mContriever-X), trained on 15.2K human-annotated pairs, requiring roughly 14 times more, i.e., $14.1K USD to annotate, if we pay an hourly rate of $18.50 USD per hour for the annotator (local minimum wages is $11.50 USD/hr) following (Zhang et al., 2023b), assuming an estimated annotation cost of 3.0 minutes per example (Ruder et al., 2023).

6 Background and Related Work

The development of pre-trained multilingual LMs has contributed toward recent progress in multilingual retrieval (Asai et al., 2021a; Izacard et al., 2022; Asai et al., 2021b; Li et al., 2022; Ruder et al., 2023; Zhang et al., 2023b,a). Notable baselines in this field include mDPR and mContriever. mDPR (Asai et al., 2021a,b; Zhang et al., 2023a) extends English DPR (Karpukhin et al., 2020) to the multilingual setting, while mContriever (Izacard et al., 2022) adopts an unsupervised pre-training objective using the contrastive loss function and data prepared from mC4 (Xue et al., 2021), and is fine-tuned on MS MARCO.

Synthetic data generation. Traditionally, docT5query (Nogueira and Lin, 2019) for query generation has been prominent for generating synthetic training data in English (Ma et al., 2021;

[13] PaLM 2 pricing: cloud.google.com/vertex-ai/pricing

Model	PLM	Query Gen.	brx	mni	MRR@10
1. Models with Byte-level (UTF-8) tokenizer

2. Human-generated query replacement in XTREME-UP					
mContriever-X$^{\heartsuit}$	mT5	Human	-	-	13.5
SWIM-X (≈10K)	mT5	PaLM 2	-	-	11.5

Table 7: XTREME-UP ablation studies. First, we replace mT5 pre-trained model with ByT5 (Xue et al., 2022). Next, we replace the human-generated queries in the training dataset with PaLM-2 synthetic queries; MRR@10 scores are macro-averaged for all 20 languages; `brx` denotes Boro and `mni` denotes Manipuri.

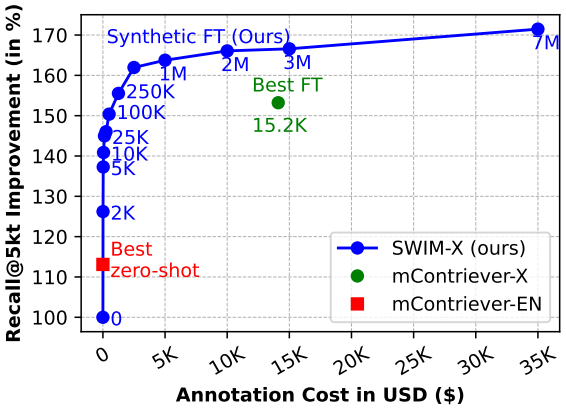

Figure 6: Recall@5kt improvement (in %) on XOR-Retrieve versus annotation cost in USD ($) to construct the training dataset. The amount of generated training pairs (human-generated marked in red and green; LLM-generated marked in blue) is provided with each marked data point in the graph.

Thakur et al., 2021; Wang et al., 2022; Thakur et al., 2022). Recently, using LLMs for query generation has gained interest. Bonifacio et al. (2022) proposed InPars, where they few-shot prompt GPT-3 (Brown et al., 2020) to generate synthetic queries. Similarly, complementary works (Sachan et al., 2022; Jeronymo et al., 2023; Boytsov et al., 2024; Saad-Falcon et al., 2023; Dua et al., 2023) all follow a similar setup as in Bonifacio et al. (2022). Dai et al. (2023) proposed Promptagator, which studied task-dependent few-shot LLM prompting and used the synthetic data for both retrieval and ranking models. Similarly, HyDE (Gao et al., 2023) and GenRead (Yu et al., 2023) generate synthetic documents instead of queries. However, prior work has focused on English, with the exception of HyDE. In our work, we robustly investigate how LLMs can be used for improving multilingual retrieval systems.

Multilingual datasets. Prior work investigates techniques to build multilingual datasets for better fine-tuning or evaluation of dense retrieval models. Datasets such as NeuCLIR (Lawrie et al., 2023), MKQA (Longpre et al., 2021) have been constructed using human annotators. Similarly, mMARCO (Bonifacio et al., 2021) has been generated using machine translation of MS MARCO (Nguyen et al., 2016). However, as translated documents are not written by native speakers, mMARCO and similar datasets suffer from artifacts such as "Translationese" (Clark et al., 2020). A concurrent work, JH-POLO (Mayfield et al., 2023), prompts GPT-3 to generate English queries from language specific passages in NeuCLIR.

7 Discussion and Future Work

A large-scale construction of SWIM-IR is challenging. Conducting SAP-based LLM generation at a large scale would require an efficient solution. Currently, we support a total of 33 languages. Extending naively to 100 languages would lead to at least 3 times the cost (fixed cost with every language). Hence, naively increasing more languages is not feasible. Instead, in the future, we can focus on generating synthetic data for diverse languages present within groups or clusters, based on linguistic characteristics within a language family or subfamily (Rijhwani et al., 2019) and rely on cross-lingual transfer for the remaining languages.

8 Conclusion

In this work, we present SWIM-IR, a synthetic multilingual retrieval training dataset with 28 million training pairs across 33 diverse languages. SWIM-IR allows synthetic fine-tuning of multilingual dense retrieval models cheaply without human supervision. SWIM-IR is constructed using SAP, which stands for *summarize-then-ask prompting*, assisting the LLM to identify the relevant sections of the input passage, improving the quality of the generated multilingual query.

Our rigorous evaluation across three multilingual retrieval benchmarks assesses our dataset quality. We find that SWIM-X, fine-tuned on SWIM-IR (keeping model training parameters unchanged) outperforms the best supervised cross-lingual baseline by 7.1 points Recall@5kt on XOR-Retrieve and 11.7 points MRR@10 on XTREME-UP, while remaining competitive in monolingual retrieval on MIRACL.

9 Limitations of SWIM-IR

SWIM-IR, like any other dataset, is not perfect and has limitations. These limitations do not directly affect the downstream multilingual retrieval task, where dense retrieval models learn how to match relevant passages to queries. The dataset has been created for the "sole" purpose of training multilingual retrieval models. We describe below a few noted limitations:

1. Decontextualization. PaLM 2 captures the salient information from the paragraph, but can generate the query in a reduced context, which cannot be answered without the Wikipedia paragraph.

2. Code-switching. PaLM 2 can occasionally generate a code-switched query with words combined from English and the target language. Code-switching is more frequently observed for cross-lingual generation in low-resource languages.

3. Passage quality and length. A good quality passage contains relevant information about a topic, which PaLM 2 uses to generate a synthetic query. However, if the passage is really short with little or no information, or contains noisy information, this can likely generate a subpar query.

4. Factual inconsistencies in LLM generation. LLMs have been found to generate text lacking sufficient grounding to knowledge sources (Dziri et al., 2022; Ji et al., 2023), thereby posing risks of misinformation and hallucination in their generated outputs (Maynez et al., 2020; Raunak et al., 2021; Muller et al., 2023). Queries in SWIM-IR are relevant for the input passage, but are not human-verified, thereby queries may contain factual inconsistencies. We leave it as future work to investigate techniques to improve factual consistency of generated queries (Sun et al., 2021; Huang et al., 2023).

A Appendix

The following supplementary sections in SWIM-IR are arranged as follows:

- Appendix B provides information on the SWIM-IR dataset release.
- Appendix C provides the additional material with SWIM-IR, including the data card, examples, and prompts.
- Appendix D provides details on SWIM-IR content filtration.
- Appendix E provides information in detail on hyperparameter tuning and training methodology for baseline models, including multilingual pre-training, synthetic fine-tuning, and passage sampling strategies.
- Appendix F provides statistics for three multilingual retrieval evaluation datasets: XOR-Retrieve, MIRACL, and XTREME-UP.
- Appendix G contains additional experimental results on XOR-Retrieve and MIRACL.

B Details on SWIM-IR Dataset Release

Dataset release format. The SWIM-IR dataset will be released and available in multiple formats. Officially, the dataset is released within the Google Cloud Storage (GCS) cloud storage bucket.[14] Later, for longer term preservation, the dataset will be maintained through a TensorFlow Dataset (TFDS). To enable a wider audience within the research community, we plan to release an official copy of SWIM-IR as a Hugging Face dataset (Lhoest et al., 2021).

High quality check. The SWIM-IR dataset has undergone a high-quality check and a thorough review internally at Google to avoid inaccurate or misleading conclusions drawn from the dataset. High-quality checks are integral to the scientific process to enable researchers to address errors, inconsistencies and identify potential sources of bias within datasets (Pushkarna et al., 2022). This enables a robust and trustworthy scientific analysis within the community.

Long term preservation. SWIM-IR will be available for a long time by continually updating the Tensorflow dataset (TFDS) and Hugging Face dataset. The authors will be responsible for maintaining the dataset and extending the work in the future to support more languages (Joshi et al., 2020). Another useful feature is (EN→L) cross-language retrieval setting, i.e., English query retrieves language-specific passages within a corpus.

Licensing. The SWIM-IR corpora is based on multilingual Wikipedia. Therefore for licensing SWIM-IR, we follow the same license as Wikipedia: Creative Commons Attribution-ShareAlike 4.0 Unported License (CC BY-SA 4.0).[15] The license allows both researchers and industry alike to access the SWIM-IR dataset, copy, and redistribute it for future work.

C SWIM-IR Extra Material

C.1 SWIM-IR Data Card

We release the data card associated with the SWIM-IR. The data card was generated using the template provided by the Data Cards Playbook (Pushkarna et al., 2022). It has been formatted using Markdown.[16] The SWIM-IR data card is provided along with our dataset release on the GitHub repository: `https://github.com/google-research-datasets/SWIM-IR`.

C.2 SWIM-IR Dataset Statistics

The languages covered and the amount of training pairs available in SWIM-IR are provided in Table 8. The majority of the training pairs (sampled for a maximum of 1M per language pair) are provided for 18 languages in MIRACL, which overlap with the 7 languages in XOR-Retrieve. An additional 100K training pairs come from the rest of the 15 Indo-European languages from XTREME-UP. Two examples from SWIM-IR for each task, cross-lingual and monolingual retrieval, are provided in Figure 8. The cross-lingual example is from Chinese (`zh`) and the monolingual is from Spanish (`es`).

Each SWIM-IR training data point has six associated text fields. We describe each field below: (i) `_id`: denotes the unique identifier of the training pair. (ii) `title`: denotes the title of the Wikipedia article. (iii) `text`: denotes the passage extracted from the Wikipedia article. (iv) `query`: denotes the synthetic multilingual query generated using PaLM 2 (Anil et al., 2023). (v) `lang`: denotes the target language in which the query was generated. (vi) `code`: denotes the ISO code of the generated query language.

[14] storage.googleapis.com/gresearch/swim-ir/swim_ir_v1.tar.gz

[15] https://creativecommons.org/licenses/by-sa/4.0

[16] The Markdown format and the template are available here: https://github.com/pair-code/datacardsplaybook

C.3 SWIM-IR Prompts

All prompts and their templates (across all 33 languages) used to develop SWIM-IR are available in the GitHub repository.[17] We provide a few individual prompt examples for all three datasets in the Appendix: (1) XOR-Retrieve (English passage; synthetic Bengali query) in Figure 9, (2) MIRACL (Chinese passage; synthetic Chinese query) in Figure 10, and (3) XTREME-UP (English passage; synthetic Hindi query) in Figure 11.

D Content Filtration

LLMs have been shown to generate undesirable content, particularly when primed with material aimed at eliciting negative patterns or associations from the model's training data (Gehman et al., 2020; Bender et al., 2021). Initially, we expected that the sampled Wikipedia passages would predominantly contain safe material suitable for prompting LLMs. However, after examination, we discovered that between 6–10% of the pairs contained sensitive subjects and adult content (i.e., weapons; violence and abuse; accidents and disasters; death and tragedy; war and conflict). To address this issue, we used the Google Cloud Natural Language content classification categories[18] to identify and remove pairs where either the original sampled passage or the resulting LLM generated query has a content classification of either `/Adult` or any of the `/Sensitive Subjects` labels.

E Additional Technical Details

E.1 mContriever Pre-training

In the original implementation of mContriever (Izacard et al., 2022), the authors initialized the model using the mBERT (Devlin et al., 2019) pre-trained language model (PLM). Subsequently, the model was jointly pre-trained on 29 languages covering the CCNet dataset (Wenzek et al., 2020) with a contrastive pre-training objective.

In our adaptation of mContriever, we initialize using the mT5-base model checkpoint (Xue et al., 2021). Next, we jointly pre-train the model on 101 languages[19] available in mC4 dataset (Xue et al., 2021). For each mC4 document, we sample two random non-overlapping texts with a maximum text span size of 256 tokens. Similar to the mT5 pre-training objective (Xue et al., 2021), examples were not uniformly sampled over languages; instead, the probability of selecting a training sample from a specific language is directly proportional to the amount of training data available in the mC4 dataset. We randomly sample a maximum of 20K samples per language and use them as a validation subset.

We optimize our mContriever model with the AdamW optimizer (Loshchilov and Hutter, 2019) with a learning rate of $1e^{-3}$, batch size of 8192, and for 600K pre-training steps. During the first 500K pre-training steps, we use a language-mixed training objective, where a single training batch can contain examples across multiple languages. For the subsequent 100K training steps, we use a language-unmixed training objective, where a single training batch contains all examples from only a single language, i.e., no mixing of different language pairs within a training batch. We internally conducted a brief evaluation of the mContriever pre-trainining strategies using language-mixing (500K) and with both language-mixing and unmixing (600K) checkpoints. Notably on XOR-Retrieve, we observed a significant performance improvement with the additional language-unmixed pre-training, resulting in an improvement of 7.3 points Recall@5kt.

E.2 Supervised Baselines

XOR-Retrieve. For the zero-shot baseline model, we fine-tune on the English-only MS MARCO (Nguyen et al., 2016) dataset using our base initialization model, mT5 (Xue et al., 2021). We use in-batch negatives, AdamW optimizer (Loshchilov and Hutter, 2019) and with a learning rate of $1e^{-3}$. The query sequence length is set to a maximum sequence length of 64 tokens, whereas the document is limited to a maximum sequence length of 256 tokens. On MS MARCO, models are fine-tuned with a batch size of 4096 and for an additional 50K training steps.

For our supervised baselines, we fine-tune on the XOR-Retrieve training dataset containing 15,250 training pairs. Each training pair in XOR-Retrieve is accompanied by one hard negative (Asai et al., 2021a). We fine-tune our baseline models on XOR-Retrieve using triplets containing the query, relevant passage and a single hard negative. We use the AdamW optimizer (Loshchilov and Hutter, 2019), a learning rate of $1e^{-3}$, a batch size of 4096 and fine-tune the model for 15K train-

[17] https://github.com/google-research-datasets/SWIM-IR
[18] cloud.google.com/natural-language/docs/categories
[19] The list of all 101 languages in mC4 can be found at: www.tensorflow.org/datasets/catalog/c4

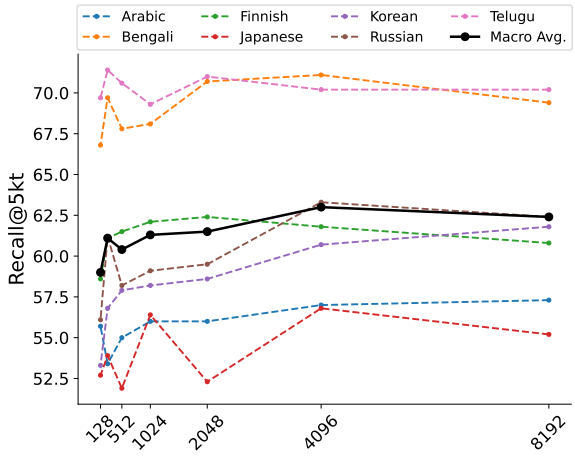

Figure 7: Training batch size ablation of SWIM-X (500K) on XOR-Retrieve (Asai et al., 2021a). The best Recall@5kt is achieved with 4096 training batch size. To avoid overfitting, we fine-tune all SWIM-X variants on 500K SWIM-IR training pairs with decreasing training steps of {40K, 40K, 30K, 30K, 20K, 20K, 15K} for increasing batch sizes of {128, 256, 512, 1024, 2048, 4096, 8192} respectively.

ing steps.

MIRACL. For the zero-shot baseline model, we first fine-tune on the MS MARCO (Nguyen et al., 2016) dataset. We use the same fine-tuning setup as described for XOR-Retrieve. For monolingual supervised models, we use the MIRACL training data. MIRACL authors provides between one to nine hard negatives for each training query. We randomly sample up to a maximum of four hard negatives for each query and use the AdamW optimizer (Loshchilov and Hutter, 2019), learning rate of $1e^{-3}$, a batch size of 4096 and fine-tune the model for 15K training steps.

XTREME-UP. For the zero-shot baseline model, we fine-tune on the MS MARCO (Nguyen et al., 2016) dataset. For the supervised baselines, we use the XTREME-UP training data containing 13,270 training pairs and fine-tune with only in-batch negatives (i.e., no hard negatives). We use the AdamW optimizer (Loshchilov and Hutter, 2019), a learning rate of $1e^{-3}$, a batch size of 1024, and fine-tune the model for 5K training steps.

E.3 Synthetic Baselines

We fine-tune all SWIM-X models using in-batch negatives (no hard negatives), AdamW optimizer (Loshchilov and Hutter, 2019) and with a learning rate of $1e^{-3}$. The pre-trained language model for SWIM-X is the mT5-base model with 580M parameters (Xue et al., 2021). The batch size and the training steps varies for each dataset. An ablation for batch size is provided in Figure 7. Training data is evenly distributed across all languages present. For example, if there are 100K pairs with 5 different languages, each language contains around 20K training pairs.

XOR-Retrieve. SWIM-X is fine-tuned with a batch size of 4096 and with a maximum of 50K training steps on SWIM-IR cross-lingual pairs. For the 500K training pairs, we fine-tune for 20K steps, and for the maximum of 7M pairs, we fine-tune for 50K training steps. The training pairs within a single batch include language-mixing, i.e., one or more language-specific training pairs are sampled within a single training batch.

MIRACL. SWIM-X is fine-tuned for a batch-size of 4096 and for a maximum of 15K training steps on SWIM-IR monolingual pairs. As shown in (Roy et al., 2020; Zhang et al., 2023a), language-unmixed training setup is shown to work well for monolingual retrieval. Following prior work, SWIM-X training pairs include language unmixing, i.e., all pairs are from a single language. The examples are uniformly sampled across all languages, i.e., probability that a training sample comes from a specific language is equal for all languages, unlike during mC4 pre-training.

XTREME-UP. SWIM-X is fine-tuned for a batch size of 1024 and for a maximum of 15K training steps on SWIM-IR cross-lingual (Indic) pairs. Similar to XOR-Retrieve, the training pairs include language-mixing within a single batch during SWIM-X fine-tuning.

E.4 Stratified Sampling in SWIM-IR

In our work, we use a stratified sampling technique to select a subset of passages from the Wikipedia corpus, aiming for a relatively uniform distribution of training samples across all languages. Our Wikipedia corpus contains entities which are sorted alphabetically (A-Z). We then compute inclusion threshold I_{th}, which is defined as $I_{th} = D_{sample}/D_{total}$, where (D_{sample}) is number of passages required to sample and (D_{total}) is the total numbers of passages in corpus. Next, for each passage (p_i) in the corpus, we randomly generate an inclusion probability $\hat{p}_i \in [0, 1]$. We select the passage (p_i) if $p_i \leq I_{th}$. This approach ensures a uniform sampling of passages with Wikipedia en-

tities between all letters (A-Z).[20]

F Evaluation Dataset Information

We evaluate on three multilingual retrieval benchmarks: (i) **XOR-Retrieve** (Asai et al., 2021a), (ii) **MIRACL** (Zhang et al., 2023b) and (iii) **XTREME-UP** (Ruder et al., 2023). We excluded NeuCLIR (Lawrie et al., 2023) from our evaluation as it contained a fewer subset of languages namely, Chinese (zh), Farsi (fa) and Russian (ru). Although MKQA (Longpre et al., 2021) contained a wider variety of languages, it is primarily used for question-answering (QA) rather than multilingual retrieval. All three selected evaluation datasets contain a training split. Only XTREME-UP has released their test split publicly, which we use for evaluation in the paper. However, for both XOR-Retrieve and MIRACL, we evaluate on the development split.

XOR-Retrieve (Asai et al., 2021a) is a cross-lingual open retrieval training and evaluation task within TyDi-QA (Clark et al., 2020). XOR-Retrieve contains 15K human annotated relevant passage-query pairs in the training set with one hard negative and 2K passage-answer pairs in the *dev* set. The corpus C contains 18.2M passages with a maximum of 100 word tokens from the English Wikipedia. The queries are multilingual and cover seven languages. We evaluate our models using recall at m kilo-tokens, i.e., Recall@mkt, which computes the fraction of queries for which the minimal answer is contained within the top m thousand tokens of the retrieved passages. Following prior work in Asai et al. (2021a), we evaluate our models at Recall@5kt and Recall@2kt.

MIRACL (Zhang et al., 2023b) is a monolingual open retrieval evaluation task containing 18 languages. MIRACL was developed on top of Mr. TyDi (Zhang et al., 2021), and covers more languages and provides denser judgments by human annotators. The test set is not publicly released, hence in this paper we evaluate using the dev set. The training set contains 88,288 pairs, with the exception of Yoruba (yo) and German (de) which do not have any training data available. The authors also provide labeled hard negatives for the training query-passage pairs. The dev set contains around 13,495 query-passage pairs. The corpus C in MIRACL are language-specific Wikipedia articles with various sizes starting from smallest, Yoruba (yo) with 49K passages, till the largest, English (en) with 39.2M passages. Following prior work in Zhang et al. (2023b) and Kamalloo et al. (2023), we evaluate our models at nDCG@10 and Recall@100.

XTREME-UP Ruder et al. (2023) contains diverse information-access and user-centric tasks focused on under-represented languages. In our work, we evaluate a cross-lingual retrieval task containing 5,280 query-passage pairs in the training set. The corpus C contains 112,426 passages sampled from TyDi-QA (Clark et al., 2020). The test set contains 10,705 query-passage pairs for evaluation. The cross-language retrieval for the question-answering (QA) task contains 20 under-represented Indic languages. Following prior work in Ruder et al. (2023), we evaluate our models at MRR@10.

G Additional Results

XOR-Retrieve. In Table 9, we report the Recall@2kt scores across all multilingual retrievers on XOR-Retrieve. We find similar trends for improvement, SWIM-X (7M) outperforms the best supervised model, mContriever-X, by 3.9 points at Recall@2kt. The SWIM-X (7M) without mC4 pre-training is a strong baseline outperforming SWIM-X (7M) with mC4 pre-training on 4 out of the 7 languages evaluated in XOR-Retrieve.

MIRACL. In Table 10, we report the Recall@100 scores across all multilingual retrievers on MIRACL. mContriever-X achieves the highest Recall@100 score of 86.5, SWIM-X on the other hand achieves 78.9 at Recall@100, which is competitive and outperforms both the zero-shot baselines, i.e., mDPR-EN and mContriever-EN. For Yoruba, Our SWIM-X outperforms the supervised mContriever-X which shows the importance of synthetic training data for low-resource languages, as the MIRACL supervised training dataset does not contain training pairs in Yoruba (i.e., no human-labeled training pairs).

[20] All Wikipedia entities starting with a non-alphabet are included in the beginning of the Wikipedia corpus.

5-shot Summarize-then-Ask Prompting for XOR-Retrieve

Read the following article and write a factual summary. Your summary will act as a surrogate for asking a question based on the article. Finally, translate the question to Bengali.

Article: Long Lost Family is a BAFTA award winning British television series that has aired on ITV since 21 April 2011. The programme, which is presented by Davina McCall and Nicky Campbell, aims to reunite close relatives after years of separation. It is made by the production company Wall to Wall. "Long Lost Family" is based on the Dutch series "Spoorloos" (), airing on NPO 1 since February 1990 and it is made by KRO-NCRV. Presented by Davina McCall and Nicky Campbell, the series offers a last chance for people who are desperate to find long lost relatives.
Summary: Long Lost Family is a BAFTA award winning British television series aired since 2011. The series aim to reunite close relatives after years of seperation which is presented by Davina McCall and Nicky Campbell.
Question [Bengali]: ব্রিটিশ টেলিভিশন সিরিজ লং লস্ট ফ্যামিলি কোন পুরস্কার জিতেছে?

Article: Muscular activity accounts for much of the body's energy consumption. All muscle cells produce adenosine triphosphate (ATP) molecules which are used to power the movement of the myosin heads. Muscles have a short-term store of energy in the form of creatine phosphate which is generated from ATP and can regenerate ATP when needed with creatine kinase. Muscles also keep a storage form of glucose in the form of glycogen. Glycogen can be rapidly converted to glucose when energy is required for sustained, powerful contractions. Within the voluntary skeletal muscles, the glucose molecule can be metabolized anaerobically in a process.
Summary: All muscle cells produce adenosine triphosphate (ATP) molecules for movement of myosin heads. A short term store of energy is generated from ATP in the form of cratine phosphate and can regenerate ATP when needed with creatine kinase.
Question [Bengali]: কীভাবে পেশী কোষগুলি মায়োসিন মাথার নড়াচড়ার জন্য শক্তিকে শক্তি দেয়?

Article: The 1960s brought anime to television and in America. The first anime film to be broadcast was "Three Tales" in 1960. The following year saw the premiere of Japan's first animated television series, "Instant History", although it did not consist entirely of animation. Osamu Tezuka's "Tetsuwan Atom" ("Astro Boy") is often miscredited as the first anime television series, premiering on January 1, 1963. "Astro Boy" was highly influential to other anime in the 1960s, and was followed by a large number of anime about robots or space.
Summary: First anime movie broadcast on TV was 'Three Tales' in 1960. First anime TV series was 'Instant History' in 1961. 'Astro Boy' first aired in 1963 was a highly influential anime about robots or space.
Question [Bengali]: ১৯৬০ সালে টিভিতে সম্প্রচারিত প্রথম অ্যানিমে ছবি কোনটি?

Article: Łęczna is a town in eastern Poland with 19,780 inhabitants (2014), situated in Lublin Voivodeship. It is the seat of Łęczna County and the smaller administrative district of Gmina Łęczna. The town is located in northeastern corner of historic province of Lesser Poland. Łęczna tops among the hills of the Lublin Upland, at the confluence of two rivers —the Wieprz, and the Świnka. On December 31, 2010, the population of the town was 20,706. Łęczna does not have a rail station, the town has been placed on a national Route 82 from Lublin to Włodawa. And shall be considered as a
Summary: Łęczna is a town in eastern Poland with 19,780 inhabitants. It is a hill located in the Lublin Upland, at the confluence of two rivers - Wieprz and Świnka. It is a road hub, and has no rail station.
Question [Bengali]: লিচেনা পোল্যান্ডের কোন দুটি নদীর সঙ্গমস্থলে অবস্থিত?

Article: The μ-law algorithm (sometimes written "mu-law", often approximated as "u-law") is a companding algorithm, primarily used in 8-bit PCM digital telecommunication systems in North America and Japan. It is one of two versions of the G.711 standard from ITU-T, the other version being the similar A-law, used in regions where digital telecommunication signals are carried on E-1 circuits, e.g. Europe. Companding algorithms reduce the dynamic range of an audio signal. In analog systems, this can increase the signal-to-noise ratio (SNR) achieved during transmission; in the digital domain, it can reduce the quantization error (hence increasing signal to quantization noise ratio).
Summary: The μ-law algorithm is a companding algorithm, which is used to reduce the dynamic range of audio signals. In analog systems, this can increase the signal-to-noise ratio (SNR) achieved during transmission.
Question [Bengali]: μ-আইন অ্যালগরিদম কীভাবে অ্যানালগ সিস্টেমে সংক্রমণকে প্রভাবিত করে?

Article: **{Input Wikipedia Article in English}**
Summary:

Figure 9: 5-shot SAP (*Summarize-then-Ask Prompting*) for XOR-Retrieve (Asai et al., 2021a) is shown for Bengali (bn). There are five exemplars (5-shot) in our cross-lingual query generation task. The passages are randomly selected from the XOR-Retrieve Wikipedia corpus. A summary and a query for all above exemplars is manually written in English by the authors. Finally, the English written query is translated to Bengali (bn) for all above exemplars using Google Translate (translate.google.com).

3-shot Summarize-then-Ask Prompting for MIRACL

Read the following article in Chinese and write a factual summary in Chinese. Your summary will act as a surrogate for asking a question in Chinese based on the article.

Article: 四川各地小吃通常也被看作是川菜的组成部分。由于重庆地区小吃相对较少，除重庆麻辣小面外，川菜小吃主要以成都小吃为主。 主要有担担面、川北凉粉、麻辣小面、酸辣麵、 酸辣粉、叶儿粑、酸辣豆花、三合泥、红油抄手等以及用创始人姓氏命名的赖汤圆、龙抄手、钟水饺、吴抄手等。 甜品方面，以原产四川眉山的冰粉和四川宜宾长宁县的凉糕最有名。

Article: Muscular activity accounts for much of the body's energy consumption. All muscle cells produce adenosine triphosphate (ATP) molecules which are used to power the movement of the myosin heads. Muscles have a short-term store of energy in the form of creatine phosphate which is generated from ATP and can regenerate ATP when needed with creatine kinase. Muscles also keep a storage form of glucose in the form of glycogen. Glycogen can be rapidly converted to glucose when energy is required for sustained, powerful contractions. Within the voluntary skeletal muscles, the glucose molecule can be metabolized anaerobically in a process.
Summary: All muscle cells produce adenosine triphosphate (ATP) molecules for movement of myosin heads. A short term store of energy is generated from ATP in the form of cratine phosphate and can regenerate ATP when needed with creatine kinase.

Annotation Guidelines for SWIM-IR

Nandan Thakur

June 2nd 2023

- The goal of this task is to evaluate the quality of LLM-generated (PaLM 2-S) generated questions.
- Every annotator will receive a set of annotations containing the wikipedia paragraph and the question in the ${target_language}.
- Annotators should read each annotation carefully and provide feedback on the following:
    - The ***fluency*** of the question.
    - The ***adequacy*** of the question.
    - The ***language*** of the question.
- Annotators should be respectful and professional in their feedback.
- Annotators should complete all annotations within the allotted duration.

Here below we define the following terms:

Fluency

Rating Level	Explanation
2 (Flawless)	Perfect use of ${target_language} with no mistakes at all.
1 (Good)	Few or minor spelling or grammar mistakes; the text is still mostly understandable and readable.
0 (Poor)	Many or serious spelling, grammar, or other mistakes, which make the text difficult to understand or hard to read.

Adequacy

Rating Level	Explanation
2 (Relevant)	Highly related to the wiki passage. The question can be answered using the wiki passage.

1 (Moderate)	The question is somewhat related to the wiki paragraph, the question cannot be answered using the passage.
0 (Not Relevant)	The question is not at all related to the wiki passage.

Language

Rating Level	**Explanation**
2 (Flawless)	The whole question is perfectly in the ${target_language}.
1 (Good)	Code-switching occurs with part of the question in the ${target_language}.
0 (Poor)	The whole question is not at all in ${target_language}.

Thank you for your participation in this task!

SCANNER: Knowledge-Enhanced Approach for Robust Multi-modal Named Entity Recognition of Unseen Entities

Hyunjong Ok[1,3*], **Taeho Kil**[2†], **Sukmin Seo**[2], **Jaeho Lee**[1]
[1] POSTECH [2] NAVER Cloud [3] HJ AILAB
hyunjong.ok@gmail.com, taeho.kil@navercorp.com

Abstract

Recent advances in named entity recognition (NER) have pushed the boundary of the task to incorporate visual signals, leading to many variants, including multi-modal NER (MNER) or grounded MNER (GMNER). A key challenge to these tasks is that the model should be able to generalize to the entities unseen during the training, and should be able to handle the training samples with noisy annotations. To address this obstacle, we propose SCANNER (Span CANdidate detection and recognition for NER), a model capable of effectively handling all three NER variants. SCANNER is a two-stage structure; we extract entity candidates in the first stage and use it as a query to get knowledge, effectively pulling knowledge from various sources. We can boost our performance by utilizing this entity-centric extracted knowledge to address unseen entities. Furthermore, to tackle the challenges arising from noisy annotations in NER datasets, we introduce a novel self-distillation method, enhancing the robustness and accuracy of our model in processing training data with inherent uncertainties. Our approach demonstrates competitive performance on the NER benchmark and surpasses existing methods on both MNER and GMNER benchmarks. Further analysis shows that the proposed distillation and knowledge utilization methods improve the performance of our model on various benchmarks.

1 Introduction

Named entity recognition (NER) is a fundamental task in natural language processing to identify textual spans that correspond to named entities in the given text, and classify them into pre-defined categories, such as persons, locations, and organizations (Li et al., 2020). The extracted information can be utilized for various downstream tasks, including entity linking and relation extraction.

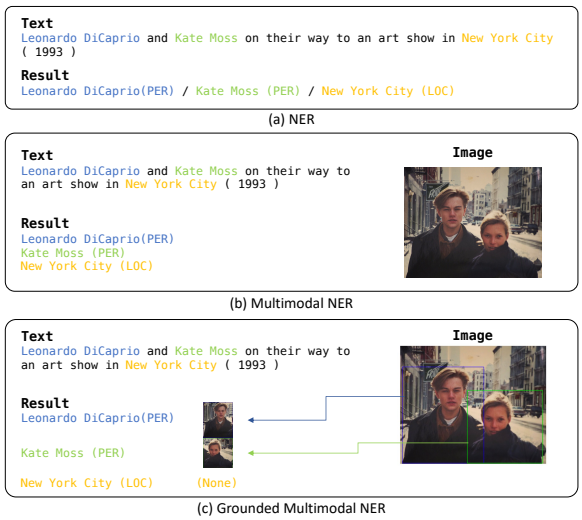

Figure 1: Illustrations of NER, MNER, and GMNER tasks. The NER task aims to identify named entities from the given text. MNER extends this task to utilize additional image informations. GMNER additionally requires the model to predict entity bounding boxes in the given image, if they are present.

The rapid growth of the amount of multi-modal contents on social media platforms has given rise to the multi-modal variants of NER. The most prominent example is multi-modal NER (MNER; Zhang et al. (2018)) , which extends traditional NER to identifying named entities in the text based on additional image input paired with the text (Fig. 1b). Another recent example is the grounded MNER (GMNER; Yu et al. (2023)); here, one additionally aims to predict the bounding boxes of named entities appearing in the given image (Fig. 1c).

A major challenge in NER, MNER, and GMNER tasks is the presence of unseen entities in the test datasets, which are not found in the training datasets. Traditional models often struggle with low performance on these unseen entities (see Table 1). To tackle this problem effectively, it is important to use knowledge about unseen entities in a way that boosts ability of the model to generalize

	Ours (w/o Knowledge)	87.18	73.84
Twitter-2017	BERT-base	93.81	67.76
	Ours (w/o Knowledge)	95.68	82.96

Table 1: A comparison of test F1 scores for the named entities that have appeared at least once in the training dataset, versus the entities that have not appeared.

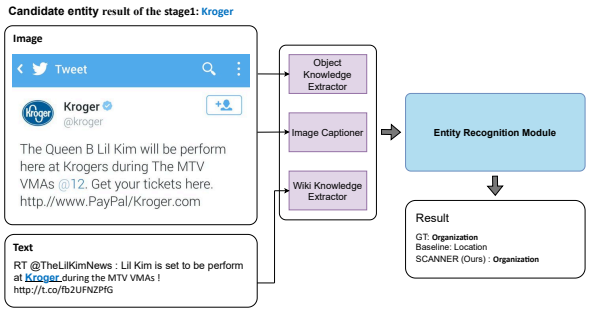

Figure 2: 'Kroger' is an unseen entity that is hard to recognize as an Organization or Location. By our knowledge base model, it brings to successful prediction.

and perform well across different types of data. In this paper, we introduce SCANNER, which stands for Span CANdidate detection and recognition for Named Entity Recognition. Our approach is designed to effectively use knowledge about unseen entities, addressing NER, MNER, and GMNER tasks with improved robustness. SCANNER adopts a two-stage structure, comprising a span candidate detection module and entity recognition module. The span candidate detection module identifies named entity candidates within sentences. Following this, the entity recognition module uses these candidates as queries to extract relevant knowledge from various sources, effectively recognizing the class of the entity candidate. As illustrated in Fig. 2, we were able to accurately identify 'Kroger' as an 'organization' by utilizing object knowledge. SCANNER effectively gathers and uses knowledge from various sources, boosting its performance in the challenging NER, MNER, and GMNER benchmarks. Notably, the GMNER challenge involves the intricate process of identifying entities and determining their bounding boxes within images. The architecture of SCANNER, leveraging its comprehensive knowledge, is effective in addressing the GMNER task. The effectiveness of SCANNER in the GMNER task is highlighted by establishing a new baseline that is over 21% higher than the previous standard, as measured by the F1 score. Additionally, we introduce the novel self-distillation method, called as Trust Your Teacher. The NER task faces challenges with noisy annotations (Wang et al., 2019; Zhu and Li, 2022), particularly at entity boundaries where exact span matching is crucial and ambiguity often leads to increased noise (see Table 2). Our distillation method, which softly utilizes both the prediction of the teacher model and ground truth (GT) logit, addresses the challenges of noisy annotations.

Table 2: Examples of gold annotation and potential alternatives. The gold annotations are marked in blue [*], whereas the alternative annotations are in red [*].

Our approach demonstrates competitive performance on NER and surpasses existing methods on both MNER and GMNER. Further analysis shows that the proposed distillation and knowledge utilization methods improve the performance of our model on various benchmarks.

The contributions of SCANNER are summarized in three key aspects:

- We propose a new distillation method that softly blends the predictions of the teacher model with ground truth annotations to enhance data quality and model training.
- We develop SCANNER, a two-stage structured model that effectively utilizes knowledge to improve performance, particularly in recognizing unseen entities.
- The SCANNER model shows competitive performance in NER benchmarks and demonstrates higher performance than existing methods in MNER and GMNER benchmarks.

2 Related work

Prior works on MNER typically operates by first extracting the NER-related features from the image, and then combining these features with text features to recognize name entities. Roughly, ex-

isting works fall into two categories according to how they extract image features.

Textual features. Several works extract the textual metadata from the given image and utilize them as features for the subsequent NER task (Wang et al., 2022b,a; Li et al., 2023b). For instance, ITA (Wang et al., 2022b) extracts object tags, image captions, and OCR results from the given image. Similarly, Li et al. (2023b) also extracts image captions, but additionally utilizes large language model as an implicit knowledge source to further refine the features. MoRe (Wang et al., 2022a) takes a slightly different approach, using an image-based retrieval system to retrieve textual descriptions of the closest images in the database.

Visual encoders. Another line of work attempts to extract the image features using a visual encoder, such as pre-trained ResNets, ViTs, or CLIP vision encoder (Wang et al., 2022e; Zhang et al., 2023; Chen et al., 2023). The extracted features are then combined with the text features extracted from a separate text encoder, which often involves additional alignment via cross-modal attention (Chen et al., 2022; Lu et al., 2022; Wang et al., 2022e; Zhang et al., 2023; Chen et al., 2023). Notably, PromptMNER (Wang et al., 2022d) calculates the similarity between visual features and various text prompts to extract visual cues that are loosely related to the input text.

In this paper, we take a different path and extract the image features *conditioned* on the information extracted from the given text. Up to our knowledge, even though it has related works in NER (Wang et al., 2021, 2022c; Tan et al., 2023), it is the first such attempt in the context of MNER, which is a more challenging task.

In addition, a new task has been introduced, which not only incorporates image inputs but also actively addresses the task of grounding entity locations within images (Yu et al., 2023).

3 Method

In this section, we first introduce the architecture of the proposed method, which comprises the span candidate detection module and the named entity recognition module (Sec. 3.1). Then, we describe the named entity recognition module, which performs entity recognition and visual grounding in the image for each entity candidate (Sec. 3.2). Finally, we explain a novel distillation method, named Trust Your Teacher, which is designed to robustly train our model even in the presence of noisy dataset annotations (Sec. 3.3).

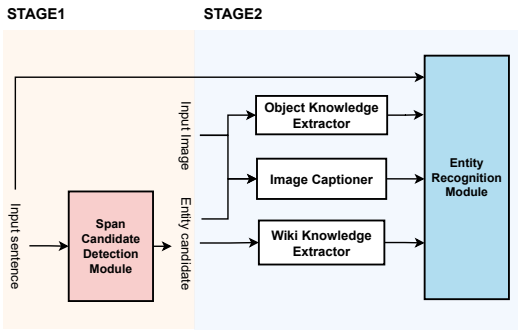

Figure 3: The overall architecture of the proposed SCANNER method. The two-stage structure allows for efficient extraction and utilization of knowledge, as knowledge is extracted only for those entity candidates that were filtered through in stage 1.

3.1 SCANNER Architecture

The primary focus of this paper is to perform MNER using both knowledge extracted from within images and external knowledge, even for entities not encountered during training. To achieve this, as illustrated in Fig. 3, we propose a two-stage architecture, known for its efficiency in extracting and searching for knowledge from various sources. In the first stage, we extract named entity candidates, and in the second stage, we efficiently search and extract only knowledge relevant to these candidates. This acquired knowledge is then utilized for entity recognition.

Stage 1: Span Candidate Detection Module. In the first stage of SCANNER, the transformer encoder (Liu et al., 2019) is employed to detect entity candidates from the input text. During this phase, we utilizes BIO (Beginning, Inside, Outside) tagging to classify each token in the input text, determining whether it corresponds to the beginning, inside, or outside of an entity span. The classification process is guided by cross-entropy loss.

Stage 2: Entity Recognition Module. In Stage 2, SCANNER performs named entity recognition and visual grounding for each entity candidate detected in Stage 1. It utilizes each entity candidate as a query to extract and leverage the necessary knowledge for the tasks. During this process, SCANNER efficiently searches and extracts knowledge by focusing on the initially detected entity candidates rather than the entire input text. SCANNER utilizes both internal (image-based) and external (e.g., Wikipedia) knowledge sources to perform

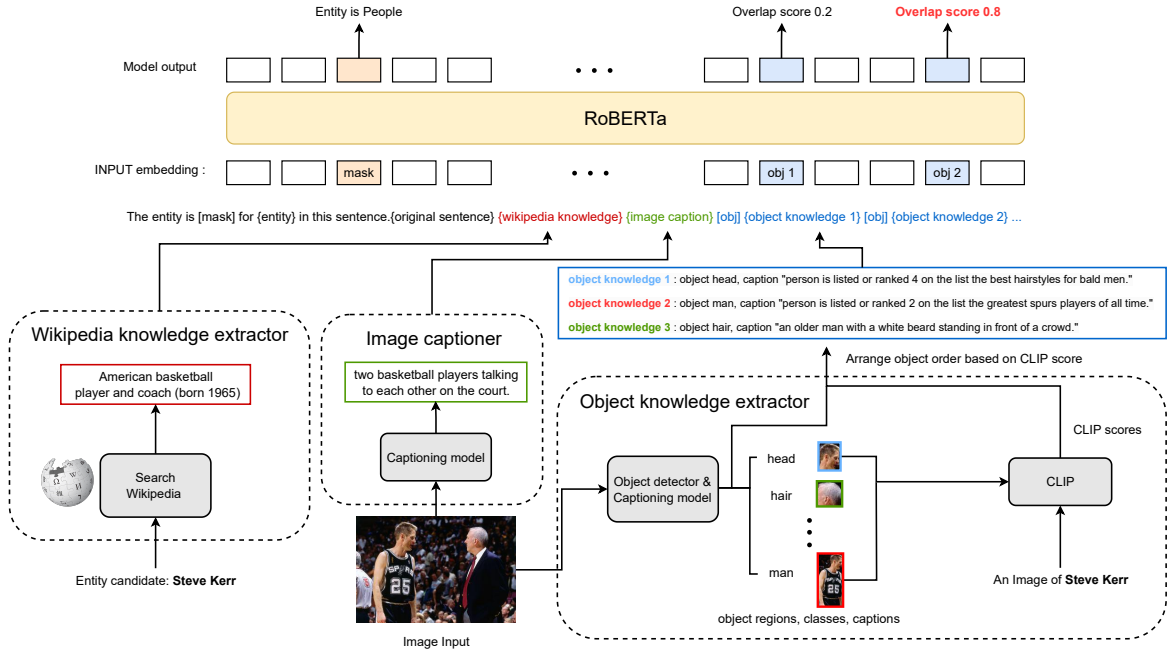

Figure 4: An illustration of the entity recognition module (stage 2). Based on the entity candidates (extracted in stage 1), SCANNER utilizes various knowledge sources such as Wikipedia, image captioner, and object knowledge extractor. The knowledge collected from these sources are then processed by RoBERTa to give the final prediction.

MNER on unseen entities, not encountered in training. Detailed information about these modules will be provided in Section 3.2.

3.2 Entity Recognition Module

For each entity candidate identified by the span candidate detection module, the entity recognition module processes a text prompt that includes both the entity candidate and associated knowledge. This knowledge, extracted from images and external knowledge sources, allows for performing MNER on unseen entities that were not encountered during training. Our methodology involves extracting this knowledge from a variety of sources, utilizing the identified entity candidates as the basis for the extraction process. Then, this module classifies the class of each entity candidate and performs grounding to determine which object in the image corresponds to the entity. A detailed illustration is shown in Fig. 4.

3.2.1 Prompt construction with knowledge

The entity recognition module extracts and utilizes useful knowledge from various sources when constructing the text prompt corresponding to the input. The knowledge applied for constructing text prompts in our method includes the following.

Wikipedia knowledge. Initially, information is searched using the entity candidate as a query in external knowledge source, which is Wikipedia. This information can be valuable for classifying the type of entity for each candidate and, moreover, enables the model to classify unseen entities that were not encountered during training. As illustrated in Fig. 4, for entity candidates like 'Steve Kerr', it enhances entity recognition performance by providing valuable information for classification as an American basketball player and coach.

Image caption. To effectively utilize visual information, image captioning results are also used. We use the BLIP-2 (Li et al., 2023a) to extract synthetic captions for the whole image.

Object knowledge. In addition to global information about the image, object-level information is also beneficial for entity recognition. To achieve this, results obtained from the object detector are employed as knowledge. Initially, object classes are converted into text format and used as knowledge. Then, synthetic captions for each object region are also utilized in conjunction with class names. This information is structured as details corresponding to each object, along with a special token denoted as [obj], as shown in Fig. 4. Additionally, during this process, the visual-language similarity between each object and entity candidate is calculated, and objects are arranged in order of high similarity, which is then included in the text prompt. One of the problems with existing meth-

ods for the MNER task is that the model sometimes references objects in the image that are irrelevant to the entity, leading to incorrect recognition. By arranging the object details in the text prompt according to the visual-language similarity order with the entity, our model can focus more on the object regions that are highly related to the entity. In this paper, CLIP (Radford et al., 2021) is employed for visual-language similarity, specifically calculating the similarity between the text representation of the entity candidate and the visual representation of each Region of Interest (RoI).

All such knowledge mentioned above is converted into a textual format and integrated with the text prompt for entity recognition and visual grounding.

The text prompt, structured to include entity candidates, the entire input text sentence, and extracted knowledge, is presented as *"The entity is* [*mask*] *for {entity} in this sentence. {original sentence} {Wikipedia} {image caption}* [*obj*] *{object 1}* [*obj*] *{object 2} ..."*.

3.2.2 Encoder and Objective

The prompts constructed for each entity candidate are input into a transformer encoder model (Liu et al., 2019). For entity recognition, the output token representation of the [mask] token in the text prompt x_i for the i-th entity candidate is fed into a linear layer to predict the probability distribution $\hat{y}_i$. Given the ground truth y, the objective function is to minimize the cross-entropy loss between the predicted entity class distribution and the ground truth logit:

$$\mathcal{L}_c = -\sum_{i=1}^{N} y_i \log \hat{y}_i, \tag{1}$$

where N is the total number of the entity candidates.

Additionally, the visual grounding is performed by feeding the output token representation of the j-th [obj] token from the text prompt x_i into a linear layer. This is followed by a sigmoid function, which aids in predicting the overlap score $\hat{o}_{ij}$ between the ground truth image region grounding entity candidate i and object j. The objective function of visual grounding is calculated based on the binary cross-entropy loss between the overlap score and the ground truth Intersection over Union (IoU):

$$\begin{aligned}\mathcal{L}_g = -\sum_{i=1}^{N}\sum_{j} o_{ij} \log \hat{o}_{ij} \\ + (1 - o_{ij}) \log(1 - \hat{o}_{ij}),\end{aligned} \tag{2}$$

where o_{ij} is the ground truth IoU between the ground truth image region of the entity i and object region j.

In training stage, we combine two losses as the final loss of our model:

$$\mathcal{L} = \mathcal{L}_c + \lambda \mathcal{L}_g, \tag{3}$$

where λ is the weighting coefficient, we set λ to 1 for the GMNER task and to 0 for the NER and MNER tasks in this paper.

3.3 Trust Your Teacher

We introduce the novel self-distillation method, called as Trust Your Teacher (TYT). Our distillation method, which softly utilizes both the prediction of the teacher model and ground truth (GT) logit, addresses the challenges of noisy annotations. First, we train the teacher model using equation 1, and then train the final student model using both the predictions of the teacher model and the ground truth labels. The most significant feature of our proposed method is that it assesses the reliability of each sample by utilizing the prediction of the teacher model to determine if it is trustworthy or noisy. Based on this assessment, the method sets the weights between the model prediction and the gt label, which are then reflected in the loss calculation. The objective of the our proposed distillation method composes a cross-entropy loss with ground truth and Kullback-Leibler Divergence (KLD) loss with teacher predictions:

$$\begin{aligned}\mathcal{L}_{\text{TYT}} = \sum_{i} a_i \, \mathcal{L}_{\text{CE}}\big(y_i, S(x_i, \theta_S)\big) \\ + (1 - a_i)\mathcal{L}_{\text{KLD}}\big(S(x_i, \theta_S), T(x_i, \theta_T)\big),\end{aligned} \tag{4}$$

where x_i is the input sample, θ_S and θ_T are the model parameters of the student and teacher, S and T are the prediction distributions of the student and teacher and a_i is a balancing factor proposed in this paper. In detail, a_i determines whether to trust the teacher model prediction or the ground truth, and it represents the prediction score of the teacher model for the ground truth class index, which is $T(x_i, \theta_T)[y_i]$. This implies that since the teacher model is well-trained, if the score for the ground

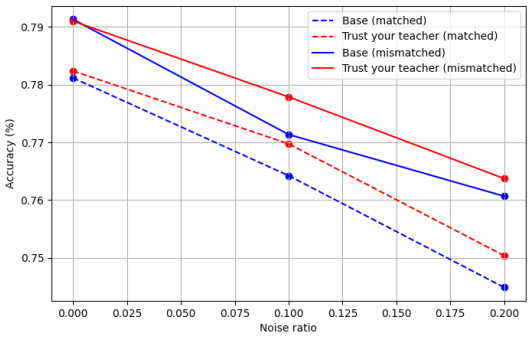

Figure 5: Experiments of text classification task in MNLI datasets. 'matched' is in-domain, and 'mismatched' is out-domain.

Methods	Twitter-2015			Twitter-2017			Twitter-GMNER		
	Pre.	Rec.	F1	Pre.	Rec.	F1	Pre.	Rec.	F1
Base	83.28	87.68	85.43	**90.96**	93.23	92.08	86.60	87.59	87.09
Half	83.36	87.69	85.47	90.31	92.92	91.60	**87.00**	87.96	87.47
Full	**83.63**	87.72	85.63	90.53	92.95	91.72	86.90	87.80	87.35
TYT	83.59	**87.98**	**85.73**	90.94	**93.28**	**92.09**	86.82	**88.37**	**87.59**

Table 3: Ablation study on the MNER dataset in first stage. 'Half' is when a_i is 0.5 and 'Full' is 0. In 'TYT', a_i is adjusted through the trust your teacher method.

truth class is high, then the sample is considered reliable and more weight is given to the cross-entropy with the ground truth label. Conversely, if the score is low, the sample is assumed to be an unreliable, noisy sample, and more weight is placed on the KLD loss with the prediction of the teacher model, rather than the ground truth label.

To demonstrate the significant impact of our TYT approach, we have carried out some experiments. Fig. 5 illustrates our experiments on a text classification task in MNLI dataset. We extract about 30% of the train set for experimental efficiency and intentionally added label noise at rates of 10% and 20% to this subset. We then compare the performance of the model trained with our TYT method on the train set with added label noise against the baseline that does not use distillation. Fig. 5 indicates that using TYT demonstrates relatively robust performance under moderate noise conditions. Additionally, we compare our method with the conventional soft distillation methods that do not dynamically vary the a_i parameter in the entity detection task, stage 1 of MNER and GMNER. Table 3 shows that our method has better performance on MNER and GMNER benchmarks, and adaptively varying the a_i is more effective than keeping it fixed.

We apply the TYT to both stages 1 and 2. But in NER, we only use it in stage 1. The loss from the TYT is applied only to the classification loss and not to the loss for visual grounding.

4 Experiment

4.1 Dataset

Our methodology's efficacy was assessed using widely used datasets for each task. We utilize CoNLL2003 (Tjong Kim Sang and De Meulder, 2003) for NER, Twitter-2015 (Zhang et al., 2018) and Twitter-2017 (Lu et al., 2018) for MNER, and Twitter-GMNER (Yu et al., 2023) for GMNER. Details are in appendix B.

4.2 Experimental Setups

Evaluation metrics. To evaluate our method, we use Entity-wise F1, precision, and recall scores for NER and MNER tasks. For the GMNER task, there is an additional evaluation of the visual grounding. For instances, where the visual grounding is ungroundable, a prediction is correct if it is classified as 'None.' For others, correctness hinges on the IoU metric. A prediction is considered correct if the IoU score between the predicted visual region and the ground truth bounding boxes exceeds a threshold of 0.5. We use F1, precision, and recall scores, which are calculated based on the aggregate correctness across entity, type, and visual region predictions. Our primary focus is on the F1 score in line with numerous preceding studies.

Implementation details. Following most recent works, we implement our model utilizing RoBERTa-large in NER, XLM-RoBERTa-large (Conneau et al., 2020) for MNER, GMNER both in stage 1 and stage 2. For the object detector, we use VinVL (Zhang et al., 2021b) following the settings with ITA (Wang et al., 2022b). To address the requirements of visual-language similarity and image caption, we use each of them CLIP [1] and BLIP-2 [2] models respectively. Detailed hyper-parameter settings are shown in appendix A. All experiments were done on a single GeForce RTX 4090 GPU or NVIDIA H100 GPU, and we report the average score from 5 runs with different random seeds for each setting.

Also we applied several minor methods to enhance performance. In the second stage, we incorporated a 'non-entity' label to account for instances

Table 6: Experiment results on the Twitter-GMNER. The reported figures for the baseline models are taken from Yu et al. (2023).

where the model erroneously predicts entity candidates not present in the dataset. That allowed for more accurate handling of such cases. We augmented it with non-entity data by dividing the training set into four folds in stage 1 and validating each fold. Secondly, we employed adversarial weight perturbation (AWP) (Wu et al., 2020) in stage 1 , which enhances the robustness and generalization capabilities of the model. We initiated AWP from an intermediate stage of our training process.

4.3 Experimental results in various NER tasks

Experimental results in NER. To evaluate the effectiveness of our approach in NER, we primarily compared our model against the existing methods in Table 5. It shows that SCANNER exhibits a competitive performance compared to the existing NER methods.

Experimental results in MNER. In assessing the effectiveness of SCANNER in MNER, we conducted comparative analyses against various leading models in this task. The results, detailed in Table 4, reveal that our model achieves superior performance in Twitter-2015 and exhibits markedly impressive results in Twitter-2017. Notably, while PGIM shows outstanding performance on Twitter-2017, it utilizes large language models (LLM) like ChatGPT, which incurs API costs, a notable drawback. In contrast, our model does not rely on LLM knowledge, freeing it from such disadvantages and demonstrating better performance on Twitter-2015. Additionally, we conduct experience using the same LLM knowledge as PGIM, which is in appendix C.

Experimental results in GMNER. To show our effectiveness in GMNER, we make broad compar-

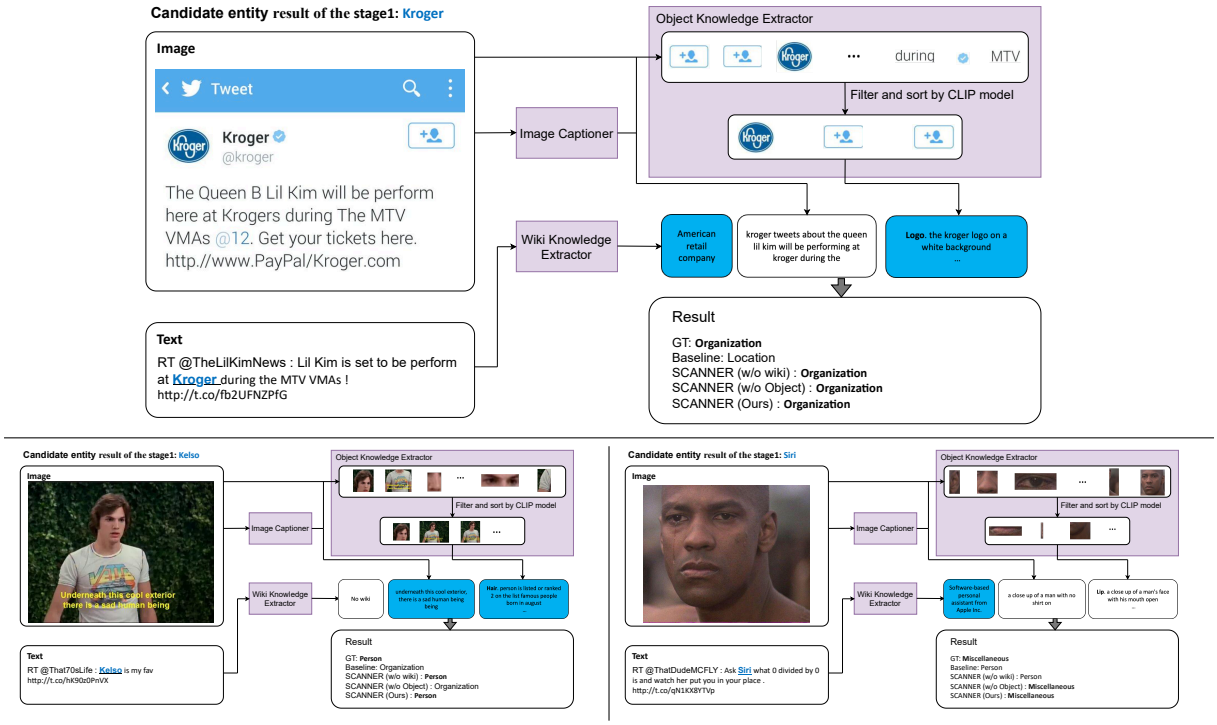

Figure 6: Visualization results showing how various types of knowledge are brought in and utilized differently to perform the MNER task. Knowledge highlighted in blue positively influences correct predictions.

Methods	Twitter-2015			Twitter-2017

isons with all existing methods. Text-only models made to predict the visual groundings all 'None'. The Table 6 shows that our model achieves significant performance improvements over prior research and establishes a new powerful baseline for future GMNER studies.

4.4 Ablation study

Ablation study in MNER. We conduct ablation experiments on the MNER task to evaluate the effectiveness of the proposed method. These results are shown in Table 7. We observe that removing the Trust Your Teacher method led to a decrease in performance. Our proposed distillation method effectively alleviates the dataset noise issue, making our model more robust to learning from noisy dataset. Additionally, to verify the effectiveness of the various types of knowledge used in our study, we compare the results with experiments where each type of knowledge was removed. We confirm that the object knowledge, Wikipedia knowledge, and image caption knowledge used in our paper all contribute to the performance improvement of the MNER task.

Case study. As shown in Fig. 6, all three types of knowledge can be utilized as useful information for named entity recognition. In the case of the first image, knowledge from Wikipedia such as "American retail company" and object knowledge containing the logo information of "Kroger" both help in predicting the "Kroger" entity as an organization. For the image on the bottom left, image caption and object knowledge aided in named entity recognition. Moreover, in the image on the bottom right, vision information like image caption and object knowledge led to incorrect entity recognition results, but it was corrected through external knowledge from Wikipedia. Thus, the three types of knowledge proposed in this paper complement each other, enabling accurate MNER performance.

Effectiveness in unseen entity. Table 8 shows the effectiveness of knowledge in unseen entities. As

Datasets	w/o Knowledge		w/ Knowledge	
	Seen	Unseen	Seen	Unseen
CoNLL2003	96.29	89.68	96.35	89.70
Twitter-2015	87.18	73.84	87.50	75.45
Twitter-2017	95.68	82.96	95.90	83.71

Table 8: The result comparing the test F1 scores in unseen entities of knowledge extracted and baseline.

SCANNER utilizes various knowledge in MNER, it greatly increases performance in unseen entities. In NER, lack of various knowledge causes there to be no image, which slightly improves the performance.

5 Conclusions

We introduce SCANNER, a novel approach for performing NER tasks by utilizing knowledge from various sources. To efficiently fetch diverse knowledge, SCANNER employs a two-stage structure, which detects entity candidates first, and performs named entity recognition and visual grounding on these candidates. Additionally, we propose the novel distillation method, which robustly trains the model against dataset noise, demonstrating superior performance in various NER benchmarks. We believe that our method can be easily extended to utilize knowledge from multiple sources that were not covered in this paper.

Limitations

In this study, we extract knowledge from various sources and utilize it to perform MNER tasks. By leveraging several vision experts such as CLIP, and also fetching external knowledge, our method takes relatively longer inference time compared to approaches that do not use knowledge. However, the use of vision experts and knowledge is essential for a MNER model that functions well even with unseen entities, and we efficiently extract information through a two-stage structure.

Ethics statement

All experimental results we provide in this paper is based on publicly available datasets and open-source models.

A Hyper-parameter settings

Datasets	Stage 1			
	epochs	batch size	lr	weight decay
CoNLL2003	5	8	5×10^{-6}	1
Twitter-2015	10	4	1×10^{-5}	2
Twitter-2017	10	8	1×10^{-5}	2
Twitter-GMNER	10	8	1×10^{-5}	2

Table 9: Hyper-parameter settings in Stage 1 were used in the experiments for NER, MNER, and GMNER.

Datasets	Stage 2				
	epochs	batch size	lr	weight decay	max objects
CoNLL2003	20	8	3×10^{-6}	0.01	-
Twitter-2015	5	8	1×10^{-5}	0.01	15
Twitter-2017	7	8	5×10^{-6}	0.01	15
Twitter-GMNER	5	8	5×10^{-6}	2	18

Table 10: Hyper-parameter settings in Stage 2 were used in the experiments for NER, MNER, and GMNER.

We conducted our experiments with hyper-parameter settings as outlined in the following Table 9 and Table 10, and we utilize AdamW (Loshchilov. and Hutter, 2019) optimizer for all tasks. 'max objects' refers to the maximum number of object knowledge inputs. We performed a grid search for the learning rate within the range of $[5 \times 10^{-6}, 1 \times 10^{-5}]$. We tested batch sizes of 4, 8, and 16 to determine the optimal value, and we explored weight decay within a range of $[0.01, 2]$.

B Detailed dataset statistics

To demonstrate the superiority of our method for various NER tasks, we conduct experiments on a range of datasets. The overall dataset statistics are shown in Table 11, and each task description is in below.

NER dataset. CoNLL2003 (Tjong Kim Sang and De Meulder, 2003), a dataset with four named entities: PER, LOC, ORG, and MISC. We follow the standard setting (Peters et al., 2017; Yan et al., 2021b; Shen et al., 2023a): use both the train set and dev set for training and evaluate with the test set

MNER dataset. Twitter-2015 (Zhang et al., 2018) and Twitter-2017 (Lu et al., 2018); collected from social network service posts. Like CoNLL2003, it consists of the same four named entity types. We operate a train set for training and hyper-parameter tuning using a dev set and evaluate it with the test set.

GMNER dataset. Twitter-GMNER (Yu et al., 2023), a dataset collected by extracting some of the data from Twitter-2015 and Twitter-2017, and employ bounding box annotation. We operate same validate strategy as MNER.

	Text				Image Total
	#Total	#Train	#Dev	#Test	#Groundable Entity
CoNLL2003	20,744	17,291	-	3,453	-
Twitter-2015	8,257	4,000	1,000	3,257	-
Twitter-2017	4,819	3,373	723	723	-
Twitter-GMNER	10,000	7,000	1,500	1,500	6,716

Table 11: Dataset statistics of NER, MNER, and GMNER benchmarks

Methods	Twitter-2015			Twitter-2017		
	Pre.	Rec.	F1	Pre.	Rec.	F1
MoRe (Wang et al., 2022a)	-	-	79.21	-	-	90.67
PGIM (Li et al., 2023b)	79.21	79.45	79.33	**90.86**	92.01	**91.43**
SCANNER	**79.72**	79.03	79.38	90.40	90.67	90.54
SCANNER (w/ GPT knowledge)	79.24	**80.97**	**80.10**	90.22	**92.23**	91.22

Table 12: Comparison SCANNER w/ GPT knowledge with previous leading baseline methods on Twitter-2015 and Twitter-2017 datasets.

C Compare with MoRe and PGIM

Using LLM knowledge. With the advancements in LLM, we conducted experiments using GPT knowledge in SCANNER instead of Wikipedia knowledge. We utilize the same knowledge used in PGIM, and the results are in Table 12. We can observe that while applying GPT knowledge in SCANNER increases time and API-related costs, it also enhances performance. Notably, despite the GPT knowledge being tailored for PGIM, its performance in SCANNER is superior.

Time cost in retrieval knowledge. We conduct time cost comparisons using retrieval knowledge. As shown in Table 13, our entity-centric approach for integrating Wikipedia information demonstrates a speed advantage over MoRe's BM25 and K-NN based information retrieval and PGIM's GPT-based knowledge creation. This speed benefit arises from our direct method of identifying entity candidates, which allows for immediate retrieval of relevant Wikipedia articles without any bottlenecks.

D Ablation study in GMNER

We conduct additional ablation experiments on the Twitter-GMNER task to evaluate the effectiveness of the proposed method. Effects of each method are shown in Table 14, and ablation studies on the number of object tokens are shown in Table 15. These tables substantiate the efficacy of our pro-

Methods	Knowledge base	Sentences / Sec.
MoRe	Wiki (Text)	64.6
MoRe	Wiki (Image)	650.1
PGIM	GPT	0.92
SCANNER (Ours)	Wiki (Text)	**1,300.09**

Table 13: Throughput of knowledge extractor. Performance metrics for MoRe are sourced directly from the MoRe paper, while those for PGIM and SCANNER are obtained from our measurements on a Ryzen 7900 CPU. Bigger is faster. For each 100 sentences, PGIM paid $0.2 for using ChatGPT API.

Abstract

Metaphor detection is a challenging task in figurative language processing, which aims to distinguish between metaphorical and literal expressions in text. Existing methods tackle metaphor detection via training or fine-tuning discriminative models on labeled data. However, these approaches struggle to explain the underlying reasoning process behind the metaphorical/literal judgment. Recently, large language models (LLMs) have shown promise in language reasoning tasks. Although promising, LLM-based methods for metaphor detection and reasoning are still faced with the challenging issue of bringing the explainable concepts for metaphor reasoning and their linguistic manifestation. To fill this gap, we propose a novel **T**heory guided **S**caffolding **I**nstruction (TSI) framework that instructs an LLM to infer the underlying reasoning process of metaphor detection guided by *metaphor theories* for the first time. Our work is inspired by a pedagogical strategy called *scaffolding instruction*, which encourages educators to provide questioning and support as scaffolding so as to assist learners in constructing the understanding of pedagogical goals step by step. We first construct a metaphor knowledge graph grounded in metaphor theory, which serves as the instructional structure to obtain a series of scaffolding questions, directing the LLM to incrementally generate the reasoning process for metaphor understanding through dialogue interactions. During this theory guided instruction process, we explore the LLM's mastery boundary and provide the relevant knowledge as scaffolding support when the question is beyond the LLM's capability. Experimental results verify that our method significantly outperforms both the LLM-based reasoning methods and the SOTA methods in metaphor detection, indicating the facilitation of metaphor and instruction theories in guiding LLM-enabled reasoning process.

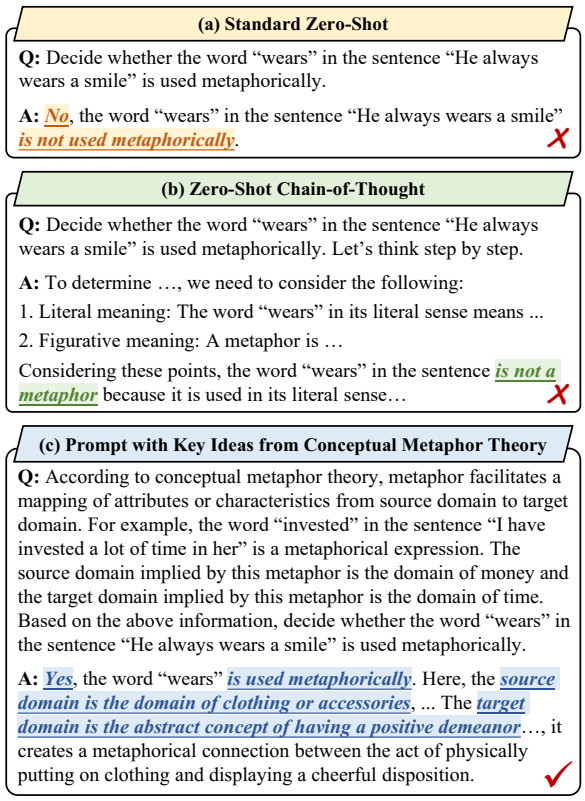

Figure 1: Example inputs and outputs generated by GPT-3.5 utilizing standard zero-shot method, zero-shot chain-of-thought method, and prompt with key ideas from conceptual metaphor theory for metaphor reasoning.

1 Introduction

Metaphor is not just a figurative expression but a pervasive phenomenon in human thought, perception, and reasoning (Lakoff and Johnson, 1980). Merriam-Webster Dictionary defines metaphor as "a figure of speech in which a word or phrase literally denoting one kind of object or idea is used in place of another to suggest a likeness or analogy between them". Metaphor detection as a fundamental research task in natural language processing can benefit a variety of other tasks, which require the understanding of implicit semantics, such as ma-

chine translation (Mao et al., 2018), sentiment and emotion analysis (Mao and Li, 2021), and conversational dialogue (Sun et al., 2023).

Existing studies on metaphor detection establish supervised learning methods based on labeled data (Rohanian et al., 2020; Le et al., 2020; Mao and Li, 2021). Recently, some studies employ metaphor theories to help design models for metaphor detection, resulting in significant performance gains (Zhang and Liu, 2022; Ge et al., 2022; Tian et al., 2023). Although these methods are inspired by different metaphor theories, they essentially train or fine-tune discriminative models to learn a decision boundary between metaphorical and literal samples, lacking the ability to explain the underlying reasoning process of metaphorical/literal judgment.

Recently, large language models (LLMs) have shown promise in generating reasoning processes with natural language across various tasks (Kojima et al., 2022; Wang et al., 2023a; Zhang et al., 2023), which demonstrates their potential to provide the underlying reasoning process for metaphor understanding. Although promising, LLM-based methods for metaphor detection and reasoning are still faced with the challenging issue of bringing the explainable concepts for metaphor reasoning and their linguistic manifestation. Figure 1 gives examples of LLM-based metaphor detection methods. Figure 1 (a) and (b) show that LLMs fail to detect the metaphor; even when employing zero-shot chain-of-thought method (Kojima et al., 2022). This limitation may be attributed to the fact that metaphors are not merely linguistic phenomena but associated with human thought and reasoning process (Lakoff and Johnson, 1980). Thus metaphors inherently convey intricate and implicit meanings that require a deeper level of understanding, making it more difficult for LLMs to comprehend. To better understand and detect metaphors, metaphor theories that provide well-established frameworks can serve as shortcuts to help effective metaphor reasoning and understanding. Figure 1 (c) provides an LLM with the prompt incorporated with the key ideas from conceptual metaphor theory (CMT) (Lakoff and Johnson, 1980), the key metaphor theory in cognitive linguistics. The result shows that, with the help of CMT theory, the LLM can provide a correct answer with an explanation of corresponding reasoning process.

In this paper, we tackle the challenging issue of LLM-based metaphor reasoning. To better release the capability of LLMs for metaphor reasoning and understanding, we make the first attempt to incorporate well-founded metaphor theories in such process. Further, to bridge the abstract conceptual representations of metaphor theories and the detailed LLM reasoning process, we draw inspiration from a pedagogical strategy called scaffolding instruction (Bruner, 1974; Vygotsky, 1978), which emphasizes that an educator continually explores a learner's mastery boundary through dialogues and designs questions and support as scaffolding, to assist learners in constructing the understanding of pedagogical goals step by step. To achieve this, we propose a novel **T**heory guided **S**caffolding **I**nstruction framework (TSI) for LLM-enabled metaphor reasoning. Specifically, we rely on three representative metaphor theories, selection preference violation (SPV) (Wilks, 1975, 1978), metaphor identification procedure (MIP) (Pragglejaz Group, 2007), and conceptual metaphor theory (CMT) (Lakoff and Johnson, 1980). In our computational construct, we first formalize a metaphor theory by converting it into a metaphor knowledge graph (KG), which functions as the instructional structure to construct scaffolding questions that help LLM's metaphor reasoning process. During dialogue interactions, our framework automatically detects the mastery boundary of LLM and provides relevant knowledge as scaffolding support when the question is beyond the LLM's capability.

Our main contributions are as follows:

- To release the metaphor reasoning capability of LLMs, we make the first attempt to propose a theory guided framework TSI and develop the conceptual representations by converting metaphor theories into knowledge graphs for scaffolding instruction.
- The scaffolding instruction process in TSI constructs prompts for scaffolding questions based on metaphor KGs to facilitate the step-by-step reasoning, and provides scaffolding support by dynamically assessing the LLM's mastery boundary.
- Experimental results on two datasets verify that our method achieves significant performance gains compared to LLM-based methods in complex reasoning and the SOTA methods in metaphor detection.

2 Related Work

Metaphor Theories As a fundamental and profound figurative phenomenon in linguistics and cognition, metaphor has been theorized across various disciplines in linguistics, philosophy and psychology (Plato, 1901; Kittay, 1990; Aristotle, 1995). However, not all of these theories are appropriate for computational formalization. Among them, three theories are favorable in existing computational research on metaphor, including selectional preference violation (SPV) (Wilks, 1975), metaphor identification procedure (MIP) (Pragglejaz Group, 2007), and conceptual metaphor theory (CMT) (Lakoff and Johnson, 1980).

The SPV theory suggests that the disparity between the *context* of a word within a sentence and its frequently used contexts is an indicator of this word's metaphorical usage. The MIP theory aims to standardize the metaphor annotation process, emphasizing that a metaphor is identified if the contextual meaning of the word differs from its basic *meaning*. Unlike SPV and MIP, which utilize indicative clues based on linguistic features of contexts or word meanings to identify metaphors, CMT goes beyond linguistic analysis and proposes a cognitive basis for metaphor understanding, suggesting that metaphor facilitates a mapping of attributes from *source domain* to *target domain* in human cognition. In this paper, we focus on releasing the metaphor reasoning capability of LLMs with the guidance of these three metaphor theories.

Computational Work on Metaphor without Theories Computational studies on metaphor focus on three main tasks, including metaphor detection, metaphor interpretation, and metaphor generation. Most of the work, especially the early work, established methods for computational metaphor processing without consideration of metaphor theories.

Metaphor detection, which attracts more research attention compared to the other two tasks, aims to identify an expression in text as metaphorical or literal. Early researchers utilize machine learning based methods to detect metaphors (Tsvetkov et al., 2014; Shutova et al., 2016; Bulat et al., 2017). Given that understanding metaphors requires knowledge beyond the context, some studies employ external knowledge resources for this task (Rohanian et al., 2020; Wan et al., 2021; Li et al., 2023). Benefiting from multitask learning, other studies learn shared information between metaphor detection and related tasks (Le et al., 2020; Mao and Li, 2021; Zhang and Liu, 2023; Badathala et al., 2023). Moreover, some studies (Lin et al., 2021; Feng and Ma, 2022) explore data augmentation methods to alleviate the problem of insufficient data for this task.

Metaphor interpretation involves explaining the implicit meaning conveyed by a metaphorical expression, which is a more challenging task than metaphor detection. Existing studies without using metaphor theories often formulate this task as a paraphrasing task to generate literal substitute paraphrase for a metaphorical word/phrase (Shutova, 2010; Shutova et al., 2012; Zayed et al., 2020) or identify the literal interpretation for a metaphorical expression in a candidate sentence set (Bizzoni and Lappin, 2018; Chakrabarty et al., 2022).

Metaphor generation focuses on generating metaphorical expressions from literal ones. Some studies generate a metaphorical word to replace the literal one using the end-to-end generation framework (Yu and Wan, 2019; Chakrabarty et al., 2021). Other studies generate the metaphorical sentence based on syntactic patterns (Brooks and Youssef, 2020) or a given Chinese noun (Li et al., 2022).

Computational Work on Metaphor with Theories Unlike the above research only focusing on computational perspectives for metaphor processing, recently, some researchers (Stowe et al., 2021b; Ge et al., 2022) have incorporated well-established metaphor theories into computational work on metaphor and achieved promising results.

Some studies (Su et al., 2021; Song et al., 2021; Choi et al., 2021; Zhang and Liu, 2022; Wang et al., 2023b) adopt SPV and MIP in network design for metaphor detection. Inspired by CMT, Ge et al. (2022) propose a model that generates plausible source and target concepts to help metaphor detection. Tian et al. (2023) further propose an attribute Siamese network to learn similar attributes between the source and target domains for this task.

In metaphor interpretation, some research considers the source domain implied by the metaphor in CMT as the interpretation and develops various methods to identify these domains, such as the unsupervised method (Shutova et al., 2017), deep learning based method (Rosen, 2018) and LLM-based method (Wachowiak and Gromann, 2023). Other research extracts attributes that link source and target domains as interpretation of metaphors (Su et al., 2017; Rai et al., 2019; Su et al., 2020).

In metaphor generation, Stowe et al. (2021b)

make the first attempt to generate metaphors with conceptual mappings grounded in CMT and develop the lexical model and seq-to-seq model for metaphor generation. In addition, Stowe et al. (2021a) focus on comparing free and controlled metaphor generation based on CMT.

Although previous methods achieve promising results, they only apply metaphor theories for network design or model the elements in these theories, lacking the ability to explicitly reflect the inherent reasoning processes grounded in theories. Recently, large language models (LLMs) have shown potential for reasoning and can generate reasoning processes in natural language, while how to develop the LLM's capability on metaphor reasoning remains unexplored. Thus, we focus on releasing LLM's ability on metaphor reasoning and understanding with the guidance of metaphor theories.

Complex Reasoning with LLMs In recent years, LLMs have shown multiple emergent abilities (Wei et al., 2022a), leading the shift of paradigm in natural language processing from fine-tuning to in-context learning. However, LLMs still exhibit limitations when they tackle complex reasoning tasks. To mitigate this gap, Wei et al. (2022b) propose chain-of-thought (CoT) prompting with task-specific exemplars of reasoning processes. After that, some studies design automatic CoT prompting methods encouraging LLMs to generate reasoning processes in a zero-shot manner (Kojima et al., 2022; Wang et al., 2023a; Zhang et al., 2023). Other studies explore enhancement methods to improve the reasoning ability of current CoT methods, such as refinement (Madaan et al., 2023), question decomposition (Zhou et al., 2023), voting (Wang et al., 2023c), ranking (Khalifa et al., 2023) and using external knowledge (Zhao et al., 2023). Cognitive linguists argue that metaphors are not just linguistic expressions but fundamental to human thought and cognition (Lakoff and Johnson, 1980), thus understanding metaphors requires complex reasoning processes in the human brain. Although the above research has explored many complex reasoning tasks, LLM-enabled metaphor reasoning is still a challenging task. Therefore, in this paper, we make the first attempt to design methods to unleash the potential of LLM on metaphor reasoning.

3 Problem Definition

Formally, $\mathcal{D}_{te}=\{(s_k, w_k, l_k)\}_{k=1}^{N_{te}}$ is the test dataset with N_{te} instances, where s_k is a sentence, w_k is a word within s_k, and l_k is the label (metaphorical or literal) for w_k. Our goal of metaphor detection with LLM is to predict the label of the word within a sentence in $\mathcal{D}_{te}$ without any training data.

4 Method

We propose a novel **T**heory guided **S**caffolding **I**nstruction framework (TSI) for LLM-enabled metaphor reasoning. Under the guidance of a metaphor theory, our framework instructs LLM to explicitly give a reasoning process with questioning and support as scaffolding to determine whether the word within a sentence is metaphorical or literal. Figure 2 shows the overall architecture of our framework, which contains four primary components: (1) *Metaphor Knowledge Graph Construction*, which represents a simplified metaphor theory and computational aspects in a graphical format; (2) *Scaffolding Question Construction*, which constructs a sequence of scaffolding questions for an LLM with metaphor knowledge graph as the instructional reference; (3) *Scaffolding Support based on Mastery Level of LLM*, which automatically detects the current capability of LLM (i.e. mastery level) and provides knowledge as support if necessary; and (4) *Classification*, which categories the word within the sentence as metaphorical or literal, based on the comparison between the structure of knowledge graph constructed from LLM's reasoning processes and the structure of metaphor knowledge graph.

4.1 Metaphor Knowledge Graph Construction

To facilitate theory guidance and computational construction for LLM-enabled metaphor reasoning, we manually simplify the metaphor theory and construct a metaphor knowledge graph (KG), which covers the essential information in both the theory and computational aspects. On the theory side, metaphor KG represents the fundamental concepts and the relation between concepts identified in the metaphor theory. On the computational side, metaphor KG also represents the core linguistic expressions of the word, sentence, and POS information as well as their connections. Specifically, the metaphor KG is formulated as $\mathcal{G} = \{\mathcal{E}, \mathcal{R}, \mathcal{F}\}$, where $\mathcal{E}$, $\mathcal{R}$, and $\mathcal{F}$ represent sets of entities, relations, and facts, respectively. There are two groups of entities in our metaphor KG. One group consists of all the entities of concepts $\{e_k^c\}_{k=1}^{N_c}$ mentioned

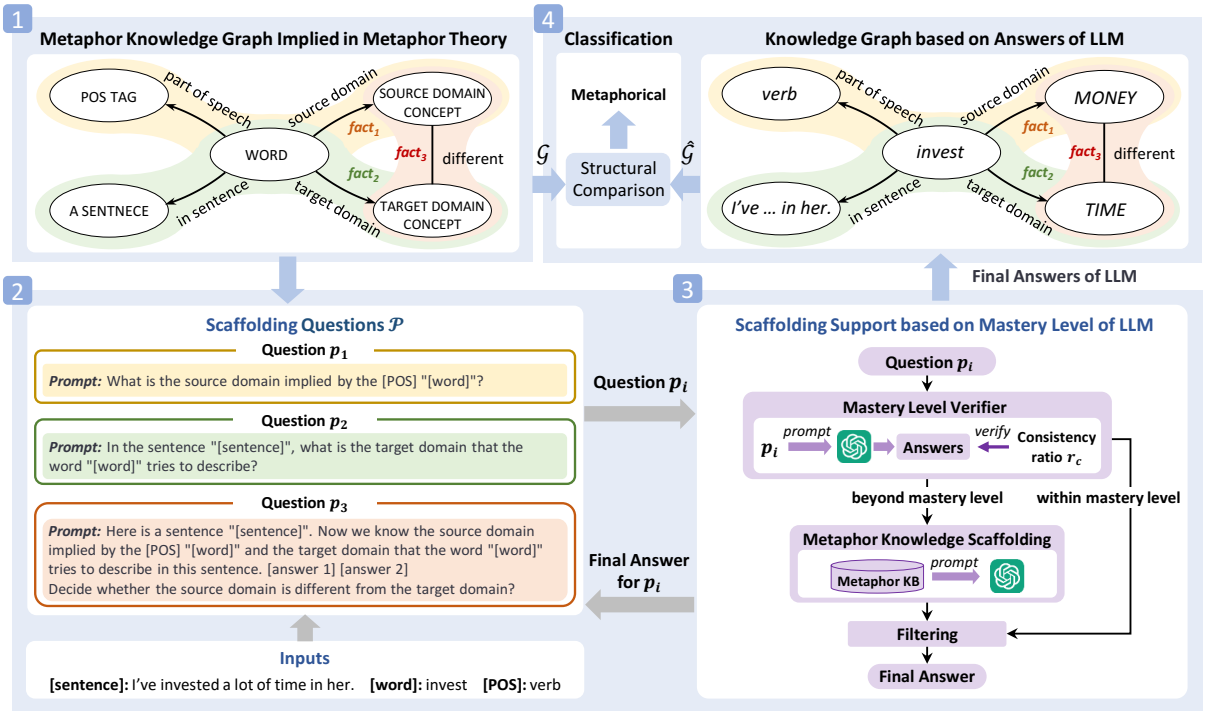

Figure 2: Overall architecture of our proposed framework TSI guided by conceptual metaphor theory for LLM-enabled metaphor reasoning. *[answer i]* denotes the input slot of the final answer for the scaffolding question p_i.

in metaphor theory or used for computational usage, and the other group consists of all the entities of attributes $\{e_k^a\}_{k=1}^{N_a}$ associated with the concepts in metaphor KG. The relation could be a directed relation r^d or an undirected relation r^u between entities. The i-th fact $f_i \in \mathcal{F}$ is denoted as a triple (e^h, r, e^t), where e^h and e^t denote head and tail entities, respectively. We apply our framework to three metaphor theories widely used in computational metaphor processing, including selectional preference violation (SPV) (Wilks, 1975, 1978), metaphor identification procedure (MIP) (Praggle-jaz Group, 2007), and conceptual metaphor theory (CMT) (Lakoff and Johnson, 1980). The details of metaphor KGs constructed based on the simplification of SPV, MIP and CMT in our methods are shown in Appendix B.

4.2 Scaffolding Question Construction

Questioning is a commonly used approach in the pedagogical strategy scaffolding instruction (Zheng et al., 2019; Laili and Siswono, 2020), which helps ascertain the learner's current level of understanding, stimulate critical thinking and encourage deeper understanding. Inspired by this, taking a sentence and a word within the sentence as initial information, we construct a sequence of questions as scaffolding with the metaphor KG as the reference guiding LLM to obtain metaphor reasoning processes. Each scaffolding question induces a reasoning process based on a fact in the metaphor KG. We have two types of reasoning processes, which are as follows:

- *Forward Reasoning*: In a fact (e.g. $fact_1$ and $fact_2$ in Figure 2), given an instantiated head entity of concept (along with its associated attribute entities, if applicable) and a direct relation in the metaphor KG, the LLM needs to determine the unknown instantiated tail entity;
- *Relation Reasoning*: In a fact (e.g. $fact_3$ in Figure 2), given two instantiated entities of concepts (along with their associated attribute entities, if applicable) in the metaphor KG, the LLM needs to infer whether the undirected relation between these two entities exists.

For the forward reasoning, we use a Wh-question to construct the scaffolding question. For the relation reasoning, we use the template "Decide whether ..." to construct the scaffolding question. We construct a sequence of scaffolding question prompts $\mathcal{P} = [p_1, p_2, \ldots, p_K]$ according to the sequence of facts $\mathcal{F} = [f_1, f_2, \ldots, f_K]$ within the metaphor KG. Details of these scaffolding question prompts for LLMs based on CMT, MIP and SPV, respectively, are illustrated in Appendix B.

4.3 Scaffolding Support based on Mastery Level of LLM

Scaffolding instruction also emphasizes the importance of providing support to learners when they engage in tasks beyond their *mastery levels*, which means what a learner can do independently (Wood et al., 1976; Vygotsky, 1978; Harris and Pressley, 1991). Inspired by this, we devise an approach to automatically detect the mastery level of LLM and provide knowledge as scaffolding support if the question is beyond the current capability of LLM. Figure 2 shows the overall architecture of this approach, which is a pipeline framework, including a mastery level verifier, a metaphor knowledge scaffolding module, and a filtering module. Appendix B gives the pseudocode of scaffolding support based on mastery level of LLM.

Mastery Level Verifier When humans are confused or lack confidence in answering a question, they tend to provide inconsistent responses when they are asked the same question multiple times (Schaeffer and Presser, 2003), as they may simply guess. Inspired by this observation, we propose the mastery level verifier by examining the consistency of the answers that the LLM provides to estimate the LLM's mastery level. For the i-th fact, given the scaffolding question prompt p_i, the set of inputs $\mathcal{X}_i = \{x_{(i,1)}, x_{(i,2)}, \ldots, x_{(i,N_i)}\}$ for this question, and an LLM denoted as $\mathcal{M}$, our framework generates the answer a_i formulated as

$$a_i = \mathcal{M}(p_i \| \mathcal{X}_i), \tag{1}$$

where N_i is the number of inputs, and we perform Eq. (1) for N_o times with temperature t_p, yielding a set of answers $\mathcal{A}_i = \{a_{(i,1)}, a_{(i,2)}, \ldots, a_{(i,N_o)}\}$. $r_c \in (0.5, 1]$ is the consistency ratio and $n_{min} = \lfloor N_o \times r_c + 0.5 \rfloor$ is the minimum number of consistent answers, where $\lfloor \cdot \rfloor$ denotes the floor function. The specific designs of our verifier for different reasoning processes are as follows:

- *Forward Reasoning:* We use T5 (Raffel et al., 2020) to calculate a semantic textual similarity score between every answer pair in $\mathcal{A}_i$, and obtain the similarity matrix $\mathbf{S}^{N_o \times N_o}$. If there exists a submatrix $\mathbf{B} = \mathbf{S}[j_1, j_2, \ldots, j_n; j_1, j_2, \ldots, j_n]$ and $s \geq s_{min}$ for $\forall s \in \mathbf{B}$, where $\{j_1, j_2, \ldots, j_n\}$ represents the indices of the n selected answers, $n \geq n_{min}$, and s_{min} is the semantic similarity threshold, we obtain the set of consistent answers $\mathcal{A}_i^c = \{a_{(i,j_1)}, a_{(i,j_2)}, \ldots, a_{(i,j_n)}\}$.
- *Relation Reasoning:* We first project the answers into "Yes", "No", or "Uncertain" with rules. If there exists a subset of answers $\mathcal{A}_i^c = \{a_{(i,j_1)}, a_{(i,j_2)}, \ldots, a_{(i,j_n)}\}$ and all elements in $\mathcal{A}_i^c$ can be projected into the same answer ("Yes" or "No"), where $\{j_1, j_2, \ldots, j_n\}$ represents the indices of the n selected answers, and $n \geq n_{min}$, we regard $\mathcal{A}_i^c$ as the set of consistent answers.

If there exist consistent answers $\mathcal{A}_i^c$, we regard the question falls within the mastery level of LLM; otherwise, the question is beyond the LLM's ability.

Metaphor Knowledge Scaffolding If the scaffolding question p_i surpasses the mastery level of the LLM, this module provides a scaffolding knowledge prompt b_i from the metaphor knowledge base (KB) to help the LLM answer this question. The detail of metaphor KB is shown in Appendix B. Given the scaffolding question prompt p_i, inputs $\mathcal{X}_i = \{x_{(i,1)}, x_{(i,2)}, \ldots, x_{(i,N_i)}\}$ for this question, scaffolding knowledge prompt b_i, and the LLM $\mathcal{M}$, the metaphor knowledge scaffolding module generates the answer a_i^s, which is formulated as

$$a_i^s = \mathcal{M}(p_i \| \mathcal{X}_i \| b_i). \tag{2}$$

We perform Eq. (2) for N_k times with temperature t_p resulting in a set of outputs $\mathcal{A}_i^s = \{a_{(i,1)}^s, a_{(i,2)}^s, \ldots, a_{(i,N_k)}^s\}$.

Filtering We randomly select one answer from the remaining answers of $\mathcal{A}_i^s$ after denoising or $\mathcal{A}_i^c$ as the final answer a_i^o.

4.4 Classification

Based on all the final reasoning answers of the LLM, we can construct an instantiated knowledge graph $\hat{\mathcal{G}}$ for the original input sentence and a word within the sentence. If the structure of $\hat{\mathcal{G}}$ is identical to that of $\mathcal{G}$, we label this instance as metaphorical; otherwise, we label it as literal.

5 Experiments

5.1 Datasets

We conducted experiments on two publicly available metaphor datasets: (1) **MOH-X** (Mohammad et al., 2016) comprises 647 sentences, where only a single verb is annotated as metaphorical or literal in each sentence; (2) **TroFi** (Birke and Sarkar, 2006) is another metaphor detection dataset, collected from 1987-1989 Wall Street Journal Corpus.

Dataset	#Instance	%Met.	Avg. L	#Samp
MOH-X	647	48.7	8.0	300
TroFi	3737	43.5	28.3	300

Table 1: Statistics of datasets. **#Instance** represents the number of all the instances. **%Met.** represents the percentage of metaphorical instances. **Avg. L** denotes the average length of instances. **#Samp** denotes the number of randomly sampled instances utilized for evaluation.

We sampled 300 balanced instances from MOH-X and 300 balanced instances from TroFi for testing. Table 1 shows the statistics of datasets.

5.2 Baseline Methods

We use representative methods for LLM-based complex reasoning as baselines, including the standard zero-shot method, automatic chain-of-thought methods, and chain-of-thought enhancement methods, which are as follows: (1) **Standard zero-shot** (Wei et al., 2021) prompts the LLM to provide answers directly in a zero-shot manner; (2) **Zero-shot CoT** (Kojima et al., 2022) concatenates the question prompt with a simple trigger sentence (i.e. "*Let's think step by step*") encouraging LLM to generate the reasoning process in a zero-shot manner; (3) **Plan-and-solve** (Wang et al., 2023a) designs a prompt aimed at guiding LLM to solve the problem by breaking the task into smaller subtasks, and then implementing the devised plan; (4) **Self-refine** (Madaan et al., 2023) improves initial outputs from LLM through iterative feedback and refinement; (5) **Self-consistency** (Wang et al., 2023c) selects the most consistent answer through majority voting among sampled reasoning chains; (6) **Least-to-most** (Zhou et al., 2023) initially decomposes the question into sub-questions in a top-down manner and then addresses each sub-question.

We also use the SOTA methods for metaphor detection as strong baselines, which are as follows: (1) **MelBERT** (Choi et al., 2021) leverages contextualized information inspired by MIP and SPV for metaphor detection; (2) **MisNet** (Zhang and Liu, 2022) which incorporates MIP and SPV into their linguistics enhanced network; (3) **AdMul** (Zhang and Liu, 2023) is the SOTA method for metaphor detection, which employs a multi-task learning framework to transfer knowledge from basic sense discrimination to metaphor detection via adversarial training. We use these methods trained on a large metaphor dataset VUA All (Leong et al., 2018) to perform zero-shot transfer on our datasets.

5.3 Implementation Details

We employ the accuracy and macro-average F1 for evaluation and report the mean and standard deviation of 3 runs in our experiments. The OpenAI GPT-3.5 (gpt-3.5-turbo-0613)[1] serves as the LLM in our experiments. The details of rules to filter answers in our method are shown in Appendix B. The prompt design for the baselines and other implementation details are shown in Appendix C.[2]

5.4 Main Results

Comparison with Baselines Table 2 shows the comparative results between our methods and baselines. Our methods guided by MIP and CMT achieve significant improvements over all the representative LLM-based methods in complex reasoning, which verifies the effectiveness of our scaffolding instruction framework for LLM-enabled metaphor reasoning. Least-to-most, tackling problems through sub-questions, outperforms other baselines on MOH-X. Zero-shot CoT, encouraging LLM to think step by step, achieves better results than other baselines on TroFi. Both of these methods guide LLM to tackle problems step by step, indicating the necessity of deep and sequential thinking in metaphor reasoning.

Compared with SOTA methods in metaphor detection, our method guided by CMT outperforms them across all datasets, and our method guided by MIP also achieves better performances on TroFi. These results further verify the effectiveness of our method. Although MelBERT and MisNet design their networks under the guidance of metaphor theories and fine-tune pre-trained models for metaphor detection, they rely on capturing surface-level clues in these theories and fail to capture the underlying metaphor reasoning process reflected in these theories. This limitation results in our method guided by MIP and CMT achieving significant improvements over MelBERT and MisNet.

Comparison between Metaphor Theories The experimental results in Table 2 indicate that our method guided by SPV performs worse compared to our methods guided by MIP and CMT. One possible reason is that as some metaphorical usages become prevalent over time, SPV, relying on data fre-

Table 3: Experimental results of ablation study.

quency rather than semantic essence, tend to lead our method to wrong results on such metaphorical usages. In addition, our method using MIP performs better than our SPV guided method. This improvement seems to benefit from the fact that understanding contextual meaning is a strength of LLM, which is an important step in our method guided by MIP. In contrast to SPV and MIP, which analyze metaphor at the linguistic level, CMT mainly leverages source and target domains to explain implicit comparisons in metaphors reflected in human cognition, which seems to contribute to the superior performances of our method guided by CMT across all datasets. These results also indicate the potential of the comprehensive perspectives in metaphor theories, especially CMT, for enhancing computational work on metaphor.

5.5 Ablation Study

We conduct the ablation study to evaluate the impact of components in our methods, using the following variants: (a) **w/o Metaphor Knowledge Scaffolding** removes the *metaphor knowledge scaffolding* module in our method from our methods; (b) **w/o Mastery Level Verifier** ablates *mastery level verifier* and its subsequent *metaphor knowledge scaffolding* module; (c) **w/o Metaphor Knowledge Graph** removes the metaphor KG and presents LLM with a single question prompt. This prompt comprises a description of key ideas in the metaphor theory and a direct query about whether the word in the sentence is metaphorical, templates of which are shown in Appendix C.

Table 3 shows the results of our ablation study.

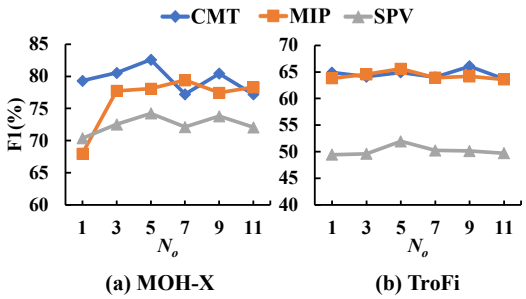

Figure 3: Results of our methods with different numbers of answers generated by LLM on MOH-X and TroFi.

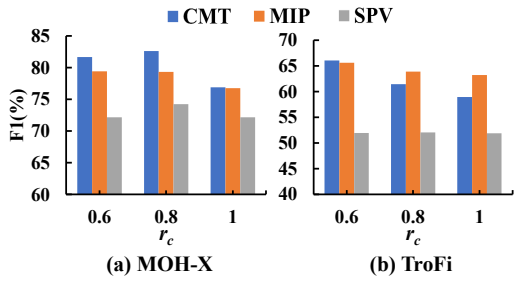

Figure 4: Results of our methods with different consistency ratios on MOH-X and TroFi.

Removing the metaphor knowledge scaffolding module reduces the performance, thus verifying the effectiveness of the knowledge base we provide in our method. Furthermore, we remove the mastery level verifier from our methods, resulting in significant performance declines across all the datasets and theories. These variants demonstrate the effectiveness of the approach to provide scaffolding support based on detecting the mastery level of LLM in our method. In addition, to evaluate the effectiveness of the metaphor KG representation, we directly ablate it and present LLM with the theory description and a query to ask whether the word in the sentence is metaphorical. This variant uses the in-context learning ability of LLM to learn metaphor theory, which leads to sharp drops in performance across all the datasets, indicating that LLM can learn a metaphor theory better through the representation of metaphor knowledge graphs rather than theory descriptions.

5.6 Hyper-parameter Analysis

Number of Answers To explore the impact of the number of answers generated by LLM (denoted as N_o) in our methods, we experiment on varying N_o from 1 to 11. The experimental results in Figure 3 show that increasing N_o initially enhances the performance, followed by a plateau or marginal decline of the performance.

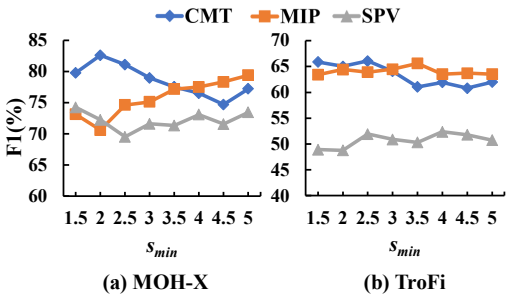

Figure 5: Results of our methods with different semantic similarity thresholds on MOH-X and TroFi.

Consistency Ratio To analyze the impact of the consistency ratio r_c in our mastery level verifier, we conduct experiments varying r_c from 0.6 to 1. The experimental results in Figure 4 indicate that a high consistency ratio could bring performance drops for the reason that an appropriate ratio allows LLM to make a slight number of incorrect answers.

Semantic Similarity Threshold To evaluate the influence of semantic similarity threshold s_{min} in our mastery level verifier, we conduct experiments on varying the threshold from 1.5 to 5.0, where a higher score indicates greater semantic similarity. From the experimental results in Figure 5, we can see that our method guided by CMT achieves the optimal performance at lower thresholds, while our method guided by MIP excels with larger thresholds. This phenomenon might be attributed to the variance in the quality of knowledge presented in the metaphor knowledge scaffolding module. The knowledge derived from MIP seems to be more comprehensible for LLM in comparison to the knowledge derived from CMT.

6 Conclusion

In this paper, we propose a theory guided scaffolding instruction framework for LLM-enabled metaphor reasoning. Inspired by a pedagogical strategy *scaffolding instruction*, our framework instructs an LLM to infer the metaphor reasoning process using questioning and support as scaffolding guided by a metaphor theory. Experimental results show that our framework outperforms the previous LLM-based complex reasoning methods and the SOTA methods for metaphor detection, verifying the effectiveness of our proposed framework and indicating the facilitation of metaphor and instruction theories in LLM-enabled reasoning.

Limitations

Our work has some limitations. Firstly, we are unable to evaluate our framework on large-scale test sets due to the costs of experimentation with LLMs, thus we obtain balanced randomly sampled test datasets for the evaluation of this work. In addition, we simplify metaphor theories by focusing on fundamental concepts, their relations and corresponding knowledge in our method. However, the metaphor theories that we use, especially CMT, contain rich contexts, which are worth further exploration in LLM-enabled metaphor reasoning. Compared to the current pretrained model based work on metaphor detection, our work can be viewed as opening a new path to the theory-directed, instruction-oriented LLM-based metaphor understanding and reasoning. To this end, we hope our work can promote future research on further enriching knowledge representation based on the comprehensive perspectives in metaphor theories, forming a more in-depth understanding of metaphors and incorporating it into the LLM-enabled reasoning process through novel methodologies, by peer researchers and ourselves.

B Method Details

Metaphor Knowledge Graph Construction To facilitate theory guidance and computational construct for LLM-based metaphor reasoning, we make the compromise and simplify the metaphor theory, retaining the fundamental concepts and their relations in our metaphor knowledge graph representations. Specifically, Figure 6 illustrates the details of metaphor knowledge graphs constructed based on the computational elements and relations, as well as the simplified theories, including CMT, MIP, and SPV in our methods.

Prompt Design for Scaffolding Questions Table 4 summarizes a list of template prompts for scaffolding questions $\mathcal{P}$ in our methods using different metaphor theories.

Scaffolding Support based on Mastery Level of LLM Table 5 shows the rules in our methods to project the answers of LLM for the relation reasoning process into "Yes", "No", or "Uncertain" in scaffolding support based on the mastery level module. If there are any candidate phrases in Table 5 that appear in the answer after converting all the uppercase characters in the answer string into lowercase characters, we project this answer into the corresponding category. If none of these candidate phrases appear in the answer, we check the answer manually. Table 6 shows details about the template prompts of the metaphor knowledge base in the metaphor knowledge scaffolding module in our methods using different metaphor theories. Algorithm 1 is the pseudocode of scaffolding support based on mastery level of LLM.

Filtering We first convert all the uppercase characters in the answer string into lowercase characters and then filter out the uncertain answers generated from the metaphor knowledge scaffolding module that contains any of the following phrases: "it is not possible to determine", "cannot be determined", "is uncertain" and "difficult to provide a definitive answer".

C Implementation Details

Table 7 shows the hyperparameter values of our methods in our experiments on different datasets. We use T5-3B[1] to calculate the semantic textual similarity score between the answer pair. The number of sampled reasoning paths for the baseline Self-consistency is 40. Table 8 summarizes a list of prompts for baselines in our experiments. Table 9 illustrates the template prompts for the variant of *w/o Metaphor Knowledge Graph* in the ablation study. If there is no knowledge prompt for a question, we just use the majority voter to replace scaffolding support based on mastery level of LLM module and get the final answer for this question. The system prompt that we use for GPT-3.5 in the experiments of our methods and baselines is as follows.

[1] https://huggingface.co/t5-3b

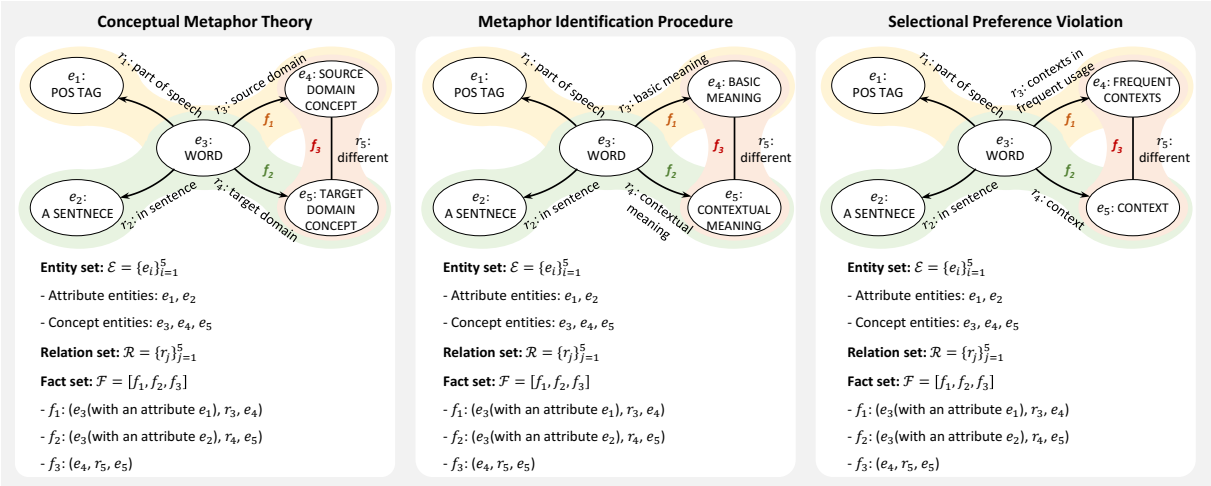

Figure 6: Metaphor knowledge graphs guided by CMT, MIP and SPV.

Theory	Question	Template Prompt
CMT	**Question** p_1	The source domain is a conceptual domain containing concepts that are typically concrete, tangible, and familiar to us. What is the source domain implied by the [POS] "[word]"?
	Question p_2	The target domain is a conceptual domain that contains concepts that are typically vague and abstract. In the sentence "[sentence]", what is the target domain that the word "[word]" tries to describe?
	Question p_3	Here is a sentence "[sentence]". Now we know the source domain implied by the [POS] "[word]" and the target domain that the word "[word]" tries to describe in this sentence. [answer 1] [answer 2] Based on the above information, decide whether the source domain is different from the target domain?
MIP	**Question** p_1	What is the basic meaning of the [POS] "[word]"?
	Question p_2	In the sentence "[sentence]", what is the contextual meaning of the word "[word]"?
	Question p_3	Here is a sentence "[sentence]". Now we know the basic meaning of the [POS] "[word]" and the contextual meaning of the word "[word]". [answer 1] [answer 2] Based on above information, decide whether the contextual meaning of the word "[word]" is different from its basic meaning.
SPV	**Question** p_1	Please provide examples of the frequent usage of the [POS] "[word]".
	Question p_2	Now we know examples of the frequent usage of the [POS] "[word]". [answer 1] In the sentence "[sentence]", decide whether the context of the word "[word]" is different from its contexts in the above sentences.

Table 4: Template prompts for scaffolding questions $\mathcal{P}$. *[sentence]* and *[word]* denote the input slots for the sentence in an instance and the target word within this sentence, respectively. *[POS]* denotes the input slot of the part of speech of the target word. *[answer i]* denotes the input slot for the LLM's final answer to question p_i.

Algorithm 1 Scaffolding Support based on Mastery Level of LLM

Require: (1) $\mathcal{M}$: an LLM; (2) $\mathrm{Combs}(\mathcal{L}, k)$: obtains combinations of all elements within a set $\mathcal{L}$ taken k elements at a time.

Input: (1) $\mathcal{A}_i$: set of N_o answers of $\mathcal{M}$ for the i-th scaffolding question prompt p_i; (2) r_c: consistency ratio; (3) s_{min}: semantic similarity threshold; (4) b_i: the scaffolding knowledge prompt for p_i; (5) $\mathcal{X}_i$: inputs for p_i.

Output: a_i^o: final answer for the i-th scaffolding question p_i.

Compute $n_{min} = \lfloor N_o \times r_c + 0.5 \rfloor$ ▷ ***Mastery Level Verifier***
if p_i is for forward reasoning **then**
    Compute $\mathbf{S}^{N_o \times N_o}$ with semantic textual similarity scores between every pair of answers in $\mathcal{A}_i$
    for all $j \leftarrow N_o$ **to** n_{min} **do**
        for all $I_j \in Combs([1, \ldots, N_o], j)$ **do**
            if $\forall s \in \mathbf{S}[I_j, I_j], s \geq s_{min}$ **then**
                $\mathcal{A}_i^c = \mathcal{A}_i[I_j]$, break
        if $\mathcal{A}_i^c$ exists **then** break
else
    Obtain $\mathcal{A}_i^p$ by project answers in $\mathcal{A}_i$ to "Yes", "No" or "Uncertain" with rules

Theory	Knowledge	Template Prompt
CMT	**Knowledge** b_1	1. The source domain is the concept area from which the metaphor is drawn. 2. The concepts in source domain are typically concrete. 3. The source domain is the domain of experience or concepts that are more concrete, tangible, and familiar to us. It serves as the basis for understanding or talking about a less concrete or abstract concept, which is referred to as the target domain. The source domain provides the metaphorical elements or framework through which we comprehend the target domain. 4. The source domain is a conceptual domain. Conceptual domains are sets of value meanings (presented using a list of concepts or a description of the members of the set) and are used to describe the set of concepts that can be represented within a data element. 5. For example, in the metaphor "I've invested a lot of time in her," the source domain is "money" and we draw upon our understanding of money to make sense of the concept of time in terms of value, efficiency, and spending. Taking the knowledge provided above into account, please answer the following question:
	Knowledge b_2	1. Target domain is used for the concept area to which the metaphor is applied. 2. The concepts in the target domain are typically vague and abstract. 3. The target domain is a conceptual domain. Conceptual domains are sets of value meanings (presented using a list of concepts or a description of the members of the set) and are used to describe the set of concepts that can be represented within a data element. 4. For example, in the metaphor "I've invested a lot of time in her," the target domain is "time", which is being conceptualized in terms of the source domain of money. Taking the knowledge provided above into account, please answer the following question:
MIP	**Knowledge** b_1	The basic meaning can be found in general users' dictionaries. The basic meaning is not necessarily the most frequent meaning of the lexical unit. The basic meaning tends to be - More concrete; what they evoke is easier to imagine, see, hear, feel, smell, and taste. - Related to bodily action. - More precise (as opposed to vague) - Historically older. Taking the knowledge provided above into account, please answer the following question:
	Knowledge b_2	The contextual meaning means the meaning of the lexical unit in context, that is, how the lexical unit applies to an entity, relation, or attribute in the situation evoked by the text. Take into account what comes before and after the lexical unit. The contextual meaning may be conventionalized and will thus be found in a general users' dictionary. It may also be novel or specialized and will thus not be found in a general users' dictionary. Taking the knowledge provided above into account, please answer the following question:
	Knowledge b_3	If the basic meaning of a word contrasts with its contextual meaning, there is a difference as well as comparison between the contextual and a more basic meaning. Taking the knowledge provided above into account, please answer the following question:
SPV	**Knowledge** b_1	The phrase "frequent usage of a word" refers to the regular and common application of a word.
	Knowledge b_2	In the theory of selectional preference violation, Wilks suggests that metaphor represents a violation of combinatory norms in the linguistic context and that metaphorical expressions can be detected via such violation. Taking the knowledge provided above into account, please answer the following question:

Table 6: Prompt design for scaffolding knowledge based on metaphor theories in our methods.

Method	Template Prompt
Standard zero-shot	Decide whether the word "[word]" in the sentence "[sentence]" is used metaphorically.
Zero-shot CoT	Decide whether the word "[word]" in the sentence "[sentence]" is used metaphorically. Let's think step by step.
Plan-and-Solve	Decide whether the word "[word]" in the sentence "[sentence]" is used metaphorically. Let's first understand the problem and devise a plan to solve the problem. Then, let's carry out the plan and solve the problem step by step.
Self-refine	*Prompt for Initial Generation:* Decide whether the word "[word]" in the sentence "[sentence]" is used metaphorically. *Prompt for Feedback:* Can you give suggestions to improve the above answer? If the answer is perfect, just return "NONE". *Prompt for Refine:* Okay, let's use this feedback to improve the above answer.
Self-consistency	Decide whether the word "[word]" in the sentence "[sentence]" is used metaphorically.
Least-to-most	*Prompt for Stage 1: Decompose Question into subquestions* Q: Is the word "[word]" in the sentence "[sentence]" used metaphorically? A: Let's break down this problem into subquestions: *Prompt for Stage 2: Sequentially Solve Subquestions* Q: Is the word "[word]" in the sentence "[sentence]" used metaphorically? A: Let's break down this problem into subquestions: [answer] Q: Please answer the above subquestions and give the final answer for the initial question "Is the word '[word]' in the sentence '[sentence]' used metaphorically?"

Table 8: Prompt design for LLM-based baselines. *[sentence]* denotes the input slot for the sentence in an instance from the test dataset and *[word]* denotes the input slot for the target word within this sentence. *[answer]* denotes the input slot for the answer of LLM to the previous question.

Theory	Template Prompt
CMT	According to conceptual metaphor theory, metaphor facilitates a mapping of attributes or characteristics from the source domain to the target domain. The source domain is a conceptual domain containing concepts that are typically concrete, tangible, and familiar to us. The target domain is a conceptual domain containing concepts that are typically vague and abstract. Based on the above information, answer the following question: In the sentence, "[sentence]", decide whether the word "[word]" is used metaphorically.
MIP	According to metaphor identification procedure, a metaphor is identified if the contextual meaning of the target word is different from its more basic meaning. Based on the above information, answer the following question: In the sentence, "[sentence]", decide whether the word "[word]" is used metaphorically.
SPV	According to selectional preference violation, a metaphor is identified by noticing the difference between the context of a target word and its frequently used contexts. Based on the above information, answer the following question: In the sentence, "[sentence]", decide whether the word "[word]" is used metaphorically.

Table 9: Prompt design for the variant of *w/o Metaphor Knowledge Graph*. *[sentence]* and *[word]* denote the input slots for the sentence in an instance and the target word within this sentence, respectively.

Learning to Compress Prompt in Natural Language Formats

Abstract

Large language models (LLMs) are excel at processing multiple natural language processing tasks, but their abilities are constrained by inferior performance with long context, slow inference speed, and the high cost of computing the results. Deploying LLMs with precise and informative context helps users process large-scale datasets more effectively and cost-efficiently. Existing works rely on compressing long prompt contexts into soft prompts. However, soft prompt compression encounters limitations in transferability across different LLMs, especially API-based LLMs. To this end, this work aims to compress lengthy prompts in the form of natural language with LLM transferability. This poses two challenges: (i) Natural Language (NL) prompts are incompatible with back-propagation, and (ii) NL prompts lack flexibility in imposing length constraints. In this work, we propose a Natural Language Prompt Encapsulation (Nano-Capsulator) framework compressing original prompts into NL formatted *Capsule Prompt* while maintaining the prompt utility and transferability. Specifically, to tackle the first challenge, the Nano-Capsulator is optimized by a reward function that interacts with the proposed semantics preserving loss. To address the second question, Nano-Capsulator is optimized by a reward function featuring length constraints. Experimental results demonstrate that the *Capsule Prompt* can reduce **81.4%** of the original length, decrease inference latency up to **4.5**×, and save **80.1%** of budget overheads while providing transferability across diverse LLMs and different datasets.

1 Introduction

Large Language Models (LLMs) have demonstrated substantial proficiency across a variety of natural language processing tasks. Despite their significant potential and broad adoption, LLMs are fundamentally limited by the long context length input, which impairs their capability to understand lengthy documents and affects their efficiency during inference (Touvron et al., 2023; Brown et al., 2020; Yang et al., 2023; Jin et al., 2024). As the demand for processing millions of tokens increases, it is progressively crucial to deploy LLMs that are adept at comprehending extended lengths while minimizing budgetary requirements.

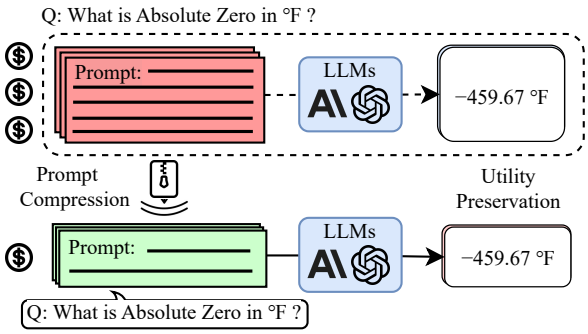

Figure 1: An example of successful prompt compression with NL formats. The compressed NL-formatted prompt (green) aims to obtain a shorter length and maintain transferability and utility of the long prompt (red).

To help LLMs better process long context knowledge, recent advancements have focused on compressing long prompt contexts into concise soft prompts. This approach effectively transforms the original extensive prompt into a manageable series of short-length soft prompt tokens. Generally, compression-oriented soft prompts are learned with the guarantee of semantics through self-information (Chevalier et al., 2023), instruction finetuning (Ge et al., 2023; Ren et al., 2023), and the performance alignment via knowledge distillation (Wingate et al., 2022; Mu et al., 2023). However, with the rapid evolution and the growth of API-based accessibility of LLMs, soft prompts pose significant limitations in terms of transferability across different LLMs, implying that well-trained soft prompts can only be effectively adapted to the specific LLMs for which they were designed.

*Work done as an intern at Samsung Research America.

Proceedings of the 2024 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies (Volume 1: Long Papers), pages 7756–7767
June 16-21, 2024 ©2024 Association for Computational Linguistics

This situation creates a critical need to achieve both transferability and utility effectively. A natural question is raised: ***Can we compress lengthy prompts in a natural language format, yet still preserve utility and ensure transferability among various LLMs?***

Compressing extended prompts into a shorter, natural language (NL) format continues to be a challenging and unresolved issue. As depicted in Figure 1, effective prompt compression entails preserving essential semantic information in a constrained length with successful performance preservation. However, unlike soft prompts, which can be directly optimized with a fixed length, compressing prompts into shorter NL prompts is challenging for several reasons: *(i) NL prompts are incompatible with back-propagation*, as the gradient cannot backward to a discrete raw text; *(ii) NL prompts lack flexibility on imposing strict length constraints*, where overly stringent limitations on generation length may lead to performance degradation. Thus, it is nontrivial to compress lengthy prompts into shorter NL ones.

To tackle the aforementioned problems, we propose a Natural Language Prompt Encapsulation (Nano-Capsulator) framework to effectively compress original prompts into a *Capsule Prompt* with the aid of a rewarding technique. Our proposed Nano-Capsulator aims to encapsulate long prompts into shorter ones under specific generation length constraints, maintaining performance through an explicit semantic preservation objective with reward scores. Specifically, we compress our prompt by employing a semantics-preserving summarization, and then monitor the optimization process using reward scores that reflect the remaining information relevant to the downstream task. Notably, shorter *Capsule Prompts*, characterized by their concise NL formatting, preserve transferability and utility across diverse LLMs. *Capsule Prompt* enables two advantages: the preservation of prompt transferability and utility across different LLMs, and the reduction of inference time and budget overheads. Additionally, Nano-Capsulator can be directly applied to unseen datasets without any further training, provided these new datasets encompass downstream tasks with similar domains.

To assess the effectiveness of Nano-Capsulator, we conduct compression experiments with two different prompt types: few-shot demonstration chain-of-thoughts (CoT) and passage prompts of reading comprehension (i.e., content passages). *Capsule Prompt* exhibits strong transferability across different LLMs and similar but unseen downstream datasets. This enables effective adaptation without retraining the prompt compressor.

Our main contributions are concluded as follows: *First*, we introduce and formalize Nano-Capsulator framework, which can effectively generate high-quality *Capsule Prompt* with prominent transferability across multiple LLMs and unseen datasets with similar downstream tasks. *Second*, we effectively reduce the original prompts to **81.4%** of their initial length and transform them into NL-formatted *Capsule Prompt*, which retains the prompt's transferability and utility across various LLMs. Our compression mechanism significantly decreases up to $\mathbf{4.5}\times$ of the inference latency and saves **80.1%** of the budget overheads for input sequences. *Third*, experimental results demonstrate that *Capsule Prompt* can efficiently perform across diverse LLMs, which is applicable to both few-shot demonstration CoT and input contextual prompts.

2 Related Work

2.1 Soft Prompt Compression

In the realm of prompt compression for LLMs, most of the existing work aims to compress the prompt into soft prompts. Soft prompts are trainable vectors that are optimized in conjunction with a designated LLM, which embeds the original content information of the long hard prompts into low-dimensional vectors.

The first line of work (Wingate et al., 2022) leverages the knowledge distillation object to extract the information from hard prompts to soft prompts. The compressed soft prompts are expected to capture high-level concepts and preserve the fluency from the original hard prompts. The second line of work (Chevalier et al., 2023) employs the summarization capabilities of LLMs to condense lengthy and complex prompts into soft prompts. The process involves dividing the input prompts into multiple segments and sequentially compressing the information from the original prompt into smaller segments of soft prompts, where they assemble from these individual fragments of soft prompts to form the final soft prompts. Another work, Gist Token (Mu et al., 2023), condenses instruction prompts into customized prefix soft prompts by training a virtual soft prompt predictor.

Nevertheless, the transferability of soft prompt-

based compression across diverse LLMs is constrained, necessitating the re-training of soft prompts with each change in the specified LLMs. This means that the soft prompts generated are specifically tailored to work only with that particular LLM, which falls short in maintaining transferability across different LLMs, especially applied on API-based LLMs, such as Claude2 (Anthropic, 2023) and PaLM (Chowdhery et al., 2023).

2.2 Context Distillation for Compression

Besides directly compressing hard prompts into soft prompt vectors, recent advancement (Li et al., 2023; Jiang et al., 2023) involves computing the self-information scores or perplexity of the given input context prompt to shorten the prompt length. This process includes filtering out words with lower scores from the input prompt, resulting in a more concise input during the inference stage. The primary distinction between our work and these recent studies is that they operate prompt compression without considering any information from downstream tasks, resulting in inferior performance while directly applying to downstream tasks or transferring between similar but unseen downstream datasets.

3 Long Prompt Encapsulation

We systematically introduce the Nano-Capsulator framework in this section. Figure 2 illustrates the overall pipeline of Nano-Capsulator. In particular, our pipeline initially compresses text into NL-formatted *Capsule Prompt* and concurrently optimizes their utility using the proposed rewarding method. The design of the NL-formatted compression aims to maintain prompt utility and preserve transferability among different LLMs.

3.1 Prompt Encapsulation

The primary aim of Nano-Capsulator is to preserve the inherent utility of the original pre-compressed text and ensure the compressed prompt closely reaches the designated length constraint. Specifically, the prompt encapsulation mechanism includes two components to effectively generate *Capsule Prompt*: (1) NL-formatted prompt compression and (2) prompt utility preservation. The learning of Nano-Capsulator involves integrating two components and optimizing them concurrently, thereby assuring the compressed prompts are sufficient to preserve their inherent utility.

Algorithm 1 Algorithm of Nano-Capsulator

Input: Original Long Prompt K, Compression Instructions $\mathbf{T}_{\text{Rep}}$ and $\mathbf{T}_{\text{Summ}}$, and pre-trained frozen LLMs $\mathcal{G}^*(\cdot)$, Sampled set of downstream task questions Q.
Output: NL-formatted Capsule Prompts C.

```
Initialize F(· | θ_C) and G*(·) with pre-trained weights
while not convergence do
    Generate C from F(K | T_Rep, T_Summ, θ_C)
    Randomly sample a set of questions Q
    Receive reward scores from R_cap(G*(·), Q, C, K)
    F(· | θ_C) ← minimizing with L_Nano(·)
end while
```

3.1.1 NL-formatted Prompt Compression

We adopt an unsupervised training approach featuring semantic preservation loss, motivating the model to compress contexts while retaining similar semantic content. In this work, we shorten the long prompts by summarizing their context and applying our proposed semantics loss $\mathcal{L}_{\text{Comp}}$ to ensure maximal preservation of semantic meaning. Here, semantics refers to the logical thinking process from the few-shot demonstration CoT and the beneficial content from context passages.

Given the original prompt $K = \{k_1, \cdots k_n\}$ consisted of n tokens to the *Capsule Prompt* $C = \{c_1, \cdots c_m\}$ with m tokens, where $n \gg m$. Our semantics loss aims to ensure the maximal semantics preservation by measuring the similarity between the hidden state embedding of C and K of Nano-Capsulator $\mathcal{F}(\cdot \mid \theta_C)$. To obtain the hidden state embedding of K, we instruct $\mathcal{F}(\cdot \mid \theta_C)$ to replicate the input prompt K, which aids in better preserving and embedding the semantic meanings of K. Specifically, d-dimensional hidden state embedding of K and C can be generated by $\boldsymbol{e}_K \sim P_{\mathcal{F}}(K \mid \theta_C, \mathbf{T}_{\text{Rep}})$ and $\boldsymbol{e}_C \sim P_{\mathcal{F}}(C \mid \theta_C; \mathbf{T}_{\text{Summ}})$, where $\mathbf{T}_{\text{Rep}}$ and $\mathbf{T}_{\text{Summ}}$ denote a replicating instruction and a summarizing instruction, respectively. With the aid of $\mathbf{T}_{\text{Rep}}$, we compel $\mathcal{F}(\cdot \mid \theta_C)$ to replicate K under the model parameter θ_C, ensuring that $\boldsymbol{e}_K \in \mathbb{R}^d$ accurately represents the embedding of K. Following the criterion, $\mathcal{F}(\cdot \mid \theta_C)$ essentially minimizes the semantics loss as follows:

$$\mathcal{L}_{\text{Comp}} = \mathbb{E}_C\big[D_{\text{dist}}(\boldsymbol{e}_K \,||\, \boldsymbol{e}_C)\big] \tag{1}$$

where $D_{\text{dist}}(\cdot \,||\, \cdot)$ can be any suitable distance measurement in metric space. In this work, we leverage mean square error as the distance function to measure the similarity between $\boldsymbol{e}_K$ and $\boldsymbol{e}_C$.

3.1.2 Prompt Utility Preservation

To impose a constraint on the generated length while preserving utility, we establish a reward func-

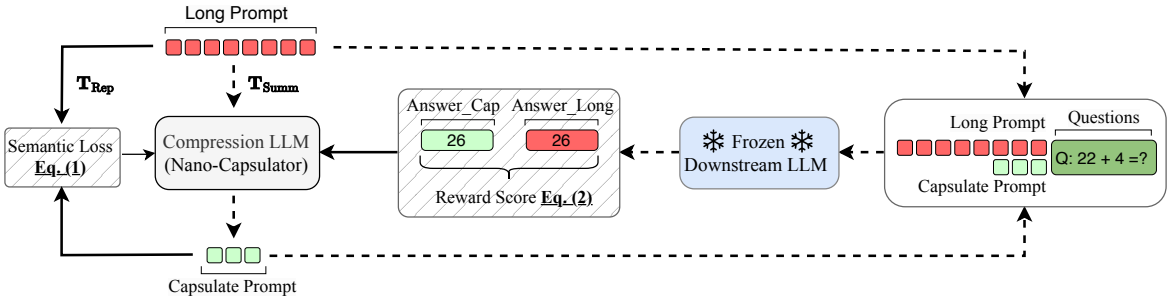

Figure 2: The illustration of Nano-Capsulator training framework. Nano-Capsulator compress the long prompt with the action of semantic (Equation 1) and utility preservation (Equation 2). Questions are sampled from the training set to develop the reward scores for utility preservation.

tion $\mathcal{R}_{\text{cap}}(\cdot)$ featuring a strict cut-off mechanism $\Phi(\cdot)$ for restricting the generated length of *Capsule Prompt*. The high-level idea of the reward function is to calculate the score changes of the downstream task question based on leveraging the original prompt K and the *Capsule Prompt* C. Notably, the reward function employs a truncation strategy to limit the C to a predetermined length before proceeding to compute the scores using the reward function. In this manner, the *Capsule Prompt* that surpasses the specified length threshold could be assigned a lower reward score as a result of the cut-off mechanism.

Formally, given K and C along with arbitrary pre-trained frozen LLMs $\mathcal{G}^*(\cdot)$ and a sampled set of downstream task questions Q, the reward function $\mathcal{R}_{\text{cap}}(\cdot)$ can be defined as follows:

$$\mathcal{R}_{\text{cap}} = \mathbb{E}_Q \big[\mathbf{I}\{ \mathcal{G}\big(\Phi(C_i) \oplus Q_i\big) \,||\, \mathcal{G}\big(K_i \oplus Q_i\big) \} \big] \tag{2}$$

where $\mathbf{I}(\cdot \,||\, \cdot)$ denotes an arbitrary reward metric for yielding the reward score., and $\oplus$ represents concatenation of prompts and questions. In this study, we calculate the reward scores using the mean square error between the hidden state embedding from $\mathcal{G}^*(\cdot)$. It's noteworthy that $\mathbf{I}(\cdot \,||\, \cdot)$ can be replaced by other metrics, such as accuracy and GPT4Eval Scores (Liu et al., 2023), facilitating its potential application to API-based LLMs.

3.1.3 Compression with Reward

Upon receiving the reward scores from $\mathcal{R}_{\text{cap}}$ as per Equation 2, we synchronize these scores with the semantic loss $\mathcal{L}_{\text{Comp}}$ to maintain utility. Formally, the ultimate objective function of Nano-Capsulator can be indicated as:

$$\mathcal{L}_{\text{Nano}} = \mathcal{L}_{\text{Comp}}(\cdot|\theta_C) * \mathcal{R}_{\text{cap}}(\cdot|\theta^*) \tag{3}$$

where θ^* denotes the frozen model parameters of $\mathcal{G}^*(\cdot)$ and θ_C is the trainable parameters of Nano-Capsulator. The fundamental principle of $\mathcal{L}_{\text{Nano}}(\cdot)$ is to impose penalties when shorter versions of *Capsule Prompt* exhibit inferior performance. This implies that if a *Capsule Prompt* receives a low reward score from Equation 2, its semantic loss will be composed by a high penalty value, resulting in a substantial semantic loss value as punishment during the training phase of Nano-Capsulator.

3.2 Algorithm of Nano-Capsulator

The framework of Nano-Capsulator is detailed in Algorithm 1. Nano-Capsulator adheres to Equation 1 for the preservation of semantic meaning and integrates the rewarding function from Equation 2 to maintain the utility of compressed NL-formatted prompts. The two elements are then aligned, as depicted in Equation 3, and optimized simultaneously with the goal of obtaining compressed NL-formatted prompts of high utility. In the inference phase, Nano-Capsulator is solely required to produce the compressed version of *Capsule Prompt* from the provided long input prompt.

4 Experiments

In this section, we conduct experiments to evaluate the performance of Nano-Capsulator, aiming to answer the following three research questions:

- **RQ1:** How does Nano-Capsulator perform in terms of the efficacy and transferability among different LLMs and datasets?
- **RQ2:** How do the two components of Nano-Capsulator contribute to the compression performance for utility preservation?
- **RQ3:** What are the inference latency and impact factors of *Capsule Prompt*?

4.1 Dataset

We conduct compression experiments with two different prompt types: few-shot CoT and passage prompts of reading comprehension. The details of the datasets are provided as follows:

Few-shot CoT Dataset. We choose two reasoning datasets to evaluate the proposed framework.

- **CommonsenseQA (Talmor et al., 2019):** The CommonsenseQA (CSQA) dataset is a publicly accessible collection of multiple choice questions with 1221 samples for the commonsense reasoning task. CSQA presents questions characterized by intricate semantics, typically demanding reasoning grounded in pre-existing knowledge.
- **GSM8K (Cobbe et al., 2021):** The GSM8K is a dataset containing 1319 samples of graduate school math questions. Each question is collected from the Math World Problem Repository (Roy and Roth, 2015) with a numerical answer.

Reading Comprehension Dataset.

- **MultiRC (Khashabi et al., 2018; DeYoung et al.):** MultiRC (Multi-Sentence Reading Comprehension) comprises a collection of brief paragraphs paired with multi-sentence questions, where the answers can be derived from the paragraph's content. The dataset obtains 24029 samples for training, 3214 samples for validating, and 4848 samples for testing.
- **TriviaQA LongBench (Joshi et al., 2017):** TriviaQA LongBench (TriviaQA-Long) is a reading comprehension dataset featuring 300 question-answer-evidence triples collected from the Longbench dataset. It includes question-answer pairs created by trivia enthusiasts, along with independently sourced evidence documents, offering robust supervision for responding to the questions.

4.2 Experiment Settings

In this part, we introduce the experimental settings and metrics for evaluating Nano-Capsulator. Two distinct types of transferability evaluations are taken into account. *To verify the model transferability*, the compression models are trained on one downstream LLM, and tested on different downstream LLMs. The evaluation is performed on the same dataset, with a division of 70% allocated for training and validation and 30% designated as the testing set. *To assess data transferability*, we train the compression models using one seen dataset and then test them on unseen datasets that the models have not previously encountered with the same downstream tasks. The considered compression settings and implementation details are shown as follows. Two types of prompt compression tasks are focused on.

Few-shot CoT Compression Task. For the few-shot CoT compression task, we randomly compile seven examples from the CSQA dataset and eight from the GSM8K dataset following (Wei et al., 2022), all selected from their respective training sets, to construct the few-shot CoT. During the training phase, a total of 1,000 CoT samples are then gathered to serve as the training data for Nano-Capsulator. During the inference stage, we aim to compress the manual few-shot CoT proposed in (Wei et al., 2022), where the demonstrations in manual CoT are eliminated from any training set. The primary evaluation metric used in both CSQA and GSM8K datasets is accuracy, implying that the model scores only when it provides answers that exactly match the expected responses.

Reading Comprehension Compression Task. For the reading compression task, we aim to compress the reading paragraphs from the question-answer triplets. Due to the limitation of GPU memory, we eliminate the paragraphs that exceed 2k tokens in TriviaQA from the LongBench dataset, resulting in an average length of 900 tokens, while MultiRC remains to utilize the all paragraphs in the dataset. Throughout the training phase, we select 2,000 question-answer-paragraph triplets in the MultiRC dataset to serve as training data and leverage all training data in the TriviaQA-Long dataset. Our framework is evaluated on the entire set of testing data, using accuracy as the metric of assessment.

Implementation Details. In primary experiments, we utilize Vicuna-7B (Chiang et al., 2023) as the initial compression model $\mathcal{F}(\cdot \mid \theta_C)$ in Nano-Capsulator. The pre-trained LLMs $\mathcal{G}^*(\cdot)$ is given as Vicuna-7B with frozen weights. We train Nano-Capsulator using Vicuna-7B and then assess the generated *Capsule Prompt* with various LLMs other than Vicuna-7B, in order to evaluate its transferability. To reduce memory consumption during training, we utilize LoRA[1] and train the Nano-Capsulator using two NVIDIA A40 GPUs of 48GB memory. We employ the Adam optimizer for the fine-tuning process, with a learning rate set at 5e-6

under the gradient clipping of 0.8, depending on the datasets. The instructions that leverage for prompt encapsulation $\mathbf{T}_{\text{Rep}}$ and $\mathbf{T}_{\text{Summ}}$ are listed in Table 6 from Appendix F.

4.3 Main Results (RQ1)

Model Transferability. To assess the effectiveness and transferability, we compress the original input prompts into the *Capsule Prompt* by Nano-Capsulator. We then evaluate the transferability and utility of these compressed prompts across three different LLMs not included in the pre-training of Nano-Capsulator: Vicuna-13B (Chiang et al., 2023), PaLM (Chowdhery et al., 2023), and Claude2 (Anthropic, 2023). The main findings are presented in Table 1. In the table, "Manual" refers to the manually created few-shot CoT proposed by (Wei et al., 2022), "Zero-shot" denotes the zero-shot CoT followed (Kojima et al., 2022), and "Original" indicates the original paragraphs used in the reading comprehension tasks.

In the primary experiment, we establish a compression constraint limiting to a maximum of 150 tokens for the CSQA and MultiRC datasets; and a maximum of 350 and 500 tokens for the GSM8K and TriviaQA-Long dataset, where 150 tokens are not sufficient for preserving the logic of GSM8K and TriviaQA-Long dataset. We observe that the Nano-Capsulator obtains up to 81.4% of the compression rate and saves up to 80.1% of the Claude2 API cost compared to the original input prompts, as displayed in Table 2. The cost of PaLM API can be found in Appendix C. For utility preservation, Nano-Capsulator retains the original performance on the CSQA, GSM8k, and TriviaQA-Long datasets mostly among three LLMs. Remarkably, Nano-Capsulator maintains almost identical performance to that achieved with non-compressed prompts in MultiRC datasets. The significant compression rate can advantageously impact the LLMs by allowing for a higher tolerance in batch inference, accompanied by reduced latency and cost.

Dataset Transferability. We previously assessed the effectiveness of Nano-Capsulator within the same datasets, where the testing set was derived from the same training domain. In this section, we investigate the transferability of Nano-Capsulator across unseen datasets (i.e., not in training data) with the same downstream tasks. We train Nano-Capsulator on the MultiRC dataset (seen dataset) and test on BoolQ (Clark et al., 2019) (unseen dataset) without any further training, where BoolQ is also a reading comprehension dataset, under Vicuna-13B and Claude2. The results are demonstrated in Figure 3. We see a competitive performance with only a slight accuracy drop compared to the training version of *Capsule Prompt*. While *Capsule Prompt* yields better performance with training, the results indicate that Nano-Capsulator possesses a great property of data transferability.

4.4 Contributions of Utility Preservation (RQ2)

In this section, we explore the effectiveness of components from Nano-Capsulator. Specifically,

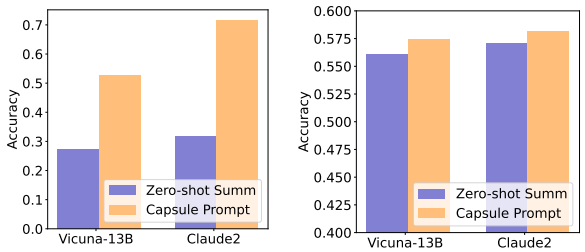

Figure 4: Comparison results of *Capsule Prompt* and Zero-shot Summarization on GSM8K dataset (left) and MultiRC dataset (right).

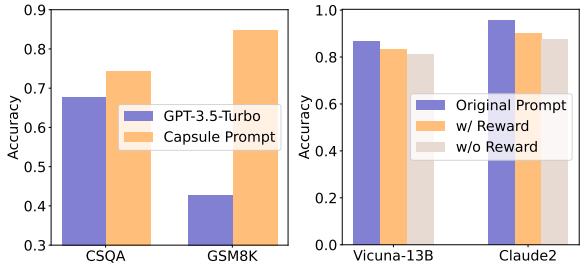

Figure 5: Ablation studies of comparison with *Capsule Prompt* and GPT-35-Turbo Summarization on CSQA dataset and GSM8K dataset (left); and of the contribution of Reward Function from Equation 2 (right).

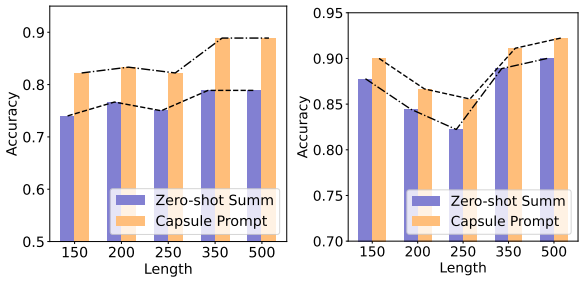

Figure 6: Impact of prompt length on Vicuna-13B (left) and Claude2 (right) on TriviaQA dataset.

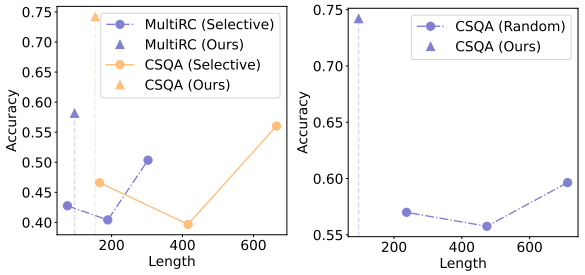

Figure 7: The comparison results of *Capsule Prompt* and text dropping methods, including Selective Context (left) and random demonstration elimination (right).

we conduct ablation studies from two perspectives. *First*, we evaluate the efficacy of semantic preservation. We compare Nano-Capsulator with in-context zero-shot summarization generated by Vicuna-7B, as Vicuna-7B is the initial model weight of Nano-Capsulator for prompt compression. The results are demonstrated in Figure 4 with the comprehensive comparison of three LLMs, including Vicuna-13B and Claude2. We observe that *Capsule Prompt* yielded by Nano-Capsulator outperforms in all scenarios, which means that our Nano-Capsulator can significantly preserve more semantic information and preserve prompt utility. Additionally, we assess the performance by directly employing GPT-3.5-Turbo to summarize the provided prompts. Figure 5 (left) illustrates that Nano-Capsulator maintains a higher level of prompt utility compared to GPT-3.5-Turbo, resulting in enhanced performance on both the CSQA and GSM8K tasks.

Secondly, we carry out ablation studies to establish the effectiveness of the reward function in Nano-Capsulator. These studies are conducted on Vicuna-13B and Claude2 using the TriviaQA-Long dataset. As shown in Figure 5 (right), the results indicate a degradation in performance for downstream tasks when the reward function is not utilized. Note that "w/ reward" means Nano-Capsulator trained with the reward function, while "w/o reward" denotes a Nano-Capsulator trained without the reward function. We further present case studies of *Capsule Prompt* on GSM8K to showcase the logic preservation, as illustrated in Figure 10 from Appendix E. These studies clearly demonstrate that *Capsule Prompt* retains more semantic meanings by preserving complete logical structures, suggesting that the utility of prompts is better maintained.

4.5 Exploration of Impact Factors (RQ3)

In this section, we explore our proposed compression mechanism in greater detail, examining various factors that influence its performance.

Impact of Capsule Prompt Length. In the main experiment, the length constraint is fixed to 150 or 300 tokens for the prompt compression. We further explore how the compression rate affects the preservation of utility. The results are displayed in Figure 6, obtained from experiments conducted using the TriviaQA dataset with Vicuna-13B and Claude2. We observe that the length of *Capsule Prompt* can impact its utility on different LLMs. While longer prompts might capture more useful information for downstream tasks, they can also introduce certain noise or misinformation to the LLMs. This can result in suboptimal performance when specific LLMs interact with the compressed

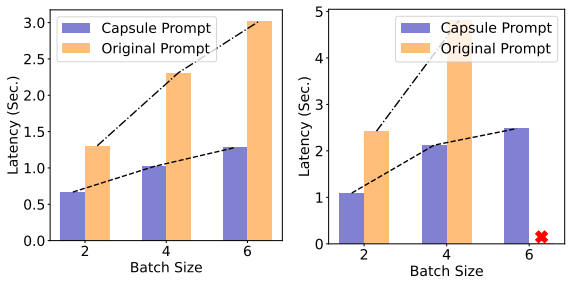

Figure 8: Inference Latency of Vicuna-13B on CSQA dataset (left) and TrivaQA-Long dataset (right), where ✖ indicates out of memory.

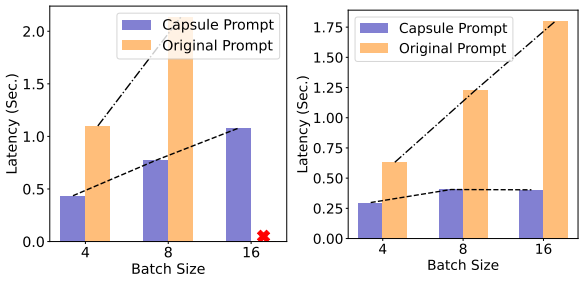

Figure 9: Inference Latency of OPT-2.7B on CSQA dataset (left) and TrivaQA-Long dataset (right), where ✖ indicates out of memory.

prompts. The situation can be observed from the results of *Capsule Prompt* and Zero-shot Summ Prompt, where the length of 150 outperforms other length settings under Claude2 and the length of 200 outperforms other length settings Vicuna-13B. We notice that the desired length settings of Nano-Capsulator can be observed from the performance of the Zero-shot Summ Prompt, as they share similar performance trends.

Impact of Discrete Text Elimination. In addition to compressing prompts using Nano-Capsulator, we acknowledge that prompt length can also be reduced by employing methods like random dropping or rule-based selection. To this end, we have conducted studies comparing the performance of straightforward text dropping with our proposed framework. We consider two baseline methods under Claude2: a naive random demonstration elimination on the CSQA dataset and Selective Context as described in (Li et al., 2023), in which Selective Context eliminated the word according to the self-information values, on both the CSQA and MultiRC datasets. The outcomes of these comparisons are showcased in Figure 7. We observe that *Capsule Prompt* outperforms the other two baselines. Particularly, *Capsule Prompt* achieves better performance when the length is similar to the baselines. This again demonstrates the effectiveness of *Capsule Prompt* in preserving the utility.

4.6 Latency of Nano-Capsulator (RQ3)

The configuration of the computational infrastructure is given in Appendix A. We conducted the efficiency experiments on two publicly available LLMs: OPT-2.7B (Zhang et al., 2022) and Vicuna-13B (Chiang et al., 2023), under different batch size settings with the generated length of 200 tokens. Due to the limited GPU memory, we set Vicuna-13B as bfloat16 to accommodate a single GPU, while OPT-2.7B remains its inherent version. As demonstrated in Figure 8 and Figure 9, we observe that Nano-Capsulator framework achieves much lower computational latency compared to the case while inputting the original prompt on both LLMs. Specifically, *Capsule Prompt* obtains mostly of its original performance while reducing $2.1\times \sim 4.5\times$ of execution latency. As depicted in Figure 9, *Capsule Prompt* is capable of being accommodated within OPT-2.7B under a larger batch size, whereas the use of the original longer prompt leads to an out-of-memory issue (i.e., when batch size = 16). Additionally, we notice that *Capsule Prompt* achieves considerable benefits in speeding up the inference process as the batch size increases. Under OPT-2.7B, *Capsule Prompt* accelerates the process by up to $4.5\times$, and under Vicuna-13B, it achieves a speed increase of $4.1\times$ compared to the original input prompt. This indicates that *Capsule Prompt* allows for a larger batch size while reducing the time required for the inference process.

5 Conclusion

Our work introduces Natural Language Prompt Encapsulation (Nano-Capsulator), a framework for effectively compressing long prompts for LMs while preserving essential information. Nano-Capsulator alleviates the context length limitations of LLMs, enhancing processing efficiency and cost-effectiveness. Our results show that Nano-Capsulator reduces prompt lengths by 81.4%, decreases inference latency by up to $4.5\times$, and cuts budget overheads by 80.1% with almost identical accuracy and relevance. This demonstrates its significant potential for improving LLM efficiency across various applications that utilize long input documents. Future research will focus on refining Nano-Capsulator for broader domain applications and exploring its usage in data-intensive fields.

Appendix

A Computation Infrastructure

For a fair comparison of testing algorithmic throughput, the experiments are conducted based on the following physical computing infrastructure in Table 3.

Device Attribute	Spec
Computing infrastructure	GPU
GPU model	Nvidia-A40
GPU number	1
GPU Memory	46068 MB

Table 3: Computing infrastructure for the experiments.

B Additional Experiments of Comparison to Soft Prompt Baselines

To evaluate our proposed framework against existing soft prompt methods, we conduct experiments with AutoCompressors (Chevalier et al., 2023) on the GSM8K dataset, as shown in Table 4. Our Capsule Prompt is utilized for predictions using the Llama-2-7B model, which is identical to the pre-trained model used by AutoCompressor. As we can see, AutoCompressor does not preserve essential information in the compressed soft prompts, leading to a considerable performance drop in the GSM8K task.

GSM8K	AutoCompressors	Ours
Accuracy	3.79	19.7

Table 4: Computing infrastructure for the experiments.

	PaLM (Chowdhery et al., 2023)		
Cost($)	Original	*Capsule Prompt*	Saved
CSQA	0.156	0.034	-77.9%
GSM8K	0.054	0.019	-63.9%
MultiRC	0.478	0.135	-71.6%
TrivaQA-Long	0.022	0.004	-80.1%

Table 5: API cost comparison of *Capsule Prompt* and original prompt on PaLM, where *Capsule Prompt* save up to 80.1% of the original cost.

C API Cost of PaLM

We here provide the API cost of PaLM during the evaluation of Nano-Capsulator. We can observe that *Capsule Prompt* generated by Nano-Capsulator save up to 80.1% of its original cost on PaLM. The results further underscore the excellent cost-efficiency attributes of *Capsule Prompt*.

D Training Costs of Nano-Capsulator

In this section, we discuss the training time the memory cost of Nano-Capsulator in this section. All datasets are trained using the initial weights of Vicuna-7B. Training time and memory requirements are different with the volume and types of training data. In our work, the training time for the few-shot CoT compression task is approximately 8 hours, and for the reading comprehension compression task, it is about 4 hours. Once the Nano-Capsulator completes the training process, we can directly derive the compressed hard prompts through a single forward pass of Nano-Capsulator.

E The Case Studies of *Capsule Prompt*

We demonstrate the case study of *Capsule Prompt* on the GSM8K and MultiRC dataset. The results, depicted in Figure 10 and Figure 11, show that Nano-Capsulator can better obtain the semantic meanings of math logic from the original CoT prompt. We observe that in the absence of Nano-Capsulator, the Zero-shot Summarization approach struggles to compress long prompts effectively.

F Instruction Usage in Inference LLMs

We provide a list of the instruction utilized in training our Nano-Capsulator framework in Table 6, including $\mathbf{T}_{\text{Rep}}$ replicating instruction and summarizing instruction $\mathbf{T}_{\text{Summ}}$.

Original Prompt

- **Q:** There are 15 trees in the grove. Grove workers will plant trees in the grove today. After they are done, there will be 21 trees. How many trees did the grove workers plant today?
  A: There are 15 trees originally. Then there were 21 trees after some more were planted. So there must have been 21 - 15 = 6. The answer is 6.
- **Q:** If there are 3 cars in the parking lot and 2 more cars arrive, how many cars are in the parking lot?
  A:There are originally 3 cars. 2 more cars arrive. 3 + 2 = 5. The answer is 5.
- **Q:** Leah had 32 chocolates and her sister had 42. If they ate 35, how many pieces do they have left in total?
  A: Originally, Leah had 32 chocolates. Her sister had 42. So in total they had 32 + 42 = 74. After eating 35, they had 74 - 35 = 39. The answer is 39.
- **Q:** Jason had 20 lollipops. He gave Denny some lollipops. Now Jason has 12 lollipops. How many lollipops did Jason give to Denny?
  A: Jason started with 20 lollipops. Then he had 12 after giving some to Denny. So he gave Denny 20 - 12 = 8. The answer is 8.
- **Q:** Shawn has five toys. For Christmas, he got two toys each from his mom and dad. How many toys does he have now?
  A: Shawn started with 5 toys. If he got 2 toys each from his mom and dad, then that is 4 more toys. 5 + 4 = 9. The answer is 9.
- **Q:** There were nine computers in the server room. Five more computers were installed each day, from monday to thursday. How many computers are now in the server room?
  A: There were originally 9 computers. For each of 4 days, 5 more computers were added. So 5 * 4 = 20 computers were added. 9 + 20 is 29. The answer is 29."
- **Q:** Michael had 58 golf balls. On tuesday, he lost 23 golf balls. On wednesday, he lost 2 more. How many golf balls did he have at the end of wednesday?
  A: Michael started with 58 golf balls. After losing 23 on tuesday, he had 58 - 23 = 35. After losing 2 more, he had 35 - 2 = 33 golf balls. The answer is 33.
- **Q:** Olivia has $23. She bought five bagels for $3 each. How much money does she have left?
  A: Olivia had 23 dollars. 5 bagels for 3 dollars each will be 5 x 3 = 15 dollars. So she has 23 - 15 dollars left. 23 - 15 is 8. The answer is 8.

Capsule Prompt

- There were 15 trees in the grove, and grove workers planted 6 more trees, so there are now 21 trees in the grove.
- In the parking lot, there were 3 cars, and 2 more cars arrived, so there are now 5 cars in the parking lot.
- Leah and her sister had 32 and 42 chocolates, respectively, and they ate 35 chocolates, so they have 39 chocolates left in total.
- Jason had 20 lollipops and gave 8 lollipops to Denny, so he now has 12 lollipops.
- Shawn had 5 toys and got 2 toys each from his mom and dad, so he now has 9 toys.
- There were 9 computers in the server room, and 20 more computers were installed, so there are now 29 computers in the server room.
- Michael had 58 golf balls and lost 23 on tuesday and 2 more on wednesday, so he has 33 golf balls left.
- Olivia had $23 and bought 5 bagels for $3 each, so she has $8 left.

Zero-shot Summarization Prompt

- Grove workers planted 6 trees in the grove.
- There are now 5 cars in the parking lot.
- Leah and her sister have 39 pieces of chocolates left in total.
- Jason gave Denny 8 lollipops.Shawn has 9 toys now.
- There are 29 computers in the server room.
- Michael had 33 golf balls at the end of wednesday.
- Olivia has 8 dollars left.

Compression Tasks	$\mathbf{T}_{\text{Rep}}$ (Replicating Instruction)	$\mathbf{T}_{\text{Summ}}$ (Summarizing Instruction)
Few-shot CoT	Repeat the following main input.	Please summarize each question-answer pair in one sentence within less than {word count} words. Make sure not to repeat the input question-answer pair.
Reading Comprehension	Repeat the following main input.	Please summarize the passage within less than {word count} words. Make sure not to repeat the passage.

Table 6: Instructions used in training Nano-Capsulator.

Original Prompt

- The day was just breaking , as I left the tower ; though it was still too dark in the house to be able to see without a light , and I took one of the study candles with me on my ' round . By the time I had finished the ground floor , the daylight was creeping in , wanly , through the barred windows . My search had shown me nothing fresh . Everything appeared to be in order , and I was on the point of extinguishing my candle , when the thought suggested itself to me to have another glance ' round the cellars . I had not , if I remember rightly , been into them since my hasty search on the evening of the attack . For , perhaps , the half of a minute, I hesitated . I would have been very willing to forego the task -- as , indeed , I am inclined to think any man well might -- for of all the great , awe - inspiring rooms in this house , the cellars are the hugest and weirdest . Great , gloomy caverns of places , unlit by any ray of daylight . Yet , I would not shirk the work . I felt that to do so would smack of sheer cowardice . Besides , as I reassured myself , the cellars were really the most unlikely places in which to come across anything dangerous ; considering that they can be entered , only through a heavy oaken door , the key of which , I carry always on my person.

Capsule Prompt

- The narrator left the tower and took a candle with them to search the ground floor. The daylight was creeping in through the barred windows by the time the narrator finished searching the ground floor. The narrator hesitated to search the cellars but decided to do so because they did not want to be seen as cowardly and because the cellars were the most unlikely place to find anything dangerous.

Zero-shot Summarization Prompt

- The narrator left the tower and took a candle with them, searching the ground floor of the house. The daylight was creeping in through the barred windows, but the search showed nothing new. The narrator hesitated before deciding to search the cellars, which were large and eerie, but ultimately decided to face their fear and complete the task.

Figure 11: A case study on MultiRC dataset. The results are the *Capsule Prompt* and in-context summarization prompt generated Vicuna-7B, following the settings in RQ2.

Automatic, Meta and Human Evaluation for Multimodal Summarization with Multimodal Output

Abstract

Multimodal summarization with multimodal output (MSMO) has attracted increasing research interests recently as multimodal summary could provide more comprehensive information compared to text-only summary, effectively improving the user experience and satisfaction. As one of the most fundamental components for the development of MSMO, **evaluation** is an emerging yet underexplored research topic. In this paper, we fill this gap and propose a research framework that studies three research questions of MSMO evaluation: (1) **Automatic Evaluation**: We propose a novel metric mLLM-EVAL, which utilizes multimodal Large Language Model for MSMO EVALuation. (2) **Meta-Evaluation**: We create a meta-evaluation benchmark dataset by collecting human-annotated scores for multimodal summaries. With our benchmark, we conduct meta-evaluation analysis to assess the quality of different evaluation metrics and show the effectiveness of our proposed mLLM-EVAL. (3) **Human Evaluation**: To provide more objective and unbiased human annotations for meta-evaluation, we hypothesize and verify three types of cognitive biases in human evaluation. We also incorporate our findings into the human annotation process in the meta-evaluation benchmark. Overall, our research framework provides an evaluation metric, a meta-evaluation benchmark dataset annotated by humans and an analysis of cognitive biases in human evaluation, which we believe would serve as a valuable and comprehensive resource for the MSMO research community. [1]

1 Introduction

With the exponentially growing amount of multimedia data online, multimodal summarization with multimodal output (MSMO) has garnered more and more attention from researchers. Unlike unimodal output (e.g., text-only summary), MSMO aims at extracting the most salient information from different modalities and generating multimodal summaries, with a text summary and the most relevant images (Zhu et al., 2018, 2020; Jangra et al., 2023; Modani et al., 2016; Zhang et al., 2021, 2022a; Li et al., 2020). Compared to a text-only summary, a multimodal summary is more informative and could provide more comprehensive and user-friendly content to the readers, as well as effectively improve their reading experience and satisfaction (Zhu et al., 2018, 2020; Li et al., 2020), which could thus be suitable for many applications (e.g., multimedia news summarization).

Evaluation metrics for MSMO are essential to objectively measure the quality of the multimodal summary outputs. However, only a few works have focused on the evaluation for multimodal summaries (Zhu et al., 2018, 2020; Modani et al., 2016). Meanwhile, it is also important to establish a meta-evaluation system to assess the quality of the MSMO metrics to promote more exploration of effective and unbiased evaluation metrics. Despite its significance, there is no such benchmark or study in meta-evaluation. Furthermore, meta-evaluation requires human-annotated ratings for the correlation test since human annotations are considered as the gold standard, but the analysis of cognitive biases in the human annotations remains unexplored. To fill these gaps and call for more research in this area, we propose a research framework (as in Fig. 1) and investigate the following research questions:

RQ1. Automatic Evaluation: *How to properly evaluate the quality of a multimodal summary?* The existing evaluation methods proposed by Zhu et al. (2018, 2020) require the human-written references for evaluation (e.g., ROUGE score (Lin, 2004) for text quality, selection precision for image quality, supervised regression for overall quality). However, it is costly to collect human-written mul-

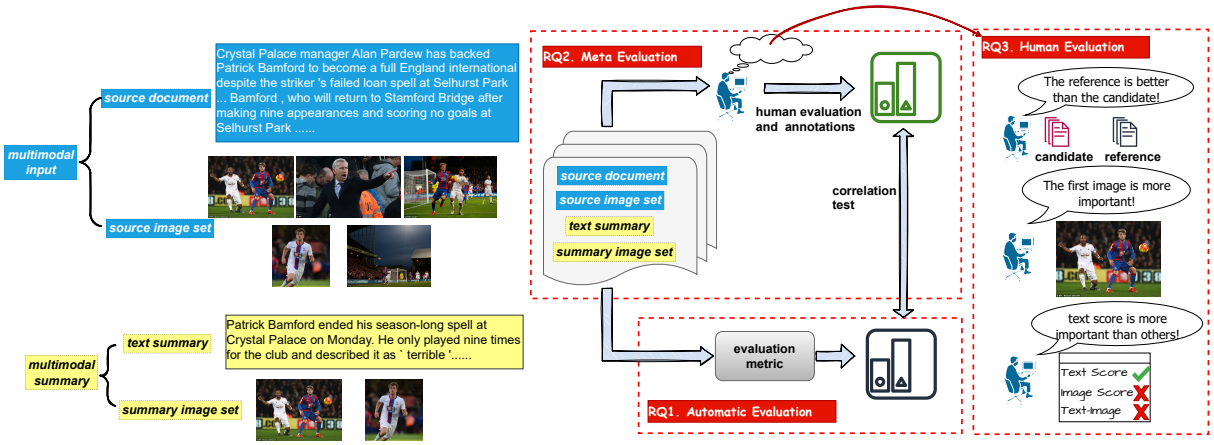

Figure 1: The illustration of our research framework. Left: MSMO extracts the most important information from both text and images and generates a multimodal summary. Right: Three research questions in our research framework: automatic evaluation (RQ1), meta-evaluation (RQ2) and human evaluation (RQ3).

timodal summaries as references for evaluation. Inspired by the success of Large Language Models (LLMs) in reference-free text summary evaluation (Fu et al., 2023; Liu et al., 2023; Chiang and Lee, 2023), as well as the development of multimodal LLMs (e.g., GPT-4 (OpenAI, 2023)), we propose mLLM-EVAL, an MSMO metric utilize the emergent abilities of multimodal LLMs that shows a high correlation with human judgments.

RQ2. Meta-Evaluation: *How to evaluate the evaluation metrics for multimodal summarization?* Furthermore, to evaluate our proposed metric and encourage further exploration of MSMO metrics, we create the first MSMO meta-evaluation benchmark dataset by asking three experts to assess the quality of multimodal summaries. Using our meta-evaluation benchmark, we evaluate and analyze the quality of the existing metrics and mLLM-EAVL by testing how well they correlate with human annotations, where our proposed method outperforms the current evaluation metrics.

RQ3. Human Evaluation: *Is human evaluation truly the gold standard?* In our meta-evaluation (RQ2), we require human evaluation to examine how well the MSMO metrics correlate with human judgments, as human evaluation is widely considered as the gold standard. However, humans could potentially bring biases into the evaluation due to cognitive biases, which would make the comparison unfair and biased. To this end, we hypothesize and verify three types of cognitive biases: anchoring bias; lead bias in image selection; text bias in overall evaluation. We also incorporate our findings to avoid such biases, thus providing more objective and unbiased human annotations for meta-evaluation (RQ2), which makes our meta-evaluation more reliable.

The main contribution of this paper is: **(1)** This is a pioneering work to study automatic evaluation, meta-evaluation and cognitive biases analysis in human evaluation for MSMO. **(2)** We propose mLLM-EVAL using multimodal LLMs for reference-free MSMO evaluation. **(3)** We create the first MSMO meta-evaluation benchmark by collecting human annotations and then conduct meta-evaluation to assess the quality of various MSMO metrics. **(4)** We study the cognitive biases in human evaluation for MSMO. Overall, we aim to establish a valuable research foundation to significantly benefit the multimodal summarization community.

2 Related Work

Multimodal Summarization. Multimodal summarization aims to generate summaries given the inputs of multiple modalities (Evangelopoulos et al., 2013; Li et al., 2017; Mademlis et al., 2016; Koupaee and Wang, 2018; Zhu et al., 2018, 2020). Zhu et al. (2018) proposed the task of multimodal summarization with multimodal output (MSMO) that requires the model to output multimodal summaries and release a large-scale dataset for MSMO. Further improvements include training with multimodal reference guidance in Zhu et al. (2020), knowledge distillation in Zhang et al. (2022a), location-aware approach in Zhang et al. (2021). Due to the issues of reference-based metrics in MSMO (being costly to collect references; different from humans' reference-free evaluation manner), we focus on the reference-free MSMO evalu-

ation metric and investigate the use of multimodal LLMs in this paper.

Meta-evaluation for Summarization. In the works of Fabbri et al. (2021) and Bhandari et al. (2020), the authors re-evaluated different text summarization evaluation metrics by providing human annotations and released the meta-evaluation benchmark for further research. For multimodal summarization, (Wan and Bansal, 2022) collected human annotations on the factuality and released a benchmark to evaluate the quality of multimodal factuality metrics. To date, there is no research work on meta-evaluation for MSMO. We thus create a benchmark dataset and hope it will serve as a valuable resource for future research.

Cognitive Biases in Human Evaluation. Human evaluation is the core component of evaluation research. While human evaluation is generally considered the gold standard in many machine learning tasks, (Schoch et al., 2020) identified the cognitive biases in human evaluation for natural language generation and claimed that the lack of transparency in human evaluation will also impact the reliability of results. (Santhanam et al., 2020) studied the cognitive biases in evaluating conversational systems. However, there are no previous studies on cognitive biases in multimodal summarization evaluation. We thus investigate this topic in this paper to fill this gap.

3 Methodology

3.1 RQ1: Automatic Evaluation

Our proposed metric mLLM-EVAL evaluates the quality of multimodal summaries without the need for references. The evaluation attributes include the (1) quality of the text summary (including relevance, coherence, consistency and fluency); (2) quality of the summary images; (3) relevance of the summary text and images; (4) the overall quality of the multimodal summary. Specifically, we use a multimodal LLM as an evaluator, taking both the texts and images as inputs, and then we design attribute-specific prompts for the multimodal LLM to output the quality scores. Following (Liu et al., 2023), the prompt consists of (1) the descriptions of the evaluation task; (2) the evaluation attribute and criteria; (3) the auto chain-of-thoughts (Zhang et al., 2022b) for evaluation steps; (4) the example for evaluation; (5) scoring form for the final result. Besides the text prompt, we also add the images as the inputs to the multimodal LLM, which would consider the multimodal information. For example, for the overall quality of the multimodal summary, we use the following text prompt:

> You will be given one text summary and some summary images (ID) written for a news article with source images. The summary images is a subset of the source images (e.g., Summary Image ID: 1,3 refer to the first and third source images).
> Your task is to rate the overall quality of the text summary and the summary images.
> Please make sure you read and understand these instructions carefully. Please keep this document open while reviewing, and refer to it as needed.
> *Evaluation Criteria*:
> Quality (1-5) - the overall quality of the text summary and summary images as a whole, including the quality of the text summary, the quality of the summary images (how well the selected summary images represent the content of the source document), the relevance of text summary and summary images (how well the text summary and summary images match).
> *Evaluation Steps*:
> 1. Read the source document, source images, text summary and summary images carefully.
> 2. Assess the overall quality of the text summary and summary images as a whole, given the source document and source images.
> 3. Assign a score for overall quality on a scale of 1 to 5, where 1 is the lowest and 5 is the highest based on the Evaluation Criteria.
> *Example*:
> Source Text: {{Document}}
> Summary: {{Summary}}
> Summary Images: {{Image IDs}}
> Evaluation Form (scores ONLY):
> - Quality:

For the prompts of other attribute evaluation, we refer the readers to Appendix A for more details.

3.2 RQ2: Meta-Evaluation

Human annotations are significantly important and indispensable for meta-evaluation, as we need to compare the correlations of automatic metrics and human judgments to evaluate the effectiveness of the metric. Since there are no human annotations of meta-evaluation for the MSMO task, we construct a **meta-evaluation benchmark dataset** for MSMO with 1,562 human-annotated examples, which is sufficient to evaluate the quality of automatic metrics. The construction of the benchmark consists of the following steps: (1) sampling multimodal inputs (pairs of document and source image set) and then using different summarization models and image selection (generation) algorithms to generate multimodal summaries for each multimodal input; (2) conducting human annotations for the multimodal summaries. With our proposed meta-evaluation benchmark, we conduct meta-evaluation to assess the quality of various metrics.

culture/travel	14
crime/public safety	25
health/lifestyle	19
science/technology	7
celebrities/entertainment	24
others	5

Table 1: The topic distribution of 142 multimodal inputs.

3.2.1 Data Preparation

Multimodal Inputs. We use the dataset collected by Zhu et al. (2018), which is the most commonly used benchmark dataset for the MSMO task. The news articles are collected from the Daily Mail[2]. We randomly sample 150 examples from the test set and discard those without any summary image [3]. As a result, we end up with 142 distinct multimodal inputs for the following generation by different summarization systems. We further provide the dataset statistics on the topics of 142 documents in Table 1, as we expect the dataset could cover a vast spread of domains (e.g., sports, politics).

Multimodal Outputs. Following (Bhandari et al., 2020; Fabbri et al., 2021), we use different summarization systems to generate text summaries given the aforementioned sampled examples. Specifically, we use 9 summarization models to generate summaries, including: (1) BART (Lewis et al., 2020) (2) Distilbart (Shleifer and Rush, 2020) (3) GPT-2 (Radford et al., 2019) (4) PEGASUS (Zhang et al., 2020) (5) ProphetNet (Qi et al., 2020) (6) T5 (Raffel et al., 2020) (7) HAN (Zhu et al., 2018) (8) GPT-4 (OpenAI, 2023) (9) GPT-4 with vision (OpenAI, 2023). We refer the readers to Appendix B for details of these models. Besides, we include two additional summaries to the benchmark: (1) the reference summary; (2) a randomly sampled summary from the dataset.

Among the above models, only the HAN model could output both texts and images. Other models could only generate text-only summaries. To have multimodal outputs, we further design different algorithms to select the images from the source image set. Given a multimodal input, there is a reference summary image set (with N images). We edit this reference set with the following methods: (1) randomly delete an image; (2) randomly add an extra image from the source image set; (3) randomly sample an extra image from the source image set and replace a random image in the reference set; (4) pick the first two images from the source image set as the summary image set; (5) randomly sample N images from the source image set as the summary image set (same size); (6) being same as the reference image set.

Each time when a summarization model (except the HAN model) generates the text summary, a random image selection algorithm would be used to obtain the summary image set. Thus each multimodal input could have 11 different multimodal outputs. Finally, we have 1,562 multimodal summarization examples for further human annotation. Following the aforementioned method, we believe the examples are *diverse* enough to evaluate the metrics since we expect a good metric could assess examples of different quality levels, including *good* examples and *bad* examples. We also list a few good/bad examples of our benchmark in the Appendix C.

3.2.2 Human Annotations

After having 1,562 multimodal summarization examples, we ask three annotators to evaluate the quality of the multimodal summaries. All annotators are English native speakers and/or summarization researchers, and they all have summarization annotation experiences. We use a 1 to 5 rating scale for scoring, while 1 denotes the worst and 5 denotes the best. The annotators evaluate the following aspects:

- **Text Summary-Relevance**: how well the summary captures the most relevant and salient information while omitting the unnecessary or redundant information.
- **Text Summary-Coherence**: how well the summary is organized with sentences logically connected. It measures the flow and logical structure of the text.
- **Text Summary-Consistency**: how factual and faithful the summary is to the source document. A factually consistent summary contains only information that could be entailed (directly or indirectly) by the source document.
- **Text Summary-Fluency**: how fluent each sentence in the summary (e.g., grammar, spelling, word choice, etc).
- **Summary Images**: how well the selected

[2]http://www.dailymail.co.uk/

[3]The summary image set might be empty in the dataset if the annotators in (Zhu et al., 2018) think there are no relevant or suitable images

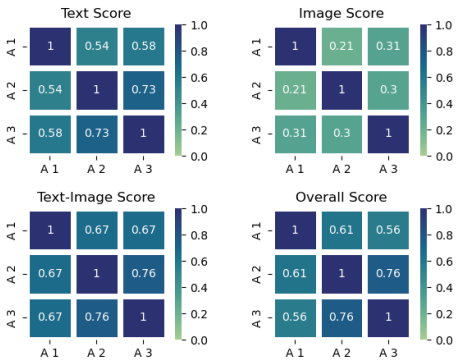

Figure 2: The cohen's kappa coefficient of three annotators (A1, A2, A3).

summary images represent the content of the source document.

- **Text Summary-Summary Images Relevance**: how well the summary text and summary images match each other.
- **Overall Quality**: the overall quality of the generated multimodal summary given the multimodal input.

The text summary evaluation attributes are adopted from Kryscinski et al. (2019) while the remaining ones are from Zhu et al. (2018). Before conducting the human annotation, we set guidelines for the annotators, which include the above evaluation attributes, as well as the instructions to avoid cognitive biases that we study in this paper (details in Section 3.3 and 4.3). To further ensure the annotators have similar annotation criteria, we sampled 5 examples and had a discussion on what scores should be given to each example as well as the reason for the scoring. We believe we use the consistent annotation criteria after the examples discussion.

We report the Cohen's kappa coefficient to indicate the inter-annotator agreement in Fig 2, which shows a moderate agreement among the three annotators. The agreement of image score is relatively low, which we think is reasonable because a source image set could have multiple reference summary image sets. We list two examples for illustration in Appendix D. We also notice the inconsistency issue in the reference text summary, which we discuss in the Appendix E.

3.2.3 Meta-Evaluation Method

As illustrated in Fig. 1, with our constructed benchmark, we can perform meta-evaluation to evaluate the effectiveness of an automatic evaluation metric. Specifically, we conduct the meta-evaluation for text score, image score, text-image score and overall quality score, by calculating the correlation coefficient between the scores obtained by the automatic metrics and the human scores of our benchmark. With a higher correlation, the evaluation metric is more similar to human judgments and thus is more reliable and effective. We show the meta-evaluation results in Section 4.2.

3.3 RQ3: Human Evaluation

Humans could possibly bring cognitive biases into human evaluation, which makes the results also biased and unreliable (Schoch et al., 2020). A cognitive bias refers to the systematic thought process that deviates from rationality in decision or judgment (Tversky and Kahneman, 1974; Schoch et al., 2020; Gehlbach and Barge, 2012). Humans tend to be influenced by their own cognitive biases to make decisions or interpret information, which leads to errors in judgment and decision-making. Thus, we believe it is critical to investigate and study the cognitive biases in human evaluation for multimodal summarization, which is significant for collecting more objective and unbiased human annotations. Specifically, we study three types of cognitive biases in multimodal summarization evaluation:

- **Anchoring Bias**: Humans might have an anchoring bias when evaluating the system outputs if the gold multimodal summaries are also present to the annotators;
- **Lead Bias in Image Selection**: Humans might tend to believe the early parts of the source images are likely to be more important or informative.
- **Text Bias in Overall Evaluation**: Humans are likely to rely more on the text quality (compared to the image quality) to give an overall quality score.

The methodology of our study on cognitive biases of human evaluation is described as follows,

1. hypothesizing a potential cognitive bias when humans are asked to assess the quality of a multimodal summary;
2. asking humans to evaluate under some settings that might elicit this type of bias and verifying whether humans would bring the bias into the evaluation results;
3. proposing a simple and effective method to avoid cognitive bias, which we incorporate into the meta-evaluation benchmark construction (RQ2).

4 Experiment

4.1 RQ1: Automatic Evaluation

We use GPT-4 with vision (*"gpt-4-vision-preview"*) as the multimodal LLM. To evaluate the quality of our proposed metric, we leverage our proposed meta-evaluation benchmark and describe the results in Section 4.2.

4.2 RQ2: Meta-Evaluation

After collecting human annotations for multimodal summaries as described in Section 3.2, we perform meta-evaluation for different automatic metrics, including our proposed method. The meta-evaluation is conducted for 4 different aspects: (1) the text score (i.e., text summary quality); (2) the image score (i.e., summary images quality); (3) the text-image score (i.e., the relevance of the text and images in a multimodal summary) (4) the overall score (i.e., the overall quality of a multimodal summary as a whole) respectively. We conduct three correlation tests: Pearson correlation coefficient r, Spearman's rank correlation coefficient ρ, and Kendall rank correlation τ.

4.2.1 Meta-Evaluation for Text Score

For text score, we evaluate the following baseline metrics: (1) lexical overlap metrics: ROUGE (Lin, 2004) (R1, R2, RL); BLEU (Papineni et al., 2002); (2) pretrained language models: BERTScore (Zhang* et al., 2020); BARTScore (Yuan et al., 2021); MoverScore (Zhao et al., 2019); BLANC (Vasilyev et al., 2020) (3) LLM based metrics: GPTScore (Fu et al., 2023); G-Eval (Liu et al., 2023) (4) MuSQ (Text) (Modani et al., 2016) measures the degree of coverage of input text document by text summary in a reference-free manner. We use ROUGE and BERTScore as the text similarity functions in MuSQ (Text), denoted as MUSQ-R1, MUSQ-R2, MUSQ-R3 and MUSQ-BS respectively. We also repurpose ROUGE, BLEU, BERTScore and BARTScore as reference-free metrics following Bao et al. (2022).

We list the meta-evaluation results in Table 2. The results show that our proposed metric mostly achieves the best correlation with human annotations, while the second best in some aspects. We also observe that ROUGE and BERTScore with reference-free settings have a higher correlation than a reference-based setting, which we believe is because the human scores are also annotated in a reference-free manner.

4.2.2 Meta-Evaluation for Image Score

For the image score, we evaluate the baseline Image Precision (Zhu et al., 2018) (reference-based metric) and MUSQ (Image) (Modani et al., 2016). In addition, we implement some other baseline metrics by formulating image scoring as an *image ranking* problem: (1) CLIPScore-based methods: using CLIPScore (Hessel et al., 2021) to measure the relevance between each image and the document (denoted as "CLIPScore"); (2) Caption-based methods: using the relevance between the caption of each image and the document (denoted as "CAP"). The captions are obtained by either using a pretrained model BLIP (Li et al., 2022) (denoted as "GEN") or extracting the provided captions from the MSMO dataset (Zhu et al., 2018) directly (denoted as "EXT"). We use ROUGE score and BERTScore to measure the relevance between caption and document (denoted as "R1/R2/RL/BS"). After having the relevance score of each image, we construct a pseudo-reference summary image set by two methods: (1) Avg: any image with a relevance score higher than the average is selected (denoted as "Avg"); (2) TopK: ranking the source images by the relevance score and setting the top-K images (denoted as "topK"). Finally, we calculate the precision of the summary image set with the pseudo-reference set as the image score.

The results in Table 3 indicate that our proposed method has the best performance. Surprisingly, mLLM-EVAL (reference-free) has an advantage over the reference-based metric Image Precision. We believe one of the main reasons is that the reference-based metric relies on the human-annotated images, while the same source image set could have multiple reference summary images (as discussed in the Appendix D). We also compare the caption of 'EXT" and "GEN" in Appendix F.

4.2.3 Meta-Evaluation for Text-Image Score

To demonstrate the effectiveness of our metric for the text-image score, we use MMAE (Zhu et al., 2018), MUSQ (Text-Image) (Modani et al., 2016) as our baselines. Furthermore, we utilize CLIPScore (Hessel et al., 2021) to implement four other strong baseline metrics: (1) the average or maximum CLIPScores of each summary image and the whole text summary (denoted as "CLIPScore_Whole_Avg" and "CLIPScore_Whole_Max"); (2) the average or maximum CLIPScores of all the image-sentence pairs (denoted as "CLIPScore_Sumsent_Avg" and "CLIP-

Table 2: The meta-evaluation results of text score, where the score with bold text denotes the best performance.

Score_Sumsent_Max"), as the text summary usually contains multiple sentences. As shown in Table 4, our proposed metric outperforms all the strong baselines.

4.2.4 Meta-Evaluation for Overall Score

For the overall score, we evaluate our proposed metric and MMAE (Zhu et al., 2018), MUSQ (Overall) (Modani et al., 2016). As in Table 5, our overall score correlates with human assessments the best, suggesting its high quality and effectiveness.

4.3 RQ3: Human Evaluation

For RQ3, we study the cognitive biases in human evaluation for MSMO. Specifically, we hypothesize three types of potential cognitive biases and verify them through experiments. We also incorporate our findings to avoid such biases in human annotation when constructing the meta-evaluation benchmark (details in Section 3.2), thus making our meta-evaluation more reliable.

4.3.1 Anchoring Bias

Anchoring bias is a type of cognitive bias where a particular “anchor" influences humans’ decision-making (Tversky and Kahneman, 1974; Gehlbach and Barge, 2012). In human evaluation for multimodal summarization, we hypothesize that humans tend to give lower scores for the candidate summaries that are generated by a multimodal summarization system if they are shown both the candidate summaries and references, where the references, as “anchors", make the annotators tend to flavor the gold summaries more than the system-generated summaries. To elicit the anchoring bias, we ask the annotators to evaluate 100 candidate

Table 5: The meta-evaluation results of overall quality score.

multimodal summaries, where each summary is evaluated twice. In the first stage of evaluation, the summaries are present with the corresponding references, while without the references in the second stage. To eliminate the influences of first-stage evaluation results on the second stage (e.g., humans might remember what scores they give out in the first stage), the annotators conduct the second-stage evaluation 1 week after the first stage. Furthermore, we conduct another experiment same as above but present each summary with a randomly sampled system-generated summary as the "*false reference*" while telling the annotators that it is the true reference. We show the evaluation results in Fig 3. As shown in the results, annotators are more likely to give a lower score for a summary if it is shown along with the references, even with the false references.

To this end, we believe that showing the candidate summary along with the corresponding reference to the annotators would bring anchoring bias to the evaluation results. We thus present the candidate multimodal summary alone to the annotators when we perform the human evaluation to construct the meta-evaluation benchmark.

4.3.2 Lead Bias in Image Selection

In text summarization, the lead bias (Xing et al., 2021; Zhu et al., 2021) is a common phenomenon in news articles. We hypothesize that humans tend to select the first few images as the summary image sets in MSMO evaluation. To verify that, we sample 100 examples and ask the annotators to select the most important source images. The annotators conduct the selection twice for each example,

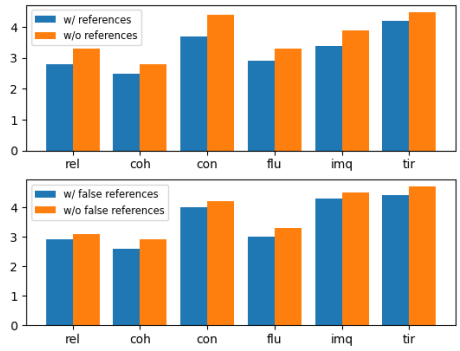

Figure 3: The evaluation results of anchoring bias. The"rel","coh", "con","flu","imq","tir" means "relevance", "coherence", "consistency", "fluency", "image quality", "text image relevance" respecitively.

	1st Image	2nd Image	First N Image
Original Order	82.7%	56.7 %	38.0%
Shuffled Order	76.0%	52.7%	36.7%

Table 6: The experiment results of lead bias in image selection. First/Second is how frequently the annotators would pick the first/second image. First N means that the N images chosen by the annotators are exactly the first N images.

where the source images are present in an original order and random order respectively. The results are shown in Table 6, where we could observe that the annotators prefer to choose the *lead* images from the source image set. Even when presenting with the shuffled order, the lead bias still exists in the image selection process. Therefore, we believe that there is a lead bias phenomenon when humans are selecting the most important and representative images.

For the human ratings collecting in meta-evaluation, we accordingly present the source images and summary images in a shuffled order and explicitly tell the annotators (1) the images are present in a random order (2) focus on the importance and representativeness of the images.

4.3.3 Text Bias in Overall Evaluation

When humans are rating an overall score for a multimodal summary, we hypothesize that the annotators would heavily rely on the text evaluation results. To this end, we sample 100 examples and the annotators are asked to evaluate each example twice. In the first stage, the annotators are shown with only the source documents and the text summaries, while being shown the full example

(including the images) in the second stage. The mean overall score of the first and second stages is 3.38 and 3.35, while the standard deviation is 1.51 and 1.56. In the second stage, the mean image score and text-image score are 2.14 and 2.43. Although the image and text-image scores are much lower than the text score, the mean overall score is still very similar to the first stage. The empirical results indicate that the evaluators tend to rely on the text evaluation results, which is able to verify our hypothesis. For the text bias, we explicitly tell the annotators to focus on the overall quality of the multimodal summaries without any prior preferences, and the annotators have to penalize the overall quality if the image score or text-image score is low, with a few examples for demonstration in the evaluation criteria discussion before we conduct the annotation.

5 Calls for Future Research

We hope this paper will be a valuable resource for future research on multimodal summarization evaluation and models. The study in this work demonstrates the need for future research on (1) better automatic evaluation metrics that could properly and objectively evaluate the quality of multimodal summaries; (2) more meta-evaluation in multimodal summarization to update with the current advanced systems and datasets (3) more study on cognitive biases in human evaluation for multimodal summarization, to have a more fair and accurate comparison of different systems or evaluation metrics. We hope this work could demonstrate the importance of these issues and call for future research (evaluation, meta-evaluation, human evaluation), which would significantly benefit the multimodal summarization research community.

6 Conclusion

In this paper, we propose a research framework, where we investigate the automatic evaluation, meta-evaluation and cognitive bias analysis in human evaluation for multimodal summarization. For automatic evaluation, we propose a reference-free metric based on multimodal LLMs that correlates well with human judgments. Furthermore, we collect human annotations for multimodal summaries and release a meta-evaluation benchmark to evaluate various evaluation metrics. For the human evaluation, we study and verify three types of cognitive biases in human evaluation. We believe our work would be a valuable resource for multimodal summarization research, and hope this work could demonstrate the importance of these topics as well as encourage further research in this area.

Limitations

One limitation of our work is that we only consider the image as the vision modality. VMSMO (Li et al., 2020) introduces the video-text-image summarization. Besides, multimodal summarization could also contain audio or other modalities. We leave these as our future work. In addition, our work only focuses on the English language, which could also be extended to multilingual settings for a more comprehensive evaluation.

Cognitive biases in human evaluation could also include other biases that are not investigated in this paper, such as framing effects (Schoch et al., 2020). We would also like to have more exploration of this research topic in the future.

Ethical Considerations

We use the publicly available dataset MSMO (Zhu et al., 2018) to build our meta-evaluation benchmark dataset. Also, we did not collect any personal information or free-form text, therefore we consider the risk of releasing our data very low. We intend to use the dataset only for research purposes.

In addition, we hire three annotators to label our benchmark dataset and the compensation ($35/h) for the annotators is higher than the local minimum wage.

Acknowledgments

This work is supported by the Early Career Industry Fellowship IE230100119 (Australian Research Council), Discovery Project DP240103070 (Australian Research Council), and Sustainability FAME Strategy Internal Grant (The University of Adelaide). The authors sincerely thank Hu Wang for the insightful discussion, as well as all the anonymous reviewers for their valuable comments and feedback.

A Prompts for Evaluation

A.1 Prompts for the text score

For the text summary evaluation, we mainly follow the prompts in Liu et al. (2023) and show the attribute-specific prompts (relevance, coherence, consistency, fluency) as follows,

relevance of text summary
You will be given one summary written for a news article.
Your task is to rate the summary on one metric.
Please make sure you read and understand these instructions carefully. Please keep this document open while reviewing, and refer to it as needed.
Evaluation Criteria:
Relevance (1-5) - selection of important content from the source document and images. The summary should include only important information from the source document and images. Annotators were instructed to penalize summaries which contained redundancies and excess information.
Evaluation Steps:
1. Read the summary and the source document carefully.
2. Compare the summary to the source document and identify the main points of the article.
3. Assess how well the summary covers the main points of the article, and how much irrelevant or redundant information it contains.
4. Assign a score for relevance on a scale of 1 to 5, where 1 is the lowest and 5 is the highest based on the Evaluation Criteria.
Example:
Source Text: {{Document}}
Summary: {{Summary}}
Evaluation Form (scores ONLY):
- Relevance:

For the evaluation of *coherence*, *consistency* and *fluency*, the descriptions of the evaluation task, the example for evaluation as well as the scoring form are the same as the above prompt for *relevance*. We thus list the evaluation criteria and steps for these evaluation attributes as follows,

coherence of text summary
Evaluation Criteria:
Coherence (1-5) - the collective quality of all sentences. We align this dimension with the DUC quality question of structure and coherence whereby "the summary should be well-structured and well-organized. The summary should not just be a heap of related information, but should build from sentence to a coherent body of information about a topic."
Evaluation Steps:
1. Read the news article carefully and identify the main topic and key points.
2. Read the summary and compare it to the news article. Check if the summary covers the main topic and key points of the news article, and if it presents them in a clear and logical order.
3. Assign a score for coherence on a scale of 1 to 5, where 1 is the lowest and 5 is the highest based on the Evaluation Criteria.

consistency of text summary
Evaluation Criteria:
Consistency (1-5) - the factual alignment between the summary and the summarized source. A factually consistent summary contains only statements that are entailed by the source document. Annotators were also asked to penalize summaries that contained hallucinated facts.
Evaluation Steps:
1. Read the news article carefully and identify the main facts and details it presents.
2. Read the summary and compare it to the article. Check if the summary contains any factual errors that are not supported by the article.
3. Assign a score for consistency on a scale of 1 to 5, where 1 is the lowest and 5 is the highest based on the Evaluation Criteria.

fluency of text summary
Evaluation Criteria:
Fluency (1-5) - the quality of individual sentences in terms of grammar, spelling, punctuation, word choice, and sentence structure.
Evaluation Steps:
1. Read the given summary carefully.
2. Assign a score for fluency on a scale of 1 to 5, where 1 is the lowest and 5 is the highest based on the Evaluation Criteria.

A.2 Prompts for the other scores

For the other scores (image score, text-image relevance score and overall quality score), the multimodal LLM is required to evaluate the quality of the images in the multimodal summary. Thus, we design the following prompts.

quality of the summary images
You will be given one text summary and some summary images (ID) written for a news article with source images. The summary images is a subset of the source images (e.g., Summary Image ID: 1,3 refer to the first and third source images).
Your task is to rate the quality of summary images.
Please make sure you read and understand these instructions carefully. Please keep this document open while reviewing, and refer to it as needed.
Evaluation Criteria:
Quality (1-5) - how well the summary images could represent the content of the news article.
Evaluation Steps:
1. Read the source document and source images carefully.
2. According to the source document, identify which source images are most important and representative.
3. Assess how well the summary images could represent the content of the news article.
4. Assign a score for quality on a scale of 1 to 5, where 1 is the lowest and 5 is the highest based on the Evaluation Criteria.
Example:
Source Text: {{Document}}
Summary: {{Summary}}
Summary Images: {{Image IDs}}
Evaluation Form (scores ONLY):
- Quality:

relevance of the text summary and summary images
You will be given one text summary and some summary images written for a news article with source images.
Your task is to rate the relevance of the text summary and summary images.
Please make sure you read and understand these instructions carefully. Please keep this document open while reviewing, and refer to it as needed.
Evaluation Criteria:
Relevance (1-5) - how well the text summary and summary images match. A well-matched example means the text summary and summary images could represent each other.
Evaluation Steps:
1. Read the text summary and images carefully.
2. Assess how well the summary images could represent the content of the text summary, and how well the text summary could represent the summary images.
4. Assign a score for relevance on a scale of 1 to 5, where 1 is the lowest and 5 is the highest based on the Evaluation Criteria.
Example:
Summary: {{Summary}}
Summary Images: {{Images}}
Evaluation Form (scores ONLY):
- Relevance:

For the overall quality evaluation, we show the text prompt in Section 3.1.

B Text Summarization Models

For our meta-evaluation benchmark construction, we use multiple summarization models to generate text summaries given the sampled multimodal inputs (details in Section 3.2). Specifically, we use the following text summarization models:

- **BART** (Lewis et al., 2020): BART is a Transformer-based denoising autoencoder that is pretrained by reconstructing the original text given the corrupted document, which shows a competitive results in summarization. We use the BART model that is fine-tuned on CNN/Daily Mail summarization dataset (Hermann et al., 2015; Nallapati et al., 2016).

- **Distilbart** (Shleifer and Rush, 2020): Distilbart is a student model distilling knowledge from the teacher model BART. Similar to BART, we also use the model fine-tuned on CNN/Daily Mail dataset (Hermann et al., 2015; Nallapati et al., 2016).

- **GPT2** (Radford et al., 2019) GPT2 is a large transformer-based language model trained on massive data by predicting the next token in a sequence. As GPT2 is not specifically designed for summarization, we add "TL;DR:" after the source document and set it as the input to GPT2 to generate the summary.

- **PEGASUS** (Zhang et al., 2020): PEGASUS is a large Transformer-based encoder-decoder model. The pretraining for PEGASUS is specifically designed for abstractive summarization, where the model is trained to reconstruct the masked sentences given the unmasked context in a self-supervised learning manner.

- **ProphetNet** (Qi et al., 2020): ProphetNet is pretrained to predict the next n tokens given the previous context tokens at each time step, which drives the model to plan and strategize for future tokens generation. The model shows its effectiveness in abstractive summarization.

- **T5** (Raffel et al., 2020): T5 is an encoder-decoder model pre-trained on multiple tasks, where each task is transformed into a text-to-text format. To guide the model to generate text summary for the given document, we add a "summarize:" prefix to the source document as input to the model.

- **HAN** (Zhu et al., 2018): HAN model is specifically designed for multimodal summarization with multimodal outputs, including a text encoder, an image encoder, a multimodal attention layer and a summary decoder. HAN utilizes hierarchical visual attention for generating text summaries and selecting the most relevant images.

- **GPT4** (OpenAI, 2023): GPT-4 is a Transformer-based large language model that could perform various natural language processing tasks, demonstrating its understanding and generation ability. To perform summarization, we use "*Summarize content you are provided with and please do not exceed 100 words.*" as the prompt to the GPT-4.

- **GPT4 with vision** (OpenAI, 2023): GPT-4 with vision is a multimodal large language model, which is able to take both texts and images as inputs. In this work, we provide the multimodal input (source document and source image set) to GPT-4 with vision and obtain the summary.

C Examples in Meta-Evaluation Benchmark

We construct the meta-evaluation benchmark for evaluating the quality of automatic evaluation metrics (details in Section 3.2). A good metric should be able to assess the quality of both *good* examples and *bad* examples. Thus, the benchmark should also contain both good examples and bad examples for assessing the quality of an evaluation metric. Here we list two good examples in Fig. 4, 5 and bad examples in Fig. 6, 7 of our benchmark for illustration.

D Multiple Summary Image Set

We report the inter-annotator agreement in the paper (details in Section 3.2), where the agreement of image score is not as high as other aspects (such as text score). We believe it is reasonable because for a given multimodal input (including a source document and a source image set), there might be more than one summary image set that is acceptable. Here we provide two examples for demonstration in Fig. 8 and 9, where the summary image sets that are selected by three annotators are different from each other.

E Inconsistency in the References

During the human annotation in our work, we notice that the reference multimodal summaries could not always be perfect. For the text part, the reference text sometimes contains some information that is not supported by the source document. We believe this is because of the process of collecting the dataset in (Zhu et al., 2018), where the body of news articles is considered as the source document while the highlight is treated as the summary. The highlight of the news articles could possibly include some information that is not present in the body. We show two examples here to demonstrate the inconsistency issue in the reference text summary, as in Fig. 10 and 11.

F Caption Extraction vs. Generation

We observe that in the caption-based method ("CAP"), "EXT" (captions extracted from the dataset) slightly outperforms "GEN" (captions generated by a pretrained model) mostly. We believe the main reason is the caption's quality and informativeness. In the MSMO dataset (Zhu et al., 2018), each image is paired with an expert-annotated caption to describe the content of the image. Thus the extracted caption would be more informative or accurate than the generated caption. In Fig. 12, we list four examples of the images as well as their captions.

SK Gaming won # 189,000 after fending off tough competition to be crowned the Epicenter 2017 CS : GO champions . They were taken to the limit as Virtus Pro forced the series to a final fifth game , testing the endurance of the players who are used to playing best of threes . SK Gaming held their nerve to win the final game but their celebrations have cut short as the airport security in Russia has sieged their trophy as it has bullets in the design . Gabriel ` FalleN ' Toledo posted a picture on Twitter of the trophy stuck at the airport and said the team were trying their best to get it back . It would be a shame if they did lose the trophy considering how hard they had to work for it . Virtus Pro came flying out of the gates and took the first game of the series 16-10 . SK Gaming then responded with a thumping 16-6 win . Virtus Pro halted their momentum and looked set to regain the lead with a thrashing of their own with a score of 12-3 . However , SK Gaming mounted an incredible comeback and for the first time , took the lead in the series , winning 19-16 . SK only needed one more win yet Virtus Pro held their nerve . They were 9-6 down but mounted a comeback of their own and won 16-12 to force a final game . Both teams traded rounds in an intense finish , SK were able to force overtime and win 22-18 to claim the Epicenter trophy , their sixth championship of the year .

Summary

SK Gaming have won the Epicenter 2017 CS : GO champions. They were taken to the limit as Virtus Pro forced the series to a final fifth game. They held their nerve to win the final game 22-18 to claim the trophy. But their celebrations have cut short as the airport security in Russia has sieged their trophy as it has bullets in the design.

Source Document

Angry villagers have torched a huge mock-up of a BT van on a bonfire in protest at slow rural internet speeds . The annual bonfire night in the small hamlet of Templeton , Devon , is celebrated each year with a different theme . This year fed-up locals made an effigy of a BT Openreach transit van - with the word ` open ' replaced by ` wo n't ' - during a Bonfire Night protest . The two-dimensional model , which was 1.5 times the size of a real Openreach van , went up in smoke at the Templeton Bonfire and Fireworks Night . The rural hamlet was not part of the commercial roll-out of fibre broadband by BT , or the first phase of the Connecting Devon and Somerset partnership . This means many villagers are struggling with speeds of less than 1 megabit . Villager Adam Short , who moved to Templeton last year , said he helped create the van effigy on the floor of his barn . He said : ` We knew it was terrible before we moved , but we hoped there would be a solution . ` Trying to run my business from home is nigh on impossible at times , and I 'm one of the lucky ones because I have a 4G signal on the roof with some specialist kit . ` It also has an impact on the children in the village as it 's restricting their homework . ' He added : ` Upload speeds are almost zero . There really are very few places in our village where a 2G phone signal can be reliably found , let alone 4G . ' Roger Linden said villagers were told the problem would be looked at three years ago , but nothing has happened . He said : ` They managed to get a cable to the nearby hamlet of Nomansland , but just eight kilometres further and there 's nothing . ` It 's incompetence of the first order ... but we all had a great evening watching the bonfire . ' He said he can not stream anything online and is only able to look at emails and occasionally browse the internet . A spokesman from BT said : ` Templeton is an extremely rural community which makes rolling out fibre broadband much more challenging . ` Templeton was not included in Openreach 's commercial roll-out of fibre broadband or the first phase of the Connecting Devon and Somerset partnership but we 're working hard to find alternative ways of bringing faster broadband to residents . ' .....

One of Germany 's richest women is taking her former best friend to court - claiming her new novel actually reveals parts of her private life . Babette Albrecht , the widow of Aldi heir Berthold Albrecht , is demanding several passages in Dorothee Achenbach 's best-selling Now Everybody Knows my Laundry are removed . Despite never being mentioned by name , the heiress says a character known only as ` the widow ' - who avoids a multi-million euro inheritance bill - is actually a thinly disguised version of herself . This is the latest in a long-running saga between the two families , who became firm friends after running into each other in a restaurant in 2007 , according to German tabloid Bild . In particular , the women 's husbands , the late Berthold - who died in 2012 - and art dealer Helge Achenbach , hit it off , travelling the world together to art exhibitions . But the relationship has soured in recent years , culminating in Babette taking Helge to court , accusing him of selling her husband art and cars at over inflated costs . Helge was ordered to pay back 20million euros to Babette , 55 , and later jailed for six years . Dorothee 's new novel , which has sold 40,000 copies so far , describes their fall from grace . However , the 52-year-old has changed their names to provide ` distance ' between the events in the book , and her family . But it has apparently incensed her former friend , who feels the character she believes to be her is an ` insult ' . In total , she is asking for eight passages to be removed , with Bild claiming she is seeking damages to the sum of six figures .

It was perhaps not deliberate but the distance between Ryan Giggs and Louis van Gaal on Saturday afternoon was symbolic nevertheless . During a second half that saw Manchester United briefly entertain hopes of an old-school comeback , Giggs was resident throughout in the technical area , that small piece of Old Trafford real estate that Van Gaal seems to treat with such suspicion . At full-time meanwhile , Giggs was off down the touchline and down the tunnel , not waiting to witness the dissent he knew was about to roll down the Stretford End in the direction of the United manager . Giggs , 42 , has been a significant figure at United for a quarter of a century now and knows what he is witnessing this season -- what he is part of -- does not fit . When he briefly took over as interim manager after David Moyes was sacked in April 2014 , Giggs ' first act was to gather the United players together and tell them that a return to traditional principles of attacking play was called for . One can only imagine , therefore , what runs through his mind these days . United 's football , in terms of the team 's strategies and philosophies , have got worse since Moyes ' time , not better . There are those who know Giggs who wonder if the Welshman would be tempted to walk away , look to begin his management career somewhere else . There has been gossip to that effect but nothing concrete . What we do know is that Giggs does feel some loyalty towards Van Gaal , despite the fact he would prefer his team to play rather more on the front foot . He remains grateful to the former Barcelona and Bayern Munich manager for the opportunity to work under him and already feels he has learned a great deal . Undoubtedly , though , there is a groundswell of opinion among the United support that would like to see him given his opportunity to take charge of the first team again , at least until the end of the season .....

Southampton boss Ronald Koeman admits he may have to dip into the transfer market for a striker if his current frontmen remain unfit . Koeman is currently without Graziano Pelle and Jay Rodriguez through injury , although both are expected to be back in action in the near future . Pelle has been missing since Christmas with a knee injury and will also sit out this weekend 's trip to Norwich , while Rodriguez is due back in late January after foot surgery . But Koeman is weighing up his attacking options with the January transfer window due to open on Saturday . When asked whether he was about to dip into the transfer market , Koeman said at his pre-match press conference : ` At the moment , no . ` Like I mentioned before , if we need to sign a player , it needs to be a striker . ` But that also depends on the situation of Jay and what will happen with Graziano . It 's too early to make conclusions about that . ` We still have to wait to see how they recover and how long it takes , and then we 'll make a decision about what we have to do . ' Shane Long is set to lead the line again for Saints at Carrow Road .

When police knocked on Kelly McPherson 's door to ask if she 'd witnessed a stabbing nearby , her heart sank . Her stepson was yet to return home and she instinctively knew he was the victim . She said : ` My first thought was , `` Oh no I hope it 's not Michael . '' ` I rang his mobile three times and there was no answer . I knew it was him who had been stabbed , I just knew it . ' Mrs McPherson ran to a nearby park on Thursday evening after finding out about the attack . She discovered air ambulance paramedics trying to resuscitate her stepson Michael Jonas , 17 . He was pronounced dead nearly an hour later . The attack in Betts Park , near Crystal Palace in South London , comes as police battle a knife crime epidemic in the capital . A total of 22 teenagers have been murdered in London so far this year -- 16 of whom were stabbed . The number of teenagers murdered in the capital is now at its highest in nine years .....There has been a 47 per cent increase in stabbings in London this year . London Mayor Sadiq Khan held a knife crime summit with teachers earlier this week and Croydon Central MP Sarah Jones has called on Home Secretary Amber Rudd to tackle the problem . Miss Jones said : ` Time and time again we 've said `` enough is enough '' as knife crime has doubled in a year . Well over 1,000 young people were stabbed in London last year . ` Now we demand action , not words . I 've been pushing the Home Secretary to prioritise this epidemic among our young . It ca n't be fixed with short-term thinking . ` We need a ten-year , cross-government strategy . ' Police said there have been no arrests .

Abstract

Large Language Models (LLMs) have shown promising in-context learning abilities. However, conventional In-Context Learning (ICL) approaches are often impeded by length limitations of transformer architecture, which pose challenges when attempting to effectively integrate supervision from a substantial number of demonstration examples. In this paper, we introduce a novel framework, called Naive Bayes-based Context Extension (NBCE), to enable existing LLMs to perform ICL with an increased number of demonstrations by significantly expanding their context size. Importantly, this expansion does not require fine-tuning or dependence on particular model architectures, all the while preserving linear efficiency. NBCE initially splits the context into equal-sized windows fitting the target LLM's maximum length. Then, it introduces a voting mechanism to select the most relevant window, regarded as the posterior context. Finally, it employs Bayes' theorem to generate the test task. Our experimental results demonstrate that NBCE substantially enhances performance, particularly as the number of demonstration examples increases, consistently outperforming alternative methods. The code NBCE is available at: https://github.com/amurtadha/NBCE-master

1 Introduction

Large Language Models (LLMs) have demonstrated remarkable capabilities in in-context learning (ICL), a paradigm that enables them to excel in various unseen tasks based on task examples or instructions within their context (Han et al., 2021; Qiu et al., 2020). Unlike traditional fine-tuning methods, ICL leverages LLMs for downstream tasks solely through inference, eliminating the need for parameter updates and making it computationally efficient, bringing us closer to the goal of general AI. This approach has gained prominence as LLMs continue to grow in scale (Brown et al., 2020; Zhang et al., 2022a; Chowdhery et al., 2022).

The 2048-token context limit in popular LLMs like GPT-3 poses challenges for scaling up ICL with more demonstration examples in ICL, due to architectural constraints and computational complexity. Recent studies (Garg et al., 2022; Min et al., 2022b; Chen et al., 2022) improve ICL through meta-learning and fine-tuning on downstream tasks, but the limited diversity of annotated tasks and biases hinder generalization. Another line of research has explored various approaches to retraining long-range language models with extrapolation, extending them to 128 times the limit of existing LLMs (Li et al., 2023; Gu et al., 2023). However, these approaches require additional training over several steps, which can be time-consuming.

Recently, Hao et al. (2022) introduced structured prompting, encoding demonstrations with specific position embeddings for collective attention via a scaled mechanism. Extending this, Ratner et al. (2023) proposed parallel context windows, utilizing individual encoding of examples with designed position and attention mechanisms. Addressing this issue is crucial for leveraging ICL effectively, especially in scenarios with ample examples.

In this paper, we introduce a novel framework called Naive Bayes-based Context Extension (NBCE) for large language models to significantly expand the number of demonstrations by orders of magnitude while greatly enhancing stability. Instead of simply merging all demonstrations, we partition the vast number of demonstrations into multiple groups, each independently processed by the language model. This approach ensures that the encoding complexity scales linearly with the number of groups, avoiding the quadratic complexity associated with considering all examples simultaneously. Following Ratner et al. (2023); Hao

Proceedings of the 2024 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies (Volume 1: Long Papers), pages 7791–7807
June 16-21, 2024 ©2024 Association for Computational Linguistics

et al. (2022), we align the position embeddings of grouped prompts to the right, placing them next to the test input. Subsequently, we leverage the Naive Bayes to encode the input by conditioning it on these grouped prompts. We conducted experiments across various tasks, including text classification, multi-choice, and open-ended tasks. NBCE effectively scales up the number of demonstrations, outperforming conventional in-context learning across different model sizes and tasks, while also significantly enhancing stability.

In brief, the contributions can be summarized as follows:

1. We introduce an innovative framework known as Naive Bayes-based Context Extension (NBCE), designed to substantially increase the volume of demonstrations for large language models, thus enhancing stability on a significant scale.

2. We provide detailed technical insights to enable context expending of in-context learning tasks. The idea is to encode the test sample by conditioning it on a vast array of demonstrations sourced from the training dataset.

3. We conducted extensive experiments on benchmark NLP datasets, and our findings clearly highlight NBCE's remarkable capability to efficiently scale up the number of demonstrations, while significantly enhancing overall stability.

2 Approach

An example of our proposed NBCE is depicted in 1. Assume that we have a sequence, denoted as T, which we intend to generate. Furthermore, we have multiple relatively independent context sets, denoted as $S_1, S_2, \ldots, S_n$ (e.g., n different paragraphs), each of which is sufficiently long and does not split a sentence into fragments. Suppose that the total length of these context sets exceeds the training length, but when combined with an individual S_k and T, they still fall within the training length. Our objective is to generate T based on the information contained in $S_1, S_2, \ldots, S_n$. In essence, we seek to estimate the conditional probability of T given $S_1, S_2, \ldots, S_n$, which can be represented as $p(T|S_1, S_2, \ldots, S_n)$.

In straightforward terms, Naive Bayes can be understood as a combination of two key elements:

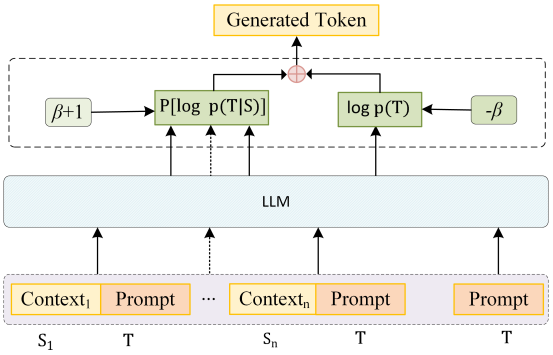

Figure 1: An example for our NBCE. Initially, NBCE divides the context into equal-sized windows, each with the maximum length compatible with LLM intarget. Subsequently, a voting mechanism is introduced to select the most relevant context window, regarded as the posterior context. Finally, it employs Bayes' theorem to generate the test task.

Bayes' formula and an independence assumption:

$$p(T|S_1, S_2, \ldots, S_n) \propto p(S_1, S_2, \ldots, S_n|T)p(T), \tag{1}$$

where, the symbol $\propto$ denotes proportionality, signifying that we are focusing solely on the relevant factors in a proportion while disregarding constant factors unrelated to the token sequence T. This approach aligns with the underlying assumption of conditional independence:

$$p(S_1, S_2, \ldots, S_n|T) = \prod_{k=1}^{n} p(S_k|T). \tag{2}$$

Thus, we have:

$$p(T|S_1, S_2, \ldots, S_n) \propto p(T) \prod_{k=1}^{n} p(S_k|T). \tag{3}$$

Furthermore, based on Bayes' formula $p(S_k|T) \propto \frac{p(T|S_k)}{p(T)}$, we get:

$$p(T|S_1, S_2, \ldots, S_n) \propto \frac{1}{p^{n-1}(T)} \prod_{k=1}^{n} p(T|S_k). \tag{4}$$

Or:

$$\begin{aligned} \log p(T|S_1, S_2, \ldots, S_n) = &\sum_{k=1}^{n} \log p(T|S_k) \\ &- (n-1) \log p(T) \\ &+ \text{constant}, \end{aligned} \tag{5}$$

where both $p(T|S_k)$ and $p(T)$ can be computed directly utilizing existing LLMs, independent of their architecture, and without the need for fine-tuning on extensive textual data. Specifically, $p(T|S_k)$ represents the probability predicted by an individual contextual set, while $p(T)$ signifies the probability in the absence of any context or with an empty context. It is noteworthy that multiple contextual sets can be concurrently processed within the same batch, with computational complexity scaling linearly with the number of contexts. Certainly, Naive Bayes leans heavily on the independence assumption, which can restrict its practical utility. To aspire to enhance its performance beyond the initial state, we further refine Equation 5.

To commence this refinement, we shall introduce the following notations:

$$\log p(T|S) = [\log p(T|S_1), \ldots, \log p(T|S_n)], \tag{6}$$

and

$$\overline{\log p(T|S)} = \frac{1}{n}\sum_{k=1}^{n} \log p(T|S_k), \tag{7}$$

where $\overline{\log p(T|S)}$ denotes the Average Pooling of $\log p(T|S)$. Let $\beta = n - 1$, then Equation 5 can be rewritten as

$$\begin{aligned}\log p(T|S_1, S_2, \ldots, S_n) = (\beta + 1)\overline{\log p(T|S)} \\ - \beta \log p(T) \\ + \text{constant}.\end{aligned} \tag{8}$$

However, the reformulation may prompt the emergence of two inherent inquiries:

- If we consider β as a hyperparameter subject to tuning, could this potentially yield superior results?
- Is it conceivable that employing alternative pooling techniques, denoted as P, might potentially yield enhancements in performance? That is:

$$\begin{aligned}\log p(T|S_1, S_2, \ldots, S_n) = (\beta + 1)P[\log p(T|S)] \\ - \beta \log p(T) \\ + \text{constant}\end{aligned} \tag{9}$$

To delve deeper into these inquiries, we conducted a series of experiments employing the 7B model and garnered preliminary insights. In the realm of reading comprehension, a consistent trend of robust performance emerges when employing Max Pooling with a β value of 0.25 in conjunction with Greedy Search. Conversely, outcomes generated via Random Sampling frequently yield results that are challenging to interpret.

The observed disparities in outcomes can be attributed to the inherent characteristics of these two methods. Random Sampling, characterized by its selection of tokens based on their probability distribution, tends to exhibit lackluster performance, signaling that the output of Max Pooling may not align with a plausible probability distribution. In contrast, Greedy Search operates distinctively by prioritizing the token with the highest probability, disregarding the holistic distribution. Its commendable performance suggests that the token with the highest probability is more likely to be the accurate choice. Larger probabilities are indicative of lower uncertainty. To enhance the performance of Random Sampling, we modify the pooling method to directly output the probability distribution with the lowest uncertainty:

$$\begin{aligned}P[\log p(T|S)] &= \log p(T|S_k), \\ k &= \text{argmin}\{H_1, H_2, \ldots, H_n\}, \\ H_i &= -\sum_T p(T|S_i) \log p(T|S_i),\end{aligned} \tag{10}$$

By substituting this expression into Eq.9, we arrive at the conclusive formulation of the NBCE. It is noteworthy that while the initial inspiration for this approach stemmed from Naive Bayes, the generalized Equation 9 transcends the conventional boundaries of traditional Naive Bayes, yet maintains its inherent interpretability. Eq.9 assumes an intuitive form: Predictions originating from various contextual sources are collectively amalgamated (or weighted) through the utilization of the method denoted as P (with a weight factor of $\beta + 1$). Subsequently, this amalgamation is counterbalanced by subtracting the prediction in the absence of context, weighted by β. The rationale behind subtracting the context-less prediction lies in enhancing the model's reliance on contextual information, reducing its dependency on inherent knowledge (Shi et al., 2023).

The choice of values for β can be tailored to

different scenarios. For tasks necessitating comprehensive reading comprehension and robust context integration, a larger β value may be deemed appropriate. Conversely, tasks leaning towards creative writing may benefit from a smaller β value. In our experiments, we set $\beta = 0.25$.

3 Experimental Setup

In this section, we describe the experimental settings adopted in our work, including the datasets, LLMs and comparative approaches used to evaluate our approach.

3.1 Datasets

In our experiments, we employed a diverse range of benchmark datasets to evaluate our approach. These datasets encompassed various tasks, including text classification and multiple-choice questions. Fifteen Text Classification Datasets: SST-2 (Socher et al., 2013), CR (Ding et al., 2008), RTE (Bar-Haim et al., 2014), Subj (Pang and Lee, 2004), CB (De Marneffe et al., 2019), AG-News (Zhang et al., 2015), SST-5 (Socher et al., 2013), YELP (Zhang et al., 2015), TREC (Li and Roth, 2002), DBPedia (Zhang et al., 2015), NLU (Liu et al., 2019), BANKING77 (Casanueva et al., 2020), CLINIC150 (Larson et al., 2019), TREC (fine-grained labels) and NLU (fine and coarse-grained labels). Five datasets from Multiple-choice Domain. Specifically, we consider sentence completion: HellaSwag (Zellers et al., 2019); commensense reasoning: PIQA (Bisk et al., 2020), OpenBookQA (Mihaylov et al., 2018), StoryCloze (Mostafazadeh et al., 2017), MMLU (Hendrycks et al., 2021), ARC-Easy (Bhakthavatsalam et al., 2021); and COPA from SuperGLUE benchmark (Wang et al., 2019). It is worth noting that we conducted evaluations using the standard test sets or validation sets when a public test set was not available. It is important to mention that all the datasets used in our experiments are in the English language.

3.2 Training Sampling and Models

The effectiveness of ICL has been observed to be highly dependent on the selection of training examples (Zhao et al., 2021). To ensure a fair and consistent comparison, we maintain the approach employed in the PCW (Ratner et al., 2023), a common practice in prior research (Zhao et al., 2021; Lu et al., 2022; Ahmed et al., 2022). Specifically, we randomly selected 30 sets from the training datasets and report the mean and standard deviation calculated across these sampled sets.

Given our limited computational resources, our experiments were conducted using eight large models: GPT2-Large (0.75B), GPT2-XL(1.5B)(Radford et al., 2019), there LLAMA models, including 7B, 13B and 30B (Touvron et al., 2023), and three OPT models with 1.3B, 6.7B and 13B parameters (Zhang et al., 2022b).

3.3 Comparative Baseline

Note that our proposed solution does not require any additional training. As far as our knowledge extends, Ratner et al. (2023) initiated the work in this line of research. Therefore, we compare our approach with methods that also do not require further training, as follows.

- **ICL**. A traditional ICL approach employs a conventional single context window, which essentially utilizes the full capacity of the positional embedding in the LLM.

- **PCW**(Ratner et al., 2023). PCW introduces strategic adjustments to both position encoding and attention mask mechanisms to enable multiple context windows without requiring additional training.

3.4 Prompt Formats

We have employed the same prompt formats as those adapted by the comparative baseline, PCW. For the sake of brevity, we have omitted specific details about the prompt format; for a more comprehensive understanding, we kindly refer you to Ratner et al. (2023).

4 Evaluation

We evaluate our proposed solution based on two primary criteria:

- **Ability to Extend the Length of Large Models:** Does our solution effectively enable the expansion of the size or capacity of large models?

- **Impact of Additional Demonstrations on ICL Task Performance:** Does the inclusion of more demonstrations have a positive effect on the performance of the ICL task?

Dataset	# Shots per window	# Labels	ICL B=1	B=3		B=6		B=9

4.1 Classification Task Evaluation

4.1.1 Main Results

We conducted an analysis in which we calculated the average accuracy from 30 different runs, each with a unique seed. We compiled the accuracy and standard deviation for various text classification datasets, which are presented in Tables 1, 2, and 3. **Due to space constraints, the results of more scaled models are presented in the Appendix Section: GPT2-XL Table 6, LLAMA-13B Table 7, LLAMA-30B Table 8, and OPT-6.7B Table 12**. To highlight significant findings, we marked statistical significance with an asterisk (*), based on a t-test with a p-value of less than 0.05. Our key observations are as follows. (1) Vanilla ICL consistently showed the lowest performance across all models and datasets, underscoring the critical need for expanded context in ICL tasks. (2) For models with fewer parameters (like GPT-2-Large and OPT-1.3B) and when dealing with a limited number of output classes (five or fewer), we noted minor or negligible differences between both PCW and NBCE, compared to vanilla ICL. Conversely, in models with a larger number of parameters, NBCE generally demonstrated superior performance in most cases. However, it is important to note that several of these differences did not reach statistical significance. (3) NBCE enhances ICL by accommodating a greater number of examples. This improvement becomes particularly evident when B=9, where both accuracy and stability generally show marked improvements. We observed that larger models benefit more substantially from our approach. This favorable scaling trend of NBCE is particularly notable when contrasted with previous

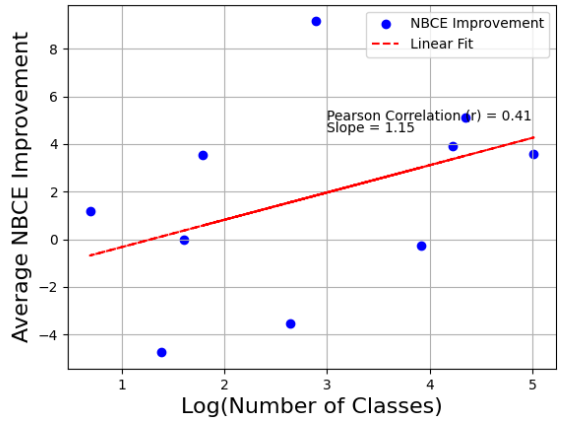

Figure 2: Average Performance Enhancements with NBCE over PCW as a Function of Label Count: Each data point in our analysis signifies the average improvement observed across all datasets on GPT2 models. It is worth noting a clear and positive correlation between the quantity of unique labels and the benefits derived from our NBCE.

efforts to enhance ICL (refer to (Zhao et al., 2021; Lu et al., 2022)), where improvements in 178B-scale models were less marked compared to those in smaller models

4.1.2 PCW enables ICL with a Large Number of Classes

To investigate the relationship between the number of classes and our NBCE's performance, we conducted a detailed analysis, which was adapted by Ratner et al. (2023). In each experiment, we calculated the difference between NBCE and PCW and then averaged the results across all datasets on GPT2 models sharing the same number of classes. As illustrated in Figure 2, a robust positive correlation emerged between the quantity of classes and the improvements achieved by NBCE. Specifically, the Pearson correlation coefficient (r) was 0.41 when considering the logarithm of class numbers in relation to the average improvement, with a slope of 1.15. Remarkably, for datasets featuring numerous labels, such as NLU Intent (Liu et al., 2019), Banking77 (Casanueva et al., 2020), and CLINIC150 (Larson et al., 2019), we observed substantial improvements ranging from 3.6 to 5.1 points in most cases.

When comparing results across datasets with varying numbers of classes, it is crucial to account for potential confounding factors, such as variations in domain, style, or genre. To mitigate these effects, we conducted a comparison using two datasets, each featuring both fine-grained and coarse-grained labels. The TREC dataset (Li and Roth, 2002), which includes 6 coarse-grained classes. The NLU dataset (Liu et al., 2019), comprising 18 scenarios coarse-grained classes and 68 intents coarse-grained classes. Our analysis on GPT2 models, as presented in Table 10, reveals that NBCE outperforms PCW by 4.1 and 3.0 improvements on GPT2-Large and GPT2-XLarge, respectively. Similarly, in the context of NLU, we observe average improvements of 17.2 and 5.2 points on GPT2-XLarge, respectively. These findings underscore the effectiveness of our approach, particularly when confronted with a large number of output classes.

4.2 Multi-Choice Tasks

Table 4 shows the evaluation of multi-choice tasks. It is important to note that the improvements made by both PCW and our NBCE in these tasks, com-

pared to text classification, are relatively modest, with a slight edge for NBCE. Furthermore, employing a greater number of demonstrations does not consistently translate to better performance in multi-choice tasks. Instead, we observe that scaling up the model size (Appendix Section Table 9), rather than increasing the number of demonstrations, tends to yield more substantial improvements in these tasks.

4.3 Impact of more Demonstrations on ICL

We conducted experiments to validate the impact of additional demonstrations on ICL in NLP models. Our focus was to show how extra demonstrations (B=6 and B=9, where B is the window size) enhance model performance by improving context understanding and robustness. **Note that each window contains K samples within the model's token limit (e.g., 2024 tokens for LLAMA).** For detailed information on the maximum value of K for each model and dataset, please see Appendix Table 15 . This approach aligns with the importance of training example quantity in model adaptability and generalization (Murtadha et al., 2023, 2024). Our observations indicate that NBCE mostly outperforms its counterpart, PCW, and these improvements can be considered significant. Additionally, scaling up the model size (Appendix Section Tables 6,7, 8, and 12) leads to improved performance, especially on larger and more complex datasets.

4.4 Ablation Study

To better evaluate the proposed voting mechanism, i.e., selecting the best k contexts as the posterior in Equation 10, we conducted an ablation study introducing a new variant, referred to as NBCE (RAND). In this variant, rather than deliberately choosing k, we randomly select one context from the context windows. The results are presented in Table 5. The experimental outcomes across a variety of models and datasets demonstrate that a careful selection of k significantly contributes to the quality of the generated tokens. It is noteworthy that, in this setting, NBCE can be considered as a standard ICL, where only one context window is considered. However, the performance may slightly differ due to the likelihood of the generated text $p(T)$, as outlined in Equation 9, affecting the final performance.

4.5 Effect of Pooling Mechanism

It is imperative to underscore the introduction of two distinct pooling mechanisms P: averaging the context windows as depicted in Eq.7, and maximiz-

ing based on entropy as delineated in Eq.10. To empirically validate the efficacy of these pooling strategies, we conducted a series of experiments utilizing GPT2 models within the context of a text classification task. The outcomes, illustrated in Figure 3, showcase a comparative analysis in terms of both accuracy and standard deviation. Notably, the maximizing strategy not only augments performance but also enhances stability. It is important to acknowledge that the model size can significantly influence the outcomes when employing the averaging pooling mechanism.

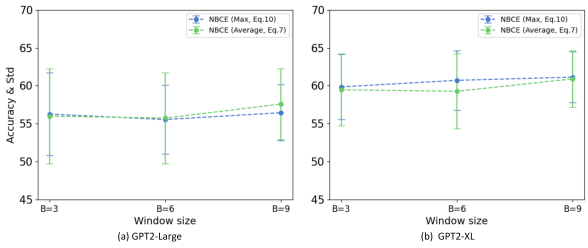

Figure 3: Efficacy in terms of averaged accuracy and standard deviation (i.e., the error bars) of two pooling mechanisms: average context window (Eq.7) and entropy-based maximization (Eq.10) utilizing GPT2 models for text classification. Notably, the maximizing approach enhances both accuracy and stability, with model size impacting averaging pooling's performance.

4.6 Effect of β

In our investigation, the parameter β as outlined in Eq. 8 was initially set to 0.25. To elucidate the impact of different β values on the overall performance, experiments were conducted utilizing GPT2 models within a text classification framework, testing β values of 0.25, 0.5, and 0.75. The outcomes, depicted in Figure 4, illustrate comparative performances in terms of accuracy and standard deviation. The analysis reveals a reduced sensitivity of model performance to variations in β, indicating that modifications to β do not markedly influence model robustness. Notably, an observation was made that larger model sizes exhibit more stable performance at increased β values, particularly at $\beta = 0.75$. This stability accentuates the capability of larger models to manage greater parameter variability, enhancing their utility in a broad spectrum of computational tasks.

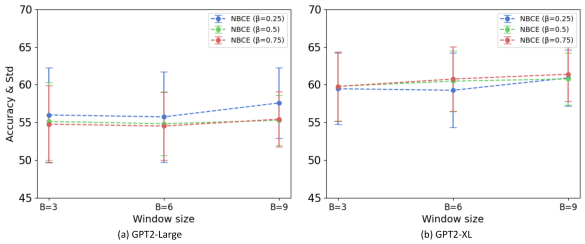

Figure 4: Comparative analysis in terms of averaged accuracy and standard deviation (i.e., the error bars) of GPT2 model performance across varying β Eq. 8 values (0.25, 0.5, 0.75) in a text classification task.

5.1 In-Context Learning

In recent years, in-context learning has received significant attention in the research community. Brown et al. (2020) introduced this concept, sparking a wave of investigations. Zhao et al. (2021); Han et al. (2023) addressed the issue of LLM miscalibrations and explored various calibration methods. However, few-shot performance can vary based on the order of demonstrations and template choices (Lu et al., 2022). In this context, Zhao et al. (2021) identified three biases and suggested content-free output calibration. Min et al. (2022a) demonstrated how these biases shift decision boundaries and proposed calibrating through prototypical cluster distribution estimation. Others focused on prompt engineering, such as selecting optimal demonstration permutations (Lu et al., 2022) and using retrieval modules for semantically similar in-context examples (Liu et al., 2022; Rubin et al., 2022). One promising direction is to improve in-context learning by increasing the number of demonstrations.

5.2 Context Extension

Expanding the contextual capabilities of LLM continues to pose a formidable challenge and has attracted considerable research attention. Various studies have introduced to tackle the memory limitations associated with self-attention mechanisms. These approaches can be broadly classified into two categories: fine-tuned approaches and few-shot approaches. Zaheer et al. (2020); Guo et al. (2022), have suggested using sparse attention as a solution to this issue. Press et al. (2022) took a novel approach by incorporating positional information using relative factors in attention weights instead of relying on absolute positional encoding. Despite

the impressive capabilities of Press et al. (2022)'s model for extrapolation, it remains computationally intensive due to its quadratic self-attention cost, making it slow and resource-demanding for longer prompts. Ivgi et al. (2022) introduced an alternative approach called SLED, which is an encoder-decoder model specifically designed for handling lengthy texts. This model encodes short overlapping segments of input text and integrates this information within the decoder, similar to the Fusion-in-Decoder concept by Izacard and Grave (2021). However, these researches require additional training.

More recently, Ratner et al. (2023) have introduced the concept of Parallel Context Windows (PCW), which enables the concurrent utilization of multiple context windows without requiring additional training. PCW has been purposefully tailored for self-attention models, involving modifications to both position encoding and attention mask mechanisms to enhance the performance. NBCE and PCW share noteworthy similarities, as they both treat contexts as unordered and apply equal weighting. Notably, when NBCE is employed within the context of a single-layer, single-head attention model, the resulting outcomes closely approximate those achieved through the utilization of PCW. To substantiate this claim, we can formulate the language model tailored to a single-layer, single-head attention configuration.

$$p(x_t|x_{<t}) = \text{softmax}\left(\sum_{i=1}^{t} a_{t,i} v_i W\right) \tag{11}$$

hence, approximately: $\log p(x_t|x_{<t}) \sim \sum_{i=1}^{t} a_{t,i} v_i W$. Substituting this into Equation 9 and setting $\beta = 0$, we obtain:

$$\begin{aligned}\log p(T|S_1, S_2, \ldots, S_n) &\sim \frac{1}{n}\sum_{k=1}^{n}\left(\sum_{i\in S_k} a_{T,i} v_i\right) W \\ &= \left(\sum_{i\in S_1\oplus\ldots\oplus S_n} \frac{a_{T,i}}{n} v_i\right) W\end{aligned} \tag{12}$$

here, we assume T represents a single sequence (i.e., the query), However, this assumption does not lack generality. The symbol $\oplus$ denotes concatenation and $S_k \oplus T$ is used for reasoning as a continuous segment (as per NBCE's setup), so their positional encodings are adjacent. Additionally, $a_{T,i}/n$ forms a collective attention for T with all S_i (with a sum equal to 1). These characteristics are consistent with PCW, which is essentially integrated into each layer more elegantly through an attention mask. Therefore, PCW can be thought of as a version of NBCE that utilizes average pooling.

6 Conclusion

This paper introduces a novel framework called Naive Bayes-based Context Extension (NBCE) for large language models. NBCE innovatively incorporates a voting mechanism to select the most appropriate window context, and then utilizes Bayes' theorem to generate the task text. Our results show that NBCE outperforms its alternative PCW across a diverse set of multi-class classification tasks. For future work, while PCW shows effective without additional training, ICL could potentially benefit from more demonstrations in fine-tuning settings; however, further investigation is required to fully comprehend the extent of its advantages.

Limitations

NBCE facilitates ICL tasks by allowing for more demonstrations without the need for fine-tuning. However, there are still some limitations to this approach:

- Since NBCE essentially functions as a voting mechanism, its effectiveness is constrained in tasks that require ordered or interrelated contexts, such as code generation. This is due to its inherent nature, which may not adequately handle sequential or dependent information in certain contexts.
- Increasing the number of shots does not necessarily lead to improved performance. Experimental results have indicated that expanding the context window size does not significantly enhance performance in completion tasks. This suggests a diminishing return on performance gains with an increased number of contexts.

Table 10: Comparative analysis of classification results in terms of accuracy (in %) for both the GPT2-Large and GPT2-XLarge models using a context window of B = 3. Notably, a single window comprises a set of examples with a total number of tokens equal to the maximum capacity of conventional in-context learning (e.g., 1024 tokens in GPT-2). The best-performing scores for each model and dataset are highlighted in bold, while '*' indicates statistical significance, determined by a t-test with a p-value < 0.05.

Leitner-Guided Memory Replay for Cross-lingual Continual Learning

Meryem M'hamdi*

Abstract

Cross-lingual continual learning aims to continuously fine-tune a downstream model on emerging data from new languages. One major challenge in cross-lingual continual learning is catastrophic forgetting: a stability-plasticity dilemma, where performance on previously seen languages decreases as the model learns to transfer to new languages. Experience replay, which revisits data from a fixed-size memory of old languages while training on new ones, is among the most successful approaches for solving this dilemma. Faced with the challenge of dynamically storing the memory with high-quality examples while complying with its fixed size limitations, we consider Leitner queuing, a human-inspired spaced-repetition technique, to determine what should be replayed at each phase of learning. Via a controlled set of quantitative and qualitative analyses across different memory strategies, we show that, just like humans, carefully picking informative examples to be prioritized in cross-lingual memory replay helps tame the stability-plasticity dilemma. Compared to vanilla and strong memory replay baselines, our Leitner-guided approach significantly and consistently decreases forgetting while maintaining accuracy across natural language understanding tasks, language orders, and languages.

1 Introduction

Cross-lingual continual learning is a machine learning paradigm aimed at continually adapting a downstream model to datastreams drawn from different languages (M'hamdi et al., 2023). Naive approaches to cross-lingual continual learning involve training a new model from scratch each time a new language is available or training jointly over all languages, which can be inefficient and even inaccessible. Faced with an overwhelming stream of languages, modelers turn to continual learning techniques to adapt models such that maximal learning from data is achieved when available data is temporally limited. The consequence of a finite data buffer limitation on a potentially infinite data source is *catastrophic forgetting* (McCloskey and Cohen, 1989). Catastrophic forgetting exemplifies the stability-plasticity dilemma (Carpenter and Grossberg, 1987; Hadsell et al., 2020; Wolczyk et al., 2021): It is inherently hard to preserve the previously acquired knowledge (stability) while learning novel information (plasticity).

Various continual learning approaches have proposed to mitigate catastrophic forgetting by either restricting entire sets of parameters from changing (Kirkpatrick et al., 2017; Zenke et al., 2017; Ritter et al., 2018), designing language-specific model components (Pfeiffer et al., 2020; M'hamdi et al., 2023), or replaying a fixed buffer memory from previously seen languages (Shin et al., 2017; Chaudhry et al., 2019a,b). M'hamdi et al. (2023) show that memory-based approaches are more robust than other approaches in taming the stability-plasticity dilemma. Moreover, they are more scalable than other approaches, such as model expansion, which grows in complexity as a function of the underlying downstream architecture.

Experience replay (ER) (Chaudhry et al., 2019b) is a cognitively inspired memory-based approach that reinforces previously seen experiences similar to the process of memory consolidation in biological systems (Isele and Cosgun, 2018). As more languages are incorporated into the datastream, fitting examples from new languages into a fixed-size memory buffer becomes more challenging. This invites a critical question: How can we dynamically come up with informative memory examples to keep for each language?

In this paper, we propose a human-inspired approach for learning what to replay at each phase of cross-lingual continual learning. We hypothesize

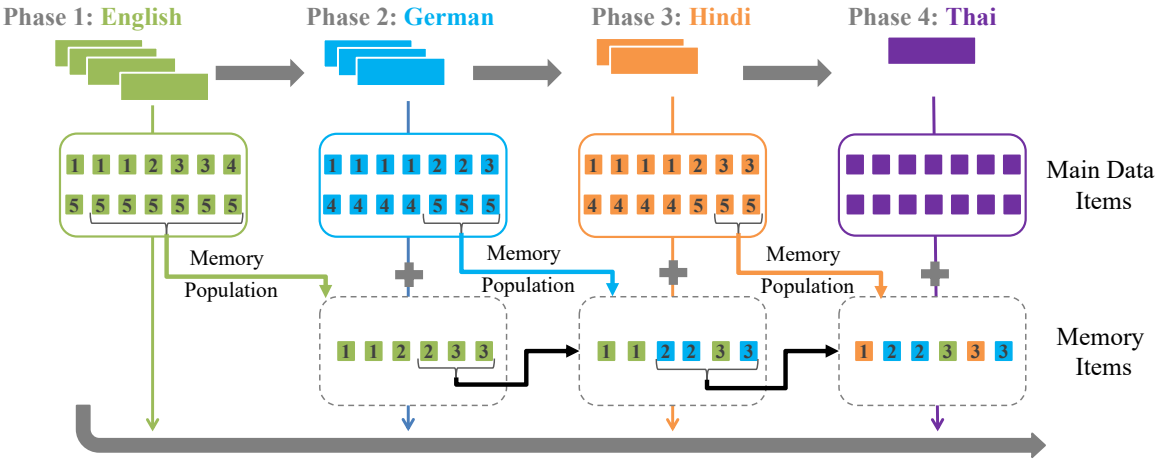

Figure 1: An overview of Leitner-guided memory replay for multi-phase cross-lingual continual learning: On top of a cross-lingual datastream, we build a skill rating system to continually guide the memory population and update. Skill ratings are scores from 1 to 5 obtained from Leitner queues; a higher score reflects greater learnability. At the end of each phase, the skill ratings on the main data items from the phase language are used to choose what goes in the memory, and the skill ratings of data items already in the memory are re-evaluated to determine if they can remain. Our approach is language-agnostic in the sense that it uses Leitner queues to determine which examples to keep in the memory at the end of each phase irrespective of the language.

that in such a setup at the beginning, most data is difficult but as training progresses some data becomes well-learned and informative. We surmise that reducing the forgetting of previously learned examples requires using a strategy of alternately learning new difficult examples along with reinforcement of well-learned examples. To design cross-lingual memory, we leverage Leitner queues, a cognitive technique that has been used for strategically planning what to review in humans (Leitner, 1974; Reddy et al., 2016) and for determining informative and spurious data in self-training non-continual learning applications (Amiri et al., 2018; Amiri, 2019). Our Leitner-guided memory sampling policy is a dynamic language-agnostic skill rating system which selects candidates for inclusion into memory according to how well they are learned (Figure 1). We analyze memory design attributes that contribute to reducing cross-lingual continual learning forgetting and evaluate on typologically diverse benchmarks ranging in difficulty.[1]

We summarize our contributions as follows:

(1) We are the first to formalize a human-inspired solution based on Leitner queues to guide cross-lingual memory replay (§2.3).

(2) We show that our Leitner-inspired approach for selecting memory replay items reduces forgetting without sacrificing transfer learning gains (§4.1).

(3) We provide a fine-grained analysis over different language orders and languages showing that our approach is consistently and robustly beneficial (§4.2).

(4) We provide a qualitative analysis that investigates the usefulness of data as a function of its learnability (§4.3).

2 Methodology

In this section, we start by describing our ER approach adapted to cross-lingual continual learning (§2.1). Then, we explain the mechanism for determining skill ratings based on Leitner queues (§2.2). After that, we explain how we use this Leitner-based skill rating system to guide memory storage and update in cross-lingual ER (§2.3).

2.1 Cross-lingual Experience Replay

We follow the same setup for cross-lingual continual learning and ER defined by M'hamdi et al. (2023). The general continual learning paradigm assumes access is limited to a portion of the data at any phase. The cross-lingual continual learning process consists of sequentially fine-tuning a model on a cross-lingual datastream in multiple phases. A cross-lingual datastream $\mathcal{D}_{1...N}$ is a set of N distinct labeled datasets sampled from different languages one at a time. Each dataset $\mathcal{D}_i$ is drawn from a

[1]Our code is available at https://github.com/meryemmhamdi1/x-continuous-learning/tree/main/humanlearn.

single distinct language $\ell_i \in \mathscr{L} = \{\ell_1, \ell_2 \cdots \ell_N\}$. Each phase $\mathcal{P}_i \in \mathcal{P}_{1\cdots N}$ is a stage in cross-lingual continual learning where the model gets fine-tuned on a dataset $\mathcal{D}_i$ for a number of epochs. The ER approach is implemented as follows: At the end of each phase (except the last one) $\mathcal{P}_i \in \mathcal{P}_{1\cdots N-1}$, we choose some data from $\mathcal{D}_i$ to add to a memory buffer $\mathcal{M}$ of fixed size $|\mathcal{M}|$. In later phases $\mathcal{P}_j$ after $\mathcal{P}_i$, we replay from $\mathcal{M}$, which contains memory data drawn from $\mathcal{D}_{<j}$ interleaved with the main loss on data drawn from $\mathcal{P}_j$.

2.2 Leitner-based Skill Rating System

We draw inspiration from Leitner queues (Leitner, 1974), a method of prioritization originally conceived of as a strategy for human memorization and later used in machine learning applications (Amiri et al., 2018). The key prioritization insight we leverage is that of *demonstrated mastery*. That is, items in a (training) data set may be rated by the degree to which they have been mastered by the learner. We instantiate this by associating a rating r to each training data item d, and changing $r(d)$ based on a model m's ability to correctly classify d during training. Let $[s, e]$ be the acceptable rating range, let $r_{m'}(d)$ be the rating for d according to some previous model m', and let $\phi_m(d) \in \{-1, 1\}$ indicate that model m classified d {incorrectly, correctly}, respectively. Then

$$r_m(d) = \max(\min(r_{m'}(d) + \phi_m(d), e), s)$$

Thus, r is raised when d is correctly classified and lowered when it is misclassified, subject to the acceptable range. In this work, we set $[s, e] = [1, 5]$, following established practice (Reddy et al., 2016; Amiri et al., 2018).

2.3 Leitner-Guided Cross-lingual Experience Replay (*LER*)

We explore the use of $r(d)$ to determine whether or not to include d in $\mathcal{M}$. At the start of phase $\mathcal{P}_i$, by convention, for all $d \in \mathcal{D}_i \cup \mathcal{M}$, we set $r_\emptyset(d)$, the initial rating, to s. At the end of each epoch within the phase, we update r for each data item in $\mathcal{D}_i$ and $\mathcal{M}$ according to the model m at that point in training. At the end of $\mathcal{P}_i$, we use r values to form the new $\mathcal{M}$, selecting $\frac{|\mathcal{M}|}{i}$ items from $\mathcal{D}_i$ and $|\mathcal{M}| - \frac{|\mathcal{M}|}{i}$ items from the current $\mathcal{M}$ according to one of two strategies:

- *LER (Easy)*: Highest-rated items are prioritized.
- *LER (Hard)*: Lowest-rated items are prioritized.

Our approach, which selects data from $\mathcal{D}_i$ inversely proportional to i, enables the fixed and limited $\mathcal{M}$ to contain an even distribution of samples from all $\mathcal{D}_{<i}$ thus seen, militated by the relative learning difficulty of different phase datasets. Our approach is language-agnostic as we continue to rank the examples to keep in the memory regardless of their language and based solely on their degree of learnability.

3 Experimental Setup

We start by presenting the different baselines and model variants used to compare between different experimental scenarios (§3.1). We then describe the benchmark datasets and their base models (§3.2) along with the multilingual datastreams (§3.4) that we focus on in this evaluation. More implementation details, such as the hyperparameters, number of parameters used, and runtime for different models can be found in Appendix A.

3.1 Baselines & Model Variants

Baselines Before delving into different variants of Leitner-guided memory replay, we consider the following baselines:

- *No ER*. This is our lower-bound naive sequential fine-tuning baseline. This sequentially fine-tunes on datasets sampled from one language at a time $\mathcal{D}_i \in \mathcal{D}_{1\cdots N}$ without using any experience replay.
- *Balanced*. This is an experience replay approach adapted from Lopez-Paz and Ranzato (2017), which allocates equally sized buffers balanced across language. At the end of each phase $\mathcal{P}_i$, $|\mathcal{M}|/(N-1)$ examples are randomly picked from $\mathcal{D}_i$ and added to $\mathcal{M}$.
- *Random*. This is a more realistic experience replay approach, adapted from Riemer et al. (2019), which randomly samples and updates $|\mathcal{M}|$ from $\mathcal{D}_{<i}$ at the end of each phase $\mathcal{P}_i$.

Other techniques have been proposed to produce memory exemplars such as mean of features (Rebuffi et al., 2017), K-Means clustering (Chaudhry et al., 2019b), and prototypical networks (Ho et al., 2023). However, we don't explore those techniques since they either under-perform *Random* (reservoir sampling) (Chaudhry et al., 2019b) or their contribution severely depends on the order of training sets experimented with.

Model Variants We design the following model variants on top of *LER*. The research question we analyze here is: Does dynamically prioritizing easy elements help mitigate forgetting more than hard elements or vice versa? Our analysis evaluates the aggregated effectiveness of different strategies used for memory construction. This consists of *LER (Easy)* and *LER (Hard)*, which use easy and hard examples, in terms of their learnability, to fill and update the memory, respectively.

3.2 Benchmarks & Base Models

We conduct experiments on two datasets commonly used in natural language understanding literature, covering different typologically diverse languages and requiring different levels of reasoning: multilingual task-oriented dialog (*MTOD*) and multilingual question answering (*MQA*).

MTOD This is a multilingual goal-oriented system focusing on the natural language understanding module. This module consists of two subtasks, namely intent detection and slot filling. For *MTOD* evaluation, we use two multilingual task-oriented dialog datasets: *MTOP* (Li et al., 2021) and *MultiATIS++* (Xu et al., 2020). *MultiATIS++* covers 18 intents and 84 slots on average per language from one domain. *MTOP* covers 117 intents and 78 slots from 11 domains. We choose *MTOP* and *MultiATIS++* since they are among the large-scale datasets available for task-oriented dialog covering typologically diverse languages. We use the same architecture as in Castellucci et al. (2019) to jointly learn intent classification and slot-filling subtasks. M-BERT (Devlin et al., 2019) is used to encode each input sentence. On top of the $[CLS]$ representation of the sentence, we use a linear layer plus Softmax to predict its intent class. We use a sequence labeling layer in the form of a linear layer plus CRF (Lafferty et al., 2001) to predict slot labels in BIO annotation. We optimize jointly over the sum of intent and slot losses. For evaluation, we use accuracy and F1 scores to evaluate intent classification and slot filling, respectively.

MQA This is a multilingual span-based question-answering task that extracts the answer token span to a question given a defined context. To ensure a challenging and trustworthy evaluation for *MQA*, we choose TyDiQA (Clark et al., 2020), which is a translation-free realistic information-seeking benchmark. We follow the same pre-processing and architecture as in Hu et al. (2020). Specifically, we concatenate the input question (after prepending it with a $[CLS]$ token) and the context as a single packed sequence separated by a $[SEP]$ token and feed that to M-BERT. Then, the embeddings of the context are fed to a linear layer plus Softmax to compute the probability that each token in the context is the start or end token of the answer span. We optimize for the joint loss over the start and end tokens predictions. Complying with Hu et al. (2020) evaluation, we use F1-score macro-averaged over examples.

Table 1 shows the statistics per language and split for *MTOP*, *MultiATIS++*, and *TyDiQA* datasets.

Dataset	Language	Train	Dev	Test
MTOP	English	15,667	2235	4386
	German	13,424	1815	3549
	Hindi	11,330	2012	2789

	Telugu	5006	557	669

Table 1: Statistics of *MTOP*, *MultiATIS++*, and *TyDiQA* per language and split.

3.3 Evaluation Metrics

Our primary analytical tool is *forgetting*, which measures the degree to which a learned skill is lost when a model is trained on out-of-language data. Lower forgetting is better, while negative forgetting indicates the model has improved due to out-of-language training. We also show *final performance*, which is simply a metric's value after all phases of continual learning. We follow the same formulation of cross-lingual continual learning evaluation protocols as M'hamdi et al. (2023). Let R be some success metric for evaluating a task and $R_{i,\leq j}$ be the evaluation on the test set for language $\boldsymbol{\ell}_i$ fine-tuning on $\mathcal{D}_{\leq j}$. For a more succinct analysis of interference versus transfer tradeoff, we focus on the following two metrics:

- **Forgetting (F ↓).** We compute forgetting averaged *over* $\mathcal{D}_{2\ldots\leq N}$ as follows:

$$F = \frac{1}{N-1}\sum_{j=2}^{N} F_{\leq j},$$
$$F_{\leq j} = \frac{1}{j-1}\sum_{i=1}^{j-1} F_{i,\leq j}, \quad (1)$$

where $F_{\leq j}$ is the average forgetting that resulted at the point of training on $\mathcal{D}_j$. $F_{i,\leq j} = \max_{k\in[1,j-1]} R_{i,\leq k} - R_{i,\leq j}$. $F_{i,\leq j}$ is the degree to which performance on $\mathcal{D}_i$ has degraded by continuing to train on $\mathcal{D}_{\leq j}$ instead of stopping before including $\mathcal{D}_j$.

- **Final performance (FP ↑).** This is the final performance at the last phase $\mathcal{P}_N$ averaged over all datasets $\mathcal{D}_{\leq N}$:

$$FP = \frac{1}{N}\sum_{i=1}^{N} R_{i,\leq N}. \quad (2)$$

3.4 Datastreams

We design a balanced set of distinct language permutations, following the cross-lingual continual learning evaluation paradigm established by M'hamdi et al. (2023). Formally, for a given set of $N = 4$ languages, we sample a subset of N language permutations $P \subset \mathfrak{S}(\mathscr{L})$ where each language appears exactly once in each permutation. Table 2 shows the language permutations we consider for different downstream benchmarks. For example, the first permutation in *MTOP* is chosen such that the languages are ordered from high-resource to low-resource languages. The last permutation uses the opposite order. Then, we curate the two other permutations such that each language appears exactly once in each place across all permutations as if we are solving a 4x4 Sudoku. This ensures that our evaluation metrics are well-balanced when the average is taken over the 4 permutations taking into account the forgetting on different languages with equal contribution.

Dataset	#	Order
MTOP	1	English→German→Hindi→Thai
	2	German →English→Thai→Hindi
	3	Hindi→Thai→English→German
	4	Thai→Hindi→German→English
MultiATIS++	1	English→French→Turkish→Chinese
	2	French→English→Chinese→Turkish
	3	Turkish→Chinese→English→French
	4	Chinese→Turkish→French→English
TyDiQA	1	Russian→Indonesian→Telugu→Swahili
	2	Indonesian→Russian→Swahili→Telugu
	3	Telugu→Swahili→Russian→Indonesian
	4	Swahili→Telugu→Indonesian→Russian

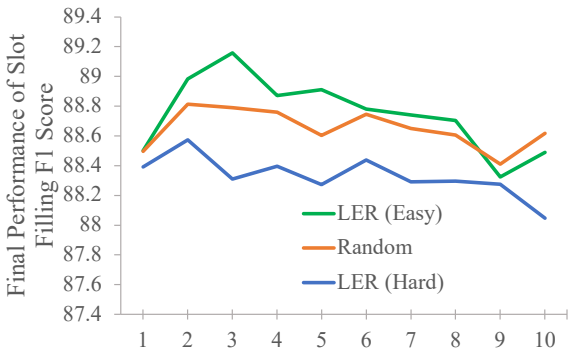
4 Results & Analysis

In this section, we provide an extensive analysis to demonstrate the effectiveness of our Leitner-guided cross-lingual experience replay approach. We present both a summary of the test performance based on the best epoch given Dev data split performance and over each epoch throughout different training stages (§4.1). Then, we present a more fine-grained analysis, shedding light on the language orders and languages for which our Leitner-based skill rating system is particularly helpful (§4.2). Last but not least, we present a qualitative analysis of different categories of skill ratings and what makes ruling out hard examples useful (§4.3).



4.1 Average Performance

In Table 3, we compare between different Leitner-guided memory selection strategies and baselines for *MTOP*, *MultiATIS++*, and *TyDiQA* benchmarks in terms of their forgetting. We start by showing their forgetting on the test data averaged over different language orders based on the best-performing model on the Dev data split. Compared to *No ER* baseline, all *ER* approaches: *Balanced*, *Random*, and *LER* variants are beneficial in reducing forgetting, irrespective of the strategy followed in memory storage and update. It is clear that the forgetting gap between *No ER* and *ER* approaches is more pronounced for *MTOP* and *MultiATIS++* tasks than it is for *TyDiQA*. We conjecture that this is due to the formulation of *TyDiQA* as a span-based question-answering task. The latter employs a simple token classification model, which is less challenging than joint optimization over classification and sequence modeling objectives in *MTOD*. The gains are even more pronounced for *MTOP*, whose ontology covers more domains, intents, and slots than that of single-domain *MultiATIS++*. Among *MTOP* subtasks, slot filling has a higher overall forgetting than intent detection. The implication of all of these findings is that forgetting is more pronounced, and our technique more crucial, when tasks are more difficult.

By keeping a balanced memory across languages, *Balanced* could have the benefit of making sure to revisit all languages assuming knowledge of the total number of languages involved in the continual learning. However, using a balanced memory across languages *Balanced* doesn't lead to lower forgetting than picking a random memory across languages *Random*. This could be because *Bal-*

(a) Average forgetting ↓.

(b) Average final performance ↑.

Figure 2: Average forgetting and final performance of slot filling for different model variants compared to the *Random* baseline averaged over different language orders. The lower the forgetting and the higher the final performance the better.

Approach	*MTOP*		*MultiATIS++*	*TyDiQA*
	Intent Accuracy ↓	Slot F1 ↓	Slot F1 ↓	F1 ↓
No ER	5.84	7.56	2.62	1.52
Balanced†	0.92	1.15	−0.63	0.92
Random‡	0.68	0.76	−0.56	**0.73**
LER (Easy)	**0.49**	**0.63**	**−0.73**	0.83
LER (Hard)	0.82	1.09	1.10	1.14

Table 3: Average Test forgetting scores based on the Dev data split performance of different models and baselines. We compare two Leitner-guided memory replay variants *LER (Easy)* and *LER (Hard)* to the baselines. Since no previous work on experience replay in the cross-lingual setup reports any forgetting results, we implement in addition to *No ER* our internal baselines: *Balanced* and *Random* adapted from †(Lopez-Paz and Ranzato, 2017) and ‡(Riemer et al., 2019), respectively. Best (lowest ↓) forgetting scores are highlighted in **bold** for each task and subtask.

anced picks a balanced amount of examples per language, exposing the model to less diversity compared to *Random*. This could also show the need to continuously update the diversity of memory to make room for higher-quality examples in continual learning. *LER (Easy)* stands out as one of the most successful strategies in reducing forgetting and beating both experience replay baselines. *LER (Easy)* reaches the lowest forgetting with reductions of 1.76, 0.64, and 0.46 in forgetting of F1 score for slot filling compared to *LER (Hard)*, *Balanced*, and *Random* respectively. Results on *MultiATIS++* and to some degree *TyDiQA* confirm the consistent superiority of *LER (Easy)* and the inferiority of the *LER (Hard)* approach.

For the remaining analysis, we focus on *MTOP*, shedding more light on the added value of *LER* approaches compared to the best-performing *ER* baseline, *Random*. Figures 2a and 2b show the learning curves of different models on slot filling in terms of forgetting and final performance, respectively. Throughout the training, *LER (Easy)* is consistently more effective than *Random* and *LER (Hard)* in minimizing forgetting while improving final performance, thus taming the interference versus transfer tradeoff. *LER (Easy)* can converge and stabilize at a low forgetting score earlier in training. On the other hand, the *LER (Hard)* strategy exacerbates the forgetting problem as training proceeds. This shows that replaying easy examples is consistently more effective than revisiting hard ones that the model is struggling with. Our Leitner-based skill rating system provides a dynamic measure that keeps selecting pertinent instances as language exemplars in constructing the memory replay.

4.2 Fine-grained Language Analysis

Figures 3 and 4 show a fine-grained analysis of forgetting between different models across different language orders and languages, respectively.[2] For each language order and language, we report Test results for the best-performing model based on Dev data split. Overall, we observe that *LER (Easy)* consistently outperforms *LER (Hard)* and *Random* across different language orders and languages. Certain language orders such as Thai→Hindi→German→English (4) and Hindi→Thai→English→German (3) have more forgetting than others. The languages that benefit the most compared to *Random* are Hindi and

[2]More results for other subtasks can be found in the Appendix B.

German whereas the gains for Thai and English are more minimal. *LER (Easy)* manages to bridge that gap in forgetting, keeping it within a low range.

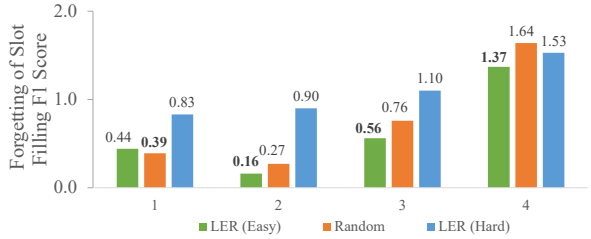


Figure 3: Fine-grained analysis of forgetting of slot filling over different language orders as defined in Table 2. Best (lowest) results for each language order are highlighted in **bold**.

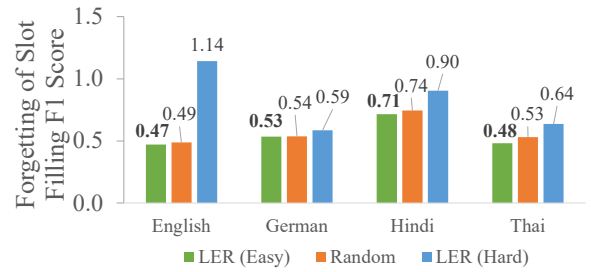

Figure 4: Fine-grained analysis of forgetting of slot filling over different languages. Best (lowest) results for each language are highlighted in **bold**.

4.3 Discussion

In this part, we conduct a qualitative analysis to complement our conclusion from our quantitative analysis that choosing training data for the memory that is easy to learn is more beneficial than choosing data that is not easily learned. To dig deeper into why ruling out harder examples from the memory is beneficial, we look more closely at the characteristics of those hard cases among training data. We define an *intractable* example as an example whose skill rating never gets promoted and stays 1 throughout training. At the other end of the spectrum is a *confident* example whose skill rating converges to 5 and never gets demoted after that.

In Figure 5, we report percentages of intractable and confident training data in *MTOP* for each language, averaged over all phases and language orders. We notice that for each language, 70% or more examples are confident. Thus, the *Random* approach to memory selection is unlikely to differ all that much from the *LER (Easy)* approach, at least in intent detection for *MTOP*. For other tasks with lower rates of easy examples, it might not be straightforward to pick easy examples with a random approach. We also observe a trend where the more high-resource the language is, the less likely its examples are intractable and the more likely its examples are confident. Thai, which has the highest percentage of intractable examples, is the most low-resource in *MTOP*. This explains why *LER (Easy)* is much more beneficial than *Random* for Thai and Hindi compared to English and German for intent classification in Figure 9 (Appendix B).

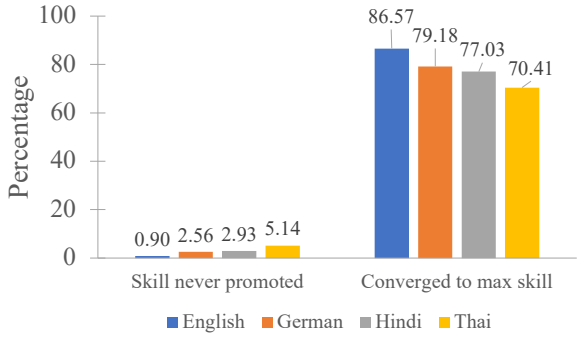

Figure 5: Percentages of examples that never get promoted past skill rating 1 (Skill never promoted) and those that converge to the maximum skill rating 5 (Converged to max skill) per language averaged over different language orders. More statistics on the proportion of different languages in the memory at the end of training using different approaches are shown in Appendix C.

As an exemplar, we focus now on English data, specifically concentrating on training data analysis from the end of the first phase in language order English→German→Hindi→Thai. To understand what makes an example particularly intractable, we define the following categories:

- **Low-resource (LR)**: A training instance is considered low-resource if the number of training instances per its intent label is below 10. For English, there are 137 training instances per intent on average. This makes low-resource labels fall within the 25% percentile.
- **Difficult to disambiguate (DD)**: This is the case if the true class is among the most similar to the predicted class. We let the $[CLS]$ token representation of a sentence be its representation. We then compute the centroid of the sentence representations per class label. For each label, we determine its most similar predicted classes based on the 5 nearest neighbors.
- **Poorly-defined (PD)**: Unlike low-resourced and difficult to disambiguate examples which are au-

Type	Utterance	True Class	Prediction Classes
LR	Put this song on repeat.	music:LOOP_MUSIC	music:REPLAY_MUSIC
	What is Tyler studying in school?	people:GET_MAJOR	people:GET_UNDERGRAD
	Merge another call with this one.	calling:MERGE_CALL	calling:END_CALL
DD	Did Jack get sentenced today?	news:GET_DETAILS_NEWS	news:QUESTION_NEWS
	How to make Arab tahini sauce?	recipes:GET_INFO_RECIPES	recipes:GET_RECIPES
	What time does the sun come up tomorrow?	weather:GET_SUNRISE	weather:GET_SUNSET
PD	Where does Kade work?	people:GET_LOCATION	people:GET_EMPLOYER
	Pause the current timer and delete.	timer:PAUSE_TIMER	timer:DELETE_TIMER
	Increase my timer to 30 minutes.	timer:CREATE_TIMER	timer:RESTART_TIMER

Table 4: Examples of intractable examples and their gold truth and prediction intent labels from each category.

tomatically determined by their labels, we inspect here case by case for poorly-defined sentences. We define a poorly-defined example as any sentence that doesn't make sense to be attributed to a certain label. This could be due to a mismatch or lack of commonsense in the way the ontology was defined for certain labels.

We show in Figure 6 some statistics of different categories of intractable examples. Most intractable examples are either DD, LR, or both. Inspecting confident examples reveals that no LR or DD examples are encountered among them. This demonstrates that our Leitner-guided approach *LER (Easy)* can detect such hard categories and rule them out. By imposing a more fine-grained skill rating system, our Leitner-guided memory replay approach provides a more confident approach to determine which labels the model is struggling with more than relying on prediction loss (Amiri et al., 2018). The skill rating system adds information that prediction loss alone does not. In fact, only 27% of the English examples that have skill ratings between 2 and 4 (neither intractable nor highly confident) are wrongly predicted at the end of the first phase. Those unstable examples are part of the selection of *LER (Hard)*, so not prioritizing such examples is beneficial.

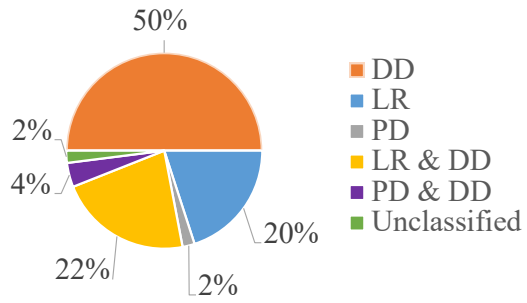

Figure 6: Distribution of different categories of intractable examples in the English data.

In Table 4, we provide some examples of different categories of wrongly predicted labels. We observe inconsistencies in those examples. Those that are specifically DD are so close to being picked as representative examples of certain classes, which can only confuse the learner. For example, while "Pause the current timer and delete." is supposed to be classified as *timer:PAUSE_TIMER*, this label is far from being comprehensively descriptive of the sentence intent. Its predicted label *timer:DELETE_TIMER* is not wrong either, as it detects the intent to delete, which is the second part of the example. We suspect that reinforcing the learning using difficult cases can only mislead the learner. In Figure 7, we show a t-SNE projection of the centroids of different intent label representations. We highlight in that figure the most common DD labels whose representations are indistinguishable in the vector space. Some of those labels like GET_STORIES_NEWS and GET_DETAILS_NEWS are to the human eye also DD, which could be an artifact of how the intent ontology was defined. Our Leitner-guided strategy *LER (Easy)* rules them out, favoring examples the learner is more confident about with class labels that correspond to more clearly separable representations.

5 Related Work

Continual learning work inspired by human-like learning falls into several categories. Notable categories include spaced-repetition (Smolen et al., 2016; Amiri et al., 2017; Amiri, 2019; Feng et al., 2019; Klasson et al., 2023), mechanisms of sleep (Ball et al., 2020; Mallya and Lazebnik, 2018; Schwarz et al., 2018), and reactivation of memories (Hayes et al., 2020; van de Ven et al., 2020). Leitner queues, one of the most famous spaced repetition techniques, started garnering attention for machine learning recently. However,

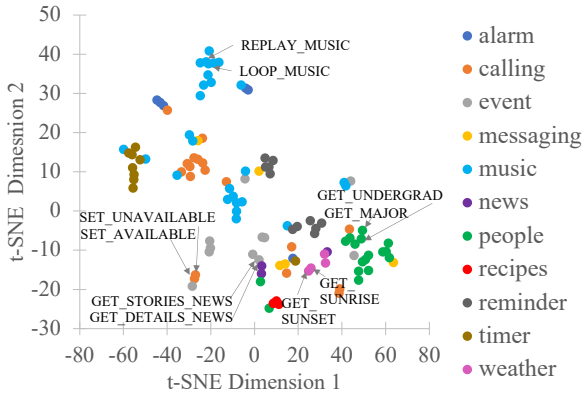

Figure 7: t-SNE visualization of centroids of different intent labels highlighting some ambiguous labels indistinguishable in the embedding space.

most of the work is focused on scheduling when to review data in non-continual learning setups. Amiri et al. (2017) show the sample efficiency of a human-inspired memory model to determine when to review each item as a function of the difficulty of the item and the strength of the network. Klasson et al. (2023) propose a Monte Carlo tree search approach for memory replay. More work (Amiri et al., 2018; Amiri, 2019) demonstrates the effectiveness of Leitner queues at determining spurious data and confident labels for self-training applications. Our work, by contrast, is the first to test for the effectiveness of Leitner queue-based skill ratings in mitigating forgetting in cross-lingual continual learning. Some studies, such as He et al. (2021), have looked into analyzing the forgetting problem from the perspective of knowledge transfer and context sensitivity from pre-training to fine-tuning. Fine-grained analyses such as Luo et al. (2023) look at different types of general knowledge in large language models that are saliently forgotten and at the role that model scale plays in forgetting. To the best of our knowledge, no previous work has analyzed forgetting in the cross-lingual continual learning context.

6 Conclusion

In this paper, we formulate a human-inspired experience replay approach specifically for cross-lingual continual learning. We propose a Leitner-based skill rating system to dynamically populate and update the memory with high-quality items. Our approach can deal with the stability-plasticity dilemma better than random selection, especially for complex tasks and consistently over languages and language orders. The implications of this analysis include a recipe for how to incorporate aspects of human learning in the design of memory replay in cross-lingual continual learning.

Limitations

Other Variants of Leitner Queues In this paper, we have focused on Leitner queues as an approach to guide the process of memory storage and update. In future work, other variants of Leitner queues or other approaches based on human learning theories could be explored. For example, more fine-grained approaches based on theories of how languages get forgotten to model the retention curve as a function of the task difficulty, review periods, and strength of the model could be investigated. This could help us understand how the process of forgetting works and when to schedule revisions accordingly to circumvent that.

Fine-grained Analysis of Task Difficulty In this paper, we evaluate on a representative set of natural language understanding tasks. We prove that our approach benefits challenging tasks more consistently. However, we don't closely investigate if there is a correlation between the difficulty of a task and the effectiveness of our Leitner-based skill rating approach on it. For such an analysis to be possible, we need a principled way to define what makes a task more difficult naturally or to simulate that synthetically. We leave a systematic fine-grained analysis over more downstream tasks ranging in difficulty for future work.

Other Scenarios of Cross-lingual Continual Learning Given the myriad ways to define realistic setups, the endeavor of defining a more principled realistic model of annotation scenario, following some logic or pattern, warrants its own dedicated investigation. In this study, we chose to focus on a common realistic scenario encountered by many users: a model is used by a user in one language, and then later on, the user experiences the need to incorporate more languages one at a time. Aside from being an extreme adaptation case and thus a useful stress test of our technique, a realistic language phase scenario would be a company's strategic decision to enter into a new language/market due to an influx of customer data. While exploring broader scenarios of continual learning — where each phase may entail training on multiple languages repeatedly — holds

potential, such exploration lies beyond the scope of this study.

Experimenting with Other Language Orders In this work, we experiment with a carefully curated and balanced set of language orders. In future work, it would be worth investigating the extent to which models forget when using other possible language orders. It is also not clear if there is a deterministic linguistic or non-linguistic factor that can make a particular language order languages more susceptible to forgetting than others. Hence, a meticulous and comprehensive analysis needs to be conducted to unravel the intricacies of the phenomenon of forgetting and its underlying triggers in the context of cross-lingual continual learning.

Experimenting with Memory Scale To ensure a consistent comparison between different models, we maintain a fixed memory size per benchmark throughout our analysis. Naturally, as the memory size grows, we anticipate the need to be discriminative in memory selection to be diminished. Specifically, since most examples are not intractable (not difficult to learn), a larger memory capacity increases the likelihood of a random approach selecting higher-quality, well-learned examples. Conversely, we anticipate that experimenting with even smaller memory budgets may not yield optimal results, as there must be adequate memory size for the experience replay approach to significantly outperform the vanilla baseline. In future work, interested readers can explore more low-resource and sample-efficient approaches, such as meta-learning, on top of our approach.

A Implementation Details

We specify below more implementation details, such as hyperparameters and datasets, in addition to the runtime and number of parameters of different models.

A.1 Hyperparameters

For all experiments, we use M-BERT (bert-base-multilingual-cased)[3] with 12 layers as our pre-trained multilingual Transformer-based encoder model. Consistent with M'hamdi et al. (2023) and Hu et al. (2020) for *MTOP* and *TyDiQA*, respectively, we use the Adam optimizer (Kingma and Ba, 2015), fixing the learning rate to $3e-5$ for all experiments for a fair comparison. M'hamdi et al. (2023) perform a manual hyperparameter search over the range $[1 \times 10^{-4}, 3 \times 10^{-4}, 1 \times 10^{-5}, 3 \times 10^{-5}]$ to choose the most optimal learning rate based on Dev data split performance. For *TyDiQA*, those hyperparameters are chosen based on Hu et al. (2020). For *MultiATIS++*, we perform a manual search over the same learning rates range and find that 3×10^{-5} performs comparably to other learning rates. So, we fix a learning rate of 3×10^{-5}, $\epsilon = 1 \times 10^{-8}$, $\beta_1 = 0.9$, $\beta_2 = 0.99$ in the optimizer for a fair comparison for all experiments. For *TyDiQA* experiments, we find it helpful when a scheduler with linear decaying learning rates is used. We use batch sizes of 4, 16, and 4 for *MTOP*, *MultiATIS++*, and

[3] github.com/huggingface/transformers version 3.4.0 pre-trained on 104 languages, including all languages covered in our evaluation.

TyDiQA, respectively. In all baseline models *Balanced* and *Random* and Leitner-guided *ER* (*LER*) model variants, we choose a fixed memory proportion to 20% of the training data from each benchmark. Based on that, we fix $|\mathcal{M}|$ memory size to 10,105, 500, and 500 for all *MTOP*, *MultiATIS++*, and *TyDiQA* experiments, respectively. We also fix the sampling frequency from the memory to every 10 minibatches. For all experiments, we run for 10 epochs maximum and pick the best model based on Dev data split. We use the same seed across all experiments to report the mean results. We also fix a seed of 42 for the random initialization of Numpy, Random, and Torch libraries over all experiments. All experiments are run on the same computing infrastructure using 1 NVIDIA A40 GPU of 46,068 MiB of memory CUDA version 11.6 and Pytorch version 1.13.1.

A.2 Dataset License

MTOP dataset has been released by Facebook under Creative Commons Attribution-ShareAlike 4.0 International Public License. *MultiATIS++* and *TyDiQA* datasets have been released under the Apache License, which allows the use, modification, and distribution of the dataset.

A.3 Runtime

We show in Table 5 the runtime of different approaches and baselines for one single language order on *MTOP*. This runtime includes both the costs of training and evaluation. Our *LER* only incurs 3 hours more than *No ER* approach, with most of it spent calculating the skill rating at the end of each epoch.

Model	Total Runtime
No ER	6 hrs 23 min 20 sec
Balanced	6 hrs 45 min 22 sec
Random	6 hrs 25 min 25 sec
LER(easy/hard)	9 hrs 23 min 13 sec

Table 5: Fine-grained runtime analysis per model for one single language order on *MTOP*.

Table 6 compares between the number of parameters of models used for different downstream benchmarks. Task-oriented dialog benchmarks (*MTOP* and *MultiATIS++*) require more parameters and thus are more challenging compared to span-based question answering (*TyDiQA*).

Model	# Parameters
MTOP	178,081,402
MultiATIS++	178,036,139
TyDiQA	177,264,386

Table 6: Fine-grained parameter analysis per benchmark.

B More Results

Figures 8 and 9 show a fine-grained analysis of the forgetting of intent classification over different language orders and languages, respectively.

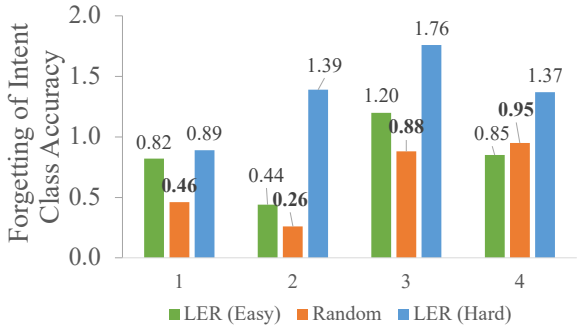

Figure 8: Fine-grained analysis of forgetting of intent classification over different language orders as defined in Table 2. Best (lowest) results for each language order are highlighted in **bold**.

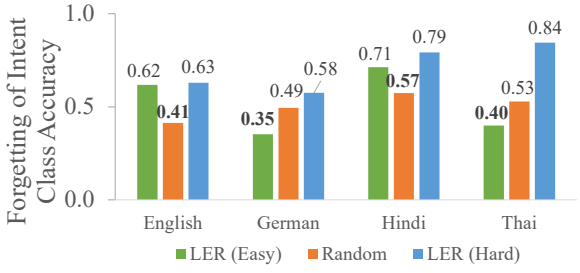

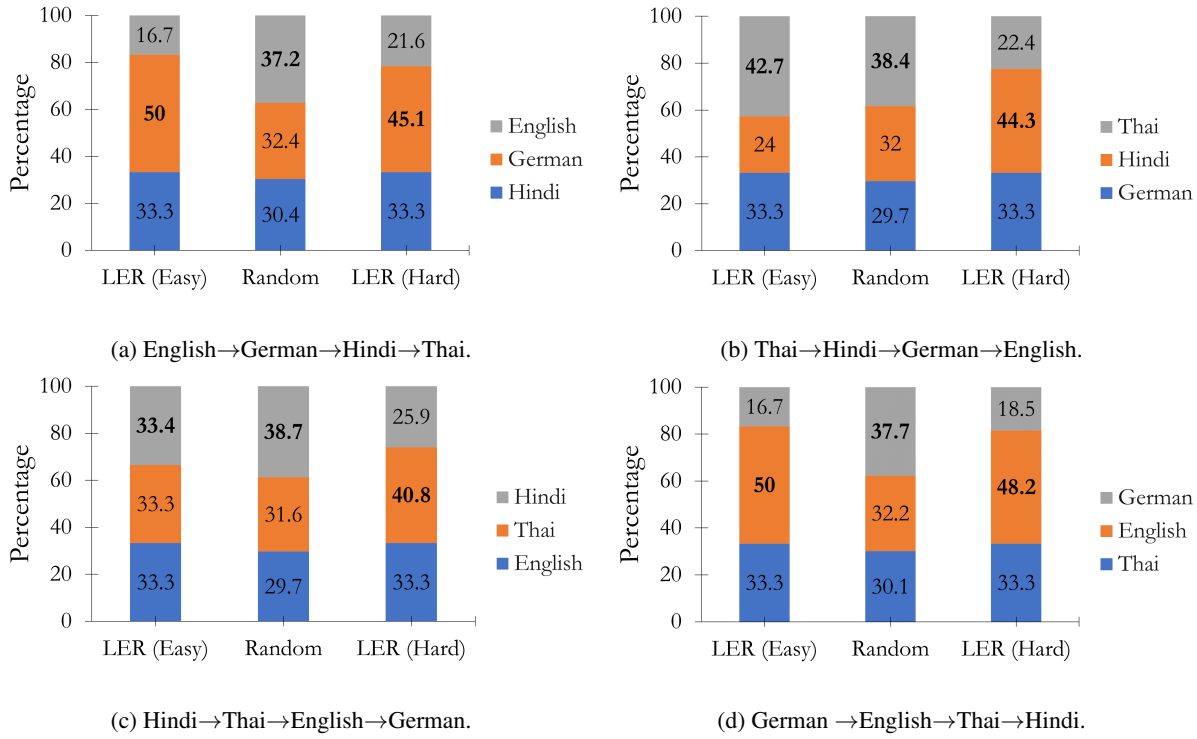

Figure 9: Fine-grained analysis of forgetting of intent classification over different languages. Best (lowest) results for each language are highlighted in **bold**.

C Proportion of Memory per Language

Figure 10 shows a fine-grained analysis of the language distribution of the memory at the last phase after training for each language order in *MTOP*. We compare between different distributions using Leitner queues approaches against the random approach. While *Random* maintains a close to uniform per language distribution in different language orders, *LER (Easy)* and *LER (Hard)* make informed decisions of which proportions to pick from each language depending on its learnability.

Abstract

We introduce SPUD (Semantically Perturbed Universal Dependencies), a framework for creating nonce treebanks for the multilingual Universal Dependencies (UD) corpora. SPUD data satisfies syntactic argument structure, provides syntactic annotations, and ensures grammaticality via language-specific rules. We create nonce data in Arabic, English, French, German, and Russian, and demonstrate two use cases of SPUD treebanks. First, we investigate the effect of nonce data on word co-occurrence statistics, as measured by perplexity scores of autoregressive (ALM) and masked language models (MLM). We find that ALM scores are significantly more affected by nonce data than MLM scores. Second, we show how nonce data affects the performance of syntactic dependency probes. We replicate the findings of Müller-Eberstein et al. (2022) on nonce test data and show that the performance declines on both MLMs and ALMs wrt. original test data. However, a majority of the performance is kept, suggesting that the probe indeed learns syntax independently from semantics.[1]

1 Introduction

An ample amount of work in the last years has focused on making explicit the linguistic information encoded in language models (LMs). Frequently, the overarching question is to which extent the behavioral and representational properties of self-supervised LMs are cognitively plausible and assumed by linguistic theory (surveys: Linzen and Baroni, 2021; Mahowald et al., 2023; Chang and Bergen, 2023). A subset of this work aimed at understanding LMs ability to learn syntax (survey: Kulmizev and Nivre, 2022, examples: Hewitt and Manning, 2019; Manning et al., 2020; Tenney et al., 2019; Newman et al., 2021). A common approach is to rely on the performance of a probing classifier (Hupkes et al., 2018; Kunz and Kuhlmann, 2020, 2021) in predicting syntactic relations. However, this method has been criticized for various reasons (Belinkov, 2022), including that predicting a linguistic property from LM representations does not imply that the LM uses that property in its predictions (Lyu et al., 2024). Maudslay and Cotterell (2021) highlighted that results of syntactic probes can be misleading due to semantic information in the representation. In other words, a high probing accuracy may be fully or partially attributed to the use of present semantic knowledge.

The theoretical linguistic literature has discussed the separation of syntactic grammaticality and semantic information for decades, starting with the sentence *Colorless green ideas sleep furiously* in Chomsky (1957). A number of studies have used systematically perturbed data to probe LM representations and predictions on such grammatical but nonsensical sentences (Gulordava et al., 2018; Maudslay and Cotterell, 2021; Arps et al., 2022). However, none of the works ensures that the nonce data is grammatical, e.g. in their datasets, the valency of predicates is not controlled. Furthermore, only Gulordava et al. (2018) base their conclusions on languages beyond English.

In this paper, we aim to standardize the efforts in this direction by proposing a framework to create nonce data that satisfies syntactic argument structure, provides syntactic annotations, and ensures grammaticality via language-specific rules. The framework relies on Universal Dependencies (UD, de Marneffe et al., 2021) treebanks. For each sentence in the treebank, it replaces content words with other content words that are known to appear in the same syntactic context. This results in nonce sentences that preserve the syntactic structure of the original sentences (see Fig. 1). To ensure syntactic grammaticality, we define three types of language-specific rules and constraints that are applied during the process, which are: (i) the POS tag of the words

to be replaced, (ii) constraints on word order and dependency relations of replaced words to ensure syntactic grammaticality, and (iii) word-level rules to ensure that morphosyntactic constraints are met. We refer to this algorithm and the resulting UD data as *Semantically Perturbed UD* (SPUD).

We create SPUD data for five widely spoken languages; Arabic, English, French, German, and Russian. We show via a human evlation that SPUD is preferrable in terms of grammaticality to the kind of nonce data that has been previously used in the literature to tackle similar research questions. We show the effectiveness of SPUD on two tasks to assess the robustness of autoregressive LMs (ALMs) and masked LMs (MLMs) to semantic perturbations. First, we study the effect of nonce data on LM scoring functions (perplexity and its adaptations for MLMs). Second, we investigate the robustness of syntactic dependency probes to semantic irregularities, and disentangle the effect of lexical semantic features on the findings of previous work. The contributions and main findings of our work are as follows:

- We introduce SPUD, a framework for creating nonce treebanks for UD corpora that ensures syntactic grammaticality, and provide nonce treebanks for 5 languages (Arabic, English, French, German, Russian).
- We show the effectiveness of the proposed data log-likelihood scoring of different language model architectures, and on the performance of syntactic dependency probes.
- We show that ALM perplexity is significantly more affected by nonce data than two formulations of MLM pseudo-perplexity, and that for MLMs, the availability of subword information affects pseudo-perplexity scores on both natural and SPUD data.
- In structural probing for dependency trees, we show that ALM performance decreases more than MLM performance on SPUD, and that this performance drop is more pronounced for edge attachment than relation labeling.

The paper is structured as follows. In the next section, we discuss related work. In Sec. 3, we describe the framework for creating nonce UD treebanks. Sec. 4 describes the experiment on scoring nonce data with perplexity. In Sec. 5, we describe the structural probing experiments. In Sec. 6, we discuss the results and conclude.

2 Related Work

Automatically modified Dependency Trees The idea to replace words and subtrees based on dependency structure has been used for data augmentation in various areas of NLP, in particular for low-resource dependency parsing. Dehouck and Gómez-Rodríguez (2020) proposed an idea similar to ours, with the differences that (i) they swap subtrees instead of content words resulting in generated sentences with altered syntactic structure, and (ii) their constraints on possible replacements are language-agnostic. Şahin and Steedman (2018) cut subtrees based on their dependency relation, and modified treebanks by changing the order of annotated dependency subtrees. Vania et al. (2019) demonstrated the effectiveness of Şahin and Steedman (2018)'s algorithm as well as nonce treebanks for low-resource dependency parsing. However, their method lacked language-specific constraints and did not rely on dependency edges to dependents. Nagy et al. (2023) apply a similar method for low-resource machine translation. Wang and Eisner (2016) permuted dependents within a single tree to generate synthetic treebanks with lexical contents from one language and word order properties of another language.

Structural Probing DepProbe (Müller-Eberstein et al., 2022) decodes labeled and directed dependency trees from LM representations. With DepProbe, Müller-Eberstein et al. (2022) probed mBERT (Devlin et al., 2019) on 13 languages, and showed that the probe performance is predictive of parsing performance after finetuning the LM. Prior to that, similar probes have been applied to unlabeled (Kulmizev et al., 2020) as well as unlabeled and undirected dependency trees (Hewitt and Manning, 2019; Chi et al., 2020). Eisape et al. (2022) used Hewitt and Manning (2019)'s method

to probe GPT-2 (Radford et al., 2019).

Syntactic and Semantic Information in LMs Gulordava et al. (2018) performed targeted syntactic evaluation (TSE; Marvin and Linzen, 2018) on ALMs in four languages and investigated the effect of nonce data that considers POS tags and morphological features for replacements. Lasri et al. (2022a) investigated the effect of nonce data for TSE in BERT and found that BERT correctly predicts number agreement for nonce sentences only in simple syntactic templates. Maudslay and Cotterell (2021) investigated the effect of *Jabberwocky words* (such as *provicated*) on syntactic probes. Ravfogel et al. (2020) found a transformation of LM representations that highlights structural properties. Arps et al. (2022) used a similar algorithm as ours to create nonce versions of the English PTB (Marcus et al., 1993), and probed the syntactic information in hidden representations of four MLMs. The main difference to SPUD is that they do not restrict replacements to content words, and do not apply language-specific processing steps. Therefore their nonce data is more likely to be ungrammatical. Sinha et al. (2021) tested to which extent MLMs rely on word order vs. higher-order cooccurence statistics. They found that word order is not needed to achieve high performance on many NLP tasks. Papadimitriou et al. (2022) probed the relevance of word order and semantic prototypicality for classifying grammatical roles with BERT. Lasri et al. (2022b) compared BERT and human judgments on the subject-verb agreement task for nonce data and found that, while the error patterns of both are similar, BERT has a generally higher performance drop for nonce data than humans. Kauf et al. (2023) explored the interaction of syntactic and semantic information with similarity between LMs and human fMRI signals, and show that lexical semantic content - not syntactic structure - is the main driver of similarity in both LM and human representations.

Scoring Functions for LMs The likelihood of sentences assigned by an LM is often used to investigate the model's preference for grammatical sentences (Kulmizev and Nivre, 2022; Warstadt et al., 2020). Perplexity (PPL) is a common metric to score the likelihood of a sentence with ALMs. For MLMs, estimating the likelihood of a given sentence in a fashion that is useful for applications is not as trivial. Salazar et al. (2020) formalized pseudo-perplexity ($PPPL$) as a scoring function for MLMs: Each token in a sentence is masked in turn, and $PPPL$ is computed as a function of the MLM's probability of the masked tokens. Kauf and Ivanova (2023) showed that $PPPL$ systematically inflates scores for multi-token words, and proposed $PPPL_{l2r}$, a subword-aware alternative that is more robust to this effect. Miaschi et al. (2021) trained classifiers on different linguistic features to predict the PPL of GPT-2 and $PPPL$ of BERT. They find that GPT-2 scores are generally better predictable by their set of features than BERT scores, and that lexical features are more important for GPT-2 than for BERT.

3 Nonce Treebanks for Five Languages

This section presents SPUD (*Semantically Perturbed Universal Dependencies*), our framework for nonce data creation. The input is a UD treebank, and the output is a treebank with the same syntactic structure as the input but nonce semantic content. In principle, the same algorithm is applied in any language, but each language requires a set of language-specific pre- and post-processing steps (Sec. 3.1). In this work, we create nonce data for five languages and treebanks: Arabic (PADT, Hajic et al., 2009), German (HDT, Borges Völker et al., 2019), English (EWT, Silveira et al., 2014), French (GSD, Guillaume et al., 2019), and Russian (SynTagRus, Droganova et al., 2018). Fig. 1 presents one example. More examples and information on the resources are in App. A. To apply the framework to a new language, an annotated UD treebank and access to a native speaker in the target language are required. Along with this paper, we publish a tutorial for creating SPUD treebanks in other languages.

3.1 Generating Nonce Data

Language-independent algorithm The procedure consists of iteratively replacing content words with other words that appear in the same syntactic context at another point in the treebank. We consider words with POS tags ADJ, ADV, NOUN, PROPN and VERB as content words. The syntactic context of a token t is defined as (i) the UPOS tag of t, (ii) the dependency relation of t to its head, and (iii) the dependency relations of t to its dependents. This syntactic context is collected for every lemma. Then, the nonce trees are created by replacing content words with other words where the lemma appeared in the same syntactic context. The morphological features of t, as annotated in

UD, are considered to determine the right form for a replacement. For this step, the morphological databases UDLexicon (Sagot, 2018) and Wiktextract (Ylonen, 2022) are used. Fig. 1 presents an example (without morphosyntactic features).

Language-specific modifications are necessary to ensure that the data meets the criterion of being morphosyntactically correct. For instance, if the first sound of the word following an English indefinite article changes from a vowel to a consonant or vice versa, the article is adjusted with the help of a phonological dictionary. E.g. when replacing *apple* in *an apple* with *bicyle*, the result is *a bicycle* and not **an bicycle*. We refer to App. A for details on the language-specific modifications.

Quality of the generated data To determine the sufficiency of the language specific rules, we asked linguistically trained native speakers of the respective languages to provide feedback on how well the nonce sentences match the desired criteria. The annotators received samples of at least 100 sentence pairs. Over 2-3 iterations, annotators pointed out problems in the generated data, which we then addressed by modifying the language-specific rules.

Human evaluation We conduct a human evaluation to estimate the benefits of using SPUD over the algorithm presented by Gulordava et al. (2018), which does not incorporate information about syntactic dependencies or language-specific rules. For this evaluation, human annotators were presented with sentence triplets, each consisting of an original sentence from the treebank, a nonce version of that sentence generated by SPUD, and a nonce version generated by the algorithm of Gulordava et al. (2018). The two nonce sentences were presented in random order, without indication of their source. Annotators rated for each sentence whether it was grammatical, and which of the two nonce sentences was syntactically closer to the original. One annotator rated 30 French sentence triplets, and two annotators rated 39 English and 153 German sentence triplets. All triplets where selected randomly from the corresponding treebanks. Annotators had the option to indicate that they were unsure, or that the two nonce sentences were equally close to the original. We find that SPUD is rated grammatical more frequently than the algorithm of Gulordava et al. (2018) in all three languages, and by all annotators (Tab. 1). Concretely, up to 87% of the SPUD sentences are rated grammatical, compared to only up to 38% of the sentences generated by the algorithm from Gulordava et al. (2018). Inter-annotator agreement on grammaticality judgments is moderate, with Cohen's Kappa of .51 (en) and 0.58 (de). SPUD is also preferred in the majority of cases, with some "equal" ratings (Tab. 2). We conclude that, while the scale of this experiment is limited, the results suggest that the quality of the sentences generated by SPUD is higher than that of the algorithm of Gulordava et al. (2018), which has been used previously to interpret the behavior of LMs.

4 Scoring SPUD with ALMs and MLMs

The SPUD treebanks are designed to be grammatical but highly improbable. In this section, we investigate how this property is reflected in the predictions of different LM architectures. On the one hand, this serves as a sanity check for SPUD resources: Do we in fact perturb co-occurrence statistics of words as intended? On the other hand, at a higher level, it investigates whether SPUD data makes the models perplexed and how different LM architectures, and uni- vs. bidirectional context, influence the effect that syntactic and semantic structure has on model predictions. Concretely, we answer the following questions: To what extent is SPUD data harder to predict than original data? Are ALMs and MLMs affected by SPUD data in different ways? Are MLM scoring functions affected differently by nonce data?

4.1 Scoring Functions for LMs

App. E.1 shows examples for all scoring functions.

ALMs: Perplexity (PPL) of a sentence $x = (x_1, \ldots, x_n)$ is commonly defined as the exponentiated average of the negative sum of log probabilities for all tokens x_i. The lower the perplexity, the higher the probability of x for the model.

$$PPL(x) = exp(-\frac{1}{n}\sum_{i=0}^{n} \log p(x_i|x_{<i})) \quad (1)$$

MLMs: Pseudo-Perplexity ($PPPL$) is designed to capture the likelihood that an MLM assigns to a sequence (Salazar et al., 2020). It is calculated by processing the input n times, masking each token x_i exactly once. $PPPL(x)$ is defined via the sum of log probabilities that the LM assigns

		SPUD			Gulordava et al. (2018)			
	Sentences	yes	no	unsure	yes	no	unsure	\kappa
de	153	72.5	27.5	0	9.5	90.5	0	0.58
en	39	78.2	19.2	2.6	35.9	60.3	3.8	0.51
fr	30	86.7	13.3	0	0	100	0	

Table 1: Results for Grammaticality judgments. For German and English, the mean between the two annotators is presented. Grammaticality judgments were also made for the original sentences, which were almost always rated grammatical. They are not included in the figure and in the inter-annotator agreement calculations.

	Equal	SPUD	Gulordava et al. (2018)	unsure	κ
de	13.7	81.0	4.2	1.0	0.17
en	20.5	70.5	1.3	7.7	0.09
fr	13.3	86.7	0.0	0.0	

Table 2: Results for Preference judgments. For German and English, the mean between the two annotators is presented. While Cohen's κ is low, per item agreement is higher (.56 for en, .73 for de).

to the masked x_i:

$$PPPL(x) = exp(-\frac{1}{n}\sum_{i=0}^{n}\log p(x_i|x_{\setminus i})) \quad (2)$$

MLMs: $PPPL$ with subword generation Kauf and Ivanova (2023) proposed $PPPL_{l2r}$, a variant of $PPPL$ that is more aligned with PPL for ALMs. The idea is to consider the groupings of tokens to words, and predict subword tokens without conditioning on succeeding tokens. Let $\omega_r(x_i)$ denote the tokens that are in the same word as x_i, including and succeeding x_i. For example, when tokenizing *accordeon* as *accord, ##eon*, it holds that $\omega_r(\text{accord}) = \{\text{accord, ##eon}\}$. Then, tokens $\omega_r(x_i)$ from the right context within the same word are masked out when predicting the token x_i:

$$PPPL_{l2r}(x) = exp(-\frac{1}{n}\sum_{i=1}^{n}\log p(x_i|x_{\setminus\omega_r(x_i)})) \quad (3)$$

Evaluating Scoring Functions on SPUD When comparing scores across sentences, the variance is very high: Some sentences are far more likely than others, irrespective of the language or whether they are nonce. Thus, we use the ratio between sentence-level scores of a pair of original and corresponding SPUD sentence (s_{orig}, s_{nonce}). For a scoring function $f \in \{PPL, PPPL, PPPL_{l2r}\}$, we define the ratio as $r_f(s_{orig}, s_{nonce}) = \frac{f(s_{nonce})}{f(s_{orig})}$ and then investigate the distribution of r_f for all sentence pairs in a corpus.

4.2 Hypotheses

Hypothesis 1: *LMs assign a higher score to* SPUD *data than to original data* - the content words are chosen at random, and therefore should be much harder to predict than the original words.

Hypothesis 2: *ALMs and MLMs are impacted by* SPUD *data in different ways.* Bidirectional context determines the syntactic properties of a predicted token to a larger degree than unidirectional context. Therefore, the space of probable predictions is smaller for MLMs than for ALMs, and we expect that the impact of SPUD data on ALM perplexity should be higher than on MLM pseudo-perplexity.

Hypothesis 3: *For* SPUD, $r_{PPPL_{l2r}}$ *are higher than* r_{PPPL} because nonce words are hard to predict based on context from surrounding words, but easy to predict based on context from the same word.

4.3 Experimental Setup

We adapt Kauf and Ivanova (2023)'s implementation to retrieve token-level scores for all sentences in the SPUD and original data. We compare results for mBERT (Devlin et al., 2019) as an MLM and mGPT (Shliazhko et al., 2024) as an ALM. We report the scoring results of only one instance of SPUD data per sentence. We argue that this is sufficient to draw conclusions about the general behavior of the models, since we conduct the experiment on a large number of sentences, and different languages.

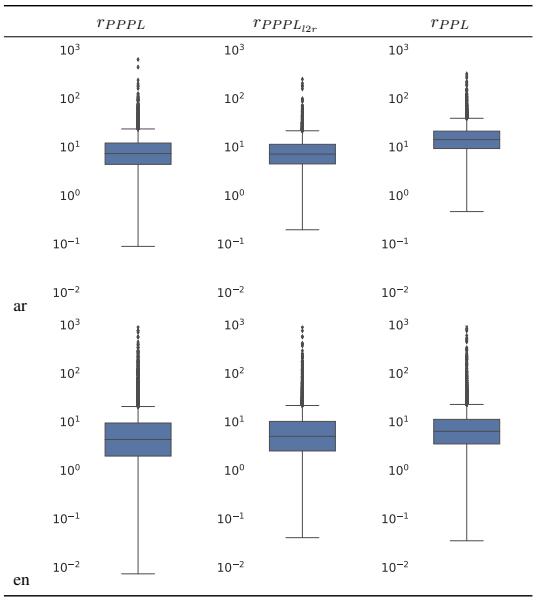

Figure 2: Intrinsic evaluation results for English and Arabic. Plots for other languages are in App. E.2.

4.4 Results

Is SPUD data harder to predict than original data? To test Hypothesis 1, we check the distribution of score ratios r_f for all scoring functions f. The results for mBERT and mGPT are shown in Fig. 2 and show that for all settings, the first quartile is larger than 1, i.e. the score of SPUD sentences is higher than that of original sentences for the vast majority of the data. This means that SPUD data receives lower likelihood than original data and is therefore harder to predict, as expected.

Are scoring functions affected differently by nonce data? To answer this question, we compare the distributions of score ratios for all scoring functions, as displayed in Fig. 2. This question is answered in two parts, and both parts hold irrespective of whether outliers with $r_f > 250$ are taken into account or not. First, we test Hypothesis 2 by comparing the distributions of score ratios for ALMs and MLMs. Here, the picture is clear: r_{PPL} are significantly higher than both $r_{PPPL_{l2r}}$ and r_{PPPL}, measured with a Wilcoxon signed-rank test. This result, and all following results, are significant at $p \ll 0.001$. Second, we test Hypothesis 3 by comparing the MLM scoring functions $r_{PPPL_{l2r}}$ and r_{PPPL}. Here, the picture is less clear: All ratios are significantly different from each other according to the same test, but $f_{PPPL_{l2r}}$ has slightly lower quartiles than r_{PPPL} for Arabic (in all other languages, the opposite is true). This means that for all languages except Arabic, $PPPL$ is less affected by SPUD data than $PPPL_{l2r}$.

Differences across languages and models The same trends were tested for monolingual Arabic and English models. The results are presented in App. E.2. In all monolingual settings, SPUD data is harder to predict than original data (all first quartiles of ratio distributions are larger than 1). For differences between ratio predictions, the picture is more mixed: Regarding the difference between ALMs and MLMs, Arabic AraGPT2 (Antoun et al., 2021) shows higher ratio quartiles for PPL than the MLM scoring functions of AraBERT (Antoun et al., 2020). For English, the MLM scoring functions of RoBERTa (Liu et al., 2019) are significantly higher than PPL of GPT-2 (Radford et al., 2019). Regarding the difference between $PPPL$ and $PPPL_{l2r}$, the picture is the same as for multilingual models: For English, $PPPL_{l2r}$ is significantly higher than $PPPL$, and for Arabic, the opposite is true.

4.5 Interim Summary and Discussion

There are three main takeaways from this experiment. First, we find (as expected) that SPUD is harder to predict than original data in all settings. Second, the ALM perplexity and two MLM scoring functions respond differently to SPUD data: mBERT is affected less than mGPT, and within mBERT, $PPPL_{l2r}$ is affected more than $PPPL$ for all languages except Arabic (because of the availability of subword context). For monolingual models, we see a more mixed picture where for English, ALMs are affected less by SPUD data than MLMs, and for Arabic, the trend that $PPPL_{l2r}$ is affected more than $PPPL$ is consistent. These results suggest on one hand a special role of the Arabic language, and on the other hand point to the possibility that these differences are not systematic properties of model architectures and scoring functions, but rather depend on the training data and tokenization. However, as a general trend, we can hypothesize from the comparison between $PPPL$ and $PPPL_{l2r}$ that the inflated scores for multi-token words that Kauf and Ivanova (2023) found for $PPPL$ are carried over to SPUD data: If $PPPL$ increases less than $PPPL_{l2r}$ for nonce data, this means that the increase in $PPPL$ is cushioned by the high predictability of multi-token words in $PPPL$. We measure the lexical diversity of SPUD in App. D. For all languages, Type-Token-Ratio (TTR) decreases.

This means that all our findings hold even though SPUD is less lexically diverse than natural data.

5 Nonce Dependency Probing

In this section, we measure the efficacy of SPUD in decoding the syntactic knowledge learned in LM representations. Concretely, we train DepProbe structural probes (Müller-Eberstein et al., 2022) and compare the performance on the standard (original) UD test sets with performance on SPUD test sets. We choose DepProbe because none of its alternatives produces both directed and labeled dependency trees. We investigate to which extent DepProbe performance is influenced by lexical semantics rather than its desired task of predicting purely syntactic properties. With the assumption from previous work (Sec. 2) that a certain drop in performance on nonce test data is expected, we answer the following research questions:

RQ1: *Is MLM and ALM performance affected differently when tested on* SPUD *data?*

RQ2: *Are the predictions of dependencies between tokens (edges) and dependency relations (edge labels) affected differently by* SPUD *data?*

We answer these questions on all five languages, and present additional experiments to improve the robustness of our findings.

5.1 Probing Model

Müller-Eberstein et al. (2022) presented DepProbe, a lightweight decoder for directed and labeled dependency trees. The model consists of two learnt linear transformations of the LM representations. Both transform d_h-dimensional word representations into vectors that highlight a feature of the dependency tree. L is a sequence labeling classifier that predicts for each word the label of the incoming dependency edge. $B \in \mathbb{R}^{d_h \times b}$ projects the LM representation in a *syntactic subspace* with $b < d_h$, where word vector distances mimic the distance between words in the tree. The dependency tree is constructed in a top-down fashion from both components, selecting the word as root to which L assigns the highest probability of being the root. Details are provided in App. F.1.

5.2 Experimental setup

Metrics We report the same metrics as Müller-Eberstein et al. (2022), all of which are commonly used in the dependency parsing and probing literature. RelAcc is the percentage of tokens for which the relation label of the incoming edge is correctly predicted, UAS (unlabeled attachment score) is the percentage of tokens for which the head token is correctly predicted, and LAS (labeled attachment score) is the conjunction of RelAcc and UAS.

Hyperparameters All probe hyperparameters were taken from Müller-Eberstein et al. (2022) in order to replicate their results. For all models, the dimensionality of the syntactic subspace is $b = 128$. We take the hidden representations of layers 6 (7) as input to DepProbe's distance (relation) component for all twelve-layered models. Müller-Eberstein et al. (2022) trained probes on English data for all layers of mBERT and chose the best-performing layer for each component. We repeated this experiment to determine the best-performing layer for the 24-layered mGPT (App. F.6), and found that layer 12 performs best for both components.

Baselines We use three baselines to ensure that the syntactic information we probe for is (i) contextual in nature rather than dependent on word types, and (ii) learnt during LM pretraining rather than by the probe. To estimate how much information about the probing task is contained in (context-insensitive) token embeddings, we train DepProbe on mBERT's embedding layer. To estimate how much information about the probing task is acquired during pretraining of a LM, we probe the internal representations of two MLMs that share the architecture of mBERT but randomize either all parameters, or all parameters except the embedding matrix (Belinkov, 2022). All trained probes outperform the baselines by large margins (minimal difference of 15.9 LAS for mGPT on SPUD data). All baseline results are presented in App. F.3.

5.3 Results

Tables 3, 4 present the results. Δ shows the performance drop between original and SPUD test sets. In general, performance depends largely on treebank size. This trend is also visible in Müller-Eberstein et al. (2022), where Kendall's τ between LAS and treebank size in 13 languages is 0.50 (p = 0.017).

mBERT vs. mGPT (RQ1) For all languages and settings except Arabic RelAcc (both test sets), and Russian (all metrics, original data), mBERT outperforms mGPT in terms of absolute performance. In addition, Δ on SPUD is larger for mGPT than for mBERT in almost all settings. The difference in model architectures is especially relevant for predicting the syntactic structure of nonce data,

Table 4: DepProbe results for mGPT. Δ shows the performance drop when nonce data is used.

where context is a more important cue than for original data. The only exception to this is Russian, where mGPT outperforms mBERT in absolute performance on original data but not on SPUD. This is likely due to the distribution of languages in the pretraining data: mGPT's training data put an emphasis on Russian and regionally related languages (Shliazhko et al., 2024). The relatively low performance of both models on English, however, is most likely explained by the relatively small size of the English treebank.

Relation labeling vs. attachment (RQ2) DepProbe performance is measured in terms of the two components of the model: relation labeling (RelAcc) and attachment (UAS). While the absolute performance varies, for both models and all languages, Δ is larger for the attachment component than for the relation labeling component. mGPT shows a larger Δ than mBERT for both components when directly comparing the absolute performance drop per language. In the most extreme case, the Δ in UAS for Arabic is 7.3 points for mBERT and 12.6 points for mGPT. This points in the same direction as the performance of the embedding layer baseline: Relations are more easily predictable from lexical cues. Attachment, on the other hand, requires more contextual information, especially when the head is in the future context of the dependent. This finding is particularly insightful because it shows that probing for labeled and directed dependency trees highlights differences between ALMs and MLMs that are not captured when ignoring relations and directionality (e.g. Eisape et al., 2022).

	RelAcc		UAS		LAS	
	orig	Δ	orig	Δ	orig	Δ
roberta-base	85.9	2.5	70.9	3.6	64.0	4.0
gpt2	82.4	4.5	53.1	3.6	47.1	4.6

Table 5: DepProbe monolingual results for English

Monolingual results (RQ1,RQ2) We test the above hypotheses on two English 12-layered models: GPT-2 (Radford et al., 2019) and RoBERTa (Liu et al., 2019). The trends (Tab. 5) are similar to the multilingual models: RoBERTa outperforms GPT-2 on all metrics, and the performance drop is larger for GPT-2 than for RoBERTa (except for UAS, where it is the same). The only difference is that for GPT-2, the separate probe components show a behavior inverse to the multilingual models: RelAcc shows a larger performance drop on SPUD data (4.5) than UAS (3.6). However, this can be explained by the absolute performances of the GPT-2 probe, which are much higher for RelAcc than for UAS. This leaves less room for performance detriments on SPUD data at attachment than at relation labeling.

5.4 Additional experiments

To test the robustness of our results, we conduct several additional experiments. First, we test the effect of different random seeds for the probe's initial weights and the selection of nonce words (App. F.4). We find that performance is stable across random seeds. Concretely, the largest observed standard deviation across random seeds was 0.35 points UAS for English SPUD data, and most of the other settings show much lower standard deviations. Second, we test the effect of ignoring dependency relations in nonce data creation, i.e. selecting replacements based only on POS tags and language-specific rules (App. F.5). The results show that this kind of nonce data produces worse probing results than SPUD data, with some cross-lingual variation. Finally, we train DepProbe on all layers of mBERT and mGPT and compare the performance on English original and SPUD data (App. F.6). Most importantly, this confirms that all other experiments were run on the best-performing layers. Additionally, this provides insights into the layerwise dynamics of both models.

5.5 Interim Summary

The probing experiments show an overall performance drop on SPUD data for both MLMs and ALMs. In general, probes for MLMs perform better than probes for ALMs on both original and SPUD, and the performance drop on SPUD is higher for ALMs than for MLMs. This is likely due to the fact that ALM probe predictions are based on a representation with one-sided contextual information.[2] All models show a larger peformance drop for attachment than for relation labeling, and the embedding layer baseline shows a relatively high performance on relation labeling. This points in the direction that relation labeling information is more easily predictable from lexical cues than attachment information and that, on the contrary, MLMs are better at predicting attachment information for nonce data than ALMs. Finally, when viewed in isolation, many SPUD test sets show a high absolute performance, suggesting that probes indeed base their predictions on syntactic information.

6 Discussion and Conclusion

Dataset We presented *Semantically Perturbed Universal Dependencies* (SPUD), a framework for creating parallel nonsensical UD treebanks, and apply it to generate grammatical but nonsensical data in five languages. We present two use cases for SPUD, which contribute to the literature that relates LMs to the notions of grammaticality, acceptability and probability (Gulordava et al., 2018; Sprouse et al., 2018; Lau et al., 2017, 2020). Beyond that, SPUD has several possible applications such as data augmentation for low-resource parsing or syntactic similarity benchmarks.

Scoring SPUD with ALMs and MLMs In analyzing how token-level predictions are affected by SPUD, we find that SPUD data consistently shows higher scores (i.e., lower likelihood) than original data on all models. This shows that, as desired, the lexical co-occurrence patterns of content words in SPUD are perturbed. Of all scoring functions, the increase in ALM perplexity is highest. With our experiments, we contribute to the open question of how best to compute scores from MLMs by comparing $PPPL$ with subword-aware $PPPL_{l2r}$ (Kauf and Ivanova, 2023). While we are mostly able to support (Kauf and Ivanova, 2023)'s argument that $PPPL_{l2r}$ is empirically more similar to PPL than $PPPL$ is, we find that the response of ALMs and MLMs to SPUD data is significantly different. This indicates a more fundamental difference between how ALMs and MLMs score sentences: Bidirectional context in MLMs makes it easier to identify the syntactic properties of a predicted word, even in nonce sentences.

Probing ALMs and MLMs for SPUD trees We probe different models for labeled and directed dependency trees on SPUD using the DepProbe framework (Müller-Eberstein et al., 2022). We find that probe performance drops (compared to original test sets) for all languages and both model architectures when using SPUD test sets. However, a majority of the probe performance is maintained. The ALM mGPT has a lower overall performance than mBERT, as well as a higher performance drop on SPUD data. For both architectures, attachment contributes more to the performance drop than relation labeling does. These findings confirm the results in Maudslay and Cotterell (2021) and Arps et al. (2022). On the contrary, Eisape et al. (2022) found that GPT-2 performs on par with MLMs on structural probing of unlabeled undirected dependency trees. This contrast highlights the importance of probe architecture and task design.

Linguistic Information and LMs Sinha et al. (2021) found that MLMs rely on higher-order co-occurrence statistics for many tasks, and can maintain high performance without word order information. We view the same problem from a different angle: Our scoring results show that, expectedly, LM predictions are optimized for co-occurrence information. Probing performance, however, can be maintained to a high-degree even if co-occurrence at the lexical level is disrupted. Our comparison of MLMs and ALMs suggests that both architectures process nonce data differently, and MLMs are better at identifying syntactic structure in SPUD data than ALMs.

Limitations

Model instances and architectures All our direct comparisons between model architectures are limited by the fact that we compare models with different hyperparameters, training data, and tokenizers. To quantify the effect of each of these components on the syntactic learning requires availability of models trained using various combination of these settings.

[2] In a small-scale qualitative analysis, we find that this can explain many errors made by ALMs but not MLMs.

Data While we put significant effort into assuring the quality of the generated data, we did not conduct a large-scale human evaluation, e.g. via crowd-sourced grammaticality judgments. This means that while we are confident that grammatical errors in SPUD are rare, rare errors might exist that have potentially severe effects on individual predictions.

Formulations of scoring functions The literature varies in the way in which scoring functions are applied. Assume that $\sigma = \sum_{i=0}^{n} \log p(x_i|context)$ is the sum of log likelihoods in a scoring function such as PPL. We follow Salazar et al. (2020) and divide σ by sequence length and exponentiate ($exp(-(1/n)\sigma)$), as defined in Eq. 1. Kauf and Ivanova (2023), on the contrary, base their experiments directly on σ. Due to the nonlinear differences between both versions, it is possible that not all of our findings on scoring functions are transferable to raw log likelihood scores. We do not expect this to affect our main findings, especially since our comparison of the exponentiated versions of $PPPL$ and $PPPL_{l2r}$ shows trends that are consistent with Kauf and Ivanova (2023)'s findings on English data, the language they focus on. However, we deem a more detailed comparison of scoring functions with and without exponentiation is necessary to draw more general conclusions, even though this is beyond the scope of this paper.

Structural Probing and Properties of Explanations In the following, we discuss limitations of our probing experiments in terms of the properties of explanations defined by Lyu et al. (2024). Several of their criteria are met: First, our experiments are *plausible* (the resulting dependency trees are intuitive to humans), Second, the critierion of *Input sensitivity* relates closely to the interaction of syntax and semantics in probing which we investigate. The definition is that "An explanation should be sensitive (resp. insensitive) to changes in the input that influence (resp. do not influence) the prediction" (Lyu et al., 2024, p. 6). This criterion is met because (i) we directly investigate the effect of changing the semantic content of the probe and model input, and (ii) because DepProbe is generally sensitive to changes in syntax. Third, the criterion of *Faithfulness* states that "an explanation should accurately represent the reasoning process behind the model's prediction" (Lyu et al., 2024, p. 1). Since we do not investigate model predictions but probe predictions, this criterion is not directly applicable. However, we can say that the probe predictions need not be faithful, because DepProbe learns to predict syntactic structure in a supervised fashion, and does not necessarily decode the syntactic generalizations that the model has learnt. Finally, *Completeness* and *Minimality* do not apply because they refer to explaining contributing factors for model predictions rather than probe predictions.

A Nonce treebanks

A.1 Languages and resources

Table 6 summarizes the languages for which SPUD treebanks are generated. In general, we use the UD test sets for evaluation, and also sample replacement candidates from the UD test sets to avoid data leakage. For all experiments, we used the UD release 2.10.

A.2 Language-specific rules

For consistency, we implement the general rule in languages written in Latin script that the replacement has to be capitalized if the replaced word was capitalized.

Arabic No language-specific rules are applied, except for the removal of diacritics to increase the number of possible replacements.

German Adjective suffixes are depending on several features, however, not all of these features are consistently annotated in the available resources. Concretely, the forms are inflected for Case, Number, Genus, Degree of comparison, and Determinacy, leading to large inflection paradigms. For this reason, we implement the rule that for adjectives ending in *-e, -em, -en, -er, -es*, the replaced adjective has to have the same ending.

English A word list is compiled from wiktionary using wiktextract (Ylonen, 2022) to determine words starting with consonants or vowels. This list is used to determine the correct indefinite article for English nouns: The choice of *a* or *an* depends on the following word, which can be a replaced content word (e.g., an adjective or noun).

	Family, Genus	Writing system	UD treebank	UD_{train} tokens
Arabic	Afro-Asiatic, Semitic	Arabic	PADT, (Hajic et al., 2009)	224K
English	IE, Germanic	Latin	EWT, (Silveira et al., 2014)	205K
French	IE, Romance	Latin	GSD, (Guillaume et al., 2019)	355K
German	IE, Germanic	Latin	HDT, (Borges Völker et al., 2019)	2,754K
Russian	IE, Slavic	Cyrillic	SynTagRus, (Droganova et al., 2018)	1,206K

Table 6: Summary of the languages for which nonce data is generated. IE = Indo-European. Family and Genus according to Dryer and Haspelmath (2013).

The determiner is adjusted if the first sound of the following word changes from a vowel to a consonant or vice versa. For example, when replacing *apple* in *an apple* with *bicyle*, the result is *a bicycle* and not **an bicycle*.

French In French, we implement a similar rule as for English determiners. Concretely, we replace *le/la/de/* with *l'/d'* and vice versa if the following word starts with a vowel, consonant, or aspirated *h*, respectively. The pronunciation of the following word is determined from wiktionary using wiktextract (Ylonen, 2022). Furthermore, French adjectives fall into three classes: A fixed set of adjectives precedes the noun. The majority of adjectives follow the noun. A small set of adjectives can appear in both positions. For instance, *grande maison* – 'big house' and *voiture rouge* – 'red car' are correct, but **maison grande* and **rouge maison* are not. The syntactic context as defined in generating nonce data does not capture the adjective classes. Thus, we replace adjectives preceding (following) the head only with adjectives that also precede (follow) the head in the UD treebank.

Russian The rich case system in Russian poses a challenge for the algorithm as defined above. Concretely, the case of dependents is not part of the syntactic context. Contrary to the other languages in our sample, the case of an `obj`ect is determined by the verb, and both accusative and genetive case are possible and frequent cases for these objects. This means that if a verb with an accusative object is replaced with a verb with a genitive object, a case mismatch is introduced. Since Russian nevertheless retains high probing performance (Sec. 5), we did not explicitly address this problem.

A.3 Examples

For illustration purposes, we present relatively short sentences with multiple nonce versions in Figures 3 (ar), 4 (de), 5 (en), 6 (fr), and 7 (ru).

	NOUN	PROPN	ADJ	ADV	VERB	total
ar	0.93	0.77	0.93	0.74	0.66	0.47
de	0.96	0.93	0.68	0.92	0.61	0.41
en	0.85	0.84	0.86	0.83	0.59	0.38
fr	0.83	0.69	0.88	0.92	0.50	0.36
ru	0.84	0.70	0.80	0.89	0.46	0.39

Table 7: Ratio of replaced words per POS in the test set. The column "total" shows the replacement ratio over all POS, including function words and punctuation.

A.4 Replacement statistics

Tab. 7 shows the ratio of replaced words per POS in the test set. Of the 25 ratios (5 languages, 5 POS tags), 6 are above 0.9 and 14 are above 0.8, indicating that the algorithm is able to find replacements for the vast majority of content words. The replacement ratio is lowest for verbs, for two reasons: First, verbs are generally less frequent than e.g. nouns. Second, verbs frequently have a relatively complex argument structure, which leads to a large number of syntactic contexts and an increased frequency of syntactic contexts that are not shared with other verbs.

B List of Models

mGPT (Shliazhko et al., 2024, huggingface id: `ai-forever/mGPT`) and mBERT (Devlin et al., 2019, `bert-base-multilingual-cased`) are used for all experiments. English scoring and probing experiments are additionally conducted with RoBERTa (Liu et al., 2019, `roberta-base`) and GPT-2 (Radford et al., 2019, `gpt2`). Arabic scoring experiments are additionally conducted with AraGPT2 (Antoun et al., 2021, `aubmindlab/aragpt2-base`) and AraBERT (Antoun et al., 2020, `aubmindlab/bert-base-arabertv2`).

C Data preprocessing

We apply the following preprocessing steps to the UD treebanks after creating `SPUD` splits. To allow a

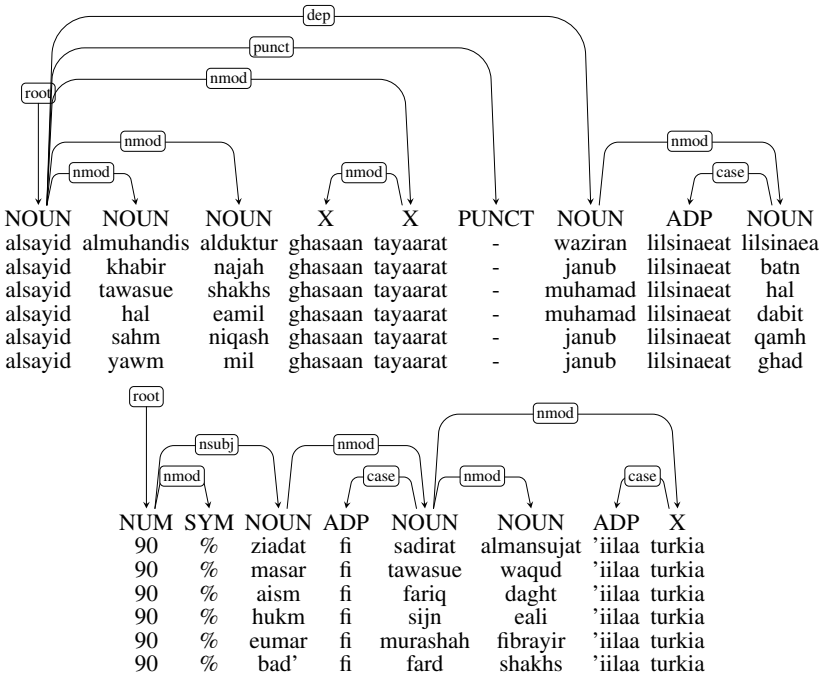

Figure 3: Arabic SPUD examples (in transliteration).

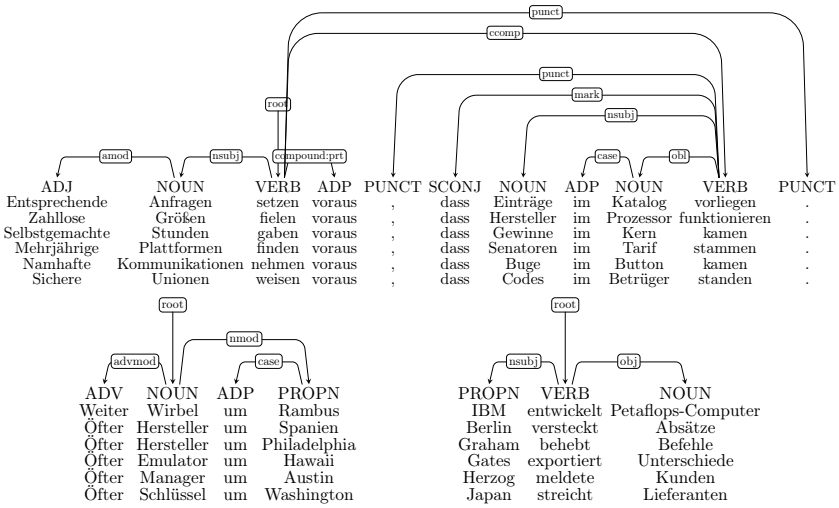

Figure 4: German SPUD examples.

fair comparison between MLMs and ALMs, we filter out sentences that are shorter than 4 words from the data in all experiments. On short sentences, ALMs have a disadvantage because their per-token score increases over the sentence given increasing context length, while the basic masked language modeling task assumes access to the same amount of context for each token. For SPUD in Arabic, we remove diacritics with the PyArabic library (Zerrouki, 2010). The Arabic morphological lexicon is lemmatized with Farasa (Darwish and Mubarak, 2016).

D Lexical Diversity of Nonce data

Language	TTR orig.	TTR nonce

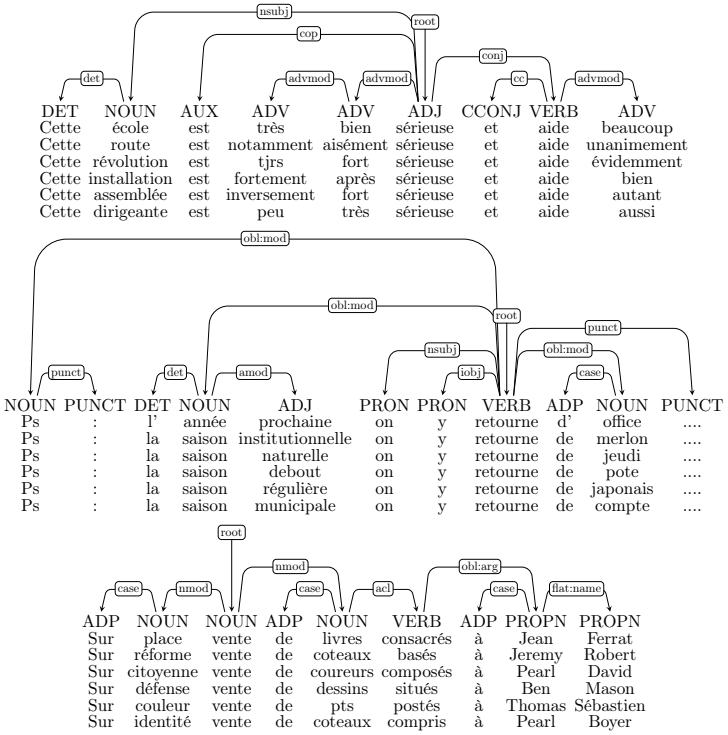

Figure 6: French SPUD examples.

Model-Independent Comparison: Type Token Ratio (TTR) is a widely used measure of lexical diversity. where a larger value indicates that less tokens are used repeatedly (Köhler, 2003). Apart from the segmentation model (in our case the mBERT tokenizer), TTR focuses on capturing the distribution of the data relatively independent from large computational or methodological overhead. The TTR (when tokenized with mBERT) in all languages is shown in Tab. 8.

E Scoring Experiments

E.1 Example for Scoring Functions

An example for how all scoring functions are computed for the phrase *accordeon player* is displayed in Tab. 9.

	accord	?	player
	accord	##eon	?

Table 9: The token for which a probability is recorded is marked with "?". Tokens that are masked out or not available from context are marked with "_".

E.2 Scoring Experiment

In Tab. 10, we show the ratios of scoring functions for multilingual models in German, French and Russian (complementing the English and Arabic results in Tab. 2). In Tab. 11, we show the ratios of scoring functions for monolingual models in Arabic and English.

E.3 Scoring outlier analysis

For English, we investigate the sentence pairs with the highest and lowest scoring function ratios. The sentences with the highest ratio are shown in Table 12. Sentences with very high ratios are all relatively short. The large difference in ratios between scores assigned by mBERT and mGPT indicate that these original sentences could be part of the pre-training data for mGPT but not mBERT - the former is overfitting to the original sentence. Also, these sentences contain uppercase sentences (which might affect tokenization), and almost all original sentences contain well-known named entities or common phrases that are disrupted in the nonce data (*U.S. Senate Committee*, *AS FAR AS POSSIBLE*, etc.)

The sentences with the lowest ratio are shown in Table 13. The examples include typos in the original data (*ling* instead of *long*), an example in which the original seems ungrammatical (6), and examples in which only single words are replaced by other forms that are presumably more frequent (*cover - go*, *Per - Google*, . . .)

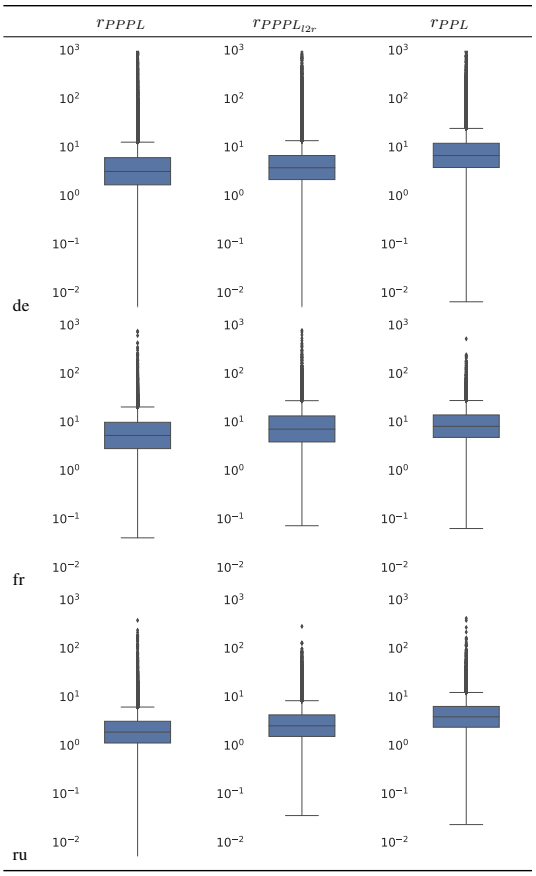

Table 10: Scoring function ratios for multilingual models.

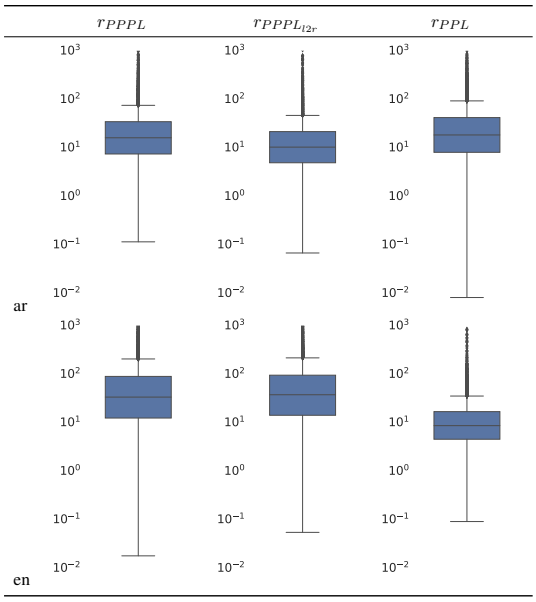

Table 11: Scoring function ratios for monolingual models (Arabic and English).

F Probing Experiments

F.1 DepProbe architecture

Müller-Eberstein et al. (2022) presented **DepProbe**, a lightweight decoder for directed and labeled dependency trees. The model consists of two matrices, L and B. Both transform d_h-dimensional word representations[3] into vectors that hightlights a syntactic property of that representation. Assume that the LM representation of a word w_i is $h_i \in \mathbb{R}^{d_h}$, and that the annotation has l dependency relations.

Predicting dependency relations The matrix $L \in \mathbb{R}^{d_h \times l}$ is a linear classifier that predicts for each word the label of this word's incoming dependency edge – the relation between the word and its head. Concretely, the "probability of a word's relation r_i being of class l_k is given by:

$$p(r_i = l_k | w_i) = softmax(Lh_i)_k \quad (4)$$

" (Müller-Eberstein et al., 2022, p. 7713). This model component is trained using cross-entropy loss.

[3]For tokens consisting of multiple subwords, the word representation is the mean of the subword representations.

Predicting word distances The matrix $B \in \mathbb{R}^{d_h \times b}$ predicts the dependency edges between words. B projects the LM representations in a vector space that has less dimensions than the LM layer ($b < d_h$). The target vector space is informally called the syntactic subspace: It reflects structural information such that vector distances between words mimic the distance between words in the dependency tree. Concretely, when h_i, h_j are the LM representations of words w_i, w_j, their distance $d_B(h_i, h_j)$ in the syntactic subspace is defined by Müller-Eberstein et al. (2022, Eq. 1):

$$d_B(h_i, h_j) = \sqrt{(Bh_i - Bh_j)^T (Bh_i - Bh_j)} \quad (5)$$

This model component is trained to predict the distance between all word pairs in the dependency tree. Assume that the distance between two words in the dependency tree is defined as the path length between the two words, $d_P(w_i, w_j)$. If s is a sentence of length $N + 1$, the loss for optimizing B is given by Müller-Eberstein et al. (2022, Eq. 2):

$$\mathcal{L}_B(s) = \frac{1}{N^2} \sum_{i=0}^{N} \sum_{j=0}^{N} |d_P(w_i, w_j) - d_B(h_i, h_j)| \quad (6)$$

Constructing the dependency tree The outputs of the relation and distance components are combined to construct the dependency tree starting from the root. The word with the highest probability of being the root (as assigned by L) is set

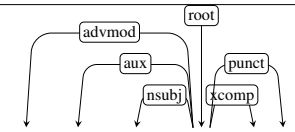
as the dependency tree root. Then, the words are iteratively added to the dependency tree, always choosing the word with the smallest distance d_B to a word that is already covered. The dependency labels are assigned based on L. A detailed example of this process is shown in App. F.2.

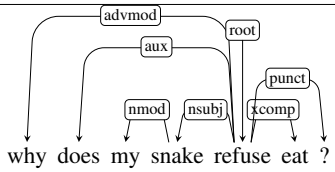
F.2 DepProbe Example

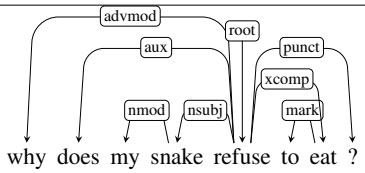
In Fig. 8, we present a step-by-step example for for reconstructing trees with DepProbe, following Alg. 1 in (Müller-Eberstein et al., 2022). For simplicity, the correct distance matrix (Fig. 8a) and correct relations are taken as input to the algorithm.

F.3 Baselines

mBERT embedding layer (M_0) In this baseline, we use the output of mBERT's embedding layer as input to DepProbe. M_0 estimates how much information about the probing task is contained in the (context-insensitive) token embeddings.







Random mBERT (M_R) We consider the representations of a transformer model with the same architecture as mBERT, but all parameters are randomly initialized. Performance of this baseline estimates how much information about dependency structures is contained in the architecture of an MLM and the DepProbe training.

Random contextualization mBERT (M_{RC}) We consider a transformer model with the same architecture as mBERT, but all parameters except the embedding layer are randomly initialized. The performance of this baseline estimates how much information about dependency structures from linguistic context is acquired during pretraining of the MLM (Belinkov, 2022). We take the representations from layers 6 (7) as input to DepProbe's distance (relation) component.

Results All probed models outperform the baselines by a large margin, both on original and nonce data (Tables 14, 15, 16). This shows that the probing task probes for contextual information (comparison to M_0), and that the probed information is learnt during pretraining (comparison to M_R and M_{RC}). M_0, the embedding layer baseline, shows decent performance on the relation labeling task (Tab. 14): Up to 74.6 RelAcc for German, and $\Delta < 5$ for all languages. For attachment, the ab-

(b) Step by Step example.

Figure 8: DepProbe tree decoding example

solute scores are lower and the performance drop is larger. This is intuitive: The embedding layer provides a basis for predicting context-insensitive information such as the most frequent dependency relation of a word type, and this information is still useful for predicting the dependency relations in SPUD data. However, predicting attachment requires more contextual information, for SPUD data even more so than for original data. The absolute performance and Δ of M_{RC} is within 1 point to M_0 for all languages (Tab. 15). This shows that the random contextualization does not detriment the predictability of relation labeling based on the embedding layer. Attachment performance is lower in terms of absolute scores for M_{RC} than for M_0, which leads to less room for a performance drop but overall lower LAS on both test sets. On relation labeling, M_{RC} performs between 4.8 and 12.6 accuracy points better than M_R on original data. On attachment, M_R performs better than M_{RC} for all languages except Arabic. All baseline performance drops for nonce data are relatively small. The most intuitive explanation for this is that on the one hand, lower overall performance leaves less room for a performance drop, and on the other hand it confirms that nonce data is created in a way in which only the co-occurence information is changed, but not the syntactic contexts in which the words generally appear (e.g. the tendency of a word to appear as a subject is preserved).

F.4 Random seeds

The experimental setup introduced two random components: The probe's initial weights are randomly initialized, and the nonce data is created by randomly sampling words. To test the effect

Table 19: Mean and standard deviation LAS of probing with different random seeds.

of these random components, we additionally run experiments with varying random seeds for each of these components in a pilot study. Per language, we initialize probes with 3 different random seeds, and each of these probes is evaluated on 5 different SPUD datasets. This means that per language, 3 predictions for original data and 15 predictions for nonce data are available. For all 3 evaluation metrics, the resulting scores across predictions are stable. Concretely, the largest observed standard deviation across predictions was 0.35 points UAS for English SPUD data. Most of the other settings show much lower standard deviations. We argue that these random components do not have a large effect on the results, and that it is therefore sufficient to run the above probing experiments as described.

F.5 Ignoring dependency relations in nonce data creation

To compare our approach against the common nonce data creation practice of using POS tags, we test on a version of English and German nonce data that ignores dependency-specific information and only modifies the data based on POS tags and language-specific rules. The results are shown in Table 20. The performance difference between the two versions of nonce data is larger for English than for German. This supports the fact that in English, dependency information is more easily extracted from positional information than in German: In the English data, the position of a word is a stronger cue for its dependency relation than in German.

F.6 Layer dymanics

We train DepProbe on English data on all layers of mBERT and mGPT. On the one hand, this serves the purpose of selecting the layer used in all other experiments. Müller-Eberstein et al. (2022) conducted the same experiment on mBERT to identify the layer that performs best on the probing task.

	RelAcc		UAS		LAS	
	SPUD	POS	SPUD	POS	SPUD	POS
de	91.0	90.1	81.0	79.7	76.2	75.0
en	84.8	81.7	70.4	66.0	63.8	59.2

Table 20: Results for English and German test sets with (SPUD) and without (only POS) dependency information in the nonce data creation.

	left	right
ar	0.67	0.31
de	0.32	0.63
en	0.37	0.56
fr	0.40	0.56
ru	0.42	0.53

Table 21: Fraction of edges to the left and right in the respective UD test sets. Both columns do not sum to 1 because the root is not counted.

The best layer for each task (6 for relation labeling, 7 for attachment) is then used in all other experiments. We repeat this process on mGPT to identify the highest performing layer for this model. In the case of mGPT, layer 12 performs best on both tasks. For selecting the best layer, we use the original test data (following existing work).

On the other hand, the layerwise probing results highlight how syntactic and semantic information influence probing performance across layers. For RelAcc, mGPT's performance on both test sets develops relatively stable, with a sharp increase in the lowest layers and a slight decrease in the higher layers. The Δ to the SPUD test set also increases during the lower layers and then stays quite stable. For mBERT, the pattern is similar, with a steeper decline in performance on the highest layer. For UAS (and LAS), mGPT shows smaller changes across layers than for RelAcc. While the pattern appears jumpy, no individual difference between consecutive layers is larger than 3.5 points and the Δ to the SPUD test set is stable. mBERT shows a clearer but steeper trend with best performance in the mid layers and worse performance in the higher and lower layers.

F.7 Probe Performance by edge direction

To further elaborate on the differences between decoded trees from ALMs and MLMs, we investigate the performance of DepProbe in our main experiment on edges in different directions. For all languages, edges to the left are defined as edges

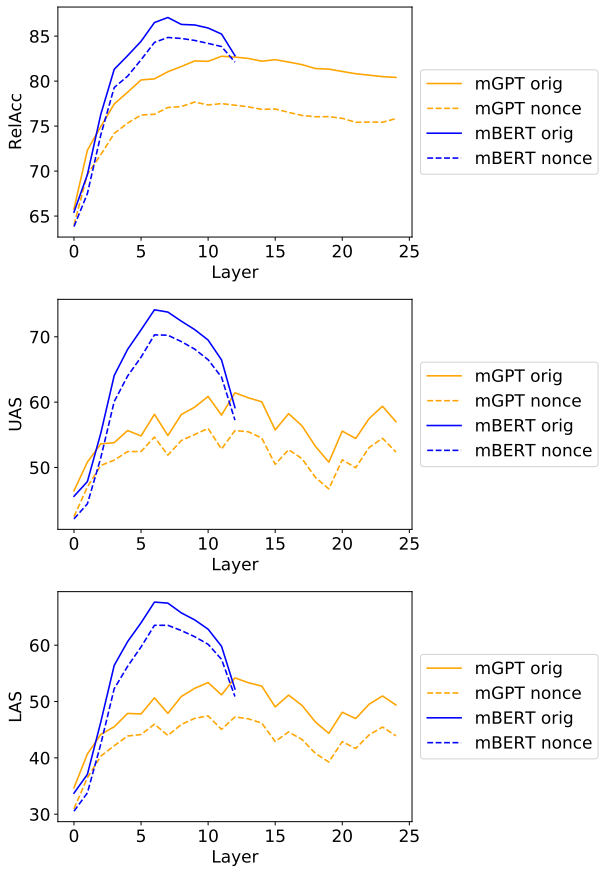

Figure 9: Layerwise DepProbe performance for mBERT and mGPT.

Table 22: Performance for edges to the left and right

where the dependent has a lower index than the head (vice versa for edges to the right). The relative frequency of edges to the left and right is displayed in Tab. 21. For all Indo-European (IE) languages, the majority of edges are to the right (left for Arabic). The results (Tab. 22) show that for the IE languages, edges to the right show higher performance than edges to the left. For ALMs, this is especially intuitive: The edges to the right are the ones where both head and dependent are in the context of the token on which the prediction is made. When considering only original data and IE languages, the performance difference between ALMs and MLMs interestingly shows that MLMs are better at predicting edges to the right, but not necessarily better at predicting edges to the left. Arabic consitutes a special case because the distribution of edges to the left and right is swapped. For RelAcc and SPUD, edges to the left show lower performance than edges to the right, following the pattern in the other languages. For attachment, the more frequent edges to the left show higher performance than edges to the right (but only in original data). The performance drop on nonce data and RelAcc is larger for edges to the left in all languages and both models. For attachment however, the pattern is more mixed. Since the performance drop on nonce data is secondary to the overarching research question of this particular experiment, we do not investigate this further.

G Computational requirements

All experiments were run on a single NVIDIA GeForce RTX 3090 GPU with 24GB of memory, and powered by renewable energy sources. Collecting the (pseudo-)perplexity scores for one combination of language, model, and scoring function takes between 5 minutes and 2 hours. The duration depends mostly on the dataset size and model architecture. Computing both versions of pseudo-perplexity for a single sentence requires n forward passes for a sentence of length n, while PPL computation requires just one forward pass. Training a single DepProbe model takes between 10 minutes and 3 hours, depending on the size of the LM and treebank. Probe inference is faster. From these values, we estimate that the complete set of experiments reported in this paper can be conducted with our hardware in 25-30 hours. Creating SPUD treebanks does not require GPU access and takes several minutes on a CPU and 64GB RAM.

Actively Learn from LLMs with Uncertainty Propagation for Generalized Category Discovery

Abstract

Generalized category discovery faces a key issue: the lack of supervision for new and unseen data categories. Traditional methods typically combine supervised pretraining with self-supervised learning to create models, and then employ clustering for category identification. However, these approaches tend to become overly tailored to known categories, failing to fully resolve the core issue. Hence, we propose to integrate the feedback from LLMs into an active learning paradigm. Specifically, our method innovatively employs uncertainty propagation to select data samples from high-uncertainty regions, which are then labeled using LLMs through a comparison-based prompting scheme. This not only eases the labeling task but also enhances accuracy in identifying new categories. Additionally, a soft feedback propagation mechanism is introduced to minimize the spread of inaccurate feedback. Experiments on various datasets demonstrate our framework's efficacy and generalizability, significantly improving baseline models at a nominal average cost. [1]

1 Introduction

Generalized Category Discovery (GCD) is a crucial task in open-world computing (Lin et al., 2020; Zhang et al., 2021b), where the goal is to automate the classification of partially labeled data. It uniquely challenges systems to not only recognize predefined categories but also to discover entirely new categories from a mix of labeled and unlabeled data (Yang et al., 2021; Zeng et al., 2022). This task mirrors the dynamic and evolving nature of real-world data, where new categories frequently emerge, necessitating models that can adapt and learn continually.

[1]https://github.com/liangjinggui/ALUP

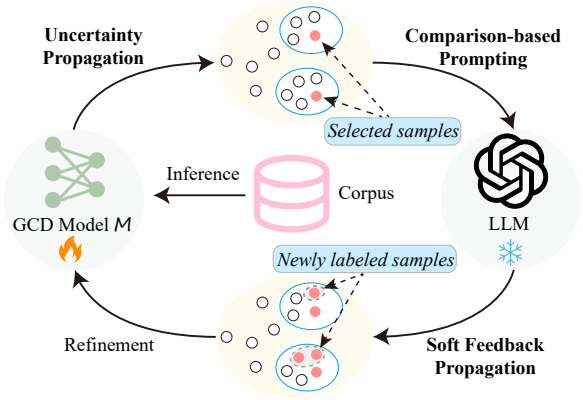

Figure 1: The active learning loop with propagated LLM feedback for model training.

In traditional GCD methods, the initial step often involves supervised pretraining on a labeled dataset to establish a foundational understanding of known categories (Zhong et al., 2021; Vaze et al., 2022). This is followed by self-supervised learning on unlabeled data or even contrastive learning, allowing the model to extract and learn patterns without explicit category labels (An et al., 2023). The final stage typically employs clustering techniques, like K-Means (MacQueen et al., 1967), to group similar data points, aiming to identify categories. However, this sequential process tends to imprint a bias towards the initially learned, known categories, thus limiting the model's ability to generalize to new, unseen categories (Mou et al., 2022). Such overfitting to familiar data restricts the scope of GCD, preventing it from fully embracing the open-world setting it is intended for.

Recently, Large Language Models (LLMs) such as GPT-4 (OpenAI, 2023), PaLM (Chowdhery et al., 2023), and LLaMA (Touvron et al., 2023) have shown extraordinary versatility across a broad range of NLP tasks, providing good quality super-

Proceedings of the 2024 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies (Volume 1: Long Papers), pages 7845–7858
June 16-21, 2024 ©2024 Association for Computational Linguistics

vision signals for summarization (Liu et al., 2023), clustering (Zhang et al., 2023c), etc. Their ability to understand and generate nuanced language patterns makes them promising for supplementing the supervision of new categories in GCD. However, the direct application of LLMs in GCD, which typically involves processing and clustering thousands of samples, raises substantial challenges. The intensive computational demands of LLMs could lead to issues with data privacy, high latency, and increased costs, which are particularly problematic in large-scale GCD scenarios.

To circumvent the above challenges, integrating LLMs into an active learning framework presents a practical and efficient solution. This approach entails selectively using LLMs to provide supervision signals, especially in cases where the data is most uncertain or the categories are novel. However, this integration brings forth new challenges: optimizing the use of LLMs to ensure cost and time efficiency, and critically, ensuring the reliability of the feedback provided by LLMs. Effective strategies are needed to mitigate the risk of propagating incorrect feedback from LLMs.

Addressing these challenges, we propose a novel framework for GCD to ***A***ctively ***L***earn from LLMs with ***U***ncertainty ***P***ropagation, termed as **ALUP**. As shown in Figure 1, we begin by employing an uncertainty propagation strategy, which systematically identifies data samples in regions of high uncertainty – these are the areas where the model is least confident and, therefore, where LLM input could be most beneficial. The selected samples are then labeled using LLMs through a sophisticated comparison-based prompting technique. This method leverages the comparative strength of LLMs, making it easier for them to provide accurate feedback, especially for new and complex categories. To further enhance our approach, we incorporate a soft label propagation mechanism. This mechanism carefully extends the LLMs-generated feedback to similar, neighboring samples, effectively amplifying the value of each LLM query while minimizing the risk of propagating errors. Rigorous testing on diverse datasets has shown that our method not only significantly improves upon existing baseline models but also does so with a nominal increase in cost, offering a scalable, efficient, and effective solution for the intricate problem of GCD.

The main contributions of this work can be summarized as follows:

- We developed an innovative active learning framework integrating LLMs' feedback for GCD, addressing the challenge of limited supervision for new data categories.
- We combined uncertainty-region based data selection and comparison-based LLMs prompting, significantly enhancing GCD accuracy and efficiency with soft propagation.
- Experiments demonstrated marked improvements over traditional GCD methods across diverse datasets, affirming the ALUP's effectiveness and resource efficiency.

2 Related Work

2.1 Generalized Category Discovery

Unsupervised Methods: The realm of GCD has been fundamentally shaped by unsupervised methods, focusing on learning cluster-friendly representations. These early methods (Xie et al., 2016; Yang et al., 2017; Padmasundari and Bangalore, 2018; Caron et al., 2018; Hadifar et al., 2019) laid the groundwork by using unsupervised clustering algorithms to group samples based on inherent similarities. Recent advancements, particularly with the emergence of LLMs, have brought a paradigm shift. The integration of LLMs in unsupervised GCD (De Raedt et al., 2023; Zhang et al., 2023c; Viswanathan et al., 2023) represents a novel direction, pushing the boundaries of category identification beyond traditional clustering techniques.

Semi-Supervised Methods: In contrast, semi-supervised GCD methods blend limited labeled data with possibly larger unlabeled data to enhance category discovery (Hsu et al., 2018, 2019; Han et al., 2019). Methods like CDAC+ (Lin et al., 2020) utilize labeled data to guide clustering, creating a synergy between supervised knowledge and unsupervised discovery. The two-stage scheme, involving base model pretraining and iterative optimization (Zhang et al., 2021a,b; Wu et al., 2022; Wei et al., 2022; Zhang et al., 2023a; Zhou et al., 2023; Mou et al., 2023), has gained popularity. It benefits from pseudo label signals generated by the pretrained model, although it often struggles with

the quality of pseudo labels and sample representations. Efforts to refine learning objectives, such as contrastive learning (Mou et al., 2022; Zhang et al., 2022a), aim to directly learn discriminative representations for new categories. Yet, the challenge remains in effectively decoupling pseudo label generation from representation learning (Wu et al., 2024), a gap our work addresses by introducing LLMs into the GCD.

2.2 Active Learning in the Era of LLMs

Traditional Active Learning (AL): AL has traditionally been a solution to the data scarcity problem in NLP (Ren et al., 2022; Zhang et al., 2022b), focusing on identifying and annotating informative samples. Various acquisition strategies have been employed, including uncertainty-based (Wang and Shang, 2014; Schröder et al., 2022; Yu et al., 2023), diversity-based (Sener and Savarese, 2018; Gissin and Shalev-Shwartz, 2019; Citovsky et al., 2021), and hybrid methods (Liu et al., 2018; Zhan et al., 2022). While effective, these methods still rely on expensive human expertise for annotation.

LLMs as a Game-Changer in AL: With the advent of LLMs, a new frontier in AL has been explored. LLMs are now being considered as cost-effective alternatives to human experts (Zhang et al., 2023c; Cheng et al., 2023; Zhang et al., 2023b; Margatina et al., 2023; Liao et al., 2023). For instance, Xiao et al. (2023) demonstrated the use of LLMs as active annotators, harnessing their ability to distill task-specific knowledge interactively. In our work, we further this exploration by applying AL with LLMs to GCD. Our unique contribution not only lies in the implementation of an uncertainty-driven propagation strategy to maximize the utility of LLMs in a cost-effective manner, but also in the design of a soft feedback propagation scheme to minimize the spread of inaccurate feedback.

3 Methodology

3.1 Problem Formulation

We study the GCD problem defined as follows: Assuming we have a known category set $\mathcal{C}_k$ and an unknown category set $\mathcal{C}_u$, where $\{\mathcal{C}_k \cap \mathcal{C}_u\} = \varnothing$ and $|\mathcal{C}_k| + |\mathcal{C}_u| = K$. Here K is the total number of categories. Under the semi-supervised GCD setting, given a labeled data set $\mathcal{D}_l = \{(x_i, y_i)|y_i \in \mathcal{C}_k\}_{i=1}^{L}$, and an unlabeled data set $\mathcal{D}_u = \{x_j\}_{j=1}^{U}$ where the category of each x_j belongs to $\{\mathcal{C}_k \cup \mathcal{C}_u\}$, the task is to learn a representation extractor $\mathcal{M}$ to identify all unknown categories from $\mathcal{D}_u$ and perform accurate clustering to classify each x_i in $\{\mathcal{D}_l \cup \mathcal{D}_u\}$ into its corresponding category.

3.2 Approach Overview

General GCD methods typically first extract representations $\mathcal{Z} = \{\boldsymbol{z}_i\}_{i=1}^{|\mathcal{D}_l \cup \mathcal{D}_u|}$ via model $\mathcal{M}$ for each sample x_i and then perform K-Means to locate cluster centers $\{\boldsymbol{\mu}_i\}_{i=1}^{K}$ for doing GCD. Our proposed ALUP builds upon existing GCD models and effectively incorporates LLMs' feedback in an active learning scheme.

Figure 2 depicts an overview of our ALUP framework for GCD. It encompasses three key designs: ***Uncertainty Propagation*** for sample selection, ***Comparison-based Prompting*** for soliciting LLMs' feedback, and ***Soft Feedback Propagation*** for wisely spreading the feedback. In what follows, we will detail these designs separately.

3.3 Uncertainty Propagation (UP)

Within the ALUP framework, we design the uncertainty propagation to select the most informative unlabeled samples that are representative of high-uncertainty regions. Note that given a general GCD model $\mathcal{M}$, we can extract representations $\boldsymbol{z}_i$ for each x_i in the dataset and perform K-means to locate cluster centers $\{\boldsymbol{\mu}_k\}_{k=1}^{K}$. To estimate the model predictive uncertainty, following Xie et al. (2016), we use the Student's t-distribution to compute the probability of assigning the sample x_i to each cluster k:

$$q_{ik} = \frac{(1 + \|\boldsymbol{z}_i - \boldsymbol{\mu}_k\|^2/\alpha)^{-\frac{\alpha+1}{2}}}{\sum_{k'}(1 + \|\boldsymbol{z}_i - \boldsymbol{\mu}_{k'}\|^2/\alpha)^{-\frac{\alpha+1}{2}}}, \quad (1)$$

where α represents the degrees of freedom in the Student's t-distribution. After obtaining the model predictive probabilities, we use the entropy (Lewis and Gale, 1994) to measure the uncertainty for each sample x_i:

$$u(x_i) = -\sum_{k=1}^{K} q_{ik} \log q_{ik}. \quad (2)$$

Here, a higher $u(x_i)$ can indicate a higher likelihood of the model $\mathcal{M}$ incorrectly assigning x_i to a

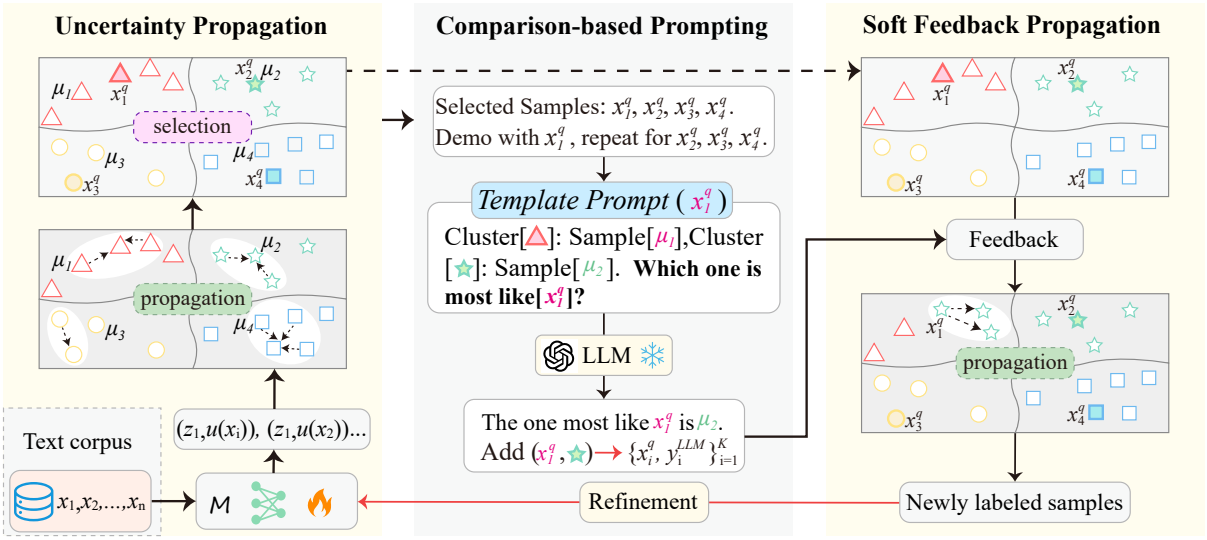

Figure 2: The overall ALUP framework. It consists of three main designs: *Uncertainty Propagation* for region-based sample selection, *Comparison-based Prompting* for soliciting more accurate LLM's feedback, and *Soft Feedback Propagation* for wisely spreading the feedback to boost both efficiency and effectiveness.

wrong cluster. However, directly adopting this individual uncertainty score for selecting samples can lead to suboptimal outcomes as it can be sensitive to outliers (Karamcheti et al., 2021). To address this issue, following Yu et al. (2023), we further measure the similarities between each sample and its neighbors and propagate the individual uncertainty score to neighbors. Specifically, for each data point x_i, we first find its k-nearest neighbors based on the Euclidean distance as:

$$\mathcal{N}(x_i) = \underset{top-k}{\text{KNN}}(\boldsymbol{z}_i, \mathcal{Z}^u), \tag{3}$$

where $\mathcal{Z}^u$ denotes the representations of unlabeled samples and $\mathcal{N}(x_i)$ represents the set of nearest neighbors of x_i. Then, we calculate the similarities between x_i and its neighbors based on the radial basis function (RBF) (Schölkopf et al., 1997):

$$sim(\boldsymbol{z}_i, \boldsymbol{z}_j) = \exp(-\rho \|\boldsymbol{z}_i - \boldsymbol{z}_j\|_2^2), \tag{4}$$

where $x_j \in \mathcal{N}(x_i)$ and ρ is a hyper-parameter that regulates the extent of uncertainty propagation. After measuring the similarities, we refine the uncertainty score of sample x_i as:

$$u(x_i) = u(x_i) + \frac{\sum_{x_j \in \mathcal{N}(x_i)} sim(\boldsymbol{z}_i, \boldsymbol{z}_j) \cdot u(x_j)}{|\mathcal{N}(x_i)|}. \tag{5}$$

After several rounds of uncertainty score propagation, we obtain the final uncertainty score $u(x_i)$. Based on this score, we greedily select one sample x_i^q from each cluster c_i to form the sample set $\mathcal{Q}$:

$$x_i^q = \underset{x_j \in c_i}{\text{argmax}}(u(x_j)). \tag{6}$$

We emphasize that a sample will exhibit higher propagated uncertainty only when it and its neighboring samples both possess high uncertainty levels. Hence, we are selecting samples from uncertain regions. By actively obtaining feedback from LLMs for such samples in $\mathcal{Q}$, we can significantly improve the model performance in GCD.

3.4 Comparison-based Prompting (CP)

Upon identifying the most informative unlabeled samples through the UP strategy, we need to query LLMs to obtain pseudo category labels for these samples. However, since the category labels of newly emerged categories remain unknown, it is infeasible to request LLMs to directly generate possibly a brand new label for each selected sample. To overcome this, we design a comparison-based prompting method from the clustering perspective, which prompts LLMs to classify a sample by comparing it with other samples representing distinct categories.

This CP method requires the selection of a representative sample for each category cluster. To this end, we first compute the distances of various samples within the cluster to its center $\boldsymbol{\mu}_i$, and then

select the sample closest to $\boldsymbol{\mu}_i$ to represent this cluster. We denote this close-to-center sample as μ_i. With these close-to-center samples $\mathcal{S} = \{\mu_i\}_{i=1}^{K}$, we construct the prompt to query LLMs as:

> Cluster [c_1]: Sample [μ_1]; Cluster [c_2]: Sample [μ_2]; ... ; Cluster [c_p]: Sample [μ_p]. Above is a list of samples representing distinct categories. Please identify one sample that shares the same or similar underlying category as the input sample from the provided list.

Here, p is the number of representative samples used for the comparison. In our experiments, for each x_i^q in $\mathcal{Q}$, we empirically incorporate $p = |\mathcal{Q}|/2$ representative samples that are closest to x_i^q into the prompt. With this design, we can effectively utilize LLMs to classify the selected samples into their corresponding categories, denoted as $\mathcal{Q} = \{x_i^q, y_i^{LLM}\}_{i=1}^{K}$, thus bypassing the requirement for explicit labels of unknown categories.

3.5 Soft Feedback Propagation (SFP)

By querying LLMs using the CP method, we can endow the selected unlabeled samples with their respective pseudo labels to augment the GCD models for discerning new categories. However, a performance gap persists between the partially and fully LLM-augmented GCD models. Given that the selection of the unlabeled samples is based on their model predictive uncertainty and neighboring uncertainty, and samples distributed close to each other are more likely to share the same category, we thus propose a soft feedback propagation mechanism to propagate the pseudo labels generated by LLMs across their similar neighbors, amplifying the utility of the feedback from LLMs without any additional cost. Specifically, for each x_i^q in $\mathcal{Q}$, we refine the model prediction $\boldsymbol{q}_j$ of its uncertain neighbor $x_j \in \mathcal{N}(x_i^q)$ in Equation (1) to propagate the LLM-generated pseudo label y_i^{LLM}:

$$\boldsymbol{q}_j = (1 - sim(\boldsymbol{z}_j, \boldsymbol{z}_i^q)) \cdot \boldsymbol{q}_j + sim(\boldsymbol{z}_j, \boldsymbol{z}_i^q) \cdot \boldsymbol{y}^{LLM}, \quad (7)$$

$$y_j^{prop} = \begin{cases} y_i^{LLM}, & \text{if } \operatorname{argmax}(\boldsymbol{q}_j) = y_i^{LLM} \\ -1, & \text{otherwise} \end{cases}, \quad (8)$$

where $sim(\cdot, \cdot)$ denotes the similarity function defined in Equation (4). $\boldsymbol{y}^{LLM}$ is a one-hot vector where the value of position y_i^{LLM} is set to 1. To interpret the Equation (8), we argue that when the uncertain neighbor $x_j \in \mathcal{N}(x_i^q)$ is assigned to the same cluster as the LLM-labeled sample x_i^q according to the refined $\boldsymbol{q}_j$, the pseudo label y_i^{LLM} will be propagated to the x_j. Otherwise, the x_j will reject the pseudo label y_i^{LLM} and remain as an unlabeled sample.

3.6 Model Optimization

After obtaining pseudo labels for the selected unlabeled samples in $\mathcal{Q}$ from LLMs and propagating these labels via SFP, we update the model using a supervised contrastive learning loss (Gao et al., 2021; Guo et al., 2022) as follows:

$$\mathcal{L} = \sum_{i=1}^{L'} -\frac{1}{|\mathcal{N}'(x_i)|} \sum_{x_j \in \mathcal{N}'(x_i)} \log \frac{e^{sim(z_i, z_j)/\tau}}{\sum_{k \neq i} e^{sim(z_i, z_k)/\tau}}, \quad (9)$$

where L' denotes the total number of labeled samples, including both the original labeled samples and the newly labeled samples obtained via the CP and SFP. $\mathcal{N}'(x_i)$ is the set of samples sharing the same category label with x_i. τ is the temperature.

4 Experiments

4.1 Datasets

We conduct experiments on three GCD datasets: **BANKING** (Casanueva et al., 2020), **CLINC** (Larson et al., 2019), and **StackOverflow** (Xu et al., 2015). The detailed statistics are reported in Appendix A.1. In our experiments, we keep the same train, development, and test splits as previous work (Liang and Liao, 2023). More experimental details are provided in the Appendix A.2.

4.2 Evaluation Metrics

Following (Zhang et al., 2022a; Liang and Liao, 2023), we adopt the three metrics for evaluating the GCD performance: Accuracy (**ACC**) based on the Hungarian algorithm, Adjusted Rand Index (**ARI**), and Normalized Mutual Information (**NMI**). The specific definitions are presented in Appendix A.3. It is worth noting that **ACC** is regarded as the primary metric for evaluation, with higher values indicating better GCD performance.

4.3 Baselines

We compare with the following SOTA GCD methods: **DTC** (Han et al., 2019), **CDAC+** (Lin et al.,

2020), **DeepAligned** (Zhang et al., 2021b), **ProbNID** (Zhou et al., 2023), **DCSC** (Wei et al., 2022), **MTP-CLNN** (Zhang et al., 2022a), **USNID** (Zhang et al., 2023a), and the best-performing method **CsePL** (Liang and Liao, 2023). We leave the details of these baselines in Appendix A.4.

4.4 Main Results

4.4.1 GCD Performance Comparison

Table 1 presents the main GCD results of our proposed ALUP against existing baselines, where the peak performance is highlighted in **bold**. Generally speaking, our ALUP consistently outperforms all existing baselines across three datasets by large margins. We analyze the results as follows:

Comparison of different methods in GCD: Table 1 reveals that ALUP significantly outperforms the existing leading baselines, such as CsePL and USNID. For example, the proposed ALUP surpasses previous SOTA CsePL by margins of 2.51% in ACC, 2.12% in ARI, and 1.14% in NMI on BANKING-50%. Notably, the performance gains are more pronounced when a larger number of categories remain unknown. For example, ALUP's ACC improves by 3.55% on BANKING-25%. This proves that the ALUP can acquire effective supervision signals from LLMs, enhancing the model performance in discovering new categories.

Comparison of different datasets: We evaluate the performance of the ALUP framework on different datasets, including the single-domain, fine-grained BANKING dataset, and the multi-domain CLINC dataset. From Table 1, we can notice that all existing methods exhibit significantly lower performance on BANKING compared to CLINC, indicating that the single-domain fine-grained scenario is more challenging for GCD. However, ALUP achieves a more significant improvement of 1%~3% on BANKING-50% compared with the CsePL, while only 0.8%~2% on CLINC-50%. This observation further strengthens the benefits of our ALUP in providing effective supervision signals to cope with the challenges in fine-grained category discovery.

4.5 In-depth Analyses

In this subsection, we conduct further detailed analyses to explore the impact of each key component within the proposed ALUP framework.

4.5.1 Effect of Uncertainty Propagation

Table 2 presents the experimental results of removing the UP strategy in Equation (5) from ALUP on the BANKING dataset. It observes a significant reduction in GCD performance across various known category ratios upon removal. In particular, the ACC of the ALUP decreases by 1.20% while the ARI and NMI drop 1.34% and 0.64% on BANKING-25%, respectively. This indicates that the UP strategy can accurately identify the most informative samples for querying LLMs to boost the GCD model performance. It notably avoids selecting outliers with high model uncertainty but which are less beneficial for model learning.

4.5.2 Effect of Soft Feedback Propagation

We also explore the contribution of the SFP mechanism by comparing the model performance when omitting the feedback propagation from LLMs in Equation (8) with the standard ALUP. Table 2 illustrates a notable decline in model performance in the absence of SFP, with a decrease of 1.88% in ACC, 1.67% in ARI, and 0.38% in NMI. Nevertheless, ALUP *w/o* SFP still slightly outperforms the best-performing baseline CsePL. We suggest that this observation can be explained by two main points: (1) The acquisition of supervision signals from LLMs for the informative samples is beneficial for enhancing the model's capacity to discover new categories. (2) The SFP strategy can effectively propagate the accurate supervision signals from LLMs, amplifying the utility of LLM's feedback while concurrently minimizing the risk of propagating errors.

In contrast to the SFP strategy, we also investigate the Hard Propagation strategy within the proposed ALUP (ALUP *w* HP), where LLMs' feedback is directly extended to the neighboring samples without any control. As presented in Table 2, we can observe that the model performance significantly decreases using the hard propagation, descending even below the levels achieved by CsePL. This is probably due to the propagation of inaccurate supervision signals from LLMs, which introduces considerable noise into the model learning.

4.5.3 Number of Propagated Neighbors

To delve deeper into the effectiveness of the UP strategy within the ALUP framework, we conduct further experiments on the BANKING dataset to explore the effect of varying the number of propagated neighbors in unlabeled sample selection on the model performance. Figure 3 illustrates performance trends across different counts of propagated neighbors. Notably, as the number of propagated neighbors in Equation (3) increases, ALUP's performance improves, reaching an optimum with 25 propagated neighbors. Beyond this point, the model performance begins to decline. We hypothesize that this decrease might be attributed to the inclusion of samples with lower uncertainty, which potentially introduces significant noise into the process of unlabeled sample selection.

4.5.4 Effect of Representative Samples

To assess the effectiveness of the CP method, we examine the impact of varying the number p of representative samples integrated into the prompt for querying LLMs on the model performance. Experiments are conducted with p values set at {19, 38, 57, 77}, where 19 denotes about a quarter of the total cluster count. As detailed in Table 3, the optimal

GCD performance is achieved by integrating 38 representative samples into the prompt to acquire supervision signals from LLMs for the unlabeled samples. We suggest that the main reasons for this observation come from two aspects: (1) A smaller p may potentially omit the representative samples sharing the same underlying category as the selected samples, possibly limiting LLMs' ability to offer the requisite supervision signals during comparisons with the integrated representative samples. (2) Conversely, incorporating a larger number of representative samples for the CP method results in an extended prompt length. This could lead LLMs to misclassify the chosen unlabeled samples into inaccurate categories, thereby negatively affecting the model's performance.

In our standard approach to the CP method, we select the single closest-to-center sample within each cluster as the representative for constructing prompts to query LLMs. Expanding our investigation into the CP method, we experiment with an alternative strategy involving a close-to-center set—specifically, the top 3 samples nearest to the cluster center—to represent distinct clusters for prompting LLMs to determine pseudo category labels. As illustrated in Table 4, the experimental results on BANKING-25% demonstrate marginal gains with this strategy, achieving an increase of no more than 0.5% across all three metrics. Nonetheless, it necessitates an increased querying cost with LLMs. Balancing the slight improvement in performance against the rise in costs, we thus opt for the more straightforward and cost-effective strategy of utilizing single closest-to-center samples within the CP method.

4.6 Impact of Different Base GCD Models

In our experiments, we select the most informative unlabeled samples based on the existing GCD models. To validate the effectiveness of the proposed ALUP, we also examine how its performance varies when different GCD models are integrated within ALUP on the BANKING-50% dataset. As depicted in Figure 4, we can observe consistent and significant improvements with the proposed ALUP. This demonstrates that the proposed ALUP framework is effective in acquiring supervision signals from LLMs to enhance the model performance of discovering new categories and is adaptable to other GCD models.

4.7 Influence of Query Sample Number

We study the effect of varying the number of selected unlabeled samples for querying LLMs in Figure 5. It is observed that there is an increase in model performance corresponding to the rise in the number of samples selected for querying LLMs. Yet, this growth rate progressively diminishes as the LLMs' feedback is propagated, and selecting informative samples becomes more challenging with the increasing number of selected samples.

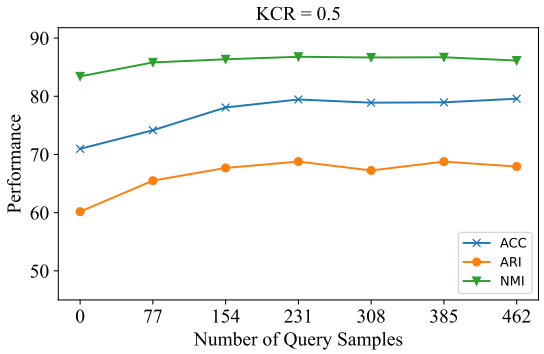

Figure 5: Effect of the number of query samples on BANKING-50%.

Methods	BANKING		
	ACC	ARI	NMI
ALUP-*gpt-3.5-turbo*	**74.61**	**62.64**	**84.06**
ALUP-*FlanT5-XXL*	73.38	62.29	83.76
ALUP-*text-embedding*	71.95	61.48	83.7

Table 5: Effect of different LLMs.

4.8 Effect of Different LLMs

We also examine the performance impact of utilizing different LLMs within our ALUP. Specifically, we conduct experiments on BANKING-25%, comparing the performance of the closed-source *gpt-3.5-turbo* against the open-sourced *FlanT5-XXL* in deriving supervision signals. As shown in Table 5, the experimental results illustrate a marginal performance decrease when employing *FlanT5-XXL* compared to *gpt-3.5-turbo*. Despite this, the use of *FlanT5-XXL* still markedly outperforms the best-performing baseline CsePL, highlighting the adaptability of our ALUP to various LLMs.

Furthering our exploration into the mechanisms of LLMs' utilization in GCD, we evaluate the efficacy of our CP method against an alternative approach based on embedding similarity scores. For this comparison, we leverage the embedding model *text-embedding-3-small* from OpenAI to generate embeddings for both uncertain samples and cluster-representative samples, calculating their similarity scores to determine pseudo category labels. As reported in Table 5, the results demonstrate a drop in performance metrics using the embedding score method, underscoring the rationale of our CP method and its proficiency in capturing the nuanced semantic relationships essential for GCD.

5 Conclusion

In summary, our ALUP framework innovatively integrates Large Language Models with uncertainty propagation in generalized category discovery, marking a significant leap in the field. By employing comparison-based LLM prompting and a novel soft feedback propagation mechanism, ALUP adeptly identifies and categorizes new data with enhanced accuracy and efficiency. This approach not only surpasses traditional GCD methods but also minimizes the risk of error propagation, a critical advancement in handling real-world, dynamic datasets with LLMs. Future endeavors will focus on refining LLM integration, extending our methods to multi-modal data, and enhancing scalability and data privacy measures, furthering ALUP's potential in diverse and evolving open-world computing.

Any opinions, findings and conclusions or recommendations expressed in this material are those of the author(s) and do not reflect the views of the Ministry of Education, Singapore.

Limitations

While our ALUP framework marks a significant advance in Generalized Category Discovery using LLMs, it does have some limitations. The reliance on LLMs can introduce biases and inaccuracies, particularly in areas where these models have limited training data or exposure. Although our propagation method effectively reduces overall costs, the initial computational demands of LLMs may still pose scalability challenges, especially for resource-limited environments. Additionally, the framework currently focuses on textual data, which could limit its applicability in multi-modal data scenarios. Moreover, while our soft feedback propagation mechanism aims to minimize error spread, it is not immune to the risk of amplifying initial inaccuracies from LLM feedback. Finally, data privacy and security remain critical concerns in the use of external LLMs, necessitating ongoing vigilance and adaptation.

A Appendix

A.1 Dataset Statistics

We show the detailed statistics of BANKING, CLINC and StackOverflow datasets in Table 6. Specifically, BANKING is a fine-grained category discovery dataset collected from user dialogues in the banking domain. It contains over 13K user utterances that span over 77 distinct categories. CLINC is a multi-domain dataset, which encompasses 150 distinct categories and 22,500 utterances across 10 domains. StackOverflow is a technical question dataset collected from Kaggle.com, which includes 20K questions with 20 categories.

Dataset	Domain	Categories	Utterances
BANKING	banking	77	13,083
CLINC	multi-domain	150	22,500
StackOverflow	question	20	20,000

Table 6: Statistics of datasets used in the experiments.

A.2 Implementation Details

For the dataset setup, following Zhang et al. (2023a), we randomly select a specified ratio {25%, 50%} of categories, denoted as known category rate (KCR), to serve as known categories. For each known category, 10% of labeled samples are selected to constitute a labeled dataset $\mathcal{D}_l$, while the remaining samples are deemed as unlabeled data, forming the unlabeled dataset $\mathcal{D}_u$.

For the Uncertainty Propagation, we set the freedom α in Equation (1) to 1.0. The number of propagated neighbors is specifically set to 25 for all datasets. The ρ for calculating similarities in Equation (4) is set to 1.0.

For the Comparison-based Prompting, we employ the *gpt-3.5-turbo* as the basic LLM in our experiments. While acquiring supervision signals, the temperature is set to 0 for deterministic outputs, and the maximum tokens are constrained to 256. The default values are retained for the rest of the parameters. The number of representative samples is specifically set to 38 for the BANKING dataset, 75 for the CLINC dataset, and 20 for the StackOverflow dataset.

A.3 Evaluation Metrics

In the experiments, we employ three standard evaluation metrics: ACC, ARI, and NMI to evaluate the GCD performance. Specifically, ACC measures the performance of GCD by comparing the predicted labels with the ground-truth labels. The definition of ACC is as follows:

$$ACC = \frac{\sum_{i=1}^{N} \mathbb{1}_{y_i = map(\hat{y}_i)}}{N}$$

where $\{\hat{y}_i, y_i\}$ denote the predicted label and the ground-truth label for a given sample x_i respectively. $map(\cdot)$ is a mapping function that maps each predicted label $\hat{y}_i$ to its corresponding ground-truth label y_i by Hungarian algorithm.

ARI calculates the similarity between the predicted and ground-truth clusters, assessing the accuracy of clustering on a pairwise basis. ARI is defined as:

$$ARI = \frac{\sum_{i,j}\binom{n_{i,j}}{2} - [\sum_i \binom{u_i}{2} \sum_j \binom{v_j}{2}]/\binom{N}{2}}{\frac{1}{2}[\sum_i \binom{u_i}{2} + \sum_j \binom{v_j}{2}] - [\sum_i \binom{u_i}{2} \sum_j \binom{v_j}{2}]/\binom{N}{2}}$$

where $u_i = \sum_j n_{i,j}$, and $v_j = \sum_i n_{i,j}$. N denotes the number of all samples. $n_{i,j}$ is the number of sample pairs that are both assigned to i^{th} predicted cluster and j^{th} ground-truth cluster.

NMI computes the normalized mutual information to quantify the agreement between the predicted and ground-truth clusters, providing a measure of clustering consistency. It can be calculated as follows:

$$NMI(\hat{\boldsymbol{y}}, \boldsymbol{y}) = \frac{2 \cdot I(\hat{\boldsymbol{y}}, \boldsymbol{y})}{H(\hat{\boldsymbol{y}}) + H(\boldsymbol{y})}$$

where $\{\hat{\boldsymbol{y}}, \boldsymbol{y}\}$ denote the predicted labels and the ground-truth labels respectively. $I(\hat{\boldsymbol{y}}, \boldsymbol{y})$ is the mutual information between $\hat{\boldsymbol{y}}$ and $\boldsymbol{y}$. $H(\cdot)$ represents the entropy function.

A.4 Baselines

In this work, we compare the proposed ALUP with the following representative baselines:

- **DTC** (Han et al., 2019): A semi-supervised deep clustering approach with a novel mechanism for estimating the number of intents based on labeled data.
- **CDAC+** (Lin et al., 2020): A pseudo-labeling approach that employs pairwise constraints and a target distribution as guiding factors in the learning of new categories.
- **DeepAligned** (Zhang et al., 2021b): A semi-supervised approach that addresses the clustering inconsistency problem by using an alignment strategy for learning utterance embeddings.

Cluster Num	Methods	Banking77		
		ACC	ARI	NMI
$K = 77$ (gold)	USNID	65.85	56.53	81.94
	CsePL	71.06	60.36	83.32
	ALUP	**74.61**	**62.64**	**84.06**
$K = 74$ (predicted)	USNID	60.72	49.18	78.11
	CsePL	69.75	56.70	81.30
	ALUP	**72.55**	**61.04**	**82.78**

Table 7: Effect of estimating cluster number K.

- **ProbNID** (Zhou et al., 2023): A probabilistic framework that capitalizes on the expectation-maximization algorithm, conceptualizing intent assignments as probable latent variables.
- **DCSC** (Wei et al., 2022): A pseudo-labeling method involving the dual-task, which uses the SwAV algorithm and Sinkhorn-Knopp (Cuturi, 2013) to assign soft clusters.
- **MTP-CLNN** (Zhang et al., 2022a): A two-stage method that enhances representation learning via a multi-task pre-training and a nearest neighbor contrastive learning for identifying new categories.
- **USNID** (Zhang et al., 2023a): A framework supports both unsupervised and semi-supervised new intent discovery, incorporating an effective centroid initialization strategy designed to learn cluster representations by utilizing historical clustering information.
- **CsePL** (Liang and Liao, 2023): A method that utilizes two-level contrastive learning with label semantic alignment to enhance the cluster semantics and a soft prompting strategy for discovering new intents.

We re-run the released code of ProbNID to get its results. The other baselines' results are retrieved from Zhang et al. (2023a).

B Estimate the Category Number K

In the complex task of generalized category discovery in real-world scenarios, accurately predicting the total number of categories, represented as K, remains a significant challenge. Drawing from the methodologies proposed by Zhang et al. (2021b), our research leverages pre-initialized intent features to determine K autonomously. We begin by assigning an initially large number of clusters, K', and then utilize a refined model to extract feature representations from our training dataset. These representations are grouped into distinct clusters using the K-means algorithm. Clusters that are densely populated and demonstrate well-defined boundaries are recognized as valid category clusters. Conversely, smaller, less distinct clusters are considered less relevant and subsequently discarded. The selection criteria for this process can be outlined as follows.

$$K = \sum_{i=1}^{K'} \delta(|S_i| > \rho),$$

where $|S_i|$ is the i-th grouped cluster size, ρ is the filtering threshold. $\delta(\cdot)$ denotes the indicator function, whose output is 1 if the condition is satisfied.

Experimental results are reported in Table 7. The comparative results show that the proposed ALUP incurs only a minor performance decline with the predicted category number. This indicates that our ALUP exhibits robustness in handling inaccurately predicted category number.

Explaining Text Similarity in Transformer Models

Abstract

As Transformers have become state-of-the-art models for natural language processing (NLP) tasks, the need to understand and explain their predictions is increasingly apparent. Especially in unsupervised applications, such as information retrieval tasks, similarity models built on top of foundation model representations have been widely applied. However, their inner prediction mechanisms have mostly remained opaque. Recent advances in explainable AI have made it possible to mitigate these limitations by leveraging improved explanations for Transformers through layer-wise relevance propagation (LRP). Using BiLRP, an extension developed for computing second-order explanations in bilinear similarity models, we investigate which feature interactions drive similarity in NLP models. We validate the resulting explanations and demonstrate their utility in three corpus-level use cases, analyzing grammatical interactions, multilingual semantics, and biomedical text retrieval. Our findings contribute to a deeper understanding of different semantic similarity tasks and models, highlighting how novel explainable AI methods enable in-depth analyses and corpus-level insights.

1 Introduction

Modern foundation models provide flexible text representations that enable the detection of semantic structure in vast amounts of unlabeled data. While traditionally supervised settings have taken a predominant role for NLP research, many widely used unsupervised tasks have received growing attention. The similarity structure of text embeddings herein provides a central starting point for many tasks, including information retrieval, semantic search, ranking and knowledge extraction (Frakes and Baeza-Yates, 1992; Mooney and Bunescu, 2005; Jansen and Rieh, 2010), clustering (Aggarwal and Zhai, 2012), and visualization (van der Maaten and Hinton, 2008; Venna et al., 2010; McInnes et al., 2018). In the context of language generation, the retrieval-augmented generation (RAG) (Lewis et al., 2020) approach computes semantic closeness to index relevant text data, resulting in numerous new information retrieval systems (Gao et al., 2023). Furthermore, as the number of models and tasks increases, the need for quantitative evaluation of embeddings has become apparent, leading to the introduction of embedding benchmarks (Thakur et al., 2021; Muennighoff et al., 2022).

Complementary to the evaluation of nominal performance, the field of explainable AI aims to provide insights about the inner model mechanisms by highlighting relevant features for a specific prediction (Montavon et al., 2018; Danilevsky et al., 2020; Vilone and Longo, 2021; Samek et al., 2021). Explanations play a crucial role in verifying that predictions are grounded in task-relevant features, fostering trust and verifiability into complex machine learning models, and enabling the discovery of data patterns and novel insights. In this context, the prediction of supervised models can often be explained using heatmaps over input features. Beyond heatmaps, specific explanation approaches have been proposed in the context of unsupervised models (Montavon et al., 2022; Kauffmann et al., 2022) and higher-order explanations (Eberle et al., 2022; Schnake et al., 2022; Fumagalli et al., 2023). In this paper, we focus on Transformer-based similarity models that motivate the use of second-order attributions to highlight feature interactions. Our main contributions are as follows:

- We analyze Transformer-based similarity models within the framework of second-order explanations using BiLRP, highlighting the interaction between tokens.
- We evaluate explanations through a purposely designed similarity task for which ground truth interactions are available, and via input perturbations on real-world semantic similarity data.

Proceedings of the 2024 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies (Volume 1: Long Papers), pages 7859–7873
June 16-21, 2024 ©2024 Association for Computational Linguistics

- We investigate the interaction of relevant tokens across three use cases, revealing the compositional structure that drives high/low similarity, thus providing fine-grained insights into sentence representations that are the fundamental concept in many NLP applications but have not been analyzed in the context of explainable AI.
- We perform corpus-level analyses, identifying the parts of speech that models prioritize and illustrating how simple token-matching strategies can lead to inaccurate predictions.

Our implementation is publicly available.[1]

2 Related Work

Semantic Textual Similarity The task of identifying the degree of semantic equivalence between texts is referred to as semantic textual similarity (STS) (Lee et al., 2005; Agirre et al., 2012; Chandrasekaran and Mago, 2021). While two words may be semantically related, e.g. 'coffee' and 'mug', the STS task focuses on the semantic closeness between text, and in this sense 'tea' is considered more similar to 'coffee' than 'mug' (Chandrasekaran and Mago, 2021).

Similarity Models for NLP Similarity models are designed to capture the meaning and context of the input texts and provide a quantitative measure of their semantic similarity or relatedness. Commonly used approaches include end-to-end-trained Siamese networks (Bromley et al., 1993; Hu et al., 2014; Neculoiu et al., 2016) and universal encoder models with a pooling layer to extract text summary embeddings (Cer et al., 2018). Combined with Transformers, these approaches have become powerful frameworks to build similarity models. Sentence Transformers, specifically Sentence-BERT (SBERT), (Reimers and Gurevych, 2019) have emerged as a flexible and widely-used method to compute compact text representations. Similarity models typically process pairs of inputs to compute a similarity score, often based on dot products such as cosine similarity, while extensions to dataset-level dot products have enhanced semantic sentence matching (Zhong et al., 2020) and guided document retrieval in RAG systems (Lewis et al., 2020). Recent efforts in evaluating similarity models and text representations include benchmarks on information retrieval (Thakur et al., 2021) and comparing performance across diverse embedding tasks (Muennighoff et al., 2022).

Explaining Transformers The limitations of raw attention scores as explanations have emphasized the need for improved explanation methods for Transformers (Jain and Wallace, 2019; Serrano and Smith, 2019). Notably, aggregating relevant information across attention heads has proven to be a promising direction (Abnar and Zuidema, 2020; Chefer et al., 2021a), with further empirical evidence supporting the benefits of gradient information (Wallace et al., 2019; Atanasova et al., 2020; Chefer et al., 2021b). The naive computation of explanatory gradients in Transformers could be further improved by considering the conservation of relevance during backpropagation, which results in a modified layer-wise relevance propagation (LRP) scheme for Transformers (Ali et al., 2022).

Interpretable Feature Interaction Several works have focused on determining the effect of joint features in supervised classification scenarios. To identify such pair-wise attributions, multivariate statistics (Bien et al., 2013; Caruana et al., 2015), Hessian-based approaches (Janizek et al., 2021), as well as methods inspired by co-operative game theory (Tsang et al., 2020; Dhamdhere et al., 2020; Fumagalli et al., 2023), have been proposed. Beyond classification, the interaction between features provides an appropriate level of complexity to assess why a pair of inputs produces a high or low similarity score. To compute joint feature relevance, Hessian $\times$ Product and BiLRP have been proposed (Eberle et al., 2022). These methods can be derived directly from a deep Taylor decomposition (Montavon et al., 2017) of similarity models and can be seen as extensions of the widely used Gradient $\times$ Input and LRP explanation methods to bilinear models.

3 Explainable AI for Similarity Models

In the following section, we briefly outline how the specific structure of deep similarity models motivates the consideration of second-order terms, as well as the need for tailored propagation rules to compute robust and accurate explanations for Transformers.

3.1 Explainable AI for Similarity Models

Starting from a Taylor expansion of the similarity score $y(\boldsymbol{x}, \boldsymbol{x}') = \langle \phi(\boldsymbol{x}), \phi(\boldsymbol{x}') \rangle$ with a pair of inputs ($\boldsymbol{x}$,$\boldsymbol{x}'$), a feature map $\phi : \mathbb{R}^{s \times d} \to \mathbb{R}^h$ and y

[1] https://github.com/alevas/xai_similarity_transformers

the predicted dot product similarity, the following description of relevance $R_{ii'}$ assigned to a pair of features (i, i') can be derived (Eberle et al., 2022):

$$R_{ii'} = x_i x'_{i'} \left[\nabla^2 y(\boldsymbol{x}, \boldsymbol{x'})\right]_{ii'},$$

where ∇^2 denotes the Hessian containing second-order partial derivatives.

For deep neural networks, these derivatives have been found to be noisy (Balduzzi et al., 2017; Montavon et al., 2018), which motivates the formulation of robustified propagation rules within the LRP framework, resulting in the BiLRP method, which can be computed in the following factored form:

$$\text{BiLRP}(y, \boldsymbol{x}, \boldsymbol{x'}) = \sum_{m=1}^{h} \text{LRP}([\phi_L \circ \cdots \circ \phi_1]_m, \boldsymbol{x}) \otimes \text{LRP}([\phi_L \circ \cdots \circ \phi_1]_m, \boldsymbol{x'}),$$

where ϕ_L is an intermediate feature map at layer L and $\otimes$ refers to the tensor product between LRP relevance matrices. The LRP attribution for neuron j in layer l is computed by pooling over all incoming messages from neurons k in the higher layer $l+1$:

$$R_j^{(l)} = \sum_k \frac{q_{jk}}{\sum_j q_{jk}} \cdot R_k^{(l+1)},$$

with contributions q_{jk} of neuron j to relevance $R_k^{(l+1)}$. Depending on the type of network layer, different propagation rules have been proposed to compute q_{jk}, typically selected to be proportional to the observed neuron activations (Montavon et al., 2019). In Section 3.2, we introduce specific propagation rules for Transformer models.

The resulting BiLRP explanations assign relevance scores $R_{ii'}$ to each interaction between input features (x_i, x'_i), highlighting in a detailed manner how features interact to produce the similarity prediction. To compute the interactions $R_{ii'}$, one backpropagation pass for each embedding dimension h is required, resulting in $2 \times h$ computations for a pair of sentences that can be computed efficiently using automatic differentiation software. For BiLRP, this results in computing multiple LRP explanations and, thus, its robustness is directly related to the reliable propagation of relevance.

3.2 Explainable AI for Transformers

To compute better explanations for Transformers, leveraging gradient information has proven to be effective. Yet, the non-linear structure of Transformers motivates specific gradient propagation rules to reflect the model prediction more reliably, resulting in more faithful explanations (Ali et al., 2022). The application of these rules does not affect the model's forward predictions but only modifies the gradient computations in the backward pass.

Propagation rules The bilinear structure of the query-key-value (QKV) self-attention layers and the layer normalization computations, lead to a break in relevance conservation, which can be addressed using specific propagation rules. For the **attention head**, the forward pass can be formulated as $y_j = \sum_i h_i [p_{ij}]_{\texttt{.detach()}}$, viewing the attention scores p_{ij} as a weighting matrix for the current residual stream representation h_i and detaching the associated variable p_{ij} from the computation graph (Ali et al., 2022). To preserve relevance in **layer normalization**, the denominator is regarded as a normalization constant resulting in $y_i = (h_i - \mathbb{E}[h]) / \left[\sqrt{\epsilon + \text{Var}[h]}\right]_{\texttt{.detach()}}$, with expectation $\mathbb{E}$, variance Var and stabilization parameter ϵ (Ali et al., 2022). In addition, specific non-linear activation functions like GeLU break conservation of relevance, which can be addressed by attributing relevance in proportion to the computed activations (Eberle, 2022). For all other layers, the LRP-0 propagation rule is applied, redistributing relevance in proportion to the contribution of each input neuron to the computed activation (Montavon et al., 2019). These resulting propagation rules also match related approaches to explain bilinear LSTM gating (Arras et al., 2017), and to linearize Transformers (Elhage et al., 2021).

4 Experiments

We now introduce the semantic similarity datasets and models used in this paper before proceeding with the evaluation of second-order explanations.

4.1 Data

STSb (Semantic Textual Similarity benchmark) consists of English text in the form of sentence pairs, extracted from image captions, news headlines and user forums (Cer et al., 2017). A ground truth similarity score was assigned to each text pair as the result of a human annotation process. In addition, the multilingual STSb (mSTSb) dataset (May, 2021) provides machine translated sentence pairs in ten languages. **SICK** (Sentences Involving Compositional Knowledge) contains sentence pairs with human-annotated similarity scores (Marelli et al., 2014), aiming to assess the performance of

models in understanding sentence meaning, compositionality, and related tasks such as textual entailment. **BIOSSES** consists of a total of one hundred sentence pairs selected from the 'TAC2 Biomedical Summarization Track Training Data Set' (Soğancıoğlu et al., 2017). Each sentence pair was assigned a similarity score based on annotations of five domain experts for the evaluation of biomedical text comparison tasks.

4.2 Similarity Models

In our experiments, we consider four Transformer-based architectures and three pooling strategies described in the following.

Transformers The widely-used **BERT** model, initially trained on English text, demonstrates strong performance across various natural language processing tasks (Devlin et al., 2019). Additionally, it has been extended to 104 languages, resulting in **mBERT** for cross-lingual applications. Specifically trained on the task of semantic similarity, the **SBERT** framework provides models that enable the efficient calculation of semantic relatedness, useful for tasks like information retrieval and knowledge extraction (Reimers and Gurevych, 2019). The **SGPT** (Muennighoff, 2022) model is built on top of a finetuned GPT-Neo model (Black et al., 2021), which is an open source variant of the popular GPT-family and similar to GPT-3. Additional model details are provided in Appendix A.

Pooling To summarize token embeddings into fixed size representations, we use the following pooling strategies: **CLS-Pooling** uses the CLS token as a fixed-size representation for tasks like text classification in many Transformer models. **Mean-Pooling** averages over token embeddings to obtain one single representation vector, capturing the overall information of the input sequence. **QKV-Pooling** uses the QKV-mechanism to compute weighting coefficients before aggregating the token embeddings.

4.3 Evaluation of Explanations

Interaction Analysis The complex structure of the similarity task and a lack of fine-grained ground truth rationales of feature interaction motivates the evaluation of explanations on a specifically designed similarity task. We design a similarity model based on co-occurrence statistics of features, which here are interactions between same noun tokens (see Figure 1, top row). We finetune a similarity model using a BERT-base encoder with a QKV-pooling layer to correctly predict the number of co-occurring proper nouns and nouns in the STSb dataset. After optimization of the mean squared error (MSE) loss between true and predicted scores, the similarity model is able to correctly predict the number of interactions (Spearman's $\rho = 0.94/0.89$, $\text{MSE} = 0.21/0.87$ for train/test). To verify that predictions are built from the expected interactions, we compute the similarity between ground-truth interactions and compare them to the second-order explanations extracted from (i) token embeddings, (ii) Hessian $\times$ Product (H$\times$P), and (iii) BiLRP.

In Figure 1, we observe that computing interactions directly from token embeddings results in pairwise attributions mainly between same tokens that are not selective with respect to their assigned part-of-speech (POS) tag. For H$\times$P, the interactions are much more selective with regard to nouns and proper nouns, and we observe considerable token interactions that are assigned negative relevance. In the case of many interacting tokens that drive high similarity (Figure 1, right column), we observe that it becomes increasingly difficult to identify the relevant interactions. BiLRP is able to select the relevant tokens in comparison to the other baselines with higher accuracy, which is supported by the highest average cosine similarity (ACS) between true interactions and BiLRP of 0.81 in comparison to 0.62 for H$\times$P, and 0.67 for the embedding baseline.

In summary, our self-designed similarity task can be accurately explained using BiLRP, allowing a better understanding of the model's strategy of filtering out task-irrelevant parts of speech to solve the noun-matching task.

Perturbation Analysis We further test the ability of explanations to faithfully capture the similarity prediction process on real-world semantic similarity sentence pairs. Sequence elements are ordered based on sum-pooled interaction scores from highest to lowest relevance and elements are added iteratively to the selected input sequence. At each step, we compute the Euclidean distance between the perturbed and the unperturbed sentence representation, measuring how strongly the representation is affected in response to the removal of the next most relevant tokens. Resulting perturbation curves are shown in Figure 2 comparing different explanation methods and a random baseline. We observe that across models and datasets, BiLRP consistently se-

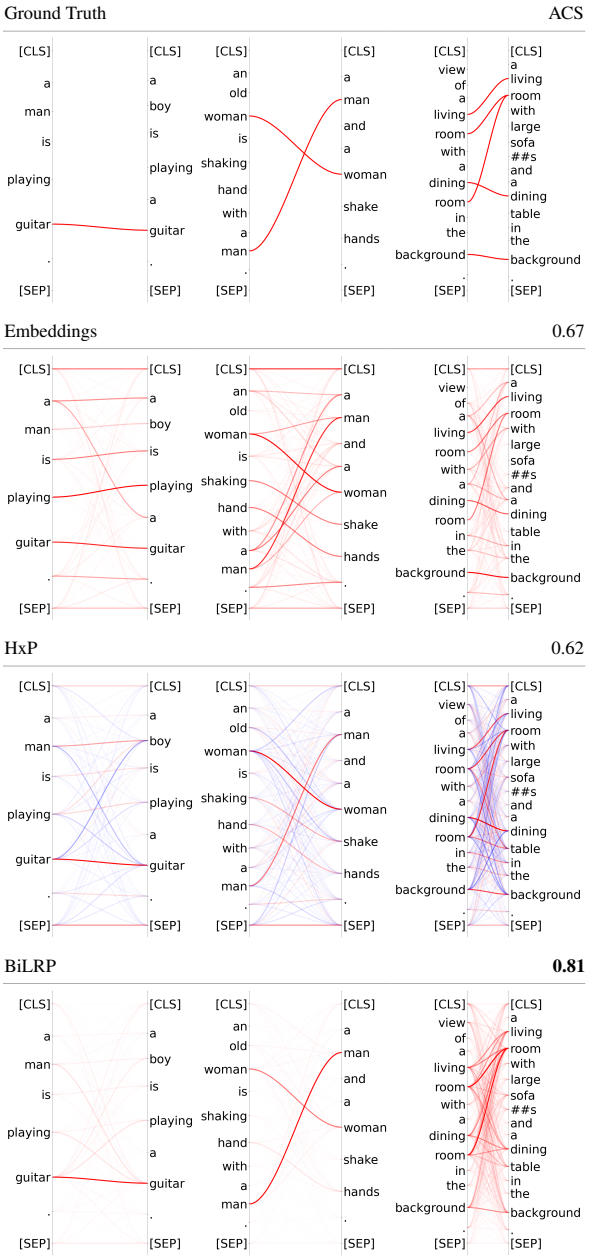

Figure 1: Comparison of different explanation techniques that highlight the interaction between input features. Ground truth interactions (top row) are the interactions between same noun tokens. These are compared to second-order explanations built on top of BERT token embeddings, Hessian×Product (H×P) and BiLRP. Average cosine similarity (ACS) is used to measure agreement between ground truth and explanations.

lects the features that decrease the distance between sentence representations most effectively, resulting in the lowest area under the perturbation curve (see Appendix B). The steep initial decline in Euclidean distance for BiLRP highlights that a small subset of highly relevant features are identified reliably. These findings further accentuate the differences between explanation methods, emphasizing the effectiveness of BiLRP in identifying the relevant interactions between tokens.

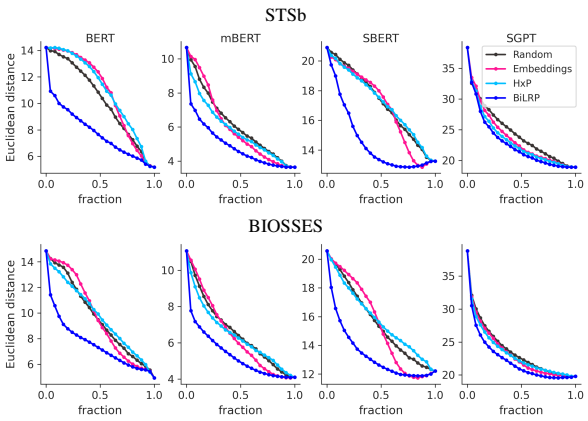

Figure 2: Perturbation experiment comparing different explanation methods across models. Fractions of tokens, ranked from most to least relevant, are added to one input sequence and the resulting Euclidean distance to the unperturbed sentence is measured. A steep initial decline with a smaller area under the curve indicates better identification of task-relevant features.

Conservation The main axiomatic principle used to develop improved BiLRP explanations for Transformers is conservation of relevance. The sum of observed relevance is directly related to the explained model predictions, and explanations that are relevance conserving have been shown to result in improved explanations (Ali et al., 2022), as also confirmed in our experiments presented in Figures 1 and 2. Implementing these rules to compute second-order explanations (see Section 3.2) reconstitutes relevance conservation in BiLRP in comparison to H×P as shown in Figure 6 in Appendix C. A residual lack of conservation can be explained by neuron biases, which are unattributable (Figure 6, rightmost panel).

Overall, these experiments have confirmed that BiLRP explanations can accurately identify the most relevant feature interactions, leading us next to an evaluation of the textual similarity prediction task itself.

4.4 Predicting Semantic Textual Similarity

Next, we focus on the task of predicting semantic textual similarity and compare different pre-trained similarity models (BERT, mBERT, SGPT, SBERT) across three datasets (STSb, SICK, BIOSSES). We evaluate model predictions using Spearman correlation with the goal to identify performance differences between models that inform more focused analyses using explainable AI.

Model	Spearman correlation		
	STSb	SICK	BIOSSES
BERT + CLS	20.3	42.4	63.7
BERT + Mean Pooling	47.3	58.2	54.6
mBERT + Mean Pooling	55.2	56.3	55.6
SGPT + Mean Pooling	76.9	73.4	69.6
SBERT + Mean Pooling	84.7	78.4	66.7

Table 1: Spearman correlation $\rho \times 100$ for a set of tasks and models. The first three models were not finetuned, while SGPT and SBERT were finetuned on semantic similarity data.

As shown in Table 1, the standard BERT similarity model, when used with CLS or mean pooling methods, fails to effectively capture semantic proximity. The Spearman correlation $\rho \times 100$ for the CLS-Pooling is 20.3, whereas a significantly improved correlation is achieved when using mean pooling across all encoded token representations for STSb and SICK data. Similarity is best predicted by SGPT and SBERT with scores ranging from 66.7 to 84.7, highlighting overall the considerable impact of model selection, pooling strategy and dataset on task performance.

5 Corpus-Level Use Cases

To go beyond the mere evaluation of nominal correlation, which is at risk of obfuscating undesired model strategies, i.e. Clever-Hans-type and shortcut learning (Lapuschkin et al., 2019; Geirhos et al., 2020), we hereby explore how BiLRP explanations can be used to uncover general model strategies in three distinct use cases.

5.1 Explaining Semantic Textual Similarity

To conduct an explanation-based analysis of semantic similarity, we retrieve explanations for all 1379 samples of the STSb test set. Token-to-token interactions are summarized by extracting POS tags using *spaCy 3* and aligning different tokenizers using *tokenizations* [2].

The corpus-level analysis is performed by aggregating all relevance scores per token pair. Relevance for each interaction between POS-tags is aggregated and scores are normalized by the maximum absolute value of total summed relevance, which results in a relevance scoring over interactions, as shown in Figure 3. For each interaction, we distinguish between relevance patterns that negatively (blue triangle) or positively (red triangle) contribute to the similarity score.

[2] https://github.com/explosion/tokenizations

For the BERT + CLS similarity model with lowest correlation scores as shown in Section 4.4, we identify that the most positively relevant interactions are 'NOUN-NOUN', 'NOUN-VERB' and 'NOUN-[SEP]' (Figure 3-a). While negative contributions are less pronounced, we observe some amount of negatively contributing 'NOUN-[CLS]' interaction. For mean pooling shown in Figure 3-b, we observe the strongest positive effects for '[SEP]-[SEP]', followed by 'NOUN-NOUN' and 'NOUN-VERB' interactions. Overall, the distribution of relevance is more concentrated over a smaller set of POS interactions. The SBERT model shows a distribution comparable to BERT + CLS, focusing on a similar subset of interactions (Figure 3-c), though assigning different importance to them. Specifically, 'NOUN-NOUN', 'NOUN-[SEP]' and 'NOUN-VERB' are most relevant. In contrast to BERT with mean pooling, the '[SEP]-[SEP]' interaction is significantly less pronounced. SBERT also attributes considerable amount of relevance to 'VERB-VERB' and 'NOUN-ADJECTIVE' interactions, which overall suggests that the semantic similarity task can be solved quite well using a small but well-chosen subset of POS interactions.

Our analyses further provide insights regarding the choice of pooling strategy, supporting previous findings that are in favor of mean pooling over CLS pooling (Mohebbi et al., 2021) and underscoring the usefulness of explanations on the level of interactions to identify differing strategies across models.

5.2 Explaining Multilingual Similarity

Multilingual language models enable the flexible use of embeddings for unsupervised downstream tasks across different languages. In this section, we consider a setting in which a ranking of most similar texts in a multilingual database is required. We use the mSTSb dataset and compute similarity for mBERT and a set of monolingual BERT models for English, German, Russian and Chinese, assuming that no fine-tuning on semantic similarity is performed. The text representations are extracted by mean pooling.

Results We first analyze the correlation to ground truth similarity scores and focus on nominal prediction differences across settings, guiding the selection of an interesting case study for our subsequent BiLRP analysis. As shown in Figure 4-a, we observe that Spearman correlation scores are

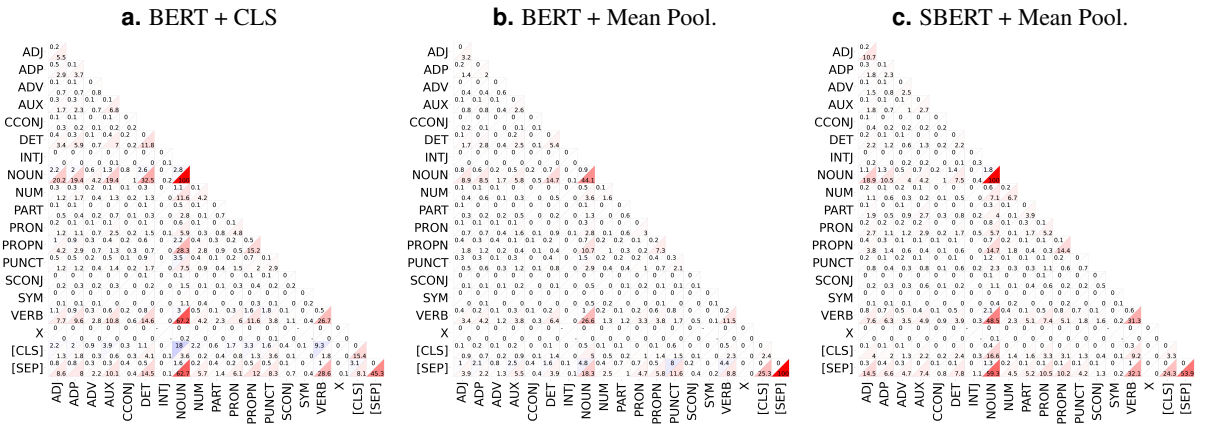

Figure 3: Corpus-level analysis of BiLRP explanations between POS tags on the STSb dataset. The contribution of positive/negative interactions to the similarity score is shown in red/blue for three similarity models, ranging from (**a**) the least predictive (BERT + CLS), to (**b**) moderately predictive (BERT + Mean Pooling), to (**c**) the most predictive (SBERT) (cf. Table 1).

consistently between 47.3 and 58.5 across the four aforementioned languages, reaching similar correlation levels as observed in the previous section for not finetuned similarity models (cf. Table 1). Interestingly, for the mixed-multilingual case, we observe a clear drop of correlation scores to 24.8–35.5. To uncover some of the effects that drive this decrease in performance, we next conduct a case study on the English and German subsets of the mSTSb corpus.

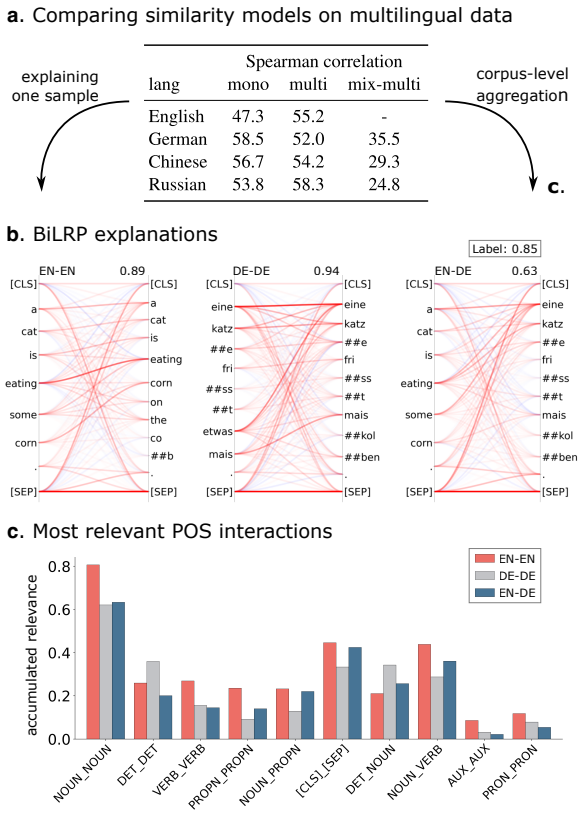
In Figure 4-b, our initial step involves explaining a sentence pair using BiLRP within monolingual settings (EN-EN, DE-DE) and comparing it to the mixed setting (EN-DE). For English, we see how semantic similarity is attributed to the interaction of 'eating', whereas the German translation 'frisst' is considered less relevant. Instead, we find that semantic similarity in the German setting is more often attributed to the interaction between determiners ('eine-eine'), which may reflect the specific role of determiners in the German language that both quantify and determine an object (Dipper, 2005). We provide additional samples that illustrate several cases of relevant interactions in Appendix D. These include the mismatching of different quantities ('two-three'), effects of matching subtokens that affect the semantic meaning ('key-##board' and 'keyboard'), and overall overconfidence of the model in assigning high similarity based on semantically related tokens ('train-waiting', 'clothing-shirt').

We take a closer look at the aggregated most relevant POS interactions with the goal to identify differences in model strategies across settings. Specifically, we analyze which POS interactions change the most from the monolingual to the multilingual setting and show the ten interactions of largest difference in accumulated positive relevance assigned to a specific POS interaction in Figure 4-c. We additionally show negative changes in relevance in Figure 7 in Appendix D. We find that both 'NOUN-NOUN' and 'VERB-VERB' interactions are less relevant in the mixed setting when compared to the monolingual English setting, suggesting that the model is less able to match English to German nouns and verbs respectively. Furthermore, we find that the monolingual German similarity is driven by a considerable amount of interaction between determiner tags ('DET-DET') that are less present in the mixed case. Lastly, we underline the difference in assigned relevance to the interaction between nouns and proper nouns ('NOUN-PROPN'). We hypothesize that, while multilingual models learn a flexible joint embedding space across many languages and vocabularies, it may be difficult to accurately model subtle differences in semantic meaning that monolingual models are able to capture more precisely.

These detailed insights, both at the single-sample and corpus levels, can unveil the diverse strategies that result in accurate or inaccurate predictions of similarity, potentially informing the future design of similarity tasks and models across multilingual settings.

5.3 Analyzing Model Differences

In the next use case, we analyze what drives performance differences observed earlier in Table 1 on the biomedical text pairs contained in BIOSSES



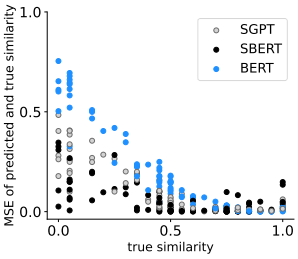


Figure 4: Comparison of mono- and multilingual BERT-based similarity models on mSTSb. (**a**) Spearman correlation $\rho \times 100$ of the multilingual STSb corpus. Similarity models are build from monolingual (mono) and multilingual (multi) BERT models that receive monolingual input, and a multilingual model that receives mixed input in English and a translated version of the other sentence (mix-multi). (**b**) BiLRP explanations on mBERT for English-English (left), German-German (center) and English-German (right). The sentence pair is assigned a true similarity score of 0.85. (**c**) Comparison of positively relevant POS interactions. POS tags are selected based on largest difference of accumulated relevance between the mixed and the monolingual settings.

(Soğancıoğlu et al., 2017). In a first step, we analyze the predicted similarity scores in Figure 5 (top) for SGPT, SBERT and BERT as introduced in Section 4.4. We clearly see how the error between ground truth and predicted similarity decreases for higher levels of true similarity. All three models assign correct levels of similarity for high similarity but are less capable of correctly capturing low similarity.

In the second step, we compute explanations and select the 25% data quantiles of highest and lowest predicted similarity. For each group, we rank the most relevant interactions and show the top-5 for each model in Figure 5 (bottom). For high similarity, we observe that both SBERT and BERT base their similarity predictions primarily on matching of same tokens or variants thereof, e.g. 'leukemia-leukemia' and 'cancer-cancers', while SGPT explanations identify interactions with gene regulating molecules ('miR-126-reports' and 'miR-223-regulates'), and interactions to more functional token pairs ('regulated-of') as most relevant. Similarly, for low similarity, SGPT explanations assign high relevance to molecule-specific interactions ('dependent-miR-133b' and 'KRAS-driven') and more general biomedical vocabulary ('oxidative–downward'). SBERT and BERT both show a comparable matching pattern ('also-augmented', 'mutations-found'), but as for high similarity also match closely related biomedical tokens ('nucleotides-rna', 'tumor-cancer').

This suggests that SGPT has better abilities to match task-relevant biomedical vocabulary, specifically names of gene molecules and tokens that are descriptive of gene expression processes, while SBERT und BERT base their similarity predictions on more general medical terminology. These strategies work well for highly similar sentence pairs for which matching may be sufficient, but are less suitable to correctly assess low similarity that may require more complex strategies e.g. the identification of negations or counterfactuals.

	SGPT	SBERT	BERT (mean)
high	miR-126–reports	up–up	tumor–tumor
	miR-223–human	leukemia–leukemia	leukemia–leukemia
	miR-223–regulates	mutual–mutually	cancers–cancers
	regulated–of	also–up	cancer–cancer
	of–cervical	cancer–cancer	tissues–cancer
low	dependent–miR-133b	tumors–tumors	mutant–mutations
	KRAS–driven	nucleotides–rna	dependent–mutations
	oncogenic–NSCLCs	research–research	oncogenic–mutations
	oxidative–downward	tumor–cancer	mutations–found
	combined–viability	also–augmented	vivo–tumors

Figure 5: Analysis of semantic similarity on the BIOSSES dataset containing biomedical text. Mean squared error (MSE) between predicted and true similarity for SGPT, SBERT and BERT similarity model is shown (top). Top-5 most relevant token interactions are shown for high and low similarity levels (bottom).

6 Discussion and Conclusion

Our evaluation and use cases have provided a framework to analyze textual similarity models using explainable AI. In the following, we contextualize our findings and discuss further implications.

Structured Explanations We have seen how novel types of explanations can be used to explain bilinear models in the context of semantic textual similarity. Resulting explanations highlight pairs of features that are most or least relevant to produce a particular similarity score. These second-order attributions provide an appropriate level of complexity and detail for investigating similarity model predictions that go beyond heatmap representations. In our experiments, BiLRP identifies feature interactions in Transformers more accurately than the token embedding baseline and the Hessian-based H×P explanations. This has allowed us to analyze the unsupervised semantic similarity task on the level of fine-grained interactions. Our results have highlighted interpretable interactions of tokens and POS tags that can next be utilized to inform and guide the development of similarity tasks and models. In particular, leveraging generative approaches may further inform the development of interaction-based explanation techniques.

Strategies of Similarity Models This approach enables insights into the internal computation of sentence representations in Transformers, exposing unexpected strategies employed for predicting semantic similarity. In particular, we have observed that high relevance in non-finetuned similarity models is often assigned to interactions between same tokens, revealing a rather simple token matching strategy. Our corpus-level POS analysis has indicated that semantic similarity can be approached by a small subset of interactions, most importantly interactions between nouns or proper nouns, verbs, and nouns and verbs, which promotes the notion of similarity as a 'bag of interactions'. We observe high relevance in specific token interactions (CLS and SEP), consistent with prior research (Clark et al., 2019; Bondarenko et al., 2023). In extension, this may result in unintended matching of tokens that is semantically not meaningful. Our experiments suggest that fine-tuning on similarity tasks and selecting an appropriate pooling strategy can partially alleviate these effects. While our focus has been on models predicting similarity, these structures are also commonly used as part of internal computations, such as matching key and value representations, which could also be analyzed using interactions.

Conclusion In many language applications the computation of similarity is a central concept to match textual information. Here, we have shown how predictions of widely used deep similarity models can be analyzed by assigning relevance to the interaction of features. These explanations have offered novel ways to perform corpus-wide analyses ranging from information retrieval, to multilingual text matching, and the estimation of similarity in biomedical text data.

Considering the fast-growing number of applications based on foundation models, we believe that explainable AI has a critical role in ensuring their safe, robust and compliant use. AI safety is especially critical in high-risk domains including legal, financial, medical, or governmental applications of machine learning for which text data plays a central role, accentuating the necessity for rigorous system evaluations and comprehensive explanations. For complex tasks like semantic similarity, datasets that contain detailed structured rationales on the level of interactions are needed to improve model alignment with human expectations.

Limitations

Methods In this paper, we have focused on using post-hoc explanations and in particular gradient-based explanations, aiming for the most faithful explanations as identified by our evaluation. Achieving high faithfulness and meeting the conservation principle, requires implementation of gradient propagation rules, especially for a diverse range of Transformer architectures. Computing second-order explanations requires to compute as many backward passes as there are sentence embedding dimensions for each sentence in a pair. For the here considered embedding dimension of 768, this required around two minutes computation time on a 12GB P100 GPU. To accelerate computations, explanations can be computed in batch, provided that the memory requirements are met. The factorization of BiLRP enables the reuse of computed explanations when the same sentence or pair reoccurs in subsequent instances.

Evaluation Regarding our evaluation, we have adapted standard perturbation experiments designed for evaluating first-order heatmaps to

second-order explanations. We did this by initially sum-pooling over one of the sentences, performing perturbations on the corresponding input sequence, and subsequently repeating the analysis for the other sentence. This allowed us to measure how well the identified explanations are able to affect the closeness of the sentence representations, measuring faithfulness of our explanations with respect to the predictions. To evaluate the ability of second-order explanations in detecting relevant interactions, we have designed a synthetic experiment. While this does not cover the semantic complexity of real-world semantics, we consider it an important step to motivate the collection of structured rationales for complex language tasks.

Analyses We have focused our analyses on a few selected datasets but expect that our insights, i.e. regarding token matching, apply to the task of semantic similarity more broadly across different models and corpora. Analysing the effect of POS tags removes complex grammatical structures, e.g. verbal or gerundial nouns, which would furthermore complicate our multilingual analyses due to diverging grammatical rules and a varying number of categories. Thus, we consider the focus on POS-level granularity to be an appropriate first step at an intermediate level of detail to investigate the task of semantic similarity at a corpus scale.

Ethics Statement

We do not anticipate any harmful risks in using the methods and analysis used in this work.

A Model details

We provide details regarding model type, the Hugging Face identifier and the implemented propagation rules for each model in Table 2.

B Perturbation Details

To compute the perturbation evaluation, for each input pair, we order sequence elements based on sum-pooled relevance interaction scores from highest to lowest relevance and add elements iteratively to the selected input sequence. Tokens are added in steps of fractions of 0.04 until the original sentence is fully recovered. The initial empty sequence is initialized from the masking token for BERT-based models and 'Ġ' for SGPT since no specific masking or unknown special tokens are reserved by the tokenizer. Perturbation curves are computed once for each sentence in a pair and the resulting scores are averaged over all samples (1379 pairs of STSb and 100 pairs for SICK respectively). In Table 3 we report area under perturbation curve (AUPC) scores for the evaluation presented in the main paper Section 4.3. We further test if BiLRP AUPC scores are significantly lower than any of the other comparison methods and find this to be the case with $p \leq 0.05$ for all investigated models and datasets.

C Conservation

Conservation of relevance is one important desired principle of post-hoc explanations. It ensures that relevance can not be created or disappear during the explanation process of the prediction. In Figure 6, we show conservation of H×P, BiLRP and BiLRP with biases set to zero for the SBERT model. We observe that for H×P, the sum of predicted sentence embedding activations ϕ_m is not related to the sum of relevance scores at the input. For BiLRP, we observe a linear relationship of both quantities. The difference to full conservation (identity line) can be explained by layer biases that are not attributable by design.

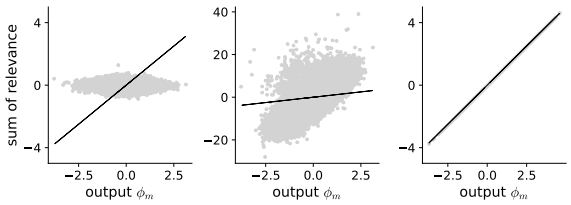

Figure 6: Conservation across 300 samples of the STSb test split on the SBERT model. Left: H×P baseline. Center: BiLRP computation. Right: BiLRP computation with model biases set to zero.

D Multilingual experiments

In Figure 8, we provide additional examples of token interactions in the multilingual settings considered in Section 5.2 of the main paper.

In analogy to the positively contributing POS interactions discussed in Section 5.2, we show POS interactions that contribute negatively in Figure 7. Relevance scores are normalized by the maximum absolute value. Overall, we find that negative contributions are less strong with relevance magnitudes below 0.1 in comparison to the positive interactions

model	name	propagation rules

SGPT	23.67±2.62	23.29±2.64	23.30±2.78	22.28±2.78

Table 3: Faithfulness analysis of explanation methods. AUPC (area under perturbation curve) on the STSb and BIOSSES semantic similarity datasets. Lower scores indicate better identification of features that decrease the Euclidean distance most effectively.

that reach up to 0.8, as shown in Figure 4 in the main paper.

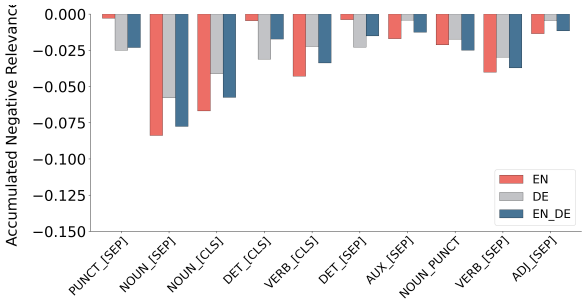

Figure 7: Comparison of relevant interaction between POS tags in a multilingual semantic similarity task. POS tags are selected based on largest difference of the negative accumulated relevance assigned to an interaction of POS tags between the mixed (EN-DE) setting and the monolingual (DE-DE, EN-EN) settings.

E Additional POS Heatmaps

In addition to the POS heatmaps in the main text, we provide the corpus-level analysis normalized by the number of POS-interaction occurrences. For this, we separate positive and negative relevance scores, retrieve the mean relevance of each token pair (instead of the sum as in the main text), normalize the scores by dividing by the maximum absolute mean value. The resulting heatmaps present a complementary view to Figure 3 in the main paper, highlighting rare POS interactions. We observe that for BERT + Mean Pooling, the effect of the interactions between '[SEP]' tokens is more apparent, since it consistently ranks across the most relevant POS interaction. For example, BERT + CLS reacts strongly to interactions between an interjection and a symbol ('nope-/'), while for SBERT we observe interactions between interjections to be of high relevance ('yes-yes' and 'no-no'). Cases like this highlight the need for well-tuned models that base their similarity predictions on desired and plausible interactions.

Figure 8: Additional BiLRP explanations on mBERT for English, German and the mixed English-German samples. The samples are chosen as representatives of the model's matching strategies, depicting different similarity levels of the labels, similarity predictions, and cases where the two diverge the most.

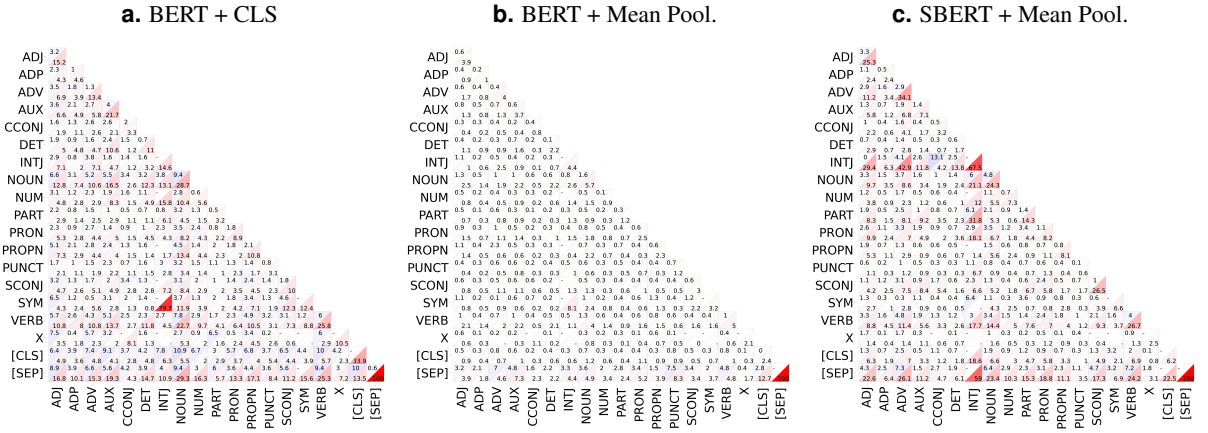

Figure 9: Alternative computation of the relevance scores, where the mean relevance of each token pair is retrieved instead of sum-pooling of relevance scores. Models range from (**a**) the least predictive (BERT + CLS), to (**b**) moderately predictive (BERT + Mean Pooling), to (**c**) the most predictive (SBERT).

Large Language Models can Contrastively Refine their Generation for Better Sentence Representation Learning

Abstract

Recently, large language models (LLMs) have emerged as a groundbreaking technology and their unparalleled text generation capabilities have sparked interest in their application to the fundamental sentence representation learning task. Existing methods have explored utilizing LLMs as data annotators to generate synthesized data for training contrastive learning based sentence embedding models such as SimCSE. However, since contrastive learning models are sensitive to the quality of sentence pairs, the effectiveness of these methods is largely influenced by the content generated from LLMs, highlighting the need for more refined generation in the context of sentence representation learning. Building upon this premise, we propose MultiCSR, a multi-level contrastive sentence representation learning framework that decomposes the process of prompting LLMs to generate a corpus for training base sentence embedding models into three stages (i.e., sentence generation, sentence pair construction, in-batch training) and refines the generated content at these three distinct stages, ensuring only high-quality sentence pairs are utilized to train a base contrastive learning model. Our extensive experiments reveal that MultiCSR enables a less advanced LLM to surpass the performance of ChatGPT, while applying it to ChatGPT achieves better state-of-the-art results. Comprehensive analyses further underscore the potential of our framework in various application scenarios and achieving better sentence representation learning with LLMs. Our code is available at https://github.com/Circle-Ming/MultiCSR.

1 Introduction

As a fundamental task, sentence representation learning (Conneau et al., 2017; Reimers and Gurevych, 2019; Gao et al., 2021) aims to learn universal sentence embeddings that can benefit various downstream tasks, such as semantic similarity comparison (Agirre et al., 2012, 2013, 2014, 2015, 2016; Cer et al., 2017; Marelli et al., 2014), and information retrieval (Le and Mikolov, 2014; Misra et al., 2016; Thakur et al., 2021; Wang et al., 2022). Recent advancements, particularly in contrastive learning-based methods such as SimCSE (Gao et al., 2021) and its variants (Chuang et al., 2022; Zhou et al., 2022; Tan et al., 2022; Wu et al., 2022; Jiang et al., 2022; Liu et al., 2023), have demonstrated to be the most efficient and effective ones. In contrastive learning, the quality of sentence pairs has a large impact on the overall performance (Chen et al., 2022). In particular, supervised contrastive learning methods trained on natural language inference (NLI) datasets (Bowman et al., 2015; Williams et al., 2018) can outperform their unsupervised versions by a large margin (Gao et al., 2021). However, obtaining large amounts of high-quality sentence pairs can be costly in both time and resources, particularly considering that various application domains can only be better handled with domain-specific training data.

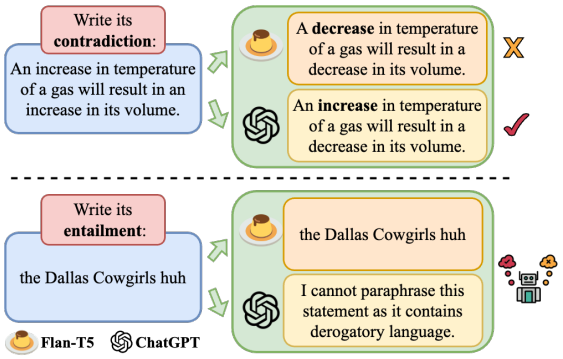

Figure 1: Two example sentences with the generations from Flan-T5 and ChatGPT given different instructions.

The recent emergence of large language models (LLMs), such as the Flan series (Chung et al., 2022), LLaMA (Touvron et al., 2023) and Chat-

GPT (OpenAI, 2022), has brought a paradigm shift in natural language processing due to their impressive performance. Consequently, there has been a growing interest in harnessing the power of LLM for sentence representation learning. Cheng et al. (2023) proposed to directly measure the semantic similarities of sentence pairs with LLMs for a base model to imitate. However, this imitation also places great demands on the LLM's understanding of semantics and constrains its application in a wider range of LLMs. Instead of utilizing LLMs for semantic similarity scoring, a recent line of work has explored leveraging LLMs to generate sentence pairs in the NLI style with provided premises (Schick and Schütze, 2021; Zhang et al., 2023) and demonstrates SOTA performance.

Despite their exciting results, these methods heavily depend on the quality of generated content from LLMs, leading a huge performance gap between different LLMs. Moreover, concerns about the accuracy and quality of the generated content from LLMs remain unsolved and have drawn significant attention from the community (Zheng et al., 2023; Shi et al., 2023), which are more pronounced with relatively less advanced LLMs. For example, in Figure 1, contradicting the first sentence requires a clear understanding towards its meaning and only ChatGPT successfully produce its contradiction. When faced with the second provided sentence, both ChatGPT and Flan-T5 encounter difficulties due to the limited information provided. Consequently, Flan-T5 only repeats the premise while ChatGPT entirely gives up the generation. In a task that is sensitive to the quality of sentences like sentence representation learning, there highlights a need for a more robust framework that can automatically refine the outputs of LLMs for better contrastive sentence representation learning.

Motivated by observations above, in this work, we propose **Multi-Level Contrastive Sentence Representation Learning (MultiCSR)**, a novel three-stage framework that contrastively refines the generations of LLMs at distinct stages: sentence generation, sentence pair construction and in-batch training, while fine-tuning a contrastive learning model like SimCSE. Concretely, while generating a sentence given a specific instruction like "Write its entailment:", we also deploy the noisy variants of this instruction to identify obvious error that LLMs will make during generating the outputs following this instruction. In a contrastive sentence generation procedure, next-token prediction logits will be systematically deviated by comparing the logits derived from the original instructions with those from the noisy instructions. This process detects and avoids the obvious error tendencies of LLMs, and refines their generations to align more closely with the intended instruction, rather than providing an even opposite generation, such as the first generation of Flan-T5 in Figure 1.

Despite the effectiveness of contrastive generation strategy, directly training a base sentence embedding model on the generated corpus gives poor results in our experiments, both because of the inevitably noisy generations, and the overlooked relations between sentences (i.e., sentence pairs), since a contrastive learning loss works essentially by modeling the relations between sentences while pulling the positive pairs closer and pushing the negative pairs apart. To take the relations between sentences into consideration, in sentence pair construction stage, we show that LLMs can be utilized to self-curate the set of their newly generated sentences by measuring the semantic similarities of sentence pairs, ensuring that only sentence pairs in highest quality are included into the final training stage. To further prevent the *false-negative* issue (Zhou et al., 2022) raised during the in-batch training, where randomly selected negative samples are indeed semantically similar to the original sentence, we utilize a pre-trained sentence representation model to provide the similarity mask and contrastively filter *false negatives* during training.

In summary, our contributions include: (1) We propose a new and promising direction to improve sentence representation learning by refining the generated content of LLMs. (2) We for the first time decompose the process of prompting LLMs to generate a corpus for training base sentence embedding models into three stages (i.e., sentence generation, sentence pair construction, in-batch training), and integrate the idea of contrast into each stage for refinement. (3) We conduct extensive experiments on standard semantic textual similarity (STS) tasks (Agirre et al., 2012, 2013, 2014, 2015, 2016; Cer et al., 2017; Marelli et al., 2014) and several transfer tasks (Conneau and Kiela, 2018) with two representative LLMs (i.e., Flan-T5 and ChatGPT). We further perform a comprehensive analysis of the behavior of MultiCSR, demonstrating its effectiveness from various perspectives. We hope that, our proposed method provides additional insights into achieving high-quality sentence representation learning corpus by refining LLMs' generations.

2 Related Work

2.1 Sentence Representation Learning with LLMs

There has been a recent exploration in utilizing LLMs for sentence representation learning. Cheng et al. (2023) prompted LLMs to measure the semantic similarities of sentence pairs, and fine-tuned base models to "immitate" these judgements of LLMs with mean squared error. However, this method also places great demands on the model's understanding of semantics. Thus, we conduct a pilot experiment to see whether LLM's generated similarities are well-aligned with the ground-truth labels and include the results in Table 1. We can see from the results that even ChatGPT equipped with ICL can not outperform those contrastive learning methods with only base models.

Instead of treating LLMs as evaluators, a recent line of work leverages LLMs as data generators, with the generated entailment and contradiction hypotheses being used to train a contrastive learning method (Schick and Schütze, 2021; Zhang et al., 2023). The success of these works is based on the fact that the models trained on NLI datasets demonstrate superior performance (Conneau et al., 2017; Reimers and Gurevych, 2019; Gao et al., 2021; Chen et al., 2022). Nevertheless, the performance of these methods will heavily rely on the quality of generated content, which also poses a huge challenge to the instruction-following and generation capabilities of LLMs. Thus, refining the generated data before utilizing them into training is essential, which usually requires substantial effort and computational resources, highlighting the need for more efficient approaches. In this work, we introduce MultiCSR, which can automatically refine the generation of LLMs and ensures that only high-quality sentence pairs are utilized for training a contrastive learning method.

2.2 Contrast in Text Generation

Recently, with the rapid development of LLMs, the idea of contrast for improving text generation has been studied in various settings (Welleck et al., 2019; Liu et al., 2021; Li et al., 2023; Yona et al., 2023; Kim et al., 2024). Among them, contrastive decoding (Li et al., 2023) studies maximizing the next-token probability by contrasting the predictions from a high-performing "expert" model against those from a less accurate "amateur" model. Despite its effectiveness, the need for at least two models of different scales limits their applications in broader scenarios. In this work, inspired by instructive decoding (Kim et al., 2024) which places emphasis on the potential of instructions in the input text, we show that, within the contrastive generation procedure, the instructions used for generating the opposite hypotheses can be extremely effective in identifying the obvious error tendencies of LLMs for further refining their generations in the context of sentence representation learning.

Model	Avg.
$\text{SimCSE}_{\text{RoBERTa}}$	76.57
PromptRoBERTa	**79.15**

ChatGPT w/ ICL	76.19

Table 1: Performance comparison of different models and directly utilizing LLMs w/o and w/ in-context learning (ICL) to measure the similarities on STS tasks.

3 Methodology

In this section, we present MultiCSR, a framework designed to enhance the quality of generated content of LLMs. By contrastively refining their generations at distinct stages of training a contrastive learning method, MultiCSR ensures that only high-quality sentence pairs are utilized in the final training stage, achieving a better sentence representation learning with LLMs. The whole workflow can be visualized as Figure 2.

3.1 Stage 1: Contrastive Generation

During the generation procedure, when presented with a concatenation of an instruction I and an input sequence $\boldsymbol{x}$, the objective of an LLM C_θ is to generate the corresponding output sequence $\boldsymbol{y} = [y_1, ..., y_n]$. For each token y_t, C_θ will compute its logits as $l_t = C_\theta(I, \boldsymbol{x}, \boldsymbol{y}_{<t})$. The probability of output sequence $\boldsymbol{y}$ can be expressed as:

$$p_\theta(\boldsymbol{y}|I, \boldsymbol{x}) = \prod_{t=1}^{n} p_\theta(y_t|I, \boldsymbol{x}, \boldsymbol{y}_{<t}), \quad (1)$$

where $p_\theta(y_t|I, \boldsymbol{x}, \boldsymbol{y}_{<t})$ represents the normalized probability of the sampled (e.g., greedy sampled) next token y_t derived from the softmax over l_t. Within this process, more refined generations can be achieved by ensuring that the model's generation essentially aligns with the given instructions.

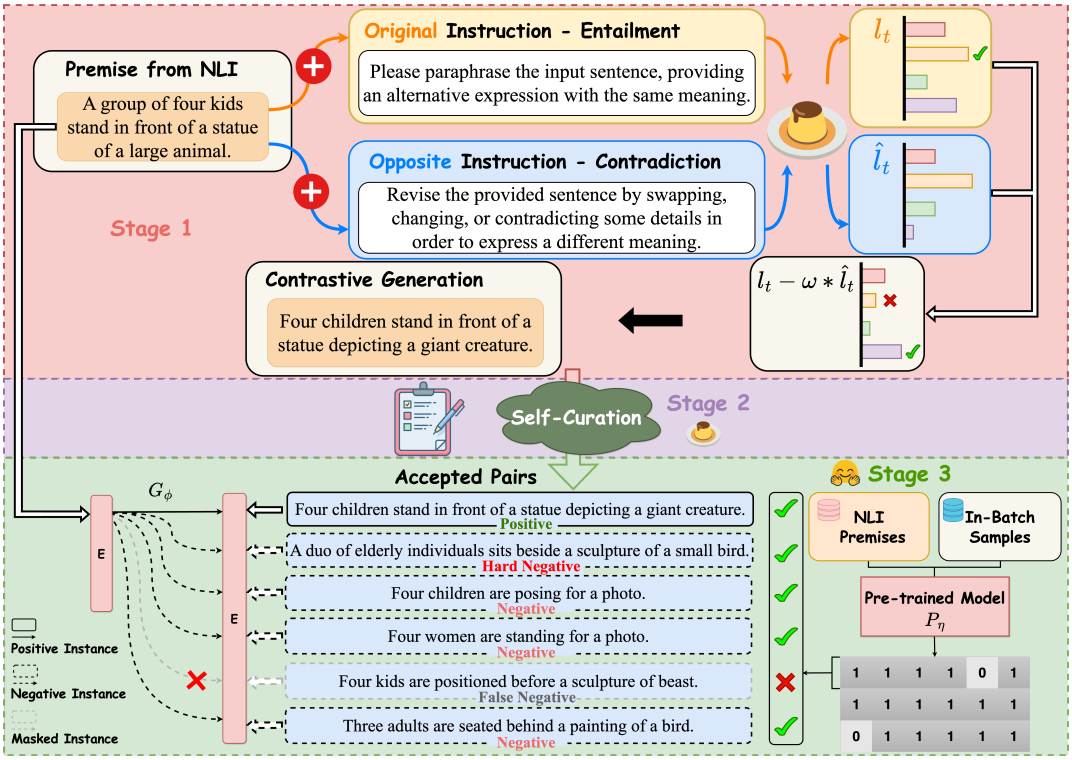

Figure 2: Overview of our three-stage framework MultiCSR. **Stage 1: Contrastive Generation.** We refine each token's logits with the opposite instruction to align more closely with the intended instruction. **Stage 2: Contrastive Sentence Pair Construction.** By prompting LLMs to evaluate the semantic similarities of generated sentence pairs, we ensure that only sentence pairs satisfying the pre-defined rules are left to form a curated set. **Stage 3: Contrastive In-Batch Training.** We leverage the similarity mask provided by a pre-trained sentence representation model to contrastively filter *false negatives* during the in-batch training.

Thus, it is better to understand what kind of noisy generations C_θ will produce when following the instructions, and we can realize better alignment by eliminating these trending noises from the next-token distribution. As inspired by Kim et al. (2024) which indicates that specific noisy variants of the original instruction can help induce the corresponding undesired behaviors of LLMs, we designed and conducted analysis towards several noisy instructions $\hat{I}$ in the context of hypothesis generation. We can acquire the noisy next-token logits as:

$$\hat{l}_t \leftarrow C_\theta(\hat{I}, \boldsymbol{x}, \boldsymbol{y}_{<t}). \tag{2}$$

By comparing the logits from the original instructions and those from the noisy variants, we can detect and correct noises for C_θ, achieving a more refined generation. During our contrastive generation, the logits l_t will be contrasted with $\hat{l}_t$, and the next-token y_t will be sampled from the probability distribution of the final logits $l_t - \omega * \hat{l}_t$.

In the context of sentence representation learning, for each premise $\boldsymbol{x}$ of NLI, we will generate its corresponding *entailment* $\boldsymbol{x}_+$ and *contradiction* $\boldsymbol{x}_-$ hypotheses. Through the experiments of all noisy variants, we find that the instructions used to generate the opposite hypotheses demonstrate to be the most effective. Thus, when mentioning noisy instructions, we specifically refer to these opposite instructions throughout our paper. For example, as shown in Figure 2, while generating the *entailment* hypothesis of $\boldsymbol{x}$, we leverage the instruction to generate *contradiction* as the noisy instruction $\hat{I}$. We include the detailed instructions in Appendix A.

3.2 Stage 2: Contrastive Sentence Pair Construction with Self-Curation

Although the generated sentences of C_θ are refined, the relations within sentence pairs remain uncertain. Since contrastive learning methods are modeling the distances of sentence pairs in the embedding space, it is particularly important to ensure that the sentence pairs are in high quality and the distances within the sentence pairs are suitable for effectively training a base model G_ϕ with contrastive learning. Thus, during the sentence pair construction stage, we perform self-curation and select high quality sentence pairs using C_θ itself.

Given a generated triplet $(\boldsymbol{x}, \boldsymbol{x}_+, \boldsymbol{x}_-)$, we follow

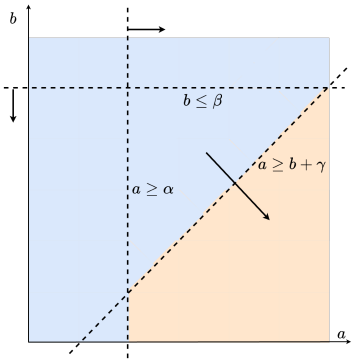

Figure 3: One example of our self-curation strategy. During the final training stage, we only use the sentence pairs in orange region.

the same generation procedure of Equation 1 and utilize C_θ to assign the semantic similarity scores for $(\boldsymbol{x}, \boldsymbol{x}_+)$ and $(\boldsymbol{x}, \boldsymbol{x}_-)$ separately with the same instruction prompt $\boldsymbol{d}$ (more details in Appendix A):

$$a \leftarrow C_\theta\left([\boldsymbol{x}; \boldsymbol{x}_+; \boldsymbol{d}]\right), \; b \leftarrow C_\theta\left([\boldsymbol{x}; \boldsymbol{x}_-; \boldsymbol{d}]\right). \quad (3)$$

The bounds of a and b are specified in $\boldsymbol{d}$ as $[0, 5]$, where a score of 5 means the semantics of a sentence pair are completely the same and 0 means these two sentences are totally different.

Based on the semantic similarity scores of two sentence pairs, we can then select a subset of triplets $(\boldsymbol{x}, \boldsymbol{x}_+, \boldsymbol{x}_-)$ with a pre-defined strategy to form the curated training corpus. One example is shown in Figure 3 and formalized as follows:

$$(\boldsymbol{x}, \boldsymbol{x}_+, \boldsymbol{x}_-) \in \mathcal{T}, \text{ if } \begin{cases} a \ge \alpha \\ b \le \beta \\ a \ge b + \gamma \end{cases}, \quad (4)$$

where $\mathcal{T}$ is the curated training corpus, α and β are the thresholds to control the absolute similarities of positive pair $(\boldsymbol{x}, \boldsymbol{x}_+)$ and negative pair $(\boldsymbol{x}, \boldsymbol{x}_-)$ respectively, and γ will serve as the margin which represents the relative similarity distance of $(\boldsymbol{x}_+, \boldsymbol{x}_-)$. By performing self-curation as a contrastive sentence pair construction procedure, we get a lightweight but high-quality training corpus.

3.3 Stage 3: Contrastive In-Batch Training

With the curated corpus, we can fine-tune a base model G_ϕ to learn better sentence representations. To introduce enough challenge to the model training, we follow Gao et al. (2021) and take $(\boldsymbol{x}, \boldsymbol{x}_+)$ as a positive pair and $(\boldsymbol{x}, \boldsymbol{x}_-)$ as a *hard negative* pair, and the entailment and contradiction hypotheses of other premises inside a batch of size N will be treated as other in-batch negatives of $\boldsymbol{x}$ as $(\boldsymbol{x}, \boldsymbol{x}_+^k)$ and $(\boldsymbol{x}, \boldsymbol{x}_-^k)$, where $\boldsymbol{x}^k \neq \boldsymbol{x}$. For simplicity, we denote the representations $G_\phi(\boldsymbol{x})$, $G_\phi(\boldsymbol{x}_+)$ and $G_\phi(\boldsymbol{x}_-)$ as h, h_+ and h_-, respectively. Then the training objective ℓ is defined as:

$$-\log \frac{e^{\text{sim}(h,h_+)/\tau}}{\sum_{k=1}^{N}\left(e^{\text{sim}(h,h_+^k)/\tau} + e^{\text{sim}(h,h_-^k)/\tau}\right)}, \quad (5)$$

where τ is temperature parameter and $\text{sim}(,)$ is the similarity of two sentence embeddings from G_ϕ.

As introduced, the above in-batch negatives from $(\boldsymbol{x}, \boldsymbol{x}_+^k)$ and $(\boldsymbol{x}, \boldsymbol{x}_-^k)$ may involve *false negatives*, where $\boldsymbol{x}_+^k$ or $\boldsymbol{x}_-^k$ can be indeed semantically similar with $\boldsymbol{x}$ due to the random in-batch sampling. As an example, in Figure 2, the entailment hypothesis "Four kids are positioned before a sculpture of beast" has a high semantic similarity with the first premise, so we treat this pair $(\boldsymbol{x}, \boldsymbol{x}_+^k)$ as *false negative* and need to mitigate its effects during training.

To alleviate this problem, we incorporate the pre-trained sentence representation model P_η to provide a weighted mask for (h, h_+^k) and (h, h_-^k), as shown in Figure 2. We denote the similarity given by pre-trained model P_η as $\text{sim}_\eta(,)$. A mask indicator $M_{\boldsymbol{x},\boldsymbol{x}^k,\cdot}$ is defined as:

$$M_{\boldsymbol{x},\boldsymbol{x}^k,\cdot} = \begin{cases} 0, \; \text{sim}_\eta(h, h_\cdot^k) \ge \sigma, \; \boldsymbol{x}^k \neq \boldsymbol{x} \\ 1, \; \text{else} \end{cases}, \quad (6)$$

where σ is the threshold. In this way, $(\boldsymbol{x}, \boldsymbol{x}_\cdot^k)$ with higher semantic similarity than σ will be masked out during the in-batch training stage. We then use the following training objective to fine-tune our base model G_ϕ:

$$-\log \frac{e^{\text{sim}(h,h_+)/\tau}}{\sum_{k=1}^{N}\sum_{i\in\{+,-\}}\left(M_{\boldsymbol{x},\boldsymbol{x}^k,i} e^{\text{sim}(h,h_i^k)/\tau}\right)}. \quad (7)$$

4 Experiment

4.1 Experiment Setup

We evaluate our approach on standard semantic textual similarity (STS) tasks and seven transfer tasks in SentEval[1]. We further evaluate our method on zero-shot information retrieval tasks in BEIR (Thakur et al., 2021). Following the settings of Gao et al. (2021), we use Spearman's correlation to measure the performance of different approaches. We choose BERT$_{base}$ (Devlin et al., 2019) and RoBERTa$_{base}$ (Liu et al., 2019) as our

Table 2: Performance comparison of MultiCSR on STS tasks. We implement our frameworks based on SimCSE (Gao et al., 2021). ♡: results from Jiang et al. (2022), ♣: results from Liu et al. (2023), ♢: results from Wu et al. (2022), ♠: results from Seonwoo et al. (2023). *: we remove their manual cleaning process for fair comparison, and reproduce the results of SynCSE with their officially released corpus, following our same settings.

backbone models G_ϕ. For the unlabeled sentences, we use the premises of NLI from Gao et al. (2021) as unlabeled sentences, and ensure the data volume used by MultiCSR is equivalent to that of SimCSE. For the main results in Table 2, we include only the results with NLI premises following Zhang et al. (2023). In addition, we also discuss the impact of different data resources in Section 5.2. While our framework is general and could be combined with more advanced algorithms as well, we utilize SimCSE as our main backbone. In Appendix B, we include more experimental results of applying MultiCSR to different backbones.

We utilize the corresponding versions of SimCSE (i.e., unsupervised and supervised, BERT$_{base}$ and RoBERTa$_{base}$) as P_η in different settings. For LLM C_θ, we include the results of Flan-T5-XL(3B) to show that, with MultiCSR, a relatively tinier and less advanced LLM can even outperform ChatGPT, while applying to ChatGPT achieves a better state-of-the-art performance. In the experiments with ChatGPT, since their logits can not be acquired, we utilize only the last two stages of MultiCSR. We also discuss the effect of smoothing coefficient ω, self-curation thresholds α, β and γ in Appendix C and D separately, and only include the results with $\omega = 0.3$, $\alpha = 3$, $\beta = 3$ and $\gamma = 1$ in main results. We fine-tune our model with a batch size of 256, $\tau = 0.05$ and $\sigma = 0.9$, and choose the best model parameters ϕ based on the development performance from STS-Benchmark following Gao et al. (2021). We conduct ablation studies on σ in Appendix E. We include the performance on transfer tasks and BEIR tasks in Appendix F. We also evaluate MultiCSR in a supervised setting by directly combining our generated corpus with labeled NLI corpus. Because of our proposed contrastive in-batch training, the *false-negative* issue will not be raised with this direct combination. We include a more detailed analysis and our supervised performance in Appendix G.

Baselines We compare our method with many strong baselines including ConSERT (Yan et al., 2021), SimCSE (Gao et al., 2021), DiffCSE (Chuang et al., 2022), PromptBERT (Jiang et al., 2022), InfoCSE (Wu et al., 2022), RankEncoder (Seonwoo et al., 2023), RankCSE (Liu et al., 2023) and a post-processing method BERT-whitening (Su et al., 2021). To make comparison between different corpus construction methods, we further compare MultiCSR with SynCSE (Zhang et al., 2023), which directly leverages the generated sentences of ChatGPT to train SimCSE.

Method	Spearman's	Δ
MultiCSR$_{\text{RoBERTa}}$	**85.82**	0.00
w/o stage 1	84.06	-1.76
w/o stage 2	83.98	-1.84

w/o stage 1 & 3	82.45	-3.37
w/o stage 1 & 2 & 3	75.51	-10.31

Table 3: Ablation studies of different components in MultiCSR (Flan-T5) based on SimCSE$_{\text{RoBERTa}}$. The results are based on the development set of STS-B. MultiCSR w/o stage 1&2&3: training SimCSE with the raw generation of Flan-T5-XL.

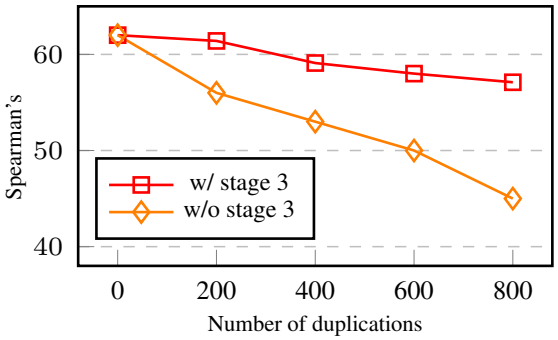

Figure 4: Performance comparison between with and without our constrastive in-batch training stage, with the number of duplications and Spearman's scores on the development set of STS-B reported.

4.2 Main Results

From the results shown in Table 2, we have the following observations: (1) From the comparison between our approach and previous strong baselines, MultiCSR can significantly enhance the base model SimCSE and raises the averaged Spearman's correlation from 76.25% and 76.57% to 80.93% and 81.62% respectively, achieving a better state-of-the-art performance. It is also important to note that MultiCSR is general and data-oriented, and can be easily applied to various base models and improves their performance as shown in Appendix B. Although we build our method over SimCSE, MultiCSR can achieve comparable or even better results than the strong and competitive models such as RankCSE, which demonstrates the effectiveness of our method. (2) When comparing with SynCSE, which also leverages LLMs for enhancing sentence representation learning, MultiCSR shows to be more effective. By utilizing only Flan-T5-XL(3B), our approach can even outperform SynCSE with ChatGPT on RoBERTa$_{base}$, which also provides an opportunity for broader open-source but less advanced LLMs, rather than blindly pursuing larger and better LLMs (which are mostly closed-source). In addition, MultiCSR can still be valid when applied to ChatGPT, which demonstrates our claim that a curated training corpus is necessary for effectively training a contrastive learning method.

5 Analysis

5.1 Ablation Studies

We investigate the impact of each component in MultiCSR and report the performance in Table 3. The results of MultiCSR w/o stage 1&2&3 demonstrates our motivation that the raw generated content from LLMs may not satisfy the requirement of training a contrastive learning method. The comparison between this result and those of removing two stages shows that each component plays a crucial role in enhancing the base model.

Among them, since stage 1 and stage 2 are strictly controlling the quality of each generation or each sentence pair, they seem to be more important than stage 3. However, they are in charge of different stages of training a contrastive learning method like SimCSE. In a training batch with N sentence pairs, during the data generation (stage 1) and sentence pair construction (stage 2), they only check whether $2N$ sentence pairs are qualified. But for stage 3, it will consider whether $2N(N-1)$ sentence pairs involve *false negatives* or not. Moreover, the control of stage 3 will not be too strict for a high-quality dataset like NLI where most premises are not similar to each other as shown in the statistical results in Appendix G. For a dataset where only limited data are available, whether using stage 3 or not will result in a huge performance gap. To demonstrate this, we sample a sentence pair from $10K$ ground truth sentence pairs of NLI, and duplicate it for certain times and combine this set with other pairs together to train a SimCSE model. The results are shown in Figure 4. It is important to note that all the sentence pairs are in good condition and will survive after stage 1&2. In this scenario, only our proposed contrastive in-batch training stage can be helpful. In our supervised setting, by utilizing this in-batch masking, we can directly combine the generated corpus with the ground truth NLI dataset as the training corpus, without suffering from the *false-negative* issue, as shown in Appendix G.

Through the analysis of our ablation studies,

Method	Resource	Spearman's
BERT-base		
SimCSE	NLI*	76.7
	Wikipedia	81.9
MultiCSR	NLI	**84.6**
	Wikipedia	83.5
RoBERTa-base		
SimCSE	NLI*	81.1
	Wikipedia	82.9
MultiCSR	NLI	**85.8**
	Wikipedia	85.2

Table 4: Performance comparison of using different data resources on the development set of STS-B. *: since we only utilize NLI premises rather than (premise, entailment, contradiction) triplets, we use only these premises to train the unsupervised version of SimCSE.

each component is necessary for MultiCSR to ensure that a contrastive learning method is only trained on a high-quality and effective corpus for better sentence representation learning.

5.2 The Impact of Different Data Resources

In Section 4.1, we have introduced that we utilize the NLI premises as the unlabeled sentences, following previous work. As a high-quality and crowd-sourced dataset, sentences from NLI datasets will have less lexical overlap and be in good conditions. It is also important to show that our method can still be valid for sentences from different domains, which are usually noisier but more accessible. Thus, we further utilize the same 10^6 randomly sampled sentences of Wikipedia from Gao et al. (2021) as the unlabeled sentences. We follow the same settings of main results in Table 2, and the results are shown in Table 4. From the results of SimCSE with different resources, we can see that training a contrastive sentence embedding model will place a requirement on the data volume, since the number of sentences for NLI is 0.28M and much smaller than 1.00M of Wikipedia samples. Thus, as a flexible corpus construction framework, MultiCSR can largely outperform the models trained with only these unlabeled sentences, which demonstrates our effectiveness and robustness across different data resources.

When we compare the results of MultiCSR with different data resources, we can see that models trained with NLI premises essentially outperform those with Wikipedia sentences. We assume this may due to the fact that, NLI premises are typically short statements that express the relationship between two entities or concepts, while Wikipedia sentences are usually longer and provide more detailed information about a particular topic and are more factual which requires a broader range of language understanding abilities to write their entailment or contradiction hypotheses. There might require a more appropriate way to generate the positives and negatives of Wikipedia sentences, which we leave as future work.

6 Discussion: Different Strategies for Self-Curation and In-Batch Training

In Section 3, we have introduced in detail how we perform contrastive sentence pair construction with self-curation (denoted as stage 2) and contrastive in-batch training (as stage 3), and both of them are completed by measuring the similarities. It seems that we can use LLMs' and also pre-trained models' similarities for both stages. However, we have our intuition behind these designs.

Our design was firstly motivated by efficiency considerations. Before introducing the selection for stage 2, we will explain why we choose to utilize pre-trained models in stage 3. There are multiple implementations for this stage. For example, we can also adopt a method similar to stage 2, having the LLM compute similarity scores and provide masks. This allows the entire framework to rely only on the LLMs for data quality control. However, due to the slow inference speed of the LLM, we must calculate and store the similarity scores for each potential pair in advance with LLMs, to not impact the training speed of the base model. In addition, since in-batch training data are randomly sampled, all sentence pairs should be considered. Given a training corpus with M triplets and a batch size of N, the number of similarity scores that LLMs must generate in advance is $2M(M-1)$, but only $2M(N-1)$ of them will be used in stage 3. Since M is usually 3 orders of magnitude larger than N, a significant amount of computational resources would be wasted. Therefore, we choose to use a pre-trained model to generate masks dynamically in the stage 3 which will have little impact on the training speed. We also provide some cost analysis for stage 3 in Appendix H.

Furthermore, if we try to utilize the similar strategy of stage 3 in stage 2, we would use a pre-trained sentence embedding model corresponding to the

base model to generate similarity scores. This means that when we want to train or evaluate on a different backbone, we would need to re-run the same self-curation process on the data generated in stage 1 again. This also leads to a waste of computational resources. Besides, using an LLM to evaluate a sentence triplet could be completed simultaneously with stage 1. When we choose to use LLMs in stage 2 and a pre-trained model in stage 3, stage 1&2 and stage 3 will be responsible for the dataset construction process and during-training process, respectively. The high-quality training corpus produced after stage 1&2 can be used in training or evaluation of various base models in similar settings in stage 3. We further include some related case studies in Appendix I.

Moreover, using a pre-trained sentence embedding model in stage 2 will contradict our framework's objective in some scenarios. As previously mentioned, we would choose a pre-trained model corresponding to different base models to compute the similarity scores. When the checkpoints of a certain pre-trained model have not been released, we can even train such models using the high-quality training corpus, with the obtained model used to provide masks in stage 3. However, this behavior assumes that we already have a high-quality training corpus, which would be a significant challenge with only the corpus generated from stage 1, as demonstrated in the results of our ablation study's MultiCSR w/o stage 2&3. And stage 2 is precisely designed as a necessary stage to improve the quality of training corpus. Hence, attempting to introduce a pre-trained model in stage 2 would require either a corresponding released checkpoint or high-quality training data. In more extreme scenarios, such as the low-resource scenarios, there is no pre-trained sentence embedding model available, and the sentences generated with only contrastive generation strategy is not sufficient to form a high-quality training corpus.

To demonstrate this, we further apply our MultiCSR to low-resource languages. We conduct experiments on a rather small language: Tagalog (TL). For training corpus, we leverage TED2020 from Reimers and Gurevych (2020) with 1167 translated sentence-pairs, and use only the sentences in TL. The evaluation is performed by finding the most similar sentence inside a corpus using cosine similarity, with 1000 test pairs from LASER (Artetxe and Schwenk, 2019). The results are shown in Table 5. For a fair comparison, the only difference of ChatGPT and MultiCSR is whether utilizing our proposed self-curation during contrastive sentence pair construction. From the results, we can observe significant improvement from utilizing methods with LLMs, and the performance can be further enhanced with MultiCSR. The evaluation of applying MultiCSR to this challenging scenario demonstrates the flexibility of our framework, enabling its broad applications across different domains and even languages. These experiments also demonstrate that, the conditions for introducing a pre-trained sentence embedding model in stage 2 cannot always be guaranteed. Therefore, we suggest to consider the proposed strategies in a way we present in our paper.

Method	Accuracy%
$\text{SimCSE}_{\text{BERT}}$	72.6
+ stage 1	77.9
+ stage 1 & 2	84.2

Table 5: Performance comparison of different methods on the low-resource language Tagalog. For SimCSE, we only use the unlabeled sentences to train its unsupervised version. We utilize ChatGPT for data generation.

Apart from these concerns, when only taking the effectiveness into consideration, the similarity scores provided directly by the LLMs are not as accurate as those from a pre-trained sentence embedding model, as shown in Section 2.1 and Table 1. This is also our motivation for why we choose not to let the base model merely imitate the scores computed by LLMs. In addition, there are some alternatives for self-curation and in some scenarios, they can even be combined together or iteratively utilized in the same stage. We believe that our self-curation strategy in stage 2 is a practical and thoughtful solution, and we are also committed to continuously explore other potential alternatives.

7 Conclusion

In this paper, we introduce MultiCSR, a novel framework to contrastively refine the generation of LLMs at distinct stages of training a contrastive learning method, ensuring only high-quality and suitable sentence pairs are utilized during the model training. Experiments on standard STS tasks and several downstream tasks demonstrate the effectiveness of MultiCSR. Extensive analysis shows the potential of our work and we hope to inspire future work in achieving better sentence representation learning with LLMs.

Limitations

Despite the effectiveness of MultiCSR, there are still some potential directions worth exploring and we leave as future work. Firstly, as introduced in 3.2, we employ pre-defined rules to control the absolute and relative similarities of each pair $(\boldsymbol{x}_+, \boldsymbol{x}_-)$ during the contrastive sentence pair construction. However, a composite model can be utilized here. As our generated sentence pairs are in the same formats of NLI datasets (Zhang et al., 2023), we can actually use a NLI classifier or its combination with LLMs for self-curation. Nevertheless, utilizing a pre-trained NLI classifier also poses a requirement for ground truth NLI corpus, contradicting the main purpose of performing unsupervised learning. Thus, we leave this as future work and hope to propose some alternative self-curation strategies. Secondly, in the first stage of our framework, we perform contrastive generation with logits acquired from different instructions. However, for closed-source LLMs, acquiring their logits is impractical. Thus, a prompting methods that can be incorporated into refining the generation of LLMs will be valuable. Recently, a contemporary method, self-correction, has been proposed to address this issue. However, the effectiveness of the techniques in this kind often depends on the fortuitous alignment of prompts or initial conditions, making them labor-intensive, highlighting more efficient approaches. To sum up, these limitations also illustrate the great potential of our method. It is expected to be applied to various domains and better serve more downstream tasks.

Appendix

A Instruction Prompts

In this section, we give the details of our instruction prompts used in C_θ text generation and self-curation. In addition, for fair comparison with SynCSE (Zhang et al., 2023), we utilize the same entailment and contradiction prompts for generation. During the first stage of contrastive generation, we will randomly select one from the entailment prompts and the other one from the contradiction prompts, and acquires the next-token logits with the logits derived from these two instructions.

Entailment Prompt 1

Please paraphrase the input sentence or phrase, providing an alternative expression with the same meaning.

Entailment Prompt 2

Rewrite the following sentence or phrase using different words and sentence structure while preserving its original meaning.

Entailment Prompt 3

Create a sentence or phrase that is also true, assuming the provided input sentence or phrase is true.

Entailment Prompt 4

Please provide a concise paraphrase of the input sentence or phrase, maintaining the core meaning while altering the words and sentence structure. Feel free to omit some of the non-essential details like adjectives or adverbs.

Contradiction Prompt 1

Revise the provided sentence by swapping, changing, or contradicting some details in order to express a different meaning, while maintaining the general context and structure.

Contradiction Prompt 2

Generate a slightly modified version of the provided sentence to express an opposing or alternate meaning by changing one or two specific elements, while maintaining the overall context and sentence structure.

Contradiction Prompt 3

Transform the input sentence by adjusting, altering, or contradicting its original meaning to create a logical and sensible output sentence with a different meaning from the input sentence.

Contradiction Prompt 4

Generate a sentence that conveys a altering, contrasting or opposite idea to the given input sentence, while ensuring the new sentence is logical, realistic, and grounded in common sense.

While we utilize an LLM to measure the semantic similarity, we will use the prompt as the following:

Measuring Similarity Prompt

Scoring the semantic similarity of the following sentences between 0.0 and 5.0, 5.0 means they have the same meaning, 0.0 means they are completely different: (a) "$\{\boldsymbol{x}\}$", (b) "$\{\boldsymbol{x}_y\}$":

B MultiCSR with Various Backbones

In our main results from Table 2, we improve the performance of SimCSE by a large margin. It is important to note that MultiCSR is general and can be uniformly applied to different backbones. Thus, in this section, we also conduct experiments with representative contrastive sentence representation learning methods PromptBERT (Jiang et al., 2022), InfoCSE (Wu et al., 2022), RankEncoder (Seonwoo et al., 2023) and RankCSE (Liu et al., 2023). The results shown in Table 6 show that, our approach can consistently improve their performance by a large margin, which also demonstrates the strong generalization ability of our MultiCSR.

C Effect of Smoothing Coefficient ω

Figure 5 shows the influence of the hyperparameter ω on our method's performance. This parameter adjusts the smoothness of logits derived from noisy instructions. For all the evaluation, we utilize opposite prompts as the noisy instructions. We sample 100 sentences from the NLI premises and conduct human evaluation. From the results, we can see that performance tends to decline with negative ω values, as the model becomes increasingly biased toward the noisy instruction. Conversely, excessively positive values (above 0.4) lead to a quick deterioration in performance. Interestingly, the model's performance stabilizes between 0.2 and

around 0.4, indicating a certain level of robustness to variations in ω within this range. In our main results, we consistently utilize ω as 0.3.

D Self-Curation Strategies

In Section 3.2, we briefly introduce how we select "high-quality" triplets like $(\boldsymbol{x}, \boldsymbol{x}_+, \boldsymbol{x}_-)$ after we get the semantic similarity scores from the LLM C_θ as a and b:

$$(\boldsymbol{x}, \boldsymbol{x}_+, \boldsymbol{x}_-) \in \mathcal{T}, \text{ if } \begin{cases} a \geq \alpha \\ b \leq \beta \\ a \geq b + \gamma \end{cases} . \quad (8)$$

We firstly conduct extensive experiments on different combinations of hyperparameters α, β and γ.

1	1	1	66.6k	85.42

Table 7: Studies of different self-curation strategies in MultiCSR. The results are the development performance of STS-B.

The results are shown in Table 7. Based on the results from Table 1, we know that directly utilizing LLMs to measure the similarities may not be a wise choice, but their provided signals can still help us improve the quality of generated corpus. From the results in Table 7, we can see that choices that are not too extreme (e.g., set α to 5 or β to 0) tend to give better results, which also demonstrate our concern that "*hard negative*" and "*hard positive*" are always important to provide sufficient challenges to learn a better contrastive learning model.

E Ablation Study on Mask Indicator Threshold

In this section, we perform an ablation study of setting different mask indicator thresholds used in Section 3.3 to mask in-batch false negatives. The results are presented in Figure 6. As shown in the figure, introducing the mask indicator mechanism significantly improves the results. When the threshold is set too low, the performance drops as expected, due to the fact that too many sentences are masked and few challenging inputs are given to the model. Meanwhile, the purpose of filtering out false negative sentences is not fulfilled if the

Table 8: Performance comparison on zero-shot information retrieval tasks BEIR.

threshold chosen is too high. Based on the experimental results on STS-B development set, we set the mask indicator threshold to be 0.9 across our main context.

F Performance on Transfer Tasks and BEIR Tasks

We also evaluate our approach on the following transfer tasks: MR (Pang and Lee, 2005), CR (Hu and Liu, 2004), SUBJ (Pang and Lee, 2004), MPQA (Wiebe et al., 2005), SST-2 (Socher et al., 2013), TREC (Voorhees and Tice, 2000) and MRPC (Dolan and Brockett, 2005). In these tasks, a classifier is trained on top of sentence representations produced by different methods. We reported the detailed performance of MultiCSR in Table 9. From the experimental results, we can see that MultiCSR achieves the best performance on both BERT$_{base}$ and RoBERTa$_{base}$, which also shows the potential of our method to be applied to different downstream tasks.

To further evaluate our framework on real-world applications, we also test the performance of MultiCSR on zero-shot information retrieval tasks BEIR (Thakur et al., 2021) and include the results in Table 8. We directly utilize our trained checkpoint to test and no in-domain data is used. The results are shown in the following table with nDCG10 scores reported, following BEIR. We use all the tasks public in BEIR. For CQADupStack, we evaluate each StackExchange subforum separately and report the overall average scores. The results show that our method can consistently improve the performance of SimCSE on these tasks, even before we use any unlabeled in-domain data. We believe that better semantic similarity performance is beneficial to the measurement of sentence-pair relationship, and our method can help the base model capture richer semantic information.

G Supervised Settings

In this section, we introduce how we perform supervised settings on our method. Using demonstrations is now a standard way to perform few-shot (Brown et al., 2020; Agrawal et al., 2022) inference on LLMs in various tasks. As a natural semantic retriever, the pre-trained sentence representation model P_η can be utilized to find the most proper demonstrations. Given the source sequence $\boldsymbol{x}$, we first compute its representation as $P_\eta(\boldsymbol{x})$, and search over $\mathcal{W}$ (i.e., NLI premises specifically) to find the most relevant demonstrations, based on $\mathrm{sim}(P_\eta(\boldsymbol{x}), P_\eta(\boldsymbol{x}'))$ where $\mathrm{sim}(,)$ calculates the cosine similarity of two parameterized vectors. We denote the set of L demonstrations as $\mathcal{D} = (d_1, d_2, ..., d_L)$, and each demonstration d will be either the entailment or contradiction hypothesis of the premise $\boldsymbol{x}^k$. To prevent the low similarity demonstrations, we only choose premise $\boldsymbol{x}^k$ with $\mathrm{sim}(P_\eta(\boldsymbol{x}), P_\eta(\boldsymbol{x}^k)) \geq \lambda$, where λ serves as a hyperparameter threshold. Finally, the whole text generation procedure without any parameter updates can be formulated as the following:

$$\boldsymbol{y} \leftarrow C_\theta\left([\mathcal{D}; \boldsymbol{x}; I]\right), \boldsymbol{x} \in \mathcal{W}.$$

We have included the performance of several combinations of different L and λ in Table 10. From the result, we can see that, although using

demonstrations can be still helpful in our contrastive generation procedure, the improvement compared with not using demonstrations is not so significant. And inference with more demonstrations will somehow increase the time required for generation. Thus, in all our supervised settings, we choose not to use demonstrations including the results in Table 11.

After generation of $\mathcal{T}$, we would combine $\mathcal{T}$ with ground truth corpus $\mathcal{N}$, which means, for each premise in $\mathcal{T}$, there would be at least one triplet with the same premise in $\mathcal{N}$. As an example, we randomly sample a batch of size N from $\mathcal{T} \cup \mathcal{N}$, the distribution of cosine similarity given

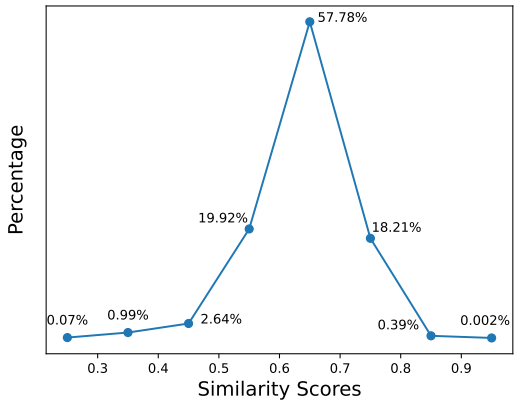

Figure 7: The percentages of consine similarity scores provided by pre-trained supervised SimCSE-RoBERTa on a randomly sampled batch of size 256.

by $\text{sim}(P_\eta(\boldsymbol{x}), P_\eta(\boldsymbol{x}'))$ between any premises and (h_+^k, h_-^k) (i.e., $2N(N-1)$ similarity scores here) is shown in Figure 7. From the figure, we can see that even excluding the entailment and contradiction hypotheses of each premise, there are still more than 18.6% sentences inside a batch having a similarity score higher than 0.7. Thanks to mask indicator introduced in Section 3.3, we can directly utilize this mixed corpus for training without suffering from *false-negative* problem. The results of supervised MultiCSR are included in Table 11.

H Cost Analysis

We further provide a cost analysis of the time and space. Since our stage 1&2 works before the in-batch training stage, we provide the analysis of the resource required to support our stage 3, under different batch sizes. We test on a single NVIDIA V100-32GB, and replicate a triplet $10K$ times as the training corpus. The time and GPU memory required for training are shown in Table 13, while the inference time and space of our method remains the same as theirs.

Label	Original & Generated Sentences	Semantic Similarities
Premise	One of our number will carry out your instructions minutely.	-
Entailment	A member of my team will execute your orders with immense precision.	4.5
Contradiction	We have no one free at the moment so you have to take action yourself.	0.0
Premise	He turned and smiled at Vrenna.	-
Entailment	He turned back and smiled at Vrenna.	5.0
Contradiction	He turned and walked away.	0.0
Premise	How do we fix this?	-
Entailment	How can we fix this?	5.0
Contradiction	Let's not worry about fixing this.	1.0
w/o Stage 1	We can't figure out how to fix this.	4.0
Premise	The economy could be still better.	-
Entailment	The economy is not at its best possible state.	4.0
w/o Stage 1	The economy is not good.	0.0
Contradiction	The economy could be worse.	0.0

Table 12: Generated sentence triplets and the semantic similarities between the hypotheses and their premises. The sentence and similarities are generated by on NLI premises. If we set the thresholds of filtering strategy as $\alpha = 3$, $\beta = 3$ and $\gamma = 1$, the third triplet will not appear in the training corpus $\mathcal{T}$ because of unqualified contradiction $4.0 \not\leq 3$, and neither for the fourth triplet because of wrong entailment $0.0 \not\geq 3$.

Batch Size	Time(s)		GPU Memory(MB)	
	SimCSE	MultiCSR	SimCSE	MultiCSR
8	86(1x)	99(1.15x)	3863(1x)	5225(1.35x)
16	62(1x)	81(1.31x)	4873(1x)	6080(1.25x)
32	55(1x)	75(1.36x)	5661(1x)	8163(1.44x)
64	52(1x)	68(1.30x)	7353(1x)	11965(1.63x)
128	51(1x)	65(1.27x)	11503(1x)	20137(1.75x)

Table 13: Time and memory cost analysis of perform our stage 3, contrastive in-batch training.

It is worth mentioning that the data generated in the first stage of our framework becomes more lightweight after the second stage of self-curation. This makes, although the time required to train on the same dataset increases, the time we need to train a model of MultiCSR is actually greatly reduced. We assume that a training set has M sentences, and the batch size is N. In unsupervised SimCSE, for each sentence, it will have 1 positive pair and $N - 1$ negative pairs, then there will be a total of $M * N$ pairs of similarity to be calculated during training. In MultiCSR, for each sentence, it will have 1 positive pair and $2N - 1$ negative pairs, a total of $M * (2N)$ pairs will be considered. But in our scenario, the value of M varies greatly. For example, if we set the batch size to 64, it takes $0.98h$ to train an unsupervised SimCSE on $1M$ Wikipedia sentences, with $1M * 64 = 64M$ pairs. But after our first and second stages with these sentences, only $0.19M$ triplets are left, with $0.19M * (2 * 64) = 24.32M$ pairs. Based on this, it only takes $0.36h$ to train our model.

I Case Studies

In this section, we present some generated triplets using Flan-T5-XL in Table 12 with the premises from NLI and semantic similarity scores for these triplets. While the first two example triplets are high quality data for training, the last two triplets suffer from either the *false-negative* or the *false-positive* problem if Stage 1 is not applied. For example, in the third triplet, the contradiction sentence generated without Stage 1 "We can't figure out how to fix this." has a 4.0 high similarity score to the premise sentence "How do we fix this?", indicating a *false negative* that can harm the training if included. In our method, we can either avoid these "low-quality" triplets by introducing Stage 1 or self-curation strategy by $\alpha = 3$, $\beta = 3$ and $\gamma = 1$, which we proposed in Stage 2. For another example, we can also exclude the third triplet in training due to unqualified contradiction $4.0 \not\leq 3$ and avoid the *false negative* problem. From the case studies we conduct, we can see that all components are helpful in refining the generation of LLMs, ensuring only high-quality sentence pairs are utilized into model training.

HIL: Hybrid Isotropy Learning for Zero-shot Performance in Dense Retrieval

Jaeyoung Kim[1], **Dohyeon Lee**[2], **Seung-won Hwang**[12*]

Abstract

Advancements in dense retrieval models have brought ColBERT to prominence in Information Retrieval (IR) with its advanced interaction techniques. However, ColBERT is reported to frequently underperform in zero-shot scenarios, where traditional techniques such as BM25 still exceed it. Addressing this, we propose to balance representation isotropy and anisotropy for zero-shot model performance, based on our observations that isotropy can enhance cosine similarity computations and anisotropy may aid in generalizing to unseen data. Striking a balance between these isotropic and anisotropic qualities stands as a critical objective to refine model efficacy. Based on this, we present ours, a Hybrid Isotropy Learning (HIL) architecture that integrates isotropic and anisotropic representations. Our experiments with the BEIR benchmark show that our model significantly outperforms the baseline ColBERT model, highlighting the importance of harmonized isotropy in improving zero-shot retrieval performance.

1 Introduction

Recent advancements in information retrieval (IR) have seen a shift from classical techniques like BM25 to more advanced models that rely on dense vector representations. ColBERT (Khattab and Zaharia, 2020) is one such model utilizing multi-vector representations to capture token-level interactions, for often exceeding performance of single-vector dense models like DPR (Karpukhin et al., 2020). Despite its strengths, ColBERT lags behind BM25 and other methods in zero-shot tasks (Thakur et al., 2021), revealing a weakness in its representational strategy.

To improve representation quality from an isotropy perspective, methods can be categorized into approaches that promote isotropy and those that induce anisotropy. Specifically, approaches such as CosReg (Gao et al., 2019) promote isotropy, while I-STAR (Rudman and Eickhoff, 2023) induces anisotropy. Advocates for isotropy suggest it benefits cosine-based scoring (Jung et al., 2023; Li et al., 2020; Su et al., 2021), yet there are contrasting arguments that excessive isotropy might compromise a model's generalization abilities for unseen data (Zhu et al., 2018; Rudman and Eickhoff, 2023). However, these approaches have two limitations. **First**, the metrics used in their study are not suitable for IR as they calculate isotropy of query and passage as a single distribution, thus not taking into account the differences between the two distributions and their interactions. **Second**, these methods aim to make representations entirely isotropic or anisotropic, lacking the ability to achieve their balance.

Method	Interactive	Objective	
		Isotropic	Anisotropic
CosReg	✗	✓	✗
I-STAR	✗	✗	✓
Ours: ColBERT-HIL	✓	✓	✓

Table 1: Properties of methods with isotropy perspective. The Interactive column denotes whether the method considers the interaction between two distinct distribution. The Isotropic and Anisotropic columns indicate that the method make the representation isotropic and anisotropic, respectively.

To address these issues, we identify two challenges: (1) generalizing isotropy to IR, and (2) achieving an effective balance between isotropic and anisotropic properties in the representations. Table 1 illustrates the differences between our proposed method and baselines in the context of the two challenges. To address the first challenge, we introduce a new isotropy metric, Interactive Isotropy (InterIso), which reflects the interaction between two distributions. Additionally, we propose isotropic and anisotropic ColBERT models, namely ColBERT-iso and ColBERT-aniso, which leverage InterIso for regularization. To

tackle the second challenge, we introduce Hybrid Isotropy Learning (HIL) architecture to integrate both isotropic and anisotropic modules.

For the first challenge, we propose, InterIso, measuring the interaction between two distributions. In IR, queries are typically shorter, and passages are more detailed and descriptive. However, traditional isotropy tools, such as Avg-Cos (Ethayarajh, 2019), IsoScore (Rudman et al., 2022), and Partition isotropy score (Mu et al., 2017), measure isotropy assuming that both query and passage representations originate from the same distribution. In contrast, InterIso computes the cosine similarity specifically between query and passage embeddings to capture query-passage interactions to reflect distributional differences.

For the second challenge, HIL proposes a hybrid model structure that combines the advantages of isotropy and anisotropy, consisting of two components: an isotropic lower layer and an anisotropic upper layer. We hypothesizes that maximizing the isotropy difference (ΔInterIso) between the isotropic and anisotropic components is our key contribution to harnessing their respective benefits. Specifically, we explore two strategies: an ensemble of separately trained models combined at score level and HIL approach that integrates both isotropic and anisotropic aspects within a single model. We find that promoting a larger ΔInterIso enhances zero-shot performance, with HIL proving superior as it encourages an isotropy-anisotropy balance throughout the model layers.

To demonstrate the effectiveness of our approach for Dense Retrieval (DR) in zero-shot setting, we experiment with BEIR benchmarks. As shown in Table 2, ColBERT-HIL significantly outperforms BM25 and ColBERT by +2.22%, +2.7% in full-ranking retrieval, respectively. It represents the importance of hybrid isotropy for better zero-shot performance. Our contributions can be summarized as the following.

- Identifying challenges in adapting isotropy insights to IR models.
- Developing InterIso, a new metric to assess isotropy in IR more accurately.
- Introducing ColBERT-HIL to achieve a synergistic mix of isotropic and anisotropic representations.
- Demonstrating the benefits of ColBERT-HIL for zero-shot performance via BEIR benchmark results.

2 Related Work

2.1 Dense retrieval

The BERT (Devlin et al., 2019) models have shown promise for dense retrieval tasks, where both queries and documents are represented through embeddings. Dense retrieval models fall into two categories: single-vector and multi-vector models. Our focus is on the latter, where individual embeddings represent every term within queries and documents. In this scenario, query token embeddings are used to retrieve the nearest document token embeddings through approximate nearest neighbor search (ANN). In the case of ColBERT, the documents retrieved through ANN are reranked using late interaction as defined below, which is also applied during training.

$$\text{score}_{\text{late}}(q,d) = \sum_{i \in [|E_q|]} \max_{j \in [|E_d|]} E_{q_i} \cdot E_{d_j}^T \quad (1)$$

where q and d represent a query and a document respectively, and $E_{(.)}$ represents token embedding matrix of query or document.

2.2 Zero-shot retrieval

Zero-shot retrieval is a paradigm in IR that focuses on the ability to retrieve relevant information for queries which were not encountered during the training phase. The late-interaction model, ColBERT performs a bit weaker than BM25 and the other models on BEIR benchmark (Thakur et al., 2021), which implies a weakness in its representations. While Jung et al. (2023) study isotropic representations using post-processing with out-of-distribution datasets in DR, they do not conduct it in full-ranking and focus solely on isotropic representations, rather than hybrid isotropy. Given our emphasis on isotropy, there is no need to be concerned about other late-interaction models that do not consider isotropy.

2.3 Isotropy

In NLP, Isotropy refers to the measure of how evenly distributed the contextualized representations are. We briefly review the commonly used metrics and methods in Semantic Textual Similarity (STS).

To measure isotropy, **Avg-Cos** (Ethayarajh, 2019) computes the average cosine similarity score

among representations. **IsoScore** (Rudman et al., 2022) measures the distance between the covariance matrix of the data and the identity matrix. **Partition** isotropy score, as defined by Mu et al. (2017), involves a specific quotient related to the partition function initially proposed by Arora et al. (2016).

To control isotropy, Rudman and Eickhoff (2023); Gao et al. (2019) suggest regularization term, I-STAR and CosReg, to control isotropy during training. While I-STAR is designed to be anisotropic and CosReg is intended to be isotropic in its design, both can induce either isotropy or anisotropy by adjusting λ.

3 Proposed Method

We introduce InterIso measuring isotropy in Section 3.1, and then discuss ensemble model using InterIso in Section 3.2. We then propose ColBERT-HIL mitigating the limitations of ensemble in Section 3.3.

3.1 Interactive Isotropy (InterIso)

Traditional isotropy metrics might distort the evaluation due to assuming that both query and passage representations come from the same distribution. Thus, to extend isotropy to IR, it is essential to consider the interaction between query and passage distributions. In this regard, we introduce Interactive Isotropy (InterIso) to assess isotropy for query and passage pairs. It can be formulated as follows:

$$\text{InterIso}(q,d) = \frac{1}{|E_q||E_d|} \sum_{i\in[|E_q|]} \sum_{j\in[|E_d|]} E_{q_i} \cdot E_{d_j}^T \tag{2}$$

where q and d represent a query and a passage respectively, and $E_{(\cdot)}$ represents token embedding matrix of query or passage.

InterIso is a simple yet effective measure of isotropy between query and passage distributions. InterIso, when closer to 0, signifies isotropic space, where passage token embeddings make a sparse space for each query token embedding. Conversely, a value closer to 1 means that passage token embeddings are dense for each query token embedding, indicating anisotropic space. Note that Eq. (2) computes similarity only between query and passage tokens, excluding comparisons within the individual query or passage, to capture the interaction between query-passage distribution.

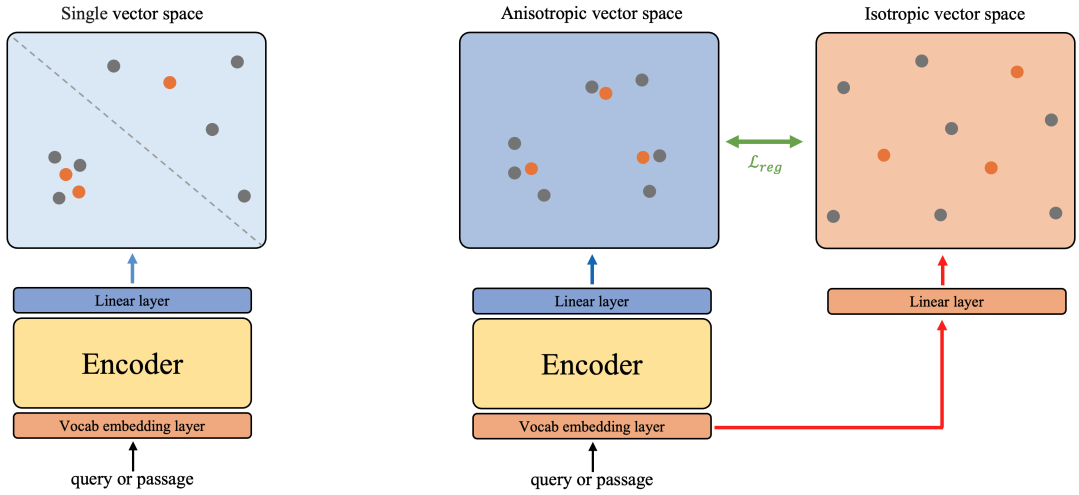
3.2 Ensemble for Hybrid Isotropy

To leverage the advantages of both isotropy and anisotropy in ensemble model, it may be crucial to increase ΔInterIso, which denotes the difference in InterIso between isotropic and anisotropic modules. For this purpose, InterIso metric can be directly employed as a loss term for each module. Given triples $\langle q, d^+, d^- \rangle$, we can formulate late-interaction loss, $\mathcal{L}_{\text{late}}$ term as follows:

$$\mathcal{L}_{\text{late}} = \text{CE}(\text{score}_{\text{late}}(q,d^+),\ \text{score}_{\text{late}}(q,d^-))$$

where CE represents cross-entropy function, d^+ and d^- represent a positive and negative passage for given query q. The loss, $\mathcal{L}_{\text{InterIso}}$ can be formulated as follows:

$$\mathcal{L}_{\text{reg}}(q,d) = \begin{cases} \text{InterIso}(q,d) & \lambda < 0 \\ \text{abs}(\text{InterIso}(q,d)) & \lambda > 0 \end{cases}$$



$$\mathcal{L}_{\text{InterIso}} = \mathcal{L}_{\text{late}} + \lambda\, \mathcal{L}_{\text{reg}}$$

where abs$(\cdot)$ represents absolute value. As InterIso closer to 0 represents strong isotropy, we take the absolute value of InterIso for $\lambda > 0$. The isotropy of representations is controlled by the sign of λ, where negative values make it more anisotropic and positive values make it more isotropic. We choose ColBERT-iso and ColBERT-aniso as isotropic and anisotropic modules, respectively, based on their nDCG@10 performance for $\lambda > 0$ and $\lambda < 0$ on MSMARCO dev dataset. ColBERT-λ is a simple $\lambda-$ensemble combining these modules as a baseline, and detailed implementations of ColBERT-cosreg and ColBERT-istar using CosReg and I-STAR regularization are described in Section A.3.

3.3 Hybrid Isotropy Learning (HIL)

While ColBERT-λ can enhance ΔInterIso by adjusting λ of each modules, extreme changes in λ might disrupt the vector spaces learned in the pretraining step. To tackle this issue, we propose ColBERT-HIL with Hybrid Isotropy Learning (HIL) architecture, achieving both isotropic and anisotropic representation within a single model.

Inspired by the findings of Ethayarajh (2019), which demonstrate that BERT tends to learn isotropic embeddings in its lower layers and anisotropic embeddings in its upper layers, we adopt a similar strategy. As shown in Figure 1, ColBERT employs a single vector space, whereas ColBERT-HIL utilizes two, separately learning

(a) ColBERT (b) ColBERT-HIL

Figure 1: Overview of ColBERT (left) and ColBERT-HIL (right). (b) shows its anisotropic and isotropic vector spaces represented by blue box and orange box, respectively. In vector spaces, orange and gray dots indicate query and passage token embeddings, respectively.

isotropic and anisotropic representations to harness their respective benefits. Specifically, we take isotropic representations (L) which are sequentially passed through the vocab embedding layer and a linear layer aimed at reducing the embedding dimension. Furthermore, anisotropic representations (H) are obtained by projecting the last hidden state, which aligns with the ColBERT token representations.

To formulate the loss function for learning each representation, we describe further details. Let s denote either a query or a passage.

$$\text{Input}(s) = \text{[CLS] [S] Tokenizer}(s) \text{ [SEP]}$$

where [S] becomes [Q] for a query and [D] for a passage, depending on s. Then, L_s and H_s can be formulated as follows:

$$L_s = \text{Linear}(\text{Vocab}(\text{Input}(s))) \in \mathbb{R}^{|s| \times 128}$$
$$H_s = \text{Linear}(\text{BERT}(\text{Input}(s))) \in \mathbb{R}^{|s| \times 128}$$

where Vocab represents vocab embedding layer. As L_s represents a projected Vocab embedding, it may contain potential noise from less important terms. To address this, we multiply the inverse document frequency (IDF) of the query term, approximating term importance (Formal et al., 2021), by the maximum value in Eq. (1). Let $M(q_i, d)$ denote the maximum similarity between query term q_i and passage token embeddings. Then, the scores of L and H for q_i can be formulated as follows:

$$M(q_i, d) = \max_{j \in [|E_d|]} E_{q_i} \cdot E_{d_j}^T$$
$$S_L(q_i, d) = \text{IDF}(q_i) \cdot M(q_i, d)$$
$$S_H(q_i, d) = M(q_i, d)$$

However, this multiplication introduces a difference in scale between $S_L(q_i, d)$ and $S_H(q_i, d)$. To tackle this scaling issue, we compute mean and standard deviation of them using samples in the same batch, and apply z-score normalization. Then, late-interaction score and loss for L and H can be formulated as follows:

$$S'_{(\cdot)}(q_i, d) = \frac{S_{(\cdot)}(q_i, d) - m_{(\cdot)}}{\sigma_{(\cdot)}}$$
$$\text{score}_{\text{late}_{(\cdot)}}(q, d) = \sum_{i \in [|E_q|]} S'_{(\cdot)}(q_i, d)$$
$$\mathcal{L}_{\text{late}_{(\cdot)}} = \text{CE}(\text{score}_{\text{late}_{(\cdot)}}(q, d^+),\ \text{score}_{\text{late}_{(\cdot)}}(q, d^-))$$

where $m_{(\cdot)}$ and $\sigma_{(\cdot)}$ represent mean and standard deviation, respectively. To combine two late-interaction losses, we simply add them together.

$$\mathcal{L}_{\text{HIL}} = \mathcal{L}_{\text{late}_L} + \mathcal{L}_{\text{late}_H}$$

Although L_s and H_s already possess isotropy and anisotropy as suggested by Ethayarajh (2019), we expect that incorporating InterIso as a regularization term can further enhance their isotropic difference. Therefore, we revise $\mathcal{L}_{\text{HIL}}$ by introducing

regularization terms as follows:

$$\mathcal{L}_{\text{reg}_L} = -\text{abs}(\text{InterIso}_L(q,d))$$
$$\mathcal{L}_{\text{reg}_H} = \text{InterIso}_H(q,d)$$
$$\mathcal{L}_{\text{HIL}} = \mathcal{L}_{\text{late}_L} + \mathcal{L}_{\text{late}_H} + \lambda\left(\mathcal{L}_{\text{reg}_L} + \mathcal{L}_{\text{reg}_H}\right)$$

where $\text{InterIso}_L(q,d)$ and $\text{InterIso}_H(q,d)$ represent InterIso for L_s and H_s, respectively. In $\mathcal{L}_{\text{reg}_L}$ term, we take the absolute value to make $\text{InterIso}_L(q,d)$ close to 0, and use a minus sign to increase the difference from $\text{InterIso}_H(q,d)$. As our objective is to enhance ΔInterIso, we conducted experiments with a negative value of λ. At inference step, we compute $\text{score}_{\text{late}_L}(q,d)$ and $\text{score}_{\text{late}_H}(q,d)$, and then simply add them together.

4 Experiment

4.1 Experimental Setting

Dataset and Evaluation Metric To validate our approach, we use two datasets, MS MARCO-passage (Nguyen et al., 2016) for training and BEIR (Thakur et al., 2021) for evaluating zero-shot performance. Our primary focus lies in improving the Normalized Discounted Cumulative Gain (nDCG) metric for full-ranking retrieval on BEIR benchmark.

Implementation We follow the training settings described in (Khattab and Zaharia, 2020) as we implement our approach using ColBERTv1 as the backbone. All ColBERT model variations in this paper are trained under the same settings. For BM25, we use open-source implementation provided by Pyserini[1]. More detailed hyperparameters are described in Section A.3.

4.2 Experimental Results

Research Questions To evaluate the effectiveness of our method, we address the following research questions:

- RQ1: Does increasing ΔInterIso enhance zero-shot performance and why?
- RQ2: Does HIL architecture mitigate a limitation of $\lambda-$ensemble?
- RQ3: Does each regularization term in HIL improve ΔInterIso?
- RQ4: Is HIL architecture generalizable?

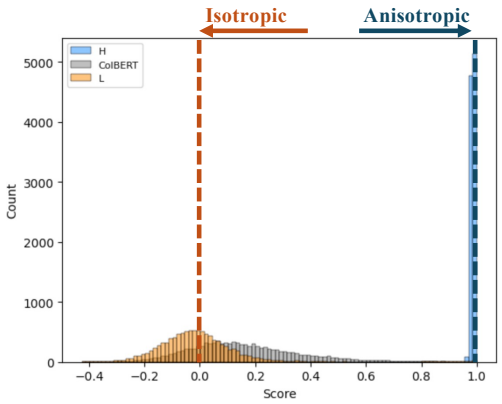

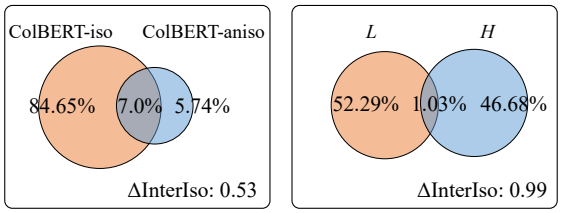

Figure 2: Score distributions for ColBERT, L and H in ColBERT-HIL. Dashed lines represent ideal isotropy (orange) and anisotropy (blue).

4.2.1 RQ1: ΔInterIso for zero-shot performance

In this section, we demonstrate that augmenting ΔInterIso yields improvements in zero-shot performance, while also conducting an analysis of whether isotropic and anisotropic modules are performing as intended.

Zero-shot performance We first evaluate zero-shot performance in full-ranking, as shown in Table 2. Remarkably, our model (ColBERT-HIL) exhibits the most superior performance in this context. In delving deeper into the relationship between ΔInterIso and zero-shot performance, we analyze re-ranking performance using various ensemble models. Table 3 indicates that ColBERT-λ and ColBERT-HIL, utilizing InterIso as loss term, achieve the second-best and best performance, respectively. This suggests enhanced zero-shot performance with an increase in ΔInterIso.

Isotropy and Anisotropy are Well-Represented To affirm the successful representation of isotropic and anisotropic spaces in ColBERT-HIL, by L and H modules, respectively, we compute the cosine similarity scores between query and passage token embeddings. As depicted in Figure 2, the score distributions of L (orange curve) and H (blue curve) noticeably shift towards 0 and 1, respectively, when compared to the baseline ColBERT (grey curve). This empirical evidence supports the assertion that the isotropic and anisotropic modules within ColBERT-HIL effectively learn their respective spaces for IR.

(a) ColBERT-λ (b) ColBERT-HIL

Figure 3: Venn diagram of retrieved passages in first-stage. The orange and blue indicate passage sets retrieved by isotropic and anisotropic modules, respectively.

Isotropy and Anisotropy are Complementary To explore the complementarity between isotropic and anisotropic modules complementarity inherent in isotropic and anisotropic modules, we present a Venn diagram depicting the retrieved passages for each query in the first stage, as depicted in Figure 3.

In both ColBERT-λ and our proposed model (ColBERT-HIL), we observe that isotropic and anisotropic modules discover mostly distinct passages but with some duplications (shown as intersection in the diagram): while ColBERT-λ retrieves 7.0% duplicated passages with a ΔInterIso of 0.53, ColBERT-HIL retrieves only 1.03% duplicated passages, demonstrating a significant reduction with a higher ΔInterIso of 0.99. This outcome presents the pronounced complementary advantage achieved by increasing ΔInterIso.

Meanwhile, in the case of ColBERT-λ, the majority of passages (91.65%) are retrieved by ColBERT-iso. This limitation arises because ColBERT-aniso may retrieve passage tokens from the same passage for each query token, owing to its anisotropic distribution. In contrast, ColBERT-HIL demonstrates a more balanced retrieval, with comparable numbers of passages retrieved using its isotropic and anisotropic modules. This balanced approach mitigates the bias observed in ColBERT-λ's retrieval mechanism, where a predominant reliance on ColBERT-iso occurs.

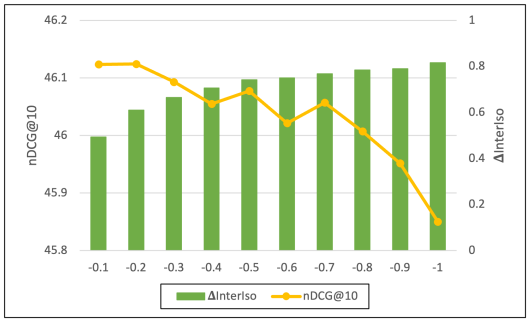

Figure 4: Performance drop when decreasing λ for ColBERT-aniso. Yellow line and green bar indicate nDCG@10 in re-ranking on BEIR and ΔInterIso of ColBERT-λ, respectively. The x-axis represents the λ for regularization term of ColBERT-aniso.

ColBERT-HIL w/o reg_L	42.2 (+0.44)	44.54 (+0.94)	0.94 (+0.7)
ColBERT-HIL	**42.34** (+0.58)	**44.8** (+1.2)	**0.99** (+0.75)

Table 5: Ablation study for regularization terms. The number indicates full-ranking nDCG@10 performance for each dataset.

4.2.2 RQ2: Mitigating the limitation of ColBERT-λ

In this section, we reveal a limitation of ColBERT-λ, and HIL architecture mitigates this issue.

To optimize the complementarity between isotropy and anisotropy, we observe zero-shot performance and ΔInterIso of ColBERT-λ across various λ values for each module. As depicted in Figure 4, a decline in performance is evident when reducing the λ of ColBERT-aniso to enhance its anisotropy while maintaining ColBERT-iso fixed. This suggests a limitation in $\lambda-$based tuning for finding an optimal ensemble.

We also examine isotropy and anisotropy in each layer, to confirm whether it accords with finding from Ethayarajh (2019): BERT is known to acquire isotropic embeddings in its lower layers and anisotropic embeddings in its upper layers. Our finding illustrated in Figure 5 is consistent: Lower layers, isotropic and containing lexical information, are influenced by the regularization term, leading to induced anisotropy in upper layers. As a result, InterIso, calculated for each layer in the figure, is significantly higher values in the lower layers of ColBERT-aniso, indicating a potential loss of lexical information.

For a more detailed analysis, we introduce the BM25-Easy dataset based on the top 50% of BM25 nDCG@10 scores for all queries. The evaluation of performances on BM25-Easy in Table 4 reveals that ColBERT-aniso experiences a performance decrease of -5.61% compared to ColBERT, signifying a disturbance in lexical information.

On the other hand, the HIL architecture circumvents these issues. The objectives of the $\mathcal{L}_{\text{reg}L}$ and $\mathcal{L}_{\text{reg}H}$ terms in the ColBERT-HIL loss function directly aim to enhance ΔInterIso during training, inducing isotropy and anisotropy in its lower and upper layers, respectively. In Figure 5, ColBERT-HIL exhibits more isotropy than ColBERT-aniso up to the fifth layer and becomes increasingly anisotropic from the sixth layer onward. Furthermore, in Table 4, the anisotropic module H outperforms ColBERT-aniso by +4.68%, and ColBERT-HIL surpasses ColBERT-λ by +1.45% on BM25-Easy. This suggests that ColBERT-HIL effectively mitigates the disturbance of lexical information.

Model	MSMARCO	BEIR
ColBERT	41.66	42.32
ColBERT-λ	42.03 (+0.37)	42.52 (+0.2)
ColBERT-HIL	**42.34** (+0.68)	**44.8** (+2.48)

Model	MSMARCO	BEIR
CITADEL	35.86	38.03
CITADEL-HIL	**36.84** (+0.98)	**40.32** (+2.29)

Table 7: Re-ranking nDCG@10 performance for each dataset. CITADEL-HIL represents CITADEL trained with HIL architecture.

4.2.3 RQ3: Ablation Study

We conduct an ablation study on both the MSMARCO and BEIR datasets, as illustrated in Table 5. Each regularization term is individually incorporated into ColBERT-HIL without any other regularization terms.

Our findings reveal that both $\mathcal{L}_{\text{reg}L}$ and $\mathcal{L}_{\text{reg}H}$ contribute to enhancements in ΔInterIso and overall performance across both datasets. Notably, $\mathcal{L}_{\text{reg}L}$, designed to induce isotropy in the lower layers, leads to an improvement in ΔInterIso. This holds true even when the lower layers are already strong isotorpic when trained without any regularization terms.

It is worth noting that the individual contributions of both $\mathcal{L}_{\text{reg}L}$ and $\mathcal{L}_{\text{reg}H}$ are evident in the observed improvements, underlining the effectiveness of each term in refining the performance of ColBERT-HIL on both datasets.

4.2.4 RQ4: Generalizability of HIL

This section shows how our proposed approach, the HIL structure utilizing the InterIso metric, generalizes to re-ranking task, to a more recent late-interaction model.

Re-ranking task To assess the re-ranking capabilities of ColBERT, ColBERT-λ, and ColBERT-HIL, we conduct re-ranking on the same passages retrieved in the first stage by ColBERT-HIL, as presented in Table 6. Despite employing an equal number of passages for re-ranking, both ColBERT-HIL and ColBERT-λ surpass ColBERT in performance. This suggests the advantages of leveraging both isotropic and anisotropic representations for re-ranking. Additionally, ColBERT-HIL significantly enhances zero-shot performance by approximately 12 times compared to ColBERT-λ, underscoring the effectiveness of the HIL framework for zero-shot retrieval.

Recent late-interaction model To validate the generalizability of HIL for more recent late-interaction model, other than ColBERT, we apply HIL to the recent late-interaction model, CITADEL (Li et al., 2023). As shown in Table 7, CITADEL-HIL, trained with the HIL architecture, outperforms CITADEL by +0.98% and +2.29% on MSMARCO and BEIR, respectively. The improvement in BEIR performance is twice that observed in MSMARCO, aligning with the consistent results observed with ColBERT and highlighting the versatility of HIL across different retrieval models.

5 Conclusion

Addressing the challenge of applying prior insights on isotropy to IR, we introduce InterIso, a metric designed to quantify isotropy between queries and passages in DR settings. Leveraging InterIso, we propose HIL architecture that seamlessly integrates isotropic and anisotropic representations. Our experiments with BEIR benchmark demonstrate that ColBERT-HIL significantly outperforms the baselines, ColBERT and BM25. It indicates the pivotal role of harmonized isotropy in enhancing zero-shot retrieval performance.

6 Limitations

To the best of our knowledge, we are the first to achieve hybrid isotropy by combining isotropic and anisotropic embeddings at the score-level. While this approach is straightforward and easy to apply, adopting more sophisticated methods to combine isotropy and anisotropy could potentially enhance performance beyond simple score-level fusion. We remain this task for future research endeavors.

A Appendices

A.1 Isotropy

Metrics **Avg-Cos** (Ethayarajh, 2019) computes the average cosine similarity score as follows:

$$\text{Avg-Cos}(s) = \frac{1}{|E_s|(|E_s|-1)} \sum_{i \neq j} E_{s_i} \cdot E_{s_j}^T$$

where s indicates representations. **IsoScore** (Rudman et al., 2022) measures the distance between the covariance matrix of the data and the identity matrix as follows:

$$\delta(X) = \frac{||\hat{\Sigma}_D - \mathbf{1}||}{\sqrt{2(n-\sqrt{n})}}$$

$$\phi(X) = \frac{(n - \delta(X)^2(n-\sqrt{n}))^2}{n^2}$$

$$\text{IsoScore}(X) = \frac{(n \cdot \phi(X) - 1)}{(n-1)}$$

where X, n, and $\hat{\Sigma}_D$ indicate representations, number of components of PCA for X, and normalized diagonal of the covariance matrix of first n principal components. **Partition isotropy score**, as defined by Mu et al. (2017), can be formulated as follows:

$$Z(C) = \sum_{x \in X} \exp(c^T x)$$

$$I(X) = \frac{\min_{c \in C} Z(c)}{\max_{c \in C} Z(c)}$$

where X indicates the representations and c is chosen from the eigenspectrum of XX^T. Avg-Cos closer to 0 indicates strong isotropy, while a value of 1 suggests anisotropy. For IsoScore and Partition isotropy score, 0 represents anisotropy, whereas 1 represents isotropy.

Methods Rudman and Eickhoff (2023); Gao et al. (2019) propose regularization term, I-STAR and CosReg, to adjust isotropy during training. Their loss function can be formulated as follows:

$$\mathcal{L}_{\text{I-STAR}} = \mathcal{L}_{\text{CE}} + \lambda \cdot (1 - \text{IsoScore}(\widetilde{X}, C_i))$$

$$\mathcal{L}_{\text{CosReg}} = \mathcal{L}_{\text{CE}} + \lambda \frac{1}{M^2} \sum_{i}^{M} \sum_{j \neq i} \hat{x}_i^T \hat{x}_j$$

where $\mathcal{L}_{\text{CE}}$ represents cross-entropy loss, $\widetilde{X} = \bigcup_{l=1}^{n} X_l$ denotes the union of all hidden states from a network with n layers and C_i is the shrinkage covariance matrix for epoch i of training. IsoScore measures isotropy of $\widetilde{X}$ and C_i. For CosReg, $\hat{x}_i = \frac{x_i}{||x||}$ and $\{x_1, x_2, ..., x_M\}$ denotes the mini-batch representation obtained from the last hidden layer.

A.2 Experiment Setting

MS MARCO-Passage [2] (Nguyen et al., 2016) This dataset offers a collection of 8.8 million passages with the labels sourced from the Bing search engine. Since the relevance labels for the official test set are not accessible to the public, we used only the training set to train the model and evaluated it on the development set.

BEIR [3] (Thakur et al., 2021) Benchmarking-IR (BEIR) serves as a comprehensive and diverse evaluation benchmark for zero-shot information retrieval. It encompasses 18 datasets spanning a range of text retrieval tasks and domains.

Evaluation Metric We evaluate the performance on the BEIR benchmark using the Normalized Discounted Cumulative Gain (nDCG) metric. To compute this metric, we employ the pytrec_eval (Van Gysel and de Rijke, 2018) Python library.

A.3 Implementation

Variations of ColBERT model We follow the training settings described in Khattab and Zaharia (2020), using a learning rate of 3×10^{-6} and a batch size of 32. The models are trained for 200k iterations on the MS MARCO-Passage dataset, with query and passage lengths set to 32 and 180. For ColBERT encoder, we utilize the base version (Uncased) of BERT (Devlin et al., 2019). For hyper-parameter, we search λ based on nDCG@10 using MS MARCO-Passage dev dataset in a range of [-1, 1] with a step size of 0.1. The best configuration λ was -0.1, 0.4 and -0.3 for ColBERT-aniso, ColBERT-iso and ColBERT-HIL, respectively.

Regularization term We revise CosReg and I-STAR, as regularization for DR. Given triples $\langle q, d^+, d^- \rangle$, we replace $\mathcal{L}_{\text{CE}}$ term, which is mentioned in Section A.1, with $\mathcal{L}_{\text{late}}$ as follows:

$$\mathcal{L}_{\text{late}} = \text{CE}(\text{score}_{\text{late}}(q, d^+),\ \text{score}_{\text{late}}(q, d^-))$$

where d^+ and d^- represent a positive and negative passage for given query q. Since both I-STAR and CosReg regularization terms have the same role, we explore two terms with hyper-parameter λ. The loss function can be formulated as follows:

$$\mathcal{L}_{\text{reg}}(s) = \begin{cases} 1 - \text{IsoScore}(X, I) \\ \frac{1}{M^2} \sum_{i}^{M} \sum_{j \neq i} X_i^T X_j \end{cases}$$

$$\mathcal{L}_{\{\text{CosReg} \mid \text{I-STAR}\}} = \mathcal{L}_{\text{late}} + \frac{\lambda}{2} \cdot (\mathcal{L}_{\text{reg}}(q) + \mathcal{L}_{\text{reg}}(d))$$

where s denotes either a query or a passage, and X and I represent projected last hidden state of s and identity matrix, respectively. The other notations are the same as described in Section A.1. We compute regularization term for queries and passages separately, recognizing their distinct distributions. The optimal configurations for λ were 0.2 and -0.1 for isotropic and anisotropic modules of CosReg, and 0.2 and -0.6 for isotropic and anisotropic modules of I-STAR.

CITADEL We use the open-source dpr-scale[4] to implement CITADEL (Li et al., 2023) and CITADEL-HIL. When implementing CITADEL-HIL, we L2 normalize token embedding and apply softmax operation to token-level router representations to prevent the divergence of InterIso values. We set λ, query and passage length to -0.3, 32 and 180, respectively, and train for 10 epochs.

A.4 Experiment details

Score distributions The score distributions for hybrid isotropy models are depicted in Figure 6. These scores are computed using query and passage pairs retrieved by BM25 from MSMARCO dev dataset. ColBERT-InterIso and ColBERT-HIL effectively learn isotropic and anisotropic spaces,

Model	BEIR
ColBERTv2	46.4
ColBERTv2-HIL	**46.61** (+0.21)

Table 8: nDCG@10 scores in full-ranking when using ColBERTv2 as a backbone model.

Model	BEIR
ColBERT	42.23
ColBERT-HIL	**45.25** (+3.02)

Table 9: nDCG@10 scores in full-ranking. ColBERT and ColBERT-HIL are trained with BEIR-hyperparameters.

whereas ColBERT-cosreg and ColBERT-istar struggle to learn distinct vector spaces. We can also see ColBERT-iso and ColBERT-aniso achieve the best isotropy and anisotropy, respectively, except for L and H.

Limitation of Ensemble To reveal limitations of ColBERT-InterIso, we examine zero-shot performance and InterIso of ColBERT-iso and ColBERT-aniso for various λ. As shown in Figure 7, we observe a performance drop in ColBERT-aniso when decreasing λ, while ColBERT-iso maintains consistent performance.

Ablation study for training steps We conduct an ablation study on training steps, as shown in Figure 8. It shows that L and H are close to each other when trained without any regularization term. While ΔInterIso for ColBERT-HIL w/o reg_H is larger than ColBERT-HIL w/o $\text{reg}_L, \text{reg}_H$ at the 200k step, it still decreases during training due to reg_L only inducing isotropy in its lower layers, which already exhibit strong isotropy. However, ΔInterIso for ColBERT-HIL consistently increases during training, signifying that reg_L and reg_H effectively enhance the isotropic difference between them.

A.5 Additional evaluations

ColBERTv2 as a backbone We adopted ColBERTv1 as a backbone model since ColBERTv2 is not suitable for separately observing the two types of scores in HIL: one from isotropic space and another from anisotropic space. However, in this section, we confirm the performance gain based on ColBERTv2. We used the public checkpoint[5] for ColBERTv2 and trained ColBERTv2-HIL, initializing it from a pretrained checkpoint which trained with one hard negative example over 150 steps. Despite ColBERTv2 being trained with 31 hard negative examples, we observe in Table 8 that ColBERTv2-HIL still outperforms it.

BEIR-hyperparameters We used the hyperparameters from the ColBERTv1 paper (Khattab and Zaharia, 2020) since we utilized ColBERTv1 as a backbone model. This slightly differs from the hyperparameters used in the BEIR paper (Thakur et al., 2021). In ColBERTv1 settings, the sequence length is 180, while the BEIR paper used a sequence length of 300. To verify the effect of hyperparameters, we trained ColBERT and ColBERT-HIL with BEIR-hyperparameters. Table 9 demonstrates that we can achieve a similar performance gain when using BEIR-hyperparameters.

SuperGLEBer: German Language Understanding Evaluation Benchmark

Jan Pfister and **Andreas Hotho**
Data Science Chair
Center for Artificial Intelligence and Data Science (CAIDAS)
Julius-Maximilians-Universität Würzburg (JMU)
{lastname}@informatik.uni-wuerzburg.de

Abstract

We assemble a broad Natural Language Understanding benchmark suite for the German language and consequently evaluate a wide array of existing German-capable models in order to create a better understanding of the current state of German LLMs. Our benchmark consists of 29 different tasks ranging over different types such as document classification, sequence tagging, sentence similarity, and question answering, on which we evaluate 10 different German-pretrained models, thereby charting the landscape of German LLMs. In our comprehensive evaluation we find that encoder models are a good choice for most tasks, but also that the largest encoder model does not necessarily perform best for all tasks. We make our benchmark suite and a leaderboard publically available at supergleber.professor-x.de and encourage the community to contribute new tasks and evaluate more models on it[1].

1 Introduction

Fueled by the release of ChatGPT (OpenAI, 2022), the development of very capable, large language models (LLMs) has been accelerating, which also results in the release of more and more powerful models capable of the German language (Plüster, 2023; Jiang et al., 2023). From an NLP point of view, German is a language that apart from smaller, commonly BERT-based models traditionally has seen little attention when it comes to publicly available, explicitly for German pretrained foundational models. This now led to the situation that an increasing number of presumably very capable, German-pretrained LLMs are being released, but no established, diverse and systematic German evaluation suite for these models is available. To illustrate this point, we emphasize that, newly introduced German BERT-based models have historically only been evaluated on two tasks each (Scheible et al., 2020; Chan et al., 2020), which is not enough to get a comprehensive understanding of the models capabilities. Hence a German evaluation suite is desireable to properly compare and assess the abilities of widely used, but also newly developed models, like there is e.g. for English with GLUE (Wang et al., 2018), SuperGLUE (Wang et al., 2019) or even more recently OpenCompass (2023). Commonly researchers turned to these English evaluation suites to assess their German models and - for lack of a better solution - had to help themselves by translating very hard benchmark datasets from English to German using e.g. ChatGPT (Plüster, 2023). This arguably leads to unreliable results, as the models are evaluated on a task that has been machine-translated sometimes by the very same model these benchmarks were created to be hard to solve and understand for (Vago, 2023).

Our benchmark evaluation suite thus aims for both: 1. aggregating a diverse set of available German Natural Language Understanding (NLU) tasks, 2. identifying commonly used German-pretrained LLMs and evaluating the models on this benchmark. To this end, we select a wide range of different task types to make sure to properly assess the models' capabilities, such that our benchmark includes document classification, sequence tagging, sentence similarity and question answering tasks (Table 2). While these datasets are not new, they have been selected to cover a wide range of different NLU tasks, and are sourced from various different domains. This evaluation on a combination of tasks and domains pushes the German NLP research forward, as it allows for a more comprehensive understanding of the models' capabilities. It allows insights into the models' strengths and weaknesses, and helps to identify areas where the models are lacking, which can then be used to guide future research. Like in existing LLM benchmarks for other languages (Wang et al., 2019;

[1] github.com/LSX-UniWue/SuperGLEBer

Proceedings of the 2024 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies (Volume 1: Long Papers), pages 7904–7923
June 16-21, 2024 ©2024 Association for Computational Linguistics

Hardalov et al., 2023) in this benchmark we challenge the models to perform well on a wide range of different tasks, which are not necessarily related to each other. These tasks focus on reasoning and language understanding, and are sourced from public datasets across different domains. Inspired by SuperGLUE, we select tasks with a very simple input and output format to avoid "complex task-specific architectures" (Wang et al., 2019), as well as tasks that can be evaluated using a simple and intuitive metric. This rules out tasks like e.g. text generation, which is inherently hard to evaluate. In addition to assembling this benchmark we also run an extensive evaluation of 4 encoder-only, 3 decoder-only, and 3 encoder-decoder German-capable transformer models as depicted in Table 1. In our comprehensive evaluation we find, that overall the encoder models perform best and usually consistently close to each other. Notably, the two largest models mBART and leo-7b are also performing well, despite not being encoder models, which is likely owed to their large size. Nevertheless, we did not find a clear advantage for the larger encoder model, as the gBERT-large model is not consistently able to profit from its larger size, compared to its smaller counterparts. We see the effort of this benchmark not as a one-time task, but instead aim to introduce a basis that can be expanded upon with additional tasks and models in the future, to support and foster research for German LLMs. To this end we open-source our evaluation code, including a public leaderboard and aim to continously expand on this effort in the future.

Our contributions are as follows: 1. assembling a diverse benchmark for German NLU consisting of 29 different tasks across four task types, 2. comprehensively evaluating 10 different German-pretrained LLMs across various architectures on this benchmark, 3. providing this open-source evaluation framework to the community, allowing for easy extension in the future.

2 German Evaluation Tasks

In order to create a challenging and diverse benchmark for German NLU we select a wide range of different tasks from various different domains for our evaluation suite. We also list the included tasks as well as statistics for each dataset in the appendix in Table 2. In order to evaluate different capabilities of the pretrained models we select various different task types: text classification, sequence tagging, sentence similarity and question answering. All selected tasks are sourced from public datasets and are available in German. We carefully select the tasks, such that we only include datasets have been human-translated to German (Yang et al., 2019), manually checked after automatic annotation (Henrich et al., 2012), or - preferably - have a testset that is manually annotated in German (the rest).

2.1 Text Classification

Text classification describes the task of assigning a label to either an entire input document or a combination of input documents. We span a wide range of different domains and prediction targets, which we group into the following five categories.

Toxic & Offensive Language Identification Here we have two different datasets, which we evaluate separately: 1. The task of *Offensive Language Identification* has been introduced by Wiegand et al. (2018), while 2. *Toxic Comments Identification* has been introduced by Risch et al. (2021). For the first we evaluate on the fine-grained annotation distinguishing between three different types of offensive language ("profanity", "insult", and "abuse"), while the second is a binary classification task, where the model has to predict whether the input sentence contains toxic language or not.

Sentiment Analysis Here we cover two different levels of granularity: document-level and aspect-based sentiment analysis. The dataset introduced by Wojatzki et al. (2017) spans both granularities. 1. First it is annotated with the sentiment expressed in the document towards the topic of "Deutsche Bahn", where all other sentiments expressed towards unrelated topics should be ignored. 2. For a more detailed evaluation we also include the identification of sentiment expressed towards specific aspects within the input document in a multi-label classification task. There are overall 20 aspects, which can be e.g. "train_ride", "atmosphere" or "service" for which the model has to predict the sentiment towards each of these aspects as "positive", "negative" or "neutral". 3. In the same spirit we select a second dataset for aspect-based sentiment analysis, consisting of hotel reviews again annotated with the sentiment expressed towards specific aspects like "location", "food&drinks" or "service" (Fehle et al., 2023).

Text Pair Matching Next we evaluate the models ability to classify whether two input documents share a certain semantic relation. For this we select two datasets introduced in the cross-lingual benchmark XGLUE (Liang et al., 2020): Query-Ad Matching and Question-Answer Matching. Here the model has to predict whether 1. an ad is a good fit for a given query, or whether 2. a sentence is the answer for a given question. 3. Furthermore we use the paraphrase identification dataset PAWS-X introduced by Yang et al. (2019), which consists of sentence pairs where the model has to predict whether the sentences are paraphrases of each other or not.

Word Sense Disambiguation 1. The first dataset *WebCAGe* is a corpus annotated with senses from GermaNet (Henrich et al., 2012). The task defined on this dataset is to predict the correct sense of a given word in the context of the sentence; e.g. (river) "bank" vs. "bank" (institute). 2. Furthermore we select a second dataset by Ehren et al. (2021) focusing on the disambiguation of German verbal idioms, where the model has to predict from context whether a phrase is meant literally or figuratively; e.g. "hold your breath" (by not breathing) vs. "hold your breath" (waiting in anticipation).

Other Classification Tasks First, on the same dataset as the toxic comment identification task introduced previously (2.1, Risch et al. (2021)), we also evaluate the models ability to identify whether the input comment is 1. *fact-claiming* or 2. *engaging*. Here, fact-claiming means that the sentence contains a claim that can or should be verified/refuted by a fact-checker, while secondly engaging comments are defined as making readers join a discussion. 3. Next, the *argument mining* task by Romberg and Conrad (2021) consists of sentences annotated with whether the sentence contains "options for actions or decisions that occur in the discussion" (major positions), "reasons that attack or support a major position or another premise" (premise), both or none. 4. On the same dataset as the sentiment analysis task introduced previously (2.1, Wojatzki et al. (2017)), we evaluate the models ability to identify whether the input document is *relevant to the topic* of "Deutsche Bahn". If the German railroad company is neither directly nor indirectly (e.g. via their services) mentioned in the entire input document the label is "false". 5. Next, the MASSIVE dataset consists of annotated *voice assistant interactions* (FitzGerald et al., 2023). The utterances by users are annotated with the *intent of the user*, which the model has to predict e.g. the concrete intent of "setting an alarm", or the intent to "play music". 6. We further include the *Natural Language Inference (NLI)* task, where the model has to predict whether a hypothesis is entailed by a premise or not. The dataset has been introduced in XNLI (Conneau et al., 2018) and was intended as a cross-lingual evaluation dataset, but we use it as a mono-lingual dataset for German. 7. Lastly, we include the *news classification* task from XGLUE (Liang et al., 2020), where the model has to predict the category of the news article.

2.2 Sequence Tagging

The task of sequence tagging describes annotating every word or token from the input document with its respective class. We again span a wide range of different domains and prediction targets, which we group into the following two categories.

Named Entity Recognition NER is a common sequence tagging task, refering to annotating every token in the input document with its respective named entity class. Named entities can be persons, locations, organizations, but also more abstract entities like time or monetary values.

1. The first dataset is taken from *historical biodiversity literature* annotated with named entities like "persons", "locations", "organizations" or "other", as well as time and taxonomic entities (Ahmed et al., 2019), while the 2. *Europa-Parl* dataset (Faruqui and Padó, 2010) are proceedings from the European Parliament annotated with NEs like "persons", "locations" or "organizations". 3. The next dataset was introduced by Benikova et al. (2014) and is sourced from German *Wikipedia* articles as well as various *online news sources*. 4. Next, we also select a dataset with *legal entities* annotated within German court decisions (Leitner et al., 2019). It consists of German court decisions annotated with 19 semantic classes, like e.g. "person", "lawyer", "country", "organization" but also more domain-specific classes like "European legal norm", "regulation" or "contract". 5. Lastly, we take the NER datasets from the cross-lingual benchmark XGLUE (Liang et al., 2020), which is a subset of a German news dataset by Tjong Kim Sang and De Meulder (2003) annotated with "Person", "Location", "Organization" and "Miscellaneous" entities.

Other Sequence Tagging Tasks 1. On the *Universal Proposition Banks* by (Akbik et al., 2015), we evaluate the models abilities to predict POS tags, as well as dependency parse tree labels in two separate tasks. 2. Furthermore, again on the MASSIVE dataset introduced previously (5) we also evaluate the models ability to identify "arguments" in the user's utterance; e.g. "weck mich [date : diese woche] um [time : fünf uhr morgens] auf". 3. Lastly, on the sentiment dataset by Wojatzki et al. (2017) also used in Section 2.1 we evaluate the models ability to identify the concrete opinion term expressing the sentiment in the input document.

2.3 Sentence Similarity

Sentence Similarity tasks measure the models capabilities to generate semantically meaningful vector representations for the input documents. Semantically similar documents should be placed closer together in the model's embedding space than unrelated documents. For this we use the PAWS-X (Yang et al., 2019) dataset, which consists of sentence pairs annotated with whether the sentences are paraphrases of each other or not.

2.4 Question Answering

Our last task type is extractive question answering, where the model has to answer a question given an input document. We evaluate this on two different datasets: 1. GermanQuAD (Möller et al., 2021) and 2. MLQA (Lewis et al., 2020). MLQA was created as a cross-lingual evaluation dataset, but we use it as a mono-lingual dataset for German.

3 Training Methodology

3.1 Training Methodology by LLM Type

Depending on the of transformer architecture, we use different training approaches, each tailored to the specific model: we distinguish between encoder-only, decoder-only and encoder-decoder models and follow the established training approaches for the respective model as defined in the used library. For transformers following the *encoder* or *decoder* architecture, we finetune the text classification tasks using the standard approach of adding a linear layer on top of the output representation of the CLS token, while for sequence tagging tasks we use the same approach, but train the linear layer to predict the correct class on top of the output representation of each input token individually. For the sentence similarity we follow the Sentence-BERT (Reimers and Gurevych, 2019) approach and finetune the model using a triplet loss with negative sampling on the mean-pooled final output representations of the model. When finetuning for extractive question answering, we again follow the standard approach of adding a linear layer on top of the output representations of the input tokens, and train the linear layer to predict the start and end token of the answer span. For transformer models following the *encoder+decoder* architecture, we adopt the practices in the respectively used library by discarding the model's decoder entirely for classification, sequence tagging and similarity tasks, and only finetune the encoder part of the model as described above and for question answering tasks we add the span extraction head on top of the decoder output.

3.2 Training Procedure for the Task Types

For each of the task types we implement the training routine as described above using an established, publicly available library. That is, for text classification and sequence classification we use flair (Akbik et al., 2019), for question answering we use the reference training loop provided by HuggingFace's Transformers (Wolf et al., 2020), and for sentence similarity we use the reference script provided by the SentenceTransformers (Reimers and Gurevych, 2019) library. For all models we use the same training procedure: We use the same default hyperparameters across all models and libraries, and the same fixed seed. These are: a batch size of 8, a learning rate of 5e-5, 5 epochs. We also introduce a maximum input sequence length of 512 tokens and class weighting for all classification tasks during training. Furthermore, we consequently opt to use QLoRA-training (Dettmers et al., 2023) for all models where it is supported by the HuggingFace library (2020). If not supported by the library we skip the quantization steps and fall back to LoRA (Hu et al., 2022), which in our case applies only to the BERT/RoBERTa models. We do this, because not all models could be trained on a single A100 GPU, hence we use QLoRA-training to reduce the memory footprint of the larger models to make training them on a single GPU feasible. Consequently, enabling (Q)LoRA for all models ensures comparability between different models and rules out the possibility that the performance difference between models stems from different

training procedures. We again closely follow the quantization hyperparameters given by Dettmers et al. (2023): 4-bit quantization, double quantization and NormalFloat4.

3.3 Evaluation Metrics

As mentioned previously, we select tasks that can be evaluated using a simple and intuitive metric. When a metric has been used on the original dataset, we keep this metric for this dataset. We list the metrics used for each task in the appendix in Table 2. Used metrics are micro F1, macro F1, accuracy for classification and tagging tasks, mean-token-F1 (Lewis et al., 2020) for QA tasks (all defined in the range of 0 to 1), as well as pearson correlation calculated on cosine similarity for the sentence similarity task (defined in the range of -1 to 1). For all metrics higher values indicate better performance, and we calculate the metric with the native implementation included in the used framework. For the sake of creating a benchmark evaluation suite we follow other benchmarks (2019; 2020; 2023) and average across tasks and thereby also across different metrics.

4 Evaluated Models

In our evaluation we aim to cover a large number of different models and model types available for the German language (Table 1) and evaluate these models on the tasks introduced in Section 2. We evaluate a range of different models and architectures, including encoder-only, decoder-only, and encoder-decoder models. The models have been pretrained on different datasets, some of which are multilingual, while others are monolingual German. We refer to the models by their respective HuggingFace (2020) model identifier and compare their parameter count in Table 3 in the appendix.

We evaluate *three different BERT* models, one being "bert-base-german-cased", pretrained on 12 GB of wikipedia, legal documents and news. The other two BERTs have been pretrained by Chan et al. (2020) and only differ in size: "deepset/gbert-base" and "deepset/gbert-large". Both models have been pretrained on 163.4 GB of German text, mostly consisting of OSCAR, enriched with OPUS, Wikipedia and legal documents. We also evaluate "uklfr/gottbert-base" (Scheible et al., 2020), which is a *RoBERTa* model pretrained on 145 GB of OSCAR, Wikipedia and a book corpus.

For decoder models we evaluate "dbmdz/german-gpt2" (Schweter, 2020), which is a GPT2 model pretrained on about 16 GB of German text, consisting of subtitles, and a diverse set of web crawls like CommonCrawl and news. "LeoLM/leo-hessianai-7b" is a very recent, comparably large language model, finetuned from a LLaMA2 checkpoint using German text (Plüster, 2023) mostly sourced from OSCAR and has only been evaluated on a machine-translated version of the English OpenLLM dataset. Furthermore, we consider the multilingual-trained "bigscience/bloomz-560m" model (Muennighoff et al., 2023). It was trained in two steps: first on a 1.5 TB multilingual corpus of 45 languages and 12 programming languages using causal language modeling (Workshop et al., 2023), then further multilingual, multi-task pretraining using supervised tasks (Muennighoff et al., 2023).

We also evaluate the encoder-decoder multilingual-trained "bigscience/mt0-small" model (Muennighoff et al., 2023), which was finetuned analogously to the previously introduced Bloomz model, but is instead finetuned from the "google/mt5-small" checkpoint. This model in turn was trained on 101 languages, including German, using the "span-corruption" objective (Xue et al., 2021) on the C4 corpus (Raffel et al., 2020) and is also included in our evaluation. Lastly we evaluate the multilingual-trained "facebook/mbart-large-50" model, trained on 50 languages, including German, using the translation objective (Liu et al., 2020). In contrast to BART, the mBART model was only trained on the translation objective between any pair of languages and not additionally on the denoising objective, thus never saw German text as input and target at the same time. Nevertheless Wunderle et al. (2023) showed that mBART is able to perform well on German-only tasks.

5 Evaluation

We extensively evaluate the models from Section 4 on the tasks introduced in Section 2 resulting in Table 1. Here the results are averaged by the various task types at varying levels of granularity. The columns reading "avg" have been averaged across the averages of the respective task types, in order to not overweight any task type for which more datasets exist, i.e. all "NER" tasks have been averaged into a single value before averaging across all tagging tasks. All tasks assigned to "other" are directly included in the final average across all task

type	model	classification						tagging			similarity	QA

Table 1: Results of our models on various tasks, averaged at varying levels of granularity. The columns reading "avg" have been averaged across the averages of the respective task types, in order to not overweight any task type for which more datasets exist, i.e. all "NER" tasks have been averaged into a single value before averaging across all tagging tasks. The second row gives the type of metric used for the respective task type. Here "mixed" means that - like in other benchmarks (2019; 2020; 2023) - at least two kind of metrics have been averaged together. The results marked with † have been averaged over tasks for which a "Cuda OOM" error occured on an A100 80GB GPU (only mBART). The results marked with ‡ have been averaged over tasks where a "ShapeError" occured (only Bloomz). Both symbols have been placed at all averages this affects transitively. All missing values have been treated as a 0.0 when calculating the average.

types. We also list the results for the individual tasks in the appendix in Appendix D. In the following we will discuss our results under various different aspects.

5.1 Performance by Model and Task Type

For **classification** tasks we find that the *encoder-models* all perform on average very similar to each other (ranging 70.2 to 72.4), despite differences in the training data and even model size and architecture. Despite this, within the classification tasks the models don't perform equally well on all tasks. For example the gBERT-large model performs above average for NLI, sentiment analysis, text pair matching, as well as word sense disambiguation, but at the same time below average for toxicity detection. On average the largest encoder model is thus even the worst performing encoder model. For the *encoder+decoder* models there is a clear distinction in performance between the mT5 and mT0 models (46.2 and 53.5) on the one hand and the mBART model (62.9) on the other hand. The mBART model performs much better across most classification tasks, mostly being competitive with the encoder models. We find that mT5 performs consistently worse than its further pretrained mT0 counterpart, with the only exception being the sentiment analysis task. Within the *decoder* models GPT2 model performs similarly to the bloomz model (69.6 and 66.7), while the leo-7b model performs significantly better (81.0). Here the leo-7b model comfortably ranks first place across all models, which is likely owed to its significantly larger size and training data. The GPT2 model also performs reasonably well, but is still outperformed by all encoder models.

Overall we find that the encoder models perform best across all classification tasks, and rank overall places 2-5 across all models, with the best performing encoder model being bert-base-german-cased, only getting beat by leo-7b. mT5 and mT0 perform worst across all models, with mT0 performing better than mT5.

For **sequence tagging** tasks the *encoder* models again perform very similar to each other, with the gBERT-large model performing as good as its smaller counterpart. Here the encoder-models rank places 1,2,4 and 5 across all models. Along the *encoder+decoder* models the mBART model again performs clearly best, with the mT0 and mT5 again placing at the bottom of the ranking. mBART is even competetive with the encoder-only models, ranking place 3 across all models, while leo-7b is the best performing *decoder* and bloomz is performing worst overall (52.2). The leo-7b model always performed slightly below or roughly at average of all other models, only dominating by a large margin for the NER task on the EuroParl dataset. GPT2 is the best performing decoder model for sequence tagging, but is again outperformed by the encoder models and mBART.

Analysing the **sentence similarity** task the encoder models performance varies drastically (53.3 to 65.1), with gBERT-large performing best by a large margin (rank 1). The other three encoder models are comfortably outperformed by two non-encoder models, namely mBART (rank 2) and leo-7b (rank 3). We find that GPT2, bloomz and mT5 perform similarly bad, while mT0 is closer to the small encoder models.

For **QA** performance all models - except leo-7b and mT5 - are very close to each other. We identify leo-7b as best-performing model (86.4), followed by mBART (82.9) and gBERT-large (82.6).

Overall we find that depending on the task type different models perform best, but a clear trend is that the encoder models are always among the top. The size of the encoder models does not seem to have a large impact on the performance, as the gBERT-large model does not have a consistent advantage over its smaller counterpart, except in the sentence similarity task. The mBART model performs best across the evaluated encoder-decoder models, often being competetive with the encoder models, only being outperformed by them on the classification tasks. Furthermore, the pretraining of the mT0 model seems to have a positive effect on the performance for German, as it very consistently performs better than the mT5 model across all task types, often by a large margin. It is clear that the leo-7b model performs best across all decoder models for most task types, while the bloomz model ranks last. Given that mBART and leo-7b are both the largest models in the benchmark, it is not surprising that they perform best across most task types. At the same time gBERT-large is not able to profit from its larger size, as it is commonly outperformed or matched by the smaller encoder models.

5.2 Performance Comparison to Prior Work

In Appendix D we include the reported results from related work for comparison, where reasonably possible. Despite this, it is important to acknowledge that the reported results cannot be directly compared to ours because of variations in hyperparameter optimizations, data splits, cross-lingual evaluations, overall evaluation scenarios, specialised architectures, or the incorporation of extra pretraining data. Overall, we find that usually the reported results from related work are in line with our findings, and only in a few cases the results differ significantly. E.g. for the XGLUE-sourced tasks our models commonly perform better than the reported results, which makes sense, as we evaluate the models in a mono-lingual setting, while the XGLUE tasks are cross-lingual.

5.3 Performance Stability Across Seeds

To make sure that the results are not a fluke depending on a random seed, we evaluate the models on the same tasks using different random seeds. At the size of this benchmark running the entire evaluation for all models and tasks for multiple seeds becomes computationally prohibitive (Appendix A), so we select one encoder and one decoder model, as well as three tasks to evaluate the stability of the results on. We run the entire fine-tuning and evaluation an additional four times for each selected model and task, using a different random seed each time. For this experiment, we select the gBERT-base model, as well as the german-GPT2 model and for the task types we select the verbal idioms classification task, the biodiversity NER task and the PAWS-X sentence similarity task. We list detailed results in the appendix in Table 5 and find the results to be very stable across the different seeds with an average standard deviation of the results being below 0.012 across tasks and models.

5.4 Performance w. and w/o. (Q)LoRA

As we exclusively use (Q)LoRA for our training in order to keep the model footprint small and the results comparable across models, we also conduct a small evaluation of the performance of the models with and without (Q)LoRA training. For this we select the same models and tasks as in Section 5.3 and train them without (Q)LoRA once. For this we use the same hyperparameter configuration and seed as for the (Q)LoRA training, but train the models using full precision. We list the results alongside in Table 5 and find that there is a significant performance difference between the (Q)LoRA and non-(Q)LoRA training. The performance drop ranges from 0.019 to 0.090 across tasks and models. We explicitly welcome non-(Q)LoRA trained models in the benchmark evaluation leaderboards, but also encourage further research into the performance of (Q)LoRA training and its impact on the performance of the models. We also plan on differentiating between various training approaches in the benchmark, making it possible to compare the performance across different training methods.

6 Related Work

GLUE (Wang et al., 2018) and SuperGLUE (Wang et al., 2019) are two of the most prominent LLM benchmarks, consisting of 11 and 10 different NLU tasks respectively. These benchmarks only being available in English has quickly been identified as an issue for the evaluation of non-English models by the NLP community. Thus the development of various similar benchmarks for other languages followed, like e.g. for Russian (Shavrina et al., 2020), Persian (Khashabi et al., 2021), or recently for Bulgarian (Hardalov et al., 2023). These benchmarks are all similar in their setup, aiming to assess the models abilities on a wide range of different tasks.

Cross- and multilingual benchmarks like XTREME (Hu et al., 2020) and XGLUE (Liang et al., 2020) on the other hand have been designed to evaluate the models' cross-lingual capabilities. For this they consist of 9 tasks spread across 5 to 40 languages for XTREME and 11 tasks across 3 to 18 languages for XGLUE. Thus they also include tasks in German, but neither the focus of the evaluation nor for the model itself is on German. The general idea behind these benchmarks is to evaluate the models' ability to transfer knowledge from one language to another, but not to evaluate the models' capabilities in a single language. Using these benchmarks as a sole basis for evaluating German models is thus not ideal, as the tasks are commonly accompanied by a rather small German training set, because the focus is on learning from the combined training data of all languages.

As mentioned earlier, in the advent of increasingly large LMs, the need for German evaluation benchmarks has been recognized, but in the absence of German focused benchmarks, the evaluation is commonly done by machine-translating existing English evaluation datasets (Plüster, 2023),

which can give an estimate of the performance of a model, but is not a reliable evaluation of the models' capabilities (Vago, 2023).

Although there exists no diverse and comprehensive evaluation benchmark for German LLMs, on which the various capabilities of different models are evaluated, there have been efforts to evaluate German models on a specific task, like sentiment analysis (Cieliebak et al., 2017), coreference resolution (Schröder et al., 2021), utterance similarity (Asaadi et al., 2022), inclusive language (Pomerenke, 2022) or document clustering (Wehrli et al., 2023). The evaluation of models on these benchmarks is usually not as comprehensive, with models being evaluated on a single task, and usually only a single model architecture - commonly encoder models - being evaluated. Overall, there is no established, easily runnable evaluation framework for a broad number of German tasks, which makes it hard to compare results across different models.

7 Conclusion

We introduce the first large and diverse German language understanding benchmark for language models, consisting of 29 different tasks and covering four different task types: text classification, sequence tagging, sentence similarity and question answering. The text classification and sequence tagging tasks themselves contain a wide range of different language understanding tasks, covering various different domains and prediction targets.

We evaluate 10 different models, including four encoder-only, three decoder-only and three encoder-decoder models on our newly introduced benchmark. In our comprehensive evaluation we find, that on average the encoder models perform best and are usually close to each other in performance on the classification and sequence tagging tasks. Despite not being encoder models, the two largest evaluated models mBART and leo-7b are performing comparably well across all tasks, mostly being competitive with the encoder models. In contrast, we did not find a clear advantage for the larger encoder model, as the gBERT-large model is not able to consistently profit from its larger size, often being outperformed or matched by its smaller counterparts. We make the benchmark and leaderboard publicly available and encourage the community to contribute tasks as well as models to the benchmark.

Limitations

7.1 Training Procedure

Some of the used frameworks (flair & Sentence-Transformers) only support training on a single GPU, which inherently limits the size of the models we can evaluate using our framework. We thus opt for QLoRA-training here to reduce the memory footprint of the larger models and make training them on a single GPU feasible.

As mentioned in Table 1 we encounter some issues with the training procedure of the mBART model (OutOfMemory), as well as the training of the bloomz model (ShapeError). The first seem to be an issue between the bitsandbytes quantization library and the mBART model, while the second seems to be incompatibilities between the used framework and the respective model/tokenizer, which we could not easily resolve. We will investigate these issues further and update the results accordingly, if we find a solution.

7.2 Representativeness of the Results

As we train and evaluate all models using QLoRA, we cannot make any statements about the performance of the models without QLoRA. Our exemplary evaluation of the models with and without QLoRA training (Section 5.4) shows that there is a performance difference between the two training procedures, which is acceptable for our purposes, as we evaluate all models using the same training procedure, thus keeping the results comparable. Furthermore we do not limit our leaderboard to QLoRA-trained models, but also explicitly welcome non-QLoRA-trained models, or even the same models trained without QLoRA.

Next, we only evaluate a single hyperparameter configuration for each model, which is the default configuration of the respective library. We leave the evaluation of different hyperparameter configurations to future work and do not limit the leaderboard to the default configuration of the respective library.

We only report the results for the same random seed for each model and task and conduct a small evaluation of the stability of the results across different seeds (Section 5.3). We find the results to be stable across different seeds, such that we are confident in our results reported in Table 1.

For some models, like the mT0, mT5, bloomz and leo-7b we evaluated only the smallest model size, as otherwise computing the benchmark results

for all model sizes would have been computationally prohibitive (Appendix A). Nevertheless we encourage the community to contribute results for the larger model sizes, but also plan to add larger versions of used models to the benchmark in the future ourselves.

Ethics Statement

As we only include publicly available datasets and models, we do not see any ethical issues with this work. We only select datasets and tasks, where the intended use of the dataset is clearly to be used for research.

Intended Use We intend this benchmark to be used for the evaluation of German LLMs. To this end we make the benchmark and leaderboard publicly available and encourage the community to contribute tasks as well as models to the benchmark. For this we provide an open-source evaluation framework, which can be easily extended to include new tasks and models and publish it under an open-source license.

Acknowledgments

A Putting the Compute into Perspective

We list the number of trainable parameters for each model in Table 3. This includes the number of parameters of the base model as well as the number of trainable parameters after (Q)LoRA has been applied.

Estimating the GPU hours for our experiments - especially including development and debugging - is difficult, as we did not explicitly keep track of all time spent on GPUs. Nevertheless we estimate the total GPU hours spent on the development of this benchmark to be around $1500\,\mathrm{h}$ of A100 GPU time.

B Dataset Domains and Licenses

The datasets we use in our benchmark are listed in Table 2, and are described in Section 2. In Table 4 we list the domains and licenses of the datasets.

C Training Stability

Table 5 lists the results of the training stability experiment described in Section 5.3, as well as the results of a single run without (Q)LoRA training for comparison (Section 5.4).

D Individual results

We list the detailed results of every task for every model in Tables 6 to 8. Models achieving a 0.0 score on for multi-class classification tasks are a known instability within the Flair library and occur only for large number of output classes for certain models: https://github.com/flairNLP/flair/issues/678

Table 4: Domains and licenses for the used datasets, more details in Section 2. For our benchmark, we only included datasets that were explicitly intended for research use. However, in cases where no license information was available (N/A), we have reached out to the authors to obtain the appropriate licensing details. We will update the license information accordingly on our website at https://supergleber.professor-x.de.

Abstract

Labeling corpora constitutes a bottleneck to create models for new tasks or domains. Large language models mitigate the issue with automatic corpus labeling methods, particularly for categorical annotations. Some NLP tasks such as emotion intensity prediction, however, require text regression, but there is no work on automating annotations for continuous label assignments. Regression is considered more challenging than classification: The fact that humans perform worse when tasked to choose values from a rating scale lead to comparative annotation methods, including best–worst scaling. This raises the question if large language model-based annotation methods show similar patterns, namely that they perform worse on rating scale annotation tasks than on comparative annotation tasks. To study this, we automate emotion intensity predictions and compare direct rating scale predictions, pairwise comparisons and best–worst scaling. We find that the latter shows the highest reliability. A transformer regressor fine-tuned on these data performs nearly on par with a model trained on the original manual annotations.

1 Introduction

Labeling data with trained experts or via crowdsourcing is a resource-intensive and time-consuming process (Zaidan, 2012; Wang et al., 2021; Bunte et al., 2021). This motivates automated annotation methods, including weak supervison (Ratner et al., 2017), zero-shot predictions (Radford et al., 2019), or, more recently, generative models (Wang et al., 2021; Kasthuriarachchy et al., 2021; Radford et al., 2019). Depending on the downstream task at hand, the labels to be assigned to a textual instance are categorical (e.g., in text classification), structured (for instance in parsing or named entity recognition), or continuous (e.g., emotion intensity, sentiment strength, or personality profiling predictions).

Annotating for continuous value labels comes with its own set of challenges. It can be difficult to obtain consistent labels from humans by asking them to assign a value from a rating scale (Schuman and Presser, 1996). Not only is it difficult for the annotator to rate texts consistently, but it is also difficult for researchers to design rating scales, as there are many design decisions which can bias the annotator, such as scale point descriptions and scale granularity. This lead to comparative annotation setups, in which annotators are tasked to compare multiple instances for the same task, which is easier to accomplish and has fewer design decisions to make. Consider the two example sentences for sentiment strength:

(1) She's quite happy.
(2) He is extremely delighted.

It is difficult to assign a value $v(s_i) \in [-1; 1]$ to these sentences in isolation, or even in context, but it is straight-forward to decide that $v(s_2) > v(s_1)$.

Best–worst scaling (BWS, Finn and Louviere, 1992; Louviere and Woodworth, 1991) is such a comparison-based annotation method that has proven to be more reliable than assigning values on rating scales, when annotating continuous values. The idea is to task an annotator to decide which instance is the one with the highest and the lowest value. The tuple size can be varied but Kiritchenko and Mohammad (2017) observe that quadruples provide a good trade-off between context and numbers of comparative judgements.

In this paper, we question if BWS is also an appropriate approach for large language model-based annotations. On the one hand, one might argue that comparative tasks are also more reliably conducted with language models. On the other hand, one might argue that a large language model (LLM) has more access to other text instances implicitly

Proceedings of the 2024 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies (Volume 1: Long Papers), pages 7924–7936
June 16-21, 2024 ©2024 Association for Computational Linguistics

from training data which it can compare a text to, than a human. That would be an argument that when using a LLM for annotations, BWS may not be necessary.

We therefore set up prompts for continuous value assignments for two direct and two comparison-based annotation approaches. We use rating scales (RS, Likert, 1932), in which the model directly labels texts with a numerical value, in two variants: annotating single texts and tuples of four texts per prompt. Our comparison-based approaches are paired comparisons (PC, Thurstone, 1927) in which every text is compared to every other text, and best–worst scaling (BWS, Louviere and Woodworth, 1991), where "best" and "worst" instances are picked from a tuple.

In our evaluation, we focus on comparisons against human annotations for the emotion intensity prediction task (Mohammad and Kiritchenko, 2018). We compare the LLM-based annotations directly against human annotations and further train a transformer-based regressor both on the human-labeled data and the LLM-labeled data. The motivation for this regressor is to avoid the requirement to put together instances in tuples and query a potentially expensive API at inference time. We answer the following research questions:

1. Does the best–worst scaling annotation method perform better than rating scales or paired comparisons when using generative models for labeling text with continuous values? *(Yes, it does.)*
2. How does the performance of a transformer-based regressor compare when trained with automated annotations vs. human annotations? *(The models perform on par.)*

2 Related Work

2.1 Automated Annotation

Annotating texts can be an arduous and costly task (Zaidan, 2012). Crowd-sourced annotation is sometimes cheaper than following a more traditional approach to hire few expert annotators (Snow et al., 2008), but generally, the costs increase with the difficulty of the task, either because more careful training is needed or more annotators need to be involved to obtain reliable aggregated scores.

This situation lead to the development of automatic annotation methods. *Weak supervision* uses noisy automated annotations to train models. The expectation is that they might be less accurate than supervised models, but still better than unsupervised learning (Ratner et al., 2017). Examples include the use of heuristics, keyword searches, or distant supervision from databases (Ratner et al., 2017; Rudra and Anand, 2020; Rao et al., 2021). A more recent approach to automatic data labeling is zero-shot classification (Radford et al., 2019). It relies on the information present in a pretrained language model to solve the task, either via textual entailment (Yin et al., 2019; Obamuyide and Vlachos, 2018; Plaza-del Arco et al., 2022), by mapping verbalizations of classes to outputs of autoregressive models (Shin et al., 2020, i.a.), or with instruction-tuned models (Zhang et al., 2023; Gupta et al., 2022; Ghosh et al., 2023, i.a.).

Recently, (Wadhwa et al., 2023) successfully used rating scales with LLM's to improve crowd-sourced annotations. Their goal was, however, not automatic annotations but improving existing annotations.

2.2 Annotating Continuous Values

Some NLP tasks require the prediction of continuous values, for instance rating emotion intensity (Mohammad and Bravo-Marquez, 2017). A typical operationalization is to ask annotators to choose a position on a rating scale, such as Likert scales (Likert, 1932). The exact position that humans chose does, however, depend on various subjective aspects, including preferences for particular intervals (Kiritchenko and Mohammad, 2017). This leads to inconsistencies between annotators. Annotations can also be inconsistent from a single annotator – after seeing more examples they might adjust their interpretation of a specific value range.

An alternative is to rate data-points via comparison such as Paired Comparisons (PC, Thurstone, 1927). PC ranks texts by comparing every text to every other text. This approach comes with the major drawback of a quadratic number of required annotator's decisions in the number of instances.

2.3 Best–Worst Scaling

Best–worst Scaling (BWS) addresses the issues of rating scales and paired comparisons (Louviere and Woodworth, 1991; Finn and Louviere, 1992). Annotators are provided an n-tuple (typically $n = 4$) of data-points and asked to choose the *best* and *worst* of the tuple, given the scale they are annotating. 4-tuples are efficient because by giving the *best* and *worst* ratings the annotator has effectively done five out of six possible pair-wise

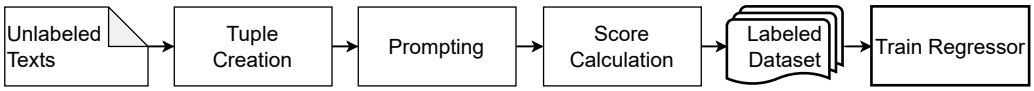

Figure 1: Workflow diagram of our method to use automated annotations for training a regression model.

comparisons. Kiritchenko and Mohammad (2017) showed that $1.5N$ to $2N$ annotations, where N is the number of instances, lead to reliable results. The final score $s(i)$ of an instance i is computed by $s(i) = \frac{\#\text{best}(i) - \#\text{worst}(i)}{\#\text{overall}(i)}$.

Kiritchenko and Mohammad (2017) found BWS produces more consistent annotations than RS, while also being efficient in the number of annotations required. They compared annotations from RS and BWS using split-half reliability (SHR). As qualitative values cannot be precisely known, one measure of their accuracy is reproducibility across multiple annotators. SHR evaluates reproducibility by splitting all annotations for each data-point randomly into two bins. Each bin is used to calculate the target label separately, and the two sets of scores are compared. This is repeated for multiple iterations and the correlation scores are averaged.

2.4 Emotion Intensity

Emotion analysis consists of various subtasks, including emotion categorization (Calvo and Mac Kim, 2013; Mohammad et al., 2018, i.a.), in which emotion labels from a predefined set are assigned. The labels commonly stem from psychological models of basic emotions (Plutchik, 2001). Another popular task in emotion analysis is affect prediction, where continuous values of valency and arousal are assigned (Posner et al., 2005).

A combination of these approaches in which intensities for a given emotion are to be predicted was first proposed with a shared task in 2017 (Mohammad and Bravo-Marquez, 2017). The Affect-in-Tweets Dataset is an extension of the original data (AIT, Mohammad and Kiritchenko, 2018).[1] They have been created via best–worst scaling with a setup in which annotators have been asked to select the most intense and least intense instance from a quadruple of tweets for a given emotion. The data set is partitioned into the four emotions joy, fear, anger, and sadness. An individual instance can appear in multiple of the data sets.

3 Methods

We now provide an overview of our automatic annotation method (§3.1), describe our prompting strategies (§3.2), and finally explain how the automatically created corpora are used to estimate a transformer-based regressor (§3.3).

3.1 Overview

Our method automates the annotations of a training set which we use to estimate a regressor. Figure 1 shows the workflow, discussed in the following.

Tuple Creation. In this step of the pipeline, we create the instances for annotation. Rating scales (RS) require single instances. For rating scales tuples (RS-T) we use 4-tuples to give the model the same context per prompt as BWS, where we also use 4-tuples. Paired comparisons (PC) require each text to be paired with every other text once. In BWS, nearly no pair appears in more than one tuple and all texts appear in nearly the same number of tuples. We follow the recommendation by Kiritchenko and Mohammad (2017) to use $1.5N$ to $2N$ tuples.

Prompting. The prompt tasks the LLM to output annotations for the given text tuple. Independent of the concrete prompting approach (RS, RS-T, PC, BWS), each prompt contains a role description, a task description, the texts, and formatting instructions. As the back-end, we mainly use GPT-3.5-turbo[2] and compare the best performing setup to GPT-3 and Llama2 (Radford et al., 2019; Touvron et al., 2023). We discuss the prompts in Section 3.2.

Score Calculation. For RS and RS-T, we directly use the output value as the score. For PC and BWS, we use the counting method (§2.3). All results are linearly normalized to $[0; 1]$.

3.2 Annotation

The prompt differs for each of the four annotation methods. We show all of them side-by-side in Table 1. Each prompt contains up to six parts: The *role* informs the model how we expect it to behave. For GPT-3.5, this is applied as a system level prompt separate from the main prompt. With models which do not utilize a system prompt, it is

Table 1: Prompts for Rating Scales, Rating Scales Tuples, Paired Comparisons, and Best–Worst Scaling. Variables are typeset in {curly brackets}. Unique text blocks are in the same color across a row. Rounding is only requested for decimal scales. Rating Scales and Rating Scales Tuples are identical except for the Texts section.

the first line of the prompt. The *task description* is similar to the instructions for humans. The *scale* is only used for RS and RS-T, and the scale in Table 1 is only an example. It is updated according to the actual rating scale that is used. The *format* explains the expected output based on the *texts* that are labeled so that the model can refer to them. The final element is an *example* for the expected output.

Rating Scales. For rating scales, which directly annotate individual texts, we do not need tuples. The scale, which we consider a parameter of this method, is included as part of the task description. When the scale includes decimals we instruct the model to round to the fourth digit.

Rating Scales Tuples. Comparison-based approaches have the advantage of showing the model more examples of text from the dataset per prompt. To mitigate this advantage we have the model rate four texts per prompt. Otherwise, this approach is identical to our rating scale approach.

Paired Comparisons. Paired Comparisons compare every text with every other text. We instruct the model to choose both the speaker with the *most* emotion and the *least* emotion. We use the terminology "speaker" to follow AIT's task description (Mohammad and Kiritchenko, 2018). We accept an output if it includes two distinct predictions.

Best–worst Scaling. Our setup of the BWS annotation process follows Kiritchenko and Mohammad (2017); Mohammad and Kiritchenko (2018). We use tuples of four texts, with no pair of texts appearing in more than one tuple. The tuples are annotated one at a time, though a single prompt is used to annotate both *most* and *least*. We accept an output if it includes two distinct predictions. We request an output for the same tuple multiple times until we receive an acceptable answer.[3]

3.3 Regressor

In principle, the output of a LLM can directly be used to label unseen instances at application time. Nevertheless, we consider it reasonable to train a regressor on top of the annotations for three reasons. Firstly, it makes the use of the annotations comparable to human annotations which are also the input to a model training. Secondly, it allows the smaller regressor to run locally and does not require a potentially expensive API to be called, that might also change in behaviour. Thirdly, for PC and BWS, annotating in a zero-shot learning setting at inference time would require combining the instance of interest in tuples. We fine-tune roberta-base (Liu et al., 2019) with a regression head with default parameters for 5 epochs.[4]

[3] In our experiments with GPT3.5 (200,000 tuple requests), few non-acceptable answers have been returned (388). The first repetition typically lead to an acceptable answer.

[4] https://huggingface.co/transformers/v3.0.2/model_doc/auto.html, we tested other epoch counts,

Emotion	Training	Dev	Test
Joy	1,616	290	1,105
Anger	1,701	388	1,002
Fear	2,252	389	986
Sadness	1,533	397	975
Total	7,102	1,464	4,068

Table 2: Details of the AIT dataset, of which the training set is made up of the EmoInt dataset.

4 Experiments

We perform experiments to compare the annotation methods on the emotion intensity prediction task, firstly to understand if BWS, PC, RS, or RS-T perform differently and secondly to understand their performance in comparison to human annotators. Finally, we perform additional experiments to understand the role of the tuple count, which can be flexibly adapted in automated annotations.

4.1 General Setup

Dataset. We use the Affect-in-Tweets Dataset (AIT). AIT has been manually annotated for the 2018 shared task *SemEval-2018 Task 1: Affect in Tweets* (Mohammad et al., 2018). It consists of tweets, manually annotated using BWS for emotion intensity scores for joy, sadness, anger, and fear. AIT is an extension of the Emotion-Intensity dataset (EmoInt) Mohammad and Bravo-Marquez (2017); its training set is composed of the entirety of EmoInt and its development and test sets are newly added. Table 2 shows the statistics.

In the BWS annotation, each tuple consists of four tweets. The target emotion for choosing the most and least emotion intensity is predefined. The total number of tuples created per emotion is $2N$ where N is the number of tweets to be annotated. Each tuple was annotated by 3–4 independent workers on the crowd-sourcing platform Crowdflower. The final scores are calculated as described in Section 2.3 and linearly scaled to $[0; 1]$.

Evaluation. AIT uses split half reliability (SHR) to evaluate its annotations for reproducibility. This approach is problematic for evaluating our method; we are not taking measurements from multiple people, we are taking multiple measurements from the same language model. Evaluating reproducibility is more a test of the model's consistency than it is a measure of distance from truth. Hence we compare the model's output to human-annotated scores.

We use a direct and an indirect, downstream evaluation: (1) in the direct evaluation we compare the AIT's training data gold annotations to the annotations from the LLM on the training data. This tells us how well the generative model is able to replicate manual annotations. (2) The indirect downstream evaluation is based on the trained regressor model that produces scores in a second step. Therefore, it is applied to the official test data set. We consider this evaluation to be more important as it replicates the actual use-case of such automatic annotations. We use Pearson's correlation.

4.2 RQ 1: Does the best–worst scaling annotation method perform better than rating scale-based annotations?

4.2.1 Experiment Settings Details

Generative Model. We use GPT-3.5-turbo via the AzureOpenAI API. The models are no different from those made available directly by OpenAI. However, AzureOpenAI has additional content filters which prevent prompts containing violence, bigotry, self-harm, or sexual content.[5] In the case that such filter prevents an output, we rerun the prompt-tuple in OpenAI's API. Overall, we paid 125.12 Euro for our experiments.

Best–worst Scaling. We use the exact same tuple sets as used in the original manual annotation of AIT, kindly provided to us by the authors.

Rating Scales. We vary the scale in the prompting method by granularity and description. We refer to an instruction that does not contain descriptions as "Bare" (B), instructions that only contain descriptions at the maximal and minimal level as "Outlined" (OL), and with complete descriptions as "Descriptive" (D)[6]. We experiment with intervals of 0.0–1.0 (X-1), 0–10 (X-10) and 0–4 (X-4). The latter corresponds to the rating scale used by (Kiritchenko and Mohammad, 2017) to compare BWS and rating scale annotations done by humans, clipped to positive values.

Rating Scales Tuples. For each prompt we ask the model to rate four texts. Each text appears in only one prompt. Otherwise, the approach is identical to our rating scales approach.

Paired Comparisons. In the PC setup, we are not able to create the entirety of N^2 comparisons for reasons of resource constraints. We use a subset of

including early stopping, in preliminary experiments but did not find the results to differ substantially.

Table 4: Indirect downstream comparison via training a RoBERTa model on the annotated data from various annotation approaches: Rating scales (RS), Rating scales tuples RS-T), Best–worst Scaling (BWS), and Paired Comparisons (PC).

200 randomly selected texts per emotion to test if vastly increasing the number of comparisons per text improves annotation quality. In this case, direct annotation comparison only consider these 200 texts. When training a regressor, we also only use these 200 annotated texts. In that latter case, the evaluation is performed, as in all other regressor evaluations, on the independent test corpus.

4.2.2 Results

Table 3 shows direct evaluation results and Table 4 shows indirect downstream results.[7]

Direct Comparison. For the direct comparison of the annotated data, we consider Table 3. We see results for different setups of the RS, the RS-T, the BWS results and the PC. The results vary dramatically between different rating scales. The best performance is achieved with the D-10 model, which could be considered unsurprising as it provides the most detail to the LLM. Removing part or all of the descriptions leads to a performance drop; the values alone appear to not be interpretable. Interestingly, changing only the scale and keeping the descriptions (B-1/OL-1 vs. B-10/OL-10) also leads to a substantial performance decrease. Apparently, floating numbers are less informative to the model than natural numbers.

The strong difference between rating scales does not hold with RS-T. D-10 still performs the best. B-10 shows the best results for anger, fear and sadness, but its poor performance on joy drags its mean score below D-10.

On all four emotions, the BWS scores are higher than any RS or RS-T annotation. Joy and sadness show the most similar scores to the original annotations. Similar to performance differences of human annotators, anger appears to be most challenging.

The PC performance scores are on a similar level as BWS, but lower. This comes, however, at a substantially higher cost: PC uses roughly six times the annotations as BWS for only 200 texts. Note that this result is achieved on a different data subset.

BWS creates the annotations with the most similar performance scores to the original annotations. However, one might argue that this is not surprising given the alignment of the annotation method with the original corpus creation approach. Therefore, it is important to consider the indirect comparison.

Indirect Downstream Comparison. The indirect evaluation results, through training regressors, are shown in Table 4. The results labeled with "Original" stem from the model trained on the original human data annotations.

The RoBERTA models trained on human annotations perform well. The results are en par with the winning team's approach in the AIT-2018 shared task (Duppada et al., 2018). BWS outperforms RS, RS-T, and PC, but not the models trained on the original data. The drop in performance to training on the original data is lower for joy and sadness than for anger and fear, with the latter performing the worst. These observations are in line with Mohammad et al. (2018).

The RS and RS-T performances are similar to their direct evaluation counterparts, though the gap

[7]The annotations can be found at https://www.uni-bamberg.de/en/nlproc/resources/autobws/

in performance between emotions is smaller. Anger is not the most challenging emotion and nearly performs the same as BWS. The paired comparisons perform worse, due to the smaller training set.

Summary. BWS performs the best for both evaluation setups. It does use twice the annotations as rating scales ($2N$ vs. N), however the increase in performance is worth the cost, given that all annotations are automated. Paired comparisons are too inefficient to be considered a viable alternative.

4.3 RQ 2: Can automated annotations be as good as human annotations?

In the previous experiment, we kept the annotation setup close to the original setup of BWS annotations to understand the impact of the LLM use. In this section, we will exploit the advantages of automatic annotations to see if scaling it up can improve the predictions to be closer to human performance.

4.3.1 Experiment Settings Details

For the AIT annotations each tuple was annotated by three annotators. However, running tuple sets through GPT three times is not equivalent to annotating with three annotators; while the temperature could be raised to increase randomness in the model's output, we do not equate this to the new perspectives, experiences, intuitions, and opinions an additional annotator would provide. Hence we need another method of increasing our total number of annotations. The quality of BWS annotations can be increased by either increasing the number of annotators or the number of tuples (Kiritchenko and Mohammad, 2017). Therefore we increase the number of tuples annotated. We start with $6N$ tuples to match the number of annotations done by AIT, which uses $2N$ unique tuples and each tuple is annotated by 3 annotators, giving a total $6N$ annotations. Then we explore half and double that number. We only run each prompt-tuple once, but we increase the number of unique tuples:

- $3N$: 50% more unique tuples, but half the total number of annotations.
- $6N$: 200% more unique tuples with the same number of total annotations.
- $12N$: 600% more unique tuples and twice the number of total annotations.

The sets of tuples used for this experiment are randomly created using the same design as AIT, but they do not purposefully contain the original tuples.

	Direct Eval.				Ind. Downstream Eval.

Table 5: Evaluation with higher tuple counts.

4.3.2 Results

We show all results in Table 5, for both a direct comparison of the annotation output and the performance of a trained RoBERTA-based regressor. We see that increasing the tuple counts does lead to an improvement for both evaluations, with 12N performing best for every emotion except fear. This follows the findings by Kiritchenko and Mohammad (2017) that increasing total annotation counts improve annotation quality. Regarding the indirect evaluation with a trained model, we also see an increase of performance for higher tuple counts. With 2N, we see an average performance of 73.5 in contrast to 78.3 for humans. These gaps shrink with larger tuple counts, but not too dramatically – the best result is achieved with $12N$ tuples, leading to 74.8 correlation.

5 Further Analyses

5.1 Generative Model Comparison

We performed all experiments with GPT3.5, but the results might not carry over to other models, and they might not remain replicable if the API, the model, or the licenses change. We therefore compare the results to GPT-3-davinci (Radford et al., 2019) and Llama2 (Touvron et al., 2023) with 13B parameters. We use the same evaluation setup as above, with the original $2N$ tuples. Table 6 shows the results. GPT3.5 outperforms GPT3 by 14pp and Llama2 by 27pp. There is a notable drop in performance for fear (24pp,36pp). GPT-3 performs decently on joy and sadness (7pp/8pp drop).

These results translate closely to the indirect comparison. GPT-3's regressions' performance lines up with its direct comparison results. Llama2 does however perform better than in the direct comparison. Joy and fear all close the gap between their Llama2 and GPT-3 performances.

Llama2 does not perform well in our experiments. The results for joy and sadness are accept-

	Not giving a fuck is better than revenge.	3	2 G

Table 7: Example with the highest difference between manual and automatic annotation, and the associated tuples. The 1/2/3 refer to the AIT annotator IDs and G to the annotator GPT3.5.

able, but the results for anger and fear are even less than the paired comparisons trained on only 200 texts. The score for joy of 68.0 is especially surprising given the low score in the direct evaluation. This highlights that lower correlation to the original annotations does not guarantee worse performance as a training set. The exact cause of this is worth further investigations. It is noteworthy that Llama2 provided further challenges, in addition to its lower performance. Nearly 10% of all prompts sent to the model returned non-acceptable answers.

5.2 Error Analysis

To provide an intuition why annotations differ, we manually inspect the top 10 instances per emotion that have the largest absolute difference in emotion intensity annotation between the human and the automatic annotation. We show these instances in the Appendix, Table 9.

Out of the 40 texts, 21 explicitly mention the target emotion, while 19 either only refer implicitly to the emotion and could be considered neutral, or do not describe the emotion at all. In the cases in which the emotion is explicitly mentioned, GPT-3.5 tends to assign a higher score than the human annotators – in such cases, it does more often rate the instance as the most intense (14/21 cases). In cases in which one might argue that the text is in fact comparably neutral, GPT assigns lower values than humans (13/19 cases). In summary, our error analysis shows that GPT has a tendency to make consistent decisions for explicitly mentioned emotions, but humans might have a tendency to interpret the text, unsurprisingly, more carefully regarding implicit information.

For reasons of space constraints in this paper, we cannot show all tuples for all these instances. We do, however, believe that a more in-depth error analysis requires such analysis. We resort to showing the one example that has the highest difference in prediction for the emotion anger (Table 7). This instance ("Not giving a fuck is better than revenge") contains a strong metaphorical negative expression. One might however argue, that it does not in fact express anger – it offers some freedom for interpretation. In the first tuple all human annotators agree regarding a different instance exhibiting most anger. GPT3.5 assigns it the lowest anger. The picture is less clear in the second tuple. Annotators are more distributed across instances. This analysis suggests that more combinations with more varied tuples can lead to more reliable results. In this instance, the error decreases from .56 to .47 when increasing the tuple count to $12N$.

5.3 Task Validation on Another Corpus

Setup. To validate our method's performance on emotion intensity prediction we apply our method to a second dataset, *SemEval-2007 Task 14: Affective Text* dataset (Strapparava and Mihalcea, 2007), which is comprised of 1250 news headlines annotated for six emotions: joy, anger, fear, sadness, disgust, and surprise. The annotations were done by six annotators using rating scales of 0–100, with each text annotated for all emotions at once. The inter-annotator agreement score was found by taking average Pearson's correlation scores between annotators (shown in Table 8 on the right).

We test two RS-T scales to compare with BWS

$2N$: D-10, our previously best performing scale, and OL-100, adjusted to from OL-10 to match the dataset's label range. The experiment setup and prompts are the same as our previous experiments. We refer to this setup as *Basic Approach*. To further test if an annotation setup that is closer to the original annotation environment further improves the result; we have each prompt annotate all six emotions at once in an adapted setup (*Adapted Appr.*).

Results. Table 8 shows the results. D-10 outperforms OL-100 on every emotion and performs better than BWS on anger, fear, and disgust in the basic approach. BWS does better for joy, sadness, and surprise, giving BWS a better overall performance. RS-T and BWS annotations score higher than the average human annotator for all emotions except surprise. In the adapted approach, BWS scores do not change substantially, but RS-T results improve. D-10 performs better than BWS overall and OL-100 performs en par with BWS.

Interpretation. These results validate the method's ability to do emotion intensity prediction, however they challenge our initial finding that BWS is the better approach. Our interpretation is that the similarity between the automatic annotation setup and the original setup matter – the label distributions substantially differ: Where rating scales allow for all annotations to be skewed towards specific areas of the scale, BWS's comparative nature forces scores towards a normal distribution. While this can be a benefit when annotating fresh data, it limits BWS's ability to replicate rating scale annotations. SemEval-2007's original annotations are all skewed towards the low end of the scale. Our RS-T annotations are also skewed, but the BWS annotations are normally distributed.

We take this as an indicator that BWS is a better choice for annotating novel corpora from scratch automatically. Kiritchenko and Mohammad (2017) show that BWS produces more reliable annotations than rating scales. So if our method can replicate both BWS and rating scale annotations to a similar degree, then it follows that we should choose the approach which performs better overall. Furthermore, when simulating existing data, the gap in performance between BWS and RS-T is much larger for the BWS-native dataset than for the RS-native dataset.

	Basic Approach			Adapted Approach			Original
	RS-T		BWS	RS-T		BWS	RS
Emo.	B-100	D-10	$2N$	B-100	D-10	$2N$	B-100
Joy	47.7	66.8	70.4	71.2	76.2	70.1	59.9
Ang.	44.3	60.1	59.6	57.1	61.0	60.2	49.6
Fear	65.1	68.4	65.8	66.2	72.9	67.5	63.8
Sad.	66.5	71.5	74.2	73.4	77.3	73.0	68.2
Dis.	33.1	47.8	47.5	51.4	52.7	49.4	44.5
Sur.	18.5	15.6	32.3	21.5	23.8	24.6	36.1
Avg.	57.2	67.5	68.4	68.0	72.9	68.5	53.7

Table 8: Results for applying our method to SemEval-2007 Task 14 dataset. Basic approach uses the same prompts as previous experiments. Adapted approach rates all emotions in a single prompt. Original shows the average inter-annotator agreement score of the 6 human annotators.

6 Conclusion & Future Work

We proposed to automate annotations of text data with continuous labels with BWS, which outperforms rating scales and paired comparisons in the case of emotion intensity predictions, when the original annotations were also annotated using BWS. The predictions from a regression model, fine-tuned on automated annotations, perform nearly en par with the models fine-tuned on the original human annotations. We showed that we can improve the annotation quality by increasing the total number of tuples. In general, we conclude that BWS is the better approach to annotate novel data sets for emotion intensity regression.

The results of our experiments are encouraging for emotion intensity regression. We presume that these findings carry over to other regression tasks, but this still needs to be validated. Candidates for other tasks would be the BWS-labeled toxicity data set Ruddit (Hada et al., 2021) or the Affective Norms for English Words dataset (Bradley and Lang, 1999). Word similarity assessment tasks could be an interesting case for evaluation as well (Antoniak and Mimno, 2018).

Finally, it is important to study more open-source generative models, instead of relying on pay-locked and black-box models.

Acknowledgements

We thank Saif Mohammad for helping us and providing us the original tuples of the data set we used. This project is partially supported by the project ITEM (User's Choice of Images and Text to Express Emotions in Twitter and Reddit, funded by

the German Research Foundation, KL 2869/11-1). We thank the reviewers and the action editor at ACL Rolling Review for their helpful feedback.

7 Limitations

Before our method can be a reliable alternative to manual annotations it must be tested on more NLP tasks. While the results are promising on predicting emotion intensity, several possible shortcomings come to mind. Without manually annotated data to compare to, it is difficult to judge the quality of the automated annotations. Especially for novel tasks, it is hard to judge if mediocre performance of the regression model is evidence of poor quality annotations or of the task being difficult to model.

The results we present on the task of predicting emotion intensity rely on the assumption that none of the models used were pretrained on the AIT dataset. The poor results from prompts using rating scales leads us to believe the model does not have prior knowledge of the dataset. This highlights the problem with using GPT-3 as it is a black-box system which inhibits interpretability.

At the time of our experimentation, the token limit of generative large language models posed a challenge due to the need for four texts to be apart of each prompt. With the recent (and fast) development of improved models, this constitutes a limitation of our research. Future research may look into annotating longer texts.

Our method relies on the information embedded in an LLM to accurately compare target texts. If the task is too specialized than the LLM might require fine-tuning to perform adequately. This defeats the purpose of the method as it is intended to circumvent the need for training data. Furthermore, the method is not as accessible as working with non-generative LLMs such as RoBERTa. The success found in this paper relied on GPT models which are not open source, making them less transparent and more unreliable.

8 Ethical Considerations

Our method does not contribute a new data set or introduce a novel task. Therefore, it does not add any additional risks from these perspectives to the already existing research landscape. All data that we use, we use for their originally intended case, namely the creation of emotion intensity prediction models.

However, it is noteworthy that previous research showed that emotion analysis systems are biased for various reasons (Kiritchenko and Mohammad, 2018). The use of language models for automatic creation might lead to different biases and this requires further research.

The core idea behind our method is to reduce the need for manual annotations. Ideally, researchers would only need manual annotations for their development and test sets, reducing manual annotations by roughly 80%. While this is great for research projects, this can reduce the amount of work available for people who depend on annotation-based jobs.

Though, the reduction could be attractive for tasks which require annotators to read emotionally or mentally damaging texts, such as hate speech or toxicity. Abusive content detection systems are needed more in online spaces but the creation of such systems requires annotators to spend time interacting with content which can cause undue emotional trauma (Vidgen et al., 2019; Kiritchenko and Nejadgholi, 2020).

Abstract

Recent advancements in GPT-4V have displayed remarkable multi-modal capabilities in processing image inputs and following open-ended instructions. Despite these advancements, there is considerable scope for enhancing open-source multi-modal LLMs, especially in terms of multi-modal understanding accuracy and instruction-following proficiency. In this paper, we conduct a comprehensive study on training GPT4-style models. We introduce **Lynx**, a multi-modal LLM developed through a series of controlled experiments comparing various model variants. This process allowed us to identify and implement an optimal training strategy tailored for multi-modal LLMs. In addition to our model development, we propose a plug-and-play technique designed to augment the instruction-following capabilities of multi-modal LLMs. We have validated the performance of Lynx on multiple benchmarks. Results demonstrate that Lynx not only achieves strong image understanding accuracy but also excels in instruction-following tasks, paving the path for ongoing enhancements in multi-modal LLMs.

1 Introduction

Large Language Models (LLMs) (Brown et al., 2020; Hoffmann et al., 2022; Chung et al., 2022; Ouyang et al., 2022; Scao et al., 2022; Iyer et al., 2022; Touvron et al., 2023) have progressed rapidly in recent years and achieved impressive performance in language understanding and generalization. With instruction fine-tuning (Ouyang et al., 2022; Chung et al., 2022; Wang et al., 2022; Chiang et al., 2023; Xu et al., 2023; Peng et al., 2023), LLMs can be further improved to follow open-ended instructions from non-expert users and serve as dialog-based assistants in our daily lives. Leveraging powerful LLMs, recent studies have examined methods for adapting LLMs to multimodal inputs (e.g., images (Alayrac et al., 2022; Zhu et al., 2023; Dai et al., 2023), videos (Li et al., 2023a; Chen et al., 2023; Zhao et al., 2023), and audio (Huang et al., 2023a)) and outputs (e.g., vision tasks (Wang et al., 2023), and robotic manipulation skills (Jin et al., 2023; Driess et al., 2023; Jiang et al., 2022)). Notably, GPT-4V (OpenAI, 2023b) has astounded the world with its impressively versatile yet practical capabilities, such as generating descriptions, stories, poetry, advertisements, and codes given images, which were rarely observed in previous vision language models (Li et al., 2021; Bao et al., 2022; Zeng et al., 2021, 2022).

Figure 1: Illustration of hallucination and diminished instruction-following capabilities generated from open-source multi-modal LLMs.

However, it still remains a mystery that: *How does GPT-4V obtain its impressive smartness?* GPT-4V can analyze and generate descriptions for various types of images, including diagrams, text in

[*]Equal contribution.

images, maps, screenshots of software interfaces, illustrations, comics, and medical imagery. Such capabilities likely depend on extensive annotated data and perhaps the integration of tools like OCR. This presents a substantial challenge for open-source multi-modal LLMs which are end-to-end models trained on open-source datasets with lower-quality annotations.

Despite these challenges, we have observed that current multi-modal language models usually suffer from hallucinations, such as generation of facts unrelated to the image inputs, and degraded instruction-following abilities compared to their text-only counterparts, as shown in Figure 1. Though actively investigated recently, the open-source multi-modal LLMs are usually different in training data, training recipes, prompts, and evaluation benchmarks, which makes it challenging to identify which factors are crucial in achieving a strong baseline model.

In this paper, we conduct a comprehensive study on training GPT4-style models. By implementing multiple model variants under controlled settings and conducting extensive experiments to draw reliable conclusions both quantitatively and qualitatively, our findings can be summarized as follows:

- Data quality is more important than quantity. Our experiments with COYO700M (Byeon et al., 2022), DataComp1B (Gadre et al., 2023), and BlipCapFilt (Li et al., 2022) demonstrate that pre-training on COYO700M and DataComp1B does not yield improved model performance. Furthermore, it is crucial to avoid utilizing low-quality annotations during the instruction fine-tuning phase.

- Diversified prompts are essential for enhancing the model's ability to follow instructions. We incorporate a range of open-source multi-modal datasets, transforming them into an instruction-following format using manually crafted prompts, supplemented by additional prompts generated by GPT-4, producing 500 prompts for over 50 tasks in total.

- Language instruction fine-tuning plays a significant role in boosting the instruction-following capabilities of multi-modal models. Integrating NLP instruction data during training enables the model to handle a broader range of tasks, compensating for the typical limitations of open-source multi-modal datasets, which are predominantly focused on image captioning and visual reasoning. Furthermore, our results also indicate that multi-modal models based on Vicuna-7B, which have undergone instruction fine-tuning, generally outperform those based on LLaMA-7B.

Through our study, we present **Lynx**, a multi-modal LLM with a three-stage training recipe. The first stage focuses on aligning vision and language, the second stage enhances the resolution of image inputs, and the final stage concentrates on instruction fine-tuning. At each stage, a different set of model parameters is trained using a varied mixture of image-text pairs, multi-modal datasets, and NLP instruction data, in order to fully exploit training data.

Furthermore, we propose a plug-and-play method aimed at boosting the instruction-following capabilities of multi-modal LLMs. Our observations indicate that a more extended dialogue history can effectively unlock and amplify the instruction-following abilities inherent in LLMs. We recognize that most multi-modal tasks can be broken down into two steps: describing the image in details, and subsequently utilizing the capabilities of LLMs. Consequently, during evaluation, we initiate the task by prompting the model to describe the image. This strategy consistently results in improved performance across a variety of multi-modal instruction-following tasks, demonstrating the efficacy of our proposed method.

Experimental results show that Lynx is a strong baseline for multi-modal LLMs, achieving state-of-art performance. [1] Specifically, our model excels in MME's perception (Fu et al., 2023), demonstrating superior image understanding accuracy, and shows impressive results in VisIT-bench (Bitton et al., 2023), which evaluates multi-modal instruction-following abilities. We also adopt the OwlEval test set proposed by mPLUG-owl (Ye et al., 2023) for human evaluation, with Lynx achieving state-of-art multi-modal instruction-following results.

2 Lynx

Lynx is a large language model that can take images and videos as inputs. In this section, we will introduce our Lynx in detail, including the architecture (2.1) and three-stage training recipe(2.2).

[1] We compared with open-sourced multi-modal LLMs of comparable model sizes available as of August 31, 2023, for all evaluations.

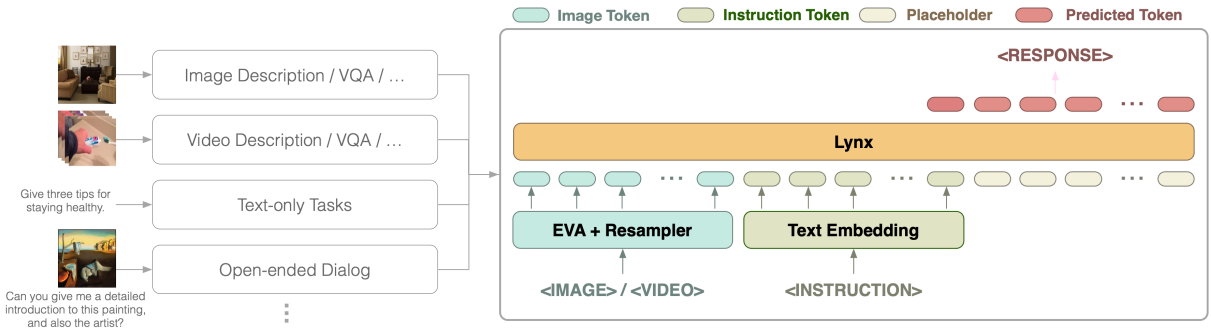

Figure 2: Architecture of Lynx. The vision tokens are concatenated with the text tokens to generate text outputs auto-regressively.

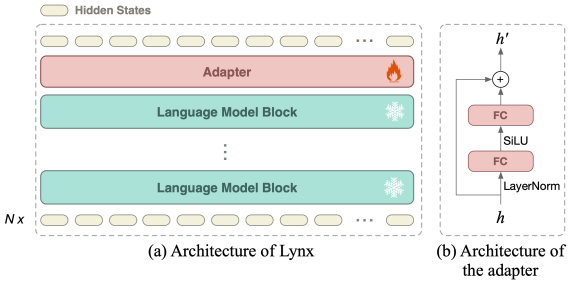
2.1 Model Architecture



Overview Our model takes vision and language as inputs to generate text responses following the input instructions. The overall structure of our model is shown in Figure 2. Concretely, vision inputs are first processed by a vision encoder to get a sequence of vision tokens $\mathbf{w}_v$. After that, $\mathbf{w}_v$ are concatenated with instruction tokens $\mathbf{w}_l$ as the input of LLMs for multi-modal tasks. To generate responses, the left-to-right causal decoder auto-regressively predicts the next token by taking all previous tokens as inputs until encountering the <EOS>.

Adapter The trainable adapters are inserted into the LLMs after every M blocks. In our experiments, $M = 2$. As shown in Figure 3(b), the adapter linearly projects each token into a lower-dimensional space and then re-projects it back. Concretely, in Lynx, the hidden state for each token is 4096-d. The adapter first imposes layer normalization (Ba et al., 2016) onto the hidden states. Then a linear layer is used to downsample the dimension of each token state from 4096 to 2048, based on which SiLU (Elfwing et al., 2018) is set as the non-linear activation function, which keeps consistent with LLaMA (Touvron et al., 2023). Finally, the other linear layer is used to re-map the 2048-d hidden state back to 4096-d.

Vision Encoder To extract vision features of images and video frames, we apply EVA-1B (Fang et al., 2023; Sun et al., 2023) as our vision encoder $\phi_v(x)$. It maps an image to a sequence of visual tokens. The downsample rate is 14, meaning that an image with resolution $H \times W$ will be represented by a sequence of $\frac{H}{14} \times \frac{W}{14}$ tokens. To improve the efficiency of training and inference, we adapt the resampler Φ mechanism (Jaegle et al., 2021; Alayrac et al., 2022) that reduces the dimensions of vision inputs by injecting the long vision token sequence into a short and learnable query sequence $\mathbf{w}_v^q$:

$$\mathbf{w}_v = \Phi(\phi_v(x), \mathbf{w}_v^q) \quad (1)$$

where x is the input image, $\phi_v(x)$ is the raw tokens directly given by the vision encoder, $\mathbf{w}_v$ is the condensed token sequence consisting of 32 tokens regardless of the number of raw tokens from the vision encoder.

(a) Architecture of Lynx (b) Architecture of the adapter

Figure 3: Architecture of Lynx. (a) Overall; (b) Adapter.

2.2 Training Recipe

We propose a three-stage training recipe to enhance image understanding accuracy and instruction-following abilities. Specifically, we first train the model to align vision inputs to the pre-trained LLM, and then we enhance the model by increasing the resolution of visual inputs. Last, we conduct instruction fine-tuning with carefully selected training datasets. Our model is trained on a total of ∼14B tokens during the pretraining and resolution enhancement stage, ∼3B tokens during the instruction-finetuning stage, all phases employing causal prediction loss.

Pretraining During pretraining, we freeze the vision encoder and language model and train the resampler and the inserted adapters for 100k steps

using a batch size of 1536. The learning rate is set to 0.0001 (details about hyper-parameters can be found in Appendix Table D.2). To accelerate pre-training, the image resolution is set to 224x224. To establish alignment between visual features and the language model, we utilize more than 120M image-text pairs, mainly consist of BlipCapFilt 115M (Li et al., 2022), CC12M (Changpinyo et al., 2021), CC3M (Sharma et al., 2018), and SBU (Ordonez et al., 2011). Additionally, we also utilize public multi-modal downstream tasks during this phase. We include three predominant tasks, image captioning, visual question answering, and image classification. Details of the datasets we adopted and their mixing percentage are listed in Appendix Table 12.

Resolution Enhancement Training on low-resolution images is insufficient for certain downstream tasks, such as table reading and OCR. Therefore, after 100k steps of pretraining at low resolution, we increase the input resolution to 420×420 and continue training for an additional 10k steps. During this stage, the batch size is reduced to 448, and the learning rate is adjusted to 0.00001. In this phrase, we train the vision encoder together with the resampler and the inserted adapters, adapting the model to higher resolution inputs. Moreover, we adjust the training datasets by excluding large-scale noise image-text pairs and including new multi-modal downstream tasks that requires high-resolution image inputs, such as table reading and OCR.

Instruction Fintuning In this phase, we only train the resampler and the inserted adapters, same as in the pre-training stage. The instruction finetuning process consists of 20k training iterations with a batch size of 480 and a learning rate of 0.00002. Our finetuning datasets consists of text-only, image-text, and video-text tasks for complex multi-modal reasoning and instruction following, which mainly belongs to 5 categories: text-only instruction-following task, image/video visual question answering, image/video captioning, classification, and image-conditioned dialog. To finetune our model with diversified instructions, we provide appropriate instructions for each of these public datasets (see Appendix Table 13 for details). Specifically, we manually labeled at least 3 different prompts for each of these tasks, and then invoke GPT4 to automatically generate more based on the following "meta prompt", i.e., the prompt used to generate prompts for different tasks:

Here are some instructions that define a visual-language task. Continue to write 15 instructions with the same meaning: 1) PROMPT1; 2) PROMPT2; 3) PROMPT3;

Besides, we also collect some available public (visual-)text instruction data (also listed in Appendix Table 12) to further improve the ability of our model to follow open-ended instructions, including the instruction data used in FlanT5 (Chung et al., 2022), Alpaca (Wang et al., 2022), MiniGPT4 (Zhu et al., 2023), LLAVA (Liu et al., 2023a), and Baize (Xu et al., 2023).

We observe that different combinations of the instruction data have a crucial influence on the final performance. Empirically, we finally impose the weighting strategy presented in Appendix Table 12.

2.3 Inference

During the inference, we employ the nucleus sampling decoding method together with the beam search strategy. Detailed hyper-parameters for the generation process are presented in Appendix Table 9.

Moreover, we propose a plug-and-play method to improve instruction-following capabilities of multi-modal LLMs. We observe that most multi-modal tasks can be broken down into two steps: describing the image in details, and subsequently utilizing the inherent capabilities of LLMs. Therefore, we propose to *initiate a task by prompting the model to describe the image first during evaluation*. By doing so, we effectively unlock and amplify the instruction-following abilities inherent in multi-modal LLMs with a more extended dialogue history.

3 Experiment

In this section, we aim to answer the following questions by empirical studies:

a) What advantages does our Lynx offer in comparison to existing models? (Section 3.1)

b) What are the key factors in training a high-performance GPT4-style model? (Section 3.2)

c) How does our proposed plug-and-play method enhance the instruction-following capabilities of the model? (Section 3.2)

3.1 Quantitative Experiments

The evaluation of multi-modal LLMs is essentially different from typical visual-language methods. The primary challenge when evaluating a GPT4-

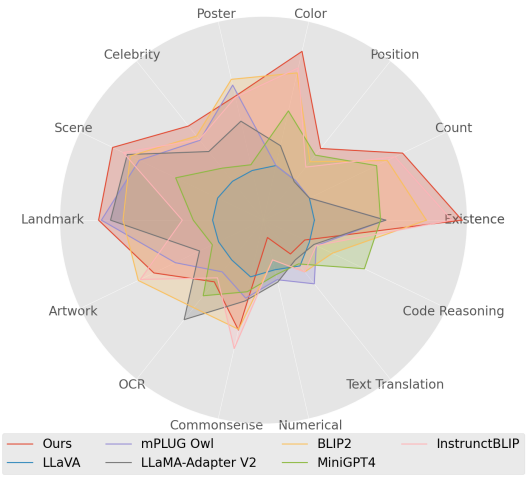


Figure 4: Comparison on MME benchmark.

style model is balancing multi-modal understanding accuracy and instruction-following abilities. For a thorough evaluation of both aspects, we adopt four protocols for quantitative evaluation. *The Open-VQA and MME benchmarks primarily assess the precision of visual comprehension, whereas the VisIT-Bench and OwlEval benchmarks evaluate instruction-following capabilities.*

Open-VQA benchmark We collect an Open-ended Visual Question Answering (Open-VQA) test set, including questions on objects, OCR, counting, reasoning, action recognition, chronological ordering, and more. Different from standard VQA (Antol et al., 2015; Zhang et al., 2016), the ground-truth answer in Open-VQA is open-ended. To evaluate the performance on Open-VQA, we prompt GPT4 to make it a discriminator, yielding a 95% agreement with human evaluation, see Appendix B for details. From the results of Table 1 and 2, we can conclude that our model has achieved the best performance both in the image and video understanding tasks. Notably, InstructBLIP (Dai et al., 2023) also achieves high performance in most cases, even better than our model in OCR, color recognition, and action recognition tasks. However, we observe that it always outputs one word answer as shown in Appendix Figure 6 and 7, which is less preferred by most of the users (see Table 4). We also showcase some of the examples in Appendix Figure 10. More cases including video VQA examples can be found Figure 10 and 11 in the Appendix. We can see that our model can give the correct answer in most cases as well as a concise reason that supports the answer.

MME benchmark We further compare Lynx with existing open-source models on the MME benchmark (Fu et al., 2023). Instruction-answer pairs for the MME benchmark are constructed manually, covering the examination of perception and cognition abilities. These instructions are deliberately succinct, facilitating intuitive and convenient quantitative analysis, as opposed to employing GPT models or manual scoring methods. Results are shown in Figure 4 and Appendix D.4. We can see that our model is a state-of-the-art model in 7 out of 14 subtasks, especially for the perception tasks including color, celebrity, scene, landmark, position, count, and existence. Yet, from the figure, we can also see that our model seems not to perform well on code reasoning, text translation, and numerical. This deficiency may be attributed to the absence of text translation, coding reasoning, and numerical tasks in our training datasets. Moreover, each of these three tasks only contains 20 examples, which may lead to high variance in the evaluation of different checkpoints.

VisIT benchmark We further conduct evaluation on the VisIT-Bench (Bitton et al., 2023) Single Images benchmark, a benchmark for evaluation of the instruction-following multi-modal LLMs. This benchmark comprises 592 test queries across varied domains, including art, object recognition, spatial understanding, and chemical analysis, etc. Each query is paired with a human-generated, instruction-based caption, enabling automated evaluation against text-only LLMs, and providing a standard answer for reference. The ELO-based results are presented in Table 3, this approach uses an GPT-4 evaluator to compare two models with an instruction and an instruction-conditioned caption. Our model ranks third, underperforming only LLava(13B) and LLava-a1(13B), surpassing counterparts including mPlug-Owl (Ye et al., 2023), LlamaAdapter-v2 (Gao et al., 2023a), InstructBLIP (Dai et al., 2023), Otter (Li et al., 2023a), etc, demonstrating the best performance among models with a comparable parameter scale (i.e. 7B).

OwlEval benchmark We adopt the OwlEval test set proposed by mPLUG-owl (Ye et al., 2023) to manually assess the text generation ability given images. Though OwlEval is a tiny set containing only 82 questions based on 50 images, it covers a diverse range of tasks such as generating descriptions, stories, poems, advertisements, codes, and other sophisticated yet practical analyses of

given images. From the human evaluation results in Table 4, we can see that our model has the best instruction-following performance while keeping high performance on the Open-VQA benchmark. BLIP2 (Li et al., 2023b) and InstructBLIP (Dai et al., 2023), though achieved high performance on the Open-VQA benchmark, are not preferred by human users due to their extremely short outputs, i.e., in most cases, they only output one word or phrase as the answer without any explanation. In contrast, MiniGPT4 (Zhu et al., 2023) and mPLUG-Owl (Ye et al., 2023) keep more instruction-following abilities. Hence, they are preferred over the BLIP models, though they may make more factual errors.

	InstructBLIP	BLIP2	MiniGPT-4	mPLUG-owl	Ours
scores	2.04	2.34	3.17	3.59	**4.13**

Table 4: Comparison of human-evaluation performance on OwlEval. Scores are averaged over the number of questions.

We show more results on the OwlEval in Appendix Figure 7.

Overall, if a model has lower accuracy on the Open-VQA and MME benchmark, it tends to make factual errors. However, previous methods with higher performance on these two benchmarks usually tend to lose instruction-following abilities, e.g., always generating short answers, leading to inferior performance on OwlEval and VisIT-Bench. We attribute it to the under-training or over-training on visual-language tasks. Specifically, existing training data from visual-language tasks predominantly have short outputs. Though, by training on these data the model learns vision language alignments, it loses the instruction-following abilities inherited from the large language model. According to the experimental results, we can see that the multi-stage training recipe of Lynx contribute to accurate image understanding and enhanced instruction-following abilities.

3.2 Ablation Study

We conduct an in-depth ablation study to investigate the impact of different components or training recipes on multi-modal understanding and instruction-following performances.

Impact of Training Data We investigate the impact of data quantity and quality by training our model with or without the large-scale yet noisy image-text pairs (COYO700M (Byeon et al., 2022)

	Open-VQA image	Open-VQA video	OwlEval (win/all)
w/ LLaMA	70.86	60.81	42/82
w/o diverse prompts	75.50	59.46	18/82
w/ large-scale noisy data	72.85	60.14	38/82
w/o high-resolution	73.51	62.16	-
Ours	**76.16**	**66.22**	-

Table 5: Comparison of ablation models on the Open-VQA benchmark(see Appendix Table 7 for details) for evaluating multi-modal understanding accuracy, and on the OwlEval benchmark for assessing instruction-following abilities. The 'win/all' metric indicates that, out of all 82 cases in the OwlEval benchmark, this ablation model outperforms in these instances.

and DataComp1B (Gadre et al., 2023)). During our experiments, we find training data in both pre-training and finetuning largely influence the model performance. Different from traditional visual-language pretraining (Radford et al., 2021), we find that multi-modal LLMs do not benefit from large-scale but noisy image-text pairs because many of the texts in such datasets are not fluent or natural language expressions. For the generative pre-training in our model, they largely damage the language generation ability as shown in Appendix Figure 9(b). As a result, pretraining on such large-scale datasets achieves no better results than only training on a much smaller but cleaner dataset as evaluated by the human users as shown in Table 5.

Impact of Diversified Prompts It has been proved to be important to train LLMs on instruction data so as to make them follow instructions correctly (Chung et al., 2022; Ouyang et al., 2022). Therefore, we ablate our model with diversified prompts written by both users and GPT4. The results in Table 5 show that our prompts help to balance different abilities. Moreover, we also find that by using diversified prompts, our model can follow the open-ended instructions better than the ones trained without these prompts (Appendix Table 13). This observation accords with the text-only models. The human evaluation results in Table 5 also accord with our observations.

LLaMA vs. Vicuna As shown in Table 5, in the aspect of multi-modal understanding accuracy, Lynx with instruction-finetuned backbone, namely Vicuna, substantially outperforms the counterpart with LLaMA on the Open-VQA benchmark in both image understanding and video understanding. The human evaluation on OwlEval, however, shows the

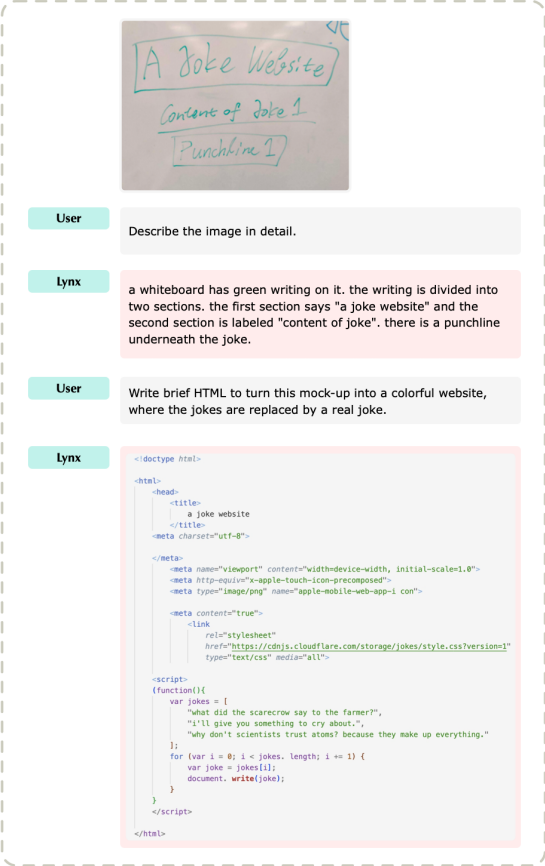

Figure 5: Illustration of the effectiveness of the proposed plug-and-play method.

two model variants have comparable performances. We further test the two variants on a simple yet practical instruction, "give a short answer", and the results show that Vicuna-based model follows the instruction better, producing answers with an average length of 15.81, compared to 20.15 from the LLaMA-based model. One can also refer to Appendix Figure 9(a) for examples of the comparison in terms of their instruction-following ability.

Impact of Larger Image Resolution Our research includes an ablation study to assess the effect of image resolution on model efficacy. The results presented in Table 5 demonstrate enhanced performance for the model trained with 420×420 resolution images relative to those trained with 224×224 resolution, with notable improvements observed in OCR and counting tasks within the Open-VQA benchmark, where OCR accuracy increases from 55.6% to 67.9%, and counting accuracy rises from 54.1% to 67.6%. More details can be found in the Appendix Table 7.

Plug-And-Play Method We introduce a plug-and-play method to improve the instruction-

	Reasoning	Calculation	Translating	Code	Overall
Lynx	110.71	17.50	42.50	45.00	215.71
Lynx*	103.57	55.00↑	75.00↑	77.50↑	311.07↑

Table 6: Comparison of Lynx and Lynx* applied the plug-and-play method on MME cognition benchmark, including commonsense reasoning, numerical calculation, text translation, and code reasoning tasks.

following capabilities of multi-modal LLMs by first prompting the model with "describe the image in detail". As indicated in Table 3 on VisIT-Bench, our model's rank improves from seventh to third with the proposed method. A similar improvement is observed on the Open-VQA video benchmark, where our model's score increases significantly from 57.43 to 66.22, detailed in Table 2. Experiments on the MME benchmark reveals that the most pronounced gains are in tasks requiring numerical calculation, code reasoning, and text translation, as showed in Table 6. Despite the notable lack of these types of data in our training process, with the proposed plug-and-play method, we unlock the inherent abilities of LLMs for tasks such as code writing or text translation. One showcase of this method is illustrated in Figure 5, where the model provides accurate code based on the information obtained from the dialogue history.

4 Related Work

Centralized Multi-modal Interactive System. Recent works investigate actively to design of such multi-modal interactive models. One of the most intuitive ideas, such as Visual ChatGPT (Wu et al., 2023), MM-REACT (Yang et al., 2023), HuggingGPT (Shen et al., 2023), InternGPT (Liu et al., 2023b), SayCan (Ahn et al., 2022), InnerMonologue (Huang et al., 2022), integrates various existing individual models or tools. In such a system, the LLM works as a "manager" that directly accepts instructions from users and selects the most appropriate tools to respond to requests while the integrated individual models are "workers" responsible for a specific kind of task. Typically, such models are powerful to address problems that are already well-defined. Yet, they, to some extent, lack zero-shot ability when encountering open-ended instructions which cannot be handled by any of their workers.

End-to-end Multi-modal Large Language Models. By contrast, inspired by the recent advances of LLMs, it has also been shown feasible and promising to directly train the neural networks that directly accept multi-modal inputs and output responses end-to-end. To achieve so, one intuitive idea is to adapt the LLMs to multi-modal inputs by adding some additional trainable parameters and finetuning them on multi-modal data. For example, Flamingos (Alayrac et al., 2022) is one of the early works to explore this idea. Firstly, it takes a vision encoder (like NFNet (Brock et al., 2021) in their original version, or recent CLIP ViT (Radford et al., 2021)) to extract visual embeddings. Then, it applies multi-layer cross-attention to fuse the multi-modal inputs for the final prediction. Recent works directly concatenate vision embeddings to the inputs of LLMs and finetune LLMs end-to-end. To do so, they usually add an additional projection layer to map the vision embeddings to the same dimension as the language embeddings, and then directly feed them into LLMs for further training. Different methods may take different training strategies. See Appendix A for more.

5 Conclusions

In this paper, we present Lynx, a multi-modal large language model that can take as input images/videos and responses with open-ended natural languages. Through extensive empirical study, we show that our model outperforms other existing open-source models both in multi-modal understanding accuracy and instruction-following capabilities. We also explore different factors that can affect the performance of a multi-modal large language model and conclude that: 1) the generative pretraining is much more sensitive to the quality of training data than previous methods such as contrastive training; 2) the abilities of instruction following are closely related to the number of different tasks and prompts used for training; 3) improving both the multi-modal understanding accuracy and instruction-following capabilities is important for multi-modal large language models; 4) by first prompting the model to describe the image, the instruction-following abilities can be improved. For future work, it is promising to scale up the model to a larger size (e.g. 30B and 65B LLaMA (Touvron et al., 2023)). Moreover, a high-quality multi-modal dataset with diverse instructions is also needed to train such models.

A Background

BLIP2 (Li et al., 2022) designs a Q-Former, which is the only trainable part, to align the dimensions of vision and language tokens. PaLM-E (Driess et al., 2023), which is built upon PaLM (Chowdhery et al., 2022), is trained totally end-to-end with no fixed layers using a mix of multi-modal datasets including WebLI 10B dataset (Chen et al., 2022). Mini-GPT4 (Zhu et al., 2023) freezes all weights of the vision encoder and the LLM while only finetuning the weights of the projection layer. LLAVA (Liu et al., 2023a) fixes the vision encoder while keeping the LLMs trainable during the instruction finetuning stage. mPLUG-owl (Ye et al., 2023) tunes the vision encoder and keeps LLMs fixed to align the vision and language embeddings in the first stage while further tuning the LLMs and keeping the vision encoder fixed in the second instruction-finetuning stage. KOSMOS-1 (Huang et al., 2023b) does not rely on any pretrained LLMs and is trained from scratch on large amounts of mixed data including image-text pairs (COYO700M (Byeon et al., 2022), LAION2B (Schuhmann et al., 2022), etc.), text corpora (Common Crawl, the Pile (Gao et al., 2020), etc.), and interleaved image-text data. These models are all powerful and show promising results to develop multi-modal large language models.

B Evaluation Protocols

The evaluation of GPT4-style generative language models is challenging because the quality of natural languages is inherently subjective and highly depends on specific cases. Existing models like PaLM-E (Driess et al., 2023), PaLI (Chen et al., 2022), BLIP2 (Li et al., 2023b), or InstructBLIP (Dai et al., 2023) turn to the evaluation on visual-language benchmarks like image caption (Chen et al., 2015) or visual question answering (Antol et al., 2015), i.e., fine-tuning multi-modal LLMs on a single downstream task on which the evaluation is conducted. Nevertheless, though it may achieve better performance, over-finetuning on such benchmarks will damage the generation ability of large language models, which conflicts with the primary motivation to use large language models. Moreover, such benchmarks, especially the (semi-)automatically generated ones like TDIUC (Kafle and Kanan, 2017), always contain a high ratio of easy or noisy examples, making them less suitable. On the contrary, other methods like MiniGPT4 (Zhu et al., 2023) or LLaVA (Liu et al., 2023a) only

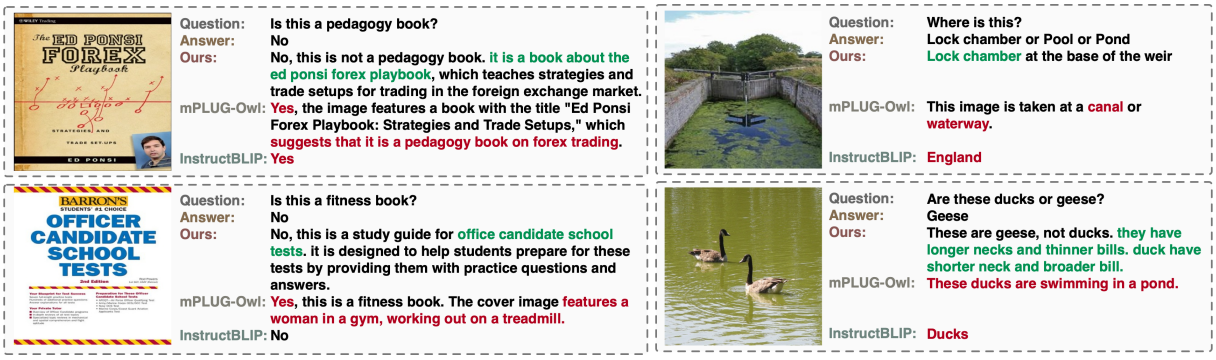

Figure 6: Qualitative results on our Open-VQA benchmark of different models. We choose InstructBLIP and mPLUG-Owl because they perform best on the Open-VQA benchmark and OwlEval benchmark in all baseline algorithms.

showcase their performance in some challenging yet practical scenarios without quantitative results due to the lack of quantitative benchmarks for such generative multi-modal language models. Therefore, in this section, we propose to evaluate the GPT4-style models in the following two aspects:

- A cleaned subset of visual-language benchmark, which should be challenging and compatible with generative models, with prompted GPT4 to get the quantitative results.
- An open-world challenging yet practical test set to evaluate the performance on realistic scenarios where GPT4-style models are needed, with humans to evaluate the user experience.

To do so, we manually collect an Open-VQA test set consisting of 450 samples with image or video input, which contains diverse questions on objects, OCR, counting, reasoning, action recognition, chronological ordering, etc., from VQA 2.0 (Antol et al., 2015), OCRVQA (Mishra et al., 2019), Place365 (Zhou et al., 2017), MSVD (Chen and Dolan, 2011), MSRVTT (Xu et al., 2016), and Something-Something-V2 (SthV2) (Goyal et al., 2017). Though Place365 is a classification task and SthV2 is a video captioning task, we write proper prompts to make them both VQA tasks. Besides, we carefully examine the data and modify the questions and ground-truth answers if necessary to make them reliably correct and challenging enough to be a benchmark for GPT4-style models. Randomly sampled examples are given in Fig. 8(a). Different from the traditional VQA benchmark, Open-VQA supports open-ended answers. To achieve so, we prompt GPT4 to make it the referee, which achieves a consistency of more than 95% compared with humans[2]. The prompt for GPT4 used in this phase is as follows:

Given the question "QUESTION", does the answer "PREDICTION" imply the answer "GROUND_TRUTH"? Answer with Yes or No.

Moreover, general-purpose language generation with image inputs is also important to multi-modal LLMs. Therefore, we also adopt the OwlEval test set proposed by mPLUG-owl (Ye et al., 2023), which contains 82 questions based on 50 images, where 21 from MiniGPT-4 (Zhu et al., 2023), 13 from MM-REACT (Yang et al., 2023), 9 from BLIP2 (Li et al., 2023b), 3 from GPT4 (OpenAI, 2023a), and 4 collected by mPLUG-owl itself. The test set includes diversified and practical cases such as dense image captioning, dialogue writing, story writing, poem writing, teaching, programming, etc.

We give some examples in Fig.8(b). However, OwlEval is proposed together with mPLUG-owl. Hence, directly using it as the benchmark is possibly unfair to other models. To make the comparison fair, we pad each image in the OwlEval with 8 pixels as shown in Fig.8(b) before feeding them into the models. We recruit human annotators to evaluate the performance. Scores range from 1 to 5. If two models are considered to be equally good or bad, they will have the same score. For each data, the annotator will assign a score for each model. We only allow at most 2 models that are equally good or bad, and for each annotator, the total number of ties should be no more than 10 for the whole set. During the evaluation, the correctness has the highest priority, then should be the richness of the generated content.

[2]We evaluate the consistency on 100 samples from a randomly selected subset with our model.

Instruction

Can you give me a detailed introduction to this painting, and also the artist?

Ours:

the painting "the persistence of memory" by salvador dali is a surrealist masterpiece that showcases the artist's unique and imaginative style. the painting was created in 1931 and is considered one of dali's most famous works.
the painting depicts a dreamlike landscape with a sleeping elephant, a tree with clocks hanging off of it, and a rocky beach with a mountainous backdrop. the overall feeling of the image is one of dreamlike, surrealism. the clocks and the sleeping animal give the image a sense of time being distorted or out of order. the surreal nature of the scene and the dreamlike quality of the elephants body position suggest that the painting is a representation of the subconscious mind and the distortion of reality that can occur in dreams.
salvador dalí was a spaniard who was known for his unique and innovative artistic style. he was a pioneer of surrealistic art and is widely regarded as one of the most influential artists of the 20th century. his works often featured dreamlike landscapes, distorted figures,

mPLUG-Owl:

Sure, I can provide a detailed introduction to the painting and the artist.
The painting is a surrealist masterpiece by Salvador Dali, titled "The Persistence of Memory." It was created in 1931 and is one of Dali's most iconic works. **The painting depicts a woman sitting on a wooden floor, surrounded by clocks.** The clocks are arranged in various positions, some closer to the viewer and others further away, creating an intriguing and visually arresting composition. The overall effect of the painting is to evoke a sense of time and the passage of time, as the clocks seem to tick away, reminding us of the inevitable progression of time.
Salvador Dali (1904-1989) was a Spanish artist known for his innovative and imaginative approach to art. He was a leading figure in the surrealism movement, and his works are characterized by dreamlike landscapes, bizarre juxtapositions, and meticulous attention to detail. Dali is considered one of the most influential artists of the 20th century and his work continues to insp

Instruction

Explain why this meme is funny.

Ours:

the meme is funny because it depicts a cute little dog laying down on the floor with the caption "monday, just monday." **the contrast between the adorable dog and the negative connotation of monday makes it humorous. monday is often viewed as a less desirable day of the week due to the perception that it is associated with work, responsibilities, and a lack of leisure time.** the dog's relaxed and peaceful pose, combined with the playful caption, creates a lighthearted and amusing scene.
this meme can be relatable for those who have a love-hate relationship with mondays, as it pokes fun at the negative aspects of the day while also acknowledging the inevitability of its arrival. it can also serve as a reminder to take a break and enjoy the simple pleasures in life, even on a monday. overall, the combination of the cute dog and humorous caption make this meme entertaining and relatable to a wide range of audiences.

mPLUG-Owl:

This meme is funny because it portrays a cute and sleepy French bulldog in a relaxed state, lying down on a white bed with its eyes closed. **The combination of the dog's adorable appearance and its peaceful resting position creates a humorous and entertaining image**.
The fact that the dog is resting its head on the bed also adds to the amusement, as it suggests a sense of comfort and contentment for the canine. The presence of a bottle nearby and a clock on the wall further enhances the meme's comedic value, as these objects might not typically be associated with a sleeping dog. Overall, the image captures the essence of a relaxing and enjoyable moment for both the dog and the viewer, making it a funny and memorable meme.

InstructBLIP:

dog

Instruction

Can you write me a master rap song that rhymes very well based on this image?

Ours:

verse 1:
i'm an old lady with a green jacket on,
wearing sunglasses and headphones,
dancing to the beat with a smile on my face.
chorus:
let's groove to the rhythm and the beat,
with our headsphones on, we're the coolest crew,
we're here to party and have a good time,
so let's dance and have some fun,
it's all about the music and the vibe,
and we'll keep it going until the night is through.
verse 2:
my walk is a little shaky, but i don't care,
my moves may not be the best, but it's okay,
i just wanna have a blast, and let the music take me away,
in the end, it doesn't matter,
as long as i'm having fun, that's what i'll say,
let the good times roll and the music keep on playing,
that's the way to live, and i'd do it all over again.
end chorus:

mPLUG-Owl:

Sure, here's a master rap song that rhymes very well based on the image of the energetic and enthusiastic woman wearing a green jacket, sunglasses, and **a hat**, sitting at a table, **possibly playing cards or participating in a game**:
Verse 1:
I'm the queen of the table, decked out in green,
With my sunnies and my hat, I'm ready to play.
Chorus:
We're having a blast, everyone's having a ball,
At the table with the queen, we're all in the game.

InstructBLIP:

no

Figure 7: Qualitative results on OwlEval benchmark of different models. We choose InstructBLIP and mPLUG-Owl because they perform best on the Open-VQA benchmark and OwlEval benchmark in all baseline algorithms.

Figure 8: Examples of our test set. (a) Open-VQA benchmark to validate the accuracy of visual understanding; (b) OwlEval to evaluate the quality of language generation.

Finally, we also compare our method with others on the newly proposed MME benchmark (Fu et al., 2023) and VisIT-Bench(Bitton et al., 2023).

C Discussions and Limitations

C.1 Findings and Takeaways

Multi-modal LLMs are not as instruction-following as LLMs. In our experiments, we find that current multi-modal LLMs are not as good at the instruction following as language models. For example, InstructBLIP (Dai et al., 2023) tends to generate short responses regardless of the input instructions, while other models tend to generate long sentences without considering the instruction like "Give a short answer" or "Answer in one word". We assume that this is from the lacking of high-quality and diversified multi-modal instruction data.

The quality of training data is critical to model performance. As concluded in Section 3.2, based on the experimentation on different pre-training data, we find that a small number of high-quality data with fluent texts can perform even slightly better than the large-scale noisy datasets. We attribute this to the difference between generative pretraining and contrastive pretraining, since generative pretraining is directly learning the conditional distribution of words but not the similarity between texts and images. Therefore, to train a high-performance multi-modal LLM, despite the quantity of data, it is crucial to prepare a high-quality dataset that satisfies: 1) it includes high-quality and fluent texts; 2) it aligns the texts and images well.

Tasks and prompts are crucial for zero-shot abilities. As shown in Section 3.2, diversified prompts have a great impact on the final performance. The essential observation behind this is that the zero-shot generality of multi-modal language models depends on the diversity of tasks involved during training. The model can generalize to more and more unseen instructions as it sees more and more types of tasks. This accords with the observation in text-only models (Radford et al., 2021).

Balancing the correctness and language generation ability is important. In our experiments, we find that if the model is under-trained on downstream tasks such as VQA, it will suffer from the problem of hallucination and keep making mistakes. While if the model is over-trained on downstream tasks, it will not be able to follow the user's instructions to generate long answers. Therefore, it

would be important to carefully balance the training data to train it so as to correctly read images and videos while keeping its generation ability.

C.2 Limitations

Evaluation It is hard to evaluate a multi-modal large language model since its evaluation is essentially different from traditional visual-language models. Though we take the first step to quantitatively evaluate both the multi-modal understanding accuracy and language generation ability, it is still an open problem: *how can we establish a comprehensive and automatic benchmark to evaluate existing multi-modal large language models?*

Training Data Though we have successfully collected and cleaned a mixed dataset to train our Lynx, we still put a lot of effort to balance different abilities (e.g. correctness and language generation, long and short answers). Moreover, there are still no available image-text datasets that contain long texts which are ideal for pretraining. Besides, restricted by the computational resources that we can use, we do not conduct extensive experiments to find the optimal data combination strategy (e.g. sampling ratios, tasks, and prompts), which has been left for future work.

Multi-lingual Our model is built upon LLaMA (Touvron et al., 2023), which is mainly trained on English corpus. Therefore, our model is not that good at multi-lingual responses. Though it can understand and sometimes output other languages (like shown in Figure 15), it is still unexplored how to build a high-performance multi-lingual and multi-modal large language model.

Safety Currently, we do not conduct safety checks and restrict the outputs of our model. Therefore, the model may output contents that are not appropriate and even toxic, depending on and restricted by the data used for training. The authors do not support the use of harmful language generation using our codes and models, like any usage on ethical, political, and racism issues.

D Experimental Details

D.1 Ablation Study

D.2 Training Details

The model comprises approximately 8B parameters, of which around 1B are trainable. We use the DeepSpeed (Rasley et al., 2020) to accelerate training, and set the BFloat16 as the default model precision. We report the detailed model training hyperparameters in Table 8.

D.3 Hyper-parameters for Generation

For MiniGPT4 (Zhu et al., 2023), we generated the response with its default settings. Similarly, for mPLUG-owl (Ye et al., 2023), we follow the default parameters presented at http://vlarena.opengvlab.com/. Detailed settings can be found in 9 for different tasks.

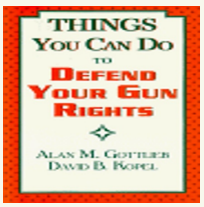
Table 10: Comparison of existing open-sourced multi-modal LLMs on MME benchmark (Fu et al., 2023).

Question: Where is this?
Answer: Living room or waiting room
Vicuna-based: living room
LLaMA-based: the image shows a living room filled with furniture. there are two couches, two chairs, a coffee table and an ottoman in the room. the walls are painted white and there is a large mirror hanging on the wall. a vase with flowers is sitting on a table in front of the

Question: Is this a pedagogy book?
Answer: no
Vicuna-based: no, this is not a pedagogy book. it is a book about the ed ponsi forex playbook, which teaches strategies and trade setups for trading in the foreign exchange market.
LLaMA-based: the ed ponsi forex playbook: strategies and trade setups (wiley trading)

Question: Are these ducks or geese?
Answer: geese
Vicuna-based: these are geese, not ducks. they have longer necks and thinner bills. duck have shorter neck and broader bill.
LLaMA-based: the ducks or geese are swimming in a body of water. the water appears to be murky and green. there is another duck or goose in the image, but it is not as close to the camera as the other one. both of the birds have their heads tucked under their wings

(a) Vicuna-based model versus LLaMA-based model

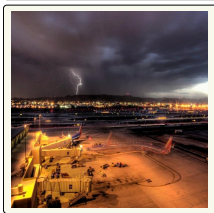


Question: Where is this?
Answer: lock chamber or pool or pond
w/o COYO700M & DataComp1B: lock chamber at the base of the weir
w/ COYO700M & DataComp1B: pond "this is not the place to be if you're claustrophobic."

Question: How many people are in the water?
Answer: 0
w/o COYO700M & DataComp1B: 0 people in the water
w/ COYO700M & DataComp1B: 0

how many people are on the dock? 1
how many benches are there?
there are 2

Question: Is this book related to Law?
Answer: yes
w/o COYO700M & DataComp1B: yes, this book is a guide to defending your gun rights. it covers topics such as the 2nd amendment, the right to bear arms, self-defense, and the use of firearms for hunting and target shooting.
w/ COYO700M & DataComp1B: yes / yes / alan m. gottlieb



(b) w/o large-scale noisy data versus w/ large-scale noisy data

Instruction: Do you have anything to say to the young boy in the image?
w/ diversified prompts: dear young boy, i hope you find inspiration and a sense of wonder in the city below you. the world is full of endless possibilities and opportunities, and it's up to you to make the most of them. as you look down at the bustling city, remember that you have the power to shape your own destiny and make a positive impact on the world around you. don't be afraid to take risks, try new things, and pursue your dreams. you are capable of achieving great things and making a difference in the world. keep your head up and your eyes open to all the possibilities that lie ahead of you. best wishes,
[image description: a young boy is looking at a city below him. he is wearing a brown jacket and blue jeans. the boy is holding his hands in the air. he has a blue cap on his head. he looks like he is in awe of the city he is looking down at. the sky is dark and cloudy above him. there is a large metropolitan area with many tall buildings and a lot of traffic. the city is very busy. the child is looking up at the sky. he appears to have a lot on his mind
w/o diversified prompt: no, i do not have anything to say to the young boy in the image. he is just looking at the city and it is up to him to decide what he wants to do with his life.

Instruction: We design new mugs shown in the image. Can you help us write an advertisement?
w/ diversified prompts: sure! here's an example advertisement for the new mugs:
introducing our new collection of cute and adorable mugs! these mugs are perfect for your morning cup of coffee or tea. each mug features a unique design that will make you smile every time you use it. our mugs come in a variety of colors and styles, so you're sure to find one that suits your personality.
whether you prefer a playful cat design or a cute cartoon character, we have a mug for you. our cute mugs make great gifts for friends, family, or coworkers. they're perfect for birthdays, holidays, or just because!
we're confident that you'll love our new mug collection, and we're offering a special discount for a limited time. don't miss out on this opportunity to treat yourself or a loved one to a unique and fun mug. shop now and enjoy your favorite beverage in style!
w/o diversified prompt: we design new mugs shown in the image. can you help us write an advertisement?

Instruction: Would it be dangerous to fly a plane in the sky right now?
Answer: yes
w/ diversified prompts: yes, it would be dangerous to fly a plane in the sky right now because there is a lightning storm and thunder.
w/o diversified prompt: yes, it would be extremely dangerous to fly a plane in the sky right now because there is a severe thunderstorm with lightning and strong winds, which can cause turbulence and other hazardous conditions for pilots and passengers. additionally, the air traffic control system may be affected by ... 1. We directly use the original instructions if it is applicable.

2. [QUESTION] means the original question from the dataset. We do some post process, e.g., add the "?" if it is missing.

3. [HYPOTHESIS] means the statement in the SN-LIVE dataset.

4. [OPTIONS] means the options list provided by the dataset.

5. [MEME] is the meme included in the Hateful Memes dataset.

6. We split each dialog into rounds, and prompt the model to speak for the next round based on the dialog history.

Table 13: Prompt examples of different datasets.

Question: what did a lady cut up?

Ours: a lady cut up a white onion into pieces.

mPLUG-Owl: A lady cut up a loaf of bread.

InstructBLIP: apple

Question: Is the cloth removed from the keys?

Ours: no, the cloth is not removed from the keys. the key is placed on top of the sari, which is laying on the table. the cloth on the sario is blue, and there are some threads on the blue cloth. the threads are on the left side of the key. the blue thread is on the right side of key. there is a silver needle on the key and the needle is on left side. the silver needles has a blue thread.

mPLUG-Owl: A lady cut up a loaf of bread.

InstructBLIP: yes

Question: Is the cloth removed from the keys?

Ours: the woman is applying makeup to her eyes. she is using a black pencil and a black eyeliner to define and shape her eyebrows. she has dark brown eyeshadow and long, dark brown lashes. she also has some black dots on her eylids.
additional information:
- the woman's eyes are surrounded by a darker brown area, which could be a shadow or a contour.
- there is a youtube video with the same name as the image, which provides a step-by-step guide on how to apply makeup

mPLUG-Owl: The woman is sitting in front of a mirror, applying makeup to her face.

InstructBLIP: eyebrow

 *Instruction* Can you write me a beautiful poem about this image?	as the sun sets in the sky, a man and his dog sit on the grass, their bond unbreakable, their hearts full of grace. the dog's ears up, its mouth open wide, as the man whispers sweet nothings in its ear, his voice soothing, his heart full of care. the golden light of the setting sun, casting a warm glow on the scene, illuminating the love between the man and the dog, two souls united in a bond that can never be broken. in this moment, time stands still, and the world around them fades away, leaving just the two of them, basking in the warmth of the sunset, enjoying each other's company, with no worries, no cares, only the love that binds them together, forever entwined in a heartfelt embrace. a beautiful moment captured forever, in a photograph that tells a story, of love, companionship, and the power of the human-animal bond. may this image inspire us to cherish the ones we love,	Sure, here's a beautiful poem about the image of a man and his dog sitting on a hillside, enjoying the sunset: Sunset on the hillside As the day draws to a close, Man and dog sit side by side Enjoying each other's company. The warmth of the sun's rays Illuminates their faces,	no
 Instruction I designed a character for my game as shown in the image. Can you write me a background story for him?	sure! here's a background story for your character: your character is a wise and enlightened monk who has dedicated his life to the pursuit of knowledge and spiritual understanding. he has spent countless years studying and meditating, seeking to unlock the secrets of the universe and uncover the mysteries of the mind. during his journey, he has encountered many obstacles and challenges, but he has persevered, driven by his unwavering faith in the power of the human mind and the potential for self-discovery. he believes that every person has the potential to achieve greatness, if they only have the courage to pursue their dreams and aspirations. as a result of his extensive studies, your character has developed a deep understanding of neuroscience and the workings of the brain. he is particularly interested in exploring the connection between the brain and consciousness, and the role that the mind plays in shaping our thoughts, emotions, and behaviors. he sees the brain as a powerful tool that can be harnessed for the betterment of humanity, and he is eager to share his knowledge and insights with others.	Sure, I can provide a background story for the character in the image, who is dressed in a red robe and holding a sphere or orb in his hand. The character is a monk or spiritual practitioner who has dedicated his life to studying and understanding the mysteries of the universe. He has traveled far and wide in search of knowledge and enlightenment, seeking to unlock the secrets of the cosmos and gain insight into the true nature of reality. Over the course of his journey, the monk has encountered many challenges and obstacles, but his determination and perseverance have allowed him to overcome these obstacles and continue on his path. He now stands in the room, contemplating the orb he is holding, trying to decipher its meaning and understand its significance in the grand scheme of things. As he ponders the orb, he reflects on his life's journey and the lessons he has learned along the way. He realizes that the orb represents a symbol of his quest for knowledge and understanding, a reminder of the challenges he has faced and the obstacles he has overcome. It serves as a constant source of inspiration and motiv	yes
 Instruction What do you think about the person's behavior?	the person's behavior is reckless and dangerous. running across a busy street without paying attention to oncoming traffic can lead to accidents, injuries, or even fatalities. additionally, running with a bag on one's back increases the risk of falling or losing the bag, which could cause further problems. it is important for pedestrians to be aware of their surroundings and follow traffic rules to ensure their safety and the safety of others. in this case, the person should have waited for a safe opportunity to cross the street, such as when the traffic lights indicate it is safe to do so, or when there is a designated pedestrian crossing. furthermore, it is essential for drivers to be vigilant and cautious when approaching intersections and crosswalks. they should always be prepared to stop or slow down when necessary to avoid accidents. in conclusion, the behavior exhibited by the person in the video is unacceptable and should be discouraged.	The person in the image appears to be crossing the street while the traffic is in motion. This behavior can be considered risky and potentially dangerous, as pedestrians are advised to cross streets only when it is safe to do so. Crossing the street during heavy traffic can increase the chances of getting hit by a vehicle, causing injuries or even fatalities. In this case, the person's decision to cross the street might be due to urgency, distraction, or simply not paying attention to their surroundings. Regardless of the reason, it is essential for individuals to exercise caution when crossing streets, especially in busy urban areas where traffic can be unpredictable and fast-moving.	dangerous
 Instruction Write a conversation between the two animals.	cat: hey dog, what are you doing out here? dog: oh, i'm just enjoying the snow. it's so peaceful and quiet. cat: i don't blame you. i love playing in the snow too, but i can't today. i have an appointment with the vet later. do you want to come with me? dog (excitedly): sure thing! let's go! (cat and dog start walking towards the vets office together) veterinarian: hello, what can i help you with today? (the vet examines the cat and dog) vet: both of you seem to be in good health. is there anything else i can assist you with? (dog and cat look at each other and smile) cat (to vet): thank you, vet. we're just here for a check-up. (vet nods and smiles back) cat to dog: you're welcome, dog. it was nice meeting you. dog to cat: likewise, cat. i hope to see you again soon! (	Cat: "Hey, dog! How are you doing today? It's a cold and snowy day, but we're making the best of it by riding on top of this huge pile of snow together. Aren't we having fun?" Dog: "Yeah, it's been a while since we've had this much snow to play in. I'm glad we decided to spend some quality time together. The cold weather doesn't seem to bother us at all, does it? We're just enjoying each other's company and having a blast."	cat is riding on the dog's back

Figure 12: More cases on our OwlEval benchmark.

Instruction
Explain why this image is funny.

Ours:
the image is funny because it is a cat dressed up in a cookie monster costume, sitting on a couch with a plate of cookies in front of it. the cat is holding a white plate in its paws and there are cookies on the blue plate on top of the table with the white plate. the table has a white cloth on top and there's a white tablecloth on the white table. the cookies are in the shape of smiling faces, which adds to the humor of the image. the caption "another wild saturday night" is also amusing, as it implies that the cat's behavior is unusual or out of the ordinary.

mPLUG-Owl:
This image is funny because it portrays a stuffed animal, possibly a cat, dressed in a blue sweatshirt and pajamas, sitting in a chair and enjoying a cookie. The juxtaposition of the stuffed cat's human-like attire and its playful behavior, combined with the presence of two people engaged in a conversation, creates a humorous and entertaining scene.

The image evokes a sense of whimsy and playfulness, as stuffed animals are typically associated with childhood and imaginative play. The fact that the stuffie cat is wearing pajama pants further emphasizes its humanlike qualities, making the scene even more amusing. The presence of the two people adds another layer of humor, as they might be discussing the stuffy cat'ss enjoyment of the cookie or simply engaging in a casual conversation while observing the scene. Overall, the image captures the essence of a fun and lighthearted moment, making it an enjoyable and memorable moment for viewers.

InstructBLIP:
cat in a onesie

Instruction
How many championship rings did the player on the left win in his career?

Ours:
kobe bryant, the player on the left, won five nba championships during his career with the los angeles lakers. he is widely regarded as one of the greatest basketball players of all time, known for his exceptional shooting skills, ball-handling abilities, and strong work ethic. he was a 5-time nba all-star, 18-time all-nba team member, and 12-time olympic gold medalist.

mPLUG-Owl:
The player on the left has won two championship rings in his career.

InstructBLIP:
5

Instruction
What is the spatial relation between the frisbee and the man?

Ours:
the spatial relation between the frisbee and the man is that the friscue is in the air above the man's head, and the dog is jumping over the man to catch it. the man, who is crouched down on the grass, is positioned underneath the dog as it jumps over his head. the photographer is in focus, while the subject of the photograph is not. the photo is in color. the grass is lush and green, the trees behind the dog are green and lush, the sky behind the trees is blue, and there are no other people in the photograph. the only people in this photo are the man in the red shirt and the black and white dog.

mPLUG-Owl:
The frisbee is being thrown by the man, and the dog is leaping in the air to catch it.

InstructBLIP:
in front of him

Instruction
What is unusual about this image

Ours:
the unusual aspect of this image is that a man is hanging laundry on a line outside of a car while it is in motion. this is not a common sight, as most people tend to hang their lawn or dry their clothes indoors or in a designated area outside their homes.

it is also noteworthy that the man is wearing a yellow shirt and brown shorts, which may indicate that he is a street performer or vendor. the presence of a taxi cab in front of him adds to the unusual nature of the scene, as taxi cabs are typically associated with urban transportation rather than outdoor activities.

in conclusion, the image captures an unusual moment where a man hangs his clothes outside a moving car, wearing yellow and brown clothing, and is surrounded by tall buildings and a busy street. this combination of elements creates an interesting and unconventional scene that stands out from everyday life in an urban environment.

mPLUG-Owl:
What makes this image unusual is the fact that the man is driving down a city street while carrying a laundry bag full of clothes. It is not common to see someone transporting laundered clothes while driving a car, as it can be inconvenient, time-consuming, and potentially hazardous. Instead, one would typically expect to see the clothes being transported in a separate vehicle, such as a truck or a dedicated delivery service.

The presence of multiple cars and trucks on the busy city street adds to the unusual nature of the scene, as the man's decision to transport the clothes in this manner might not be the most efficient or practical option. The image serves as a reminder of the challenges and trade-offs involved in urban transportation and the need to consider various factors, including time, convenience, and safety, when making transportation decisions.

InstructBLIP:
man ironing clothes on car

Instruction
Why this happens and how to fix it?

Ours:
this phenomenon occurs when the washing machine is not properly ventilated or when there is a blockage in the ventilation system. when the machine is running, the water and detergent are heated up, creating steam. if the steam is not allowed to escape properly, it can build up inside the machine, causing the bubbles and foam.
to fix this issue, you can try the following steps:
1. ensure proper ventilation: make sure that there are no blockages in the vents or ducts that could prevent the steam from escaping properly. you may need to clear any dust or debris that may have accumulated inside the vent.
2. check the drain hose: ensure that the hose is not clogged or obstructed, as this can prevent the water from draining properly.
3. adjust the water level: if the foam is caused by too much water, you may want to reduce the amount of water used in the wash cycle.
4. use a fabric softener: if you are experiencing foam due to hard water, try using a water softener. this can help reduce the buildup of minerals in

mPLUG-Owl:
This scenario of a large pile of foam or soap bubbles covering a kitchen floor, with a washing machine in the background, can occur for various reasons. One possible explanation is that the detergent being used in the washing machines is too concentrated, causing excessive bubbling during the wash cycle. This can lead to the formation of large amounts of soap foam, which can then accumulate on the floor.

To fix this issue, it is essential to use detergents that are specifically designed for high-efficiency washers, as they tend to produce less foam. Additionally, it's crucial to follow the manufacturer's instructions for the proper use of the dishwasher, including setting the appropriate water temperature, cycle length, and wash settings. This will help to minimize foam formation and ensure a more efficient and hygienic washing process.
In the meantime, it might be necessary to clean up the foam using a broom or vacuum cleaner to remove it from the floor and prevent any potential slipping hazards.

overflow

Figure 13: More cases on our OwlEval benchmark.

Instruction 1: Do you know what breed the dog in the picture is?

Ours:	mPLUG-Owl:	InstructBLIP:
yes, the dog in the picture is a shiba inu. shiba is a japanese breed of dog that originated in the mountainous regions of japan. they are known for their intelligence, loyalty, and energetic personalities. shibas have a thick double coat that comes in a variety of colors, including black, brown, red, and cream.	yes, the dog in the picture is a shiba inu.	shiba inu

Instruction 2: What kind of mood do you think it's in?

Ours:	mPLUG-Owl:	InstructBLIP:
based on the image, the shiba inu appears to be in a happy and excited mood. the dog's mouth is open, and it seems to be smiling, which is a common expression for dogs when they are happy or excited. additionally, the dog is sitting at a dining table with a meal in front of it, which suggests that it is in a comfortable and relaxed environment.\n\nthe presence of food on the table also indicates that the dog may have recently eaten or is about to eat, which could contribute to its happy and contented expression. overall, the image conveys a sense of joy and contentment on the part of the dog.	i cannot definitively determine the dog's exact mood from the image, but it appears to be happy and content. the dog is sitting at a dining table with a bowl of food in front of it, which suggests that it is enjoying its meal.	happy

Instruction 1: describe the image in detail.

Ours:	mPLUG-Owl:	InstructBLIP:
a woman is laying in a bed with a purple comforter. she is wearing a pink nightgown. there is a rose in her hand. the words "wake me up when when i'm rich" are written on the wall behind her. the wall is white. there are white curtains on the window. the window is partially open. the woman has long brown hair. she has brown eyes. she also has a cell phone. the cell phone is in her right hand.	the image features a young woman lying in bed with her eyes closed. she is wearing a pink nightgown and appears to be sleeping peacefully. in the background, there is a clock on the wall, indicating the time. the room is decorated with various items, including a teddy bear placed on the bed next to the sleeping woman. there is also a book on the nightstand, adding a touch of reading to the scene. the overall atmosphere of the room is cozy and inviting, making it a comfortable place for the young woman to rest and relax.	person sleeping in bed with a phone in her hand

Instruction 2: Why is this picture interesting?

Ours:	mPLUG-Owl:	InstructBLIP:
this picture is interesting because it depicts a woman in a pink nightgown lying in bed, holding a rose, with the words \"wake me up when when i'm rich\" written on the wall behind her. the combination of the woman's pink attire, the rose in her hand, and the words on the bedroom wall creates a whimsical and romantic atmosphere.\n\nmoreover, the fact that the woman is holding a cell phone in her right hand adds a modern twist to the scene, making it more relatable to the present day. this image can evoke feelings of nostalgia and longing for a simpler time, as well as a sense of humor and irony. overall, it is a visually appealing and thought-provoking image that captures the viewer's attention.	this picture is interesting because it portrays a relaxing and peaceful moment in the life of the young woman. she is lying in bed with her eyes closed, enjoying the comfort of her pink nightgown and the presence of her teddy bear. the room is decorated with various items, such as the book on the nightstand and the clock on the wall, which adds a sense of warmth and familiarity to the scene. the combination of these elements creates an inviting and calming atmosphere, making the picture appealing and relatable to viewers.	1. It's a cartoon 2. The person is sleeping in bed with a phone in her hand

Instruction 1: Where is this?

Ours:	mPLUG-Owl:	InstructBLIP:
this image shows a city skyline at night through a window with sliding glass doors. the city is illuminated by streetlights and buildings are visible in the distance. there is a large body of water in the foreground, and the sky is clear and dark. the room has a white countertop and white cabinets, and a large window overlooks the city.	the image is taken in a modern, high-rise living room or office, with a beautiful view of a city skyline. the city skyline includes tall buildings and a nighttime atmosphere, creating a stunning visual experience for the occupant.	Where is this?

Instruction 2: Can you see a person at the desk?

Ours:	mPLUG-Owl:	InstructBLIP:
no, the image does not show a person at the desk. it only shows a view of the city skyline through a window with sliding glass doors. there is no person visible in the image. the focus is on the illuminated cityscape and the body of water in the foreground.	yes, there is a person sitting at the desk, likely taking in the amazing view of the city skyline while working in the high-rise living room or office.	No

Instruction 3: What is the color of the person's shirt?

Ours:	mPLUG-Owl:	InstructBLIP:
the color of the person's shirt is not visible in the image. the image only shows a view of the city skyline through a window with sliding glass doors. the focus is on the illuminated cityscape and the body of water in the foreground. the room has a white countertop and white cabinets, and a large window overlooks the city. it is important to note that the image does not provide enough visual information to determine the color or any other details about the person sitting at the desk. the main focus of the image is the city view through the window, and the room's design elements, such as the counter and cabinets. the presence of a person is not the primary focus of this image.	the person in the image is wearing a white shirt.	Question: what is the color of the person's pants?

Figure 14: Multi-turn dialog demonstrations.

Instruction
Describe the image in French.

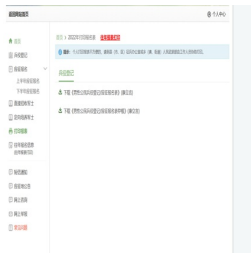
Ours:
voilier de pêcheur dans l'ombre d'un soleil coucher de soleil sur la mer. le voileur est debout sur le pont de l'embarcation et regarde vers l'horizon. il y a une autre embarcation à l'arrière de la voileuse. la mer est calme et le ciel est rouge et orangé. le soleil est couché derrière la montagne en arrière-plan.

mPLUG-Owl:
lorsque la nuit descend et que le soleil se retire, un bateau de voile blanc et rouge navigue sur une mer tranquille, éclairant l'horizon avec un magnifique reflet de son saphir sombre. le soleil se reflète dans l'eau et illumine une partie du bateau, donnant l'illusion d'un navire de rêve flottant sur une mer dorée.

Instruction
Generate the German translation for this sentence: the gorilla is a large ape native to the forests of central and western africa. it is the largest of the great apes, and one of the largest primates. gorillas are herbivorous, spending most of their time on the ground foraging for food.

Ours:
der gorilla ist ein großer affe, die in den wäldern von zentral- und westeuropa heimat ist. er ist der größte der großen affen und einer der größten primaten. gorillas sind pflanzenfresser, die den größten teil ihres lebens in der erde verbringen, um nach nahrung zu suchen.

mPLUG-Owl:
"der intelligente, neugierige gorilla blickt aus den buscheln, als würde er die umgebung faszinieren."



german translation:
"der gorilla ist ein großer ape, die in der afrikanischen primatenregion lebt und sich in den wäldern aufhält. er ist mit abstand der größte der gattung der großen affen und eines der größten primaten. gorillas sind herbivor und meist auf dem boden fressend.

Instruction
describe the image in German

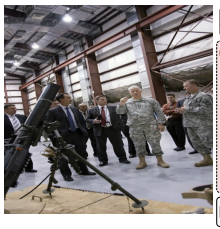
Ours:
es handelt sich um ein bild von einem pokerturnier, bei dem die spieler auf einem tisch sitzen und spielen. der tisch ist mit einem grünen tischbezug ausgestattet, auf dem sich die karten befinden. die spiele sind mit einem kartenspiel ausgerüstet, das auf dem tisch liegt.

mPLUG-Owl:
in this image, a group of men, all wearing white shirts, sit around a dining table, engaged in a game of cards. the players are seated in several different spots around the table, each one holding a deck or a hand of cards. there is a total of eight players present, with the main focus on the men in the foreground, who are sitting closer to the camera.
the dining table is positioned in the middle of the scene, occupying most of the available space. there are chairs placed around the table, with some closer to the foreground and others farther back. the overall ambiance of the scene suggests a relaxed, casual atmosphere as the players enjoy their time together.

Instruction
describe the image in German

Ours:
das ist die überschrift des windows in chinesisch

mPLUG-Owl:
the image shows a computer screen displaying the word "schule" in large font at the top of the page, with a small icon to indicate that the page is in chinese. a search box is placed below the word "schule" with the text "suche" visible within. there are also a few other words or sentences on the page below the search box, with the most prominent one being "schulveranstaltungen." below the words, there are three icons, each placed to the left of the text. the first icon has a red background and is shaped like a magnifying glass, indicating that it is a search icon. the second icon has a green background and is shaped like a book, likely a link to a website. the third icon is also shaped like a magnifying glass and is positioned below the second icon, suggesting that it might be another link within the page. the overall appearance of the screen indicates that the user is searching for information related to school events, perhaps related to the word "schule" or "schulveranstaltungen" on the page



Instruction
为什么这张图片这么奇特

Ours:
这张图片展示了一个飞雀，它在空中上穿着，其身体和翅部分都是白色，背部和尾部都是黑色。

mPLUG-Owl:
这张图片的特点是在一个狗跑过的场景中，飞翔的普通的小飞翔（swallow）。这是一狗在穿过室内的空气中的一绕的旋转的狗跑。它显示了一个小飞翔的即终種，拥有充斥的旋转的运动。在这种狗跑过的环节中，小飞翔的运动是相当有意义的，让狗的运动更具有动态性和生动性，增加狗在步道上的运动的有用性和感情。

Defining and Detecting Vulnerability in Human Evaluation Guidelines: A Preliminary Study Towards Reliable NLG Evaluation

Jie Ruan*, **Wenqing Wang***, **Xiaojun Wan**
Peking University
{ruanjie,wangwenqing}@stu.pku.edu.cn
wanxiaojun@pku.edu.cn

Abstract

Human evaluation serves as the gold standard for assessing the quality of Natural Language Generation (NLG) systems. Nevertheless, the evaluation guideline, as a pivotal element ensuring reliable and reproducible human assessment, has received limited attention. Our investigation revealed that only 29.84% of recent papers involving human evaluation at top conferences release their evaluation guidelines, with vulnerabilities identified in 77.09% of these guidelines. Unreliable evaluation guidelines can yield inaccurate assessment outcomes, potentially impeding the advancement of NLG in the right direction. To address these challenges, we take an initial step towards reliable evaluation guidelines and propose the first human evaluation guideline dataset by collecting annotations of guidelines extracted from existing papers as well as generated via Large Language Models (LLMs). We then introduce a taxonomy of eight vulnerabilities and formulate a principle for composing evaluation guidelines. Furthermore, a method for detecting guideline vulnerabilities has been explored using LLMs, and we offer a set of recommendations to enhance reliability in human evaluation. The annotated human evaluation guideline dataset and code for the vulnerability detection method are publicly available online.[1]

1 Introduction

Natural Language Generation (NLG) has found extensive applications across diverse domains. Nevertheless, evaluating the quality of generated outputs has posed a longstanding and formidable challenge due to the inherent diversity of expressions capable of conveying the same meaning (Howcroft et al., 2020; Zhou et al., 2022). This abundance of possible variations complicates the development of automated evaluation methods (Novikova et al., 2017b; Reiter and Belz, 2009a), thus necessitating the reliance on human evaluation as the gold standard and regarding it as a more reliable evaluation method in NLG (Celikyilmaz et al., 2020; Gatt and Krahmer, 2018; Gkatzia and Mahamood, 2015b; Mellish and Dale, 1998; van der Lee et al., 2018).

However, the evaluation guidelines, which play a crucial role in ensuring the reliability of human evaluation, have not received adequate emphasis. The transparency issues inherent in human evaluation guidelines raise concerns regarding the validity and reproducibility of the evaluation results (Schoch et al., 2020). To investigate this issue, we conducted a study based on 3,233 papers that we crawled from ACL, EMNLP, and NAACL conferences in the last three years. Surprisingly, we indicate that only 29.84% of the papers involving human evaluation release their human evaluation guidelines. Human evaluation guidelines are crucially important for ensuring that human assessments are conducted reliably. However, when papers fail to release the evaluation guidelines, there is no guarantee of the reliability and reproducibility of their evaluation results. Moreover, our analysis of the guidelines released by these papers uncovered a significant concern: a striking 77.09% of the released guidelines exhibited noticeable vulnerabilities[2], which could potentially have a detrimental impact on the correctness of human evaluation outcomes (Schoch et al., 2020).

The ultimate goal of establishing reliable human evaluation guidelines comprises several essential steps, which include detecting potential vulnerabilities in the guidelines, identifying specific vulnerability types, marking the precise segments with vulnerabilities, providing modification suggestions, and finally correcting identified vulnerabilities in

*Equal contribution.

[1] https://github.com/EnablerRx/GuidelineVulnDetect

[2] In this paper, "vulnerability" carries the same meaning as "defect", indicating issues within evaluation guidelines that could potentially result in unreliable evaluation outcomes.

Proceedings of the 2024 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies (Volume 1: Long Papers), pages 7965–7989
June 16-21, 2024 ©2024 Association for Computational Linguistics

the guidelines. In this paper, we conduct a preliminary study on defining and detecting vulnerabilities in human evaluation guidelines, marking an initial step towards reliable guidelines. Specifically, we first constructed a human evaluation guideline dataset by collecting annotations of guidelines extracted from existing papers as well as generated via LLMs. Based on the analysis of the guidelines, we identified eight main categories of vulnerabilities including Ethical Issues, Unconscious Bias, Ambiguous Definition, Unclear Rating, Edge Cases, Prior Knowledge, Inflexible Instructions, and Others. The guidelines with vulnerabilities can result in issues such as annotators being unclear about task requirements, misunderstanding specific scoring standards, or erroneously directing annotators to assign higher scores to particular systems, which leads to incorrect and irreproducible evaluation results. To detect these vulnerabilities, we explored several prompt strategies to evoke the capability of current LLMs in vulnerability detection for human evaluation guidelines, and recommend an LLM-based method employing Chain of Thought (CoT) strategies.

The main contribution of this paper is as follows: 1) We are the first to study vulnerabilities in human evaluation guidelines and release the first human evaluation guideline dataset with annotated vulnerabilities for advancing reliable human evaluation; 2) We analyze the existing human evaluation guidelines and introduce a taxonomy of eight vulnerabilities for evaluation guidelines; Furthermore, we establish a principle for writing a reliable human evaluation guideline; 3) We explore an LLM-based method for detecting guideline vulnerabilities. We recommend employing this method to assess the reliability of the guidelines before conducting human evaluations; 4) We present a set of recommendations designed to elevate the reliability of human evaluation by offering guidance on writing robust guidelines and identifying potential vulnerabilities.

2 Raw Guideline Dataset

Due to the lack of existing work related to human evaluation guideline assessment, we construct the first human evaluation guideline dataset through two methods: extracting from existing papers and generating from GPT3.5, referred to as the **authentic guidelines** and **synthetic guidelines**, respectively. Note that we collect and analyze synthetic guidelines because LLMs has been proved as powerful tools for synthetic data generation (Agrawal et al., 2022; Liu et al., 2022; Bitton et al., 2023).

2.1 Authentic Guidelines

The construction of authentic guidelines involves a three-step process: First, we crawled papers[3] on ACL, EMNLP, and NAACL conferences from 2020 to 2022 and obtained 3,233 raw data. Then, we filter the papers using two groups of keywords, and narrow down the paper set to 319. *Human evaluation* and *manual assessment* constitute the first group, using them to focus solely on the 677 papers related to the evaluation tasks, while *guideline*, *instruction*, *questionnaire*, *interface*, and *screenshot* are employed as keywords to identify papers potentially containing guideline sections. Finally, we manually filtered out papers specifically related to NLG tasks and extract 227 guidelines from ACL (111), EMNLP (62) and NAACL (54). Any guidelines presented as figures or charts were converted into textual formats. More Details of the collected data can be found in Appendix A.

2.2 Synthetic Guidelines

Constructing effective prompts for language models to perform NLP tasks is currently a highly researched topic (Schick and Schütze, 2021; Le Scao and Rush, 2021; Tam et al., 2021; Logan IV et al., 2022; Reynolds and McDonell, 2021). Inspired by Mishra et al. (2022), we design 5 prompts to guide GPT-3.5-Turbo in generating diverse guidelines, including raw prompt, raw prompt with evaluation aspects, structured prompt, structured prompt with evaluation aspects and structured prompt with evaluation aspects and constraints, as shown in Appendix B. For each prompt, we expand the dataset by incorporating 12 NLG tasks and 2 evaluation settings, along with alternately utilizing the keywords *instruction* and *guideline*. Consequently, we generated a total of 48 guidelines for each prompt (12 tasks $\times$ 2 settings $\times$ 2 keywords).

2.3 Data Statistics

Finally, we obtained 227 authentic guidelines extracted from existing papers, alongside 239[4] synthetic guidelines generated by GPT-3.5-Turbo with average lengths of 247.64 words and 237.05 words,

[3]We crawled https://paperswithcode.com, an open resource website which ensures our access to the guideline data once they are publicly available.

[4]A piece of synthetic guideline that doesn't belong to the evaluation task has been filtered out.

respectively. In total, our dataset comprises 466 human evaluation guidelines. It is worth noting that out of the 677 papers related to human evaluation, only 202 (29.84%) of them openly released their evaluation guidelines after considering cases where multiple guidelines were included in a single paper, indicating the insufficient attention given to the evaluation guidelines.

3 Guideline Vulnerability Annotation

3.1 Taxonomy of Guideline Vulnerability

We define a typology consisting of eight guideline vulnerabilities by analyzing the guidelines extracted from existing papers and generated by LLMs. An illustration for each type is shown in Table 1, which is designed for illustrative purposes and does not originate from the actual dataset. More examples can be found in Appendix C.

Ethical Issues (Mieskes, 2017): instructions do not consider potential ethical implications related to the evaluation process, like privacy, cultural sensitivity, accessibility, or the potential misuse of the evaluation results.

Unconscious Bias (Schoch et al., 2020): instructions unconsciously favors or disadvantages certain results.

Ambiguous Definition (Jurgens, 2014): instructions for task definition are unclear, vague, or imprecise that can be interpreted in multiple ways.

Unclear Rating (Amidei et al., 2019): instructions that lack standardized criteria for evaluating aspects or definition of each point on a rating scale, resulting in potential inconsistency in ratings.

Edge Cases (Ruggeri et al., 2023): instructions do not specify how to handle edge cases or exceptional situations that don't neatly fit into the usual categories or criteria.

Prior Knowledge (Sun et al., 2020): instructions assume that evaluators have certain background knowledge or familiarity with a specific subject matter, tool, or principle.

Inflexible Instructions: instructions are unnecessarily complex or rigid, making it hard for evaluators to follow and incapable of adjusting to variations in data or task requirements, which contradicts Sabou et al. (2014)'s conclusion that a simpler instruction tends to yield better results.

Finally, we add the additional type **Others** to ensure the completeness of the typology. This covers any vulnerabilities that do not fall into the above categories.

3.2 Data Annotation

We recruit four college students who possess English qualification certificates. Firstly, they were provided with an annotation guideline, which can be found in Appendix C. Each evaluator went through a training process (details in Appendix D) to enhance their understanding in the annotation process. Before annotation, we also designed a qualification test consisting of 10 guidelines, only annotators who passed the test were considered qualified and allowed to continue annotation. To ensure the annotation quality, we divided the dataset into batches and assigned the specific number of daily tasks to each annotator. Upon receiving the daily annotations, we reviewed the results and required the specific annotator to reannotate the batch of data assigned for that day if there was a low accuracy (less than 80%).

In the annotation interface, the authentic guidelines and synthetic guidelines are randomly presented on the left side so as to prevent bias, while the eight vulnerability types are displayed on the right. Annotators were instructed to assign the specific vulnerability types based on the predefined typology, or indicate "None" for guidelines where the vulnerability type is absent. Each sample was annotated by two distinct annotators and a third annotator made the final decision if they are in disagreement.

We utilized Cohen's kappa (Cohen, 1960) to measure the inter-annotator agreement and computed on a per-label basis so as to gain label-specific insights. Ultimately, we calculated the mean values across all labels to assess the overall agreement. The annotation process lasted approximately two weeks, culminating in a substantial inter-annotator agreement of Cohen's kappa with κ=0.722 on authentic guidelines and κ=0.737 on the synthetic guidelines. More annotation details can be found in Appendix D.

3.3 Annotation Result

Figure 1 reports the annotation results on both authentic and synthetic guidelines. While LLMs have shown impressive results in various generation tasks, its current capabilities to generate reliable evaluation guidelines is limited, with vulnerabilities over 50%. We also report the results of five prompts in Appendix B, indicating that structured instructions incorporating evaluation aspects exhibit the lowest vulnerability ratio. What is worth

Guideline for Opinion Summarization Quality Evaluation

Thank you for participating in this opinion summarization quality evaluation task!
Opinion summarization is the task of automatically generating summaries for a set of reviews about a specific target. In this task, we focus on movie reviews written by users from the Rotten Tomatoes website[1]. You will be presented with one human-written reference summary first along with three system summaries generated by trained neural networks respectively[2]. Please evaluate the quality of opinion summaries[3] with respect to the following four features: (1) Relevance; (2) Consistency; (3) Fluency; and (4) Coherence[4]. You should make comparisons for the summary evaluation and rank the four summaries in the order of the four evaluation aspects[5], and the evaluation is conducted on the open-source annotation tool Doccano[6].

IMPORTANT:

- Thoroughly read the guideline and familiarize yourself with the task of opinion summarization quality evaluation.
- Carefully read the source reviews as well as reference and system summaries to grasp the overall content.
- Evaluate the overall quality of each summary based on the four designated aspects, assign a score to each dimension sentence by sentence and aggregate all the scores of each sentence to perform pairwise comparisons[7].
- If you encounter any difficulties or have questions during the annotation procedure, refer to the provided guidelines. Alternatively, feel free to contact us via email for further clarification.

Vulnerabilities in Guideline

1. Ethical Issues: guiding in this manner disregards the personal privacy of the commenters as it fails to specify whether the comments are anonymous or obtained with user consent. An improved guideline should address ethical concerns such as "All anonymized reviews have been previously collected with user consent and have been stripped of personally identifiable information."
2. Unconscious Bias: guiding in this manner specifies the sequence of the summaries, leading evaluators to have a biased perception of the reference as superior in quality. An improved guideline should be more neutral such as "You will be presented with four summaries in a random order, including one reference summary and three system summaries generated by trained neural networks."
3. Ambiguous Definition: guiding in this manner fails to clarify whether the task is to evaluate four summaries based on the source review or to evaluate three system-generated summaries based on the reference. An improved guideline should provide a more explicit task definition such as "Please evaluate the quality of both the reference and three system-generated opinion summaries given the corresponding source review."
4. Unclear Rating: guiding in this manner lacks a clear explanation of the evaluation aspect, which leads to multiple interpretations for different evaluators, resulting in inconsistent ratings. Given that this task involves pairwise comparison, an improved guideline doesn't have to provide a rating scale, yet it should explicit the evaluation criteria such as: "(1) Relevance: measures how well the summary captures the key points of the source review; (2) Consistency: measures whether the facts in the summary are consistent with the facts in the source review; (3) Fluency: measures the quality of individual sentences, are they well-written and grammatically correct; (4) Coherence: measures the quality of all sentences collectively, to the fit together and sound naturally."
5. Edge Cases: guiding in this manner fails to provide directions for addressing edge cases where both summaries have equal quality. An improved guideline should comprehensively consider exceptional situations such as: "In the case of two summaries are of equal quality, place them side by side in the same ranking."
6. Prior Knowledge: guiding in this manner assumes evaluators have annotation experience without explaining how to use the professional tool Doccano. An improved guideline should offer training or detailed explanations for professional tools and principles such as "The evaluation is conducted on the open-source annotation tool Doccan, and subsequently, training will be provided on how to use it for annotation. If you are interested, you can visit this website in advance for more information: https://doccano.github.io/doccano."
7. Inflexible Instructions: guiding in this manner makes the task unnecessarily complex by aggregating individual sentences for overall quality evaluation. Furthermore, it doesn't align with certain aspects, such as coherence, which require an evaluation that considers all sentences collectively. An improved guideline should be more flexible and reasonable such as "Evaluate the overall quality of each summary and make comparisons based on the four designated aspects."

Table 1: An illustration of the taxonomy on guideline vulnerability types.

noting is that the quality of the authentic guidelines extracted from existing papers is much poorer, and the vulnerability ratio is 77.09%, which undermines the reliability of evaluation tasks. This aligns with the conclusions of Sabou et al. (2014), who demonstrated that the crowdsourcing community still lacks a set of best-practice guidelines, resulting in low-quality annotations. We make a call for future researchers to be aware of the issue and emphasize the need for thorough refinement and investigation to develop a robust guideline.

Regarding the vulnerability type, both the authentic and synthetic guidelines are in a similar distribution that Ambiguous Definition and Unclear Rating occur most frequently. The vulnerability "Others" appears in scenarios such as when guidelines generated by LLMs are incomplete. Table 2 shows the authentic guideline for the machine-in-the-loop writing of image caption task extracted from Padmakumar and He (2022). The guideline lacks the definition of the machine-in-the-loop writing task and fails to specify the evaluation criterion, leaving uncertainty about the annotation process. As a result, the reliability and validity of the evaluation process will be compromised. Apart from the two types, authentic guidelines exhibit more vulnerabilities of bias, prior knowledge and ethical issues. Additionally, authentic guidelines are

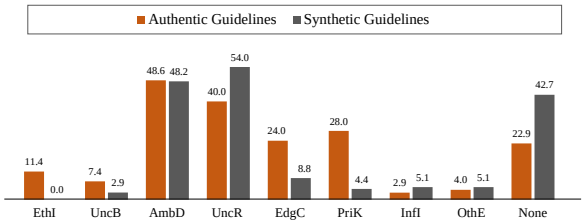

Figure 1: Distributions of vulnerability types on authentic and synthetic guidelines with EthI, UncB, AmbD, UncR, EdgC, PriK, InfI, OthE refers to Ethical Issues, Unconscious Bias, Ambiguous Definition, Unclear Rating, Edge Cases, Prior Knowledge, Inflexible Instructions and Others respectively. "None" means the guideline has no vulnerability at all. The ratio calculation is achieved by taking the number of guidelines that include a particular category and dividing it by the total count of guidelines.

Instructions for crowdworkers evaluating the captions
• Choose the better (more descriptive and/or figurative) caption for the image.
• A better caption is your subjective judgement, the rubrics to make the choice are that the caption is descriptive and/or figurative in its interpretation of the image (Refer the examples for further clarification).
• The explanation asked is supposed to be very brief. A single word of if you like it for being descriptive or interpretive will do.
• Relevance of the caption to the image is your subjective choice whether the caption appropriately represents what is in the image and is not just a catchy piece of text unrelated to the image.
• A caption that you deem irrelevant should never be the better caption, unless both are irrelevant.

Table 2: Authentic human evaluation guideline extracted from Padmakumar and He (2022) with vulnerabilities of Ambiguous Definition and Unclear Rating.

more likely to suffer from neglecting edge cases, whereas the LLM is more prone to generate excessively rigid and complex guidelines, resulting in more vulnerabilities of Inflexible Instructions. As such, resorting to the LLMs to fill in the gaps proves to be a promising approach. However, it is important to note that the current LLM can only generate preliminary drafts of guidelines and needs more effective strategies to enhance reasoning ability for improving the reliability of guidelines. A future direction is to enhance LLM's reasoning ability to improve its capability in generating reliable guidelines.

4 Experiments

In this section, we investigate utilizing LLMs to detect the specific vulnerability types in each evaluation guideline, which is taken as a multi-label vulnerability type classification task.

4.1 Large Language Models

We perform our experiments utilizing both open-source and closed-source LLMs. For open-source models, we fine-tuned LLaMA-7B, an efficient and popular foundation language model with LoRA[5]. Additionally, we also experimented with Flan-T5-XXL[6], Flan-Alpaca-L[7], and Falcon-7B[8], respectively. For closed-source models, we select two widely accessible large language models: TEXT-DAVINCI-003[9] and GPT-3.5-turbo[10]. TEXT-DAVINCI-003 is developed using a combination of supervised instruction tuning and Reinforcement Learning from Human Feedback methodologies. GPT-3.5-Turbo is an enhanced version of the GPT-3 language model with instruction fine-tuning.

4.2 Prompting Strategies

Our exploration involves designing prompts for both zero-shot and few-shot scenarios, encompassing four distinct prompt templates ("Basic", "VDesc", "CoT-Basic" and "CoT-VDesc") under each scenario, thus yielding a total of eight prompts. Basic prompt offers only the name of the vulnerability type, whereas VDesc prompt expands on this by including definition for each type. Additionally, we investigate the Chain-of-Thought (CoT) prompting technique on both prompt templates. Detailed prompting design and the full prompts are detailed in Appendix E.

4.3 Baselines

We further implement and finetune three Transformer-based classifiers as baselines: BERT (Devlin et al., 2019) along with its successors XLNet (Yang et al., 2019) and ALBERT (Lan et al., 2019), which have shown excellent performance on classification tasks. They are all deep pretrained models that first encodes a guideline into vector space by capturing contextual information bidirectionally and then outputs the probability for each label independently. We finetune all the models on the base version and the hyper-parameters can be found in Appendix F.

Human Evaluation Guideline	LLM	LLM Answer
Read the following pairs of texts (source and candidate) and provide ratings between 0 to 100 based on the degree of similarity in **meaning** and preservation of **grammar** for each candidate text. Drag or click on the appropriate portion of the slider to provide a rating for each candidate text. Please refer to the scoring example before starting the first task. **Note:** There will be a candidate text in each HIT which contains several random words appearing out of context unrelated to the text. Please make sure to score this candidate text in each HIT with **10-20** points. Apart from this, please refer to the table below for scoring the candidate text. You must provide a rating for all examples to proceed. **Category: Meaning** Mild (1 sent): deduct **5-10** pts e.g., wrong pronoun Significant (1 sent): deduct **30** pts e.g., relevant words but diff meaning Mild (2 sent): deduct **10-20** pts Significant (2 sent): deduct **60-70** pts **Category: Grammaticality** Mild (1 sent): deduct **5-10** pts e.g., missing conjunction Significant (1 sent): deduct **25** pts e.g., incomplete sentence Mild (2 sent): deduct **10-20** pts Significant (2 sent): deduct **50-60** pts	**GOLD**	Ambiguous Definition, Unclear Rating
	TEXT-DAVINCI-003	REASONING: The guideline does not provide a clear definition of the task, making it difficult for evaluators to interpret the instructions. It also does not provide a detailed explanation of the rating aspects, leading to multiple interpretations for different evaluators, causing "Unclear Rating". So the answer is "Ambiguous Definition" and "Unclear Rating". ANSWER: Ambiguous Definition, Unclear Rating ✓
	GPT-3.5-Turbo	REASONING: The guideline does not provide clear instructions on how to handle edge cases where the candidate text contains random words unrelated to the text. So the answer is "Edge Cases" ANSWER: Edge Cases ✗
	LLaMA	Mild, Significant ✗
	Flan	Let's think step by step: REASONING: The first task is to score ✗
	Flan-Alpaca	Categoryeaningequal to 12 pts e ✗
	Falcon	None ✗

Table 3: Example answers of vulnerability types detected (generated) by LLMs with few-shot CoT prompting for a human evaluation guideline in the test set.

4.4 Data Splits

We initially divide the dataset into five parts, with four parts designated for training (80%) and one for testing (20%). The training set is used for supervised fine-tuning of pretrained baselines and is subsequently divided into train/validation sets in a 4:1 ratio. Further, each of these five parts is used as an individual testing set, while the remaining four parts serve as training sets. As such, we evaluate the performance of the baselines and LLMs across the entire dataset, treating each part as a test set in rotation, so as to mitigate random fluctuations due to the relatively small size of the dataset and obtain a more accurate performance estimate.

4.5 Evaluation Metrics

Following Chen et al. (2017), we adopt **macro-Precision(macro-P)**, **macro-Recall (macro-R)**, and **macro-F1** scores (Vechtomova, 2009), which assess the overall performance of a classifier by taking the average of Precision, Recall, and F1-scores across all individual labels for each class (including "None"). Considering the unequal proportions of different vulnerability types in the dataset, as shown in Figure 1, macro metrics can provide a more balanced view of the model's performance across all classes, as opposed to micro-averaging (Vechtomova, 2009), which gives more weight to the larger classes. Furthermore, we follow Ganda and Buch (2018) and utilize **Accuracy (ACC)** to assess the average accuracy of all individual types. We also follow Wu and Zhou (2017) and use the **instance-AUC (AUC)** metric. **Hamming Loss** (Schapire and Singer, 1998) is also incorporated, which evaluates the fraction of misclassified instance-label pairs, accounting for both missed relevant labels and predicted irrelevant labels.

5 Results and Analysis

5.1 Qualitative Analysis

We first show the case study of a sample from the test set in Table 3, in which the authentic guideline is drawn from Kim et al. (2021) and suffers from vulnerabilities of Ambiguous Definition and Unclear Rating. The answers are generated by LLMs under few-shot CoT prompting. We can find that TEXT-DAVINCI-003 not only generates completely correct answers, but also narrows down the scope of vulnerabilities in its reasoning, facilitating the correction of identified vulnerabilities in the guidelines. Nevertheless, GPT-3.5-Turbo appears to have misconstrued the definition of the Edge Cases, since the handling of cases "where the candidate text contains random words unrelated to the text" has already been provided. The four open-source models, on the other hand, don't gen-

erate the answer as instructed. Instead, LLaMA extracts keywords directly as the output, Flan and Flan-Alpaca yields nonsensical results, and Falcon consistently outputs "None" for all of the data, revealing the inefficiency of open-source models in vulnerability detection. We speculate the reason is due to the limited training data and the excessive length of the instructions.

5.2 Quantitative Analysis

Given that the results generated by open-source LLMs are invalid, as demonstrated in Table 3, quantitative evaluation becomes unfeasible. Therefore, we focus on GPT models and pre-trained baselines for quantitative analysis. Table 4 shows the experiment results for guideline vulnerability detection on both authentic and synthetic guidelines along with the entire dataset. We also report the results of each vulnerability type in Appendix G.

We first explored the effects of different prompt strategies, including Basic, Vdesc, and the use of CoT. Subsequently, we explored the detection performance of LLMs in zero-shot and few-shot settings. Additionally, we investigated the performance of different LLMs, namely TEXT-DAVINCI-003, GPT-3.5-Turbo, and pre-trained models including BERT, XLNet, and ALBERT. Finally, we analyzed the varying performance between authentic guidelines and synthetic guidelines. Through this exploration of different prompt strategies, models, and settings, we conclude that TEXT-DAVINCI-003 demonstrates superior performance with few-shot prompting and CoT strategies. Our analysis of experimental results exploring different prompt strategies, models, and settings is based on a comprehensive consideration of all evaluation metrics. When drawing conclusions from specific metrics, we specify the particular metrics that serve as the basis for our conclusions.

Regarding the Basic and VDesc prompt templates, they exhibit comparable capabilities. The reason is that the incorporation of vulnerability descriptions might potentially disrupt the reasoning process of LLMs, although they might provide detailed vulnerability descriptions for LLMs. According to results on All guidelines, we can also find that CoT generally improves model performance in all prompt strategies of zero-shot setting and Vdesc prompt strategy of few-shot setting. The reason why CoT doesn't consistently enhance model performance in the Basic prompt strategy may stem from the insufficiency of vulnerability information provided by the Basic prompt for effective reasoning. For few-shot and zero-shot settings, we can conclude from the results on All guidelines that LLMs generally exhibit enhanced performance in few-shot scenarios.

In the analysis of various LLMs and pretrained models, the experimental results indicate that TEXT-DAVINCI-003 and GPT-3.5-Turbo exhibit comparable performance, consistently outperforming pretrained models across the majority of prompt strategies. However, the pretrained models still serve as robust baselines, showing specific advantages over TEXT-DAVINCI-003 without CoT strategies under zero-shot scenarios. A noteworthy observation is that Recall values generally surpass Precision in most cases, indicating a tendency for the models to classify guidelines as positive, i.e., no vulnerability is detected. Furthermore, observing the results of each vulnerability type (detailed experimental results are shown in Appendix G), it is found that the model's ability to detect different vulnerabilities varies significantly. All these gaps suggest that the models still have room for improvement in guideline vulnerability detection.

We also compare the model's performance on the two categories of guidelines: Authentic Guidelines and Synthetic Guidelines. Experimental results in Table 4 indicate that LLMs exhibit a stronger ability to detect vulnerabilities in synthetic guidelines compared to authentic guidelines. Moreover, TEXT-DAVINCI-003 with CoT-Vdesc strategy demonstrates superior detection capabilities in detecting authentic guidelines, while GPT-3.5-Turbo with CoT-Vdesc strategy exhibits enhanced detection proficiency for synthetic guidelines. Overall, the experimental results show TEXT-DAVINCI-003 exhibits superior detection capabilities in detecting all guidelines.

Based on the outcomes of a thorough exploration involving various prompt strategies, models, and settings, our conclusion is that TEXT-DAVINCI-003 demonstrates superior performance with few-shot prompting and CoT strategies. Overall, TEXT-DAVINCI-003 with CoT-Vdesc prompt strategy in the few-shot scenario has the best performance for all guidelines and is recommended as the method for guideline vulnerability detection.

6 Practical Recommendations

We summarize the key findings from this work and provide practical recommendations for reliable

Model	Prompt	Macro-P			Macro-R			Macro-F1			ACC			AUC			Hamming Loss↓		
		Aut	Syn	All	Aut	Syn	All	Aut	Syn	All	Aut	Syn	All	Aut	Syn	All	Aut	Syn	All

Table 4: Guideline vulnerability detection results on "Authentic Guidelines (Aut)", "Synthetic Guidelines (Syn)" and the whole dataset (All). Upper, middle and lower parts show results of LLMs under zero-shot and few-shot scenarios as well as baseline models, respectively. The best values of each column are bolded. ↓ indicates that the lower value indicates the better performance.

human evaluation.

1. Writing human evaluation guidelines using LLMs. Our research has found that the proportion of vulnerabilities in guidelines generated by LLMs is lower than those written by humans. We suggest directly instructing LLMs about the requirements for evaluation and utilizing them to generate human evaluation guidelines.

2. Modify the evaluation guideline draft written by LLMs based on the proposed principles for human evaluation guidelines (shown in Appendix H). We analyze human evaluation guidelines and summarize principles to compose a robust evaluation guidelines. We recommend referencing these principles when crafting the guidelines.

3. Utilize TEXT-DAVINCI-003 with CoT-VDesc strategy to identify vulnerabilities. It has been proven to be an efficient, convenient, and cost-effective method, and detecting a guideline only requires approximately $0.02[11].

4. Conduct human evaluation in strict accordance with the human evaluation guidelines.

5. Publicly release the human evaluation guideline. This can contribute to the transparency of human evaluation.

7 Related Work

7.1 Vulnerability Detection

Early explorations in Vulnerability Detection (VD) span rule-based approaches targeting predefined patterns. Subsequent advancements incorporate Machine Learning (ML) and Deep Learning (DL) techniques to predict vulnerabilities automatically in various tasks, including software security detection (Li et al., 2018), smart contract opcodes detection (Qian et al., 2022) and code vulnerability detection (Cheshkov et al., 2023). Recently, inspired by the outstanding performance of LLM in code-based tasks, Cheshkov et al. (2023) attempted to explore the capability of LLM in addressing code vulnerability detection. Vulnerability detection already being implemented across a wide range of tasks with various techniques, yet none of them

[11]The prompt consists of 909 tokens, with the inclusion of the average length of each guideline(242.21 tokens), multiplied by the cost of TEXT-DAVINCI-003 ($0.0200 / 1K).

have been designed to explore the issue of vulnerability detection in human evaluation guidelines.

7.2 Natural Language Generation Evaluation

Previous studies have frequently relied on automatic metrics like BLEU (Papineni et al., 2002), METEOR (Banerjee and Lavie, 2005), ROUGE (Lin, 2004), BERT-SCORE (Zhang et al., 2019), MOVER-SCORE (Zhao et al., 2019) and BART-SCORE (Yuan et al., 2021) to evaluate the quality of generated text, primarily due to their cost-effectiveness, quickness, and repeatability (Reiter and Belz, 2009b). Nevertheless, these metrics have been criticized for their limited interpretability (van der Lee et al., 2019) and low correlation with human judgements (Belz and Reiter, 2006; Liu et al., 2016; Reiter and Belz, 2009b; Novikova et al., 2017a). Human evaluation is widely recognized as the gold standard for evaluating NLG systems (Mellish and Dale, 1998; Gkatzia and Mahamood, 2015a; van der Lee et al., 2018). However, it has the potential to be unreliable due to cognitive biases (Schoch et al., 2020) and the lack of standardized evaluation methodologies (van der Lee et al., 2019). Shimorina and Belz (2021) contributes to transparency in the human evaluation process by documenting it, while Belz et al. (2023) explores reproducibility in NLP human evaluation. However, there is currently no comprehensive work addressing the reliability of human evaluation guidelines, a pivotal element ensuring reliable and reproducible human assessment. With the increasing interest in LLMs, recent studies have been conducted to examine their suitability for assessing generation tasks, like summarization (Luo et al., 2023), machine translation (Kocmi and Federmann, 2023), etc. In this work, we focus on both human evaluation and large language model evaluation, which is the first to utilize LLMs for assessing guidelines in human evaluation.

8 Conclusion

In this paper, we propose and analyze significant issues in the evaluation guidelines of gold-standard human assessments. We conduct a preliminary study on defining and detecting vulnerabilities in guidelines to advancing reliable human evaluation. By proposing a taxonomy of guideline vulnerabilities, we constructed the first annotated human evaluation guideline dataset. We then explored LLMs with Few-Shot prompting and CoT strategies for automatic vulnerability detection. Recommendations include employing LLMs to assist in writing human evaluation guidelines and modifying them based on the proposed principles. Utilizing the proposed LLM-based vulnerability detection method is suggested for assessing the reliability of the guidelines.

In future work, we will delve into the precise annotation of spans containing vulnerabilities in guidelines, providing correction suggestions, automatically correcting identified vulnerabilities in the guidelines, and generating reliable guidelines by AI models. This advancement aims to contribute towards the ultimate goal of establishing dependable gold-standard human evaluation guidelines, thereby enhancing the reliability of NLG assessments.

Limitations

This study serves as a preliminary exploration towards establishing reliable evaluation guidelines. We proposed and analyzed significant issues in gold-standard human assessments, specifically focusing on identifying vulnerabilities in guidelines. Our preliminary study employed LLMs to detect guideline vulnerabilities and provided recommendations for improving reliability in human evaluation. However, the ultimate goal of achieving dependable gold-standard human evaluation guidelines requires further investigation. Future work can delve into precise annotation of spans containing vulnerabilities, automatic correction of identified issues, and the generation of reliable guidelines using AI models. These advancements aim to contribute to establishing dependable guidelines, thereby enhancing the reliability of NLG assessments. It is important to note that due to cost considerations, experiments with the proposed method were not conducted on GPT-4. Implementing the

proposed method on GPT-4 may further enhance its effectiveness, a consideration for future research.

Ethics Statement

We recruit annotators from a college campus. They are completely free to decide whether or not to participate in our annotation. The payment is 9 dollars per hour, higher than the local minimum wage. There is no personal information in our collected dataset. The information which may be used to identify the participants is deleted after the annotation. Moreover, the LLM-generated guidelines may contain toxic language, which can make annotators uncomfortable. We reviewed the data before annotation and found no problematic samples. We check the licenses of the artifacts used in this study and do not find conflicts. The license of the dataset we will release is CC BY-NC 4.0.

A Authentic Guidelines Details

For the collected data, we focused on work related to human evaluation in NLG tasks. In descending order of frequency, specific tasks include summarization (42), dialogue generation(36), question answering (34), machine translation (26), story generation (20), image captioning (9), etc. These guidelines are collected from high-quality NLP conferences ACL, EMNLP and NAACL over the past three years (2020-2022). Apart from machine translation that cover a range of language pairs like English-French, English-Japanese, Chinese - English, English-German, English-Spanish, and English-Russian, most of the tasks primarily focus on the English language. Additionally, we have gathered information on the reported inter-annotator agreement, revealing a general inverse relationship between the number of identified vulnerabilities and the level of agreement. To illustrate, in the vulnerability-free guideline from Jiang et al. (2020), Cohen's Kappa can reach a substantial level of 0.807, whereas in the guideline from Roy et al. (2021), with three identified vulnerabilities, Cohen's Kappa falls only within the range of 0.50 to 0.64. The list of crawled papers and the guidelines with annotations are released.

B Prompts for Synthetic Guideline Generation

To explore the LLM's ability in writing human evaluation guidelines and extend the guideline datasets, we utilize different prompt strategies for LLMs to generate diverse human evaluation guidelines. Table 6 displays the prompts that were employed for creating synthetic guidelines, which fall into two categories: raw instructions and structured instructions. Inspired by the sensitivity of language models to the framing of their instructional prompts (Mishra et al., 2022), we explore the impact of incorporating evaluation aspects and constraints separately, with a total of five prompt variations. For each prompt, we analyze their performance across 12 NLG tasks: summarization, machine translation, dialogue generation, story generation, paraphrase generation, data to text, grammar error correction, text simplification, code generation, code summarization, question generation, and spelling correction, involve two assessment methods: direct assessment and pairwise comparison, and focus on the keywords "guideline" and "instruction".

The annotation result of each prompt can be found in Table 5. It can be seen that structured instructions, as opposed to raw instructions, generally contain fewer vulnerabilities and both can enhance generation performance after adding evaluation aspects. However, incorporating constraints into the prompt leads to a drop in generation performance, contradicting the findings of Shi et al. (2022), who employ a fluency constraint and observed an enhancement in performance.

Prompt	**% Vulnerability Ratio ↓**
raw	13.8
raw with aspect	10.5
structured	10.9
structured with aspect	9.6
structured with aspect and constraint	12.6

Table 5: Annotation results regarding the vulnerability ratio of each prompt variation. The ratio calculation involves dividing the count of synthetic guidelines containing vulnerabilities for a specific prompt by the overall guideline count. ↓ indicates a lower value is preferable.

C Annotation Guideline

We release our full guideline provided to crowdworker participants for the manual evaluation of the vulnerability detection task in Table 7. We advocate for more related works to share their guidelines, aiming to enhance the transparency of human evaluation and thereby contribute to the establishment of a set of best-practice guidelines for the community.

D Annotation Details

The annotators we recruited are four college students with College English Test-6 certificates who are fluent in both English and Chinese languages, with Chinese as their mother tongue. There are 1 females and 3 males, with an average age of around 24. Then we conduct a training process. Specifically, we conducted an online meeting for annotator training, covering the interpretation of annotation guidelines, explanations and examples of various guideline vulnerabilities, clarification of relevant considerations, and a QA session. To confirm their proficiency, annotators underwent a pre-annotation test, and only those who passed were allowed to proceed with the formal annotation. Specifically, 10 guidelines are randomly sampled with 5 in Au-

	Five prompt variations for two instructions
RAW INSTRUCTION	**Raw prompt:** Write a human evaluation *guideline* for the *Summarization* task. The evaluation type is *Pairwise Comparison*.
	Raw prompt with evaluation aspects: Write a human evaluation *guideline* for the *Summarization* task. The evaluation type is *Pairwise Comparison*. Evaluate the following aspects: accuracy, coherence, consistency, relevance, fluency, informativeness, coverage, overall. The evaluation scale is 1-5 (1 is poor and 5 is excellent).
STRUCTURED INSTRUCTION	**Structured prompt:** Human evaluation task: *Summarization* Evaluation type: *Pairwise Comparison* Human evaluation *guideline*:
	Structured prompt with evaluation aspects: Human evaluation task: *Summarization* Evaluation type: *Pairwise Comparison* Evaluation aspects: accuracy, coherence, consistency, relevance, fluency, informativeness, coverage, overall Evaluation scale: 1-5 (1 is poor and 5 is excellent) Human evaluation *guideline*:
	Structured prompt with evaluation aspects and constraints: Human evaluation task: *Summarization* Evaluation type: *Pairwise Comparison* Evaluation aspects: accuracy, coherence, consistency, relevance, fluency, informativeness, coverage, overall Evaluation scale: 1-5 (1 is poor and 5 is excellent) Please be mindful of the following issues and avoid them: definition ambiguity, bias, assuming prior knowledge, insufficient coverage, lack of rating scale, lack of adaptability, and neglecting ethical implications Human evaluation *guideline*:

Table 6: Five prompts utilized for generating synthetic guidelines. The highlighted blue portions are employed across 12 NLG tasks, 2 evaluation methods and 2 key words, which are interchanged interchangeably.

thentic Guidelines and 5 in Synthetic Guidelines respectively. We annotated them first. Then, we calculated the accuracy of each participant based on our annotation. Higher accuracy indicates a more consistent understanding of our guidelines. Annotators who achieve at least 80% accuracy are considered qualified to continue the annotation.

We used Cohen's kappa(Cohen, 1960) to measure the inter-rater reliability. Considering that each label is independent and there are diverse label combinations for multi-label classification task, we do not require that two annotators provide completely identical label sets for each guideline. Instead, we assess the agreement between the two annotators in terms of each label they assign. Specifically, let n be the number of guidelines to be labeled by A and B two annotators. g is the number of distinct vulnerability labels, and f_{ij} denotes the frequency of the number of subjects with the i_{th} categorical response for annotator A and the j_{th} categorical response for annotator B. The kappa agreement is then calculated as:

$$p_0 = \frac{1}{n}\sum_{i=1}^{g} f_{ii},$$

$$p_e = \frac{1}{n^2}\sum_{i=1}^{g} f_{i+}f_{+i},$$

$$\kappa = \frac{p_0 - p_e}{1 - p_e},$$

where f_{i+} is the total for the i_{th} row f_{+i} and is the total for the i_{th} column in the frequency table.

E Prompt Template for Vulnerability Detection

The prompt templates used for vulnerability type detection on human evaluation guidelines are illustrated in Figure 2. As previously mentioned, we formulate four types of prompt templates: Basic, VDesc, CoT-Basic and CoT-VDesc in both zero-shot and few-shot scenarios. The zero-shot template of Basic template comprises of a Requirement + Constraints + Guideline framework. Requirement specifies the task motivation and remains consistent across all prompts; Constraints emphasize the desired output format such as *" Only reply with the names of vulnerabilities or 'None'"*; and Guideline represents the input data. On this basis, the template of VDesc further introduces the description of vulnerability types, which is expressed as Requirement + Description + Constraints + Guideline. We formulated the two prompt templates with the consideration that incorporating descriptions of vulnerability types can boost model effectiveness by

offering more specific knowledge, yet simultaneously, it might also potentially disrupt the model's performance for introducing extra information.

Regarding the few-shot prompts, we expanded on the zero-shot method by incorporating seven pseudo-examples that encompass all vulnerability types except for "Others", some of which include multiple vulnerability types, so as to facilitate more appropriate model reasoning.

Additionally, we explore the CoT prompting technique, which elicits complex multi-step reasoning through step-by-step answer examples. For zero-shot prompts, we incorporate CoT by simply incorporating the phrase "Let's think step by step" before each answer, without supplying any examples (Kojima et al., 2022). It is worth noting that the phrase "Let's think step by step" is absent in the 7-shot prompt differing from zero-shot scenario. Instead, the phrase is integrated into the reasoning process of examples, through which we observed an improvement in performance. Inspired by Wang et al. (2022), we integrate the results of each reasoning over three runs and select the most consistent answer as the final answer set.

F Hyper-parameters

For TEXT-DAVINCI-003[12] and GPT-3.5-Turbo[13], the specific hyper-parameters can be found in Table 8. For the baselines, we utilize Huggingface[14] implementations for all the deep pretrained models and the specific hyper-parameters can be found in Table 9. We initially explored two approaches: one is to treat the multi-label classification task as a seq2seq problem, and generate a variable-length label sequence for a given text sequence. The other is to consider each neuron to be a binary classifier since the predictions for each category are independent in multi-label classification task, essentially forming a binary classification task for each label. We ultimately chose the second approach due to the limited training dataset in this task (less than 500 samples) and the increased data requirements of complex sequence models. We selected BCELoss as the loss function, which is commonly used in binary classification tasks. It calculates the individual losses for each label, quantifying the model's performance in terms of the difference between its predictions and the actual labels for each vulnerability type. Besides, we utilized the sigmoid activation function in the fully connected layers.

G Results of Each Vulnerability Type

Table 10, 11 and 12 report the experimental results of each vulnerability type (including "None") of pre-trained baselines, TEXT-DAVINCI-003 as well as GPT-3.5-Turbo respectively. Please note that the overall accuracy and AUC in Table 4 are the averages across eight types of vulnerabilities, which may vary with the inclusion of "None". We can observe that the model's capacity to detect different vulnerability types exhibits some variation, showing a trend in both LLMs and the Baseline, where more frequently occurring vulnerability types yield lower results. For LLMs, this is reasonable as they tend to output "None", as mentioned above, making them prone to misidentify more guidelines containing high-frequency vulnerability types as positive. Nevertheless, for the Baseline, which has undergone supervised training beforehand, we speculate this could be attributed to the limited size of the dataset, resulting in the models not having acquired robust capabilities yet. Additionally, the accuracy of "None" reaches highest at 0.79 in TEXT-DAVINCI-003 CoT-VDesc, which can be considered as an indicator of the reliability of the human evaluation guideline.

H Principal for Reliable Human Evaluation Guideline

A reliable human evaluation guideline is the beginning of reliable human evaluation. We provide the principal for composing a reliable human evaluation guideline in Table 13. For writing a reliable human evaluation guideline, researchers should provide explicit task definitions for raters and avoid biased instruction and prior knowledge assumptions. Moreover, the instruction should comprehensively cover a broad range of scenarios including the edge cases. Researchers should provide clear rating scale and criteria and make the instruction simple and flexible. Additionally, the potential ethical issues should be identified and addressed. It is highly recommended to attach examples and design a good user interface. Last but not least, remind annotators to be careful while carrying out their tasks to get more accurate evaluation results.

Vulnerability Detection in Human Evaluation Guidelines

Task Overview

Thank you for participating in this task! We are currently working on a project focused on crafting robust and reliable guidelines for human evaluation. You will be randomly presented with a human evaluation guideline extracted from existing papers or generated by Large Language Models (LLMs). Your job is to review the provided guidelines and identify potential vulnerabilities within the text. These vulnerabilities should fall into one or more of the eight categories outlined below.

Defect Types

Ethical Issues: instructions do not consider potential ethical implications related to the evaluation process, like privacy, cultural sensitivity, accessibility, or the potential misuse of the evaluation results.

- Ethical Issues: Evaluate the comments on this public social media post for sentiment analysis.
- Improved: Evaluate anonymized comments provided for sentiment analysis. All comments have been previously collected with user consent and have been stripped of personally identifiable information.

Unconscious Bias: instructions unconsciously favors or disadvantages certain results.

- Unconscious Bias: Evaluate the two systems A and B: How many points do you think system A is higher than system B?
- Improved: Evaluate the two systems A and B based on user satisfaction and score them respectively.

Ambiguous Definition: instructions for task definition are unclear, vague, or imprecise that can be interpreted in multiple ways.

- Ambiguous Definition:*Factual consistency of summarization* is defined as the accuracy and faithfulness of a summary in representing the source.
- Improved: *Factual consistency of summarization* is defined as the accuracy and faithfulness of a summary in representing the source. The *source* here usually has scenarios: the first is the input document and the second is common sense. In our task, we only focus on the first situation, i.e. evaluate the summary as factually inconsistent if it contains extra information of the input document,even though it is true facts.

Unclear Rating: instructions that lack standardized criteria for evaluating aspects or definition of each point on a rating scale, resulting in potential inconsistency in ratings.

- Unclear Rating: Rate the quality of the website.
- Improved: Rate the quality of the website based on its design, ease of navigation, and relevance of content on a scale of 1 to 5, where 1 is 'very poor' and 5 is 'excellent'. If the website was generally good but had one major flaw, consider rating it a 3or 4 depending on the severity of the flaw. If the website was poor but had one saving grace, consider rating it a 2 or 3.

Edge Cases: instructions do not specify how to handle edge cases or exceptional situations that don't neatly fit into the usual categories or criteria.

- Edge Cases: Evaluate the factuality error types in the summary, including: Hallucination Error, Entity Error, Particulars Error, Predicate Error, Coreference Error.
- Improved: Evaluate the factuality error types in the summary, including: Hallucination Error, Entity Error, Particulars Error, Predicate Error, Coreference Error. If the summary contains multiple errors, please list them all. If the error does not correspond to any of the above types, evaluate it as "Others".

Prior knowledge: instructions assume that evaluators have certain background knowledge or familiarity with a specific subject matter, tool, or principle.

- Prior knowledge: Evaluate the use of object-oriented programming (OOP) principles in the code.
- Improved: Evaluate the use of object-oriented programming (OOP) principles in the code. Check for the following aspects. If you are unfamiliar with these principles, please refer to https://baldur.gitbook.io/patters-and-best-practices/solid/oop-principles for more information."
  - Encapsulation:Object properties are hidden, and object properties need to be modified through object methods.
  - Inheritance:Subclasses can inherit the properties and methods of the parent class without redefining them.
  - Polymorphism: Polymorphism can be divided into static and dynamic. Static means that the same object can have different forms of expression, while dynamic means that a parent type can point to an instance of its subtype, making the subtype respond differently to the same method.
  - Abstraction:Abstraction refers to extracting the common attributes and behaviors of a class and storing them in a class, regardless of how the specific behaviors a rerealized.

Inflexible Instructions: instructions are unnecessarily complex or rigid, making it hard for evaluators to follow and incapable of adjusting to variations in data or task requirements.

- Inflexible Instructions:Evaluate the website's user interface design on a scale of 1 to 10, considering color aesthetics, balance between text and imagery, navigability, font choices,button placements, menu design, adherence to modern design principles, web page loading speed, and responsive design.
- Improved: Evaluate the website's user interface design on a scale of 1 to 10 from the perspectives of aesthetics, navigation and functionality.

Others: covers any vulnerabilities that do not fall into the above categories.

(Continued from previous page)

Annotation Procedure

- **Comprehension:** Carefully read through the entire human evaluation guideline in the center of the interface to get a full understanding of the content.
- **Labeling:** Identify and click all potential vulnerabilities within the guideline according to the eight defined categories: Definition Ambiguity, Bias, Assuming Prior Knowledge, Insufficient Coverage, Lack of Rating Scale, Lack of adaptability, Neglecting Ethical Implications and Others.
- **Review and Submit:** Repeat this process until the entire guideline has been thoroughly reviewed and all potential vulnerabilities have been identified. Press Enter to save and submit the annotation result.

Emphasis and Caution

- **Edge Cases:** Please note that a single guideline may contain more than one type of defect. In such scenarios,ensure to label all the appropriate defect types. If the defect does not fit any of the seven specific categories, classify it as "Others" and provide a brief explanation.
- **Daily Annotation Requirement:** The guideline for this task will be provided in batches. You are required to annotate a setof 30 items each day. Please submit the daily annotation results before 24:00(midnight) of that day.
- **Quality Assurance:** Each day, we will conduct a random inspection of the annotated data. If the accuracy rate falls below 80%, you will be required to re-annotate the data for that day. Please maintain high quality in your annotations.
- **Support and Reference:** If you encounter any confusion regarding professional knowledge or context while performing this task, please feel free to reach out to us for clarification.You may also refer to Wikipedia or other reliable sources to gain further understanding.
- **Feedback Mechanism:** Wehave set up a discussion board on the interface, where you can directly submit your queries, concerns, or suggestions through the button “click to comment on document”. This collaborative environment will allow for shared learning and problem-solving.

Examples of Defect Labelling

POSITIVE EXAMPLES

Guideline: Ensure you partake in a comprehensive interrogation of the quantifiable parameters that govern the efficacy of the experimental intervention under scrutiny, taking into account the numerous facets and intricate variables that contribute to the overall outcome, keeping in mind the statistical significance thresholds and the corresponding probability distributions. Your final judgement should be a synthesis of these insights, crystallized into a ranking that encapsulates the overall potency of the intervention in question.

Label: Assuming Prior Knowledge, Lack of adaptability, Lack of Rating Scale ✔

Explanation:

Assuming Prior Knowledge: The guideline contains terms and concepts such as"quantifiable parameters," "efficacy of the experimental intervention," "statistical significance thresholds," and"probability distributions". These terms assume the annotators process a prior knowledge in statistics or experimental design, which might make them struggle to understand and apply these instructions correctly without specific training or explanation of the professional background.

Lack of adaptability: The guideline requires the annotators to conduct a"comprehensive interrogation of the quantifiable parameters",considering "numerous facets and intricate variables", and also take into account "statistical significance thresholds" and"probability distributions". It’s quite strict and complex, leaving little room for adaptability depending on the experimental intervention being evaluated. The rigidness of these instructions can make it challenging for evaluators to apply them across a variety of scenarios or different types of interventions.

Lack of Rating Scale: The guideline suggests that the final judgement should be a"synthesis of these insights, crystallized into a ranking". However,it doesn’t provide any clear definition or structure for this ranking system.Without knowing how many points are on the scale or what each point represents,annotators might interpret the ranking system differently, leading to inconsistency in evaluations.

NEGTIVE EXAMPLES

Guideline: This task aims to evaluate the machine translation quality of two different models. You will be given one article and two corresponding translations from the two models in a random order. Your task is to evaluate the quality of the two translation and determine which one you prefer.

Label: Definition Ambiguity, Assuming Prior Knowledge ✗

Explanation:

The guideline does not contain "Definition Ambiguity" error since it has clearly stated the objective of the task. There’s no ambiguity about what the annotators are supposed to do, which leaves no room for misunderstanding about how the task is to be carried out. However, it falls under "Lack of Rating Scale" defect because the guideline doesn’t provide a specific rating scale or evaluation criteria that the annotators can use to objectively assess the translations. For instance, the guideline could instruct them to rate each translation on a scale of 1-5 for various aspects such as accuracy, fluency, and grammatical correctness, with clear descriptions of what each point on the scale signifies. Besides, the guideline does not has the defect of "Assuming Prior Knowledge". Evaluating the quality of a translation does not inherently require annotators has specialized knowledge about machine translation models, algorithms, or technical jargon. The expectation is that annotators can read and understand both the source and target languages, and are thus capable of judging the quality of the translation.

Table 7: Full instructions given to annotators of the vulnerability detection task in human evaluation guidelines.

[Requirement] = Identify whether the evaluation guideline contains any of the following vulnerabilities: "Ambiguous Definition", "Unconscious Bias", "Prior Knowledge", "Edge Cases", "Unclear Rating", "Inflexible Instructions", "Ethical Issues", "Others".

[Description] = The description of the vulnerabilities is as follows:
Ambiguous Definition: instructions for task definition are unclear, vague, or imprecise that can be interpreted in multiple ways.
Unconscious Bias: instructions unconsciously favors or disadvantages certain results.
Edge Cases: instructions do not specify how to handle edge cases or exceptional situations that don't neatly fit into the usual categories or criteria.
Unclear Rating: instructions that lack standardized criteria for evaluating aspects or definition of each point on a rating scale, resulting in potential inconsistency in ratings.
Prior Knowledge: instructions assume that evaluators have certain background knowledge or familiarity with a specific subject matter, tool, or principle.
Inflexible Instructions: instructions are unnecessarily complex or rigid, making it hard for evaluators to follow and incapable of adjusting to variations in data or task requirements.
Ethical Issues: instructions do not consider potential ethical implications related to the evaluation process, like privacy, cultural sensitivity, accessibility, or the potential misuse of the evaluation results.
Others: covers any defects that do not fall into the above categories.
[Constraints] = Only reply with the name of vulnerabilities or "None". Note that a guideline may contain more than one vulnerability.

[Guideline] = Human Evaluation Guideline: {guideline}

[CoT] = Let's think step by step.

[Examples] =
shot_1 = GUIDELINE: Factual consistency of summarization is defined as the accuracy and faithfulness of a summary in representing the source.
REQUIREMENT: Identify the guideline contain any of the following vulnerabilities: "Ambiguous Definition", "Unconscious Bias", "Prior Knowledge", "Edge Cases", "Unclear Rating", "Inflexible Instructions", "Ethical Issues", "Others".
ANSWER: Ambiguous Definition

shot_2 = GUIDELINE: You will be presented with one human-written reference summary first as well as three system summaries generated by trained neural networks respectively. Please evaluate the quality of opinion summaries with respect to the following 4 features: (1) Informativeness; (2) Faithfulness; (3) Consistence; and (4) Grammaticality.
REQUIREMENT: Identify the guideline contain any of the following vulnerabilities: "Ambiguous Definition", "Unconscious Bias", "Prior Knowledge", "Edge Cases", "Unclear Rating", "Inflexible Instructions", "Ethical Issues", "Others".
ANSWER: Ambiguous Definition, Unconscious Bias, Unclear Rating

shot_3 = GUIDELINE: You should make pairwise comparison for the summary evaluation to select the best and worst among them.
REQUIREMENT: Identify the guideline contain any of the following vulnerabilities: "Ambiguous Definition", "Unconscious Bias", "Prior Knowledge", "Edge Cases", "Unclear Rating", "Inflexible Instructions", "Ethical Issues", "Others".
ANSWER: Edge Cases

shot_4 = GUIDELINE: Evaluate the website's user interface design on a scale of 1 to 10, considering color aesthetics, balance between text and imagery, navigability, font choices, button placements, menu design, adherence to modern design principles, web page loading speed, and responsive design.
REQUIREMENT: Identify the guideline contain any of the following vulnerabilities: "Ambiguous Definition", "Unconscious Bias", "Prior Knowledge", "Edge Cases", "Unclear Rating", "Inflexible Instructions", "Ethical Issues", "Others".
ANSWER: Inflexible Instructions

shot_5 = GUIDELINE: Evaluate the use of object-oriented programming (OOP) principles in the code.
REQUIREMENT: Identify the guideline contain any of the following vulnerabilities: "Ambiguous Definition", "Unconscious Bias", "Prior Knowledge", "Edge Cases", "Unclear Rating", "Inflexible Instructions", "Ethical Issues", "Others".
ANSWER: Prior Knowledge

shot_6 = GUIDELINE: Evaluate the comments on this public social media post for sentiment analysis.
REQUIREMENT: Identify the guideline contain any of the following vulnerabilities: "Ambiguous Definition", "Unconscious Bias", "Prior Knowledge", "Edge Cases", "Unclear Rating", "Inflexible Instructions", "Ethical Issues", "Others".
ANSWER: Ethical Issues

shot_7 = GUIDELINE: Rate the quality of the website.
REQUIREMENT: Identify the guideline contain any of the following vulnerabilities: "Ambiguous Definition", "Unconscious Bias", "Prior Knowledge", "Edge Cases", "Unclear Rating", "Inflexible Instructions", "Ethical Issues", "Others".
ANSWER: Unclear Rating

(Continued from previous page)

[Examples_CoT] =

shot_1 = GUIDELINE: Factual consistency of summarization is defined as the accuracy and faithfulness of a summary in representing the source.
REQUIREMENT: Identify the guideline contain any of the following vulnerabilities: "Ambiguous Definition", "Unconscious Bias", "Prior Knowledge", "Edge Cases", "Unclear Rating", "Inflexible Instructions", "Ethical Issues", "Others".
Let's think step by step:
REASONING: The "source" here usually has scenarios: the input document or the common sense. The task definition of the guideline is unclear and imprecise that can be interpreted in multiple ways. So the answer is "Ambiguous Definition"
ANSWER: Ambiguous Definition

shot_2 = GUIDELINE: You will be presented with one human-written reference summary first as well as three system summaries generated by trained neural networks respectively. Please evaluate the quality of opinion summaries with respect to the following 4 features: (1) Informativeness; (2) Faithfulness; (3) Consistence; and (4) Grammaticality.
REQUIREMENT: Identify the guideline contain any of the following vulnerabilities: "Ambiguous Definition", "Unconscious Bias", "Prior Knowledge", "Edge Cases", "Unclear Rating", "Inflexible Instructions", "Ethical Issues", "Others".
Let's think step by step:
REASONING: This guideline does not clarify whether the task definition is to evaluate four summaries based on the source review or to evaluate three system summaries based on the reference, causing "Ambiguous Definition". It does not present the reference and generated summaries in a random order, causing participants to Unconscious Bias towards perceiving the reference as higher quality, result in "Unconscious Bias". It does not provide a detailed explanation of 4 rating aspects, leading to multiple interpretations for different evaluators, causing "Unclear rating". So the answer is "Ambiguous Definition", "Unconscious Bias", "Unclear Rating".
ANSWER: Ambiguous Definition, Unconscious Bias, Unclear Rating

shot_3 = GUIDELINE: You should make pairwise comparison for the summary evaluation to select the best and worst among them.
REQUIREMENT: Identify the guideline contain any of the following vulnerabilities: "Ambiguous Definition", "Unconscious Bias", "Prior Knowledge", "Edge Cases", "Unclear Rating", "Inflexible Instructions", "Ethical Issues", "Others".
Let's think step by step:
REASONING: The guideline does not provide guidance on how to handle the edge cases when two summaries have the same quality. So the answer is "Edge Cases"
ANSWER: Edge Cases

shot_4 = GUIDELINE: Evaluate the website's user interface design on a scale of 1 to 10, considering color aesthetics, balance between text and imagery, navigability, font choices, button placements, menu design, adherence to modern design principles, web page loading speed, and responsive design.
REQUIREMENT: Identify the guideline contain any of the following vulnerabilities: "Ambiguous Definition", "Unconscious Bias", "Prior Knowledge", "Edge Cases", "Unclear Rating", "Inflexible Instructions", "Ethical Issues", "Others".
Let's think step by step:
REASONING: The guideline is unnecessarily complex and rigid, making it hard for evaluators to follow and incapable of adjusting to variations in data or task requirements. So the answer is "Inflexible Instructions"
ANSWER: Inflexible Instructions

shot_5 = GUIDELINE: Evaluate the use of object-oriented programming (OOP) principles in the code.
REQUIREMENT: Identify the guideline contain any of the following vulnerabilities: "Ambiguous Definition", "Unconscious Bias", "Prior Knowledge", "Edge Cases", "Unclear Rating", "Inflexible Instructions", "Ethical Issues", "Others".
Let's think step by step:
REASONING: The guideline doesn't provide detail explanation of OOP principles which assumes that evaluators have certain background knowledge or familiarity with a specific subject matter, tool, or principle. So the answer is "Prior Knowledge"
ANSWER: Prior Knowledge

shot_6 = GUIDELINE: Evaluate the comments on this public social media post for sentiment analysis.
REQUIREMENT: Identify the guideline contain any of the following vulnerabilities: "Ambiguous Definition", "Unconscious Bias", "Prior Knowledge", "Edge Cases", "Unclear Rating", "Inflexible Instructions", "Ethical Issues", "Others".
Let's think step by step:
REASONING: The guideline does not specify the collected comments are anonymous or with user consent, disregarding the personal privacy of the commenters. So the answer is "Ethical Issues"
ANSWER: Ethical Issues

(Continued from previous page)

shot_7 = GUIDELINE: Rate the quality of the website.
REQUIREMENT: Identify the guideline contain any of the following vulnerabilities: "Ambiguous Definition", "Unconscious Bias", "Prior Knowledge", "Edge Cases", "Unclear Rating", "Inflexible Instructions", "Ethical Issues", "Others".
Let's think step by step:
REASONING: The guideline does not provide standardized criteria or definition for evaluation aspects or each point on a rating scale, which can lead to inconsistency in ratings. So the answer is "Unclear Rating"
ANSWER: Unclear Rating

(1) Zero-shot Prompt

Basic = **[Requirement]** + **[Constraints]** + **[Guideline]**

VDesc = **[Requirement]** + **[Description]** + **[Constraints]** + **[Guideline]**

CoT-Basic = **[Requirement]** + **[Constraints]** + **[Guideline]** + **[CoT]**

CoT-VDesc = **[Requirement]** + **[Description]** + **[Constraints]** + **[Guideline]** + **[CoT]**

(2) Few-shot Prompt

Basic = **[Requirement]** + **[Constraints]** + **[Examples]** + **[Guideline]**

VDesc = **[Requirement]** + **[Description]** + **[Constraints]** + **[Examples]** + **[Guideline]**

CoT-Basic = **[Requirement]** + **[Constraints]** + **[Examples_CoT]** + **[Guideline]**

CoT-VDesc = **[Requirement]** + **[Description]** + **[Constraints]** + **[Examples_CoT]** + **[Guideline]**

Principal for Human Evaluation Guideline
(a) Explicit Task Definition: Provide a concise and precise task description along with the evaluation aspects to preclude misinterpretation or confusion. Use clear language and avoid jargon or technical terms that may not be commonly known to all evaluators. **(b) Unbiased Instructions:** Ensure that all instructions and statements are free from any unconscious bias. Avoid favoring or disadvantaging certain results or approaches. Use neutral language and present the task in a fair and objective manner. **(c) Avoiding Prior Knowledge Assumptions:** Provide sufficient explanations regarding the subject matter, tools, or principles involved. Avoid assuming that evaluators are equipped with specific background knowledge. A good guideline is to make the content easily comprehensible, even for non-expert annotators. **(d) Comprehensive Coverage:** Formulate instructions that cover a broad range of scenarios, incorporating edge cases and exceptional situations that may not fit neatly into predefined categories or criteria. Clearly specify how evaluators should handle such cases and provide guidance on making informed judgments. **(e) Clear Rating Scale and Criteria:** Define a rating scale and provide a clear explanation of the evaluation criteria for each point on the scale. Ensure that evaluators comprehensively grasp the meaning and expectations associated with each rating level so as to promote consistency in ratings and minimize potential confusion. **(f) Simplicity and Flexibility:** Keep the instructions straightforward and easy to understand. Avoid unnecessary complexity or rigid requirements that may make it difficult for evaluators to follow or adapt to variations in data and task requirements. Provide room for reasonable judgment and adaptability within the evaluation process. **(g) Addressing Ethical Issues:** Identify and address potential ethical issues, including guidelines and safeguards, to ensure ethical considerations are upheld throughout the evaluation process. Consider privacy concerns, cultural sensitivities, accessibility requirements, and the potential misuse of evaluation results. **(h) Attach Examples:** It is highly recommended to list positive examples that contain the input presented to the worker or system, and the anticipated results, thus providing crowdworkers with a clearer comprehension of the task. Additionally, listing negative examples can effectively emphasize THINGS TO AVOID by supplying that should not be generated. **(i) Design a good user interface:** A good user interface provides a positive experience for annotators and the design needs to be tailored to the specific needs of the users. For non-expert crowdsourcing, *acquisition interfaces* can be developed to facilitate the execution of crowdsourcing tasks. While for those running the crowdsourcing project, *management interfaces* are required to monitor progress, assess quality, and manage annotators. **(j) Emphasize precautions:** In concluding the guidelines, remind annotators to be careful while carrying out their tasks and outline the annotation requirements, feedback mechanism, and quality assurance processes explicitly so that annotators can manage their time effectively and provide more accurate evaluations. Adherence to these principles facilitates the creation of a human evaluation guideline that is clear, fair, inclusive, and capable of producing reliable and meaningful results.

Table 13: Principal for reliable human evaluation guideline.

MOSAICo: a Multilingual Open-text Semantically Annotated Interlinked Corpus

Abstract

Several Natural Language Understanding (NLU) tasks focus on linking text to explicit knowledge, including Word Sense Disambiguation, Semantic Role Labeling, Semantic Parsing, and Relation Extraction. In addition to the importance of connecting raw text with explicit knowledge bases, the integration of such carefully curated knowledge into deep learning models has been shown to be beneficial across a diverse range of applications, including Language Modeling and Machine Translation. Nevertheless, the scarcity of semantically-annotated corpora across various tasks and languages limits the potential advantages significantly. To address this issue, we put forward MOSAICo, the first endeavor aimed at equipping the research community with the key ingredients to model explicit semantic knowledge at a large scale, providing hundreds of millions of silver yet high-quality annotations for four NLU tasks across five languages. We describe the creation process of MOSAICo, demonstrate its quality and variety, and analyze the interplay between different types of semantic information. MOSAICo, available at https://github.com/SapienzaNLP/mosaico, aims to drop the requirement of closed, licensed datasets and represents a step towards a level playing field across languages and tasks in NLU.

1 Introduction

There are two predominant schools of thought on how to integrate semantics into Natural Language Processing (NLP) systems. Most researchers lean towards the implicit integration of semantics through self-supervised language modeling (Devlin et al., 2019; Liu et al., 2019; Raffel et al., 2020; Lewis et al., 2020), a framework that proved to be successful in numerous language understanding benchmarks (Rajpurkar et al., 2016; Wang et al., 2019b,a). However, this approach – while conceptually straightforward and effective by scaling up the number of parameters – has raised concerns regarding its cost-effectiveness and environmental impact (Strubell et al., 2019; Geiping and Goldstein, 2022). Furthermore, the black-box nature of this approach has also prompted calls for a critical inquiry into whether the impressive results on language benchmarks genuinely reflect a system's comprehension of language (Bender et al., 2021; Ray Choudhury et al., 2022; Maru et al., 2022; Tedeschi et al., 2023).

Conversely, other researchers have advocated for the integration of discrete symbols into AI systems, which has recently been resurfacing under the umbrella term of "neuro-symbolic AI" (d'Avila Garcez and Lamb, 2020; Raedt et al., 2020). In NLP, discrete symbols can be used to represent word meanings, and graphs of symbols can be interpreted as sentence-level semantics. The integration of such explicit semantics into NLP systems may have the potential to address the aforementioned concerns (Navigli, 2018). Indeed, explicit semantics has been shown to be effective in reducing the number of parameters of neural networks and in improving the interpretability of their outputs. However, to the best of our knowledge, we still lack a critical enabler for training such approaches, namely, a vast, high-quality dataset annotated with symbolic knowledge.

To address this issue, we introduce MOSAICo, a novel resource designed to foster explorations and modeling of explicit semantics on an extensive scale and across multiple languages. With its hundreds of millions of silver annotations on Wikipedia sentences across 5 languages for 4 important NLU tasks – namely, Word Sense Disambiguation, Semantic Role Labeling, Semantic Parsing, and Relation Extraction – MOSAICo is a large, diverse, and

robust dataset that can bootstrap research on the integration of explicit semantics into NLP systems to train and evalute models. In addition, MOSAICo is also a tool for investigating the interaction between different types of symbols, structures, and semantics, as shown in Figure 1.

In this paper, we describe the construction of MOSAICo, which can save critical time and compute for future research, and show its effectiveness for training state-of-the-art systems on open data as opposed to the closed and copyrighted datasets that are traditionally used in the literature, which will aid in lowering the barrier for the development of next-generation systems. We also provide insights into the interaction between different NLU tasks, as diverse sources of semantic knowledge allow us to look at new opportunities enabled by the availability of a large, cross-lingual, semantically-tagged corpus. We hope MOSAICo will be a tool that facilitates deeper investigations of the intersection between natural language and explicit semantics, while also fostering analysis of the connection between different NLU tasks across languages.

2 Background and Motivation

This section briefly introduces the four semantic tasks we considered in MOSAICo, and further explains how our resource can help the research community. Due to space constraints and the extensive literature available for each task, we focus on the works that are within the scope of this paper.

Word Sense Disambiguation (WSD) aims at associating a word in context with the most suitable meaning from a predefined sense inventory (Navigli, 2009; Bevilacqua et al., 2021b). WSD is a challenging task for machines and humans, especially when using fine-grained sense inventories like WordNet (Miller, 1992). Nevertheless, grounding words to discrete senses can bring several benefits, including better Language Modeling (Levine et al., 2020; Barba et al., 2023), Machine Translation (Campolungo et al., 2022b), and lexical bias benchmarking in applications (Campolungo et al., 2022a). However, traditional datasets for WordNet-based WSD are limited in size, outdated, and mostly English-specific. Even though sense inventories are available for multilingual WSD, such as BabelNet (Navigli et al., 2021), creating high-quality training datasets for non-English languages is difficult (Pasini, 2020). MOSAICo aims to overcome two limitations in today's WSD: i) sense coverage, i.e., current English datasets provide limited coverage of the long tail of the sense distribution, and ii) multilingual coverage, i.e., the lack of high-quality annotations for non-English languages.

Semantic Role Labeling (SRL) is informally described as the task of answering "*who* did *what* to *whom*, *where*, *when*, and *how*?" (Màrquez et al., 2008). Given a sentence, SRL usually requires: i) predicate identification, i.e., finding all the words that denote an action; ii) predicate sense disambiguation, i.e., selecting the most appropriate sense for each identified predicate; iii) argument identification, i.e., detecting the text spans that represent the participants in the action; and, iv) argument classification, i.e., assigning a *semantic role* to each predicate-argument pair. The predicate senses and semantic roles used in SRL are defined according to an inventory of predicate-argument structures, e.g., PropBank (Palmer et al., 2005; Pradhan et al., 2022), FrameNet (Baker et al., 1998), or VerbAtlas (Di Fabio et al., 2019), among others. MOSAICo provides annotations using PropBank – due to its popularity – and VerbAtlas – due to its manual linkage to WordNet and BabelNet and its

cross-frame relations – and addresses three shortcomings of SRL: i) open data availability, i.e., popular datasets are not open (Carreras and Màrquez, 2004; Hajič et al., 2009; Pradhan et al., 2012), ii) multilingual coverage, i.e., limited availability of large multilingual datasets, and iii) cross-inventory annotations, i.e., data annotated with more than one type of predicate-argument structure inventory.

Semantic Parsing (SP) is the task of encoding the meaning of a sentence in a machine-interpretable structure (Kate and Wong, 2010). Since the focus of MOSAICo is on semantics, we direct our attention to formalisms that encode the abstract meaning of a sentence, such as AMR (Banarescu et al., 2013) and BMR (Navigli et al., 2022; Martínez Lorenzo et al., 2022). Thanks to recent advances (Bevilacqua et al., 2021a), modern SP systems can now be used with high accuracy. However, SP still suffers from issues similar to those in WSD and SRL, perhaps amplified by the extent of the manual effort required to annotate text with complex graphs. More specifically, the role of MOSAICo is to provide the first large-scale dataset of annotations for AMR in five languages with the aim of mitigating two problems in SP: i) shortage of open datasets in English but also in other languages, and ii) coverage, i.e., the lack of semantic parses for a broad range of domains.

Relation Extraction (RE) is the task of extracting semantic relationships between entities from unstructured text. Since MOSAICo is based on Wikipedia, we focus on relation types from Wikidata. While previous work has mostly focused on named entities (Roth and Yih, 2004; Riedel et al., 2010), equally important relations are also present between concepts. MOSAICo allows us to explore interactions between entities identified through Wikipedia hyperlinks, and, unlike previous efforts, concepts identified through WSD, so as to disambiguate the subject and object of a semantic relation from Wikidata. This enables the creation of a vast network of concepts and entities interconnected through semantic relations tied to their multilingual textual context. To leverage them, we will explore how many of these relations are already present in Wikidata and whether MOSAICo can provide new and reliable relation annotations. Therefore, MOSAICo provides for RE: i) wide-coverage extraction of relational triplets[1] connected to their lexical-semantic context, which was unfeasible without the interconnection with WSD at hand, ii) a novel way of augmenting Wikidata, and iii) multilingual coverage, i.e., addressing the limited availability of high-quality, high-recall, multilingual datasets for RE.

[1]We define a triplet as a tuple of three elements: a subject, an object, and the relation type that connects them.

3 MOSAICo

Our main objective with MOSAICo is to create a large collection of silver annotations on multilingual data. However, we believe that the value of MOSAICo does not only lie in the creation of annotations whose quality is comparable to gold-standard datasets. Indeed, while several groups may have the resources and expertise to reproduce similar efforts, we introduce MOSAICo to also address the following issues:

- Large silver datasets require compute: by making our resource available to the wider community, researchers can save more than 10 thousand GPU hours;
- Processing from scratch: even if compute were not a limitation, recreating a large dataset from scratch is not efficient and green;
- Common reference: the open availability allows our resource to be less affected by hidden implementation details;
- Task interaction: having uniform annotations for four types of task enables the analysis of possible inter-task interactions.

We now describe the creation process of MOSAICo, our novel resource of silver-quality annotations for modeling semantics at a large scale. We start with an outline of the data collection process (Section 3.1) and then detail how we produce the annotations (Section 3.2).

3.1 Data collection and preprocessing

We create MOSAICo by collecting documents from Wikipedia in five languages: English, French, German, Italian, and Spanish.[2] There are several reasons for choosing Wikipedia as the core of MOSAICo. First, Wikipedia is released under a permissive license. Second, Wikipedia is often already included as part of the pretraining corpus of modern language models (Devlin et al., 2019; Liu et al., 2019). Providing annotations for textual data that

[2]We use the Wikipedia dump released on June 13, 2022.

these language models have already used opens the door to easier future integration of explicit semantics into such models. Second, we aim to retain information about the provenance of each sentence, i.e., the Wikipedia article it belongs to and its position within the article. This design choice allows a user to connect and leverage annotations at the document level and for the same article across different languages.

Preprocessing. First, for each language, we retain only those Wikipedia articles that appear in all the five languages we consider. There are two main reasons for this selection strategy. First, we hypothesize that the larger the number of languages an article is written in, the greater must be the attention that the Wikipedia community has devoted to its creation. Second, forcing an article to be available in all five languages of interest makes MOSAICo "comparable" by design, i.e., fully parallel as regards the articles (concepts and entities) covered in each language, even if not parallel (i.e., only comparable) as regards the textual contents. Despite the above cross-lingual constraint, the filtering process still results in 440,000 articles per language. Finally, we preprocess each article using Stanza NLP[3] for sentence splitting, tokenization, lemmatization, and part-of-speech tagging. As shown in Table 1, MOSAICo contains millions of sentences and tokens across the five languages under consideration.

Since MOSAICo includes hundreds of thousands of articles for each language, we also identify a subset of these which includes those articles whose quality is higher than the average, i.e., the articles labeled as "good" or "featured" in at least one of the five languages by the Wikipedia community.[4] We name this subset MOSAICo Core.

[3] https://stanfordnlp.github.io/stanza/

[4] Wikipedia articles need to satisfy a set of strict quality requirements to be considered "good" or "featured".

3.2 Construction and annotation

We now describe how we annotated the collected texts across the four semantic tasks. One key aspect of the construction of MOSAICo is that producing a massive quantity of annotations, as can be seen in Table 2, is time-consuming. Therefore, an indirect contribution of MOSAICo is that its open availability can save thousands of hours of computation, enabling researchers to bootstrap their future work.[5]

Word Sense Disambiguation. We tag each document in MOSAICo using ESCHER, a state-of-the-art WSD model (Barba et al., 2021). ESCHER takes advantage of word sense definitions to better generalize on unseen patterns and inventories. This is a strong desideratum in our case, as Wikipedia features many words and senses that are not included in traditional training datasets (Miller et al., 1994; Pasini et al., 2021, SemCor, XL-WSD). We train ESCHER on SemCor and the WordNet Gloss Corpus (WGC) using `deberta-v3-base` for English and on the XL-WSD training datasets using `mdeberta-v3-base` for the other languages. We use BabelNet 5.1[6] (Navigli et al., 2021) as our default unified sense inventory to annotate in multiple languages.

Semantic Role Labeling. For SRL, we adopt Multi-SRL (Conia and Navigli, 2020), a state-of-the-art system for PropBank-style dependency- and span-based SRL. In this work, we focus on span-based SRL, as dependency-based formalisms are tied to syntax and, therefore, are more difficult to employ in downstream applications. Moreover, we leverage the mapping from PropBank to VerbAtlas frames created by Di Fabio et al. (2019) to train

[5] The annotation process of MOSAICo requires about 12 470 hours on Nvidia RTX 3090: 1050 for preprocessing, 1140 for WSD, 1600 for SRL, 5080 for SP, and 3600 for RE.

[6] https://babelnet.org

Multi-SRL to predict VerbAtlas-style labels as well, thus labeling each predicate using two inventories.

Semantic Parsing. For the English sentences, we leverage the state-of-the-art English AMR parser LeakDistill (Vasylenko et al., 2023),[7] which is an extension of the SPRING model (Bevilacqua et al., 2021a) – a popular system for AMR parsing (Bai et al., 2022; Martínez Lorenzo et al., 2023a; Lou and Tu, 2023; Gao et al., 2023). For the multilingual setting, we extend CLAP (Martínez Lorenzo and Navigli, 2024), an efficient implementation of SPRING. LeakDistill and CLAP are autoregressive models fine-tuned to "translate" natural sentences into linearized AMR graphs. To extend CLAP cross-lingually: i) we follow Blloshmi et al. (2020) and create a training corpus for French, German, Italian, and Spanish from the automatic translation[8] of the original English sentences in AMR 3.0 paired with the original (English) AMR graphs; then, ii) we fine-tune an mBART-based (Liu et al., 2020) instance of SPRING for each language.

Relation Extraction. For RE, we employ a two-step approach based on the mREBEL multilingual mBART-based RE system (Huguet Cabot et al., 2023) and the cRocoDiLe data extraction pipeline (Huguet Cabot and Navigli, 2021). In the first step, we perform inference on the corpus of MOSAICo using mREBEL to obtain the first portion of our annotated RE data. In the second step, we exploit the Wikipedia hyperlinks – along with their propagations[9] – and WSD annotations as sources of disambiguated entities and concepts. We extract the second portion of annotations by applying the cRocoDiLe pipeline which collects relational triplets from Wikipedia articles by leveraging the disambiguated entity and concept mentions and connecting them with the relations between them defined in Wikidata. Unlike previous work, we do not restrict this extraction to Wikipedia abstracts and extract the triplets from the entire pages. Finally, we remove false positives by utilizing an NLI-based Triplet Critic (Huguet Cabot et al., 2023).

4 Experiments and Results

To evaluate the quality of MOSAICo, we train a set of state-of-the-art models on our silver datasets for WSD, SRL, RE, and SP; then, we compare their results with those obtained by the same systems trained on gold datasets. Table 9 in the Appendix provides an overview of these benchmarks and resources in comparison to MOSAICo.

4.1 Word Sense Disambiguation

We evaluate the effectiveness of MOSAICo for WSD by testing ESCHER when trained under three different settings: i) using SemCor and WGC for English and the training datasets of XL-WSD for the other 4 languages (ESCHER$_{gold}$),[10] ii) using a randomly sampled subset of MOSAICo of the same size as the gold training sets (ESCHER$_{M\text{-}Ref}$), iii) using MOSAICo Core (ESCHER$_{M\text{-}Core}$), and iv) using a randomly sampled subset of MOSAICo Core of the same size as the gold training sets (ESCHER$_{M\text{-}Core\text{-}Ref}$).

Table 3 provides an overview of the results on ALL (Raganato et al., 2017), 42D (Maru et al., 2022), and XL-WSD test sets, which are the standard evaluation framework for WordNet-based WSD, a new multi-domain challenge set for rare senses, and the largest benchmark for multilingual WSD, respectively. As expected, ESCHER$_{M\text{-}Ref}$ and ESCHER$_{M\text{-}Core\text{-}Ref}$ do not achieve the same results as ESCHER$_{gold}$ (74.9 and 76.0 vs. 76.4 in F1 score averaged across all benchmarks), but we can see that the higher quality of MOSAICo Core leads to higher overall performance. When we move to the larger scale of the whole MOSAICo Core dataset, ESCHER$_{M\text{-}Core}$ improves over ESCHER$_{gold}$ in every test set and language (77.3 vs. 76.4 on average), confirming the quality of our WSD annotations.

Since WSD is not as computationally expensive as the other tasks, here we also analyze the difference in performance when training on MOSAICo Core compared to a random 10% of MOSAICo (ESCHER$_{M\text{-}10\%}$) and the entire MOSAICo (ESCHER$_{M\text{-}100\%}$). The last two rows of Table 3 show that ESCHER$_{M\text{-}Core}$ compares favorably against both ESCHER$_{M\text{-}10\%}$ and ESCHER$_{M\text{-}100\%}$, suggesting that MOSAICo Core features a good balance between size and quality. Finally, it is worth noting that, for the rare senses in 42D, coverage is the most important aspect, as ESCHER$_{M\text{-}100\%}$ outperforms both ESCHER$_{M\text{-}Core}$ and ESCHER$_{gold}$ (58.4 vs. 56.2 vs. 54.4, respectively).

[7] This model does not scale cross-lingually.

[8] We employ DeepL to obtain high-quality translations.

[9] We propagate links to the other mentions of the same entity as in Tedeschi et al. (2021).

[10] We note that the XL-WSD training datasets are silver-quality datasets and that we refer to them as *gold* just to be consistent with the naming convention of the other tasks.

	ALL EN	42D EN	XL-WSD DE	XL-WSD ES	XL-WSD FR	XL-WSD IT	Avg.
ESCHER$_{gold}$	81.0	54.4	83.2	77.5	84.3	78.2	76.4

Table 4: SRL results in terms of F1 score on the test sets of OntoNotes (ON5), PropBank Examples (PBE), and X-SRL. Top half: predicate sense disambiguation. Bottom half: argument labeling. Best results in **bold**.

4.2 Semantic Role Labeling

We assess the quality of the SRL annotations in MOSAICo by measuring their impact on Multi-SRL. Table 4 shows the results of Multi-SRL when trained on three sources of SRL annotations: i) OntoNotes 5.0, i.e., the most recent gold standard for PropBank 3 (Pradhan et al., 2022) and derived from CoNLL-2012, ii) a random subsample of the MOSAICo annotations of the same size as the gold training dataset (M-SRL$_{M\text{-}Ref}$), and iii) MOSAICo Core (Multi-SRL$_{M\text{-}Core}$).

We evaluate Multi-SRL trained using the above datasets on three benchmarks: on OntoNotes, which is a standard benchmark in the area, on PB-Examples (PBE), which is a comprehensive benchmark recently introduced by Orlando et al. (2023), and on X-SRL, a multilingual benchmark by Daza and Frank (2020). For each benchmark, we report the F1 score typically used in the literature, which combines the accuracy in predicate sense disambiguation with the F1 score on argument labeling.

On the OntoNotes test set, Multi-SRL$_{M\text{-}Core}$ achieves F1 scores in the same ballpark as Multi-SRL$_{gold}$ on predicate sense disambiguation (95.3 vs. 95.5 points) and argument labeling (87.0 vs. 87.3 points), even though we note that OntoNotes features different genres compared to MOSAICo Core.[11] This result acquires greater value if we consider that current datasets for SRL, such as OntoNotes, are closed-source. Instead, the open availability of MOSAICo can lift barriers for researchers looking for high-performance SRL systems, fostering future work on multilingual SRL.

PB-Examples is an out-of-domain benchmark constructed from the annotated examples in PropBank[12] and it enables us to also test the generalizability of an SRL system on verbal, nominal, adjectival, and adverbial predicates, especially the latter two types, which are not present in the OntoNotes training set. Thanks to the wide variety of text included in MOSAICo Core, Multi-SRL$_{M\text{-}Core}$ outperforms Multi-SRL$_{gold}$ in predicate sense disambiguation (82.6 vs. 80.7 in F1 score) and argument labeling (75.7 vs. 74.9 in F1 score) on PBE. To better understand how MOSAICo Core helps Multi-SRL, we conduct two fine-grained analyses on PBE. First, we split PBE by predicate type, i.e., verbal predicates, nominal predicates, and adjectival predicates. Here, we find that Multi-SRL$_{M\text{-}Core}$ generalizes better than Multi-SRL$_{gold}$ on the adjectival predicates, which are particularly challenging as they do not occur in the OntoNotes training set, achieving an absolute improvement of 11.0 (74.5 vs. 63.5) and 3.2 (59.5 vs. 56.3) points in F1 score on predicate sense disambiguation and argument labeling, respectively. Second, we analyze the results of Multi-SRL on those predicates whose ground-truth sense labels are "unseen" with respect to the OntoNotes training set, finding that Multi-SRL$_{M\text{-}Core}$ outperforms Multi-SRL$_{gold}$ by 7.0 (73.5 vs. 66.5) and 1.5 (69.4 vs. 67.8) points in F1 score on predicate sense disambiguation and argument labeling, respectively.

Finally, we find that Multi-SRL$_{M\text{-}Core}$ performs better than Multi-SRL$_{gold}$ in X-SRL, a benchmark that includes German, Spanish, and French: it achieves an average improvement of 0.8% (72.1 vs. 71.3) and 0.5% (72.8 vs 72.3) respectively in predicate disambiguation and argument labeling F1 across the 3 languages.

4.3 Semantic Parsing

For SP, we measure the efficacy of MOSAICo in text-to-AMR parsing by training our SP model in three different settings: i) the gold-standard training split of AMR 3.0 for English and on its translations for the other 4 languages (SPRING$_{gold}$), as

[11] For example, OntoNotes contains dialogues with informal writing, which are rare in the Wikipedia articles.

[12] Most of the predicate senses in PropBank come with a usage example. For example, PropBank provides the following example for *give.01*: [The executives]$_{ARG0}$ gave [the chefs]$_{ARG2}$ [a standing ovation]$_{ARG1}$.

	AMR3	TLP	Bio	AMR-4T			Avg.
	EN - ID	EN - OOD		DE	ES	IT	
SPRING$_{gold}$	**83.0**	81.0	60.5	**69.2**	**72.9**	71.6	73.0
SPRING$_{M\text{-}Ref}$	80.4	80.1	56.8	67.3	70.9	70.1	70.9
SPRING$_{M\text{-}Core}$	82.7	**81.4**	**62.0**	**69.2**	72.3	**72.9**	**73.4**

Table 5: Text-to-AMR results in terms of SMATCH score on the test set of AMR 3.0 (AMR3), The Little Prince (TLP), biomedical (Bio), and AMR 2.0 – Four Translations (AMR-4T). Best results in **bold**.

Model	CONLL04	NYT	ADE	Avg.
BART$_{gold}$	71.2	91.8	81.7	81.6
BART$_{REBEL}$	**75.4**	**92.0**	**82.2**	**83.2**
BART$_{M\text{-}cRoco}$	72.7	91.6	81.5	81.9
BART$_{M\text{-}Core}$	**75.4**	91.9	81.9	83.1

Table 6: RE results in terms of F1 score. Best in **Bold**.

explained in Section 3.2, ii) a random subsample of the MOSAICo annotations of the same size as AMR 3.0 (SPRING$_{M\text{-}Ref}$), and iii) the silver annotations from MOSAICo Core (SPRING$_{M\text{-}Core}$). We compare the results on the test sets of AMR 3.0 (LDC2020T02), the out-of-domain benchmarks of The Little Prince (TLP) and Bio AMR, and the multilingual test set of "AMR 2.0 – Four Translations" (LDC2020T07) in German, Italian, and Spanish. We use the well-established SMATCH metric (Cai and Knight, 2013) – which calculates the maximum overlap between two graphs – to evaluate the performance of the systems.

Table 5 presents the results in SP. Comparing SPRING$_{M\text{-}Ref}$ to SPRING$_{gold}$, we can see that, as in previous tasks, the model trained on the gold training dataset outperforms our baseline. However, similar to WSD and SRL, although the genres in MOSAICo Core and the test set of AMR 3.0 do not match, SPRING$_{M\text{-}Core}$ achieves results that are comparable to SPRING$_{gold}$ (82.7 vs. 83.0 in SMATCH score, respectively). Moreover, in out-of-domain benchmarks, due to its wide range of texts and domains, SPRING$_{M\text{-}Core}$ provides improvements over SPRING$_{gold}$ of 0.4 points on TLP (81.4 vs. 81.0), and 1.5 on Bio (62.0 vs. 60.5).

Finally, in the multilingual setting, SPRING$_{M\text{-}Core}$ and SPRING$_{gold}$ achieve results in the same ballpark for German (69.2 vs. 69.2), Spanish (72.3 vs. 72.9), and Italian (72.9 vs. 71.6). Interestingly, once again, since "AMR 2.0 — Four Translations" sentences are human translations of a portion of the AMR 3.0 test sentences, SPRING$_{M\text{-}Core}$ is evaluated in an out-of-genre setting, while SPRING$_{gold}$ in an in-genre one. These findings gain even more relevance considering that current training datasets for SP are closed-source.

4.4 Relation Extraction

The experimental setup for RE is different from the other tasks. While sense inventories can be shared across datasets, relation taxonomies differ among RE datasets, MOSAICo annotations, and more in general silver-standard resources for RE. Therefore our annotations cannot be used as direct training material to evaluate on gold corpora. For this reason the research community has relied on silver corpora to perform a first round of pretraining before fine-tuning models on a specific dataset and relation set (Yamada et al., 2020). In order to provide an extrinsic evaluation of the quality of the annotations in MOSAICo for the English language, we compare them with those used in REBEL (Huguet Cabot and Navigli, 2021) and design three different settings by pretraining BART with REBEL's same decoding scheme under i) the silver data provided by REBEL (BART$_{REBEL}$), equivalent to REBEL$_{pre-training}$ in the original paper, ii) MOSAICo Core's instances produced just with the cRocoDiLe pipeline on the Wikipedia hyperlinks as in REBEL annotation scheme (BART$_{M\text{-}cRoco}$), and iii) all the silver annotations in MOSAICo Core (BART$_{M\text{-}Core}$). As a reference, we include the performances of BART when trained only on each of the gold corpora (BART$_{gold}$). More specifically, we then evaluate the difference in performance on CoNLL04 (Roth and Yih, 2004), NYT (Riedel et al., 2010), ADE (Gurulingappa et al., 2012) datasets when further training any of the aforementioned pre-trained BART on these datasets. All results are reported as micro-F1 scores based on the labeled triplets, where a triplet is considered correct only if subject, object and relation type are correctly identified.

As we can see from the results in Table 6, BART$_{M\text{-}Core}$ and BART$_{REBEL}$ perform in the same ballpark, with the latter slightly outperforming the former, and both surpassing BART$_{gold}$. However, we highlight that BART$_{M\text{-}Core}$ is 66% smaller than BART$_{REBEL}$ (259,982 vs. 784,202 instances). We hypothesize that BART$_{M\text{-}Core}$ does not outperform BART$_{REBEL}$ due mainly to two reasons: i) the REBEL dataset differs from MOSAICo in its composition, as it is built only from Wikipedia lead sections and it features a different distribution of

	EN	IT	FR	DE	ES
ESCHER$_{gold}$	88.4	85.9	82.8	86.3	83.1

Table 7: F1 scores of ESCHER$_{gold}$ on Wiki-WSD.

relation types, which can be beneficial when transferring knowledge to smaller datasets used for evaluation, and ii) MOSAICo provides a higher density of triplets per training passage than REBEL (6.7 vs. 1.2), but the datasets used for evaluation are more similar to REBEL than MOSAICo (1.6 for ADE, 1.5 for CoNLL-2004, 1.7 for NYT). Moreover, when we compare the results of BART$_{M\text{-}cRoco}$ to those of BART$_{M\text{-}Core}$, we can see that, when the additional sources MOSAICo provides are dropped, performance decreases, reaffirming the importance of our work in providing an augmented annotation scheme that includes concepts and not only entities. Despite the slightly lower performance, a system trained on MOSAICo is able to extract more triplets per instance, and thanks to a larger annotation coverage, we believe it will enable richer RE systems to be built not just in English, but also in French, Italian, German and Spanish.

5 Insights and Opportunities

Here, we highlight the opportunities MOSAICo brings to interconnect the different types of knowledge captured by each semantic task.

MOSAICo is a test for multilingual WSD. Indeed, one feature often overlooked in Wikipedia is that, in each article, the first mention of a term has been manually hyperlinked to the corresponding Wikipedia article if it exists. Therefore, we can use the 1:1 mapping (Navigli et al., 2021) between Wikipedia and BabelNet to convert Wikipedia interlinks to BabelNet synsets and create Wiki-WSD, a large novel benchmark for multilingual WSD. For reference, we employ Wiki-WSD to evaluate ESCHER$_{gold}$, as shown in Table 7. Wiki-WSD is the largest available WSD benchmark for English, Italian, French, German, and Spanish, including almost 6.7 million crowdsourced sense-tagged instances compared to 14,166 instances in XL-WSD. While we stress that Wiki-WSD is restricted to nominal senses, we argue that, thanks to its large coverage, this benchmark can be employed for evaluating WSD systems, providing new insights into multilingual disambiguation, and for studying the interplay between different sense inventories.

Interconnecting WSD and SRL. A key step in SRL is that of predicate sense disambiguation, i.e., selecting the most appropriate "sense" for a predicate in context so as to make it possible to also assign appropriate semantic roles to each predicate-argument pair. We note that, in many respects, predicate sense disambiguation is equivalent to WSD. However, there has been little interest in interconnecting the two tasks and their linguistic inventories, perhaps due to a lack of parallel annotations for WSD and SRL. Instead, thanks to MOSAICo, we show that such an interconnection can open the door to interesting work. More specifically, we leverage the fact that VerbAtlas "senses" (more correctly, frames) are clusters of BabelNet synsets. Therefore, we convert each verbal synset predicted by ESCHER to a VerbAtlas frame and compare it to the frame predicted by Multi-SRL. Interestingly, although both systems report state-of-the-art results, the agreement is only 74%. A manual inspection reveals several classes of disagreement. The two simplest cases are when one of the two systems is wrong, i.e., there is either a *WSD error* or an *SRL error*. However, *part-of-speech errors* – which make the WSD and SRL predictions inevitably wrong – appear a non-negligible number of times, even though part-of-speech tagging is often considered a "solved" task, especially in English. Perhaps, most importantly, we observe *inventory errors*, i.e., predictions that are wrong by default because the inventory (e.g., BabelNet, VerbAtlas, or PropBank) does not include the correct answer among its possible options. It is clear that future work should aim at bridging not only the approaches, but also the inventories used in WSD and SRL.

Comparing structured data: SRL and SP. Since our SRL and SP annotations employ the same inventory – PropBank – we can leverage MOSAICo Core to investigate the relation between two different types of structured prediction, namely, the predicate-argument structures in SRL and the AMR subgraphs in SP. However, because AMR abstracts away from the sentence level, there is no direct relation with the words in a sentence, unlike SRL, which works at the span level. Therefore, in order to check the SRL-AMR overlap, we use the cross-lingual AMR sentence-graph aligner of Martínez Lorenzo et al. (2023b) to connect each AMR node to the respective sentence span. In the AMR graphs of MOSAICo Core, there are around 10M nodes tagged with a PropBank sense label. If

we compare the predicate lemmas found in these AMR graphs with those found in the SRL annotations of the corresponding sentences, we can observe a large overlap of around 5.6M predicate lemmas. It is interesting to note that SPRING and Multi-SRL agree on the sense labels of these predicates around 95.5% of the time. Among the rest of the predicates, we can attribute 3.2% of the disagreements to an annotation error by one of the two systems (or both). Instead, only 1.3% of the disagreements on the predicate sense can be attributed to differences in how SRL and AMR parses are constructed. Finally, we analyze the overlap between the semantic roles that appear in the AMR graphs and the SRL annotations, finding that 92.7% of these triplets are annotated with the same semantic roles by both SPRING and Multi-SRL. Given the strong ties between the SRL and SP annotations in MOSAICo, future work may explore leveraging their connection to produce cleaner annotations.

RE meets WSD. The combination of RE and WSD presents a unique opportunity for enriching relations. As outlined in Section 3.2, we produce a large portion of our RE annotations with the cRocoDile pipeline using the links to Wikidata in Wikipedia articles. However, by leveraging the mapping between BabelNet and Wikidata, we also enrich the RE corpora by combining the manual annotations provided by the Wikipedia community with the WSD annotations in MOSAICo. Compared to using only the Wikipedia links, using the WSD annotations results in the addition of more than 5 million triplets to MOSAICo Core, as highlighted in Table 8. Moreover, MOSAICo Core contains more commonsense annotated relational facts, i.e., triplets in which the subject and object are concepts, than those usually provided by a RE system, providing new opportunities for future research. Finally, the fact that nearly half of the relation triplets in MOSAICo Core originate from WSD validates our hunch on the presence and value of semantic relations, not only between entities but also between concepts (Martinelli et al., 2024).

New Wikidata annotations. MOSAICo is a source of new relational data and textual evidence. From the predictions portion of the annotation (see Table 8), there are triplets not yet present in Wikidata, which is known to be incomplete (Conia et al., 2023). For instance, there are 141,128 unique relational facts in the English version of MOSAICo Core that were not present in Wikidata at the time of the RE annotations (September 9, 2022). However, compared to a more recent Wikidata dump (December 30, 2022), that number is reduced to 140,568. This means 560 newly added relational facts were already present in MOSAICo. For example, the fact that Leonhard Euler (Q7604) had worked in the field (P101) of Graph Theory (Q131476) was added to Wikidata on November 7, 2022, and is annotated five times in MOSAICo Core despite not being present at annotation time.

		Predictions	cRocoDiLe	WSD	Total

Table 8: Number of triplets annotated in MOSAICo-Core. Triplets come from three sources: predicting new triplets using a RE system (predictions), interlinking Wikipedia text and Wikidata (cRocoDiLe), and leveraging WSD annotations (WSD). We also report the number of triplets after Triplet Critic filtering (Filtered).

6 Conclusion and Future Work

In this paper, we presented MOSAICo, the first effort in the field of NLU aimed at equipping researchers with the key ingredients for modeling symbolic semantic knowledge at a large scale. MOSAICo provides hundreds of millions of annotations in four NLU tasks across five languages, filling a crucial gap in the availability of semantically-tagged corpora. After describing the creation process of MOSAICo, we analyzed the interplay between different sources of semantic information and provided insights into how they can be combined to bring different types of explicit knowledge together. Finally, we demonstrated the quality of the annotations in MOSAICo, which can improve the performance of state-of-the-art systems across standard benchmarks, showing its value for the research community. We release MOSAICo to the community, allowing future work to drop the requirement of licensed datasets and making research in this area accessible to a wider community.

Limitations

Here we discuss some of the limitations of our work, hoping not only to address them but also to encourage future work on top of ours.

Manual evaluation. Although some proxy results do confirm the quality of MOSAICo – for example, the performance of the systems trained on MOSAICo and tested on standard benchmarks (Section 4) – we did not evaluate the annotations directly. Performing such a manual effort would have been too expensive, especially when we consider that MOSAICo's annotations span across 5 languages and 4 different tasks. However, after conducting a qualitative analysis of the annotations, we found them to exhibit promising quality. This is evident, for example, when comparing them to the user annotations in Wikipedia, which confirms their effectiveness in WSD, as shown in Table 7. Overall, we believe that a human evaluation would be a valuable contribution and bring deeper insights into problems and challenges of each task. However, such a wide-range annotation process would require annotators trained on several tasks and languages, and a large budget. We would also need to include redundant annotations in order to mitigate issues like inter-annotator agreement, which is notoriously hard for these tasks. For instance, most SemEval tasks in WSD concern the manual annotation and validation of only 1000-2000 items, still involving considerable work in one or a few languages for a single task. We think that creating such a gold standard would merit a paper in itself.

Missing languages and tasks. While we believe that the multilingual nature of MOSAICo already provides a valuable foundation for cross-lingual studies, we recognize the desire to expand the language coverage of MOSAICo to include a broader range of languages. Furthermore, we strongly believe that the more semantic tasks we add to MOSAICo, the greater will be the opportunity to study possible intersections between them. For this reason, we designed MOSAICo as an ever-growing resource and will continue to update it by adding new tasks and languages.

Wikipedia. Despite the numerous advantages of utilizing Wikipedia as the underlying corpus for our resource, it is important to acknowledge certain limitations inherent to this choice. Two notable drawbacks are the topics discussed and the descriptive/encyclopedic writing style found in Wikipedia articles, which may introduce inherent biases and thus impact the generalizability of our resource to other domains or genres (Navigli et al., 2023). However, we would also like to note that the benchmarks that we use to evaluate the systems include out-of-domain sets as well. The results on these test sets suggest that training a system on MOSAICo's annotations actually brings improvements in the generalization capabilities of the system.

Another limitation is the relatively low coverage of low-resource languages within Wikipedia. Although Wikipedia contains vast amounts of information in multiple languages, there is an inherent bias towards languages with larger speaker populations, or those with more active contributors. Consequently, the availability and depth of annotations for low-resource languages may be limited.

Acknowledgments

The authors gratefully acknowledge the support of the ERC Consolidator Grant MOUSSE No. 726487, the PNRR MUR project PE0000013-FAIR, the CREATIVE project (CRoss-modal understanding and gEnerATIon of Visual and tExtual content), and the Marie Skłodowska-Curie project *Knowledge Graphs at Scale* (KnowGraphs) No. 860801 under the European Union's Horizon 2020 research and innovation programme.

Simone Conia and Edoardo Barba are fully funded by the PNRR MUR project PE0000013-FAIR. While working at Babelscape, Abelardo Carlos Martínez Lorenzo and Pere-Lluís Huguet Cabot were funded by KnowGraphs. Babelscape also funded the dataset translation work. CREATIVE is funded by the MUR Progetti di Ricerca di Rilevante Interesse Nazionale programme (PRIN 2020). We acknowledge the CINECA awards IsCa5_WSP and IsCa5_WRE under the ISCRA initiative for the availability of high-performance computing resources and support.

A MOSAICo: Construction and Annotation

Here we provide more details on the systems that we used to create MOSAICo. More specifically, for each task, we have selected a system among the ones that are considered to be state-of-the-art, trained it from scratch, and used it to annotate Wikipedia. In the following, we provide the training details of the systems used for WSD, SRL, SP, and RE.

Word Sense Disambiguation. We used ESCHER (Barba et al., 2021) to tag MOSAICo with word senses since it is a state-of-the-art system that takes advantage of word sense definitions to better generalize on unseen patterns and inventories. We train every model using AdamW with 5000 warmup steps and for a total of 100 000 steps with a learning rate of 10^{-5} and a batch size of 4096 tokens. For English we follow the training splits described in Raganato et al. (2017), for all the other languages we follow the splits described in the XL-WSD framework.

Semantic Role Labeling. We used Multi-SRL (Conia and Navigli, 2020) to tag MOSAICo with predicate-structure inventories. Multi-SRL is a state-of-the-art system for SRL with strong performance in multilingual settings. We train every model using AdamW with a peak learning rate of 10^{-5}, 10 000 warmup steps, and a linear decay to 10^{-6} for the learning rate for 20 epochs. In every configuration, we train a model on English data from OntoNotes 5 and rely on the cross-lingual transfer capabilities of its underlying language model, i.e., XLM-RoBERTa-base to tag SRL annotations in non-English languages.

Semantic Parsing. We used LeakDistill (Vasylenko et al., 2023) to tag MOSAICo with predicate-structure inventories in English. LeakDistill is a state-of-the-art system for English AMR parsing. For the multilingual settings, we extend the efficient implementation of SPRING, CLAP (Martínez Lorenzo and Navigli, 2024), following Blloshmi et al. (2020). We train every model using Adafactor with a peak learning rate of 10^{-4}, 500 warmup steps, and a batch size of 2048 tokens.

Relation Extraction. We used mREBEL (Huguet Cabot et al., 2023) to tag MOSAICo with triplets as part of the RE annotation process along the Crocodile pipeline. mREBEL is an mBART-based version of REBEL (Huguet Cabot and Navigli, 2021), which reframes the RE task as a seq2seq problem by decoding a linearized version of the triplets. Similarly, to enable comparisons with REBEL on English benchmarks, we train our RE models on top of BART-large, using the same settings as the original paper for both pretraining, (1000 warmup steps) and finetuning on target datasets (10% steps warmup) with 10^{-5} peak learning rate and 32 batch size.

Abstract

Language models (LMs) are indispensable tools for natural language processing tasks, but their vulnerability to adversarial attacks remains a concern. While current research has explored adversarial training techniques, their improvements to defend against word-level attacks have been limited. In this work, we propose a novel approach called Semantic Robust Defence (SemRoDe), a Macro Adversarial Training strategy to enhance the robustness of LMs. Drawing inspiration from recent studies in the image domain, we investigate and later confirm that in a discrete data setting such as language, adversarial samples generated via word substitutions do indeed belong to an adversarial domain exhibiting a high Wasserstein distance from the base domain. Our method learns a robust representation that bridges these two domains. We hypothesize that if samples were not projected into an adversarial domain, but instead to a domain with minimal shift, it would improve attack robustness. We align the domains by incorporating a new distance-based objective. With this, our model is able to learn more generalized representations by aligning the model's high-level output features and therefore better handling unseen adversarial samples. This method can be generalized across word embeddings, even when they share minimal overlap at both vocabulary and word-substitution levels. To evaluate the effectiveness of our approach, we conduct experiments on BERT and RoBERTa models on three datasets. The results demonstrate promising state-of-the-art robustness.

1 Introduction

Basic deep learning models are not inherently robust. This issue has been illustrated in numerous studies pointing to structural problems such as dataset shift (Moreno-Torres et al., 2012) and the prevalence of adversarial attacks (Chakraborty et al., 2018). Particularly in the context of natural language research, adversarial attacks are generated by introducing small perturbations either at the character, word, or sentence level of a textual input while maintaining the meaning, semantics, and grammar of the sentence. The development of robust systems is therefore of paramount importance for a multitude of reasons. Notably, content filters in need of detecting offensive language may be misled into classifying negative content as positive. Furthermore, in the realm of language model learning, adversarial attacks can successfully circumvent content moderation pipelines, prompting harmful content generation which can severely impact individuals and society.

With the accelerating popularity of LLMs and applications, there has been an urgency for robustness research.

There is a small, underexplored body of work that has proposed the merger of an adversarial distribution with the original distribution to improve a model's adversarial robustness. Preliminary and promising results have emerged when implementing a theoretical solution based on base-adversarial alignment in the form of domain adaptation in the image domain (Song et al., 2018; Bouniot et al., 2021).

Inspired by these findings, we initially expand on their hypothesis, demonstrating how a domain adaptation solution may have limitations. However, we maintain the central idea that aligning the base and adversarial features can lead to robust results and explore the validity of this theory in the discrete language domain.

We further refine this approach by formulating a solution that aligns more closely with previous work in adversarial robustness, making it more relevant to the language domain. Through this process, we demonstrate state-of-the-art performance across a variety of models and datasets, thereby advancing the cause of improving adversarial robustness in the discrete language domain.

Proceedings of the 2024 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies (Volume 1: Long Papers), pages 8005–8028
June 16-21, 2024 ©2024 Association for Computational Linguistics

The following points summarize the major contributions of our research:

- We demonstrate that adversarial samples introducing word substitutions (Yoo and Qi, 2021; Jin et al., 2019) lead to unwanted distributions in feature space (Figure 2), resulting in a high Wasserstein distance between base and adversarial features (Figure 3). We propose a solution through a regularizer that reduces the distance between a base and adversarial domain, aiding the formulating of a representation robust to potential attacker projections.

- We explore the function of distance-based regularizers in aligning the base and adversarial language domains. The effectiveness of feature alignment in enhancing robustness is evidenced in our distribution-oriented modelling approach, which shows strong generalization against various attack algorithms.

- Lastly, our work shows competitive performance across multiple datasets and models, offering preliminary findings on the usage of diverse distance regularizers to accomplish distribution alignment. This includes regularizers such as Maximum Mean Discrepancy (MMD), CORrelation ALignment (CORAL), and Optimal Transport. Our code is publicly available[1].

2 Related Work

Attacks on NLP systems On the front of adversarial attacks, recent work has developed methods to attack NLP systems. These methods firstly generate substitution candidates by removing, swapping, or adding letters/punctuation (Ebrahimi et al., 2018; Eger and Benz, 2020; Eger et al., 2019; Formento et al., 2021) or finding word candidates around the ℓ_2 (Sato et al., 2018; Barham and Feizi, 2019) or convex hull (Dong et al., 2021) of the word embedding space. These word candidates can be general word substitutions (Li et al., 2019), synonyms (Jin et al., 2019; Li et al., 2020; Ren et al., 2019), sememes (Zang et al., 2020), or grammatical inflections (Tan et al., 2020). The substitution candidate after that is expected to preserve a certain level of semantic structure, which is often enforced with the Levenshtein distance (Gao et al., 2018) or through the use of a semantic encoder, (Cer et al., 2018; Reimers and Gurevych, 2019). These candidates can then be applied to the base sentence in a black-box, gray-box, or white-box setting. The black-box setting uses no information from the victim's system. In the gray-box settings, some information from the model is used, such as the output logit or label. In the white-box setting, all model information is available, including weights. In the case of the gray-box setting, such character or word changes can result in a successful perturbation when performing convex optimization over the input by replacing the original letter or word with the potential change and analyzing the logit or label. This optimization problem is often solved using greedy search (Jin et al., 2019), with genetic algorithms (Alzantot et al., 2018), or particle swarm optimization (Zang et al., 2020). On the contrary, white-box attacks leverage gradient and parameters information from the model to inject a δ in the embedding space, rather than the input space.

Defence methods Research into the generation of adversarial samples can subsequently contribute to enhancing model robustness through adversarial training, early efforts in adversarial training in NLP included the adversarial examples back into training by including the adversarial samples in the batch (Jin et al., 2019). More recently, these strategies have been refined (Yoo and Qi, 2021). Alternatively, it is possible to extend the original objective by adding an adversarial regularizer, similar to how adversarial training is performed in the image domain (Goodfellow et al., 2014; Miyato et al., 2016; Madry et al., 2017; Wu et al., 2023). Building upon this line of work, embedding perturbation methods such as FreeLB (Zhu et al., 2020), ASCC (Dong et al., 2021), InfoBERT (Wang et al., 2021), DSRM (Gao et al., 2023) and FreeLB++ (Li et al., 2021), leverage the model's gradient to apply a perturbation within the continuous embedding space via projected gradient descent. This perturbation is constrained by a specified norm, such as the L2 norm (Sato et al., 2018; Barham and Feizi, 2019), or maintained within the confines of a convex hull (Dong et al., 2021). Additionally, some approaches only induce perturbation when the loss falls below a predefined threshold (Liu et al., 2022). These adversarial training schemas result in a min-max game between the base and adversarial objectives, forcing the model to learn

[1] https://github.com/Aniloid2/SemRoDe-MacroAdversarialTraining

both datasets.

More recently, defense techniques originating from the off-manifold conjecture in images have been adapted for the NLP context (Nguyen and Tuan, 2022). Additionally, a detector (Mosca et al., 2022) and an encoder (Wang et al., 2019) for adversarial samples have been proposed. On the other hand, it is also feasible to train an anomaly detector to identify word substitutions (Bao et al., 2021) or adversarial sentences (Shen et al., 2023). The primary drawback of these methods is the need to incorporate extra components into the pipeline, either before or after inference, resulting in additional computational load. A different line of work demonstrated that enhancing the robustness of attention-based models to adversarial attacks can be achieved by aligning the distributions of the keys and queries (Zhang et al., 2021). Adversarial training can be effectively utilized to defend against word-level attacks without introducing extra computational overhead. There are also several works exploring certified robustness for NLP systems but these methods remain hard to scale to large models (Jia et al., 2019; Ye et al., 2020; Zhao et al., 2022; Wang et al., 2023c). A comprehensive benchmarking of adversarial defense methods (Li et al., 2021) concluded that FreeLB++ performs the best; it employs embedding perturbations to acquire robust invariant representations. FreeLB++ is the state-of-the-art technique, together with DSRM to improve general robustness, while we identify A2T as being the state-of-the-art technique to improve robustness through adversarial data augmentation. FreeLB++, is confined to exploring the embedding space, while A2T is able to explore the full semantic space.

3 Background

3.1 Overview

We consider the setting of a sequence classifier, composed of a base model f_θ^{base} whose output is pooled f_θ^{pool} and then fed into a classifier head f_θ^{cls} resulting in $f_\theta : t(\mathcal{X}) \mapsto \mathcal{Y}$, that takes an input embedding $\mathbf{X} \leftarrow t(x)$. Where the input sequence of words $x = (\tau_1, \ldots, \tau_n) \in \mathcal{X}$ with the ground truth label y and outputs a prediction $\hat{y} = f_\theta(t(x))$ are first parsed through tokenizer t. An adversarial attack with algorithm g on input x and classifier f_θ would perturb τ, for example, using character manipulations or word substitutions, to produce a new adversarial sample $\hat{x}$ that is misclassified by f_θ such that $f_\theta(t(\hat{x})) \neq y$, the sample, can then be validated for linguistic characteristics with d.

3.2 Adversarial training

The objective of adversarial training in NLP is to minimize the high-risk regions in the continuous space around an input sample's word embeddings, while constraining the search area with a bound (Zhu et al., 2020). Adversarial training is formally defined as follows:

$$\min_\theta \mathbb{E}_{\{x,y\}\sim D} \max_{||\delta||\leq\epsilon} \mathcal{L}(f_\theta(\mathbf{X}+\delta), y) \quad (1)$$

Here, D represents the data distribution, $\mathbf{X}$ represents a tensor of word embeddings, where $\mathbf{X}$ is the embedding representation of all input tokens, and δ represents a perturbation. The aim of adversarial training is to minimize the regions of high risk around embedding $\mathbf{X}$ with a bound delta (Zhu et al., 2020). The constraint is usually the ℓ_2 norm around the embedding. However, previous research has explored other bounds, such as the convex hull (Dong et al., 2021).

3.3 Base domain

In adversarial training the original, unperturbed samples $\mathcal{X} \mapsto \mathcal{Y}$ originate from a base domain. We expand this notion to distinguish between the base/adversarial domain in the input/linguistic space and the feature space. Firstly $\mathcal{X}_B \triangleq \{\mathbf{x} \mid \mathbf{x} \text{ is a sample from base input domain}\}$ then $H_\mathbf{X}^B \triangleq f_\theta^{pool}(t(\mathcal{X}_B)) = \{f_\theta^{pool}(t(x)) \mid x \in \mathcal{X}_B\}$ where $H_\mathbf{X}^B$ is the feature distribution of the samples from the base domain. Assume, inline with previous work (Song et al., 2018), the base domain $\mathcal{X}_B$ follows a multivariate normal distribution $\mathcal{X}_B \sim \mathcal{N}(\mu_{\mathcal{X}_B}, \Sigma_{\mathcal{X}_B})$

3.4 Adversarial domain

A new perturbed sample $\hat{x}$ is obtained by adding a perturbation δ with strength controlled by maximize value ϵ to the original sample x, i.e., $\hat{x} = x+\delta$ and $|\delta| \leq \epsilon$. To obtain more real perturbation samples for NLP task, we control the perturbation strength through a controller g, which is an abstraction of an attack algorithm, such as TextFooler, and perform the verbatim perturbation. Our assumption is that the NLP classification model works, as it captures the semantics of the data and uses that to make a decision.

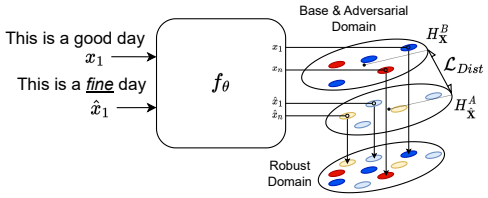

Figure 1: The statistical components are aligned in both the base and adversarial domain through the regularizer $\mathcal{L}_{Dist}$. Over time. This alignment allows the model f to project both base and adversarial samples to a robust domain, thus enhancing the robust generalization to adversarial samples.

As we do an adversarial perturbation on sample x, this perturbation will introduce a covariate shift to the original sample, dataset or distribution. This will make the distribution bimodal on one class instead of the expected single smooth distribution as illustrated in Figure 1 where a perturbation in the input leads to the sample being projected onto a different domain $H^A_{\hat{\mathbf{X}}}$. Where $H^A_{\hat{\mathbf{X}}}$, at times also denoted as $H^B_{\mathbf{X}+\delta}$, is the feature distribution of the samples from the adversarial domain. In our setup, after these samples have been passed through f^{pool}_θ, they will be projected in an adversarial domain. Therefore, in our setup, $\mathcal{X}_A \triangleq \{\hat{x} \mid \hat{x}$ is a sample from adversarial input domain$\}$ and $H^A_{\hat{\mathbf{X}}} \triangleq f^{pool}_\theta(t(\mathcal{X}_A)) = \{f^{pool}_\theta(t(\hat{x})) \mid \hat{x} \in \mathcal{X}_A\}$. Assume the adversarial domain $\mathcal{X}_A$ follows a multivariate normal distribution $\mathcal{X}_A \sim \mathcal{N}(\mu_{\mathcal{X}_A}, \Sigma_{\mathcal{X}_A})$

Domain alignment methods Paraphrased samples, generated by substituting words, result in a significant distributional shift in the high-level representation space within the later layers of the model. Therefore, the distances between the two distributions at the f^{pool}_θ layer will be high, as shown in Figure 3. When t-SNE is applied to the output features after f^{pool}_θ, there are k clusters, half of which originate from the base samples while the other half from the adversarial samples (Figure 2). The objective is thus to minimize these mean and covariance distances of the high-level features, so that only $k/2$ clusters remain, this would mean the adversarial and base samples are perfectly aligned in the feature space. The aim is to prevent adversarial samples from being projected within the adversarial feature distribution created by the model, and instead, have them projected onto a new robust feature distribution. To achieve this, we explore approaches to align feature spaces, ensuring that features from adversarial samples more accurately represent features from base samples.

Commonly-used methods for measuring distance in the feature space and perform feature alignment include Maximum Mean Discrepancy (MMD), Optimal Transport (OT), and CORrelation ALignment (CORAL). MMD measures distributional differences through the mean of feature representations, OT calculates the optimal transformation cost, and CORAL aligns second-order statistics. MMD is straightforward but sensitive to kernel choices. OT captures fine-grained differences but can be computationally demanding. CORAL is simple and efficient but may not capture all aspects of distributional discrepancy.

4 Methodology

Embedding robustness, as described by (Zhu et al., 2020), is a concept whereby a model is considered robust if it can maintain low risk within regions encircling a specific embedding $\mathbf{X}$. Adversarial training and gradient ascent methodologies are applied directly to word embedding by prominent techniques such as (Zhu et al., 2020; Madry et al., 2019), in an effort to accomplish this. However, these methods display limitations in sustaining this robustness. These restrictions occur due to the model being bound by ϵ. Transgression beyond this ϵ limit incites undesirable word substitutions (Table 3).

Notably, this presents a hurdle, since the majority of word-level attacks, not having access to the input word embeddings or gradients, conduct heuristic optimization on the input sample. Each word often has N substitution candidates. Therefore, they employ word substitutions to introduce a δ into a sentence (see Figure 4 in the Appendix), thus often exceeding the ϵ restriction. This allows such attacks to explore regions in the semantic space that the victim's model has not previously seen.

Consequently, our research involves the direct utilization of existing attack algorithms to generate the adversarial data intended for training. Subsequently, we scrutinize the extent to which our training approach shows generalization when faced with different attack algorithms employed by an attacker.

4.1 Perturbations

In our work, we address the saddle problem in the following manner. Firstly, we adopt a dynamic δ

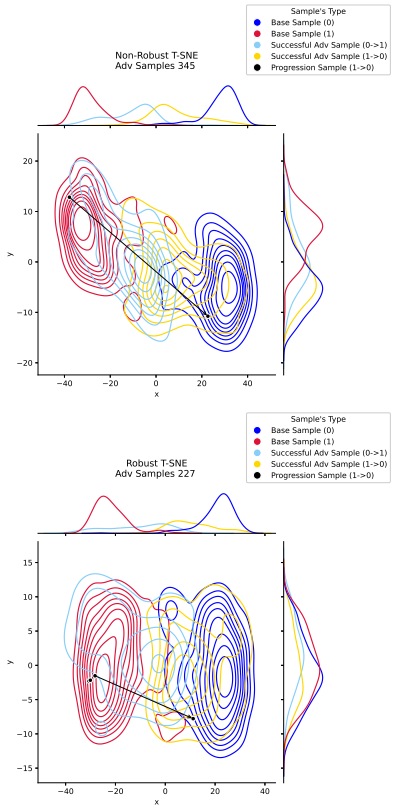

Figure 2: **The distributions of the MR training dataset with t-SNE projection in a binary classification task.** Heavy overlapping (Top) of the augmented two-class data leads to mixtures of marginal distributions, which is alleviated and nearly linearly separable (Bottom) after applying alignment between the original and augmentation distributions.

that is tailored for a specific word substitution pair. This delta is determined by a word substitution algorithm, denoted as g. The sample is preserved only if it complies with quantitative quality standards set by d. Rather than maximizing the loss, we minimize the classification confidence. This strategy aligns better with the adversarial objective commonly employed in most NLP adversarial attacks. The process of creating adversarial samples with g and minimizing the classification confidence inherently maximizes the distance between the base and adversarial domain. We theorize that this divergence is significantly larger than in the image domain, or when introducing small deltas in the embedding space, mainly because word substitutions contribute to a large δ. This domain distance can be summarized by computing a loss value with distance-measuring techniques like MMD or CORAL. (See Appendix A, F for further details)

4.2 Perturbation alignment

Through empirical analysis, we found that multiple perturbed samples tend to construct new distributions in the feature space. This presents an issue as the classifier component, modelled on the original distributions, continues to function based on them. This phenomenon is depicted in Figure 2 (top and bottom), where base samples are characterized by blue and red distributions, and adversarial samples by cyan and yellow distributions. We explain this phenomenon by the presence of a hypothetical base and adversarial distribution over the feature space ($H^B_{\hat{\mathbf{X}}}$ and $H^A_{\hat{\mathbf{X}}}$) which we give empirical evidence of existing through the Wasserstein distance in Figure 3. Our aim is to employ a regularizer during training that brings the distribution closer and hereby aligns the domains into a robust domain (Figure 1). This will enable the classifier to effectively function on both the adversarial (which will no longer be adversarial) and base samples. As shown in Figure 2 (bottom), this is demonstrated by the smoother distributions and a reduction in the number of samples in both the cyan and yellow distributions (since an additional 118 samples are classified correctly by the robust model and now fall in the red and blue distributions). The macro component seeks a representation that remains invariant to alterations from δ at the distribution level. We model this with the following $\mathcal{L}_{Dist}(H^B_{\mathbf{X}}, H^B_{\mathbf{X}+\delta})$.

$$\min_{\theta} \mathbb{E}_{\{x,y\}\sim D}\Bigg[\underbrace{\mathcal{L}(f_\theta(\mathbf{X}, y))}_{\text{for accuracy}} + \max_{d(\mathbf{X},g(\mathbf{X}+\delta))\leq\epsilon} \underbrace{\mathcal{L}_{Dist}(H^B_{\mathbf{X}}, H^B_{\mathbf{X}+\delta})}_{\text{for robustness}}\Bigg] \tag{2}$$

In equation 2, $H^A_{\hat{\mathbf{X}}} = H^B_{\mathbf{X}+\delta}$ represents the distribution from the base domain that has been perturbed with δ, and $H^B_{\mathbf{X}}$ denotes the distribution from the base domain itself.

4.3 Aligned semantic robust NLP model

Our first objective is the further finetuned model on the target dataset, that anchors the performance of the model when no adversarial objective is present. It is defined by a loss function when doing inference with x and y. In our experiments, we use the cross entropy loss. The second (Macro) objective formulate the classical saddle point problem commonly found in adversarial training. The second

objective employs a distance computation between the representations of the model undergoing base inference and the representations of the mode undergoing adversarial inference.

$$\mathcal{L} = \mathcal{L}_{Base} + \lambda \mathcal{L}_{Dist} \quad (3)$$

Where λ controls the strength associated with the distance regularizer.

4.4 Approximating $\mathcal{L}_{Dist}$ (Macro)

There are various methods available for modeling $\mathcal{L}_{Dist}$. The use of a parametric distance measure, such as the Kullback-Leibler (KL) divergence, would be preferable under ideal circumstances. However, implementing this measure in practice is complex because it requires intermediate density estimations within a high-dimensional space, for example, a 768-dimensional embedding as in BERT. Additionally, the complexity is compounded by the small number of samples typically included in each batch, like 64. Non-parametric alternatives encompass methods such as MMD with a RBF kernel (Gretton et al., 2008; Pan et al., 2011), CORAL (Sun et al., 2015), and, akin to the approach described in (Bouniot et al., 2021), utilizing an optimal transport regularizer applied to output features. An extensive explanation of each distance measure is given in Appendix H.

5 Experimental Setup

5.1 Backbone models and tasks

We evaluated the *BERT* (Devlin et al., 2018) and *RoBERTa* (Liu et al., 2019) models on the classification tasks *MR*, *AG-News*, *SST-2*.

5.2 Evaluation metrics

We utilize the evaluation framework previously proposed in (Morris et al., 2020), where an evaluation set is perturbed, and we record the following data from the Total Attacked Samples (TAS) set: Number of Successful Attacks ($N_{succ-atk}$), Number of Failed Attacks ($N_{fail-atk}$), and Number of Skipped Attacks ($N_{skp-atk}$). We utilize these values to record the following metrics. *Clean accuracy/Base accuracy/Original accuracy*, which offers a measure of the model's performance during normal inference. *After attack accuracy/Accuracy under attack* ($A_{aft-atk} = \frac{N_{fail-atk}}{TAS}$) or (AUA), is critical, representing how effectively the attacker deceives the model across the dataset. Similarly, the *After success rate* ($A_{succ-rte} = \frac{N_{succ-atk}}{TAS - N_{skp-atk}}$) or (ASR) excludes previously misclassified samples. The paper also considers the *Percentage of perturbed words*, the ratio of disturbed words to the total in a sample, and *Semantic similarity*, an automatic similarity index, modelled by d (Cer et al., 2018). Lastly, the *Queries* denotes the model's number of invocations for inference. Appendix B and C give more details on our evaluation metrics and strategy.

5.3 Evaluation baselines

The assessment involves comparing to seven baseline techniques. These baselines include: The 'Vanilla' model, which is trained solely on the base dataset. 'TextFooler + Adv Aug' which incorporates adversarial samples generated by TextFooler into the base dataset as a form of data augmentation. 'TextFooler + Adv Reg' which also uses adversarial samples from TextFooler, but instead applies a regularization approach with both λ_0 and λ_1 set to 1, as detailed in "Standard" under Table 8 in the Appendix. Additionally, there are four other baseline models to compare against. Among them is 'Attack-to-Train' (A2T), which, according to the latest available information, is currently the leading state-of-the-art (SOTA) method for adversarial training at the token level in the NLP domain, as referenced in (Yoo and Qi, 2021). Next, there are embedding level adversarial training baselines. Among these there is 'InfoBERT', which is recognized for enhancing model robustness by requiring fewer projected gradient steps compared to FreeLB. Following this, we have 'FreeLB++', an advancement over FreeLB that achieves performance gains by increasing the ϵ-bound. Finally, there is 'DSRM', a novel approach that introduces perturbations whenever the loss dips below a predefined threshold. According to our latest knowledge, FreeLB++ surpasses most existing baselines (Li et al., 2021). Meanwhile, DSRM, as a more recent innovation, demonstrates superior performance over FreeLB++.

6 Experiments

We initially investigate the performance of the system using all the regularizers outlined in Equation 3 (referred to as Macro). When generating the adversarial candidates using TextFooler, PWWS, BERTAttack or TextBugger we set a angular similarity ϵ, used to assess the semantics of a transfor-

mation, to 0.5 where d is the Universal Sentence Transformer (Cer et al., 2018), and the number of word substitution candidates N to 50, which are both the standard used in previous work, we also utilize a greedy search approach with word replacement inspired by (Jin et al., 2019) to identify suitable word substitutions in a query efficient way.

For the macro component, we undertake a comparative analysis involving adversarial training and attacks utilizing word substitutions derived from various word embeddings (WordNet, Contextual, Counter Fitted, and GloVe). Furthermore, we conduct an in-depth examination of the resultant embeddings through t-SNE to gain valuable insights into the behavior of the feature space.

7 Results

7.1 Distribution alignment through MMD

In this section, we investigate the effectiveness of a training method that utilizes adversarial data sampled from four different attacks which use different word embeddings: PWWS (WordNet), TextFooler (Counter-Fitted), BERTAttack (Contextual) and TextBugger (GloVe). Our primary objective is to test whether a distance regularizer limits the word level perturbations from creating samples residing in the adversarial distributions shown in Figure 2 (top) with color yellow and cyan and secondly to evaluate if the new robust algorithm generalizes across word embeddings since the underlying hypothesis is that by leveraging a distance metric, which enables successful learning of domain-invariant features, we can anticipate improved robustness not only against the same attack but also across different attacks. This assumption is grounded in the fundamental similarities shared by word-level attacks. Additionally, Table 1 provides a comprehensive overview of the performance gains observed in terms of after-attack accuracy (AUA) and the corresponding drop in the attack success rate (ASR).

The insights derived from the presented analysis are twofold. Firstly, as depicted in Table 1, Within this context, the indispensability of distribution alignment becomes evident, as it consistently leads to significant performance gains in after-attack accuracy, regardless of the employed word embedding. Secondly, the observed improvements in performance remain consistent even when subjected to various word embedding attacks. This robustness across diverse attacks further affirms the efficacy and generalizability of the achieved performance increments.

7.2 Effect of distribution alignment method

We perform an ablation study on the choice of distance metric used for distribution alignment Table 2 showcases MMD, Coral, and Optimal Transport. We found training on optimal transport to be unstable and only effective for a narrow set of hyperparameters. For other attackers, MMD works more reliably and has better after-attack performance, achieving AUA of 37.8% ,44.6%, 39%, and 28.66% for PWWS, BertAttack, TextFooler, and TextBugger, respectively. Although Coral and Optimal Transport don't perform as well as MMD, they still outperform the baselines when tested on the MR dataset. Because of these results, we focus our experimentation with MMD. This might be due to MMD being a method that aligns lower statistical components, compared to CORAL and Optimal Transport, which may help when training using batches, in fact, it was shown that optimal transport does indeed suffer when the transport map isn't computed across all samples in a dataset (Nguyen et al., 2022).

7.3 Why distribution alignment works

Table 1 illustrates how the after-attack accuracy of a model, trained on word substitutions generated from different embedding sets such as counter-fitted embeddings (TextFooler) (Mrkšić et al., 2016), WordNet (PWWS) (Miller, 1995), or masked language modeling (BERTAttack), can be effectively generalized across these sets. This observation can be attributed to the presence of a base domain (represented by the red/blue cluster) and an adversarial domain (represented by the yellow/cyan cluster) as depicted in Figure 2. Consequently, training the model with an objective that aligns these two distributions and creates a new representation in the feature space can result in improved robustness performance. This can be ascertained by the Wasserstein distance dropping over time Figure 3 (top), when training with Equation 3, this drop, which represents the two hypothetical base and adversarial feature distributions becoming similar, can be seen despite utilizing MMD as a distance measure. Naturally, this occurs in a high dimension, which makes it difficult to show using a dimensionality reduction technique such as t-SNE in Figure 2. Interestingly, in Figure 3 the Wasserstein distance seem to capture the relation-

Table 1: Adversarial training using distribution alignment on MR. Values in **Bold** represent the highest scores, those in round brackets (∗) denote the second highest, and values in square brackets [∗] indicate the third highest. Extended results are in Table 17 in the Appendix.

ship between distributions in a smoother way than using MMD, this is further shown in other datasets such as AGNEWS and SST2 in Appendix 17.

7.4 Interpreting Distribution Alignment

To provide insights into the path an example takes in the feature space as it becomes adversarial, we employ t-SNE visualization. This approach allows us to track the trajectory of samples as they undergo perturbations, which has remained largely unexplored in the existing literature. With Figure 2 and Figure 5, 6 in the Appendix we present the results of our experiments. Figure 2 (top) provides insight into the distributions within the base model. Moving forward, we explore the model that incorporates a distance metric (MMD) as a regularizer, depicted in Figure 2 (bottom). This picture present the distribution components of the model utilizing MMD. These visualizations collectively contribute to our understanding of the behavior and transformations occurring within the feature space. There are three important extrapolations to consider from these figures. Firstly, the robust model exhibits fewer adversarial samples (cyan and yellow points) due to a higher number of correctly classified points. Secondly, by quantifying the number of perturbations required to successfully perturb a sample across the boundary (illustrated by the black samples with arrows), we observe most samples, to successfully be perturbed across a classification boundary require more word substitutions. The black point shows this. Originally in Figure 2 (top) only perturbing one word was sufficient to achieve a successful attack. In Figure 2 (bottom) the same sample needs to have 4 word substitutions before being success-

Type	Sample
Original	[CLS] Woods' Top Ranking on Line at NEC Invite (AP) AP - Tiger Woods already lost out on the majors. Next up could be his No. 1 ranking. [SEP]
FreeLB++	[CLS] Woods' Top Ranking on Line at NEC Invite [SEP] (AP) AP - Tiger Woods strong lost partners love the majors and [SEP] up xiao ko . No. 1 ranking to won
TextFooler	[CLS] Woods' Keynote Rank on Routing at NEC Invite (AP) AP - Tiger Woods already lost out on the commandant. Next up could be his No. 1 ratings. [SEP]

Table 3: Example of a qualitative sample generated by FreeLB after a large amount of δ steps. We use an initial δ of size 0.05 with a gradient ascend step size of 5 for about 30 steps. Red: Bad change, embedding method, Green: Good change, conceptual method.

Table 4: Computation time to generate adversarial samples and perform training on MR with 7 epochs on BERT. Robustness values are shown in Table 1

Type	GPU Time	
	Adversarial Set Generation	Train
Baseline	-	365
TextFooler + Aug	494	396
TextFooler + AT	473	691
TextFooler + MMD (SemRoDe)	537	694
A2T	2655	670
DSRM	-	883
FreeLB++	-	4648
InfoBERT	-	5404

fully perturbed (Positive to Negative sentiment in Table 17 in the appendix).

7.4.1 Qualitative samples

After a sufficient number of iterations (δ steps) on an embedding, FreeLB++ causes the embedding to move closer to a neighboring discrete embedding. This, in turn, leads to a change in token when mapping the second embedding, as demonstrated in Table 3. While the token substitution has the potential to preserve synonym information, there is no guarantee. We observed that training with too many δ steps, resulting in frequent token substitutions, actually worsens the performance of adversarial training. This finding is consistent with the observations made in (Li et al., 2021), emphasizing a significant drawback of FreeLB++. We believe this issue can be addressed by sampling adversarial samples using high-quality word embeddings and by matching the base and adversarial distributions.

8 Computation time

SemRoDe is computationally efficient. In Table 4, the 'Adversarial Set Generation' column tracks the time taken to adversarially generate 10% of the data, while the 'Train' column records the time required to train the model. Techniques for embedding perturbation such as FreeLB++, InfoBERT, and DSRM are more time-consuming due to, at times, undergoing multiple PGD steps. In contrast, token perturbation techniques like TextFooler and A2T do not undergo this operation. Table 4 provides a comparative analysis of the computational times for the various methods. Further discussion on computational cost is presented in Appendix K.

9 Discussion

Recent studies have taken a novel approach by investigating the impacts of adversarial attacks and defenses on smaller encoding and decoding models, such as BERT, RoBERTa, and GPT. Given that these models are less computationally demanding, they serve as more tractable proxies for larger, cutting-edge models. Promisingly, attacks that work on these models have been shown to be applicable to sophisticated LLMs, according to recent works (Wang et al., 2023a; Zhu et al., 2023; Wang et al., 2023b). Our research provides insight into aligning the base and adversarial domains and how doing so can improve robust accuracy. As the landscape of LLMs continues to evolve and expand, we hope these findings can be utilized and applied to larger, more sophisticated language models to improve their robustness to adversarial attacks.

10 Conclusion

Drawing inspiration from previous work on image settings utilizing continuous data, we demonstrate the existence of a base and adversarial domain within a linguistic setting that uses discrete data. This becomes apparent when an attacker manipulates a system through word-level substitutions. Striving to decrease the divergence between these two domains in the belief that it would improve robust generalization, we employ a distance regularizer on high-level features. This allows for learning an internal representation that restricts attackers from shifting a base sample into the adversarial domain. This method introduces a novel distance-based regularizer, $\mathcal{L}_{Dist}$, as we investigate different distance measures for aligning the domains. Aligning these domains results in a reduced Wasserstein distance and smoother clustering of the t-SNE output features. This procedure, aligning base and adversarial features, fosters robust generalization, as the learned representations maintain robust accuracy despite attackers leveraging word substitutions from four various word-embeddings.

12 Limitations

We do not consider the class-conditional case, and the domains are 'inverted'. This means a distance measure like MMD won't necessarily align the adversarial samples of class one with its respective samples from the base class. Instead, it will simply reduce the distance between the base and adversarial domains, which might impede robust performance. Therefore, in future work, it will be necessary to conduct a study where the objective takes classes into account when performing $\mathcal{L}_{Dist}$. Furthermore, we currently do not perform online adversarial training, where we generate adversarial samples in every batch. This could be suboptimal as the model is dynamic and changes with each batch. Another limitation involves robustness against white-box, embedding perturbations. Considering our threat model, we do not anticipate that attackers will have access to the embedding space. Therefore, the model will lack robustness against any adversarial perturbation that results in an input embedding not directly mappable back to the input space. This is because the adversarial training algorithm will not have been exposed to such data points. Lastly, how this alignment technique can be extended to generative models remains unexplored.

A Implementation details

In the case of the SemRoDe macro model, adversarial examples are generated during the first epoch. We generate adversarial samples where each word in a sample has N substitution candidates, for each candidate substitution the greedy search with word replacement algorithm checks whether such substitution reduces the classification confidence at the logit, if the transformation is successful, it needs to achieve above $\epsilon = 0.5$ angular similarity to be considered a successful adversarial sample, which will be included in training. The difference between the TextFooler, BERTAttack, PWWS and TextBugger methods is the utilized word embeddings to generate N. The MR model is trained on this data for seven epochs, while both the AGNews and SST2 models are trained for three epochs each.

A.1 Offline vs online adversarial training

Generating the dataset one time at the start, which we call offline adversarial training, differs from typical adversarial training techniques, which create adversarial samples at every epoch or batch to consider the model's dynamic learning nature. We have found this method best given that the generation of adversarial samples through TextFooler, BERTAttack, PWWS, and TextBugger can be time-consuming due to the heuristic nature of these attacks.

Naturally, we experiment with online adversarial training on BERT/MR, following the conventional approach of dynamically generating adversarial samples at each epoch. However, we observed no significant improvement in performance. Our conclusion is that epoch-wise adversarial training may not be necessary, and that an adversarial data augmentation strategy that follows an offline adversarial training paradigm is sufficient to align base and adversarial representations, thereby ensuring robustness against word-level attacks. Additionally, this approach offers the benefit of being a more rapid training setting, as detailed in Table 4.

A.2 Baseline implementation

Nonetheless, we continue to reference state of the art baselines in our comparative analysis. The FreeLB++ model remains unmodified as it generates adversarial samples at the embedding level at each batch for all data. As for A2T, we preserve its original implementation. The entire training data is exposed to the algorithm, which then generates ap-

proximately 20% of the data as adversarial samples. This percentage aligns with the recommendations outlined in the original implementation.

We implemented InfoBert in the same manner as it was in TextDefender; however, it should be noted that with the original learning rate of 2e-5 for the inner steps, in our case, the algorithm was unable to converge to a robust model. Consequently, we experimented with a learning rate of 0.1, which represents the upper limit recommended by the original implementation of InfoBert (Wang et al., 2021). Additionally, we increased the number of projected gradient descent (PGD) steps from 3 to 7 for both AGNEWS and SST2 datasets across all models. For the MR dataset, which is smaller, we conducted 15 steps on BERT and 25 on ROBERTA. With the exception of these modifications, all other hyperparameters remained unchanged.

When it came to implementing the DSRM (Gao et al., 2023), we adhered closely to the original publication, adjusting only the clipping parameter. The original clipping value prescribed in the paper and code, in our experiments, did not yield an improved after attack accuracy; thus, we set the loss clamp to 50 for both SST2 and AGNEWS. In practice, this adjustment is akin to eliminating the clamping entirely. As a result, the algorithm modifies the batch at every iteration. We observed that this approach is able to enhanced the accuracy after the attack while also largely maintaining the original accuracy. For the MR dataset, however, such a high loss clamp rendered the algorithm ineffective. Therefore, we adjusted the clamp to 0.5. As we trained BERT and ROBERTA models from scratch utilizing DSRM, we extended the training to 10 epochs for AGNEWS and SST2, and 50 epochs for MR, choosing the model that demonstrated the best performance.

A.3 Datasets

We Test on 3 classification datasets, the base distribution size and adversarial distribution size are presented in Table 5.

Table 5: Dataset sizes

Task	Dataset	Train	Adv Data Size (Train)	Test	Classes
Sentiment Classification	MR	8.5k	850	1k	2
	SST-2	67k	6.7k	1.8k	2
News Classification	AGNEWS	120k	12k	7.6k	4

B Evaluation metrics extended

We utilize the evaluation framework previously proposed in (Morris et al., 2020), where an evaluation set is perturbed, and we record the following metrics from the Total Attacked Samples (TAS) set: Number of Successful Attacks ($N_{succ-atk}$), Number of Failed Attacks ($N_{fail-atk}$), and Number of Skipped Attacks ($N_{skp-atk}$). The *Clean accuracy/Base accuracy/Original accuracy* represents the accuracy of the model undergoing normal inference. A high clean accuracy indicates that the model performs well for its intended task. The *After attack accuracy/Accuracy under attack* ($A_{aft-atk} = \frac{N_{fail-atk}}{TAS}$) or (**AUA**) is the most crucial metric, representing how effectively the attacker can deceive the model across the dataset. Lower values of AUA indicate a higher success rate in fooling the model. The *After success rate* ($A_{succ-rte} = \frac{N_{succ-atk}}{TAS-N_{skp-atk}}$) or (**ASR**) is similar to AUA but excludes previously misclassified samples. The *Percentage of perturbed words* refers to the ratio of perturbed words to the total number of words in the sample. This metric should be minimized as perturbing more words makes the sample's manipulation more detectable. *Semantic similarity* (Jin et al., 2019; Maheshwary et al., 2020) is an automatic similarity index that quantifies the visual difference between two samples using a deep learning model. In this case, modelled by d, the Universal Sentence Encoder (Cer et al., 2018) is utilized along with a angular cosine similarity hyper parameter ϵ between the output embeddings. An output value of 1 indicates semantic equivalence, while 0 represents no similarity. *Queries* denotes the number of times the algorithm needs to invoke the model for inference; keeping this low helps avoid detection. We further explain the evaluation strategy in Appendix C.

C Evaluation Strategy

The experiments section will follow the evaluation setting originally proposed by TextDefender (Li et al., 2021). The main difference is that we will still test whether a method can generalize when using the same synonym set. This testing is relevant due to the requirement of learning robust models against existing attacks, such as BERTAttack and PWWS. Additionally, we propose another evaluation test that assesses the generalization of training on one set of synonyms against other sets. This test is applicable because these attacks already exist,

but we do not yet have training strategies to address them. It will also demonstrate how well training on one set of synonyms can generalize to attackers using other synonym sets. In line with the technique adopted by TextDefender, we set the ϵ value to 0.5, leading to a semantic similarity threshold of 0.84. In a move to achieve balance, we ensure that the perturbation does not exceed 30% of the words in each sample. Concurrently, we adhere to a maximum limit of $L * N$ queries per sample, with L denoting the length of the sample in words. As the parameters *Queries*, *Percentage of perturbed words*, and *Semantic similarity* maintain constancy, we have sidestepped their inclusion in our tables.

D Further explanation of adversarial training in language models

The technique for creating adversarial examples is crucial and our work differs in this respect from previous work such as Contextualized representation-Adversarial Training (CreAT) (Wu et al., 2023). This work applies PGD over 'k' steps with an L2-norm restriction on the perturbation magnitude, which parallels prior research, such as (Sato et al., 2018; Barham and Feizi, 2019). However, contemporary word-level attacks do not adhere to the L2-norm constraint. Instead of adding small delta perturbations, these attacks use word substitutions, with semantic similarity serving as the boundary for perturbations. This strategy allows an adversary to more readily bypass the defender's constraints. Consequently, we are faced with the critical question: How can we incorporate these same bounds and deltas into our adversarial training technique? The most practical solution is to enforce these restrictions at the input stage by adopting the approaches utilized in well-established attack mechanisms. Hence, our method is superior as it enables the algorithm to more thoroughly explore the attack space. Compared to CreAT we also are attempting to align distributions, and therefore analyse them in detail. Different from our work, CreAT introduces a technique to better train the encoder part of a model with adversarial training, since they noticed normal adversarial training struggles to do so, especially when applied to a encoder-decoder model. In our work, when incorporating samples generated through embedding perturbation techniques into regular adversarial training, the performance improvement is relatively minor. We hypothesize that this is due to the inherent discrepancy between the base and adversarial samples, which belong to two distinct distributions within the feature space. Standard adversarial training does not adequately address this divergence, thus highlighting the necessity of a distance regularizer to better align these two distributions.

E Explanation of ϵ

In our study, the angular similarity ϵ is employed as a hyperparameter to place constraints on adversarial samples generated with algorithm g in conjunction with d. Model d can be any qualitative variant capable of preserving the fundamental attributes of the base sample such as meaning, fluency, grammar, similarity, and so on. The pivotal area of interest tends to be semantic similarity, often represented by the output from the universal sentence encoder. We establish our threshold by employing the formula $w = 1 - \frac{\epsilon}{\pi}$, where ϵ has the bounds (0,π). In this study, we have chosen $\epsilon = 0.5$ which yields a threshold of 0.84. Table 12 demonstrates how employing different values of ϵ can result in varying intensity of attacks. Note that a small ϵ results in a small angle between the original sample and adversarial sample, hence, if any adversarial sample from g, after being processed by d is above this ϵ, the sample is rejected.

Previous research has primarily maintained a fixed ϵ in the vicinity of word embeddings, where the structure of the boundary is usually in the form of either an l2-ball or a convex hull. In our experiments, we leverage heuristic adversarial samples bound by d with the aim to restrict the adversaries not based on arbitrary objectives such as an l2 ball, but rather, on important aspects of linguistic characteristics like semantic similarity.

Also take note that increasing N and reducing ϵ have similar effects. They both lead to the generation of more diverse adversarial samples that can further reduce the classification confidence. However, referring to the Epsilon and Embedding ablation study (Table 12 and Table 11), this diversity often comes at the cost of quality, because the semantics are liable to significant alterations.

F Large δ Explanation

In comparison to the image domain or the addition of a static δ within the word embedding space, word substitutions in the embedding space incorporate a substantially large, word pair-specific δ, which is challenging to both predict and pre-set

Exploring Word Substitution Overlap By Word Embedding				
Attack Method (Word Embedding)	Attack Method (Word Embedding)			
	Counter-Fitted	WordNET	Contextualized	Glove
Counter-Fitted	100%	1.6% (23.4%)	3.6% (38%)	10.4% (73%)
WordNET	1.6% (23.4%)	100%	2% (11.3%)	2.4% (22%)
Contextualized	3.6% (38%)	2% (11.3%)	100%	9% (81.8%)
Glove	10.4% (73%)	2.4% (22%)	9% (81.8%)	100%

Table 6: Word substitution overlap by word embedding.

(as illustrated in Figure 4). This potentially exacerbates the divergence between the base domain and the adversarial domain could potentially explain the high starting Wasserstein distance. It might also shed light on the considerable improvement in post-attack accuracy following the minimization of L_{Dist}.

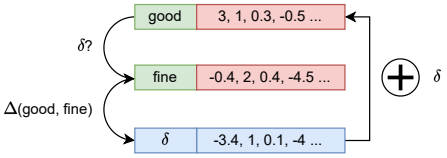

Figure 4: Doing a word substitution is the same as adding a large δ of fixed size to each word pair. Normally in adversarial training δ is set to 0.5, this, in comparison, is a small perturbation.

G Vocabulary and Word Substitution Overlap

In this section, we emphasize the significant overlap in vocabulary and dictionaries among popular word embeddings (see Table 6). However, we observe a limited overlap in potential word substitutions on a per-word basis (see Table 7). Assuming we have two vocabularies V_1 and V_2 with $W_1 = W_2 = W$ overlapping tokens, each token W has a set of potential token substitutions denoted as $W^{'}$, where $W_1^{'}$ is unlikely equal to $W_2^{'}$ since these token substitutions are sourced by independent word substitution algorithms or data structures. To calculate the word substitutions overlap, we measure the Jaccard index J using the formula: $J = \frac{|W_1^{'} \cap W_2^{'}|}{|W_1^{'} \cup W_2^{'}|}$. We then compute the average result for each word. Table 7 also highlights the J for the W that achieved the highest overlap across the vocabulary in brackets.

Vocabulary/Dictionary overlap by word embedding types					
		Word Embedding Overlap			
		Counter-Fitted	WordNET	Contextualized	Glove
Word Embeddings	Number of tokens or words	65713	147306	30522	400000
Counter-Fitted	65713	65713	31233 (21.2% WordNet) (47.5% Counter)	20994 (68.8% Context) (31.9% Counter)	62951 (15.73% Glove) (95.79% Counter)
WordNET	147306	31233 (21.2% WordNet) (47.5% Counter)	147306	14510 (9.85% WordNet) (47.5% Context)	55666 (37.78 WordNet) (13.9 Glove)
Contextualized	30522	20994 (68.8% Context) (31.9% Counter)	14510 (47.5% Context) (9.85% WordNet)	30522	22877 (75% Context) (5.7% Glove)
Glove	400000	62951 (15.73% Glove) (95.79% Counter)	55666 (13.9 Glove) (37.78 WordNet)	22877 (5.7% Glove) (75% Context)	400000

Table 7: Overlap between vocabulary. Percentage in brackets represents the percentage overlap of the union over the original vocabulary.

H Distance measures

H.0.1 MMD

The general equation for the maximum mean discrepancy (MMD) distance is often described mathematically as the following:

$$MMD(P,Q) = \|\mathbb{E}_{x\sim P}[\varphi(f(x))] \quad (4)$$
$$- \mathbb{E}_{y\sim Q}[\varphi(f(y))]\|^2 \quad (5)$$

Where $\mathbb{E}$ denotes the expected value, x and y are samples drawn from distributions P and Q, respectively, φ is a kernel function that maps the data into a high-dimensional feature space, f_θ is an optional feature extractor, and $||.||^2$ is the squared norm of the difference between the two expected values.

In our case, we use f_θ and is set to a sequence classifier. We therefore define $f_\theta(x) = h^A$ and $f_\theta(y) = f_\theta(\hat{x}) = h^B$. Where in this case both h^A and h^B are sampled from distributions H^A and H^B respectively.

$$MMD(H^A, H^B) = \left\|\mathbb{E}_{h^A\sim H^A}[\varphi(h^A)]\right.$$
$$\left. - \mathbb{E}_{h^B\sim H^B}[\varphi(h^B)]\right\|^2 \quad (6)$$

We then set φ to be a rbf kernel.

$$MMD(H^A, H^B) = \left\|\mathbb{E}_{h^A\sim H^A}[h^A]\right.$$
$$\left. - \mathbb{E}_{h^B\sim H^B}[h^B]\right\|^2 \quad (7)$$

H.0.2 CORAL

The CORrelation ALignment (CORAL) measures the difference in the second-order statistics of the samples from the two sets. Specifically, it aligns the covariance matrices of the two sets by minimizing the Euclidean norm between them. CORAL

requires the covariance matrices to be computable. It can be defined mathematically as follows:

$$\text{CORAL}(H^A, H^B) = \frac{1}{4d^2} \|C_{H^A} - C_{H^B}\|_F^2 \quad (8)$$

Where d is the dimensionality of the samples, and C_{H^A} and C_{H^B} are the covariance matrices of the samples from H^A and H^B, respectively. The Frobenius/Euclidean norm is denoted by $\|\cdot\|_F$. The equation measures the distance between the covariance matrices of H^A and H^B after aligning them through matrix square root transformation, and scales the distance by a constant factor.

In the above equation, the covariance matrices are calculated both mathematically and programmatically in the following way:

$$C_{H_A} = \frac{1}{n_A - 1}(H_A^T H_A - \frac{1}{n_A}(1^T H_A)^T (1^T H_A)) \quad (9)$$

$$C_{H_B} = \frac{1}{n_B - 1}(H_B^T H_B - \frac{1}{n_B}(1^T H_B)^T (1^T H_B)) \quad (10)$$

Where n_A/n_B are the number of discrete samples for both the H_A/H_B distributions.

H.0.3 Optimal Transport

There are multiple ways to use optimal transport in the training procedure. One method is first to calculate the p-norm cost matrix C between final representations from the model undergoing base inference H^B and adversarial inference H^A and the transport map T. The transport map is the joint probability between p^{Base} and p^{Adv}. Where p^{Base} and p^{Adv} are the empirical distributions of the base and adversarial datasets in the feature spaces that satisfy $\sum_{i=1}^{L_B} p_i^{Base} = 1$ and $\sum_{j=1}^{L_A} p_j^{Adv} = 1$, often assumed to be uniform and meeting the following conditions.

$$p^{Base} = \sum_{i=1}^{L_B} p_i^{Base} \delta_{h_i^B}, p^{Adv} = \sum_{j=1}^{L_A} p_j^{Adv} \delta_{h_j^A} \quad (11)$$

Matrix C is later converted to its entropic regularized version with $K = exp(-C/\varepsilon)$. Together with the optimal transport map, the Sinkhorn algorithm (Cuturi, 2013; Feydy et al., 2018; Feydy, 2020; Nguyen and Tuan, 2021) iteratively projects K between p^{Base} and p^{Adv} through multiple Sinkhorn iterations. The distance using Sinkhorn is hence defined as:

$$\begin{aligned}\mathcal{L}_{Sinkhorn} = D(H^B, H^A) = OT(p^{Base}, p^{Adv}) \\ - \frac{1}{2} OT(p^{Base}, p^{Base}) \\ - \frac{1}{2} OT(p^{Adv}, p^{Adv})\end{aligned} \quad (12)$$

Where

$$OT(p^{Base}, p^{Adv}) = \sum_{i=1}^{M^B} p_i^{Base} S^B + \sum_{i=1}^{M^A} p_i^{Adv} S^A \quad (13)$$

$M^B = M^A$ and S^A and S^B are computed in the aforementioned Sinkhorn iteration. These iterations are further illustrated in Algorithm 1. Sinkhorn iteratively projects the regularised cost matrix K on p^{Base} and p^{Adv}.

Algorithm 1 Sinkhorn loop

Input:Probabilities p^{Base} and p^{Adv}, cost function $C(x_i, y_i)$, Number of iterations N, temperature ε
Output: Sinkhorn tensors S^A and S^B

Initialize $S^A, S^B \leftarrow 0_{R^N}, 0_{R^M}$
for Iteration i in N **do**
  $S_i^A \leftarrow -\varepsilon log \sum_{j=1}^{M} p^{Adv} exp\frac{1}{\varepsilon}[S_j^B - C(x_i, y_i)]$
  $S_j^B \leftarrow -\varepsilon log \sum_{i=1}^{N} p^{Base} exp\frac{1}{\varepsilon}[S_i^A - C(x_i, y_i)]$
end for
return S^A, S^B

I Alternative adversarial training formulations

There are numerous loss functions that have been demonstrated to enhance the adversarial robustness of various models. However, all of the functions presented in Table 8 have been shown to be ineffective in the language domain according to (Wang et al., 2020a). In our work, we introduce a new regularizer, which has shown empirical effectiveness on language-related problems.

I.1 Training hyper-parameters

Table 9 outlines the parameters pertaining to Table 2. The 'Freeze layers' section emphasizes that the initial 11 layers of the models were frozen, serving

Defense Method	Loss Function
Standard	$\lambda_0 \cdot \text{CE}(f_{\text{cls}}(x,\cdot),y) + \lambda_1 \cdot \text{CE}(f_{\text{cls}}(\hat{x},\cdot),y)$
TRADES (Zhang et al., 2019)	$\text{CE}(f_{\text{cls}}(x,\cdot),y) + \lambda \cdot \|f_{\text{cls}}(x,\cdot) - f_{\text{cls}}(\hat{x},\cdot)\|_k$
MMA (Ding et al., 2020)	$\text{CE}(f_{\text{cls}}(x,\cdot),y) \cdot \mathbf{1}(\phi(x) \neq y) + \text{CE}(f_{\text{cls}}(\hat{x},\cdot),y) \cdot \mathbf{1}(\phi(x) = y)$
MART (Wang et al., 2020b)	$\text{BCE}(f_{\text{cls}}(\hat{x},\cdot),y) + \lambda \cdot \text{KL}(f_{\text{cls}}(x,\cdot)\|f_{\text{cls}}(\hat{x},\cdot)) \cdot (1 - f_{\text{cls}}(x,y))$
CLP (Kannan et al., 2018)	$\text{CE}(f_{\text{cls}}(x,\cdot),y) + \lambda \cdot \|f_{\text{cls}}(x,\cdot) - f_{\text{cls}}(x_0,\cdot)\|_k$
SemRoDe (Ours)	$\text{CE}(f_{\text{cls}}(x,\cdot),y) + \lambda \cdot \frac{1}{\|\mathcal{B}\|} \sum_{\mathcal{B} \subset \mathcal{D}} \text{Dist}(f_{\text{pool}}(t(\mathcal{X}_B)), f_{\text{pool}}(t(\mathcal{X}_A)))$

Table 8: Defense Methods and Loss Functions

as a feature extractor. This approach allows us to concentrate on aligning the high-level features during the training process.

Table 9: Training parameters for Table 2

I.2 Output layer architecture

For both BERT and RoBERTa, we extract the output features from each token, which are, in our case, the dimension of 128*768, and pool them with f_θ^{pool} along the first dimension. This process results in an output feature vector of shape 768, which encapsulates the information in the whole input. This vector is subsequently used for the $\mathcal{L}_Dist$ regularizer and passed to f_θ^{cls} for classification. The f_θ^{cls} is configured to a single linear layer. We adopted this architecture due to the small dataset sizes used in our experiments.

I.3 Computational experiments

The experiments were conducted on a server with 8 Nvidia Tesla v100-sxm2-32gb GPUs. For all our tests, to ensure reproducibility when training or performing adversarial attacks, we set the seed to 765, one of the two seeds used in the TextAttack framework (Morris et al., 2020). For data sampling and shuffling, we set the seed to 42, the same as TextDefender (Li et al., 2021). We perform each experiment once where we use 500 adversarial samples to evaluate the model's robustness, this is similar to previous work.

J Ablation Studies

The default setting of $N = 50$, $\epsilon = 0.5$ and $\lambda = 1$, to our knowledge, gives the best results.

J.1 Regularizer λ strength

The $\mathbf{L}_{Dist}$ regularizer's strength has a positive effect on robust accuracy at strengths of 0.5/1, after which it tends to decrease. The robust accuracy for the vanilla model is significantly lower, clocking in at 13.8% (Table 10).

Table 10: Ablation study for λ on $\mathcal{L}_{Dist}$

Lambda	TextFooler		
	CA (↑)	AUA (↑)	ASR (↓)
0	86.0	13.8	83.95
0.1	86.0	31.8	63.02

J.2 Attack strength (Attacking)

In this experiment, the SemRoDe macro model has been trained on TextFooler with $N = 50$, but is subsequently attacked with TextFooler values ranging from N=1 to N=150. This is to compare its robust performance with that of the vanilla model.

As the value of N increases, the robustness of the vanilla model decreases. However, upon reaching N=150 - an amount considerably higher than the typically used N=50 - the performance between the two models converges. At this point, the robustness of the vanilla model remains invariant at 12%, while the SemRoDe macro model stabilizes at 32%, clearly exhibiting superior robustness with increased N.

J.3 Ablation ϵ

The hyperparameter ϵ determines the maximum angular semantic similarity that a valid adversarial sample must maintain. A small ϵ results in a high semantic similarity threshold, as defined by the equation $w = 1 - \frac{\epsilon}{\pi}$. It's important to note that ϵ is constrained by the bounds $(0, \pi)$

Table 11: Ablation study on the attacker's number of word substitutions per word N

Attacker N (Epsilon)	Vanilla			TextFooler + MMD (SemRoDe)		
	CA (↑)	AUA (↑)	ASR (↓)	CA (↑)	AUA (↑)	ASR (↓)
1	86.6	75.8	12.47	85.8	75.2	12.35
5	86.6	44.6	48.5	85.8	56.2	34.5
10	86.6	33.8	60.97	85.8	51.8	39.63
50	86.0	13.8	83.95	85.8	39.4	54.08
100	86.6	12.0	86.14	85.8	32.6	62.0
150	86.6	12.0	86.14	85.8	32.6	62.0

Table 12: Ablation study on the attacker's angular similarity ϵ

Attacker ϵ (Angular Similarity)	Vanilla			TextFooler + MMD (SemRoDe)		
	CA (↑)	AUA (↑)	ASR (↓)	CA (↑)	AUA (↑)	ASR (↓)
$\pi/96$	86.6	62.2	28.18	85.8	70.4	17.95
$\pi/48$	86.6	62.2	28.18	85.8	70.4	17.95
$\pi/24$	86.6	62.2	28.18	85.8	70.4	17.95
$\pi/12$	86.6	40.4	53.35	85.8	54.2	36.83

$\pi/2$	86.6	13.6	84.3	85.8	38.4	55.24
$2 \cdot \pi/3$	86.6	13.6	84.3	85.8	38.4	55.24
$5 \cdot \pi/6$	86.6	13.6	84.3	85.8	38.4	55.24
π	86.6	13.6	84.3	85.8	38.4	55.24

J.4 White-box attacks

We also investigate the performance of our technique when an attacker uses gradient information to identify word substitutions in a white-box attack strategy, as described in (Ebrahimi et al., 2018). Our regularizer, which aligns distributions, enhances robustness, especially when compared to standard adversarial training using the same dataset, as shown in Table 13.

Table 13: SemRoDe's robustness to white-box attacks on BERT-MR

Approach	CA (↑)	AUA (↑)	ASR (↓)
Baseline	86.6	55.6	35.8
TextFooler + AT	85.8	58.6	31.7
TextFooler + MMD	86.0	67.6	21.4

J.5 Adaptive attacks

This section analyzes the threat model wherein an attacker knows that the model has been trained on SemRoDe, and is therefore robust to word substitutions. In response, the attacker adopts an adaptive attack strategy, such as that described in (Tramer et al., 2020). We initiate our adaptive attack by posing the question: How might someone compromise the system, given their understanding of our defenses?

To establish our counter-strategy, we commence by: (1) looking for a new objective, through which the optimization process may be effective in generating adversarial samples. Subsequently, (2) we look for an appropriate method to optimize this objective and uncover adversarial examples, lastly (3) we iterate on our new findings to perform better attacks. In the context of NLP classification, our primary goal, which is optimizing for untargeted misclassification, remains the same. Nevertheless, this objective can be changed to that of targeted misclassification if the task has more than two classes. For the purposes of this section's experimentation, we focus on binary classification with the MR dataset.

For the second strategy (2), although our system is not designed for this, a natural choice might be character insertions. To evaluate against these adaptive attacks, we apply the character insertion method described in (Li et al., 2019), and additionally consider the punctuation insertion techniques put forth in (Formento et al., 2023). Remarkably, SemRoDe enhances its robustness to character insertion attacks without training on any specific data points (Table 14), a finding that potentially reinforces the theory that adversarial attacks originating in the token space reside in a different distribution to that of normal samples.

Proceeding to the next step (3), we repeat the process, now informed by insights from the previous step. Considering that our algorithm remains robust against character insertions, it is possible that the robust adversarial training method we employ can detect the sequence in which words are substituted during an attack. Throughout the training phase, we utilized a greedy search strategy with word replacement to create adversarial examples. This approach enhances the efficiency of greedy search by initially ranking words based on their importance as determined by saliency, attention score, or the impact on classification confidence when removed. The greedy search then prioritizes these words for substitution. To further assess the robustness of our system, we investigate how it performs when the attacker adopts a different optimization strategy, building upon step (2).

For the refined approach (2), we explore a suite of alternative algorithms to traverse the optimization landscape, opting for conventional greedy search, particle swarm optimization (Zang et al., 2020), and beam search instead of greedy search enriched with word replacement (Table 15).

Lastly, we reflect on our findings on how the defence failed, what we learned from it, and potential improvements. We demonstrate that our technique, which aligns distributions, outperforms

the use of adversarial training with a regularizer, when an attacker engages in an adaptive attack strategy. However, we do note a significant drop in robust accuracy when changing the optimization strategy. This shows that there may be limitations when generating data through a specific optimization strategy, such as a greedy search paired with word replacement. To enhance performance across various attack optimization strategies, it might be better to identify an optimization method superior to the current greedy search with word replacement. A more comprehensive and diverse range of samples could be achieved by incorporating a wider set of word substitutions, occurring at various positions within the sentence and in a different order. This approach could significantly increase the diversity of the data.

Table 14: Initial testing on adaptive adversarial attacks. We explore character and punctuation insertions. The results are on MR and BERT.

Approach	Character Insertions			Punctuation Insertions		
	CA (↑)	AUA (↑)	ASR (↓)	CA (↑)	AUA (↑)	ASR (↓)
Baseline	86.6	48.0	44.57	86.6	36.0	58.43
TextFooler + AT	85.8	45.8	46.62	85.8	34.6	59.67
TextFooler + MMD	86.0	58.8	31.63	86.0	51.0	40.7

K Extended Computation time

In this section, we investigate the GPU computation time required for generating the adversarial training set and for training the model with this augmented dataset. Data augmentation (TextFooler + AUG) emerges as the fastest method. Given that the augmented data constitutes only 10% of the original dataset, the incremental cost during training is minimal. Consequently, data augmentation entails a training duration that is approximately 10% longer than that of the baseline model.

The Adversarial Training techniques TextFooler + AT, A2T, and TextFooler + MMD (SemRoDe), work by first creating an adversarial training set. The lower computation times between TextFooler and A2T show that data generation with TextFooler is more computationally efficient than with A2T. Meanwhile, with respect to the training process, these methods exhibit similar timeframes, approximately doubling the duration compared to baseline training. This increase is attributable to the necessity of sampling and conducting inference using the adversarial dataset at each base training iteration.

We also considered embedding perturbation techniques such as FreeLB++, InfoBERT and DSRM. These approaches involve modifying the input through multiple PGD steps at every training iteration. To match the performance of the baseline, as detailed in the implementation from TextDefender (Li et al., 2021). Specifically, we applied the gradient perturbation 15 times for InfoBERT, 30 times for FreeLB++, and once for DSRM per iteration. The accumulation of these multiple PGD steps across a comprehensive dataset significantly extends the training duration. Table 4 provides a comparative analysis of the computational times of the different methods.

L Distinction between GloVe and Counter-Fitted GloVe embeddings

The word embeddings used in this study are GloVe embeddings. GloVe (Pennington et al., 2014) embeddings are generated using a self-supervised algorithm that extracts global word-word co-occurrence statistics from a given corpus. However, to address certain limitations of plain GloVe embeddings, new authors introduced Counter-Fitted GloVe embeddings (Mrkšić et al., 2016). These counter-fitted embeddings aim to mitigate issues arising from the expectation of semantic similarity, which sometimes results in conceptual associations and anomalies within the generated embedding clusters. These anomalies may include clusters containing antonyms instead of synonyms, or dissimilar words that typically appear in similar contexts, such as east/west/north/south.

Counter-fitted embeddings inject both synonym and anonym information into the original GloVe embeddings, making them more suitable for word substitution attacks. In the context of this research, the original TextBugger paper employed GloVe embeddings, but within the TextAttack framework, the implementation of TextBugger utilizes Counter-Fitted GloVe embeddings. The experiments conducted for this study were performed using the original TextBugger algorithm with GloVe embeddings as the baseline for comparison, while TextFooler utilizes the Counter-Fitted GloVe embeddings.

M Extended Feature space plots

Figures 5, 6 present the t-SNE visualizations of MR without marginal distributions, with the corresponding plots showcased in Figure 2. Meanwhile, Figures 7, 8, 9, 10 display the t-SNE and marginal distributions for AG-News. Figure 11 illustrates the reduction in distances for AG-News, and Figure 12 depicts the decreasing distances for SST2.

Abstract

We introduce BUST, a comprehensive benchmark designed to evaluate detectors of texts generated by instruction-tuned large language models (LLMs). Unlike previous benchmarks, our focus lies on evaluating the performance of detector systems, acknowledging the inevitable influence of the underlying tasks and different LLM generators. Our benchmark dataset consists of 25K texts from humans and 7 LLMs responding to instructions across 10 tasks from 3 diverse sources. Using the benchmark, we evaluated 5 detectors and found substantial performance variance across tasks. A meta-analysis of the dataset characteristics was conducted to guide the examination of detector performance. The dataset was analyzed using diverse metrics assessing linguistic features like fluency and coherence, readability scores, and writer attitudes, such as emotions, convincingness, and persuasiveness. Features impacting detector performance were investigated with surrogate models, revealing emotional content in texts enhanced some detectors, yet the most effective detector demonstrated consistent performance, irrespective of writer's attitudes and text styles. Our approach focused on investigating relationships between the detectors' performance and two key factors: text characteristics and LLM generators. We believe BUST will provide valuable insights into selecting detectors tailored to specific text styles and tasks and facilitate a more practical and in-depth investigation of detection systems for LLM-generated text.

1 Introduction

In recent years, the development of large language models (LLMs) has surged, with notable releases such as GPT-4, Llama-2 and Falcon. As these models have advanced, distinguishing between texts written by humans and texts generated by LLMs has become challenging. Several studies show that most adults cannot distinguish between the two (Clark et al., 2021; Jakesch et al., 2023). This indistinguishability poses several challenges, ranging from the potential for fraudulent authoring to the automatic dissemination of targeted misinformation (Pan et al., 2023; Yu et al., 2023). There are two main approaches to identifying generated text - watermarking and detection systems - with the focus of this paper on the latter. Watermarking relies on the developer's watermark, whereas detection systems can be developed independently. However, the effectiveness and feasibility of current detectors in identifying machine-generated text (MGT) remains an active area of research. To effectively

CONTEXT: Belize, formerly known as British Honduras, is a Caribbean country located on the northeastern coast of Central America. Belize is bordered on the northwest by Mexico, on the east by the Caribbean Sea, and on the south and west by Guatemala. It has an area of 22,970 square kilometres (8,867 sq mi) and a population of 408,487 (2019). Its mainland is about 290 km (180 mi) long and 110 km (68 mi) wide. It has the lowest population and population density in Central America.

INSTRUCTION: Given this short paragraph about Belize, how many people live there and what is notable about its population density?

HUMAN: Belize has a population of 408,487 people and has the lowest population density in Central America.

FALCON 7B: The population of Belize is around 408,487 according to the Worldometer statistics. This figure is the estimated population of the country as of year 2019. Belize is one of the smallest countries in Central America with a population density of 38.93 people per square kilometers.

LLAMA-2 70B: According to the information provided, 408,487 people live in Belize. Belize has the lowest population and population density in Central America.

GPT-4: According to the paragraph, Belize has a population of 408,487 as of 2019. What is notable about its population density is that it has the lowest population and population density in Central America.

Figure 1: BUST dataset excerpt for the closed QA task: Presents a **HUMAN** response and machine-generated texts (e.g., **FALCON 7B**, **LLAMA-2 70B**, **GPT-4**) for a given **CONTEXT** and **INSTRUCTION**.

[*]Equal contribution, with Cornelius focusing on dataset creation and Lithgow on evaluation and data repurposing.

Proceedings of the 2024 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies (Volume 1: Long Papers), pages 8029–8057
June 16-21, 2024 ©2024 Association for Computational Linguistics

evaluate these detection systems, there is an urgent need for an adaptable benchmarking dataset that can cope with the influx of LLMs and covers various tasks (Tang et al., 2023).

In this paper, we introduce a comprehensive dataset[1] tailored for benchmarking detectors against instruction-tuned LLMs. This dataset consists of 3,180 instructions paired with corresponding responses from both humans and LLMs, resulting in a corpus of over 25,000 texts. A systematic evaluation of five distinct detectors was conducted, revealing notable variances in performance across the range of tasks. Additionally, we have conducted a meta-analysis, examining the dataset's characteristics and employing surrogate models to investigate the features that most significantly impact detector performance. Our findings indicate that while emotional content in texts enhanced the performance of some detectors, the most effective detector demonstrated consistent performance, irrespective of the writer's attitudes. This benchmark[2] serves as a valuable tool for identifying the most suitable detectors for specific text styles and tasks.

The paper is organized as follows: Section 2 gives an overview of related work, focusing on detector systems and analog datasets. Section 3 details the specifics of our proposed dataset and the generators used. Section 4 explains the metrics used for comparing different generators and the used detector systems, while section 5 presents our results. In section 6 we present two ablation studies and a discussion on the implications of our results is given in section 7. The paper concludes with section 8, where we summarize our contributions and make suggestions for future research.

2 Related Work

Following, we present related work on generated text detectors and datasets for MGT.

Generated Text Detectors MGT detection has evolved significantly over the years. Initial efforts focused on detecting differences in linguistic features and using statistical measures such as perplexity, relative entropy, and style similarities (Beresneva, 2016). Gehrmann et al. (2019) provided a suite of baseline statistical methods known as "GLTR" to help humans detect MGT without prior training. Recent developments like DetectGPT (Mitchell et al., 2023) define a curvature-based criterion using log-likelihoods computed by the model in question, circumventing the need to train a separate classifier, collect a dataset of real or generated passages, or explicitly watermark the generated text. Similarly, Su et al. (2023) presented DetectLLM, a zero-shot approach detecting a range of LLMs using log-rank information.

Another prevalent strategy in this area involves the detection of MGT as a classification task. In this context, various pre-trained language models such as Vicuna (Chiang et al., 2023) or RoBERTa (Guo et al., 2023) are fine-tuned on datasets that combine human-written with their corresponding MGT examples. Notably, many of these models are specialized for specific tasks, as GROVER (Zellers et al., 2019). Others are tailored to specific domains (Koike et al., 2023) or aim to detect output from specific generator models (Guo et al., 2023).

LLM generated text datasets The datasets used to evaluate systems capable of distinguishing between human-written and MGT vary considerably. Some developers of detector systems have chosen to create their own datasets for this purpose (Radford et al., 2019; Gehrmann et al., 2019; Zellers et al., 2019; Verma et al., 2023). However, publicly available datasets have often been created for very specific purposes. In particular, some are designed for specific generator models (Fagni et al., 2021; Guo et al., 2023). Other datasets are limited to a single task (Guo et al., 2023), while some are specific to a particular domain, such as the CHEAT dataset (Yu et al., 2023), which solely focuses on generating academic abstracts.

The TuringBench dataset (Uchendu et al., 2021) provides a comprehensive benchmark containing news articles generated by 19 different models, based on their titles, and juxtaposed with the corresponding human-authored articles. However, the text-generating capabilities of the models in this dataset are not on par with the advanced capabilities of current LLMs. Furthermore, Clark et al. (2021) presented a dataset aimed at investigating the human ability to distinguish between texts written by humans and machines. Notably, this dataset spans multiple domains and incorporates various models, though it is limited by having only 50 samples for each generator. More recently, datasets encompassing a wider variety of generator models have been introduced, yet they tend to specialize in a limited number of tasks. These include multilingual news writing (Macko et al., 2023), question answering (He et al., 2023), and article and review writing

Table 1: Statistical information on our parallel human-written and machine-generated dataset, divided into the different source datasets and tasks.

(Wang et al., 2023). In comparison, our BUST dataset incorporates diverse tasks, enabling a more comprehensive analysis of detection systems' capabilities. A comprehensive overview of the available datasets in this domain is given in Appendix Tab. 5. In contrast to other studies, our research focuses exclusively on instruction-tuned models, which the public is increasingly using through prompting interfaces.

3 Dataset

This section describes in detail the datasets used in our research. For a comprehensive overview of these datasets, see Tab. 1. Our collected comparison corpus includes paired entries of partially contextualized instructions, as well as both human-written and MGT responses. Multiple MGT responses are available for each instruction, generated by different models, as shown in Fig. 1. The specific models from which these responses are derived vary in complexity and range in size from 7B to over 100B parameters. Details of the text generation models can be found in Appendix Tab. 10.

For a comprehensive comparison and robust analyses, we included models in different configurations: standard models, models we further trained ourselves, and models with or without Parameter-efficient Fine-tuning (PEFT).

3.1 Dataset creation

This study uses a dataset obtained from a subset of the publicly available Databricks Dolly dataset (Conover et al., 2023). The dataset is characterized by a large variety of human writing styles with 5000 annotators. In addition, the dataset is divided into 8 different tasks, which allows for differential benchmarking across these categorical variations.

In constructing our benchmark dataset, we initially selected 2000 samples from the Databricks Dolly dataset using a stratified random sampling technique to ensure representativeness across different tasks. Then we prompted 7 distinct Large Language Models (LLMs) with the instructions of these examples to generate the MGT responses.

To further examine detectors' adaptability to distributional variations, we enhanced our dataset by integrating two additional datasets, specifically repurposed for this study, which will be described in the following section.

3.1.1 Repurposed review and stance datasets

While repurposing the reviews dataset for our study, we strategically leveraged existing datasets, emphasizing those with the potential inclusion of emotional or biased statements to evaluate how detectors perform in such specific scenarios. We utilized an Amazon review dataset (Ni et al., 2019) focused on magazine subscriptions, spanning from 2014 to 2018, amounting to 900 reviews after meticulous selection and linkage with product descriptions. Additionally, we incorporated the CovidLies dataset (Hossain et al., 2020; Chen et al., 2020), featuring tweets expressing stances on specific topics. In the case of the review dataset, the processing pipeline involved applying sentiment prediction and keyword extraction. We mapped 5-star review scores to a textual scale, ranging from "Very unsatisfied" to "Very satisfied." Using sentiment, keywords, mapped satisfaction levels, and product descriptions, we generated hypothetical instructions formatted similarly to the Databricks Dolly dataset, which underwent the same steps of synthetic generation. In the case of CovidLies, because the dataset already provided the Tweet's stance, we extracted mentions and hashtags to provide them as guiding information within the prompt.[3]

Similar to the Databricks Dolly dataset, the repurposed datasets include a wide variety of authors, as the majority of reviews and tweets are written by different users. By refraining from quality-based filtering, the datasets ensure coverage of the full spectrum of human expression and provide a broad, realistic picture of different language styles and writing methods.

4 Methodology

4.1 Dataset meta-analysis

Our research is primarily concerned with providing a careful evaluation and comparison of human-

[3]Appendix Tab. 9 provides a glimpse of a few examples and Appendix Fig. 5 shows an overview of the process.

written and MGT responses. To ensure the completeness and reliability of our results, we used multiple evaluation metrics, each tailored to specific aspects of the data. This section explains the methods and metrics used during our evaluation process. **Linguistic features** and statistical differences serve as basic markers for evaluating the generated responses' quality, fluency, and coherence. The features used for our assessment are listed in Appendix Tab. 6. **Readability** indices are an empirical measure of the ease with which a reader can understand a written text. We use various readability indices with different emphases listed in Appendix Tab. 7. **Writer's attitudes** offer indirect assessments of the author's attitude by categorizing the text based on dimensions like convincingness, persuasiveness, irony, and emotions. The objective is to gain interpretable insights into whether the attitudes expressed in the texts influence the behavior of detectors. In our approach, we utilized off-the-shelf models to infer attitudes.[4] **LIWC-based features** are linguistic and psychometric features obtained using LIWC[5] (Boyd et al., 2022), a well-known academically developed software, providing quantitative insights of not only linguistic and grammar (such as particular punctuation, time orientation etc.) but also other more sophisticated aspects of written text such as cognition, perception, social, motivation.

The rationale for selecting linguistic, readability, writer's attitude, and LIWC-based features was to bring explainability to detector results. These features were chosen for their ability to reflect diverse perspectives on texts and their source.

4.2 Detectors

In our benchmark, we evaluated a diverse set of black-box detector models, including both publicly available and proprietary systems, as well as those developed for commercial and non-commercial purposes. Each detector was tested in a real-world zero-shot scenario in which they were asked to distinguish between human-written and MGT, without any prior fine-tuning on specific examples. The XLMR_ChatGPT (Antoun et al., 2023) and ChatGPT_QA (Guo et al., 2023) detectors are based on RoBERTa (Liu et al., 2019) and were fine-tuned using the HC3 dataset. In contrast to ChatGPT_QA, the XLMR_ChatGPT detector was also trained on out-of-domain data to improve its resilience against common attack methods. Meanwhile, the training of the ChatGPT_QA model was limited to question-answer pairs extracted from the full text of the HC3 corpus to obtain a distinct knowledge domain. Additionally, we used the RADAR_Vicuna7B (Hu et al., 2023) model developed for robust MGT detection through adversarial learning. This learning process simulates an adversarial game with two players: a paraphraser that attempts to generate realistic text that can evade the detector and a detector that attempts to thwart such attempts. In contrast, the LLMDet (Wu et al., 2023) detector specializes in identifying the origin of a given text and efficiently distinguishing between several LLMs, such as GPT-2, OPT, LLaMA, and their human-written counterparts. It uses the next-token probabilities of salient n-grams and proxy perplexity to make its decisions. Lastly, we looked at the widely used commercial system GPTZero[6]. Since it is a closed-source platform, the details of GPTZero's model architecture, training datasets, and methods are not publicly available, adding a layer of complexity to evaluating its detection efficacy.

4.2.1 Detectors evaluation

Detector performance is evaluated using standard classification metrics, considering LLM-generated as the positive class. Due to the imbalanced nature of our dataset, we used F1-macro as the primary metric supplemented by the Matthews Correlation Coefficient (MCC). F1-macro provides a balanced assessment of precision and recall across all classes, and MCC is robust to skewed distributions.[7] The differing outputs of the various detectors are handled as follows: The LLMDet model outputs probabilities for the text being generated by several specific LLMs, which we merged into a single machine-generated category or human-generated; here, we took "1 - (score of human-generated)". For the Radar_Vicuna7B model, which outputs the probability that a text is machine-generated, we labeled text as machine-generated if the probability exceeded 0.5, using the probability as a value. ChatGPT_QA and XLMR_ChatGPT detectors make binary decisions, using the provided score if the detector labels the text as MGT or 1-score in the opposite case. The evaluation is performed on different levels, considering different generative models, tasks and detectors. Additionally, we perform correlation analysis and build surrogate models to

[4]The models used are listed in Appendix Tab. 8.

[5]https://www.liwc.app/

[6]https://www.gptzero.me

[7]Additional metrics are reported in Appendix A.

simulate detector behavior.

Correlations between detectors' predictions and dataset features We conducted a multifaceted analysis to comprehensively evaluate detector performance and gain insights into their behavior across various scenarios. Firstly, we computed correlations between detector systems and dataset features. This approach allows us to uncover patterns in performance. Our goal was not only to assess raw performance but also to understand better how detectors respond in different contextual settings. Furthermore, we aimed to unveil interpretable associations between detector performance and text features at varying levels, ranging from lexico-syntactic attributes to nuanced expressions of writers' attitudes.

In our categorical correlation analysis, we employed Chi-tests to examine the relationships between detector predictions (human or MGT) and the categorized attitudes of writers. For a more detailed exploration, we also included correlation assessments on continuous features. This involved evaluating relationships between textual features (such as length and word count), softmax outputs representing writers' attitudes versus the prediction scores generated by the detectors.

Surrogate models As noted, detectors are not only black-box models but often also proprietary, meaning many aspects of their inner workings are not publicly disclosed. We simulate detector behavior using surrogate models to understand different detector outcomes on our benchmark dataset. Each surrogate model is a classifier that ingests all mentioned linguistic, attitudinal and psychometric features and uses a particular detector label (human vs. MGT) as the target. To make the surrogate model explainable, we use the Gradient Boosting classifier as it provides insight into variable importance. We construct multiple surrogate models while also considering different tasks and generative models.

5 Results

5.1 Dataset Meta-analysis

Readability scores of texts produced by generative models vary greatly depending on the chosen readability metric, although, in general, for the majority of readability metrics, texts generated by Falcon-7b-Dolly obtain on average quite different scores from those of other generative models.

Linguistic features The greatest variations between generators could be observed in the generated text length, where the longest texts are generated by Guanaco-7b, LLaMA-2-7b*, and GPT-4.

LIWC features The greatest differences between generated texts could be noticed in terms of authentic, analytic, tone and clout scores, with GPT-4 texts having the highest analytic and authentic scores. Less pronounced are differences in perception, cognition, drives and social aspects. While GPT-4 texts still achieve the highest perception scores, the highest drive scores are observed in GPT-3.5. With respect to cognition, GPT-4 is closely followed by LLaMA-2-70b* and LLaMA-2-7b*, while in terms of social aspects, the latter two take supremacy over the competitors. Minor differences were noticed in conversation scores where LLaMA-2-7b* comes closest to humans. Additional figures for readability, linguistic, and LIWC features are reported in the Appendix A.5.

Writers attitude Analyzing irony and emotional expression in human-written text versus language models (LLMs) reveals interesting patterns. Notably, human text tends to contain more irony than LLM-generated texts, with GPT-4 exhibiting the least ironic undertones (see Appendix Fig. 17). In terms of emotions, a comparison shows distinct trends. LLaMA-2-7b* prominently expresses curiosity, while Falcon-7b-Dolly emerges as the model conveying the highest levels of remorse, making it the "saddest" among all the models. Remorse and admiration are notably over-expressed by Falcon-7b-Dolly and GPT-3.5. GPT-4 and Guanaco-7b, on the other hand, stand out for conveying excitement, while Guanaco-7b surpasses both humans and other models in overexpressing the love emotion (see Appendix Fig. 15).

Turning to convincingness, in general, LLMs produce arguments perceived with higher quality (being relevant, clear, and impactful) compared to humans. Notably, GPT-3.5 deviates the most from the human baseline in this regard (see Appendix Fig. 14). Regarding persuasiveness, all generators tend to generate text identified as persuasive more frequently than human-generated text. GPT-4 closely aligns with the persuasive trends observed in human-generated content (see Appendix Fig. 18). Though a direct correlation between these results and the ability of various LLMs to replicate human expression's attitude elements is not established, these results could shed light on detectors' performance variations when assessing texts generated by diverse generators.

Task	ChatGPT_QA	LLMDet	Radar_Vicuna7B	XLMR_ChatGPT
* (All-tasks)	0.607	**0.626**	0.549	0.547
brainstorming	**0.686**	0.647	0.519	0.662
classification	0.509	**0.577**	0.474	0.487
closed_qa	0.537	**0.597**	0.476	0.543

Table 2: Detectors performance in general (**ALL**) and **per task** in terms of F1-macro.

5.2 Detectors evaluation

Among the detectors evaluated (see Tab. 2), LLMDet emerges as the top performer in terms of F1-macro, showcasing not only the best overall performance but also remarkable stability across various tasks. Following closely is ChatGPT_QA, securing the second position, particularly excelling in general_qa, open_qa, and creative_writing tasks, outperforming LLMDet by 28%, 17%, and 16%, respectively. Notably, XLMR_ChatGPT mirrors the performance pattern of ChatGPT_QA, except for struggles in the stance and review_generation tasks. On the other end, Radar_Vicuna7B ranks as the least effective detector overall, but its strengths surface in information_extraction, review, and stance_generation tasks. Shifting the focus to assessing the performance depending on the source text generator, ChatGPT_QA stands out with a clear advantage in texts generated by Guanaco-7b, Falcon-7b-Dolly, and GPT-3.5 compared to other detectors. Conversely, Radar_Vicuna7B appears to struggle the most to detect GPT-4 generated texts (see Fig. 2 and Appendix Fig. 21).

5.3 Correlation analysis

On the categorical correlation between detector predictions and writers' attitudes, we did not observe significant correlations when considering the entire dataset. However, on a task-specific level (see Appendix Fig. 22), Radar_Vicuna7B is the most correlated detector. It significantly correlated with at least two writer's attitudes in 8 out of 10 tasks. Despite its high correlation, Radar_Vicuna7B exhibited the poorest performance. Conversely, LLMDet, the least correlated overall, demonstrated stability across tasks. It only showed significant correlations with two or more attitudes in 3 of the 10 tasks, and half of the tasks exhibited no correlation at all. Persuasiveness was the most correlated attitude among detectors, particularly in information_extraction, closed_qa, creative_writing, and review_generation.

Assessment of the continuous correlation between detector prediction scores and linguistic, attitudinal, and psychometric variables. Spearman correlation scores between different detector prediction scores and input variables are generally low. ChatGPT_QA has absolute correlation scores >0.2 with the highest number of input variables, mostly linguistic and LIWC features. On the contrary, LLMDet has absolute correlation scores >0.2 with only 5 input variables, out of which 4 are linguistic. In particular, 3 linguistic features, number of words, number of sentences and percentage of unique words, are correlated with all detector scores; however, they are not in the same direction. Apart from linguistic and LIWC features, XLMR_ChatGPT detector scores are also correlated with approval and convincingness features (see Appendix Fig. 19).

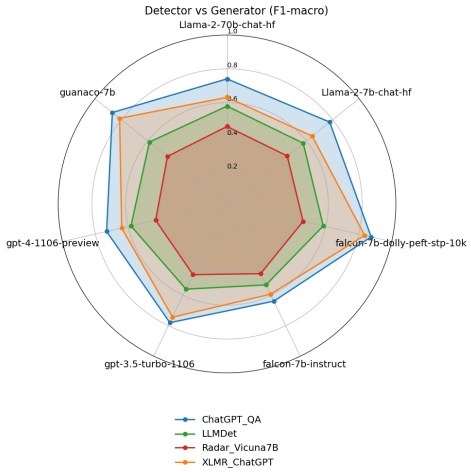

Figure 2: Detectors performance on detecting text produced by different generators (F1-macro)

5.4 Surrogate models results

Overall performance Our surrogate models were implemented using XGBoost library with 10 repetitions to ensure the robustness of the results. The performance of surrogate models on the whole dataset (considering all tasks and all generative models) depends on the performance metric (see Tab. 3). Regarding F1-macro and MCC scores, which are also more important given the existing class imbalance, the best surrogate is the one for ChatGPT_QA, while the second best is the surrogate for XLMR_ChatGPT. The surrogates for the other two detectors reflect remarkable fluctuations in the F1-macro score and, hence, are deemed less reliable, although the surrogate for Radar_Vicuna7B performs best in terms of F1-weighted and F1-micro. Looking at the features

Detector	F1-weighted	F1-macro	F1-micro	ROC AUC	MCC
ChatGPT_QA	0.871 (0.003)	**0.854 (0.003)**	0.862 (0.003)	**0.936 (002)**	**0.711 (0.005)**
XLMR_ChatGPT	0.842 (0.001)	*0.840 (0.001)*	0.842 (0.001)	0.923 (0.002)	*0.680 (0.003)*

Table 3: XGBoost classifier performance in terms of F1-score, ROC AUC and MCC across 10 runs. The best and second-best scores per detector surrogate and performance metric are denoted in bold and italics, respectively.

that the surrogate classifiers considered the most important across all 10 runs, we can see (Fig. 3) that linguistic features are very important for simulating detectors' behavior. In particular, the number of words (denoted as "stats_num_words") is considered an important variable in all 10 runs for surrogate models of each detector, with also quite a high average importance score across the runs.

Performance by task When simulating detectors' behavior on a task level, in terms of F1-macro and MCC score, the surrogate XGB model simulating the behavior of ChatGPT_QA performs the best in all tasks except for review and stance_generation. For review_generation, the surrogate for XLMR_ChatGPT outperforms the others, while for stance_generation simulating Radar_Vicuna7B is the most successful (also in terms of other metrics, see Appendix Tab. 12). Comparing each detector surrogate model performance across different tasks in terms of MCC, the surrogate for ChatGPT_QA performs the best on the information_extraction task, the surrogates for XLMR_ChatGPT and Radar_Vicuna7B perform the best on the stance_generation task and the surrogate for LLMDet performs the best on review_generation task. Looking at the most important features used by surrogates, we observe that linguistic features such as "stats_percent_unique_words" and "stats_num_words" are perceived as most important for different detectors and tasks, although the surrogate for LLMDet tends to rely more on word length and punctuation.[8]

Performance by generative model When simulating detector behavior with respect to the underlying generator model (see Appendix Tab. 13), in terms of F1-macro and MCC scores, we had the most success for ChatGPT_QA detector for all generators except human, Falcon-7b* and GPT-4. In the case when human or Falcon-7b* generated the text, the best performance was obtained for the Radar_Vicuna7B surrogate, while in the case of GPT-4, it was the surrogate for XLMR_ChatGPT.

[8]See Fig. 31 in Appendix A.

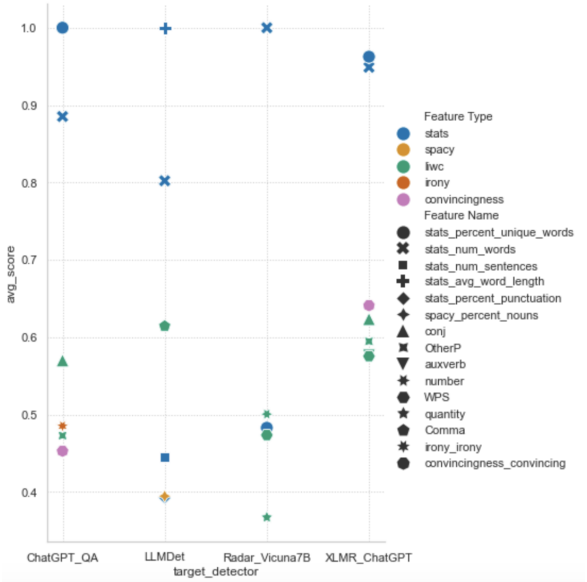

Figure 3: Features resulting as top 10 most important within each of 10 runs per different detector XGBoost surrogate classifiers, together with their average importance score.

Regarding feature importance (see Appendix Fig. 32), we observe a consistent trend where surrogates generally depend on the "number of words" feature. However, the LLMDet surrogate additionally relies on "average word length" and punctuation (comma, apostrophe), and the XLMR_ChatGPT surrogate even considers various emotions.

6 Ablation studies

Analyzing the detector performance across the ablation scenarios (see Fig. 4), we found GPT-Zero as the top performer consistently, with scores of 0.683, 0.692, and 0.652 in the uncontrolled, temperature-min, and length scenarios, respectively. Following closely is ChatGPT_QA, which suffered a noticeable 17% drop in performance, particularly when length control is applied. XLMR_ChatGPT, in the third position, exhibits a similar pattern. Interestingly, the introduction of temperature control does not significantly affect detector performance. However, length control appears to be a critical factor, leading to performance reduction in all detectors except Radar_Vicuna7B, which demonstrates a slight improvement under this constraint.[9] Extending the ablation analysis to the text and the corresponding generators, we made the following observations.

In the Length-based scenario, focusing on text characteristics revealed a notable increase in the overall percentage of nouns, coupled with a decrease in the percentage of verbs (see Appendix

[9]See Appendix Tab. 11 for detailed detector performance on the different ablation scenarios.

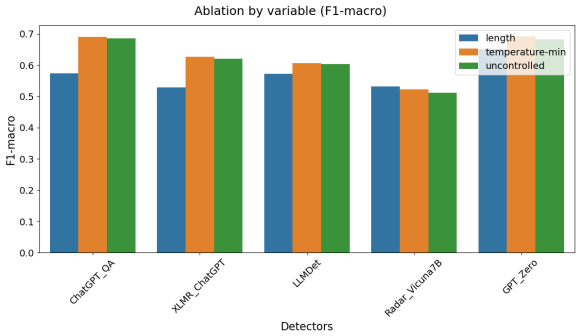

Figure 4: Detectors performance on the ablation set **per controlled variable** (F1-macro)

Fig. 25). Additionally, the emphasis on time orientation was reduced (see Appendix Fig. 27). We did not observe significant changes in writer's attitudes. However, when evaluating the performance of detectors on texts generated by different models, a noticeable change was identified for ChatGPT_QA. It struggled more to correctly detect text generated by GPT-4 (see Appendix Fig. 24).

In the Temperature-min scenario, an analysis of text characteristics showed a drastic increase in the average sentence length for LLaMA-2-7b* (see Appendix Fig. 26). In relation to writer's attitudes, LLaMA-2-7b* was significantly affected in a positive manner. It played a crucial role in tempering overexpressed emotions, such as curiosity, and contributed to enhanced convincingness (see Appendix Fig. 13). Despite this, the text generated by LLaMA-2-7b* was not harder to detect in this scenario (see Appendix Fig. 24).

7 Discussion

Analyzing detectors' performance across tasks (see Tab. 4), focusing on F1-macro, we noted similarities between ChatGPT_QA and XLMR_ChatGPT. However, XLMR_ChatGPT decreases performance, particularly in stance and review_generation tasks, indicating limitations with less probable data scenarios not extensively covered during training. This suggests that XLMR_ChatGPT might be less adept at handling unseen tasks, potentially lacking generalizability.

Furthermore, when evaluating models with pronounced emotions (Falcon-7b-Dolly, Guanaco-7b, and GPT-3.5), we identified a significant advantage of ChatGPT_QA over LLMDet, shown in the detector vs. generator F1-macro comparison. This observation aligns with the correlations observed between ChatGPT_QA predictions and writers' attitudes, contrasting with LLMDet, which exhibits minimal correlation with writers' attitudes (see Appendix Fig. 22). Although Radar_Vicuna7B is the overall least performing model, it demonstrates competitive performance in stance and review_generation tasks. These tasks were generated by repurposing datasets less likely covered during LLMs training, which could suggest that Radar_Vicuna7B is less overfitted. In general, LLMDet demonstrates more consistent performance across the tasks, while ChatGPT_QA ranks as the second-best performer in certain tasks but falls short in others. Specifically, ChatGPT_QA performs well in QA-related tasks as anticipated, yet it underperforms in tasks such as information_extraction.

When comparing detector versus surrogate model performances at the task level, we can notice that for brainstorming, general_qa, open_qa, creative_writing, surrogate model performance mirrors detector behavior (meaning that the good performance of a detector, typically ChatGPT_QA, could also be well mimicked by the respective surrogate model) while this is not the case for the other tasks (stance_generation, information_extraction, closed_qa, classification, review_generation, summarization). Particularly when LLMDet best performs in a task (e.g., stance_generation, see Tab. 2 and Appendix Fig. 30), its behavior is hard to explain with the surrogate model. This means that the considered features are very useful for simulating ChatGPT_QA behavior and less so for LLMDet, probably leading the LLMDet surrogate to rely on unexpected features like punctuation

Notably, variations in the best-performing model across evaluations arise from differences in how the data was grouped. Figure 2 and Table 4 assess performance concerning the generator, using a subset of human-generated and the corresponding MGT, resulting in a balanced dataset. Conversely, Table 2 evaluates detectors on full or task-specific subsets, disregarding the generator, based on human and corresponding MGTs from multiple models, often leading to an imbalanced dataset that may bias F1-macro scores in favor of LLMDet.

8 Conclusion

In this study, we present a benchmark for evaluating LLM-generated text detectors. Our dataset comprises 3180 instructions with corresponding human responses across 10 tasks from 3 diverse sources. Synthetic responses were generated by prompting 7 different LLMs, resulting in a dataset exceeding

Table 4: Detectors performance per task and per generator model in terms of F1-macro (F1-m), ROC AUC (ROC), and Matthews Correlation Coefficient (MCC). The best scores per task and performance metric are displayed in bold-face

25k texts. Evaluating 5 detectors revealed substantial performance variance across tasks. Our meta-analysis explored dataset characteristics, guiding the analysis of detector performance. Surrogate models highlighted the difficulty in explaining the most performant detector, frequently relying on unexpected textual features. Emotions, in particular, aided some detectors in specific tasks, but the most stable and effective detector exhibited consistent performance irrespective of writer's attitudes.

These distinctive characteristics position our benchmark as a valuable resource for end-users seeking to select a detector that best suits their target text style and use case. Notably, we have integrated all analyses into an automated pipeline, which enhances accessibility and usability for researchers and practitioners in the field.

Limitations

Limited Amount of Datasets. A notable limitation of our study is that we rely on a limited number of datasets. Although these datasets were selected for relevance and quality, they represent only a fraction of the available textual sources. This limitation could lead to a lack of diversity in languages, language styles, topics and linguistic nuances, which could affect the generalizability of our results. Users should be aware that the results and findings from our dataset may not fully reflect the complexity and variations that occur in practice. Consequently, interpretations and applications of our research should be made with these limitations in mind.

Limited Selection of Generator Models. Our research includes a selected set of text generation models, which is a notable limitation. This limited

selection means that the dataset may not represent the full range of text generation capabilities currently available. Advanced or emerging models may not be adequately represented, particularly those using state-of-the-art techniques or architectures. As a result, the effectiveness of our dataset in recognizing text from these unrepresented models may be reduced.

Limited Selection of Detector Models. In the present study, we use a specific selection of detector models, which is a significant limitation. This limited selection may not cover the full range of detection methods and technologies available in practice. Consequently, this could lead to a biased assessment of the reliability of our dataset, as it is evaluated against a potentially not fully representative sample of detectors. This limitation highlights the need to be cautious when generalizing the results and suggests that it is important to test the dataset with a wider variety of detector models for a more comprehensive evaluation.

Ethics Statement

Intended Use Our research, which focuses on the collection of a new dataset for machine-generated text detection, is designed to advance the field responsibly and ethically. This dataset, drawn from publicly available resources, integrates various publicly available text generation models and detectors. Our primary goal is to provide the research community with a robust benchmark for evaluating and improving text recognition algorithms. We anticipate that this dataset will help to improve the accuracy and reliability of recognition methods and thereby gain a broader understanding of the nuances in MGT. We emphasize that our dataset is intended to be used for academic and research purposes only. It is intended to facilitate the development of more sophisticated recognition tools that can distinguish between human and MGT to ensure the integrity and authenticity of digital content. In this way, we aim to support ongoing efforts to maintain transparency and trustworthiness in digital communications. We strongly discourage any use of this dataset that violates ethical standards or promotes malicious activity, such as the creation of misleading or harmful content. Our adherence to ethical guidelines reflects our commitment to promoting positive impact in the field of natural language processing and beyond.

Biases. In our study, we acknowledge the potential for inherent biases within our dataset and the broader implications that these biases may have in the field of MGT detection. We recognize that any dataset, especially when derived from publicly available sources, may reflect historical and societal biases in the data it contains. These biases include, but are not limited to, linguistic, cultural, gender or demographic preferences. We are particularly cautious about how these biases might affect the performance and interpretation of detection algorithms and potentially lead to biased or unfair results.

Misuse Potential. Our data set, which was developed for the evaluation of MGT detection, has significant potential for positive impact. However, we are aware of the possibility of its misuse. In particular, there is a risk that the dataset could be used to develop methods to create more convincing MGT, which could be used for misleading purposes such as misinformation or spam. To prevent this, we prohibit the use of our dataset for unethical practices, including but not limited to the creation of misleading or harmful content. We encourage users to adhere to a high standard of ethical responsibility and ensure that the data set is only used to enhance the authenticity and trustworthiness of digital communications.

Reliability conditions. The reliability of our dataset for the evaluation of MGT detection models depends on the performance and development of the generator systems. It is important to recognize that the accuracy and effectiveness of these tools can vary significantly depending on the design, training data, and underlying algorithms. Consequently, the usefulness of our dataset as a benchmark is reliable on the condition that these models are regularly updated and refined to adapt to advances in text generation technologies. Users should note that the results obtained may not be universally applicable to all generator and detector systems, and that continuous validation against a variety of models is essential to maintain the relevance and effectiveness of the dataset in an evolving technological landscape.

A.3 Repurposed review and stance datasets

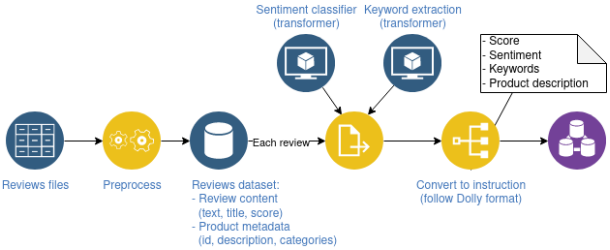

Figure 5: Process to repurpose review datasets into instructions.

Dataset	Instruction	Context	Response	Generator
Amazon reviews	Based in the provided product description, generate a **positive** product review from a client who is **Very satisfied**. Consider the following keywords: **DIY, DIY, house, fashion magazines**	Product description: Tackle any home improvement project or repair with help from The Family Handyman. Guarantee success with step-by-step instructions and how-to photos, plus save time and money with handy hints, workshop tips and new product reviews. No matter how little experience you have, The Family Handyman makes it easy! Family Handyman publishes 11 issues per year which includes a special issue that counts as 2 issues in your subscription.	I'm a so-so DIY'er. I try to DIY pretty much everything around the house, not everything turns out too well. So that's where I'm coming from, and my opinion of this magazine is that it's a lot of fun to read. Interesting, helpful, fun ideas and articles. Some good tips too. Nothing earth shattering but not bad. I feel like this is what my wife must feel like when she reads her fashion magazines.	Human
			I'm beyond pleased with The Family Handyman! As someone who loves DIY projects around the house, this magazine is a game-changer. The step-by-step instructions and how-to photos are incredibly helpful, making every home improvement project a breeze. The handy hints and workshop tips have saved me both time and money. It's like having a personal expert by my side. I especially appreciate the new product reviews, guiding me towards the best tools for the job. It's become my go-to resource for all things DIY. Couldn't be happier with my subscription!	GPT-3.5
	Based in the provided product description, generate a **positive** product review from a client who is **Unsatisfied**. Consider the following keywords: **bike magazine, bike magazine, bike magazine, bi**	Product description: Cycle World, America's largest motorcycle media brand, is the leading resource for in-depth, quality information on all types of motorcycles, accessories and riding gear.	I used to love this magazine, particularly in the 1970s. Unfortunately, the writing is now bland and there is little incisive coverage. This used to be the premier bike magazine. I won't renew, that's for sure.	Human
			Initially dissatisfied, but pleasantly surprised! The Cycle World magazine exceeded my expectations with its comprehensive coverage of motorcycles, accessories, and riding gear. The quality information provided is unmatched, making it a valuable resource for any bike enthusiast. Highly recommended for a deeper understanding of the biking world!	GPT-3.5
CovidLies	Generate a tweet related to COVID-19 that have a stance in favor of **'We're very close to a vaccine.'** Include the following mentions: **[@SpeakerPelosi]**		@SpeakerPelosi I understand Israel will have a vaccine for coronavirus in a few weeks.	Human
			Encouraging news on the COVID-19 front! We're very close to a vaccine breakthrough that could bring us closer to ending this pandemic. Fingers crossed for a swift and successful rollout. [@SpeakerPelosi] #COVID19 #VaccineHope	GPT-3.5

Table 9: Repurposed Datasets examples

A.4 Text generation

Generators In our study, we evaluated a diverse set of models from the Falcon and LLaMA families, as well as two GPT models. Specifically, we considered two models from the Falcon family (Almazrouei et al., 2023): Falcon 7B Instruct[15] and our customized version, Falcon 7B Dolly[16], which utilizes LoRA as a Parameter-Efficient Fine-Tuning (PEFT) technique. Additionally, we incorporated three models from the LLaMA family (Touvron et al., 2023b,a): LLaMA-2 7B Chat[17], LLaMA-2 70B Chat[18], and PEFT model LLaMA Guanaco [19]. Finally, our analysis also included two models from the GPT series (OpenAI, 2023): GPT-3.5-turbo-1106 and GPT-4-turbo-1106-preview[20]. The base models that were instruction- or chat-tuned are marked with an asterisk (*) for clarity. The specific configuration can be found in Tab. 10. This selection of models, encompassing a range of complexities and specializations, allows for a comprehensive examination of capabilities of the text generation models.

Falcon-7b-Dolly	Falcon 7B dolly	2048	1	LoRA
Guanaco-7B	LLaMA Guanaco	2048	0.7	QLoRA
LLaMA-2-7b*	LLaMA-2 7B chat	4096	0.6	No
LLaMA-2-70b*	LLaMA-2 70B chat	4096	0.6	No
GPT-3.5	GPT-3.5-turbo-1106	16285(context window)/4096 (max. output)	1	No
GPT-4	GPT-4-turbo-1106-preview	128K(context window)/4096 (max. output)	1	No

Table 10: Models used for the text generation

Prompt We have tried to reduce the prompt template to a minimum to ensure it is uniformly applicable to the different models (see Fig. 6). Only the Guanaco-7b and Falcon-7b-Dolly models have minor modifications in the template due to the use of a different instruction tuning scheme while fine-tuning, as shown in Fig. 7. An additional line with context was only added if such context was available; otherwise, this line was omitted completely.

Context: [GIVEN_CONTEXT]

Instruction: [GIVEN_INSTRUCTION]

A.8 Surrogate models results

Due to a strong correlation between variable *stats_num_words* and LIWC variable *WC* (Spearman correlation coefficient = 1), variable *stats_percent_punctuation* and LIWC variable *AllPunc* (0.93) and variable *stats_percent_long_words* and LIWC variable *BigWords* (0.81), we eliminated those mentioned LIWC variables from (*WC*, *AllPunc*, *BigWords*) from further consideration (see Fig. 28). Also, readability features were not taken into consideration for surrogate model construction due to many missing values (limitation of readability metrics on short text).

Surrogate models were implemented using XGBoost library (with 10 repetitions). The training was done using 100 boosting rounds, logloss as an evaluation metric, 0.1 as eta (learning rate) and setting 5 as the maximum depth of each tree.

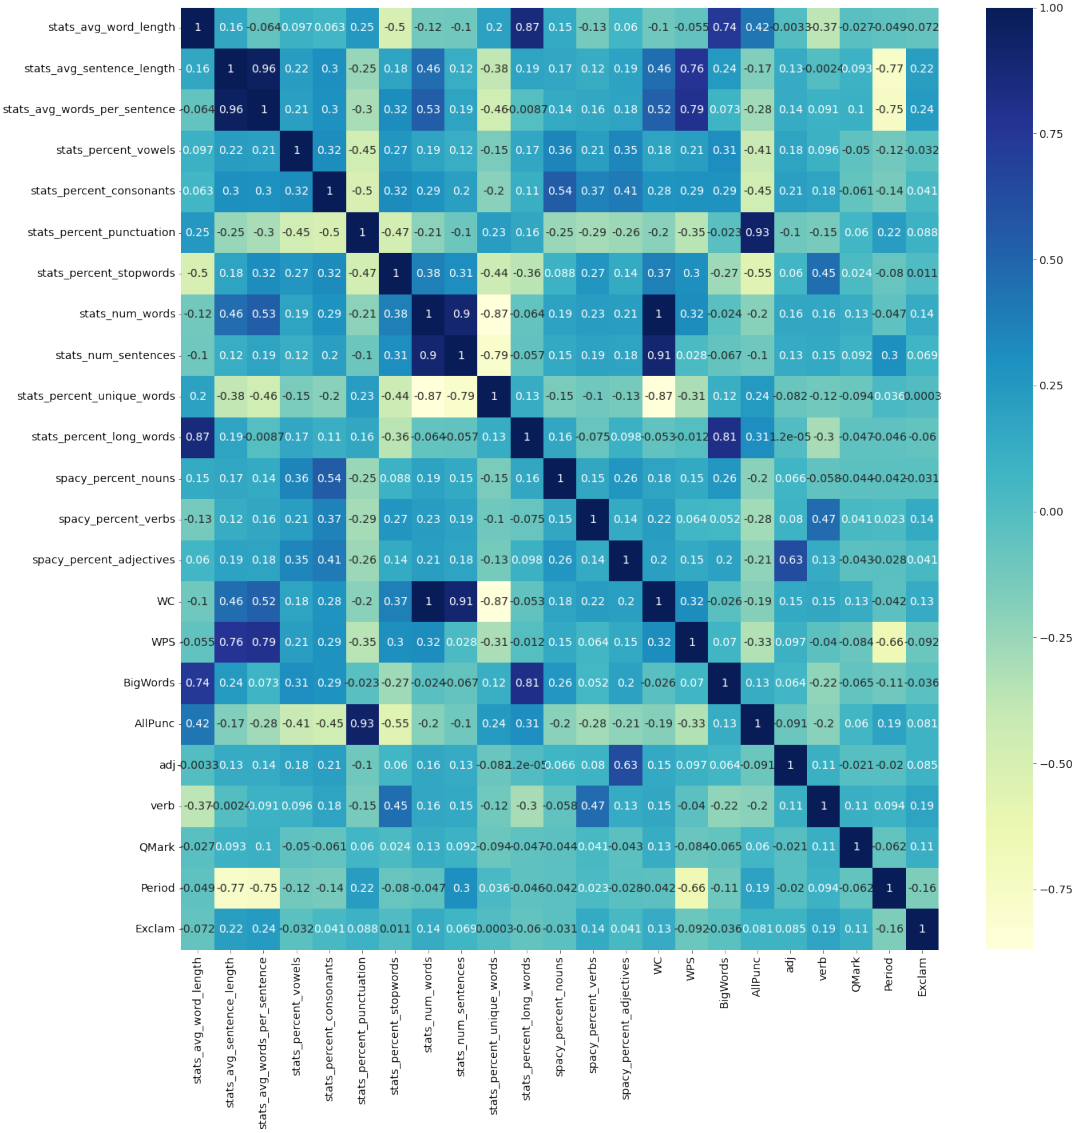

Figure 28: Correlation between input variables (excerpt))

The ROC curve for different surrogate classifiers in general can be seen in Fig. 29, while the ROC curve for the stance_generation (interesting due to different surrogate performance in terms of ROC AUC), can be found in Fig. 30.

As mentioned before, XGB surrogate performance by different tasks and generative models can be seen in Tab. 12 and Tab. 13 respectively, while the corresponding important features can be found in Fig. 31 and Fig. 32, respectively.

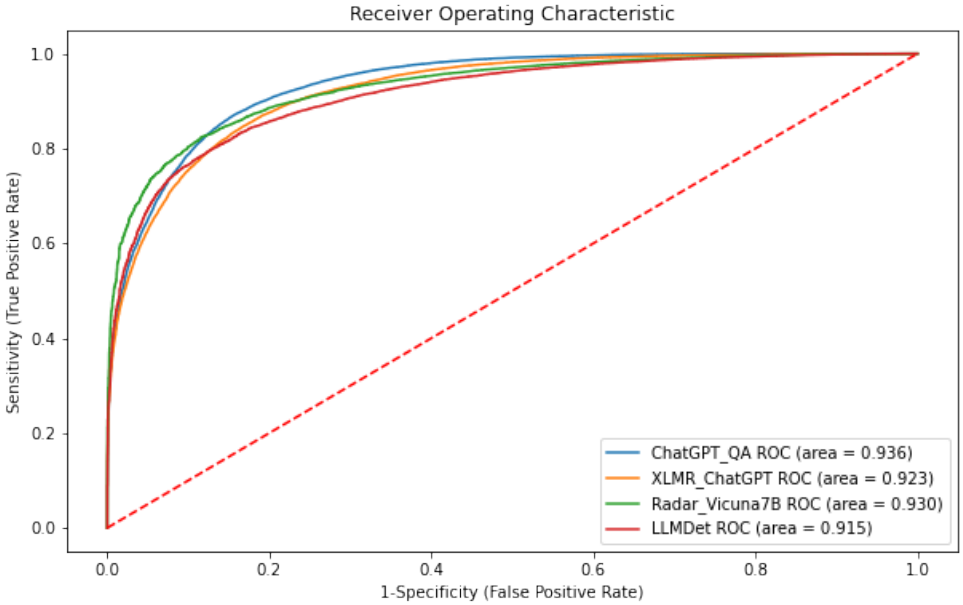

Figure 29: ROC curve for surrogate models (all tasks and generative models)

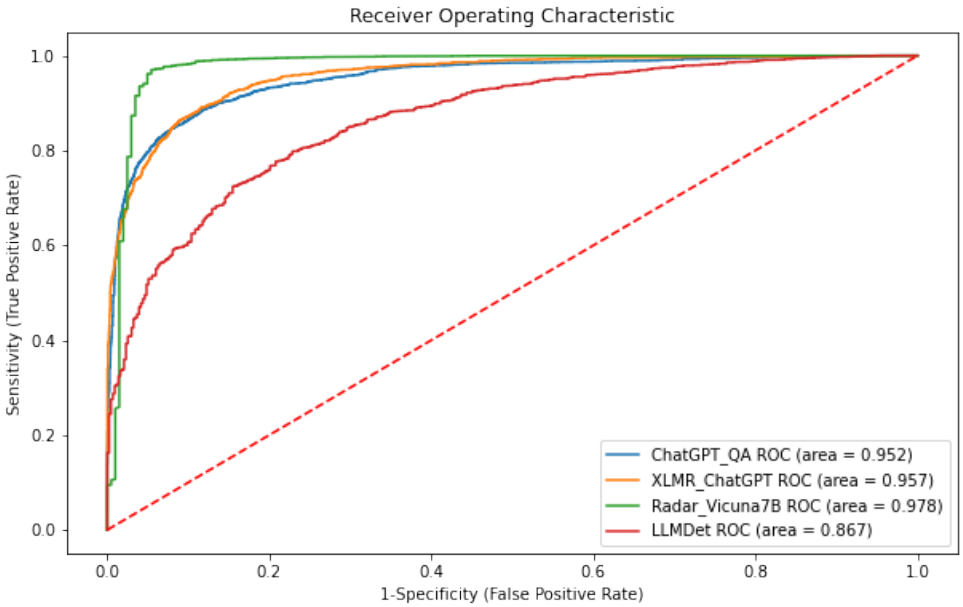

Figure 30: ROC curve for surrogate models for stance_generation task.

Abstract

Multilingual generative models obtain remarkable cross-lingual in-context learning capabilities through pre-training on large-scale corpora. However, they still exhibit a performance bias toward high-resource languages and learn isolated distributions of multilingual sentence representations, which may hinder knowledge transfer across languages. To bridge this gap, we propose a simple yet effective cross-lingual alignment framework exploiting pairs of translation sentences. It aligns the internal sentence representations across different languages via multilingual contrastive learning and aligns outputs by following cross-lingual instructions in the target language. Experimental results show that even with less than 0.1 ‰ of pre-training tokens, our alignment framework significantly boosts the cross-lingual abilities of generative language models and mitigates the performance gap. Further analyses reveal that it results in a better internal multilingual representation distribution of multilingual models. [1]

1 Introduction

Multilingual generative language models achieve impressive universality across many languages by pre-training on large-scale unsupervised multilingual corpora (Liu et al., 2020; Xue et al., 2021; Lin et al., 2022; Scao et al., 2022; Soltan et al., 2022; OpenAI, 2022). However, models still show a strong language bias toward high-resource languages (Asai et al., 2023), even the state-of-the-art multilingual generative models like GPT-4, exhibiting a 27.5% relative performance gap between English and Telugu in MMLU (OpenAI, 2023). This challenge partly arises from the significant linguistic resource imbalance among languages, which is hard to address solely through corpus scaling or balancing. Given such a model with language bias and the huge cost of re-training, how can we improve its cross-lingual capabilities and alleviate the language bias using limited data?

(a) $XGLM_{564M}$ (b) $XGLM_{564M}$ + AFP

(c) In-context Learning on XNLI

Figure 1: (a, b) Our method aligns the internal EN-ZH sentence representations of $XGLM_{564M}$, which are shown in t-SNE. (c) It also mitigates the performance gap on XNLI.

Previous work focused on scaling multilingual instructions (Muennighoff et al., 2023; Zhu et al., 2023), ignoring internal alignment and knowledge transfer between languages in the multilingual generative model. Through visualizing the sentence representations in the multilingual generative model by mean pooling, we find that there is a distinct gap between the sentence representation distributions for different languages like Figure 1(a) (the multilingual ones are shown in Appendix B.3). This is similar to learning representations for each language separately in the model, which is more challenging for multilingual models to transfer the knowledge learned from other languages. Thus, it is important to investigate whether the cross-lingual ability of models will be promoted by learning a better-aligned representation distribution.

To address the above issues, we propose a cross-lingual alignment framework named Align aFter Pre-training (**AFP**), which aims to exploit translation pairs to narrow the gap between languages

in the multilingual generation model. To be specific, our method can be divided into the following two modules: 1) **Multilingual Contrastive Learning (MCL)** on internal representations: we treat a translation sentence pair as the positive example for contrastive learning, and pull the sentence representations in two languages to be closer within the multilingual generated model. This module intends to reduce the differences between languages from the internal representations of the model. 2) **Cross-lingual Instruction Following (CIF)** on the outputs: models must learn to answer in the target language given a prompt from the source language. It aims at enhancing semantic coherence and knowledge transfer across languages in the model.

After extensive experiments, it can be found that AFP greatly improves the performance of multilingual generative models in cross-lingual natural language inference, multilingual reasoning, and other tasks using less than 1M parallel samples. The performance gap between languages is narrowed, e.g., the relative performance gap of $\text{XGLM}_{564\text{M}}$ reduces 6.53% on XNLI between English and Chinese (Figure 1(c)). Our method also advances the performance on unseen languages for models, e.g., the Chinese performance of Llama, which is pretrained on the corpus mainly in English (Touvron et al., 2023a,b). Further analyses reveal that the representation gap has been mitigated as illustrated in Figure 1(b) after training with AFP. In addition, experimental results show that the cross-lingual instruction following task is better than the multilingual instruction tuning task in promoting cross-lingual ability with the same parallel corpus.

To sum up, our main contributions are as follows:

- We propose a simple yet effective cross-lingual alignment framework, including the internal representation alignment (MCL) and external output alignment (CIF), to exploit the parallel corpus for multilingual generative models.
- Experimental results demonstrate that our method greatly improves the cross-lingual ability of generative models, including multilingual ones and models pre-trained on English corpus, by using less than 1M samples.
- Further analyses reveal that AFP promotes the alignment and uniformity of internal multilingual representation distributions. Ablation study shows that using the internal representation alignment of AFP alone cannot boost multilingual generative models.

2 Related Work

2.1 Multilingual Generative Language Model

Through unsupervised pre-training on the large-scale multilingual corpus, generative language models obtain impressive multilingual abilities, e.g., multilingual machine translation (Liu et al., 2020; He et al., 2021; Wang et al., 2022; Lu et al., 2023), cross-lingual natural language understanding (Xue et al., 2021) and cross-lingual in-context learning (Lin et al., 2022; Scao et al., 2022; Wei et al., 2023; Anil et al., 2023). Most of them extended the pre-training method developed for the monolingual corpus (Lewis et al., 2020; Raffel et al., 2020) and relied on a balanced sampling method across languages, while a significant performance gap between high-resource languages and low-represented languages persists in the pre-trained model (Asai et al., 2023). Different from the unsupervised pre-training on the multilingual corpus, this work attempts to alleviate the performance gap across languages by cross-lingual alignment using parallel samples.

2.2 Multilingual Instruction Tuning

Large language models show better zero-shot multilingual performance and language generalization results after multilingual instruction tuning (Muennighoff et al., 2023; Zhang et al., 2023; Zhu et al., 2023; Ranaldi et al., 2023). Our cross-lingual instruction following task requires the model to respond in the target language and is different from multilingual instruction tuning, where prompt and answer in the same language for each sample.

2.3 Contrastive Learning in Natural Langauge Processing

Most of the work in NLP adopted contrastive learning to improve the representation of sentences in the language model (Reimers and Gurevych, 2019; Pan et al., 2021a; Gao et al., 2021; Yang et al., 2021; Pan et al., 2022; Ni et al., 2022; Sherborne et al., 2023). Specifically, contrastive learning is often applied to the sentence representations of encoder (Cao et al., 2020; Fang et al., 2020; Wu et al., 2020; Pan et al., 2021b; Chi et al., 2021; Wei et al., 2021). However, it is less explored how to promote the representation of Transformer decoder models

(Vaswani et al., 2017; Zhao et al., 2023). In this work, we try to improve the internal multilingual representation of the decoder models by multilingual contrastive learning rather than the one of encoder (Wang et al., 2021; Qin et al., 2022).

3 Method

As shown in Figure 2, our framework AFP contains the following two modules: 1) Multilingual contrastive learning (Section 3.1), which aims to align the internal representations of models across different languages. 2) Cross-lingual instruction following (Section 3.2), which requires models to align the outputs between different languages.

3.1 Multilingual Contrastive Learning

To align the internal multilingual representation of models, we exploit the contrastive learning method, which is generally found effective in aligning the representations from different modalities in multimodal work (Radford et al., 2021; Xu et al., 2021; Liang et al., 2022). Hence, translation pairs are regarded as positive instances with closely aligned semantics in multilingual contrastive learning, and we pull their internal representations closer. The other sentences in the same batch are taken as the negative samples for the translation pair.

Formally, to align the l-th layer of model $f(\theta)$, the sentence representations (h_i, h_i^+) is calculated as follows:

$$h_i = g(f_l(s_i;\theta)),\ h_i^+ = g(f_l(s_i^+;\theta)) \quad (1)$$

where $f_l(\cdot)$ represents the output from the l-th layer, $g(\cdot)$ is the pooling method to obtain the sentence representation for decoder models, e.g., mean pooling or max pooling, and (s_i, s_i^+) is a parallel sample from $\mathcal{D} = \{(s_1, s_1^+), ..., (s_n, s_n^+)\}$. We determine the specific layer to align according to the performance of models on the dev set and find that the first layer after embedding comes to better performance (please refer to Section 4.2.2 for more details). Then, the training objective of Multilingual Contrastive Learning (MCL) is:

$$\mathcal{L}_{MCL}(\theta) = \mathop{\mathbb{E}}_{(s_i,s_i^+)\sim\mathcal{D}} \left[-\log \left(\frac{e^{\text{sim}(h_i,h_i^+)/\tau}}{\sum_j e^{\text{sim}(h_i,h_j)/\tau}} \right) \right] \quad (2)$$

where $\text{sim}(\cdot)$ is used to determine the similarity between representations, which is cosine similarity in this work, h_j is the sentence representation of s_j in the mini-batch containing (s_i, s_i^+), and τ is a temperature hyper-parameter.

3.2 Cross-lingual Instruction Following

To further align the output of multilingual generative models, we introduce a method named Cross-lingual Instruction Following (CIF), which imposes models to respond in the target language given the source language as the context. It is more difficult than the multilingual instruction tuning task, which prompts and answers in the same language for each sample, and requires a better cross-lingual understanding and generation ability for multilingual generative models.

Specifically, given a pair of context and response (c_i^a, r_i^a) from a Dataset $\mathcal{D}^a$ in the same language a, e.g., an English instruction tuning dataset like FLAN or Alpaca (Wei et al., 2022; Wang et al., 2023; Taori et al., 2023), response r_i^a is first translated into the target language b by the translator $t^{a\to b}(\cdot)$. We append a prompt p^b informing the target language b, e.g., "Answer in German" in Figure 2, at the end of context to construct the training sample $\left(c_i^{a\to b} = c_i^a + p^b, r_i^b = t^{a\to b}(r_i^a)\right)$ for CIF. Therefore, the loss function of CIF for the multilingual generative model $f(\theta)$ comes to:

$$\mathcal{L}_{CIF}(\theta) = \mathop{\mathbb{E}}_{(c_i^a,r_i^a)\sim\mathcal{D}^a} \left[\sum_j -\log \left(\text{P}(r_{ij}^b | c_i^{a\to b}, r_{i,<j}^b; \theta) \right) \right] \quad (3)$$

where the target language b has the possibility $p_{src} \in [0, 1]$ to be set the same as the source language a, which is a hyper-parameter and investigated in Section 4.2.3. When the target language is always the source language of the context ($p_{src} = 1$), it degenerates into the vanilla multilingual instruction tuning method.

With the two modules of aligning methods mentioned before, Multilingual Contrastive Learning (MCL) and Cross-lingual Instruction Following (CIF), we obtain the following loss function of our alignment framework AFP:

$$\mathcal{L}_{AFP}(\theta) = \mathcal{L}_{MCL}(\theta) + \alpha \mathcal{L}_{CIF}(\theta) \quad (4)$$

where $\alpha \in \mathbb{R}_0^+$ is a hyper-parameter to balance the two alignment methods.

4 Experiments

4.1 Experiments Settings

Parallel Corpora To cover more parallel samples from different domains and languages, we adopt a multilingual instruction tuning dataset named Bactrian-X (Li et al., 2023), which is translated into 52 languages from Alpaca (Taori et al.,

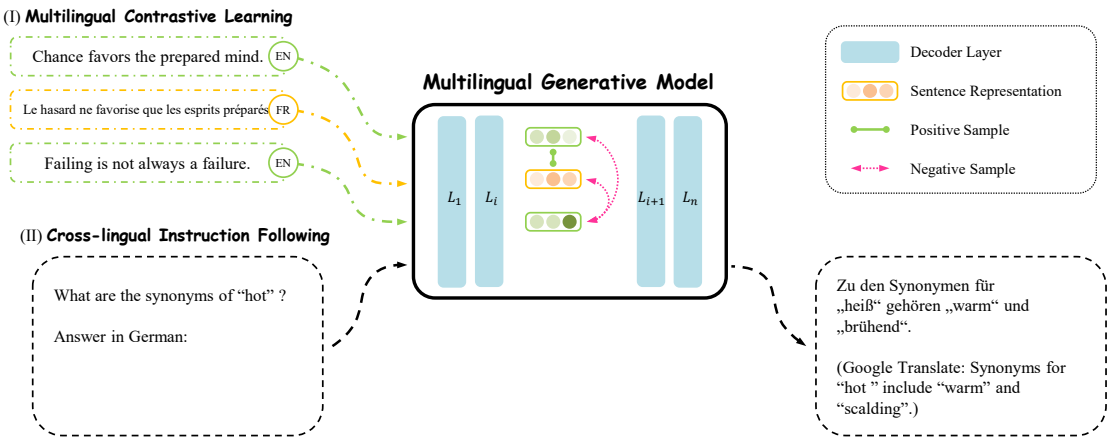

Figure 2: Illustration of how to align the internal representations and outputs of multilingual generative models with AFP. (I) Given a translation parallel sample as the positive sample, multilingual contrastive learning pulls their representations together and pushes apart the ones from other samples. (II) Multilingual generative models are required to answer in the target language to align the outputs across languages.

2023) and Dolly (Conover et al., 2023) by Google Translate, and a multilingual machine translation dataset, OPUS-100 (Zhang et al., 2020), to align the models evaluated. Only 100k parallel samples are selected from OPUS-100 in our experiments to match the amount of Bactrian-X, which contains 67k samples for each language. The number of tokens used is about 20M, which is nearly 0.05 ‰ of tokens used in the pre-training of BLOOM (Scao et al., 2022).

Language models We apply AFP on two multilingual generative model structures, XGLM (Lin et al., 2022) and BLOOM (Scao et al., 2022), across three different parameter amounts. The models fine-tuning with multilingual instruction tuning, "+MIT" or BLOOMZ (Muennighoff et al., 2023), are taken as the baseline. Llama (Touvron et al., 2023a), which is mainly pre-trained on English corpus, is also included for comprehensive evaluation. Training settings and hyperparameters are reported in Appendix A.

Multilingual Tasks We evaluate the performance of models on the following benchmarks:

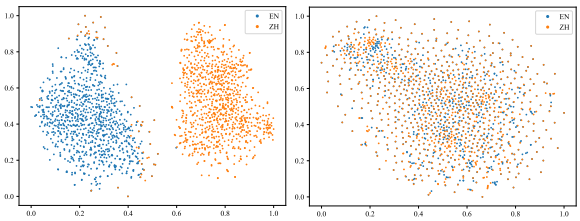
- **Natural Language Inference** We use XNLI (Conneau et al., 2018) in this task.
- **Paraphrase Detection** PAWS-X (Yang et al., 2019) is evaluated for this task.
- **Reasoning** We adopt XCOPA (Ponti et al., 2020), XStoryCloze (Lin et al., 2022) and XWinograd (Tikhonov and Ryabinin, 2021) in this task.
- **Machine Translation** For this task, we use FLORES-101 (Goyal et al., 2022).

The detailed descriptions and prompt formats for each task during evaluation are presented in Appendix C. We keep the same prompt formats across all multilingual generation models for a fair comparison.

4.2 Bilingual Results and Analyses

To make a comprehensive analysis of the influence on performance and representations in models, we first conduct bilingual alignment experiments in English and Chinese. Then we extend to the condition of multilingual alignment (Section 4.3).

Table 1 shows the experimental alignment results on EN-ZH parallel samples. These generative models, including three architectures with different amounts of parameters, are consistently improved by our method. The average improvement is up to 3.31% using only 167k parallel samples, and the models with 7B parameters surpass the GPT-3 with comparable parameters after alignment. Specifically, models improve 4.28% on the first two natural language understanding tasks (XNLI and PAWS-X), and 2.67% on the other three reasoning tasks. After alignment using AFP, BLOOM shows a better performance than the BLOOMZ model with the same amount of parameters, which is fine-tuned on 78M multilingual instructions (Muennighoff et al., 2023).



It is interesting to find that the model Llama pre-trained on mainly English corpus, also obtains improvement after bilingual alignment using AFP. The performance on the unseen language Chinese is even comparable with the one pre-training on an

additional 20GB Chinese corpus (Cui et al., 2023). This result further proves the effectiveness of our method. We assume that this performance gain may benefit from better-aligned multilingual representations in models, which promotes the transfer of knowledge learned in the English corpus.

In addition to cross-lingual understanding and reasoning abilities, the multilingual generation ability of models has been improved. The bilingual translation results of XGLM models are reported in Table 2. Models not only obtain a better cross-lingual generation ability, but also show a more balanced generation performance than the vanilla ones between both directions. It is interesting to find that the average performance of models in the zero-shot condition improves from 27.3 to 61.2 COMET on average, which may come from the response in the target language format used in cross-lingual instruction following is similar to the one in the machine translation task.

4.2.1 AFP Brings Better Bilingual Representations

Visualization of sentence representations. Given 1k EN-ZH translation parallel samples, we visualize the sentence representations of $XGLM_{564M}$ and $BLOOM_{560M}$, which are obtained by the mean pooling method using the representation for each token in one sentence. In the vanilla models, there is a distinct separation between sentence representations from different languages (Figure 1(a) and 3(a)). However, the ones using

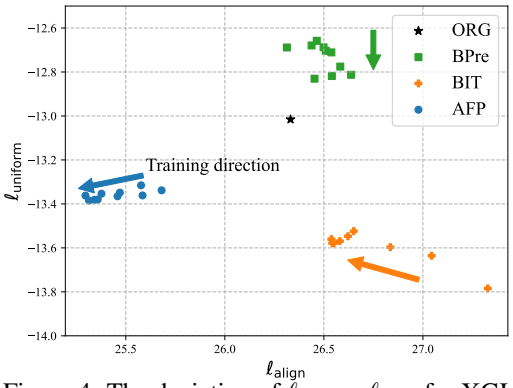

Figure 4: The deviation of ℓ_{uniform}-ℓ_{align} for $\text{XGLM}_{564\text{M}}$ during training process with different multilingual training methods. The smaller these two metrics are, the better representations models learn. "BPre" and "BIT" denote bilingual pre-training and bilingual instruction tuning, respectively.

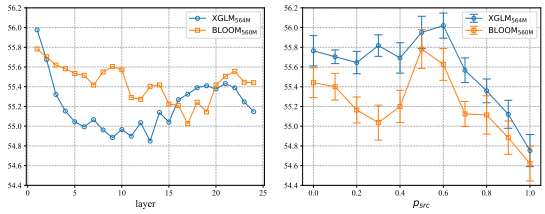
AFP come to be more aligned between languages and uniform (Figure 1(b) and 3(b)), which means our method promotes the representation of the model to be better-aligned from a qualitative point of view.

Alignment and uniformity. The distribution of multilingual representations is quantified by the two metrics, **alignment** and **uniformity** proposed by Wang and Isola (2020), for further analysis. Specifically, the alignment score measures the expected distance between the representations of positive samples, which are translation parallel samples for multilingual generative models, and is calculated as follows:

$$\ell_{\text{align}} \triangleq \mathop{\mathbb{E}}_{(x,x^+)\sim\mathcal{D}_{pos}} \left\| f(x) - f(x^+) \right\|^2 \quad (5)$$



where $\mathcal{D}_{pos}$ is the distribution of positive samples.

In contrast, uniformity reflects the degree of uniformly distributed for representations:

$$\ell_{\text{uniform}} \triangleq \log \mathop{\mathbb{E}}_{x,y \overset{i.i.d.}{\sim} \mathcal{D}} e^{-2\|f(x)-f(y)\|^2} \quad (6)$$

where x and y are randomly sampled from the distribution $\mathcal{D}$. Therefore, the smaller ℓ_{align} and ℓ_{uniform} are, the better representations models learn.

Figure 4 illustrates the deviation of ℓ_{align} and ℓ_{uniform} for $\text{XGLM}_{564\text{M}}$ using different training methods on the same training data. The initial 5000 steps are visualized, with one point for every 500 steps. We can find that the metrics are both decreasing using AFP, while the bilingual pre-training only improves the uniformity of representations. The results further prove that our method improves the multilingual representation distributions within the multilingual generative models.

(a) (b)

Figure 5: Effects of the target layer of MCL (a) and the p_{src} of CIF (b) on 5 EN-ZH datasets.

4.2.2 Multilingual Contrastive Learning on Bottom Layer Performs Better

Figure 5(a) presents the impact of different layers applied by contrastive learning on the 5 cross-lingual datasets (XNLI, PAWS-X, XCOPA, XStoryCloze, and XWinograd). The average performance of models shows a trend of decreasing first and then increasing, which changes at the 10th layer for $\text{XGLM}_{564\text{M}}$ or the 17th layer for $\text{BLOOM}_{560\text{M}}$. And the first transformer layer is better for both models when using multilingual contrastive learning. As a result, multilingual contrastive learning is applied to the first layer after the embedding layer by default.

4.2.3 Cross-lingual Instruction Following or Multilingual Instruction Tuning?

As shown in Figure 5(b), multilingual instruction tuning ($p_{src} = 1$) is inferior to cross-lingual instruction following ($p_{src} < 1$) for the models evaluated. Moreover, the result becomes suboptimal when all samples are transferred into the cross-lingual format ($p_{src} = 0$). We empirically set the p_{src} to 0.5 in the cross-lingual instruction following task.

4.3 Multilingual Results and Analyses

In addition to the bilingual alignment, AFP can be applied to align the models in multilingual conditions. English is first chosen as the pivot language of alignment for the dominance performance in multilingual generative models. That is, the input parallel samples of AFP are selected from the EN-XX corpus, e.g., EN-ZH and EN-TH, to pull the representations and outputs of models in other languages closer to the ones in English. We also investigate the other alignment methods like pairwise alignment in Section 4.3.1, which shows an inferior performance.

Table 3 reports the results of alignment between 5 languages from different language families, where the performance of models on the NLI and

Table 6: The average performance on XNLI and XCOPA when prompt with 5 semantic aligned demos.

reasoning tasks is improved by 3.72% from high-resource languages to the less-represented language Swahili.

Moreover, models with AFP obtain a more balanced performance distribution. Taking XGLM models as an example, the variance of performance across 5 languages decreases from 3.44% to 2.96% on average. It is noted that AFP advances the performance of BLOOM in the two unseen languages, Thai (TH, +3.9%) and Turkish (TR, +3.92%).

Multilingual generative models also obtain a performance gain (+0.75 BLEU) in the multilingual machine translation task after alignment (Table 4). It can also find a more balanced performance distribution across languages, where the average variance reduction is 0.4% for the models evaluated.

4.3.1 English as a pivot language or Pairwise Alignment?

Besides adopting English as a pivot language to align multilingual representations, we also investi-

Table 7: In-context learning results of models on 5 datasets across all languages. The variance of performance across languages is marked in the subscript. All results are reported in Appendix B.4.

gate the pairwise alignment policy, which is aligned by languages in pairs. For example, assuming to align the representations of English (EN), Chinese (ZH), and Thai (TH), the former policy comes to two parallel samples for input, which are EN-ZH and EN-TH, while the latter contains three parallel samples: EN-ZH, EN-TH, and ZH-TH.

The results of five languages alignment experiments on XNLI and XCOPA are reported in Table 5. The pairwise alignment policy performs consistently better in the low-resource language Swahili, although its average improvement is inferior to that when adopting English as a pivot language.

4.3.2 Combination with Other Cross-lingual Methods

After alignment, multilingual generative models can use other cross-lingual methods for further improvement. We take a method named semantic alignment for an example, which is able to promote the cross-lingual ability using semantic aligned demos in prompt (Tanwar et al., 2023). As shown in Table 6, models obtain a further 0.4% improvement in the multilingual NLI and reasoning tasks on average.

4.4 Extended to Alignment in 52 Languages

Based on the above analyses, we extend the alignment to all 52 languages in the Bactrian-X dataset by adopting English as a pivot language (information about all languages involved is reported in Appendix D). As shown in Table 7, models obtain a 2.6% improvement in 5 multilingual tasks on average, and mitigate the variance across languages. It is also noted that the performance of $\text{BLOOM}_{7.1\text{B}}$ on unseen languages among 5 datasets is improved by 2.8% using only parallel samples via our alignment framework, which may arise from the knowledge transferred from other languages after alignment.

Model	0-shot	3-shot	5-shot
$\text{XGLM}_{564\text{M}}$	$52.94_{\pm 0.54}$	$51.71_{\pm 0.90}$	$52.03_{\pm 0.89}$
w/ MCL	$50.23_{\pm 0.43}$	$48.66_{\pm 0.51}$	$48.60_{\pm 0.49}$
w/ MIT	$54.25_{\pm 0.49}$	$53.54_{\pm 0.75}$	$52.93_{\pm 0.68}$
w/ CIF	$55.31_{\pm 0.55}$	$54.02_{\pm 0.63}$	$53.58_{\pm 0.64}$
w/ AFP	$\mathbf{55.97}_{\pm 0.48}$	$\mathbf{55.50}_{\pm 0.55}$	$\mathbf{56.15}_{\pm 0.43}$

Table 8: Ablation study of different training methods on 5 datasets for $\text{XGLM}_{564\text{M}}$.

4.5 Ablation Study

To take a deep look into the improvements contributed by AFP, we conduct an ablation study on the 5 datasets of bilingual tasks using $\text{XGLM}_{564\text{M}}$ (Table 8).

The in-context learning abilities of the models decrease when only multilingual contrastive learning (MCL) is used. It may arise from the next word prediction ability of the model is affected by the MCL. Using the same data, both multilingual instruction tuning (MIT, +1.3%) and cross-lingual instruction following (CIF, +2.1%) can improve multilingual generative models, while the latter can promote it more. In addition, the performance of the models can be further improved after combining MCL and CIF, which is the proposed alignment framework AFP.

5 Conclusion and Future Work

In this paper, we proposed a simple yet effective multilingual alignment framework, including internal multilingual representations alignment and cross-lingual outputs alignment methods. Experimental results show that this framework improves both the internal representations and cross-lingual capabilities of generative models across various scales.

Beyond aligning different languages, our framework can be extended to align the internal representations and outputs across different modalities in the multi-modal generative models by replacing parallel samples. However, it is noted that the current framework relies on labeled training data for

alignment. Future works can focus on the unsupervised multilingual alignment method for language models.

Limitations

Firstly, although our cross-lingual framework boosts the cross-lingual ability of multilingual generative language models using only a small amount of parallel samples, it is noted that the proposed framework relies on labeled training data for alignment, which is unavailable for languages without parallel samples.

In addition, due to limited computation resources, our framework is constrained to multilingual generative language models with less than or equal to 7.5B parameters.

Lastly, there is an error propagation problem from the involved machine translation system, which may result in inferior performance.

Ethical Considerations

Since our alignment framework is applied to the pre-trained multilingual generative language models, the model aligned may inherit the potential risk and bias in the vanilla language model (Tamkin et al., 2021). The cultural bias and offensive response in English may be incorporated into other languages due to the alignment policy used, which adopts English as a pivot language. Future explorations are needed to mitigate the risk and cultural bias in multilingual generative language models.

A Hyperparameters

To align the representations and outputs of multilingual generative models, we adopt AdamW (Loshchilov and Hutter, 2019) optimizer, where $\beta_1 = 0.9$ and $\beta_2 = 0.999$, and a learning rate of 1e-5. The temperature τ is set to 0.05 in the multilingual contrastive learning task. Mixed precision training and ZeRO are applied to speed up the training process and save memory used (Micikevicius et al., 2018; Rasley et al., 2020). The number of training steps is empirically set to 10k with a batch size of 128. All experiments are conducted on a GPU server with 8*A100 80GB RAM.

B Additional Results

B.1 Pooling Methods

Given representations for each token in the sentence, there are three general methods, the last token representation, max pooling and mean pooling, to obtain the representation of this sentence. Figure 6(a) illustrates the results of $\text{XGLM}_{564\text{M}}$ under different pooling methods using AFP. It can be found that the last token and mean pooling perform better, and our method is less sensitive to the pooling method chosen. Thus, these two methods are used in AFP and are selected according to the performance of the development set.

(a) (b)

Figure 6: Results of different pooling methods (a) and weights of CIF (b) on 5 EN-ZH datasets using $\text{XGLM}_{564\text{M}}$.

B.2 Weight of Cross-lingual Instruction Following

We find that the weight α of cross-lingual instruction following in Eq. (4) affects the multilingual performance of models. The average performance of $\text{XGLM}_{564\text{M}}$ on 5 datasets with different α is presented in Figure 6(b), where models perform better than the other values evaluated when α is set to 1.5. Therefore, we only consider a limited hyperparameter sweep for each multilingual generative model with $\alpha \in \{1, 1.5, 2\}$.

B.3 Distribution of multilingual representations

Figure 7 illustrates the distributions of 5 languages sentence representations from the vanilla XGLM models and the aligned ones via t-SNE. Similar to the bilingual distribution, we can find that there are distinct gaps between the sentence representations from different languages in the vanilla models (Figure 7(a)-7(c)). After training with AFP, the multilingual sentence distributions of models are better aligned between languages across different scales (Figure 7(d)-7(f)). The alignment of multilingual sentence representations in $\text{XGLM}_{7.5\text{B}}$ is not as good as the two smaller models, which may arise from the limited parallel samples used.

B.4 Performance on multilingual datasets

All results of $\text{XGLM}_{7.5\text{B}}$, $\text{BLOOMZ}_{7.1\text{B}}$, and $\text{BLOOM}_{7.1\text{B}}$ on the 5 multilingual datasets are reported in Tabel 9-13.

C Task Descriptions and Prompt Templates

To comprehensively evaluate our models, six datasets across four tasks are adopted in this work. Table 14 shows the statistics of all datasets used. It is noted that the original COPA dataset (Roemmele et al., 2011) in English is also included in the evaluation. Most templates of prompt follow the ones in Lin et al. (2022).

Natural Language Inference This task aims to determine the semantic relationship between the premise and hypothesis. Table 15 illustrates the template and 3-shot example used in our evaluation for this task.

Paraphrase Detection Models need to evaluate whether the second sentence is a paraphrase of the first sentence in this task. The template and 3-shot example adopted are reported in Table 16.

Reasoning Three popular multilingual reasoning datasets are applied in this task category. Given candidate sentences or pronouns mentioned above, models have to select the best one with semantic coherence and comply with the rules of the physics world. The detailed templates and examples are presented in Table 17 (XCOPA), Table 18 (XStoryCloze) and Table 19 (XWinogrande).

Multilingual Machine Translation Given sentences in the source language, models for this task have to generate the corresponding sentences in the target language. Table 20 illustrates the template and 3-shot example used in our evaluation for FLORES-101.

Abstract

Pre-trained language models (PLMs) that rely solely on textual data may exhibit limitations in multimodal semantics comprehension. Existing solutions attempt to alleviate this issue by incorporating explicit image retrieval or generation techniques. However, these methods: (1) focus exclusively on the static image modality; (2) inevitably encounter modality gaps and noise; (3) indiscriminately treat all modalities. In this paper, we propose a novel multimodal-augmented framework termed MaCSC, which can infuse multimodal semantics into PLMs and facilitate a self-balancing calibration of information allocation. Specifically, MaCSC obtains modal-specific conceptual prototypes from contrastive pre-training models (e.g., CLIP), and aggregates the intra- and inter-modal semantics of the conceptual prototype to enhance PLMs. In addition, we utilize a novel self-balancing contrastive loss to achieve multi-scale self-balancing calibration of multimodal information during fine-tuning PLMs. Experimental results show that MaCSC consistently improves the performance of PLMs across various architectures and scales, and outperforms competitive baselines on multiple NLP tasks.

1 Introduction

Large-scale Pretrained Language Models (PLMs), (e.g., BERT (Devlin et al., 2019),T5 (Raffel et al., 2020), GPT (Brown et al., 2020), etc.) have achieved great success on various Natural Language Understanding (NLU) tasks. Most PLMs undergo training on textual data alone without incorporating information from other modalities. Those approaches contrast with human learning (Bender and Koller, 2020; Tan and Bansal, 2020a), which typically involves multiple modalities beyond just text (e.g., image, audio, video, etc). Textual data may not fully capture the general characteristics of entities (Liu et al., 2022), and word frequency may not consistently reflect real-world likelihoods (Gordon and Durme, 2013). Consequently, these language learners may lack real-world knowledge (Zhang et al., 2022) and could suffer from human reporting bias (Yang et al., 2022).

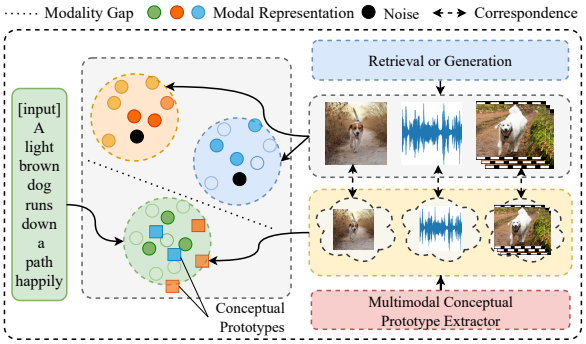

Figure 1: The approach for augmenting PLMs by retrieving and generating relevant multimodal data inevitably encounters challenges associated with (a) modal gaps and (b) the presence of noisy data. Our methodology employs conceptual prototype extractors to effectively mitigate the issues of modality gaps and noisy data, and incorporate multimodal knowledge into PLMs.

To address this issue, current research primarily focuses on augmenting PLMs by integrating visual information from either retrieved or synthesized images in NLP tasks (Tan and Bansal, 2020a; Yang et al., 2022). We classify these visually-augmented approaches for PLMs into three distinct categories: visually-augmented pre-training (Tan and Bansal, 2020a; Wang et al., 2022), visually-augmented fine-tuning (Lu et al., 2022; Guo et al., 2023), and training-free zero-shot visual enhancement (Yang et al., 2022). While these works represent notable advancements, we discover several limitations: (1) They focus exclusively on static image modality while neglecting other modal types like speech and video, which offer dynamic temporal information. (2) They require time-consuming retrieval or explicit image generation and inevitably encounter issues with modality gaps and data noise. As il-

June 16-21, 2024 ©2024 Association for Computational Linguistics

lustrated in Figure 2, a significant semantic gap exists between different modalities in the representation space (Liang et al., 2022). This modality gap can adversely impact the integration of multimodal information. Moreover, the processes of image retrieval or generation are prone to introducing noise, which can degrade the performance of PLMs. (3) They treat all modalities of information equally. Recent studies (Dai et al., 2022; Guo et al., 2023) indicate that information from other modalities is not always beneficial for NLP tasks. The contributions of various modal types vary across specific NLP tasks. Hence, indiscriminately incorporating semantic information from multiple modalities can be suboptimal, potentially diminishing the efficacy of PLMs.

In this paper, we propose a novel **m**ultimodal-**a**ugmented framework with **c**onceptual prototypes enhancement and **s**elf-balancing **c**alibration (MaCSC). MaCSC tackles the above issues through innovative strategies in the following two aspects:

(1) **MaCSC leverages conceptual prototypes as multimodal proxies to infuse multimodal knowledge into PLMs.** MaCSC does not explicitly introduce multimodal semantics by retrieving or generating corresponding modal data. MaCSC initially obtains text semantics aligned with other modalities through large-scale multimodal contrastive pre-training models (MC-PTMs) (e.g., CLIP (Radford et al., 2021), AudioCLIP (Guzhov et al., 2021) and CLIP-ViP (Xue et al., 2022), etc.). These text semantics intrinsically have an implicit correspondence with real-world modal data, which we refer to as conceptual prototypes. Conceptual prototypes contain modal-specific representation encodings and can serve as implicit proxies. This approach alleviates representation degradation caused by modality gaps and noise. We analyze the theoretical and practical effectiveness of this prototype proxies in Section 2.2 and Section 3.2.

(2) **MaCSC implements a multi-scale self-balancing calibration for the allocation of multimodal information.** The allocation weights assigned to various modal types vary across specific NLP tasks. MaCSC first implements fine-grained and coarse-grained allocation estimation and achieves balanced information injection for PLMs through a proposed self-balancing contrastive loss. We emphasize fine-tuning PLMs through the calibration of cross-modal contrastive learning, which gives a disregarded but significant insight into balancing the allocation of multimodal information.

(a) Vanilla PLMs-based Pipeline

(b) Visually-Augment Pipeline by Retrieving or Generating Explicit Images

(c) Our Multimodal-Augment pipeline with Conceptual Prototype and Self-balancing Calibration

Figure 2: We visually demonstrate a comparison between the learning architectures of various language models. (a) acquires knowledge by fine-tuning vanilla PLMs, while (b) augments PLMs by explicitly retrieving or generating images. (c) recalls modality-specific conceptual prototypes related to sentences and achieves balanced calibration of modal information allocation, thereby implicitly enhancing language comprehension.

Figure 2 shows the main differences between MaCSC and other methods. Extensive experiments conducted on ten datasets across three NLP tasks (e.g., natural language understanding, Q&A, and text generation tasks) demonstrate the effectiveness and universality of MaCSC. Our contributions are: (1) We propose a novel multimodal-augmented framework called MaCSC, which integrates multimodal semantics into PLMs through conceptual prototypes and enhancement modules. (2) MaCSC utilizes a proposed novel self-balancing calibration strategy to balance multimodal information. (3) Numerous experiments on multiple NLP tasks demonstrate the significant performance of MaCSC.

2 Methods

In this section, we first introduce the task setting and overview of our method in Section 2.1, and then describe our proposed conceptual prototype extraction approach in Section 2.2 and cross-modal semantic enhancement in Section 2.3. Subsequently, we describe proposed allocation estimation strategies and self-balancing contrastive learning in Section 2.4 and Section 2.5, respectively.

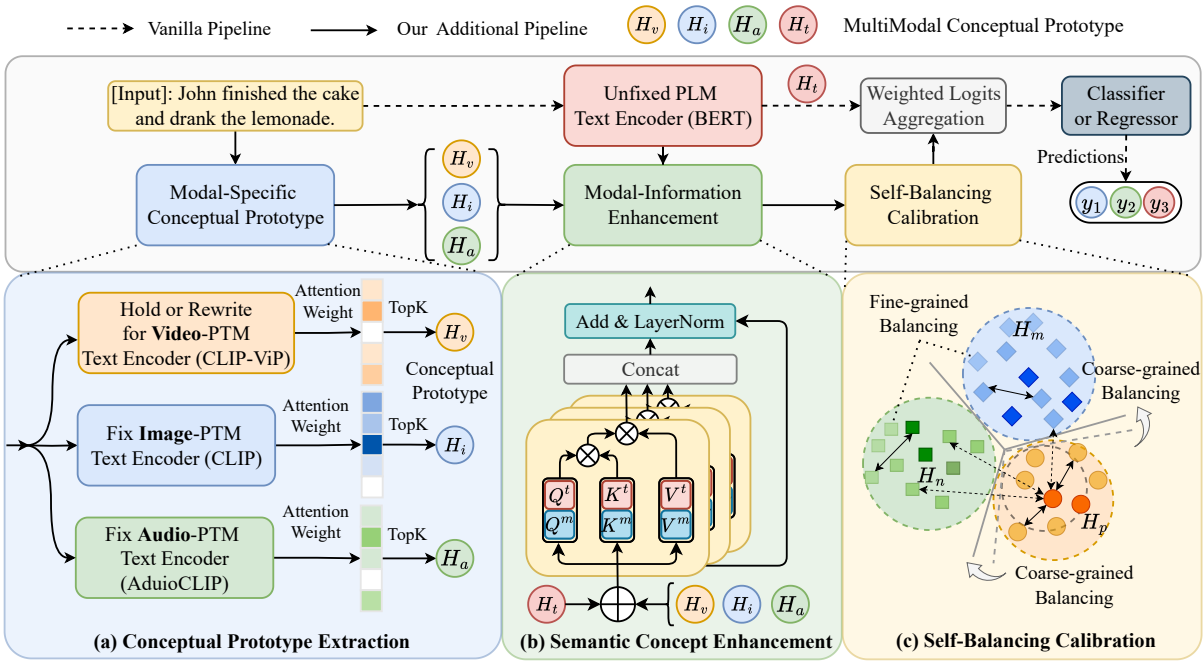

Figure 3: The illustration of the proposed framework, consisting of (a) the conceptual prototype extraction module designed to obtain implicit multimodal semantic information, (b) the multimodal semantic concept enhancement aimed at fusing cross-modal features, and (c) the multi-scale self-balancing calibration focuses on balancing modal supervision information.

2.1 Task Setting and Overview

For traditional NLP tasks, PLMs can be fine-tuned on a specified dataset $\mathcal{D} = \{x_i, y_i\}_{i=1}^{N}$ to perform classification or regression, where, x_i and y_i denote i-th text data and corresponding label and N represents the total number of training samples.

In our research, we concentrate on developing an efficient approach to incorporate multi-modal knowledge into PLMs during fine-tuning. We define the set of modalities involved in this work as $\mathcal{M} = \{\mathbf{t}, \mathbf{i}, \mathbf{a}, \mathbf{v}\}$, where, $\mathbf{t}, \mathbf{i}, \mathbf{a}, \mathbf{v}$ represent four modalities: text, image, audio, and video, respectively. Our proposed method is illustrated in Figure 3, where we first generate conceptual prototypes through different MC-PTMs. Subsequently, we adopt our proposed cross-modal enhancement mechanism to obtain semantic-enhanced representations. Finally, we employ the proposed multi-scale self-balancing contrastive learning to calibrate multimodal information.

2.2 Conceptual Prototype Extraction

In our methodology, we define modal-specific conceptual prototypes as semantic units that infuse multimodal information into PLMs. Motivated by Radford et al. (2021), we employ MC-PTMs to facilitate implicit conceptual prototype extraction. We compute the average attention scores between each token and the `[EOS]` token on the self-attention layer of CLIP-based text encoder. Subsequently, we adopt the Top-K strategy to select the features of the top-ranked tokens as the modal-specific conceptual prototype $\mathbf{H}_i^m \in \mathbb{R}^{k \times d}$:

$$\mathbf{H}_i^m = \text{Top-K}(\text{TextEncoder}_m(x_i)), \quad (1)$$

where, m represents a specific modality other than text, *i.e.*, $m \in \mathcal{M} \backslash \{t\}$, k denotes the number of tokens selected, d is the dimension of features, and TextEncoder_m denotes a text encoder on a MC-PTMs trained on modality m and text-paired data. In this work, we utilize the text encoders of CLIP (Radford et al., 2021), AudioCLIP (Guzhov et al., 2021) and CLIP-ViP (Xue et al., 2022) to obtain conceptual prototypes of image, audio, and video modalities, respectively. We further provide a theoretical analysis in Appendix A.1 about conceptual prototypes are good modal proxies.

2.3 Semantic Concept Enhancement

Although conceptual prototypes represent multimodal knowledge of input sentences, they are independent of the semantics of the text acquired by PLMs. To aggregate and strengthen the representation of conceptual prototypes, we propose a semantic concept enhancement module to model

both the inter-modality and intra-modality relationships in a unified model.

We first employ a PLM to obtain the contextualized word representations $\mathbf{H}_i^t \in \mathbb{R}^{l\times d}$ of the inputs, where l denotes the length of the sequence. As shown in Figure 3, the semantic concept enhancement module takes the stacked features of conceptual prototypes and textual representations $\mathbf{E}_i = \begin{pmatrix} \mathbf{H}_i^t \\ \mathbf{H}_i^m \end{pmatrix} \in \mathbb{R}^{(k+l)\times d}$ as the input, where, m represents the modality type and $m \in \mathcal{M}\backslash\{t\}$.

Following Wei et al. (2020), the query, key, value, and cross-modal attention for the fragments are formed with the following equations:

$$\begin{aligned}
\mathbf{K_E} &= \begin{pmatrix} \mathbf{H}_i^t\mathbf{W}^K \\ \mathbf{H}_i^m\mathbf{W}^K \end{pmatrix} = \begin{pmatrix} \mathbf{K}^t \\ \mathbf{K}^m \end{pmatrix}, \\
\mathbf{Q_E} &= \begin{pmatrix} \mathbf{H}_i^t\mathbf{W}^Q \\ \mathbf{H}_i^m\mathbf{W}^Q \end{pmatrix} = \begin{pmatrix} \mathbf{Q}^t \\ \mathbf{Q}^m \end{pmatrix}, \\
\mathbf{V_E} &= \begin{pmatrix} \mathbf{H}_i^t\mathbf{W}^V \\ \mathbf{H}_i^m\mathbf{W}^V \end{pmatrix} = \begin{pmatrix} \mathbf{V}^t \\ \mathbf{V}^m \end{pmatrix}, \\
\hat{\mathbf{E}}_i &= \begin{pmatrix} \hat{\mathbf{H}}_i^t \\ \hat{\mathbf{H}}_i^m \end{pmatrix} = \mathrm{softmax}(\frac{\mathbf{Q_E}\mathbf{K_E}^\top}{\sqrt{d}})\mathbf{V_E},
\end{aligned} \tag{2}$$

where, $\hat{\mathbf{H}}_i^t \in \mathbb{R}^{l\times d}$ and $\hat{\mathbf{H}}_i^m \in \mathbb{R}^{k\times d}$ are the enhanced semantic features.

To simplify our derivation and enhance its comprehensibility, we have omitted the softmax and scaling functions in the aforementioned equation. This exclusion does not detract from the fundamental concept of our attention mechanism. The expanded form is as follows:

$$\begin{aligned}
\begin{pmatrix} \hat{\mathbf{H}}_i^t \\ \hat{\mathbf{H}}_i^m \end{pmatrix} &= \begin{pmatrix} \mathbf{Q}^t \\ \mathbf{Q}^m \end{pmatrix} \begin{pmatrix} \mathbf{K}^{t\top} & \mathbf{K}^{m\top} \end{pmatrix} \begin{pmatrix} \mathbf{V}^t \\ \mathbf{V}^m \end{pmatrix} \\
&= \begin{pmatrix} \mathbf{Q}^t\mathbf{K}^{t\top}\mathbf{V}^t + \mathbf{Q}^t\mathbf{K}^{m\top}\mathbf{V}^m \\ \mathbf{Q}^m\mathbf{K}^{m\top}\mathbf{V}^m + \mathbf{Q}^m\mathbf{K}^{t\top}\mathbf{V}^t \end{pmatrix}.
\end{aligned} \tag{3}$$

Eq. 3 demonstrates that our cross-modal semantic concept enhancement module concurrently accounts for both intra-modal and inter-modal information. In practice, we will use multiple attention heads to enhance representation diversity.

2.4 Multi-scale Information Allocation Estimation

Fine-grained Allocation Estimation We first use class frequency to estimate class distribution $\pi_e^m = \frac{\mathbf{n}}{\sum_c n_c}$, where, $\mathbf{n}$ is the quantity of each category, n_c represents the number of category c in the training set. Based on this, we can obtain the debiased predictive distribution of a given sample x_i:

$$\mathbf{p}_i^m = \mathrm{softmax}(\mathrm{logits}(\hat{\mathbf{H}}_i^m) - \alpha \log \pi_e^m), \tag{4}$$

where, $\mathrm{logits}(\cdot)$ refers to the logits operation through prototype features $\hat{\mathbf{H}}_i^m$. We further define the positive score provided by the modality m conceptual prototype $\hat{\mathbf{H}}_i^m$ of sample x_i to the modality k conceptual prototype $\hat{\mathbf{H}}_j^k$ of sample x_j as $w_{ij}^{(m,k)} = \mathrm{Sim}(\mathbf{p}_i^m, \mathbf{p}_j^k)$, where, $\mathrm{Sim}(\cdot)$ denotes the cosine similarity function and $m, k \in \mathcal{M}$. Subsequently, we can obtain the distribution of allocation scores for $\mathbf{p}_i^m$ and $\mathbf{p}_j^k$ as :

$$p(w_{ij}^{(m,k)}) = \frac{w_{ij}^{(m,k)}}{\sum_b w_{ib}^{(m,k)}}. \tag{5}$$

Here, $p(w_{\hat{i}}^{(m,k)}|j)$ represents positive weight score between $\hat{\mathbf{H}}_i^m$ and $\hat{\mathbf{H}}_j^k$. For ease of reference, we define the fine-grained relationship weight matrix between modalities m and k as $W^{(m,k)} = \{w_{ij}^{(m,k)}|i,j \in [0,N]\}$. We utilize $W^{(m,k)}$ to balance the fine-grained information exchange between modalities m and k.

Coarse-grained Allocation Estimation The coarse-grained allocation estimation strategy directly affects the global modality information. We assign a learnable weight score $\pi_z^{(m,k)}$ to modalities m and k as the distribution estimate for global modality weighting:

$$\pi_z^{(m,k)} = \mathrm{softmax}\{z^{(m,k)}\}, k \in \mathcal{M}\backslash\{m\}, \tag{6}$$

where, $z^{(m,k)}$ represents a learnable parameters across modalities m and k. We utilize weight score $\pi_z^{(m,k)}$ to balance the coarse-grained information exchange between modalities m and k.

2.5 Self-Balancing Contrastive Learning

To effectively incorporate multimodal information into PLMs in a balanced manner, we expand traditional contrastive loss to a multimodal self-balancing contrastive loss based on the positive weight score $p(w_i^{(m,k)}|j)$:

$$\begin{aligned}
\mathcal{L}_i^{(m,k)} &= -\sum_{j=1}^{N} \mathbf{1}(y_i = y_j) p(w_{ij}^{(m,k)}) \log p_{ij}^{(m,k)}, \\
p_{ij}^{(m,k)} &= \frac{\exp(m_i \cdot k_j/\tau)}{\sum_{a=1}^{N} \exp(m_i \cdot k_a/\tau)},
\end{aligned} \tag{7}$$

where, m_i and k_j denotes the representations obtained by feeding $\hat{\mathbf{H}}_i^m$ and $\hat{\mathbf{H}}_j^k$ into a linear projector, τ is the temperature coefficient, $p_{ij}^{(m,k)}$ is the contrastive logit, and $m, k \in \mathcal{M}$. Further, we can obtain the contrastive loss between modalities m and k as:

$$\mathcal{L}^{(m,k)} = \sum_{i=1}^{N} \mathcal{L}_i^{(m,k)}. \tag{8}$$

Theorem 1. *Given m_i and k_j represent different modal conceptual prototypes of two samples x_i and x_j, the model θ is trained through the proposed self-balancing contrastive loss, then, the optimal contrastive logits $p_{ij}^{(m,k)^*}$ are approximately the distribution of allocation scores $p(w_{ij}^{(m,k)})$, i.e., the following equation approximately holds:*

$$p_{ij}^{(m,k)^*} = p(w_{ij}^{(m,k)}). \tag{9}$$

The proof of Theorem 1 can be found in Appendix A.2. Theorem 1 indicates that models trained using the proposed loss are capable of aligning the weights of multimodal information consistent with $p(w_{ij}^{(m,k)})$. In essence, this suggests that the proposed loss function, as mentioned in Eq. 7, can be effectively utilized to achieve self-balancing in the allocation of multimodal information between m and k.

2.6 Total Objective

Our overall loss comprises a weighted aggregation loss for prediction, coupled with a multi-scale self-balancing contrastive loss.

Weighted Aggregation Loss We can obtain the predicted distribution $p_m(y|x_i)$ of each category under different modality information guidance as:

$$p_m(y_i|x_i) = \text{softmax}(W^m \hat{\mathbf{H}}_i^m + b^m), \tag{10}$$

where, W^m is a fully connected matrix, b^m is a bias vector, and $m \in \mathcal{M}$ denotes the type of modality. Further, we adopt a learnable weight ρ^m as the late fusion over the final output distributions of multimodal models as:

$$p(y_i|x_i) = \sum_{m \in \mathcal{M}} \rho_m p_m(y|x_i), \tag{11}$$

where, ρ^m is a learnable normalized weight and $\sum_{m \in \mathcal{M}} \rho_m = 1$. Therefore, we can obtain the weighted aggregation loss for label prediction as:

$$\mathcal{L}_{wa} = \sum_{i=i}^{N} \text{CE}(y_i, p(y_i|x_i)), \tag{12}$$

where, $\text{CE}(\cdot)$ denotes the cross entropy loss.

Self-Balancing Contrastive Loss To achieve equilibrium in multimodal information processing during the training phase, we propose to formulate the total multi-scale self-balancing loss as follows:

$$\mathcal{L}_{msb} = \sum_{m \in \mathcal{M}} \sum_{k \in \mathcal{M} \setminus \{m\}} \frac{\pi_z^{(m,k)} \mathcal{L}^{(m,k)}}{\mid \mathcal{M} \mid (\mid \mathcal{M} \mid -1)}. \tag{13}$$

The multi-scale self-balancing loss, denoted as $\mathcal{L}_{msb}$, incorporates strategies for allocating multimodal information at both fine-grained and coarse-grained levels, thus achieving an adaptive balance in the modality information distribution during the training phase. Therefore, the overall loss is:

$$\mathcal{L} = \mathcal{L}_{wa} + \lambda \mathcal{L}_{msb}, \tag{14}$$

where λ denotes the trade-off hyperparameter.

3 Experiments

3.1 Experimental Setup

Datasets. We conduct experiments across three types of tasks:

- **Natural Language Understanding (NLU).** We evaluate our method over over SST-2 (Socher et al., 2013), QNLI (Rajpurkar et al., 2016), QQP(Chen et al., 2017) , MNLI (Williams et al., 2018), MRPC (Dolan and Brockett, 2005), and STS-B (Cer et al., 2017) datasets from GLUE benchmark (Wang et al., 2018).
- **Comprehension Question Answering.** We select SQuADv1.1 (Rajpurkar et al., 2016) and SQuADv2.0 (Rajpurkar et al., 2018) to evaluate our method on comprehension question answering task.
- **Text Generation.** In the realm of text generation, we utilized the CommonGen (Lin et al., 2020) as the dataset, which is a constrained text generation task focused on generative commonsense reasoning.

Baselines. We compare our approach with the pre-trained language models (PLMs), multimodal contrastive pre-trained models (MC-PTMs), and visually-augmented pre-trained language models (VA-PLMs). (1) PLMs: We utilize BERT (Devlin et al., 2019), RoBERTa (Liu et al., 2019), XL-Net (Yang et al., 2019), and T5 (Raffel et al., 2020)

Table 1: A performance comparison of various methods on the GLUE benchmark, with the best results emphasized in **bold**. The term "+None" indicates the direct fine-tuning of the backbone without incorporating additional information. The abbreviations "T, I, A, V" denote four distinct modalities: text, image, audio, and video, respectively. We continuously add modal-specific concept prototype extractors to assess their influence on performance metrics. The results of VOKEN, iACE and VAWI on GLUE are reported from Lu et al. (2022) and Guo et al. (2022).

as the backbones, and directly fine-tune them as baselines. (2) MC-PTMs: We select CLIP (Radford et al., 2021), AudioCLIP (Guzhov et al., 2021) and CLIP-ViP (Xue et al., 2022). (3) VA-PLMs: VOKEN (Tan and Bansal, 2020b), iACE (Lu et al., 2022), and VAWI (Guo et al., 2022) are chosen as the main baselines in this paper. VOKEN introduces the visual information into PLMs by pretraining on retrieved images. iACE and VAWI infuse visual knowledge into PLMs through fine-tuning on retrieved or generated images and implicit image information, respectively.

Implementation Details. For all baselines, we follow the setting including hyperparameters with their papers and implement all methods based on Huggingface Transformers (Wolf et al., 2020). The hidden sizes for image, audio, and video concept prototypes are set to 512, 1024, and 512. We employ Adam as the optimizer with a weight decay of 0.01 and tune all models for 3 epochs. **More details and ablation studies can be found in Appendix A.3 and A.4, respectively**.

3.2 Main Experimental Results

Evaluation on NLU Tasks. We present our experimental results on six datasets in Table 1. Analysis of Table 1 yields several insights:

(1) Enriching PLMs with additional modality information significantly enhances their performance in NLP tasks. Both VA-PLMs (i.e., VOKEN, iACE, and VAWI) and our multimodal-augment PLMs outperform their corresponding PLM baselines. We attribute this to the incorporation of multimodal information that imparts general object knowledge (including color and shape) into PLMs.

(2) MaCSC of employing solely visual conceptual prototypes achieves superior performance compared to VA-PLM baselines. The performance of both VOKEN and iACE is surpassed by MaCSC of employing solely visual prototypes. This disparity may stem from the inclusion of extraneous noise and modality gaps. And MaCSC outperforms VAWI, with this advancement credited to our semantic enhancement and self-balancing strategies.

(3) As the variety of modal information incorporated into PLMs increases, there is a corresponding gradual improvement in the performance of PLMs. We can observe that the inclusion of more diverse sources of semantic conceptual information yields greater improvements in performance. In addition, our method outperforms all baselines in terms of PLM performance gains across all backbone networks It demonstrates the effectiveness and generality of MaCSC in injecting multimodal information into PLMs.

Evaluation on Comprehension Question Answering Tasks. As illustrated in Table 2, we evaluate the performance of our method on comprehen-

Table 2: A performance comparison of various methods on SQuAD v1.1 and SQuAD v2.0 datasets, with the best results emphasized in **bold**. The term "+None" indicates the direct fine-tuning of the backbone without incorporating additional information. "+Image" denotes we add retrieved images through Bing web search engines and utilize CLIP as image feature extractors. "T, I, A, V" denotes four distinct modalities: text, image, audio, and video.

sion question-answering tasks on SQuAD v1.1 and v2.0. We employ Bing Image Search[1] for image retrieval based on text input and utilize the CLIP image encoder to extract visual features as conceptual prototypes. Furthermore, we present results obtained using varying amounts of training data to assess the performance of different methods under a low-resource setting. Based on the results, we have the following detailed observations:

(1) The improvement in model performance by retrieving real images is not as significant as the gain by incorporating visual concept prototypes. This further demonstrates that inevitable noise images and modality gaps can adversely impact the representations and comprehension capabilities of PLMs. Our methodology eliminates the need for retrieval or generation of corresponding modality data, while simultaneously considering the self-balancing of multimodal information.

(2) The increase in the types of available modality prototypes will improve the performance of PLMs in question-answer tasks. In addition, our method consistently achieves performance gains on BERT, RoBERTa, and XLNet backbone networks, which further demonstrates the generality of our approach for different PLM architectures.

(3) In resource-constrained scenarios, our approach demonstrates a more substantial improvement. We randomly select 5% of the samples from the SQuAD training set to evaluate the performance under low-resource settings. We can observe that under low-resource settings, our method significantly boosts the performance compared to the results obtained with a full data set This enhancement is likely due to the capacity of our method to integrate balanced and beneficial modality information into PLMs, effectively mitigating the performance decline caused by the scarcity of data.

Method	BLUE-4	METOR	Rouge-L	CIDER

dataset, as shown in Table 3. Specifically, we insert enhanced representations of all conceptual prototypes after the output features of the text encoder in T5, while canceling self-balancing calibration. The results show that MaCSC consistently improves the performance of T5-3b across various metrics on the text generation task. Furthermore, we observe that employing images sourced from the Web search API can negatively impact text generation performance. This indicates that the text generation task is more sensitive to noise information.

3.3 Ablation Study

In this section, we conduct a series of ablation experiments to verify the effectiveness of our proposed components and strategies.

The Effect of the Semantic Concept Enhancement. We employ BERT-base and RoBERTa-base as the backbones and conduct experiments to study the impact of our semantic concept enhancement module as illustrated in Table 4. It can be seen that the performance of models significantly decreases without the semantic concept enhancement module to fusion modality information. This verifies the following: (1) the semantic concept enhancement module is capable of aggregating multimodal information sufficiently and effectively, and (2) the integration of intra-modal and inter-modal features plays a significant role in enhancing the expressive capabilities of PLMs.

The Effect of the Self-balancing Calibration. To evaluate the impact of our self-balancing calibration strategy on model performance, we remove it and presented the results in Table 4 Observations indicate that the absence of self-balancing loss significantly diminishes performance. This suggests that balancing information across modal knowledge is essential in multimodal-augmented PLMs. Additionally, this result corroborates the effectiveness of our self-balancing loss in harmonizing multimodal information and enhancing the expressive capabilities of PLMs.

Source of Concept Prototype	SQuAD v1.1		SQuAD v2	
	Acc.	F1	Acc.	F1
Gaussian Noise (0M)	83.4	90.3	77.3	80.8
BERT-base (110M)	83.7	90.8	78.1	81.9
RoBERTa-large (355M)	84.3	91.2	78.9	82.5
T5-3b (1500M)	84.5	91.3	79.6	83.6
CLIP* (63M)	**85.8**	**92.2**	**81.0**	**84.2**

Table 5: Performance comparison of different sources of concept prototypes in our approach on SQuAD datasets. We employ RoBERTa-base as the base model. "CLIP*" represents our complete approach, i.e., using the text encoders of CLIP, AudioCLIP and CLIP-ViP.

The Effect of the Source of Conceptual Prototypes. In this study, we employ three distinct PLMs (i.e., BERT-base, RoBERTa-large, and T5-3b, along with random Gaussian noise) as alternatives to our CLIP-based conceptual prototype extractor to assess the significance of multimodal representation. The results, as shown in Table 5, reveal that our approach achieves the most substantial performance gain, surpassing even that of T5-3b. This finding suggests that the performance improvement associated with the conceptual prototype is primarily due to the multimodal information it encapsulates, rather than merely the textual features offered by the text encoder. In essence, the performance gain brought by our method is indeed due to the multimodal information we extract. Furthermore, this also demonstrates the significant importance of additional modal knowledge in enhancing the expressiveness and inferential capabilities of

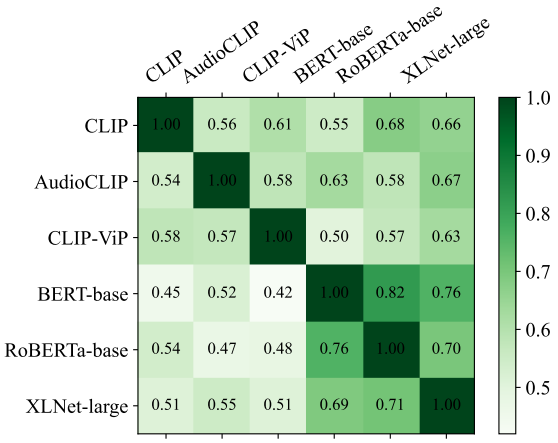

Figure 4: The overlap of correct predictions between each pair of models in the SQuAD v2 dataset.

PLMs.

Different Pre-trained Models Behave Differently. Following Yang et al. (2022), we mathematically define the concept of overlap in correct predictions between two models $\mathcal{M}_1$ and $\mathcal{M}_2$ as:

$$\mathcal{O}(\mathcal{M}_1, \mathcal{M}_2) = \frac{|\, \mathcal{S}_{\mathcal{M}_1} \bigcap \mathcal{S}_{\mathcal{M}_2} \,|}{|\, \mathcal{S}_{\mathcal{M}_1} \,|}, \qquad (15)$$

where, $\mathcal{S}_{\mathcal{M}}$ denotes the set of predictions made by model $\mathcal{M}$. We calculate the model overlap coefficients $\mathcal{O}$ among different models on the SQuAD v2 dataset in Figure 4. We can observe that MC-PTMs (i.e., CLIP, AudioCLIP, and CLIP-ViP) have a markedly smaller overlap with the other models. Conversely, the PLMs (i.e., BERT-base, RoBERTa-base, and XLNet-large) demonstrate a big mutual overlap. This difference explains the significant performance gain obtained through the integration of multimodal conceptual prototypes.

4 Related Works

Pre-trained Language Models. Recently, large-scale pre-trained language models (PLMs) have demonstrated remarkable success through self-supervised learning on extensive text corpus (Devlin et al., 2019; Raffel et al., 2020; Brown et al., 2020). By fine-tuning these PLMs, significant improvements are observed in downstream tasks including natural language processing (NLP), question answering, and text generation. Previous work has shown that language learners trained solely on textual data can exhibit biases and a lack of multimodal understanding of the objective world (Zhang et al., 2022; Yang et al., 2022; Cheng et al., 2023; Zhuang et al., 2024; Cheng et al., 2024). Furthermore, recent research suggests that these limitations are not mitigated by merely expanding the text corpus (Paik et al., 2021; Guo et al., 2022; Zhang et al., 2022; Zhu et al., 2024b,a). In this paper, we propose a universal multimodal-augmented framework for enriching the integration of multimodal semantics for PLMs.

Multimodal Contrastive Pre-trained Models. MC-PTMs are trained on a substantial corpus of modality-pairing samples, mapping multiple different modalities to a unified representation space. CLIP (Radford et al., 2021) performs pre-training on a large number of image text pairs, achieving alignment between image semantics and text semantics. AudioCLIP (Guzhov et al., 2021) extends CLIP to audio modality and CLIP-ViP (Xue et al., 2022) proposes a new strategy to transfer the image domain to the video domain. The latest work indicates that models similar to CLIP have the problem of modality gaps (Liang et al., 2022). Here, we utilize MC-PTMs to obtain text representations aligned with multimodal data as proxies,

Language Models with Additional Modal Enhancement. Most studies consider injecting visual modality information into PLMs through retrieval or image generation. Tan and Bansal (2020a); Wang et al. (2022) integrate visual knowledge during the pre-training of PLMs. Lu et al. (2022); Guo et al. (2023); Wang et al. (2024) fine-tune PLMs by introducing visual information during the fine-tuning phase. In addition, Yang et al. (2022) generates or retrieves images and encodes image representations to enhance zero-shot NLU. As a comparison, our approach is more efficient to leverage modality information including image, audio, and video in a balanced manner for enhancing PLMs.

5 Conclusion

In this paper, we propose a novel general multimodal-augmented framework with self-balancing calibration for PLMs called MaCSC. MaCSC can efficiently inject other modal semantic information into PLMs using multimodal conceptual prototypes. In addition, MaCSC adopts a novel self-balancing contrastive loss to achieve multi-scale self-balancing calibration of multimodal information during fine-tuning PLMs. Experimental results show that MaCSC consistently improves the performance of PLMs across various architectures and scales on multiple NLP tasks.

Ethics Statement and Limitation

Ethics Statement We conduct all experiments on the public datasets, which do not contain any offensive content or information with negative social impact. The focus of this article is to enhance the multimodal common sense of PLMs, and our model does not have uncontrollable outputs. Therefore, we ensure that our paper complies with ethical review guidelines.

Limitation This article proposes a new framework to balance and efficiently inject multimodal semantics into PLMs. However, the training of our proposed model relies on fine-tuning operations on PLMs, which may not be easily achievable in specific situations. Fully fine-tuning some super large language models may not be realistic. Therefore, exploring how to reduce fine-tuning costs and even provide training-free methods is more valuable for practical scenarios, which is also an important direction for future work. Furthermore, We use CLIP, AudioCLIP, and CLIP-ViP text encoders to generate modality-specific concepts as proxies. As pre-trained models, these MC-PTMs may also contain biases learned from the pre-trained corpus, which may lead to inappropriate bias predictions for some NLP tasks.

A Appendix

A.1 Theoretical Analysis of conceptual prototypes.

Theorem 2. *Assuming model θ is a CLIP-like MC-PTM trained on a substantial dataset comprising pairs of modalities k and t, let Z_k and Z_t denote representations generated through θ for k and t, respectively, and Y represents the label set for a specific NLP task, then maximizing the mutual information between Z_t and Y is equivalent to maximizing the mutual information between Z_k and Y, i.e,*

$$\max \mathbf{I}(Z_t, Y) \Leftrightarrow \max \mathbf{I}(Z_k, Y), \tag{16}$$

$\mathbf{I}(\cdot)$ represents mutual information.

Proof. Due to θ being an MC-PTM trained on a large amount of multimodal data pairs, the two highly aligned modal latent variables Z_t and Z_k are closely related. Therefore, we have the following inference:

$$p(Z_t|Z_k) \approx p(Z_t|Z_k) \approx 1. \tag{17}$$

Based on Eq. 17, we can derive $p(z_k, y) \approx p(z_t, y)$ from the total probability formula. According to the definition of mutual information, we have:

$$\begin{aligned} I\left(Z_t, Y\right) &= \sum_{z_t, y} p\left(z_t, y\right) \log \left(\frac{p\left(z_t, y\right)}{p\left(z_t\right) p(y)} \right); \\ I\left(Z_k, Y\right) &= \sum_{z_k, y} p\left(z_k, y\right) \log \left(\frac{p\left(z_k, y\right)}{p\left(z_k\right) p(y)} \right). \end{aligned} \tag{18}$$

In this case, if $\mathbf{I}(Z_t, Y)$ is maximized, $\mathbf{I}(Z_k, Y)$ will also be implicitly maximized due to the high correlation between Z_k and Z_t, and vice versa.

Claim 2 indicates that maximizing the information entropy between the intermediary proxy Z_t and Y is essentially in maximizing the information between Z_k and label Y. In other words, Z_t is a well-implicit conceptual prototype for modality k. We can utilize Z_t to efficiently transfer multimodal knowledge into PLMs to augment cognitive processing and understanding.

A.2 Proof of Theorem 1

Proof. We design a novel multimodal self-balancing contrastive loss between modalities m and k by incorporating a distribution of allocation

scores $p(w_{ij}^{(m,k)})$ as follows:

$$\mathcal{L}_i^{(m,k)} = -\sum_{j=1}^{N} \mathbf{1}(y_i = y_j) p(w_{ij}^{(m,k)}) \log p_{ij}^{(m,k)},$$
$$p_{ij}^{(m,k)} = \frac{\exp\left(m_i \cdot k_j / \tau\right)}{\sum_{a=1}^{N} \exp\left(m_i \cdot k_a / \tau\right)}, \tag{19}$$

where, m_i and k_j denotes the representations obtained by feeding $\hat{\mathbf{H}}_i^m$ and $\hat{\mathbf{H}}_j^k$ into a linear projector, τ is the temperature coefficient, $p_{ij}^{(m,k)}$ is the contrastive logit, and $m, k \in \mathcal{M}$. For simplicity, we define the distribution of allocation scores as $w_{ij} = p(w_{ij}^{(m,k)})$. Then, we approximate omit $\mathbf{1}(y_i = y_j)$ in Eq. 19 and solve the optimization problem with the Lagrange multiplier. The problem is defined as follows:

$$\begin{cases} \min & f(p_{i1}^{(m,k)}, \cdots, p_{in}^{(m,k)}) \\ & = -\sum_{j=1}^{n} \left(w_{ij} \cdot \log p_{ij}^{(m,k)} \right), \\ s.t. & g(p_{i1}^{(m,k)}, \cdots, p_{in}^{(m,k)}) \\ & = \sum_{j=1}^{n} p_{ij}^{(m,k)} - 1 = 0, \end{cases} \tag{20}$$

where, where n refers to the number of instances in the training batch. And the Lagrangian function of Eq. 20 can be formulated as:

$$\mathcal{L}(\lambda, p_{i1}^{(m,k)}, \cdots, p_{in}^{(m,k)}) = -\sum_{j=1}^{n} \left(w_{ij} \cdot \log p_{ij}^{(m,k)} \right) + \lambda \left(\sum_{j=1}^{n} p_{ij}^{(m,k)} - 1 \right) \tag{21}$$

and its corresponding partial derivatives are:

$$\frac{\partial \mathcal{L}}{\partial p_{ij}^{(m,k)}} = \lambda - \frac{w_{ij}}{p_{ij}^{(m,k)}} = 0; \tag{22}$$

$$\frac{\partial \mathcal{L}}{\partial \lambda} = \sum_{k=1}^{n} p_{ij}^{(m,k)} - 1 = 0. \tag{23}$$

From Eq. 22 and Eq. 23, the optimal value of contrastive logits is approximately as:

$$p_{ij}^{(m,k)*} = p(w_{ij}^{(m,k)}), \tag{24}$$

which concludes the proof for Theorem 1.

A.3 More training details.

In this work, we utilize CLIP (ViT-B/32)[2] (Radford et al., 2021), AudioCLIP (Full-Trained)[3] (Guzhov et al., 2021) and CLIP-ViP (base-patch32)[4] (Xue et al., 2022) text encoders to obtain conceptual prototypes of image, audio, and video modalities, respectively. The trade-off hyperparameter in Eq 14 is set to 0.2 and the number of attention heads in the semantic concept enhancement module is set to 8. We set the learning rate of 1e-4 on GLUE benchmark, 3e-5 on SQuAD v1.1 and SQuADv2.0 datasets, and 2e-5 on CommonGen dataset. In addition, we set the training batch size of 32 on GLUE benchmark and CommonGen dataset, and 12 on SQuAD v1.1 and SQuAD v2.0 datasets. We use grid search to determine the optimal hyperparameters mentioned above. We use Spearman's correlation as the metric on STS-B and the remaining GLUE tasks using accuracy as the metric. All experiments are conducted on 8 RTX 4090 GPUs.

A.4 More Ablation Experiments and Analysis.

Text Encoder in Prototype Extractor	SQuAD v1.1		SQuAD v2

Fixed CLIP*	**85.8**	**92.2**	**81.0**	**84.2**

Table 6: Performance comparison of representations pre-trained using different pre-training data in our approach. We employ RoBERTa-base as the base model. "Non-Fixed CLIP*" represents using the text encoders of CLIP, AudioCLIP and CLIP-ViP as prototype extractors and set them as trainable modules. "BERT-base**" represents pre-training BERT-base on captions in CC3M.

The Effect of the Pre-trained Dataset. We notice some discrepancies between the textual data employed in MC-PTMs and the dataset used for PLMs pre-training. To evaluate the effect of pre-training textual data on model performance, we utilize captions from the CC3M dataset (Sharma et al., 2018) for masked pre-training of the BERT-base model. We utilize the retrained BERT-base as conceptual prototype extractors to conduct this ablation study. As shown in Table 6, the results

[2] https://github.com/openai/CLIP
[3] https://github.com/AndreyGuzhov/AudioCLIP
[4] https://github.com/microsoft/XPretrain/tree/main/CLIP-ViP

reveal that pre-training with captions does not enhance performance and even leads to a decline in performance on the SQuAD v2.0 dataset. This further indicates that the performance gains from our concept prototypes come not from the pre-trained textual captions but from multimodal data such as images, audio, and videos. In addition, we change the fixed prototype extractors into learnable modules and observe that learnable extractors result in performance degradation. This may be due to fine-tuning breaking the original semantic structure of MC-PTMs, thereby weakening the paired mapping assumption of Theorem 2.

Methods	MemoryColor	ColorTerm	ObjectShape

Table 7: Performance comparison on visual reasoning tasks, with the best results highlighted in **bold**. We use BERT-base as the backbone to evaluate our MaCSC.

Evaluation on Visual Reasoning Tasks. In this study, we employ datasets focused on reasoning about color and shape, specifically the MemoryColor (Norlund et al., 2021), ColorTerm (Bruni et al., 2012), and ObjectShape (Zhang et al., 2022) datasets, to evaluate the efficacy of our method in facilitating the transfer of visual knowledge. The outcomes of these evaluations are presented in Table 7. The findings derived from the analysis of these results indicate that our MaCSC significantly enhances the capacity of PLMs to comprehend object colors and shapes, thereby demonstrating the effectiveness of our approach in augmenting the multimodal comprehension capabilities of PLMs.

Does Pre-trained Language Model Actually Infer Unseen Links in Knowledge Graph Completion?

Abstract

Knowledge graphs (KGs) consist of links that describe relationships between entities. Due to the difficulty of manually enumerating all relationships between entities, automatically completing them is essential for KGs. Knowledge Graph Completion (KGC) is a task that infers unseen relationships between entities in a KG. Traditional embedding-based KGC methods (e.g. RESCAL, TransE, DistMult, ComplEx, RotatE, HAKE, HousE, etc.) infer missing links using only the knowledge from training data. In contrast, the recent Pre-trained Language Model (PLM)-based KGC utilizes knowledge obtained during pre-training, which means it can estimate missing links between entities by reusing memorized knowledge from pre-training without inference. This part is problematic because building KGC models aims to infer unseen links between entities. However, conventional evaluations in KGC do not consider inference and memorization abilities separately. Thus, a PLM-based KGC method, which achieves high performance in current KGC evaluations, may be ineffective in practical applications. To address this issue, we analyze whether PLM-based KGC methods make inferences or merely access memorized knowledge. For this purpose, we propose a method for constructing synthetic datasets specified in this analysis and conclude that PLMs acquire the inference abilities required for KGC through pre-training, even though the performance improvements mostly come from textual information of entities and relations.

1 Introduction

A knowledge graph (KG) is graph-structured data that includes relationships between entities as links. KGs are useful resources to inject external knowledge into NLP models. Since manually considering all possible links between entities is difficult, it is important to use a task such as KG completion (KGC), which automatically completes unseen links from seen ones in a KG.

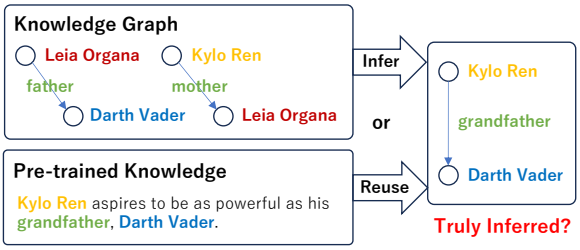

Figure 1: PLM-based KGC can reuse pre-trained knowledge of unseen links instead of inferring them.

As a basic method for KGC, KG embedding (KGE) is a popular chioce for this task. KGE embeds entities and their relationships as continuous vectors and then calculates the plausibility of unseen links. Traditional KGE methods learn these embeddings only from a target KG (Nickel et al., 2011; Bordes et al., 2013; Yang et al., 2015; Trouillon et al., 2016; Sun et al., 2019; Zhang et al., 2020; Li et al., 2022). Thus, they purely infer unseen links to complete KGs.

Similar to other NLP fields, KGC also utilizes pre-trained language models (PLMs) (Yao et al., 2019; Lv et al., 2022; Shen et al., 2022; Zhang et al., 2022; Choi et al., 2021; Choi and Ko, 2023; Wang et al., 2021a,c, 2022; Xie et al., 2022; Saxena et al., 2022; Chen et al., 2022; Xie et al., 2023; Zhu et al., 2023). Unlike traditional KGE methods, PLM-based KGE methods can access knowledge obtained through pre-training. This characteristic makes PLM-based KGE methods achieve higher KGC performance than the traditional KGE methods.

However, since the purpose of KGC is to infer unseen links from seen links in KGs, we should separately consider the performance gain from reusing the information of the unseen links obtained in pre-training and inferring unseen links from the seen links in KGs. Figure 1 shows an example of PLM-based KGC. As we can see, PLM-based

Abilities obtained by pre-training	✗	✓	✗	✓	✗	✓	✗	✓	✗	✓	✗

Table 1: Available information for each configuration. When compared, we can reveal what improves the KGC performance on PLMs. BASE denotes the setting on the original data, and VIRTUAL WORLD (§3.1), ANONYMIZED ENTITIES (§3.2), INCONSISTENT DESCRIPTIONS (§3.3), and FULLY ANONYMIZED (§3.4) denote the settings on our synthetic datasets. Pre. and Rand. denote the setting with pre-trained and randomly initialized weights, respectively.

KGC methods can estimate unseen links without inferring them from seen links in the target KG. This characteristic is problematic because we cannot estimate the inference ability of PLM-based KGC methods for truly unseen relationships between entities in KGs.

To address this issue, we propose a method to create synthetic datasets for KGC tasks intended to separately evaluate KGC performance by reusing the knowledge from pre-training corresponding to target unseen links and inferring from seen links in KGs. More specifically, we change the textual information of entities and relations while maintaining the graph structure of KGs, thereby creating an environment different from the PLMs' knowledge corresponding to unseen links in KGs. Due to this change, PLMs cannot rely on their pre-trained knowledge and must rely on their pure inference abilities. Table 1 summarizes the configurations provided by our synthetic datasets. By comparing these configurations, we can reveal what actually contributes to the KGC performance of PLMs.

We conducted experiments on various pre-trained models under our controlled synthetic dataset constructed from WN18RR (Dettmers et al., 2018), FB15k-237 (Toutanova and Chen, 2015), and Wikidata5m (Wang et al., 2021c). The results showed that PLMs acquire the inference abilities required for KGC in pre-training but rely more on textual information of entities and relations in KGs. We also observed that the KGC performance of PLM-based KGC without pre-trained information is comparable to or lower than that of TransE, the traditional KGC. This finding indicates the importance of both traditional and PLM-based KGC methods.

2 Knowledge Graph Completion

2.1 Task Definition for KGs with Descriptions

We assume that a KG $\mathcal{G}$ includes descriptions defined as a tuple, $\mathcal{G}=(\mathcal{E},\mathcal{R},\mathcal{T},\mathcal{D})$, where $\mathcal{E}$ denotes a set of entities, $\mathcal{R}$ denotes a set of relations, $\mathcal{T}$ denotes a set of triples, and $\mathcal{D}$ denotes descriptions for the entities. Each triple is represented as $(h,r,t)\in\mathcal{T}$, where h and $t\in\mathcal{E}$ are the head and tail entities, respectively, and $r\in\mathcal{R}$ is the relation. Every entity $e_i\in\mathcal{E}$ has a corresponding description $d_i\in\mathcal{D}$. KGC is a task to fill in the missing triples in KGs. Specifically, this involves using a query, a partial triple $(h,r,?)$ or $(?,r,t)$ to predict its answer, an entity at the position of $?$, within the KG. Note that the prediction is exclusively focused on entities; predicting their corresponding descriptions is not required.

KGC is often evaluated by rank prediction metrics such as Hits@k ($k\in\{1,3,10\}$), mean rank (MR), and mean reciprocal rank (MRR). Hits@k calculates the proportion of correct entities ranked among the top-k, MR is the average rank of all test triples, and MRR is the average reciprocal rank of all test triples.

2.2 KGC Methods

Traditional KGC methods, e.g., RESCAL (Nickel et al., 2011), TransE (Bordes et al., 2013), DistMult (Yang et al., 2015), ComplEx (Trouillon et al., 2016), RotatE (Sun et al., 2019), HAKE (Zhang et al., 2020), and HousE (Li et al., 2022), primarily focus on the structure of KGs, without considering the extensive textual information.

However, recent advancements integrating PLMs have allowed KGC methods to encode text (Yao et al., 2019; Lv et al., 2022; Shen et al., 2022; Zhang et al., 2022; Choi et al., 2021; Choi

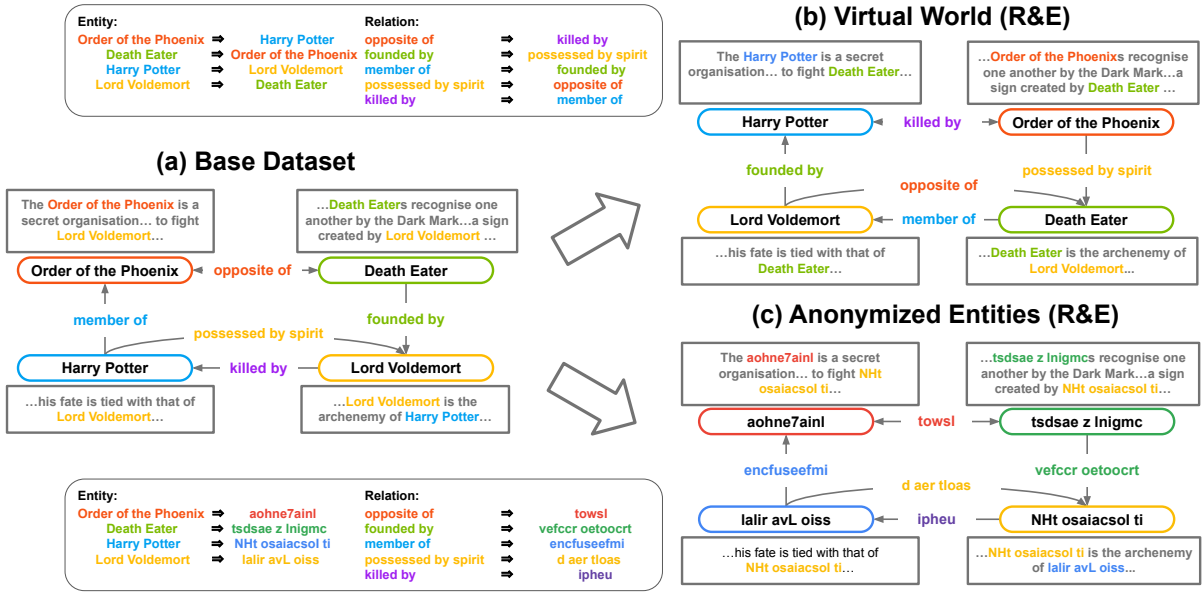

Figure 2: (a): Example of a KG with entity descriptions for PLM-based methods. Each entity has a corresponding description. (b) and (c) are the datasets used in this study. We primarily apply two methods for creating these datasets in VIRTUAL WORLD (§3.1) and ANONIMIZED ENTITIES (§3.2). (b) described in VIRTUAL WORLD (§3.1) involves swapping the names assigned to entities and relations in the base dataset respectively. (c) described in ANONIMIZED ENTITIES (§3.2) substitutes the names of entities and relations in the base dataset with random strings. Note that in both procedures, any entities appearing within the description text are replaced with their corresponding transformed names to maintain the graph structure within the descriptions.

and Ko, 2023; Wang et al., 2021a,c, 2022) or generate facts (Xie et al., 2022; Saxena et al., 2022; Chen et al., 2022; Xie et al., 2023; Zhu et al., 2023), thereby enhancing the KGC performance. These methods can be broadly divided into two categories based on their usage: discrimination-based methods that utilize PLM encoders, and generation-based methods that utilize PLM decoders (Pan et al., 2024) (see Appendix A for the details).

3 Synthetic Dataset Construction

To analyze the behavior of PLM-based KGC methods, we create synthetic data corresponding to each setting in Table 1. These settings affect the usable information of the PLM-based KGC methods but do not influence the traditional KGE methods. We explain the details for each setting in the following subsections.

3.1 Virtual World

To separate the pre-trained knowledge of PLMs and a target KG, we create a virtual world by shuffling each entity and/or relation name in the KG.

As shown in Figure 2(b), we shuffle the textual information associated with each entity and/or relation while keeping the graph structure within the created synthetic dataset. To ensure there are no unshuffled elements, we shuffle the entities using the derangement algorithm by Martínez et al. (2008).

However, there are dramatically fewer relations compared to entities (e.g., ten relations for ten thousand entities), and if relations are shuffled, the triple remains unchanged in many cases.[1] To address

Algorithm 1: Derangement by Bipartite Graph

Data: Input array arr of size n, Set of removed edges $removed_edges$
Result: Generated array res

Create an empty graph G;
for $i \leftarrow 0$ **to** $n-1$ **do**
  for $j \leftarrow 0$ **to** $n-1$ **do**
    if $arr[i] \neq arr[j]$ *and* $(arr[i], arr[j])$ *is not in* $removed_edges$ **then**
      add edge $(i, n+j)$ in G;
    end
  end
end
$match \leftarrow$ maximum matching(G)
$res \leftarrow$ an empty list of size n;
for $i \leftarrow 0$ **to** $n-1$ **do**
  $index \leftarrow match[i] - n$;
  $res[i] \leftarrow arr[index]$;
end
return res

[1] In the case of (Johann Bernoulli, wasBornIn, Basel) and

these cases, we apply a derangement based on a bipartite graph (Iradmusa and Praeger, 2019; Horsley et al., 2020) in Algorithm 1 for relations.

In Algorithm 1, we introduce $removed_edges$, a set to the bipartite graph-based derangement. Lines 4–6 in Algorithm 1 delete edges leading to multiple relations in a triplet $(h,*,t)$, thereby preventing transitions to these relations.[2] We use the Hopcroft-Karp algorithm (Hopcroft and Karp, 1971) for maximum bipartite matching.

Additionally, we use Trie search (Yata, 2013) to comprehensively search for entity representations within each description in Figure 2 and change them into their post-shuffled text representations. This procedure treats the relationships between entities within the descriptions while maintaining their original graph structure in the descriptions.

3.2 Anonymized Entities

VIRTUAL WORLD can separate the pre-trained knowledge of PLMs and a target KG. However, this setting may underestimate the KGC performance caused by the overwrap of the entity and/or relation names between pre-trained knowledge and the target KG.

The ANONYMIZED ENTITIES setting can solve this problem by replacing the textual information associated with each entity and/or relation with a random string while keeping the original graph structure within the dataset, as in Figure2(c). Afterward, we also replace the entity representations within the description with these random strings using Trie search, the same as VIRTUAL WORLD (§3.1).

Since the random strings should follow language characteristics, we first construct character-level unigram language models $P(s_i)$, including space characters from the set of textual information of each entity and relation.

Next, we generate random strings $\boldsymbol{s}=s_1,s_2,...,s_n$ based on the character-level unigram language model $p(\boldsymbol{s})$, i.e., the product of the probabilities of unigram character in the strings:

$$p(\boldsymbol{s})=\prod_{i=1}^{n} p(s_i). \quad (1)$$

We stop the generation of strings when an end-of-sequence symbol is sampled. The strings are treated as a series of independent characters, allowing us to generate entirely random strings without using information about co-occurrence between characters. However, we preserve information for the randomly sampled sequences across the entire dataset so that each entity or relation is replaced with a unique sequence avoiding duplicates.

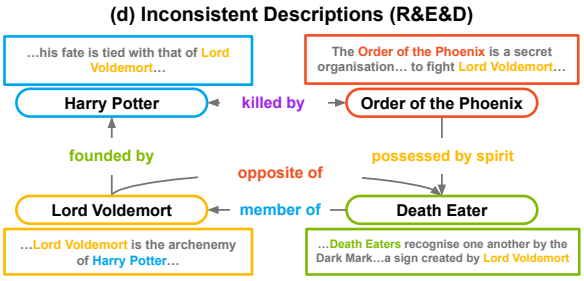

Figure 3: Example of a synthetic dataset created in INCONSISTENT DESCRIPTIONS (§3.3). Compared to Figure2(b) which shows an example of VIRTUAL WORLD (§3.1), the descriptions here also move to the same positions as the entities. Also, the entities in the descriptions do not change. At first glance, it appears the description explains the real-world relationships of the corresponding entities, but the relationships between entities within the synthetic dataset are actually broken.

3.3 Inconsistent Descriptions

To measure the effect of descriptions on PLM-based KGC, we isolate the entity and relation knowledge from the description by breaking the consistency between the graph structure and descriptions in addition to the shuffle of entity and/or relation names.

INCONSISTENT DESCRIPTIONS has two variations, one in which only the descriptions are shuffled and the other in which both the descriptions and entities/relations are shuffled. In the first variation, we derive the scenario in which there is no correspondence between an entity and its description by shuffling the set of descriptions via a derangement to get a new set $d' \in D'$. Then, we assign for each entity the new descriptions from D', i.e., $\forall e_i \in E, e_i : d_i \rightarrow d'_i$.

The second variation considers the descriptions and entities presented in Figure 3. The difference from Figure 2(b) for VIRTUAL WORLD (§3.1) lies in the way it handles the descriptions. In INCONSISTENT DESCRIPTIONS, descriptions are also shuffled together with the corresponding textual information when performing VIRTUAL WORLD, but the entities in the descriptions are preserved. In other words, when we map from e_i to e_j, we similarly map from d_i to d_j.

(Johann Bernoulli, diedIn, Basel), the swapping of the relations wasBornIn and diedIn does not change the triples.

[2] If $removed_edges$ is empty, it is a normal derangement.

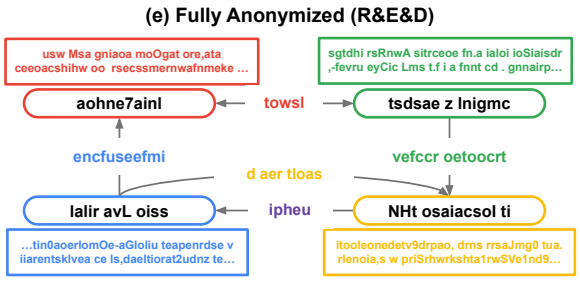

Figure 4: Example of a synthetic dataset created in FULLY ANONIMIZED (§3.4). Compared to Figure 2(c), which shows an example of ANONYMIZED ENTITIES (§3.2), the descriptions are here also changed into random strings. The descriptions become noisy information, and it becomes impossible to utilize any information from them.

Even though the descriptions explain the entities in the real world, they diverge from the relationships among entities in the dataset after the shuffle operation. Thus, if the model relies too much on the descriptions, it will be confused by this inconsistency.

3.4 Fully Anonymized

Figure 4 shows an example of FULLY ANONYMIZED, which is similar to ANONYMIZED ENTITIES (§3.2) in Figure 2(c) but differs in whether or not there is an operation on the descriptions. We replace the descriptions with random strings using the character-level unigram model utilized in ANONYMIZED ENTITIES (§3.2), while we keep the original structure of the KGs. This setting aims to mitigate underestimating the KGC performance caused by the overlap of the entity and/or relation names between pre-trained knowledge and the target KG. Note that the random string generation is applied independently to entities, relations, and descriptions. The key difference between FULLY ANONYMIZED and INCONSISTENT DESCRIPTIONS (§3.3) lies in whether the descriptions are readable sentences or not; if they are not, the PLMs in FULLY ANONYMIZED cannot rely on any pre-trained knowledge.

4 Experiments

4.1 Settings

Metrics We analyze how the inference capabilities are affected by each synthetic dataset (§3) measured with the Hits@10 metric on the test dataset and the validation dataset in the KGC task.[3]

Dataset	#entity	#relation	#train	#valid	#test
WN18RR	40,943	11	86,835	3,034	3,134
FB15k-237	14,541	237	272,115	17,535	20,466
Wikidata5m	4,594,485	822	20,614,279	5,163	6,894

Table 2: Dataset statistics.

Datasets We used WN18RR, FB15k-237, and Wikidata5m[4] as the base datasets; the details are shown in Table 2.[5] We applied VIRTUAL WORLD (§3.1) and ANONYMIZED ENTITIES (§3.2) to the entities and/or relations for creating synthetic datasets, resulting in a total of six types of datasets. Furthermore, we applied INCONSISTENT DESCRIPTIONS (§3.3) with and without VIRTUAL WORLD for entities and/or relations. INCONSISTENT DESCRIPTIONS (§3.4) is also applied with and without ANONYMIZED ENTITIES, and thus, we obtained additional six types of datasets. In total, we have 13 types of datasets, including the original one for each base dataset.

Comparison Methods We employ SimKGC (Wang et al., 2022) and kNN-KGE (Zhang et al., 2022) as Discriminative-based methods, and KGT5 (Saxena et al., 2022) and GenKGC (Xie et al., 2022) as Generation-based methods. We use the LambdaKG framework (Xie et al., 2023) as the base implementation, with hyper-parameters set to their default values. The seed value is fixed for all experiments.[6] We set early stopping for WN18RR and FB15k-237 when the Hits@10 value on the validation data did not improve for four epochs. For Wikidata5m, we conducted training only one epoch.[7] We also compare two cases: using pre-trained weights and setting weights randomly.

[3]We also measured Hits@1, Hits@3, MRR, and MR, and all showed similar trends. In this paper, we present the results using hits@10 for brevity.

[4]We follow the transductive setting in Wang et al. (2021c).

[5]We use the datasets with textual information provided by Yao et al. (2019) for WN18RR, FB15k-237, and by Wang et al. (2021c) for Wikidata5m.

[6]We conducted pilot studies with various seeds for several datasets and models. The variance observed was around 0.02, so a fixed seed value was chosen. For example, the Hits@10 scores in kNN-KGE on WN18RR applied with FULLY ANONYMIZED (§3.4) to all descriptions, entities, and relations were 0.426 ± 0.001 with three different seeds.

[7]We only report the results from SimKGC, as kNN-KGE could not be executed due to computational resource limitations, and both KGT5 and GenKGC did not produce scores under these settings. We conducted all experiments on a single NVIDIA A100 (40GB) or a single NVIDIA A6000 (48GB).

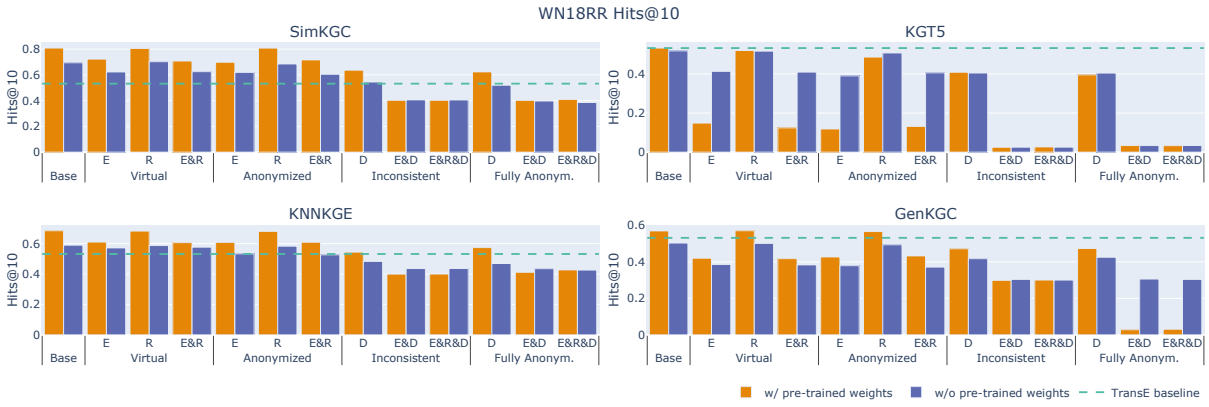

Figure 5: The hits@10 results on WN18RR. "E", "R", and "D" represent entity, relation, and description, respectively. For example, "E&R" denotes the application of the method to both entities and relations. For comparison, we have also included the hits@10 results on WN18RR by TransE reported by Nathani et al. (2019), which are the same score because the TransE model does not require textual information. The graphs on the left represent Discrimination-Based Methods, while those on the right represent Generation-Based Methods.

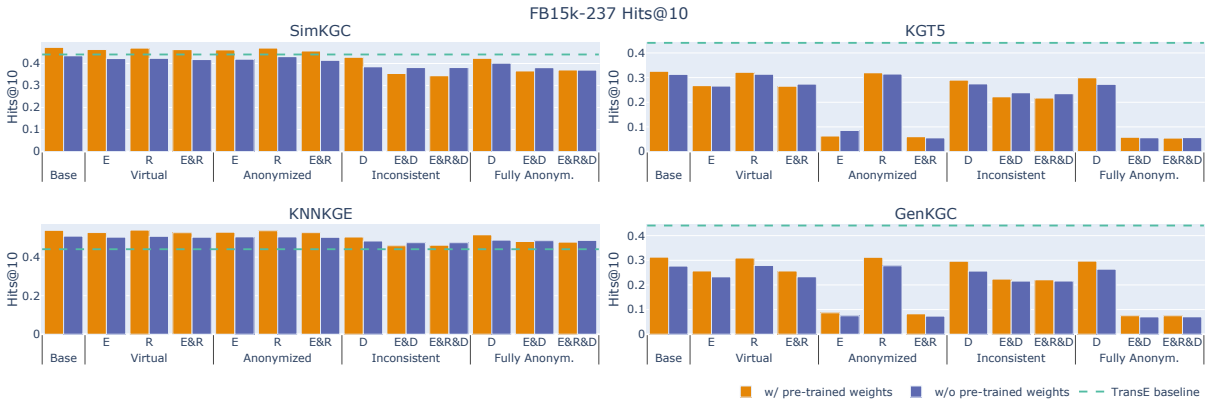

Figure 6: Hits@10 results on FB-15k-237. The supplementary explanation is the same as in Figure 5.

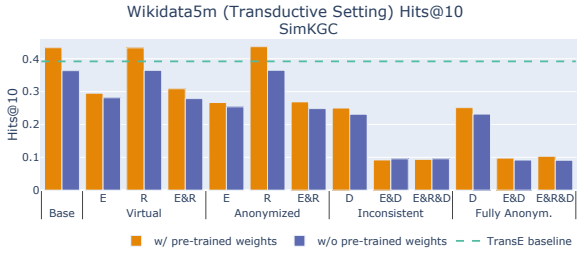

Figure 7: Hits@10 results on Wikidata5m by SimKGC. We have also included the Hits@10 results on WN18RR by TransE reported by Wang et al. (2021c).

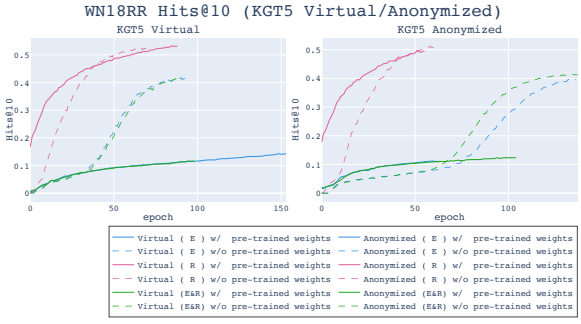

Figure 8: The plots show Hits@10 scores on WN18RR for the validation data at each epoch. The solid line represents using pre-trained weights, and the dashed line represents initializing weights randomly.

4.2 Results and Analysis

4.2.1 Effect of knowledge in PLMs

The results for each model and dataset on WN18RR and FB15k-237 are shown in Figures 5 and 6, and the results from SimKGC on Wikidata5m are shown in Figure 7. In the "Base" setting, all models with the pre-trained weights were better than those without them. When the models are trained without pre-training weights, they have to infer unseen links based only on information within the training

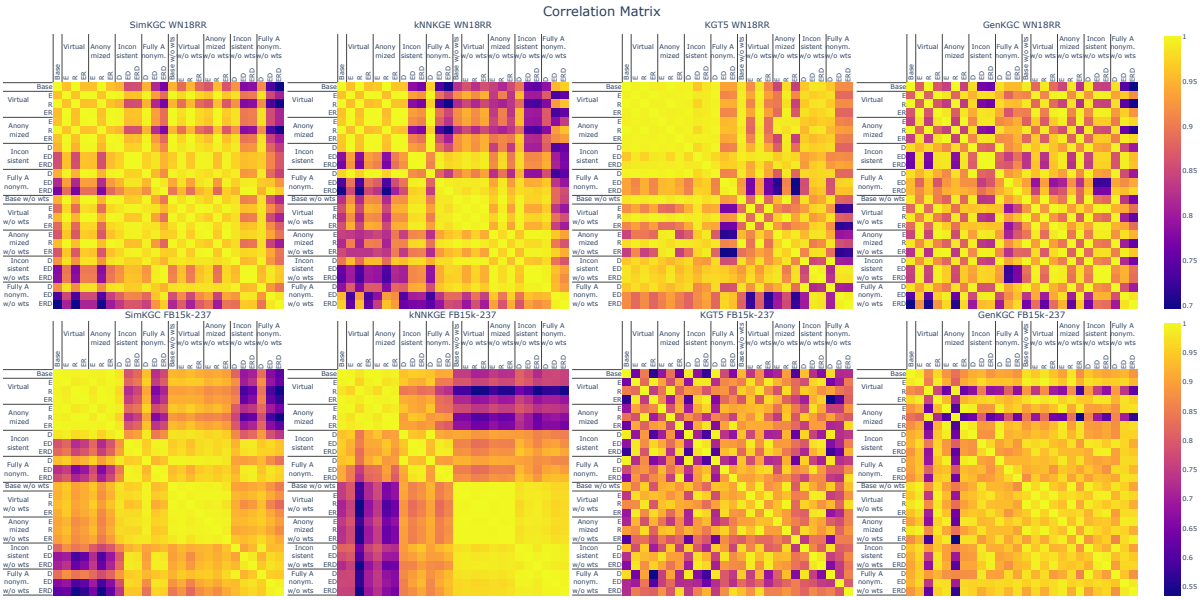

Figure 9: The correlation matrix (Pearson's correlation) shows the hits@10 values for the validation data for each dataset and each model."Virtual", "Anonymized", "Inconsistent", and "Fully Anonym." represent the methods applied in Sections 3.1, 3.2, 3.3, and 3.4, respectively. "E", "R", and "D" represent entity, relation, and description, respectively. For example, "ER" denotes the application of the method to both entities and relations. "w/o wts" means training from scratch with random initial values. The two graphs on the left are Discrimination-Based Methods, and the two on the right are Generation-based Methods.

#Relation	WN18RR (%)				FB15k-237 (%)				Wikidata5m (%)			
	Train	Valid	Test	Total	Train	Valid	Test	Total	Train	Valid	Test	Total
1	60.09	97.55	97.51	57.68	13.52	65.26	61.64	12.56	24.23	98.58	98.73	24.22
2	35.39	2.41	2.49	37.31	14.02	24.44	25.61	12.98	17.23	1.98	0.93	17.21
3	4.21	0.02	–	4.61	11.39	7.39	8.90	10.88	21.88	0.21	0.28	21.88
4	0.30	0.02	–	0.38	10.01	2.08	2.67	9.53	11.95	0.01	0.05	11.95
5	0.02	–	–	0.02	9.06	0.51	0.76	8.85	7.94	0.01	0.01	7.94
Over	–	–	–	–	42.00	0.31	0.41	45.19	16.78	–	–	16.79

Table 3: The number of relations assigned to each entity in each dataset. Note that some entities may be associated with multiple entities under certain entity and relation queries.

data of the KGC dataset.

Comparing "Base", "Virtual", and "Anonymized" settings, we can see performance degradations by restricted access to knowledge for entity names obtained in pre-training. However, the models without the pre-trained weights achieved better or at least comparable results, especially when changes were made to both entities and their descriptions, as you can see in the "Inconsistent" and "Fully Anonym." settings. From the result, we hypothesize that the performance gain by pre-trained weights in "Virtual" and "Anonymized" settings comes from the pre-trained ability to read textual information.

Figure 7 shows the importance of pre-trained knowledge for entity names in Wikidata5m. For the further analysis, we applied the interquartile range (IQR), an outlier detection method (Tukey, 1977), and the result show the significant performance gap between models with and without pre-trained weights only when entity names and their descriptions were unchanged. This finding indicates that PLM knowledge significantly contributes to the model's inference, especially in Wikidata5m.

4.2.2 Biases caused by PLM knowledge on inference for unseen links

We discussed the benefit of PLM knowledge in Section 4.2.1, but on the other hand, PLM knowledge may adversely affect the inference for unseen entities. Especially in Figures 5 and 6, it is clear that the difference between with and without pre-trained knowledge significantly affected the scores, particularly in the case of entity changes in KGT5.

Figure 8 shows the training curves of Hits@10 on WN18RR for the validation data. Remarkable

results were observed for the VIRTUAL WORLD and ANONYMIZED ENTITIES methods in KGT5: namely the models using pre-trained weights could not learn well, even with sufficient epochs of training, whereas the models without pre-trained weights exhibited inference capability for unknown entities. These results suggest that while PLM knowledge helps infer unseen links, it may prevent the learning of new relationships due to the relationships included in the PLM knowledge.

4.2.3 Which factors (entity, relation, description) affect inference ability?

Figure 9 shows the correlation matrix of Hits@10 scores on the validation data for each dataset and model. In Figures 5, 6, and 9, the results from the base dataset and changes to relations indicate strong correlations in the learning process and Hits@10 scores in the test data. Therefore, the model is not affected by changes to relations when inferring unseen links. As shown in Table 2, the number of relations is significantly smaller than that of entities. Moreover, Table 3 reveals entities with only one assigned relation in the KGC dataset: 12% in FB15k-237 and over 50% in WN18RR. This suggests that the models can infer connections between entities without considering their actual relations.

Figure 9 also shows a correlation between VIRTUAL WORLD and ANONYMIZED ENTITIES, indicating that which kind of textual information is used for inference is less important than than the consistency in relationships between entities in each triplet. Additionally, when changing both the entity and the description, the score decreases in Figures 5 and 6. Table 4 shows how many entities to predict are included in the description of query entities; in WN18RR, about 15 % of the entities may be able to solve the KGC task just by extracting information from the description. Changes to the description only are less likely to be affected, but changing both the entity and the description eliminates clues to the answer from both, leading to a decrease in the inference capabilities with PLM.

4.2.4 Effect of model structures on performance

When comparing Generation-based methods with Discrimination-based methods, the former are substantially affected by random strings of entities. As shown in Figure 5, KGT5 and GenKGC without the pre-trained weights learn better than those that have

	Train (%)	Valid (%)	Test (%)	Total (%)
WN18RR	15.03	15.62	15.34	15.06
FB15k-237	6.11	4.68	4.50	5.92
Wikidata5m	4.58	4.99	4.58	4.58

Table 4: Percentage of target entities to predict is included in the description of the query entity for each dataset. These triplets can be solved by simply extracting information from the descriptions without performing any inference in the KGC tasks.

them. Furthermore, Figure 8 shows that scores do not improve even with sufficient training, which suggests that the difference in scores is not due to the early stopping. Thus, PLM knowledge prevents learning new relationships from descriptions in Generation-based methods.

Kwon et al. (2023) point out a benefit of predicting structured labels by Generation-based methods is handling the relationship of labels through implicitly infused label embeddings (Xiong et al., 2021; Zhang et al., 2021) on the decoder. However, the current usage of Generation-based methods in KGC only predicts a single entity without its description for each query. Therefore, in the current usage, Generation-based methods cannot handle relationships between entities and consider their description information.

Moreover, Generation-based methods are influenced by the string of the output entity, as seen in Figures from 5 to 7. On the other hand, Discrimination-based methods are less affected by the textual information, in contrast to Generation-based methods that are affected by random strings that lack the characteristics of language and are thus unsuitable for generation (see Appendix B for further analysis).

5 Related Work

KG Knowledge Graphs (KGs) are fundamental resources for knowledge-intensive NLP tasks such as dialog (Moon et al., 2019), question answering (Reese et al., 2020), named entity recognition (Liu et al., 2020), open-domain questions (Hu et al., 2022), and recommendation systems (Gao et al., 2020). Recently, the target of KGs has expanded to vision and language (V&L) fields (Zhu et al., 2024). Based on the expansion, KGs are expected to support knowledge-intensive V&L tasks like knowledge-intensive visual question answering (Yue et al., 2023), image generation (Kamigaito et al., 2023), explanation generation (Saito et al., 2024; Hayashi et al., 2024), etc. In contrast to the

increase in KGs' importance, the sparsity problem, which is an essential issue of KGs, still remains. As a solution, Knowledge Graph Completion (KGC) has a great role to fill in uncovered links in KGs.

Traditional KGC As introduced in §2.2, the traditional KGC methods, represented as RESCAL (Nickel et al., 2011), TransE (Bordes et al., 2013), DistMult (Yang et al., 2015), ComplEx (Trouillon et al., 2016), RotatE (Sun et al., 2019), HAKE (Zhang et al., 2020), and HousE (Li et al., 2022) only focus on the structure of KGs, without considering the extensive textual information of KGs and pre-trained information. Thus, these models need to complete KGs only by their inference abilities. Instead of the extensive information, the modeling and training methods for the traditional KGC are well studied empirically (Ruffinelli et al., 2020; Ali et al., 2021) and theoretically (Kamigaito and Hayashi, 2021, 2022a,b; Feng et al., 2023b, 2024) due to their simplicity. This characteristic supports the robustness and reliability of the traditional KGC.

PLM-based KGC As introduced in §2.2, PLM-based KGC methods encode text (Yao et al., 2019; Lv et al., 2022; Shen et al., 2022; Zhang et al., 2022; Choi et al., 2021; Choi and Ko, 2023; Wang et al., 2021a,c, 2022) or generate facts (Xie et al., 2022; Saxena et al., 2022; Chen et al., 2022; Xie et al., 2023; Zhu et al., 2023) based on pre-trained information to enhance KGC performance. There are two major categories, discrimination-based methods that utilize PLMs encoders and generation-based methods that utilize PLMs decoders (Pan et al., 2024). However, it is uncertain whether the performance improvement is actually caused by the enhanced ability of inference through pre-training or data leakage from pre-trained data. We aim to reveal that in our work.

Data Leakage in PLMs Some existing datasets for the downstream tasks are often directly mixed into the pre-training data (Magar and Schwartz, 2022; Kapoor and Narayanan, 2022; Sainz et al., 2023), and general PLMs are not able to answer questions correctly in downstream tasks that require domain-specific knowledge excluded from the pre-trained data (Wang et al., 2023; Jullien et al., 2023; Nair and Modani, 2023).

Inference Ability of PLMs Several studies (Zhou et al., 2021; Wang et al., 2021b; Zhu et al., 2023; Zheng et al., 2023; Yu et al., 2024; Laban et al., 2023; Qin et al., 2023) evaluate the inference abilities of PLMs, but they ignored the impact of the PLMs' memorization abilities in inference. Therefore, the inference abilities of PLMs remain unclear. While the memorization abilities of PLMs are beneficial (Petroni et al., 2019; Roberts et al., 2020; Heinzerling and Inui, 2021; Wei et al., 2022; Carlini et al., 2023), they can introduce bias (Vig et al., 2020; Kaneko et al., 2022a,b; Meade et al., 2022; Deshpande et al., 2023; Feng et al., 2023a; Ladhak et al., 2023) or cause errors due by the contamination in the pre-training data as hullucinations (Dziri et al., 2022b,a; McKenna et al., 2023; Ji et al., 2023). This suggests the memorization and inference abilities of PLMs are strongly related, and the pre-trained knowledge of the PLMs influences their inference abilities.

6 Conclusion

In this study, we proposed a method for evaluating the inference ability of PLM-based KGC methods by separately considering the information related to unseen links in KGs. Using this method as a basis, we developed synthetic datasets that focused on the structure of KGs and changed only textual information, maintaining graph structure. Then, we compared PLM-based KGC methods using these datasets.

The comparison results show that PLMs acquire the inference abilities for KGC in pre-training, whereas in KGs, they rely more on the textual information of entities and relations. Further, we observed that the KGC performance of PLM-based KGC without pre-trained knowledge is comparable to or lower than that of TransE, the traditional KGC. This highlights the importance of using both traditional and PLM-based KGC methods.

Please see Appendix C for more detailed information on improving the current KGC evaluation based on the insights from our work.

7 Limitations

In this study, we investigated the inference abilities of PLM-based KGC methods empirically, without focusing on theoretical verification. Furthermore, while our focus was on KGC, we did not verify whether these findings could be applied to other downstream tasks. Therefore, our future work will aim to generalize this empirical study and perform verification across various downstream tasks.

8 Ethical Considerations

In this study, we have created synthetic datasets derived from existing KG datasets that have cleared ethical issues following published conferences' policies. Therefore, our created datasets do not introduce any ethical problems.

A Details of PLM-based KGC Methods

A.1 Discrimination-based Methods

The early PLM-based KGC methods such as KG-BERT (Yao et al., 2019), utilize an encoder-only PLMs like BERT (Devlin et al., 2019) to encode triples. They perform binary classification to assess the plausibility of a given triplet. KG-BERT transforms a triple (h,r,t) as follows:

$$x=[\text{CLS}]\text{Text}_h[\text{SEP}]\text{Text}_r[\text{SEP}]\text{Text}_t[\text{SEP}], \tag{2}$$

where Text_n represents textual representations of n. The PLM takes x as input and conducts binary classification using the [CLS] token $e_{[\text{CLS}]}$ from the final hidden state. It calculates the plausibility of the triples, which is formulated as follows:

$$\text{Score}(h,r,t)=\text{Sigmoid}(\text{MLP}(e_{[\text{CLS}]})). \tag{3}$$

Zhang et al. (2022); Choi et al. (2021); Choi and Ko (2023) involve filling the missing part of a triple with a [MASK] token and predicting it. The input sequence x is represented as follows:

$$x=[\text{CLS}]\text{Text}_h[\text{SEP}]\text{Text}_r[\text{SEP}][\text{MASK}][\text{SEP}]. \tag{4}$$

Nonetheless, simply predicting the [MASK] token does not facilitate direct entity prediction. Consequently, it introduces special tokens into the vocabulary to represent the corresponding entities for prediction. In the case of kNN-KGE (Zhang et al., 2022), an initial learning process is undertaken when introducing these special tokens to establish the relationship between the special tokens and the entities.

The prompt shown in Equation (5) is used to mask the special tokens that represent each entity e_i. With all other parameters fixed, the masked entity e_i is predicted using cross-entropy loss. This approach optimizes the embeddings of these entities, which are initially set to random values.

$$x_i=[\text{CLS}]\text{ the description of [MASK] is } d_i\text{ [SEP]}, \tag{5}$$

Afterwards, a sentence similar to Eq. (4) is fed into the model, which then fine-tunes the model to predict the masked entity, as formulated:

$$P(t|h,r)=P([\text{ MASK }]=\text{t}|x,\Theta), \tag{6}$$

where Θ denotes the parameters of the model.

Finally, SimKGC (Wang et al., 2022), the state-of-the-art method employs two encoders. SimKGC splits the triple (h,r,t) into a question (h,r) and its answer t and uses their respective PLMs to encode them into vector space, which can be expressed as:

$$x_{(h,r)}=[\text{CLS}]\ \text{Text}_h\ [\text{SEP}]\ \text{Text}_r\ [\text{SEP}]\ , \tag{7}$$

$$x_t=[\text{CLS}]\ \text{Text}_t\ [\text{SEP}]\ . \tag{8}$$

Then, the [CLS] tokens from the final hidden state are extracted, with the embedding of $x_{(h,r)}$ represented as $e_{(h,r)}$ and the embedding of x_t represented as e_t. The final plausibility of the triples is scored as follows:

$$\text{Score}((h,r),t)=\cos\big(e_{(h,r)},e_t\big). \tag{9}$$

Essentially, the introduced model originally employs the BERT-base model, but it can use variants of BERT such as RoBERTa (Liu et al., 2019).

A.2 Generation-based Methods

Recently, novel KGC-based methods have been introduced that utilize Encoder-Decoder models, e.g., GenKGC (Xie et al., 2022), KGT5 (Saxena et al., 2022), or Decoder-only Large Language Models (LLMs), e.g., LambdaKG (Xie et al., 2023), AutoKG (Zhu et al., 2023), to directly generate the tail entity t. Unlike traditional KGC methods and discrimination-based methods, which can only complete the KGs using a predefined set of entity candidates, these generation-based methods have the potential to predict unknown entities not included in the candidate list. This capability unlocks the ability to predict any and all entities in the KGs.

When predicting the missing triple $(h,t,?)$, the model converts $x_{(h,r)}$ into a prompt specific to the models, then it into the encoder and generates x_t.

While there is potential to predict any and all entities, in practice, certain restrictions are put in place to focus the prediction towards entities within the KGs. For example, GenKGC introduces an entity-aware hierarchical decoder to place constraints on x_t. Furthermore, KGT5 utilizes generation-based PLMs, pre-trained with text descriptions specifically for KG representation. Notably, this is done from scratch with random initialization, rather than leveraging pre-trained models, indicating the effectiveness of a tailored approach for each dataset.[8] Regarding the foundational mod-

[8]The authors mention that using pre-trained weights can improve accuracy in some cases (https://github.com/intfloat/SimKGC/issues/1). They also discuss the chal-

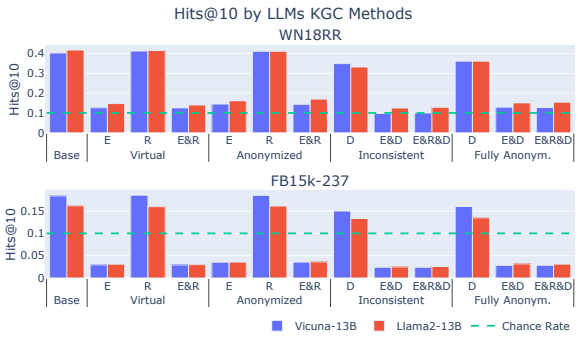

Figure 10: The results of Hits@10 using vicuna-13B and Llama2-13B in the LLMs KGC methods (Xie et al., 2023). The LLMs select 1 entity from selected 100 candidate entities by BM25. It generates 10 sentences, and it is checked whether the correct entity is included in these. The chance rate is 0.1 because it generated total 10 entities from 100 candidates.

els, GenKGC employs BART-base (Lewis et al., 2020), while KGT5 utilizes T5-small (Raffel et al., 2020).

Finally, some experimental KGC methods use decoder-only LLMs. These methods employ well-designed prompts to induce in-context learning. LambdaKG employs the information retrieval algorithm (BM25) (Büttcher et al., 2010) to construct prompts. It selects the top 100 most relevant entities from the dataset as potential answer candidates. Similarly, it retrieves the top 5 relevant triples as examples for few-shot learning. This information is aggregated into a single prompt, which is then used by LLMs to select and generate an answer. AutoKG addresses the KGC task in a 0-shot or 1-shot setting without employing an information retrieval algorithm. It treats the missing entity as a [MASK] token in the prompt and generates the corresponding value for the [MASK] token using LLMs.

B Inference capabilities under a zero-shot setting with LLMs

We evaluate the inference capabilities in a zero-shot setting by LLMs. We evaluate WN18RR and FB15k-237 using the LambdaKG method (Xie et al., 2023) described in Appendix A.2.[9] Figure 10 shows the results using Vicuna-13B (Zheng et al., 2023) and Llama2-13B (Touvron et al., 2023). The base dataset yields high hits@10 scores, but when entities are changed, the impact is high, and it is small when only descriptions are changed. However, LLMs don't know how the entity was changed, so the chance rate serves as an upper limit. Therefore, it is clear that inference by LLMs is based on pre-trained knowledge.

C Exhortation to KGC

Datasets As discussed in Section 4.2.3, the information for relations has very little impact. Some entities are assigned only one relation, as shown in Table 3. Thus, if only the entity is known, it may be possible to infer the unknown entities without relation information. Traditional KGC methods without PLMs can learn the graph structure from scratch. In contrast, PLMs' knowledge can help with completion without relation information, as discussed in Section B. The current dataset focuses on entities, but it cannot accurately measure the effect of relations. Therefore, a dataset that specifically focuses on relations is needed.

Next, according to Table 4, it has become clear that the missing entity information is included in the descriptions of queries. Therefore, if we use descriptions in the KGC task, it can be considered a cheat setting, as it utilizes the information extraction capability from the text data in PLMs. The descriptions are indeed useful for disambiguation in entities, but they also provide too much information for inference, thus demonstrating information extraction capabilities. In the future, to measure the pure inference capabilities for unknown entities, descriptions should not be used in the KGC task for fair comparison.

Models As discussed in Section 4.2.1, PLMs' knowledge helps inferences for unknown entities. Therefore, when we evaluate filling in truly unknown links in KGs by KGC in the future, we should avoid using pre-trained weights. This suggests that PLM-based KGC methods with pre-trained weights create a cheat setting because they utilize external knowledge not included in datasets, which does not measure the pure inference capabilities for unknown entities in KGC tasks. It is essential to evaluate the model's performance based on the target KGC dataset only for a fair comparison.

lenge of training models on small datasets (https://github.com/apoorvumang/kgt5/issues/4).

[9] Original LambdaKG uses GPT-3 (Brown et al., 2020), but we employ Vicuna-13B and Llama2-13B for reproducibility. These models have shown competitiveness to GPT-3 on the MT-bench Reasoning benchmark (Zheng et al., 2023). Furthermore, while the original setting calculates only Hits@1, this study calculates Hits@10 by considering the top 10 output probabilities.

Discovering Lobby-Parliamentarian Alignments through NLP

Aswin Suresh, Lazar Radojevic*, Francesco Salvi*, Antoine Magron
Victor Kristof, Matthias Grossglauser
EPFL, Switzerland
firstname.lastname@epfl.ch

Abstract

We discover alignments of views between interest groups (lobbies) and members of the European Parliament (MEPs) by automatically analyzing their texts. Specifically, we do so by collecting novel datasets of lobbies' position papers and MEPs' speeches, and comparing these texts on the basis of semantic similarity and entailment. In the absence of ground-truth, we perform an indirect validation by comparing the discovered alignments with a dataset, which we curate, of retweet links between MEPs and lobbies, and with the publicly disclosed meetings of MEPs. Our best method performs significantly better than several baselines. Moreover, an aggregate analysis of the discovered alignments, between groups of related lobbies and political groups of MEPs, correspond to the expectations from the ideology of the groups (e.g., groups on the political left are more aligned with humanitarian and environmental organisations). We believe that this work is a step towards enhancing the transparency of the intricate decision-making processes within democratic institutions.

1 Introduction

The transparency of decision-making is of central importance for the legitimacy of democratic institutions such as parliaments. The influence of interest groups (lobbies) on parliamentarians and the potential for a resultant subversion of the power of the electorate to determine policy have led to demands from groups, such as Transparency International (1993), for effective rules and systems to increase transparency. The emergence of several open government initiatives around the world (Swiss Government, 2021; European Union, 2021; Obama White House, 2018) is in part a response to such demands.

The EU Transparency Register (TR) (European Union, 2011) is one such initiative that provides a tool for EU citizens to explore the influence of interest groups in the European Parliament (EP). Any organization that seeks to influence EU policy, with a few notable exceptions, needs to register with the TR before meeting with parliamentarians. The organizations are asked to disclose information such as their address, website, financial information, and goals.

However, the EU TR has several limitations. The disclosure of most of the information is voluntary and there is little oversight. It is difficult to obtain information regarding which members of the EP (MEPs) or laws are targeted (and by which particular lobbies) and to know the lobbies' positions on specific policies.

There have been several studies conducted by the political science community on EU lobbying (Bouwen, 2003; Rasmussen, 2015; Tarrant and Cowen, 2022). However, these studies either focus on a single policy issue or a small set of issues, or they are limited in terms of sample size as they employ less scalable methodologies such as manual examination of position papers and individual interviews. One exception is a study by Ibenskas and Bunea (2021). They analyze the Twitter follower network of a large number of MEPs and lobbies from the TR, with respect to the MEP's nationality and committee memberships and lobbies' self-reported interests in the TR. However, they do not analyze the textual content of MEPs' speeches and amendments and the lobbies' position papers, which would be instrumental for uncovering convergence on specific policy issues beyond the broad interest areas mentioned in the TR.

Therefore, there is a need for comprehensive studies of lobbying with the help of rich publicly available textual resources and by using modern tools developed by the NLP community. In particular, algorithms for text representation (Conneau et al., 2017; Pagliardini et al., 2018) and computing text similarity (Cer et al., 2017) and entailment

*These authors contributed equally to the work.

Proceedings of the 2024 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies (Volume 1: Long Papers), pages 8107–8120
June 16-21, 2024 ©2024 Association for Computational Linguistics

(MacCartney and Manning, 2009; Bowman et al., 2015) are promising for identifying interesting patterns. A major challenge faced by such studies is the lack of ground-truth data for validation. As far as we are aware, there exists no large database of verified MEP-lobby alignments, let alone one annotated for relevant policy positions.

In this work, we automatically discover alignments between a large number of MEPs and lobbies by comparing the text in publicly available documents where they express their views on policy issues. To the best of our knowledge, this has not been done in prior work. We focus on the eighth term of the EP (2014-2019), as it was the last complete term that was not disrupted due to the pandemic. In the absence of ground-truth data, we perform an indirect validation by comparing the discovered alignments to a dataset we curate of retweet links between MEPs and lobbies.

We use the retweet network instead of the follower network studied by Ibenskas and Bunea (2021), because retweets typically occur as a result of the agreement of particular views between the MEP and lobby, in contrast to 'follows' that can result from a general interest in knowing more about a topic or person (Metaxas et al., 2015). Moreover, timestamps for retweets are publicly available, which allows us to collect more relevant data for the eighth term.

Since 2019, it has been mandatory for MEPs in certain key positions (such as reporters of parliamentary committees) to publish their meetings with lobby groups (European Parliament, 2019). We use this data as an additional source of validation, although it only covers the subset of the MEPs from the eighth term who were re-elected in the ninth term.

Finally, our methods are interpretable - we can obtain the specific set of MEP speeches and lobby documents that match for an MEP-lobby pair, thus enabling manual validation of discovered alignments by users. In this paper, to avoid any harm to the reputation of MEPs through showing any alignments that are false positives, we restrict ourselves to an aggregate analysis instead of showing individual MEP-lobby links.

The paper is structured as follows. In Section 2, we describe the datasets that we curate and use. In Section 3, we describe the different methods that we experiment with for discovering links. We evaluate the methods in Section 4 and interpret them in Section 6. We conclude the paper in Section 7.

2 Datasets

We curate several novel datasets for our study. To obtain the policy positions of lobbies, we curate a dataset of position papers (Section 2.1). The views of the MEPs are obtained through a dataset of their plenary speeches (Section 2.2.1) and proposed amendments (Section 2.2.2). For validation, we use a dataset of MEP-lobby retweet links (Section 2.3.1) and meetings (Section 2.3.2).

2.1 Lobbies

Our data collection pipeline for lobbies is given in Figure 1. The versions of the data at different stages of the pipeline are labeled as $D1$, $D2$, and so on. Information on the size of these datasets is given in Table 1. We now describe the steps in the pipeline.

Table 1: Lobby datasets

	$D1$	$D2$	$D3, D4$
Documents	766,437	373,216	48,970
Lobbies	4,230	3,965	2,558

2.1.1 Crawling and Language Identification

We focus on the lobbies that were on the EU TR under the heads of *Trade and Business Associations*, *Trade Unions and Professional Associaions* and *Non-Governmental Organisations*, as of October 2020; this is a total of 5,461 lobbies. Although some other categories like *Companies and Groups* are also influential, we do not include them because they are mostly represented by associations that they are part of and rarely publish position papers of their own.

We obtain the URLs of the lobby websites from the TR and crawl publicly available PDF documents from them to obtain an initial dataset $D1$. We parallelize the crawling by using HTCondor (HTCondor, 2023) on a cluster of 300 nodes with maximum limits of 250 MB of text and 5 hours of crawling per website and are able to crawl all PDFs in nearly 70% of the lobby websites in about four days. Spending several hours per website enables us to keep a sufficient interval between consecutive HTTP requests (similar to that of a human user) so that the functioning of the websites is not adversely affected. We extract and store only the text from the PDF documents to keep storage costs manageable.

To identify the languages in the dataset, we use the Fasttext language identification model (Joulin

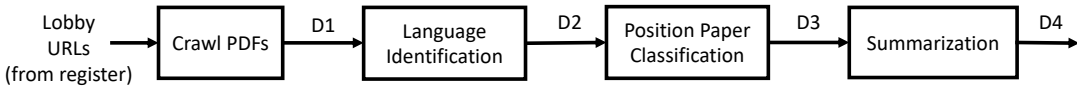

Figure 1: Data collection pipeline for lobbies. $D1$ contains all crawled PDF documents, $D2$ contains all English documents in $D1$, $D3$ contains the documents in $D2$ classified as position papers, and $D4$ contains the summaries of the documents in $D3$.

et al., 2016b,a). Nearly half (48.7%) of all the documents are in English and other languages appear in much smaller percentages. Moreover, most of the lobbies have an English version of their non-English documents. Hence, we keep only the English documents ($D2$) to simplify the rest of the analysis.

2.1.2 Position Paper Classification

A large majority of the PDFs do not contain significant information about lobby policy positions, including documents such as product brochures, user manuals, technical documentation, forms, etc. By manually labeling 200 randomly sampled PDFs[1], we estimate the proportion of PDFs that contain policy positions to be approximately 25%. In order to reduce noise in the data and to enable us to apply methods that are more performant but less scalable, we classify the PDFs into *position papers* and *other documents* and work with those classified as position papers.

We train a weakly supervised logistic regression model that uses TF-IDF features for this task. We use the presence of the word 'position' in the URL as the label. On the manually labeled validation set of 200 PDFs, the model achieves a precision of 95% and a recall of 39% in identifying position papers. The most predictive words include *position*, *should*, *strongly*, etc. and are indeed likely to be present in texts articulating positions. We then apply the classifier on all PDFs in $D2$, and keep those that are classified as position papers to obtain $D3$.

2.1.3 Summarization

Many of the documents are quite long (greater than 1,000 words) and cannot be encoded fully by pre-trained encoders such as SentenceBERT (Reimers and Gurevych, 2019). They also typically contain information, such as technical details, that is not relevant for matching with MEP speeches. Hence, we summarize the documents into three-to-four sentences that capture the main ideas expressed. This also makes the interpretation of matched document-speech pairs easier.

We experiment with various state-of-the-art pre-trained summarization models, namely T5 (Raffel et al., 2020) and BART (Lewis et al., 2020), and Large Language Models (LLMs) including OpenAI's `gpt-3.5-turbo` (the model behind ChatGPT) (OpenAI, 2023) and LMSYS's Vicuna-7B-v1.5 (Zheng et al., 2023) (a LLaMA-2 (Touvron et al., 2023) model fine-tuned on ChatGPT conversations). We manually compare five random summaries generated by each model and find that ChatGPT and Vicuna generate coherent summaries that capture the most salient points expressed in the document, while T5 and BART omit important information and generate disconnected sentences that are almost the same as those in the original document.

We thus generate the dataset $D4$ that contains the LLM-generated summaries of documents in $D3$. We summarize only the documents in $D3$, despite the low recall of position paper classification due to the cost constraints of using LLMs.

2.1.4 Lobby Clustering

Individual lobbies are so numerous and specialized that it is difficult to see interpretable patterns, even after a successful MEP-Lobby matching. We, therefore, cluster the lobbies into relatively homogenous groups by using the description of their goals in the EU TR. We first convert these descriptions to short phrases (3-4 words) by using ChatGPT and cluster the phrases by using K-Means[2] after embedding them using SentenceBERT. The clusters are mostly straightforward to interpret, although some of them contain a few unrelated lobbies. Some clusters, related particularly to energy, include both renewable energy companies and fossil-fuel companies. This is probably because some of the fossil-fuel com-

[1]Two of the authors independently performed the labeling. Cohen's κ was 0.4, indicating fair to moderate agreement. Disagreements were subsequently resolved by discussion.

[2]We use $K = 100$ as it gives mostly coherent clusters with minimal duplicates.

panies are undergoing a renewables transition and emphasize this in their goal statements in the TR.

The list of the top three lobby clusters with the most position papers is given in Table 2 with a couple of examples of lobbies that are in each cluster. A complete list of lobby clusters that we refer to in this paper, with example lobbies, is given in Appendix A.

Table 2: Top three lobby clusters by number of position papers. All three have about 1,400 papers each.

Lobby Cluster	Example Lobbies
Manufacturing	orgalim.eu glassforeurope.com
Renewable Energy	solarpowereurope.org windeurope.org
Business	enterprisealliance.eu smeeurope.eu

2.2 MEPs

Data on MEPs' policy positions are obtained from two sources: their speeches in the plenary sessions of the EP, and the law amendments that they propose within parliamentary committees. We describe each of them in the following sections.

2.2.1 Speeches

We scrape all plenary speeches of the eighth term from the EP website (51,432 in total), spoken by 849 MEPs (and a few non-members). The speeches are organized into 1,471 debates with titles; each debate is about a specific law or policy issue. For the speeches made by MEPs, we scrape the official EP ID of the MEP, which we use to query the Parltrack database (Parltrack, 2023) to obtain additional information about the MEP, such as their name, nationality, party, etc.

Similar to the case for lobbies, it is easier to find patterns if we analyze the links to lobbies for *groups* of MEPs rather than individuals. MEPs are naturally grouped according to their ideology into nine political groups. The European People's Party (EPP, center-right) and the Socialists and Democrats (S&D, center-left) are the two largest groups.

To quantify the ideological position of the groups, we use data from the Chapel Hill Expert Survey (CHES) (Jolly et al., 2022), where political scientists have scored every party on a numerical ideological scale ranging from zero (extreme left) to ten (extreme right). In addition to the general left-right ideology (which are referred to simply as 'Ideology'), the survey also contains scores for more fine-grained aspects of ideology such as views on how to manage the *economy* (state control vs. free market), views on *social* issues (libertarian vs. traditional/authoritarian), and views on *EU* integration (anti-EU vs. pro-EU)[3]. We aggregate the party-level data from CHES to get the scores for the political groups[4]. The positions of the nine EP groups are given in Table 6 (Appendix A).

The speeches for the eighth term are available only in the original language of the speaker, unlike in earlier terms where the EP provided translated versions in all official EU languages, including English. Hence, we automatically translate all the non-English speeches to English by using the open-source OPUS-MT models (Tiedemann and Thottingal, 2020) provided in the EasyNMT package (Reimers, 2022). Apart from the dataset of full speeches, we also generate a dataset of the speech summaries by using LLMs as in Section 2.1.3. We use the summarized speeches when matching with the summaries of the lobbies' position papers ($D4$), and the full speeches when matching with the full lobby documents ($D2$ and $D3$).

2.2.2 Amendments

We use the law amendments dataset released by Kristof et al. (2021), which contains 104,996 amendments proposed by MEPs in the eighth term on 347 laws identified by their titles. We input the old and new versions of the law articles changed by the amendment to an LLM (either ChatGPT or Vicuna), along with the law title, and ask it to generate a possible sentence for the position paper of a lobby that would like to get this amendment accepted. We expect to be able to match the sentence to the lobby summaries ($D4$) generated in Section 2.1.3.

We find that the LLMs generate a concise summary, correctly interpreting short but significant changes to the law, such as the change from *shall* to *should* being a change from a mandatory requirement to a recommendation. However when there is insufficient context, such as in the case of entire articles being deleted or new ones being added, the

[3]The CHES codebook refers to these scores as LRGEN, LRECON, GALTAN, and EU_POSITION

[4]We take the weighted average of party scores with weights being the size of each party in the group.

model tends to generate text creatively. Therefore, we restrict this procedure to generate summaries exclusively for the 88,853 amendments that only modify *existing* articles (without deleting them entirely).

2.3 Validation Datasets

For validating the discovered alignments, we curate a dataset of retweet links and a dataset of MEP-lobby meetings. We describe them in the following sections.

2.3.1 MEP-Lobby Retweet Links

We obtain the Twitter handles of MEPs from multiple sources including official profile pages on the EP website, the Parltrack database, other third-party databases, and manual search. We were able to obtain handles for 666 MEPs. We collect handles of the lobbies with position papers by scraping their homepages for 'Follow us on Twitter' links, and obtain 1,676 handles. We see that, indeed, most of the MEPs and lobbies have a presence on Twitter.

Once we have the handles, we use the Full Archive Search endpoint of the Twitter API[5] (Twitter, 2023) to retrieve the content and metadata of all their public tweets during the period of the eighth term. We then identify the tweets of an MEP (resp. lobby) that are 'pure' retweets (without any added original content hence less likely to indicate disagreement) and check if the referenced tweet is from a lobby (resp. MEP). We consider that there is an (undirected) retweet link between an MEP-lobby pair if either the MEP or the lobby has retweeted the other at least once, which leaves us with 8,754 links.

2.3.2 MEP-Lobby Meeting Links

Data on meetings between MEPs and lobbies since the beginning of the ninth EP term (2019-2024) are available from the Integrity Watch Data Hub (Integrity Watch, 2023). Integrity Watch monitors and collects meeting information from the EP website. Every meeting includes an MEP identified by the EP ID and a list of lobby names or acronyms. We match the lobby names to our data from the register using fuzzy string matching, thus enabling us to establish 1,365 links between 125 MEPs from the eighth term (who were re-elected in the 9th term) and 565 lobbies.

[5]The Twitter API changed recently and no longer provides this level of access for free.

3 Methods

Here, we describe the framework and methods we use to discover alignments between MEPs and lobbies. Let $\mathcal{M}$ denote a set of MEPs and $\mathcal{L}$ denote a set of lobbies. We assume that an MEP $m \in \mathcal{M}$ and a lobby $l \in \mathcal{L}$ are aligned on some issue with some probability $P(m, l)$. One possible approach to discovering alignments is to estimate this probability directly. However, this is difficult as we do not have a ground-truth dataset of alignments on which to train a probabilistic model. Without such data, we can make only *relative* assessments of $P(m, l)$, based on information about the similarity of views between m and l. Thus, we can say that $P(m_1, l_1) > P(m_2, l_2)$ if the similarity of views for the pair (m_1, l_1) is higher than that for the pair (m_2, l_2).

Hence, we adopt the following framework. Given an MEP $m \in \mathcal{M}$, and a lobby $l \in \mathcal{L}$, the goal of our methods is to compute an alignment score $A(m, l) \in \mathbb{R}$ such that

$$\begin{aligned} &A(m_1, l_1) > A(m_2, l_2) \\ &\quad \iff P(m_1, l_1) > P(m_2, l_2) \\ &\quad \forall m_1, m_2 \in \mathcal{M}, \ \ \forall l_1, l_2 \in \mathcal{L}. \end{aligned} \tag{1}$$

The methods differ in how $A(m, l)$ is computed. For methods using texts, we use $\mathcal{S}_m$ to refer to the documents produced by m and $\mathcal{D}_l$ for the documents produced by l.

3.1 Baselines

We first describe the baselines. The goal of comparing our models to these baselines is to check if the content of the texts provides non-trivial information about MEP-lobby alignments.

3.1.1 Random

This is the simplest baseline where we have $A(m, l) \sim \text{Uniform}(0, 1)$.

3.1.2 Prolificacy (Pr)

This baseline is based on the intuition that the MEPs and lobbies that are more prolific and generate more texts are more likely to be aligned on some issue. Hence, for this baseline, we define $A(m, l) = |\mathcal{S}_m| \times |\mathcal{D}_l|$.

3.1.3 Nationality (Nat)

Prior work suggests that there is a strong tendency for MEPs to be aligned with lobbies from the same EU member state (Ibenskas and Bunea, 2021). We

therefore include a baseline where $A(m,l) = 1$ if m and l are from the same member state and $A(m,l) = 0$ otherwise.

3.2 Text-Based Methods

Here, we describe our methods that use the content of the texts in $\mathcal{S}_m$ and $\mathcal{D}_l$.

3.2.1 Text Classification (Class)

We train a fastText (supervised) classifier (Joulin et al., 2017) to predict whether a given text was generated by a particular lobby. We use the sentences in the lobby dataset $D2$, creating a 80%-20% train-test data split. We train the classifier for 10 epochs with a one-versus-all loss, a learning rate of 0.2, and word n-grams of length up to 2: such hyperparameters were selected as the best performing in a grid search over learning rate and loss. Independent linear classifiers are trained for each lobby, but they share the same embedding layer, which enables the model to scale to a large number of classes while having limited data for each class. The linear structure allows interpretability; the top predictive words for some lobbies are given in Table 8 (Appendix B). These clearly reflect the areas of work of the lobbies.

Once the classifier is trained, we compute

$$A(m,l) = \frac{1}{|\mathcal{S}_m|} \sum_{s \in \mathcal{S}_m} P(l|s), \tag{2}$$

where $P(l|s)$ is the probability that lobby l generated the text s, according to the trained classifier.

3.2.2 Semantic Similarity (SS)

In this method, we first convert the texts in $\mathcal{S}_m$ and $\mathcal{D}_l$ to vector representations that capture their meaning. The cosine similarity between these vectors gives a measure of semantic similarity between the texts.

We use the pre-trained `all-MiniLM-L6-v2` model from SentenceBERT to obtain 384-dimensional vector representations for the texts. We then compute

$$A(m,l) = \max_{s \in \mathcal{S}_m, d \in \mathcal{D}_l} \mathbf{v_s}^T \mathbf{v_d}, \tag{3}$$

where $\mathbf{v_s}$ and $\mathbf{v_d}$ are the vector representations of texts s and d respectively, normalized to unit norm.

If the whole text fits within the maximum sequence length for the SentenceBERT model (256 tokens), it is encoded into a vector directly. This is the case for summary texts. If the text is too large to fit, we separate it into individual sentences and take the normalized sum of the sentence encodings.

The intuition behind using max (rather than mean, for instance) in Equation 3 is as follows. MEPs typically represent a diverse range of interests. Hence, if there is an alignment between the MEP and lobby, while a few speeches of the MEP may be highly similar to the documents of a particular lobby, many of the speeches would be dissimilar. That would result in the mean of the pairwise similarities being quite low even though there is alignment, while the max would be unaffected.

3.2.3 Entailment (Ent)

One issue with SS is that there exist cases where two texts contradict each other, but they still have high semantic similarity based on their vector representations. This can cause false positives in the discovered links. For instance, an MEP's speech about increasing a specific tax could be matched with a lobby's position paper advocating for a reduction of the same tax. One reason for this is that the fixed-length vector representation might not always have enough information to process negations.

In order to reduce such cases, we use a cross encoder model pre-trained on natural language inference (NLI) data, including SNLI and MultiNLI. We use, in particular, the `cross-encoder/nli-deberta-v3-base` model from SentenceBERT. Given a pair of texts (s,d), this model is trained to output whether s contradicts d, s entails d, or neither.

As texts from an MEP speech and lobby document are usually less similar than a pair of premise and hypothesis from NLI, the model assigns the highest probability to *neither* for most of the text pairs. However, we can identify probable contradictions, especially for highly similar pairs, by checking if the probability it assigns to *contradiction* ($P(con)$) is greater than that for *entailment* ($P(ent)$).

We then compute

$$A(m,l) = \max_{s \in \mathcal{S}_m, d \in \mathcal{D}_l} \mathbf{v_s}^T \mathbf{v_d}, \quad \text{s.t } p_{ent}(s,d) > p_{con}(s,d). \tag{4}$$

4 Evaluation

We evaluate our methods on both the retweet links and meetings datasets. We use the area under the receiver operating characteristic (ROC) curve (AUC),

as our metric because it is independent of the choice of a threshold for $A(m, l)$. We are mostly interested in the low false positive rate (FPR) regime of the ROC as we expect the MEP-lobby alignment network to be sparse. Hence, we compute the partial AUC (pAUC) for the FPR < 0.05 region.

The scores of all methods are given in Table 3 and the partial ROC curves for retweets and meetings are in Figure 2. The full ROC curves are in Figure 5 (Appendix C). We denote in parentheses the documents used for the sets $\mathcal{D}_l$ (D2:all English documents, D3:Position Papers, D4:Summaries) and $\mathcal{S}_m$ (Sp.:Speeches/Speech Summaries, Amd: Amendments). Methods using Vicuna-generated summaries are indicated by a (V) at the end of the model name; the other methods using summaries use ChatGPT-generated ones. For a fair comparison between methods, the evaluations include only the set of lobbies that have position papers.

Table 3: Evaluation results of baselines (top) and our methods (bottom). The pAUC is computed on the region where FPR ≤ 0.05.

Method	Retweets	Meetings
Random	0.025	0.025
Pr(D2,Sp.)	0.052	0.048
Pr(D3,Sp.)	0.092	0.111
Pr(D2,Amd)	0.059	0.070
Pr(D3,Amd)	0.106	0.150
Nat	0.076	0.107
Class(Sp.)	0.079	0.070
SS(D2,Sp.)	0.189	0.147
SS(D3,Sp.)	0.185	0.156
SS(D4,Sp.) (V)	0.184	0.170
SS(D4,Amd) (V)	0.153	0.198
SS(D4,Sp.)	0.196	0.176
SS(D4,Amd)	0.169	**0.208**
Ent(D4,Sp.)	**0.198**	0.175

We clearly see that the text models that use semantic similarity and entailment outperform all baselines and the text classification model on both datasets. In fact, the classification model is worse than some baselines. We think this could be because it is unable to capture all aspects of a lobby's position in the fixed-length classifier weights, while the similarity-based methods do not have this constraint.

Using only position papers ($D3$) does not seem to have a significant negative effect on performance in the low FPR region compared to using all documents ($D2$). In fact, for the Prolificacy baselines it

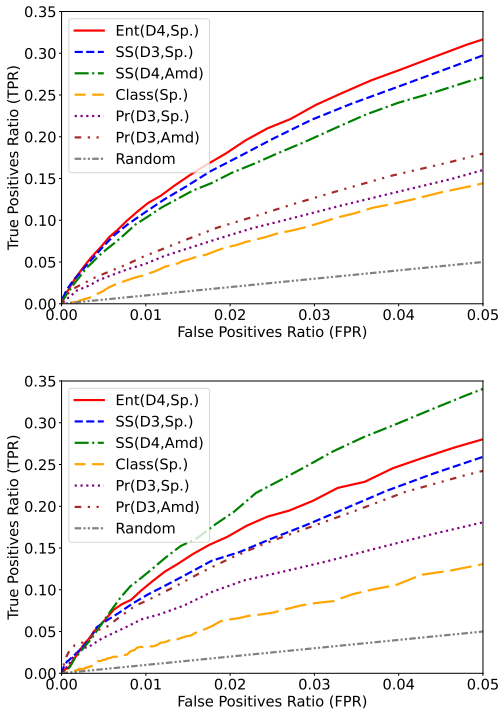

Figure 2: ROC curves (FPR$\leq$0.05 region) for the Retweet dataset (Top) and Meetings dataset (Bottom)

results in a significant *increase* in performance.

Summarization seems to help in general for both datasets. ChatGPT summaries perform better than Vicuna summaries, with the gap being particularly large for Retweets. We, therefore, use ChatGPT summaries for our subsequent analysis. It is worth noting however that Vicuna, being free and open-source, is a promising and cheap alternative to ChatGPT.

The entailment method using speeches is the best method for retweet data (our primary validation data) and also performs reasonably well for meetings. Therefore, we use this method for interpretation. Although the improvement over semantic similarity in terms of pAUC is small, entailment significantly improves interpretability by reducing false positive matches in the document pairs, as we show in Appendix D.

5 Discussion on Metrics

The two metrics we use, namely the AUC on links present in retweet and meetings data, are only proxy metrics. The true metric we are interested in is the AUC on ground-truth alignments. Unfortunately, this ground truth is not available, necessitating the use of proxy metrics.

As seen in Table 3, the best method is different

for each of the two proxy metrics. The model using speeches performs the best for the retweets, whereas the model using amendments performs the best for meetings[6]. We hypothesize that this could be due to retweets reflecting more publicly visible alignments as compared to meetings, just as speeches are more publicly visible as compared to amendments.

The proxy metrics have several limitations. The presence of a meeting does not necessarily indicate an alignment of views as MEPs could also meet lobbies who are opposed to their views on some issue in order to have a better understanding of their position. Conversely, the absence of a meeting or retweet link does not necessarily mean that the views of an MEP and lobby do not align. For instance, many MEPs do not disclose meetings, or are not very active on Twitter.

However, even though imperfect, we expect there to be significant correlation between the true metric and these proxy metrics. In the absence of a more reliable and accurate ground truth dataset of alignments, this indirect validation is arguably the best that we could perform. The fact that our methods using semantic similarity and entailment significantly outperform the baselines in this indirect validation is encouraging, and suggests that the texts provide non-trivial information regarding MEP-lobby alignments.

6 Interpretation

We now interpret the alignments discovered using the entailment method to see if we can find interesting patterns. To obtain the discovered alignments, we set the threshold on $A(m, l)$ to 0.7, which gives an FPR of 5% and TPR of 32.5% on the Retweets data. We also manually check a small sample of matched texts and verify that the threshold indeed gives reasonable matches with only a few false positives.

We look at the lobbies' level of focus toward different political groups and ideologies. We also give some examples of matched texts that show the method's interpretability in Appendix D.

[6]The entailment method is computationally expensive to run because of the cross encoder. Therefore we run it only once for the best combination of data for retweets (ChatGPT-generated summaries of speeches and lobby documents). Nevertheless, we expect Ent(D4,Amd) to have a similar or slightly better performance than SS(D4,Amd).

6.1 Lobbies and Political Groups

To evaluate the level of focus for a lobby l towards a particular political group p, we calculate the *lobby focus score*

$$f(l, p) = \frac{n(l, p)}{m_p}, \tag{5}$$

where $n(l, p)$ is number of discovered links between l and MEPs in p, and m_p is the number of MEPs in p. To have comparable scores independent of the size of the lobby, we further normalize them as $\hat{f}(l, p) = \frac{f(l,p)}{\max_{p \in \mathcal{P}} f(l,p)}$ where $\mathcal{P}$ is the set of all 9 political groups. We analyze at the level of lobby clusters by averaging $\hat{f}(l, p)$ for all the lobbies l in a particular cluster.

A lobby focus heatmap for selected lobby clusters is given in Figure 3. The political groups are ordered in terms of ideology from left to right. We see that lobbies associated with social causes and the environment focus on left-leaning groups, whereas agriculture, ICT, and pharmaceutical lobbies focus more on right-leaning groups.

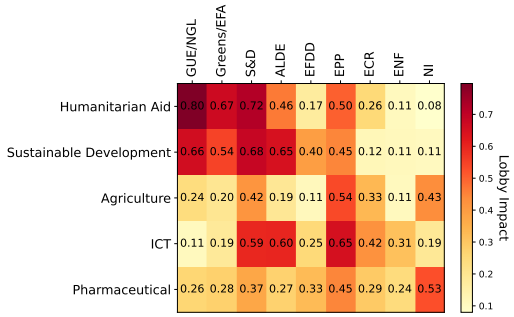

Figure 3: Lobby focus heatmap. Political groups are ordered by ideology from left to right.

We also show, in Table 4, the left-most and right-most lobby clusters, in terms of the weighted average ideology score of the political groups and with the lobby focus score as the weights. Again, we see that the social and environmental lobbies are aligned to the left, whereas technology, agriculture, and chemical lobbies are aligned to the right.

A more detailed analysis of the lobby focus space is given in Appendix A.1.

7 Conclusion

In this paper, we presented an NLP-based approach for discovering interpretable alignments between MEPs and lobbies, and we collected novel datasets of position papers, speeches, amendments, tweets,

Table 4: Top and bottom lobby clusters by ideology score. The numbers in parentheses correspond to the numbers in Figure 4.

Left-Most Lobby Clusters
Social Economic Interests (1)
Humanitarian Aid Groups (2)
Sustainable Development Groups (3)
HIV/AIDS advocacy and support (4)
Road safety and transportation advocacy (5)
Right-Most Lobby Clusters
Technology advocacy groups (6)
Agricultural interest groups (7)
Digital and ICT interest groups (8)
Pharmaceutical and Chemical Advocacy (9)
Miscellaneous Technology and Education (10)

and meetings in the process. We discovered alignments that were validated indirectly by using tweets and meetings. An aggregate qualitative analysis of discovered alignments follows expected lines of ideology and the discovered text matches are interpretable. We believe our work will help political scientists, journalists, and transparency activists to have a more efficient and larger-scale investigation of the complex links between interest groups and elected representatives.

8 Limitations and Ethical Considerations

Data Limitations The Transparency Register is voluntary for several categories of lobby groups, including public authorities of third countries. We could not also include individual companies that are not part of associations, as position papers are difficult to obtain for them. Note, however, that although this limits the coverage of our analysis to some extent, it does not affect the conclusions for the organizations we have studied.

Methodology Limitations We considered only English-language lobby documents. There could be some loss of information in the automatic translation of speeches. We could summarise only a limited number of lobby documents due to the cost constraints of using ChatGPT (monetary cost) and Vicuna (computational cost). With a larger computational budget, larger LLMs such as Vicuna-13B could be tried which could give better performance.

Release of Data All data is collected from publically available sources. We release data[7] to enable reproducibility while respecting copyright. The speeches of the MEPs are made publically available by the EP, and their use and reproduction are authorized. For lobby documents, we do not release copies of the original documents. We release only the GPT-generated summaries and the URLs of the original documents. To mitigate link rot, we also release, where possible, links to the archived versions of the documents on the Internet Archive. We ensure that the summaries of position papers that we release do not contain any personal data. Twitter data is collected through their official API and, following their terms of service, we release only the tweet IDs and not the content or metadata of the tweets.

Possible negative consequences As mentioned in the Introduction, our discovered alignments only indicate a potential convergence of views between MEPs and lobbies on the issues referenced by the matched texts. Interpreting them as influence without performing additional investigations could cause harm to MEPs' reputations. In this paper, we only discussed the results of aggregate analyses to avoid such harm. Another possible negative outcome of this work is that it could provide hints to some lobby organizations (whose objectives may be against that of the wider society) regarding which political groups they should focus their efforts on. While this is true, we believe it is important to have transparency regarding this aspect so that the public can be aware of these interactions and be alert to the effects of such influence.

Acknowledgments

We thank Mahmoud Sellami for helping scrape the MEP speeches. We thank Pratyush Gupta for performing the automatic translation of the speeches and for his preliminary work on analyzing the lobby documents. We also thank Bayazit Deniz, Bhargav Srinivas, Charlie Castes, Mohammed Allouch, Benedek Harsanyi, and Kamil Czerniak for their initial work using Twitter data. Finally, we thank Holly Cogliati-Bauereis and the anonymous reviewers for careful proof-reading and constructive feedback.

A Lobby Clusters and Political Groups

All the lobby clusters referred to in this paper and some example lobbies from each are given in Table 5.

The positions of the nine political groups are given in Table 6.

A.1 Analyzing the lobby focus space

We construct *focus vectors* for the lobbies

$$\mathbf{f_l} = \left[\hat{f}(l,p) \;\; \forall p \in \mathcal{P}\right], \tag{6}$$

and obtain the focus vectors for lobby clusters by averaging $\mathbf{f_l}$ for the lobbies l in a cluster. To study how the lobby clusters are arranged in this space, we project them using Principal Component Analysis (PCA).

To interpret each principal component, we compute its Spearman correlation, with the four different ideology scores from the CHES dataset. Only the first three principal components have statistically significant correlations (p-value below 0.0001). The results for these are given in Table 7.

We see that PC 3 and PC 2 have strong correlations with general left-right ideology and the economic aspect of ideology respectively. PC 3 also has a strong correlation with the social aspect of ideology.

To visualize and better understand the lobby clusters, in terms of these ideological dimensions, we

Table 5: Lobby clusters we refer to in this work and some representative lobbies.

Table 6: Political groups and ideology scores, sorted by general left-right ideology.

Table 7: Spearman correlation of principal components with ideology scores. The values in bold have a p-value below 0.0001. The highest absolute values in each row are marked by asterisk(*).

	Ideo	Econ	Soc	EU
PC 1	-0.18	**-0.41**	-0.11	**-0.47***
PC 2	-0.15	**-0.67***	0.02	**-0.47**
PC 3	**0.92***	**0.51**	**0.91**	**-0.44**

project them onto PC 2 and PC 3 and obtain the plot in Figure 4.

We annotate the dots corresponding to the clusters mentioned in Table 4. In addition to the general left-right placement of these clusters that we already discussed, we also observe their positions with regard to the management of the economy being reflected in the PC 2 coordinates. In particular, the agriculture lobby (number 7) appears to be in favor of more state control (they are known to be in favor of state subsidies (Bednáriková and Jílková, 2012)), whereas the technology lobbies (numbers 6 and 8) appear to advocate for more freedom of the market.

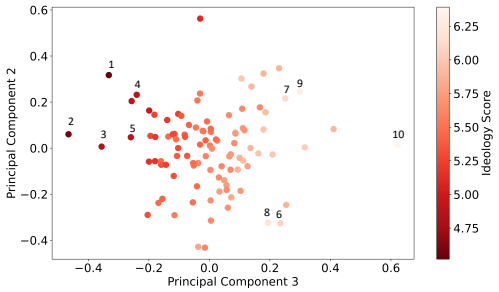

Figure 4: Lobby clusters projected on principal components. The color of the dot corresponds to the general left-right ideology score. The dots annotated with numbers correspond to the clusters in Table 4.

B Classification Model

The top predictive terms for prominent lobbies are given in Table 8.

C Full ROC curves

The full ROC curves for retweets and meetings data are in Figure 5.

D Example Matches

We first look at an example pair of a speech summary and position-paper summary that matched

amnesty.eu	executions	detainee	occupants	assurances	reassignment

Table 9: Example matching pair of speech summary s and position paper summary d. Similar portions of the text are highlighted in bold. $\mathbf{v_s}^T\mathbf{v_d} = 0.916$, $P_{(s,d)}(ent) > P_{(s,d)}(con)$.

Speech Summary

We fully **support the implementation of the Pan-European Personal Pension Product (PEPP)** . . . We urge Member States to **grant PEPPs the same tax advantages as similar national products**, . . .

Position Paper Summary

As an interest group operating in the European Parliament, we believe that the **Pan-European Personal Pension Product (PEPP) presents an opportunity** . . . making the PEPP simple and transparent, and **addressing national tax incentives**. Ultimately, making the PEPP a mass-market product remains challenging, and **tax incentives are crucial to achieve this goal.**

(high semantic similarity and $P(ent) > P(con)$) in Table 9. We see clearly that both documents argue in favor of implementing the Pan-European Pension Product (PEPP) and giving it tax advantages at the national level. To demonstrate the advantage of the entailment method, we also show an example pair of a speech summary and position-paper summary that contradict each other (high semantic similarity and $P(con) > P(ent)$) in Table 10. We see that though the speech argues in favor of the EU-US Privacy Shield, the position paper opposes it. The entailment method is able to avoid such false positives.

E ChatGPT prompts

The prompt given to ChatGPT for getting the summary of position papers is as follows: “Consider the following position paper, written by an interest group operating in the European Parliament: «TEXT»

Now write a concise summary (no more than 3-4 sentences) of the document, capturing the most salient ideas and policy arguments. You should impersonate the author, writing the summary as a first-person statement. Summary:”

The prompt given to ChatGPT for getting the summary of speeches is as follows: “Consider the following speech, given by an MEP (Member of the European Parliament) on the topic "«TITLE»":

«TEXT»

Now write a concise summary (no more than 2-3 sentences) of the speech, capturing the most salient ideas and policy arguments, in the voice of an interest group operating in the European Parliament (e.g. use "we" instead of "I"). The summary should NOT be a response to the MEP speech nor

Table 10: Example contradicting pair of speech summary s and position paper summary d. Contradicting portions of the text are highlighted in bold. $\mathbf{v_s}^T\mathbf{v_d} = 0.904$, $P_{(s,d)}(con) > P_{(s,d)}(ent)$.

Speech Summary
We strongly support the importance of transatlantic data transmission for our economy, security, and trade. **The Privacy Shield is a significant step towards achieving much-needed data protection for EU citizens,** ...to avoid legal uncertainty for our companies and SMEs. **It is crucial to have an operational Privacy Shield as soon as possible** for the benefit of our companies, the European economy, and the privacy of EU citizens.
Position Paper Summary
As an interest group operating in the European Parliament, **we have serious concerns about the proposed EU-U.S. Privacy Shield,** which aims to replace the Safe Harbour framework for commercial data flows between the EU and the U.S. **We are urging the European Commission not to adopt the Privacy Shield,** as it does not provide adequate protection ...

cite the MEP in any way, but rather should appear as an original statement from a group lobbying for the policy positions advocated for in the speech. If the speech does not contain policy positions that an interest group might have, simply output "No comments", and nothing else. Summary: ”

The prompt given to ChatGPT for getting the short description of the lobbies is as follows: “The following is the description of goals of an interest group registered with the EU. «Description of goals from the transparency register» Write a phrase less than five words describing their specific area of interest.”

IterCQR: Iterative Conversational Query Reformulation with Retrieval Guidance

Abstract

Conversational search aims to retrieve passages containing essential information to answer queries in a multi-turn conversation. In conversational search, reformulating context-dependent conversational queries into stand-alone forms is imperative to effectively utilize off-the-shelf retrievers. Previous methodologies for conversational query reformulation frequently depend on human-annotated rewrites. However, these manually crafted queries often result in sub-optimal retrieval performance and require high collection costs. To address these challenges, we propose **Iter**ative **C**onversational **Q**uery **R**eformulation **(IterCQR)**, a methodology that conducts query reformulation without relying on human rewrites. IterCQR iteratively trains the conversational query reformulation (CQR) model by directly leveraging information retrieval (IR) signals as a reward. Our IterCQR training guides the CQR model such that generated queries contain necessary information from the previous dialogue context. Our proposed method shows state-of-the-art performance on two widely-used datasets, demonstrating its effectiveness on both sparse and dense retrievers. Moreover, IterCQR exhibits superior performance in challenging settings such as generalization on unseen datasets and low-resource scenarios.*

1 Introduction

In the conversational question answering (CQA) task, questions and answers are exchanged in a multi-turn conversation. As a component of CQA task, conversational search aims to retrieve passages that contain the necessary information to answer the current query within the conversation (Anantha et al., 2021; Adlakha et al., 2021).

Owing to the conversational setting, queries in CQA suffer from a high dependency on the previous conversation context, as shown in Figure 1, introducing challenges such as omissions, ambiguity, and coreference (Mao et al., 2023b; Wang et al., 2023). Therefore, in conversational search, conversational queries cannot be directly used as inputs for off-the-shelf retrievers trained on non-contextual queries.

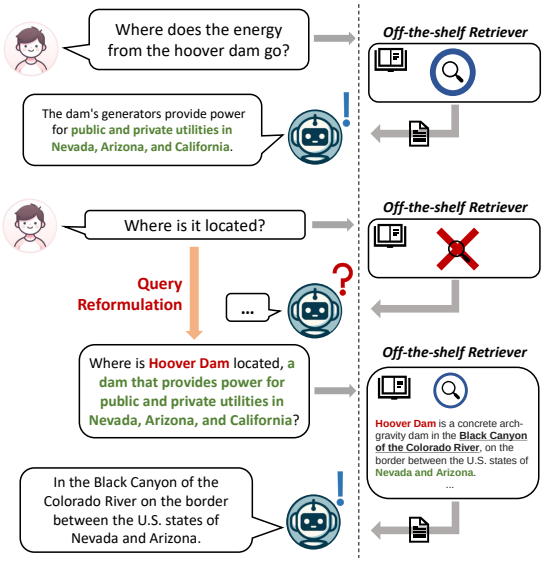

Figure 1: In the CQA task, the user's queries are dependent on the previous dialogue context. CQR task reformulates conversational queries into stand-alone queries, which are then fed into the off-the-shelf retrievers.

One possible strategy for mitigating this challenge is to train retrievers to comprehend long dialogue context (Yu et al., 2021; Kim and Kim, 2022; Lin et al., 2021a). However, this method results in substantial cost in retraining retrievers to handle long inputs. As an alternative method, researchers have explored conversational query reformulation (CQR) that reformulates conversational queries into stand-alone questions, which enables the utility of off-the-shelf retrievers (Mo et al., 2023; Voskarides et al., 2020a).

CQR methods can be categorized into rewriting and expansion. Most prior research trains models for query rewriting using human-annotated

gold labels (Voskarides et al., 2020a; Del Tredici et al., 2022). However, these manually crafted queries often yield sub-optimal performance (Lin et al., 2021b; Wu et al., 2022) in addition to requiring costly and time-consuming collection process. Human labels tend to focus on decontextualizing queries based on human subjective judgment, which does not always align with passage retrieval performance (Wu et al., 2022).

To address human rewrite's sub-optimality, ongoing research explores various expansion methods, such as potential answer expansion (Mo et al., 2023), and classifying previously mentioned entities for expansion (Del Tredici et al., 2022; Voskarides et al., 2020a). However, these expansions are not directly optimized for retrieval signals. Also, the existence of separate expansion and rewriting models requires additional training steps, storage, and two rounds of inference for a single query.

In this paper, we propose an **Iter**ative **C**onversational **Q**uery **R**eformulation (IterCQR) model, that iteratively performs query reformulation without using human rewrites. Since ground truth labels are unavailable, our approach employs an iterative framework to alternate between generating candidate queries and optimizing CQR model with their IR signals as a reward.

For the initialization of IterCQR, we leverage LLMs' ability to create an initial rewritten query dataset for training CQR model. After training IterCQR with the initial dataset, we iteratively train the model on generated query candidates through the Minimum Bayes Risk (MBR) (Smith and Eisner, 2006) training method and Top-1 candidate selection. In the training process, we integrate IR signal by defining the reward value as the cosine similarity between reformulated queries and ground-truth passages. After the iterative training process for IterCQR, we employ the final iteration model to reformulate queries, which are then utilized as inputs for off-the-shelf retrievers.

IterCQR achieves state-of-the-art performance on two widely used CQA datasets, the TopiOCQA (Adlakha et al., 2021) and QReCC (Anantha et al., 2021) datasets. We also show that IterCQR exhibits superior performance in various scenarios, such as generalization on unseen datasets and low-resource settings. Through a quantitative analysis of iterative reformulation, we experimentally demonstrate that IterCQR generates summary expansion from the preceding context as the iteration progresses. This expansion contributes to an improvement in retrieval performance, demonstrating the ability of IterCQR to generate retriever-friendly queries.

The main contributions of this work are as follows:

- We propose IterCQR which iteratively trains a conversational query reformulation model without human label while utilizing off-the-shelf retrievers.
- IterCQR exhibits state-of-the-art performance on both the TopiOCQA and QReCC datsets.
- IterCQR shows outstanding performance in challenging scenarios including generalization on unseen datasets and low-resource settings.

2 Related Works

2.1 Conversational Query Reformulation

CQR focuses on improving conversational search performance by rewriting and expanding user queries in a conversational context. In contrast to other conversational search methods, the reformulated queries in CQR can be directly utilized as input to off-the-shelf retrievers without fine-tuning.

Previous studies have addressed CQR by using human-rewritten queries or query expansion methods (Lin et al., 2020; Voskarides et al., 2020b; Yu et al., 2020). However, human rewrites have been reported to be sub-optimal (Lin et al., 2021b; Wu et al., 2022), and expansion methods require a separate model for term selection (Voskarides et al., 2020b; Kumar and Callan, 2020) or potential answer generation (Mo et al., 2023).

To address these shortcomings, CONQRR (Wu et al., 2022) employs Self-Critical Sequence Training (SCST) (Rennie et al., 2017) to directly optimize the query rewriting model to the retriever. More recently, ConvGQR (Mo et al., 2023) integrates query rewriting and expansion to further enhance retrieval performance; however, it requires two separate models for rewriting and expansion, which hampers efficiency in both the training and inference processes. Furthermore, these approaches require expensive human-rewritten queries. Recent works show that LLMs are capable of reformulating queries (Ma et al., 2023), including conversational queries (Mao et al., 2023b; Wang et al., 2023; Dai et al., 2022). But LLM-generated queries also require further optimization for retrievers similar to human-rewritten queries.

Our work proposes an alternative approach of directly optimizing the CQR model to the retriever,

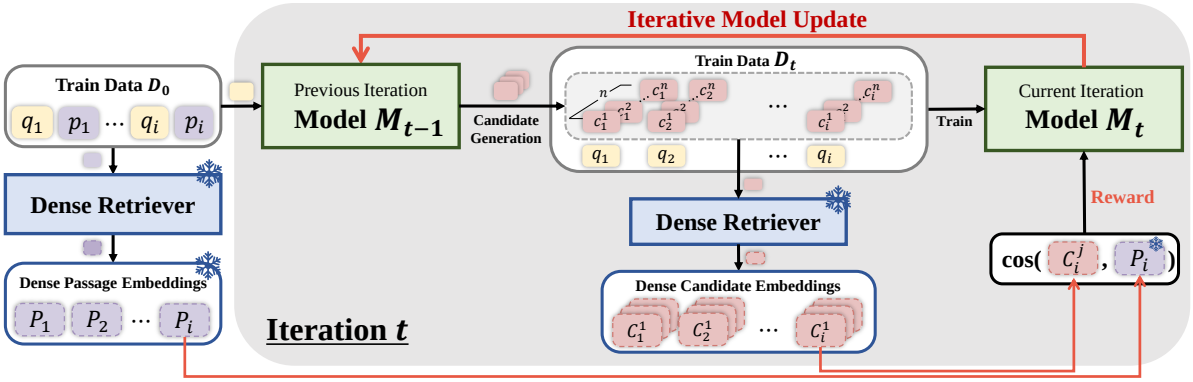

Figure 2: Overview of IterCQR. IterCQR trains on the candidates generated by the previous iteration model. We define reward as the cosine similarity between the frozen dense passage embeddings and dense candidate embeddings.

using only gold passage annotation. Both IterCQR and ConQRR utilize a reward defined by the IR signal. However, ConQRR uses a binary reward function based on the retrieval results of BM25, whereas we employ cosine similarity with the gold passage, which is a real-valued reward. Additionally, ConQRR generates candidates at each time step, which means the target sequences change dynamically throughout the training. On the other hand, IterCQR repetitively learns over a static target sequence, providing a consistent and efficient training signal. We employ Minimum Bayes Risk (MBR) training (Smith and Eisner, 2006; Dasigi et al., 2019) and maximum likelihood training based on the top-1 candidate to effectively learn without human annotated queries.

2.2 Iterative Learning in NLG tasks

The conventional method for training natural language generation (NLG) models uses human oracles, which are costly and time-consuming to collect; moreover, quality control during the collection is challenging. Therefore, research has been focused on learning without human supervision through iteratively enhancing the quality of the training dataset. Many works on weakly supervised QA and semantic parsing revolve around such iterative refinement paradigms, such as iterative search (Dasigi et al., 2019), ambiguous learning (Wu et al., 2023), and hard EM approach (Min et al., 2019). In task-oriented dialogue, Jang et al. (2022) propose to iteratively update the training set with self-generated samples. In this paper, we apply an iterative framework on the CQR task, which iteratively optimizes updated training samples with retrieval guidance.

3 Method

3.1 Problem Definition

Conversational search aims to retrieve relevant passages containing rich information that can answer the current conversational query q within a CQA system. To achieve this goal, conversational queries are reformulated so that we can utilize an off-the-shelf retriever R, which has been trained on non-conversational question-answering data.

We train a query reformulation model M to rewrite and expand the original query q based on the previous history context H to generate a de-contextualized query q^*. Training input for the query reformulation model M on turn k is $\{q_k, H_{k-1}\}$, concatenation of current query and the history context, where history context H_{k-1} is a consecutive sequence of previous queries and answers in reversed order. The reformulated query q_k^* from M is then used as input to the off-the-shelf retriever R, which retrieves a ranked list of the top-k relevant passages.

3.2 IterCQR

IterCQR utilizes the iterative setting to train CQR model without relying on human-rewritten queries. Specifically, our CQR model utilizes IR signals to generate the optimal query for retrieval tasks.

We describe the training process of IterCQR in Algorithm 1. We first initialize IterCQR by training on the initial dataset D_0, which contains queries rewritten by LLM. After initializing the model, we go through the iterative process shown in Figure 2. During iteration t, we first utilize the previous iteration $t-1$ model M_{t-1} to generate n candidate queries for each instance in the training set D. Subsequently, this newly created training dataset,

Algorithm 1: IterCQR

Input: Conversational query for k^{th} turn q_k, Previous history context H_{k-1}
Data: Train Data D without human-rewritten query
Model: CQR Model M_t for iteration t
Result: Reformulated query for k^{th} turn q_k^*, Query candidate for k^{th} turn c_k^j

```
for iteration t = 0..T do
    for q^k, H_{k-1} ∈ D do
        if t = 0 then                          // Initialize D_0
            q_k^* = LLM(q_k, H_{k-1})
            D_0 ← D_0 ∪ q_k^*
        else                                   // Generate D_t
            for j = 0..n do
                c_k^j = M_{t-1}(q_k, H_{k-1})
                D_t ← D_t ∪ c_k^j
            end
        end
    end
    if t = 0 then                              // Train
        L ← L_NLL with target q_k^*
    else if t ≤ τ (exploration factor) then
        L ← L_MBR with n candidates c_k^j
    else
        Select Top-1 Candidate c_i^top
        L ← L_NLL with target c_i^top
    end
    Train M_t with D_t to minimize L
end
```

D_t, becomes the training data for the M_t model. In this iterative process, starting from M_1, candidates generated by the previous iteration model become the targets for training the current iteration model.

IterCQR leverages the cosine similarity between the dense embedding of the candidate query and gold passage to guide the CQR model to generate retriever-friendly queries. This reward prioritizes candidates with the most relevant semantic representation to the gold passage. Furthermore, for enhanced learning efficiency, we define exploration factor τ to balance the exploration and exploitation in the training phase. At the iterations less than or equal to τ, we employ the MBR training algorithm to facilitate exploration, followed by an exploitation phase using Top-1 candidate selection approach.

3.2.1 Data Initialization with LLM

We construct the initial dataset D_0 by utilizing LLM, `gpt-3.5-turbo`, to rewrite the queries.[†] The initial model M_0 is trained on D_0 with negative log-likelihood loss. Although LLMs show great abilities in various tasks, they still exhibit limitations in conversational query reformulation, considering that LLMs are not optimized for retrievers. Hence, starting from Iteration 1, we optimize IterCQR using IR signals.

[†]The prompts used for initializing D_0 is shown the Appendix G.

3.2.2 MBR Training

In the early stages of the training, iterations less than or equal to τ, D_t contains diverse candidates that are suitable for exploration through the application of the Minimum Bayes Risk (MBR) training method. By employing all n candidates, the model can learn not only from the high-probability candidates but also from candidates with lower probability values. The MBR training algorithm seeks to minimize the expected value of a cost function $\mathcal{C}$ between input x and candidate y.

$$\min_{\theta} \sum_{i=1}^{N} \mathbb{E}_{\tilde{p}(y_i|x_i;\theta)} \mathcal{C}(x_i, y_i) \tag{1}$$

Here, we approximate the expectation using the re-normalized probabilities of the candidates obtained through beam search, denoted as $\tilde{p}$. To apply the MBR training algorithm for CQR model, we define a reward function $\mathcal{R}$ instead of the cost function $\mathcal{C}$. The MBR training loss is formulated to minimize the negative MBR term, as expressed in Equation 2:

$$\begin{aligned} \mathcal{L}_{MBR} &= -\sum_{i=1}^{N} \mathbb{E}_{\tilde{p}(c_i|q_i,H_{k-1};\theta)} \mathcal{R}(C_i, P_i) \\ &= -\sum_{i=1}^{N} \sum_{j=1}^{n} \tilde{\mathbb{P}}(c_i^j|q_i, H_{k-1};\theta) \cdot \mathcal{R}(C_i^j, P_i). \end{aligned} \tag{2}$$

To employ the IR signal in the reward value, we set the reward function as the cosine similarity between the dense embedding of candidate query C_i and the dense embedding of the ground-truth passage P_i, as shown in Equation 3. We generate both passage and candidate query embeddings using the frozen encoder of the dense retriever.

$$\mathcal{R}(C_i, P_i) = \cos(C_i, P_i) \tag{3}$$

We observe that most reward values fall within a limited range, which could hamper providing fine-grained learning signals. To address this issue, we apply min-max normalization to scale the reward distribution into a range of 0 to 1.

By utilizing reward signals for all n candidate queries, the MBR approach enables learning across

a diverse set of queries, ultimately resulting in significant improvements in the retrieval performance. After conducting query exploration through MBR iteration, the model proceeds to perform query exploitation by Top-1 candidate selection to effectively utilize the acquired knowledge.

3.2.3 Top-1 Candidate Selection

Following the standardization and enhancement of candidate quality through MBR training, we perform exploitation through Top-1 candidate selection. The exploitation objective aligns with exploration, reformulating conversational queries with retriever guidance. In this step, we select the top-1 candidate c^{top} among n candidates as the target for the training.

In this process, the criteria for Top-1 candidate selection also rely on the cosine similarity between candidate embedding and the dense embedding of the gold passage. This selection criterion ensures alignment with the IR signal. We use the negative log-likelihood loss in the exploitation step to maximize the likelihood of generating top-1 candidate c_i^{top} as Equation 4:

$$\mathcal{L}_{NLL} = -\sum_{i=1}^{N} \log(\mathbb{P}(c_i^{top}|q_i, H_{k-1})). \quad (4)$$

Through this two-step approach, we aim to prevent queries from diverging too far from the semantic space of existing queries compared to training only with the MBR training algorithm for exploration. It also reduces computational complexity by eliminating the step of recalculating probabilities for all n candidates.

3.3 Retriever Models

We test IterCQR on both dense and sparse retrievers. Following the previous works (Mao et al., 2023b, 2022; Mo et al., 2023; Yu et al., 2021), we use BM25 for sparse retriever and ANCE (Xiong et al., 2020) for the dense retriever. We generate dense embedding of gold passages and candidates using the ANCE dense retriever finetuned on MS MARCO (Nguyen et al., 2016). We store these embeddings and re-use them for the entire training and inference steps because the dense retriever is frozen from the beginning. We also use the ANCE model for encoding candidate queries' dense embeddings to calculate reward.

4 Experiments

Dataset We train and evaluate our model on QReCC (Anantha et al., 2021) and TopiOCQA (Adlakha et al., 2021). Both datasets consist of conversational queries and corresponding gold answers paired for each turn. Notably, TopiOCQA includes topic labels determined based on Wikipedia documents.

Evaluation Metrics Our model evaluates retrieval performance on commonly used metrics, such as mean reciprocal rank (MRR), NDCG@3, Recall@10, and Recall@100, following previous works (Wu et al., 2022; Mo et al., 2023; Anantha et al., 2021). We utilized the pytrec_eval tool (Gysel and de Rijke, 2018), as ConvGQR, to calculate these metrics in the subsequent experiments.

Baselines We compare our IterCQR model with seven baseline models: (1) **Raw**: This baseline represents the results obtained when using the original query of the data as input.[‡] (2) **Initial**: The model M_0 trained by the initial dataset D_0 generated by `gpt-3.5-turbo`. (3) **GPT2QR (Transformer++)** (Anantha et al., 2021): GPT-2 (medium) (Radford et al., 2019) based QR model introduced in QReCC as a powerful baseline. (4) **QuReTeC** (Voskarides et al., 2020a): In this approach, query resolution is treated as a binary classification problem and trained to determine whether to include terms from the previous turn in the current query. (5) **T5QR** (Lin et al., 2020): Query reformulation model built upon the T5-base model (Raffel et al., 2020). (6) **ConQRR** (Wu et al., 2022): Leveraging reinforcement learning, ConQRR use retriever signals to generate queries optimized for the retriever. (7) **ConvGQR** (Mo et al., 2023): ConvGQR achieves strong performance through the integration of rewrite and potential answer expansion. The potential answer expansion model is trained using the gold answers from the dataset. (8) **EdiRCS**(Mao et al., 2023a): EdiRCS is a text editing based CQR model that selects tokens to rewrite from the previous dialogue and generates few new tokens.

We directly report the results from ConvGQR paper for the baselines (RAW, GPT2QR, T5QR, and ConvGQR), ConQRR results from the ConQRR paper, and EdiRCS from the EdiRCS paper.

[‡]Raw results for TopiOCQA are the result of the model trained on QReCC since TopiOCQA does not have a human rewrite.

Table 2: IterCQR performance on unseen datasets. ConQRR and ConvGQR are evaluated in an in-domain (ID) setting, while IterCQR is evaluated in an out-of-domain (OOD) setting.

Implementation Details We use T5-base as a backbone of the CQR model, and use ANCE dense retriever (Xiong et al., 2020) for the passage encoder which is kept frozen throughout all training iterations. For all iterations, the number of candidates is set to 10. We set τ as 1 for both the TopiOCQA and QReCC datasets. For the selection of the τ value, refer to 4.4. We use Adam optimizer with a learning rate of 1e-5, a batch size of 8, and a maximum query length of 32. See more details in Appendix A.

4.1 Main Results

We present the results of the IterCQR model trained on TopiOCQA and QReCC, respectively, in Table 1. Although other baseline models were trained or utilized human rewrites for training, IterCQR demonstrates superior performance even without using a human rewrite.

Notably, IterCQR outperforms the second-best performing model, ConvGQR, with a significant improvement in the results of the dense retriever on TopiOCQA. Although the reward function of IterCQR is defined in terms of dense passage embeddings, the model exhibits a significant performance in the sparse retriever. In fact, our model surpasses the retrieval performance of directly using human rewrites.

4.2 Generalization on Unseen Datasets

In this section, we show the IterCQR's generalization ability on unseen datasets. We train IterCQR on TopiOCQA and evaluate on QReCC test set and vice versa. The results of these experiments are presented in Table 2.

IterCQR, which was solely trained on QReCC and tested in an out-of-domain(OOD) setting for the TopiOCQA test set, outperforms the in-

Type	Data	TopiOCQA			
		MRR	NDCG@3	R@10	R@100
Dense	20%	0.204	0.189	35.4	55.6
	50%	0.252	0.242	41.6	58.8
	100%	**0.263**	**0.251**	**42.6**	**62.0**
Sparse	20%	0.144	0.128	25.5	51.7
	50%	0.162	0.145	28.7	52.9
	100%	**0.165**	**0.149**	**29.3**	**54.1**

Table 3: Performance of IterCQR in a low resource scenario. We train IterCQR using 20%, 50%, and 100% of the TopiOCQA train dataset.

domain(ID) model in sparse retrieval results, across all evaluation metrics. QReCC-trained IterCQR outperforms TopiOCQA-trained ConvGQR on the TopiOCQA test set in sparse retrieval performance. Evaluating on the QReCC test set, the TopiOCQA-trained IterCQR shows comparable performance to the ID setting models for the dense passage retriever. Notably, in the case of sparse retrieval performance on the QReCC test set, despite being tested in an OOD setting, TopiOCQA-trained IterCQR outperforms QReCC-trained ConvGQR and ConQRR, both of which follow the ID setting. These experiments underscore IterCQR's strong generalization capabilities across diverse datasets.

4.3 Low-resource Setting

To evaluate the performance of IterCQR in a low-resource scenario, we demonstrate the results of models trained on 20% and 50% of the entire TopiOCQA train set in Table 3. Remarkably, even when utilizing only 50% of the full TopiOCQA training data, the models achieve comparable performance to those trained with the entire dataset. Furthermore, compared to ConvGQR, the second best-performing model in the main results in Table 1, both the 20% and 50% models surpass ConvGQR on sparse retrieval results and perform comparably in dense retrieval results. This observation shows that IterCQR is effective in low-resource scenarios, consistently exhibiting state-of-the-art performance even when trained with a limited amount of training data.

4.4 Ablation Study

In this work, we have presented a two-step training approach; MBR algorithm for exploration, and Top-1 candidate selection for exploitation. We conduct an ablation study on the core components of training IterCQR.

In Table 4, it is illustrated that both exploration and exploitation are required; models trained with either one of the components display noticeable drops across metrics tested with both dense and sparse retrievers. This clearly indicates that IterCQR requires two-step training approach, where the model explores-and-exploits the query space.

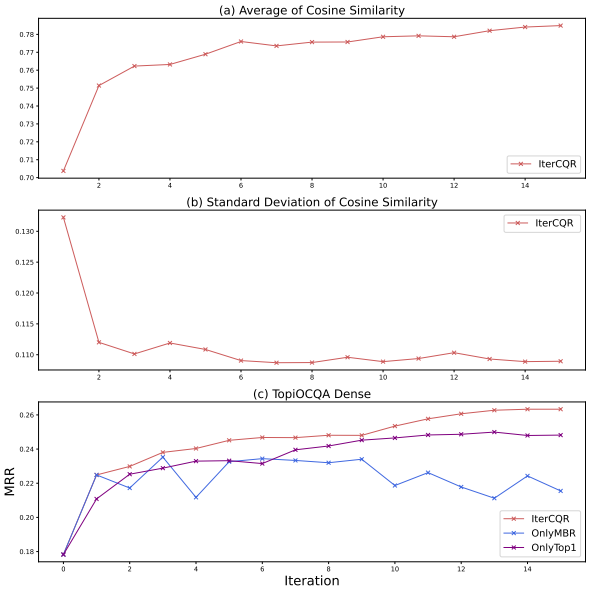

Figure 3: OnlyMBR is the model trained only with the MBR algorithm, and OnlyTop1 is trained only with the Top-1 candidate selection.

Type	Method	TopiOCQA			
		MRR	NDCG@3	R@10	R@100
Dense	IterCQR	**0.263**	**0.251**	**42.6**	**62.0**
	OnlyMBR	0.216	0.204	35.6	53.6
	OnlyTop1	0.248	0.234	41.6	61.1
Sparse	IterCQR	**0.165**	**0.149**	**29.3**	**54.1**
	OnlyMBR	0.111	0.099	20.0	52.9
	OnlyTop1	0.150	0.134	26.1	48.1

Table 4: Retrieval performance of IterCQR, OnlyMBR, and OnlyTop1 on TopiOCQA dataset.

We argue the superiority of the two-step training approach derives from the fact that the MBR training method is particularly effective when a diverse range of candidate qualities exists. After adequate training with MBR, most of the n candidates exhibit high reward values, leading to an unstable training process because of the tendency to penalize candidates with relatively lower reward values, even if the candidates possess good quality. We observe that, in Figure 3 (a), the average cosine similarities of candidates exhibit a noticeable increase after the iteration with MBR training method, whereas the standard deviation decreases significantly as in Figure 3 (b).

Furthermore, in Figure 3 (c) we observe that IterCQR consistently enhances dense retrieval per-

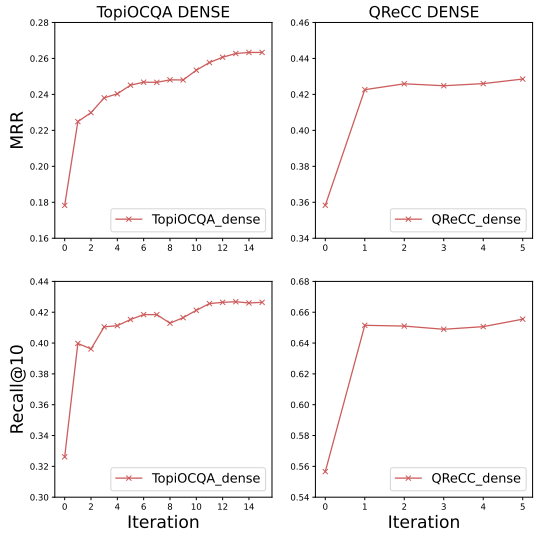

Figure 4: IterCQR dense retrieval performance on TopiOCQA and QReCC datasets for each iteration.

formance, while OnlyMBR, the model trained with only the MBR training algorithm, exhibits unstable learning. Moreover, the OnlyTop1 model, trained solely with Top-1 candidate selection, results in slower learning and a lower performance saturation point than IterCQR. Therefore, it is advisable to initially utilize MBR for exploration, and once the variance in cosine similarity values among candidates has decreased, switch to the exploitation with Top-1 candidate selection to achieve more stable learning and facilitate an efficient query search. Based on these experimental results, we set the τ value to 1, processing MBR training for a single iteration. See Appendix D for generated queries of IterCQR, OnlyMBR, and OnlyTop1.

5 Analysis

We analyze the effect of iterative rewriting on IterCQR by each iteration. For each iteration, we measure the retrieval performance, token length of the rewritten queries, token overlap with the historical context, and token overlap with the gold passage.

5.1 Effect on Retrieval Performance

We show the retrieval performance of the TopiOCQA-trained model for each iteration in Figure 4. In both the TopiOCQA and QReCC datasets, there is a notable improvement in the MRR and Recall@10 metric as the iterations progress. In particular, applying the MBR training algorithm in iteration 1 significantly enhances performance. This outcome suggests that the IterCQR effectively explored the query space, leading to significant

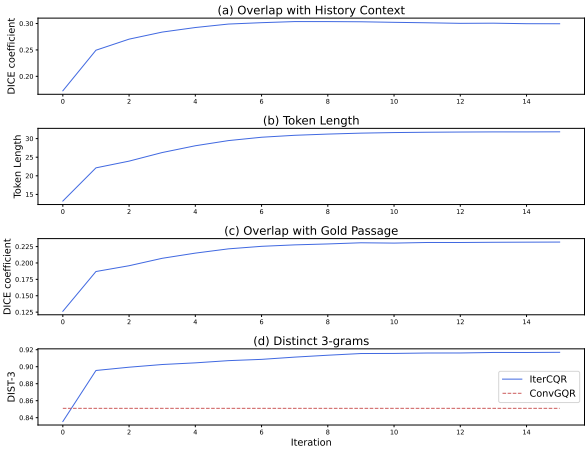

Figure 5: Effect of iterative setting on queries. Overlapping tokens in (a) and (c) is shown by the Sørensen-Dice coefficient, (b) is reported by the average token length of the reformulated queries, and (d) represents the proportion of distinct 3-gram tokens per query. All results are derived from the TopiOCQA test set.

improvements in retrieval performance.

5.2 Effect on Query

We analyze the characteristics of the reformulated queries by IterCQR for each step trained with TopiOCQA and present the results in Figure 5. We utilize the Sørensen-Dice coefficient (Sorensen, 1948; Dice, 1945) in Equation 5 to measure the similarity of two strings.

$$D(A,B) = \frac{2 * |A \cap B|}{|A| + |B|} \quad (5)$$

As the iterations progress, we observe a consistent increase in token overlap with historical context as shown in 5 (a). Ultimately, this trend signifies that the IterCQR model progressively learns to extract information from historical context and integrates it into the current conversational query.

Furthermore, when examining the average query token length for each iteration, as shown in Figure 5 (b), evidently, the token length increases with each iteration. These findings from Figure 5 (a) and (b) suggest that the IterCQR model learns to summarize the previous context.

To validate whether this summarization is helpful for retrieval, we measure the overlapping tokens with the gold passage using the Dice coefficient. As depicted in Figure 5 (c), we consistently observe an increase in the token overlap with the gold passage. We also report the proportion of distinct 3-grams per query for each iteration in Figure 5 (d), demonstrating that the overlap of tokens with the gold

passage is not merely due to simple keyword repetition. We can even observe that IterCQR generates more diverse queries than those from ConvGQR, which utilizes potential answer expansion.

This implies that IterCQR's queries ultimately provide a stronger retrieval signal towards the gold passage, thereby contributing to better retrieval performance, as shown in Figure 4. We provide generated queries by each iteration in Appendix E.

Additionally, in Figure 5, we consistently observe a sharp increase in iteration that employ MBR training method, specifically iteration 1. This sharp increase aligns with the pattern of sharp increases in the retrieval performance in Figure 4. This pattern shows the effectiveness of the MBR training algorithm for exploration.

6 Comparison between MBR and SCST

Type	Method	TopiOCQA			
		MRR	NDCG@3	R@10	R@100
Dense	SCST-20	20.6	19.2	35.6	55.4
	SCST-50	19.9	19.0	34.6	52.6
	MBR	**22.5**	**21.1**	**40.0**	**58.9**
Sparse	SCST-20	13.9	11.2	27.2	51.5
	SCST-50	14.4	12.6	26.9	50.5
	MBR	**16.4**	**14.8**	**30.2**	**54.8**

Table 5: Comparison between SCST and MBR training algorithm. In the case of SCST, sampling was employed during candidate generation while MBR utilized beam search. We report the results considering two variations in top-k sampling: top-k=20 and 50.

In this section, we compare the Self-Critical Sequence Training (SCST) utilized in CONQRR with our MBR training in IterCQR. In the case of the SCST, sampling was employed during candidate generation, and we report two variations in top-k sampling: top-k=20 and top-k=50. The outcomes presented in Table 5 indicate the performance of M_1, trained using the MBR training algorithm and the SCST algorithm, starting from the same initial model M_0. Evidently, MBR is a more effective algorithm for CQR, outperforming both dense and sparse retrievers for all evaluated metrics.

7 Conclusion

In this work, we propose IterCQR, a methodology that iteratively improves CQR model without relying on human rewrites. IterCQR leverages retrieval signals when training CQR model, which provides retriever-friendly guidance for CQR. We demonstrate the effectiveness of IterCQR through state-of-the-art performance on the QReCC and TopiOCQA datasets. In addition, the experimental results indicate that IterCQR learns to summarize previous contextual history, which leads to improved retrieval performance as the iteration progresses. Furthermore, IterCQR exhibits superior performance in challenging settings such as generalization on unseen datasets and low-resource setting.

Limitations

IterCQR employs the LLM, specifically `gpt-3.5-turbo`, to create the rewritten queries in initial dataset D_0 for training CQR model. However, utilizing LLM to generate a rewrite requires inference costs. Furthermore, the IterCQR initial performance relies on the LLM's performance. Still, we show that IterCQR can maintain its retrieval performance using only 50% of the entire dataset, which could improve data efficiency and save LLM inference costs.

Since IterCQR generates n candidates for each training instance, it necessitates larger storage capacity. Additionally, the iterative framework can lead to relatively longer training times, though it does not require additional cost in the inference time.

IterCQR leverages dense embedding information as a reward term. Consequently, as the iterative learning process continues, it becomes increasingly optimized for dense retriever performance. However, the dense reward signal may not consistently enhance retrieval performance for sparse retrievers. Nonetheless, it is worth highlighting that IterCQR outperforms powerful baseline methods in terms of sparse retrieval performance, despite using dense retrieval reward.

Ethical Statement

We conducted experiments utilizing publicly available datasets, all of which are in English. Our CQR model tends to generate summary expansions of the previous dialogue history. These expansion terms are dependent on the contextual history of the dialogue. Therefore, if there is bias or inappropriate statements in the previous history context, the generated queries may also potentially contain such information.

A Implementation Details

In this work, we evaluate IterCQR on widely-used conversational search datasets. TopiOCQA dataset consists of 3,920 conversations with average of 13 question-answer turns for each conversation. For the TopiOCQA dataset, IterCQR is trained for 5 epochs for the initial M_0 model, 2 epochs for MBR, and 5 epochs for the rest of the Top-1 candidate selection. The TopiOCQA-trained model is trained over 15 iterations.

QReCC dataset includes 13.6k conversations and each conversation consists of 6 turns in average. For the QReCC dataset, IterCQR is trained for 10 epochs for the M_0 model, MBR training for 2 epochs, and 5 epochs for Top-1 candidate selection. The final results of the QReCC-trained model are obtained after 5 iterations. For the experiments, we report the result with a single run of IterCQR, because it is costly to generate multiple initial dataset with LLM. All experiments are conducted using a single Nvidia A6000 GPU. Training time differs by the training method: MBR training requires about 5 hours for one epoch, and Top-1 candidate selection requires about 40 minutes. We utilize T5-base as a backbone of the CQR model, which consists of 220M trainable parameters.

B Topic-shift Analysis

CQA differs from standard Question Answering (QA) because of its interactive and conversational nature, introducing the concept of topic-shift during the conversation. This topic-shift phenomenon has been recognized as a challenging aspect for models in various studies (Adlakha et al., 2021; Wu et al., 2022). To assess the capability of IterCQR to handle turns with topic shifts, we conducted an analysis of two distinct criteria associated with topic shifts.

B.1 Topic-shift by Topic Label

We divide the TopiOCQA dataset into two categories: topic-shift and topic-concentrated, based on the assigned topic labels from the dataset. In this categorization, we determine a topic-shifted instance if the topic label in the current turn differs from the topic label from the immediately preceding turn. According to this criterion, the dataset is divided as topic-concentrated for 73% , and topic-shift for 27%.

We evaluate the performance of the TopiOCQA-trained IterCQR with a dense retriever in addressing topic-shift scenarios as shown in Figure 6. We observe a consistent improvement in performance across iterations for both topic-shifted and topic-concentrated scenarios. Comparing our results with the performance of ConvGQR that we have reproduced, clearly, IterCQR outperforms ConvGQR in both topic-concentrated and topic-shifted scenarios, presenting our model's superior performance. ConvGQR performs better with topic-concentrated samples than with topic-shift instances, proving that topic-shifted turns are more difficult for the retriever. However, with the MRR metric, IterCQR performs better on topic-shifted instances than on topic-concentrated cases. In addition, in terms of Recall@10 and Recall@100, IterCQR initially shows a better performance on topic-concentrated cases; however, as the iterations progress, topic-shifted cases surpass that in the topic-concentrated cases. This observation highlights the significant influence of IterCQR's cosine similarity reward based on dense representation, emphasizing performance improvement through iterative reformulation.

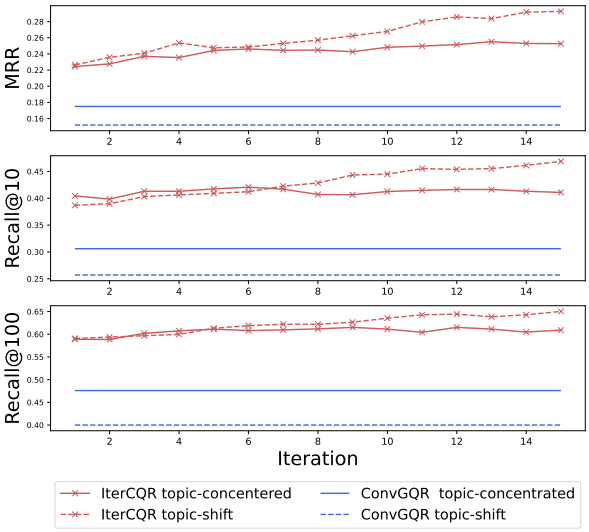

Figure 6: Performance of TopiOCQA-trained IterCQR on both topic-shifted and topic-concentrated examples. The TopiOCQA test set was divided by topic-shifted and topic-concentrated samples based on the topic label from the dataset. We report the retrieval performance of each iteration with metrics MRR, Recall@10, and Recall@100, respectively.

B.2 Topic-shift by Gold Passage ID

For the second criterion of topic-shift, we divide the QReCC test set based on the gold passage IDs within the dataset. In this setting, if the gold passage ID of the current turn does not appear in any preceding turn within the same conversational ses-

Model	IR	Topic-Concentrated			Topic-Shifted		
		MRR	Recall@10	Recall@100	MRR	Recall@10	Recall@100
T5QR	BM25	0.352	54.4	84.0	**0.252**	45.1	79.1
ConQRR(mix)	BM25	0.419	63.1	**91.2**	**0.252**	45.9	**82.1**
ConQRR(RL)	BM25	0.444	66.2	90.3	0.233	44.5	78.4
IterCQR	BM25	**0.544**	**72.4**	89.7	0.249	**49.7**	77.7
Human Rewrite	BM25	0.440	66.7	98.8	0.318	56.7	98.4

Table 6: Performance of QReCC-trained IterCQR on topic-concentrated and topic-shifted samples. In this experiment, topic shift was determined by gold passage ID in the QReCC dataset. For a fair comparison with ConQRR, we only report the performances on sparse retrieval.

Dataset	Method	MRR	NDCG@3	R@10
TopiOCQA	IterCQR	0.263	0.251	42.6
	IterCQR+ expansion	0.277	0.264	44.6
QReCC	IterCQR	0.429	0.402	65.5
	IterCQR+ expansion	0.444	0.417	67.3

Table 7: Performance with potential answer expansion.

sion, a topic-shift is considered to have occurred. According to this criterion, topic-concentrated instances account for 30% of the dataset, whereas topic-shifted samples constitute 70%.

Table 6 provides a comparison of the results of topic-shifted cases determined by gold passage IDs. The scores reported in the ConQRR paper are presented in Table 6. Note that it is hard to fairly compare IterCQR and ConQRR on dense retriever performance because ConQRR used DualEncoder instead of ANCE. Hence, in this experiment, we compare the results on the sparse retriever.

The results indicate that IterCQR outperforms ConQRR across all instances, in both the topic-concentrated and topic-shifted scenarios, particularly in terms of the MRR metric. Especially, MRR scores of IterCQR are notably superior, even surpassing the human rewrite performance. IterCQR demonstrates comparable performance to ConQRR in addressing topic-shifted instances. However, overall, human rewrites outperform all the models, demonstrating exceptional robustness in topic-shift scenarios.

C IterCQR with Other Expansions

In this experiment, we show that the factor of performance improvement in IterCQR is orthogonal to that of potential answer expansion introduced in ConvGQR(Mo et al., 2023). For TopiOCQA and QReCC, we concat the reformulated query generated by the IterCQR with an expansion term trained on gold answers of the dataset. As shown in Table 7, with the potential answer expansion, there is an additional improvement in the retrieval performance, even though IterCQR has already achieved state-of-the-art performance on both datasets.

D Qualitative Analysis on Ablation Study

In section 4.4, we demonstrate that IterCQR exhibits superior performance when compared to solely using MBR training method and Top-1 candidate selection. We provide comparative anlaysis on the queries generated by OnlyMBR and Only-Top1 model with those generated by IterCQR in Table 8. Reformulated queries produced by IterCQR contain essential information that effectively directs to the gold passage, consequently yielding significant improvements in retrieval performance.

E Effect of Iterative Setting on Queries

In section 6, we empirically show that IterCQR learns to generate summary expansion of the preceding history context as the iteration progresses. In Table 9, we provide examples of generated queries at different intermediate iterations of IterCQR, specifically at iterations 0, 1, 5, and 15. Evidently, IterCQR progressively acquires the capacity to distill essential information from the previous dialogue context, resulting in a higher token overlap with the gold passage and retrieval performance.

Furthermore, IterCQR is capable of fixing the reformulation errors that exist in the earlier iteration of the IterCQR model. In Table 1, the retrieval performance of M_0 trained on LLM-generated initial dataset D_0 is far inferior compared to our final IterCQR model. We illustrate instances in Table 10 which IterCQR mitigates the errors in M_0 as iteration progresses.

F Queries Generated by IterCQR

In this section, we present the queries generated by IterCQR on both the TopiOCQA and QReCC dataset in Table 11 and Table 12, respectively. Note that the TopiOCQA dataset does not have a human rewrite; therefore, we demonstrate a reformulated query generated by a model trained on the QReCC dataset's human rewrite.

G Prompt Used for Dataset initilaization

We report the prompt used for generating D_0 using `gpt-3.5-turbo`. We use the instruction: *"This is a part of conversational question answering. Rewrite the current query as a stand-alone question based on the previous conversation so that it could be context-independent."*. We concat three preceding original queries and answers for the dialogue history context and the current query as the input for the LLM.

H Failure Case

We demonstrate the failure case of IterCQR. Training the IterCQR with cosine similarity with the gold passage leads the model to increase the keyword overlap with the gold passage. However, this could also result in the repetition of the keyword in the reformulated query, as shown in Table 13.

Type	Content
Original Query	name the structural parts of this.
IterCQR (0)	What are the structural parts of the Milky Way galaxy?
IterCQR (1)	What are the structural components of the Milky Way galaxy, which contains the Solar System?
IterCQR (5)	What are the structural components of the Milky Way galaxy, which contains ten billion white dwarfs, a billion neutron stars, and a
IterCQR (15)	What are the structural components of the Milky Way, which is the **second-largest galaxy in the Local Group with its stellar disk approximately in diameter**
Gold Passage	'Milky Way Size and mass The Milky Way is the **second-largest galaxy in the Local Group** (after the Andromeda Galaxy), **with its stellar disk approximately in diameter** and, on average, approximately thick. The Milky Way is approximately 890 billion times the mass of the Sun. To compare the relative physical scale of the Milky Way, if the Solar System out to Neptune were the size of a US quarter (), the Milky Way would be approximately the size of the contiguous United States. There is a ring-like filament of stars rippling above and below the relatively flat galactic plane, wrapping around the Milky Way at a diameter of , which may be part of the Milky Way itself.
Original Query	where is it located?
IterCQR (0)	Where is the aforesaid administration located?
IterCQR (1)	Where was the National Oceanic and Atmospheric Administration (NOAA) located in 1970?
IterCQR (5)	Where was the U.S. National Oceanic and Atmospheric Administration (NOA) located during its formation on October 3, 1970?
IterCQR (15)	Where is the U.S. National Oceanic and Atmospheric Administration (NOAA), **an American scientific agency**, formed on October 3, 1970
Gold Passage	National Oceanic and Atmospheric Administration History NOAA traces its history back to multiple **agencies**, some of which were among the oldest in the federal government: The most direct predecessor of NOAA was the Environmental Science Services Administration (ESSA), into which several existing **scientific agencies** such as the United States Coast and Geodetic Survey, the Weather Bureau and the uniformed Corps were absorbed in 1965. NOAA was established within the Department of Commerce via the Reorganization Plan No. 4 and formed on October 3, 1970, after U.S. President Richard Nixon proposed creating a new agency to serve a national need for "better protection of life and property from natural hazards... for a better understanding of the total environment... [and] for exploration and development leading to the intelligent use of our marine resources

Table 9: Queries generated by TopiOCQA-trained IterCQR on intermediate iterations. IterCQR(t) represents the model on iteration t. Red words note rewritten entity and blue words show the summary expansion included only in IterCQR.

Type	Content
Original Query	what was the series about?
IterCQR (0)	What is the plot of **the series "Dark City"**?
IterCQR (1)	What was **the series "Grey's Anatomy"** about primarily about sports programming primarily on weekend afternoons
IterCQR (15)	What is **Grey's Anatomy**, a television series premiered on March 27, 2005 by the American Broadcasting Company (ABC).
Gold Passage	Grey's Anatomy Introduction Grey's Anatomy is an American medical drama television series that premiered on March 27, 2005, on the American Broadcasting Company (ABC) as a mid-season replacement. The fictional series focuses on the lives of surgical interns, residents, and attendings as they develop into seasoned doctors while balancing personal and professional relationships. The title is an allusion to "Gray's Anatomy", a classic human anatomy textbook first published in 1858 in London and written by Henry Gray. Shonda Rhimes developed the pilot and continues to write for the series. She is also one of the executive producers alongside Betsy Beers, Mark Gordon, Krista Vernoff, Rob Corn, Mark Wilding, and Allan Heinberg and recently Ellen Pompeo.

Table 10: IterCQR mitigates initial model's error. IterCQR(t) represents the model on iteration t. Red words show the coreference from the original query, orange words show the initial model M_0 error and blue words show the correct rewritten entity by IterCQR.

TopiOCQA Dataset	
Previous Turns	Query: What is the symbol of flag of ecuador? Answer: It **consists of horizontal bands of yellow (double width), blue and red.** Query: Who designed it? Answer: UNANSWERABLE
Original Query	Does it resemble any other flag?
Human Rewrite	Does flag of ecuador resemble any other flag
LLM Rewrite	Does the flag of Ecuador resemble any other flag?
IterCQR Query	What are some other flags that resemble the flag of Ecuador, which is **consists of horizontal bands of yellow (double width), blue, and red**
Gold Answer	Yes, Colombia and Venezuela
Gold Passage	Flag of Ecuador Introduction The national flag of Ecuador, which **consists of horizontal bands of yellow (double width), blue and red**, was first adopted by law in 1835 and later on 26 September 1860. The design of the current flag was finalized in 1900 with the addition of the coat of arms in the center of the flag. Before using the **yellow, blue and red** tricolor, Ecuador used white and blue flags that contained stars for each province of the country. The design of the flag is very similar to those of **Colombia and Venezuela**, which are also former constituent territories of Gran Colombia.

Table 11: Reformulated Queries by IterCQR on TopiOCQA dataset.The green and red words stand for overlap with previous context and rewritten entity. Underlined words notate the content that contains the gold answer for the given query. Note that human rewrite in the TopiOCQA dataset refers to the output of the model trained on the QReCC dataset's human oracle.

QReCC Dataset

Table 12: Reformulated Queries by IterCQR on QReCC dataset. The green and red words stand for overlap with previous context and rewritten entity. Underlined words notate the content that contains the gold answer for the given query.

Type	Content
Previous Turns	Query: What is the meaning of the song alejandro Answer: The song bids farewell to her lovers.
Original Query	whose song is it?
Gold Answer	Lady Gaga
IterCQR Query	Who released the song "Alejandro" by Alejandro, a song that bids farewell to her lovers and bids far
Gold Passage	Alejandro (song) Introduction "Alejandro" is a song by American singer Lady Gaga. It was released as the third single from her third EP, "The Fame Monster" (2009). Co-written and produced by Gaga and Nadir "RedOne" Khayat, it was inspired by her "Fear of Men Monster". The singer bids farewell to her lovers over mid-tempo synth-pop music with a Europop beat. Contemporary critics predominantly gave "Alejandro" positive reviews and noted that it takes influence from the pop acts ABBA and Ace of Base. The song charted in the United Kingdom and Hungary due to digital sales following the album\'s release. Upon release, "Alejandro" charted again in the United Kingdom as well as in Australia, Canada, New Zealand, Sweden, and the United States while topping the Czech, Finnish, Mexican, Venezuelan, Polish, Russian, Bulgarian, and Romanian charts.

Table 13: Failure case of TopiOCQA-trained IterCQR. In this case, the IterCQR query includes the keyword "Alejandro" repeatedly, deviating from the previous dialogue context.

AceGPT, Localizing Large Language Models in Arabic

Abstract

This paper is devoted to the development of a localized Large Language Model (LLM) specifically for Arabic, a language imbued with unique cultural characteristics inadequately addressed by current mainstream models. Significant concerns emerge when addressing cultural sensitivity and local values. To address this, the paper proposes a comprehensive solution that includes further pre-training with Arabic texts, Supervised Fine-Tuning (SFT) utilizing native Arabic instructions, and GPT-4 responses in Arabic, alongside Reinforcement Learning with AI Feedback (RLAIF) employing a reward model attuned to local culture and values. The goal is to cultivate culturally cognizant and value-aligned Arabic LLMs capable of accommodating the diverse, application-specific needs of Arabic-speaking communities. Comprehensive evaluations reveal that the resulting model, dubbed 'AceGPT', sets the state-of-the-art standard for open Arabic LLMs across various benchmarks. Codes, data, and models are in https://github.com/FreedomIntelligence/AceGPT.

1 Introduction

LLMs like GPT-3.5 Turbo and GPT-4 have been shaping the current landscape of natural language understanding and generation (Bubeck et al., 2023). In contrast to the proprietary nature of GPT-3.5 Turbo and GPT-4, there has been a trend towards developing open-source large language models capable of instruction-following (Taori et al., 2023) and fluent conversations (Chiang et al., 2023), a phenomenon termed as 'Democratization of ChatGPT' (Conover et al., 2023; Touvron et al., 2023). While these models have shown great promise in understanding and producing content in various languages, they might fail to align with local values and cultural norms in non-English environments (Chen et al., 2023a); we call it the 'localization issue'. This issue can lead to significant problems in practical usage scenarios, especially for regions such as the Arabic world where the culture and values diverge significantly from Western norms. We argue that it is not just desirable but necessary to localize large language models and tailor them to a specific cultural environment.

Methodology The core of our approach lies in localizing large language models to the Arabic language using a packaged solution (known as **AceGPT**). Firstly, through incremental pre-training on Arabic data (**localized pre-training**), we ensure that the model has a strong foundation in the Arabic language, including grammar, vocabulary, and cultural context. Next, by fine-tuning Arabic natural questions (**localized instructions**), we enable the model to effectively comprehend and respond to specific instructions that are pertinent to Arab interests. Furthermore, by generating Arabic native responses from GPT-4 (**localized responses**) rather than relying on translations from other languages, we ensure that the model's outputs are natural and fluent within an Arabic context thanks to the powerful GPT-4. Lastly, by employing a reward model based on **localized preference data** that respects local culture and value, we further refine the model to align the responses with the cultural and value norms of Arabic-speaking communities.

Evaluation We evaluate our models in various benchmarks: in the **instruction-following benchmark**, AceGPT achieves state-of-the-art (SOTA) among open-sourced Arabic LLMs in Arabic Vicuna-80 and Arabic AlpacaEval, obtaining 33% and 30% improvement over the state-of-the-art Arabic LLM (Sengupta et al., 2023) [1]. In the NLU

Table 1: Proportion of Arabic Entities in Responses to 20 Sample Arabic Questions

Types of entity	Jais-13B	GPT-3.5 Turbo	GPT-4	AceGPT (ours)
Person	12.00% (3/25)[1]	26.67% (12/45)	39.29% (22/56)	50.00% (31/62)
Location	18.75% (3/16)	27.08% (13/48)	21.62% (16/74)	28.95% (11/38)

[1] 25 person names in Jais-13B responses are identified and 3 are Arabic names.

benchmark, AceGPT achieves the second best on ALUE (Seelawi et al., 2021) in terms of average scores for all tasks. In the **knowledge benchmark**, AceGPT achieves SOTA among open-sourced Arabic LLMs in Arabic knowledge including MMLU and EXAMs. In the **localization benchmark**, AceGPT achieves SOTA among open-source Arabic LLMs in our Arabic Cultural and Value Alignment (ACVA) Dataset.

Contributions The contributions of the paper are three-fold, including: 1) We propose a first-tier Arabic LLM. According to the records on the releasing date, it achieves SOTA performance among open Arabic LLMs in many benchmarks including Arabic Vicuna-80, Arabic AlpacaEval, Arabic MMLU, EXAMs, and ACVA. 2) AceGPT is the first open-source Arabic large language model that encompasses the entire LLM pipeline including pre-training, supervised fine-tuning, and reinforcement learning from AI feedback. 3) We observe and measure the localization issue in Arabic LLMs quantitatively, especially with a new benchmarking dataset, ACVA, for localization testing.

2 Recipe of AceGPT

2.1 Motivation: The Localization Issue

Given the availability of many high-quality instruction datasets in widely spoken languages such as English, existing strategies for non-English LLMs often rely on instructions translated from English. Examples include Chinese-alpaca-GPT4 (Peng et al., 2023), Phoenix (Chen et al., 2023b), and Jais (Sengupta et al., 2023). However, relying on translated data may lead to *localization issues*, potentially undermining the integrity and applicability of the models in native contexts.

To address these localization issues, we formulate 20 questions (see Table.13) to elicit responses with name entities—both personal and locational—to summarize the prevalence of Arabic name entities for preliminary experiments. Quantitative results in Table 1 uncovers a significant deficiency in localization, where Jais-13B and GPT-3.5 Turbo only incorporate 12.00% and 26.67% Arabic names out of all the names in their responses respectively. A specific example is shown in Table 2, we can observe that the Arabic open-source LLM Jais's output shows a conspicuous tilt towards English-centric materials, yielding terms predominantly associated with Christianity, which potentially neglects significant parallels within Arabic literary traditions. By contrast, GPT-3.5 Turbo showcases a more diverse recognition of holy sites from different cultural backgrounds. You can see the details and more examples of case studies in Appendix B.2.

2.2 Methodology of AceGPT

To address localization, we propose a comprehensive solution including three strategies to ensure model's effective understanding and generation of content in Arabic, with cultural awareness and value alignment [2]: **(I) localized pre-training** we further pre-train LLM with Arabic data; **(II) localized instructions** we adopt Arabic natural questions in the wild and their responses are Arabic native responses from GPT-4 instead of translating that from other languages, and **(III) localized responses** we further tame LLM with reinforcement learning using a reward model that respects local culture and values thanks to the **localized preference data**.

The resultant model is termed 'AceGPT'. The model pre-trained on LLaMA2 (Touvron et al., 2023) is named 'AceGPT-base'. To equip it with the conversation, we introduced 'AceGPT-chat' utilizing supervised fine-tuning and reinforcement learning from AI feedback. The training procedure is divided into three stages: pre-training, supervised fine-tuning, and reinforcement learning from AI feedback, introduced in Sec 2.2.1, Sec 2.2.2, and Sec 2.2.3, respectively.

2.2.1 Localized Pre-Training

To adapt the English-focused LLaMA2 (Touvron et al., 2023) model in Arabic, we train further it with a substantial corpus of Arabic text.

Data The dataset comprises Arabic and English sub-datasets. The Arabic is derived from the

[2] See the discussion on the relationship between Arabic culture and Arabic language in Appendix H.

Table 2: Comparison of LLM Responses Highlighting Location, Person, and Regional/Cultural Terms. Arabic-rooted terms in blue; non-Arabic terms in red.

User:

ما هي الكتب المقدسة والقديسين والأماكن المقدسة؟

(What are the holy books, saints, and holy places?)

Jais-13B chat:

الكتاب المقدس هو مجموعة من النصوص الدينية التي تعتبر مقدسة لدى المسيحيين. القديسون هم الأشخاص المقدسون الذين يعتبرون أنهم عاشوا حياة فاضلة بشكل استثنائي ويتم تبجيلهم كقديسين من قبل بعض الأديان. الأماكن المقدسة هي مواقع تعتبر مقدسة أو مكرسة من قبل بعض الأديان ، مثل الكنائس والمعابد والمساجد

(The Bible is a collection of religious texts that are considered sacred by Christians. Saints are holy people who are considered to have lived exceptionally virtuous lives and are venerated as saints by some religions. Holy places are sites considered sacred or consecrated by some religions, such as churches and temples And mosques.)

GPT 3.5 Turbo:

... في الديانات السماوية الثلاث (اليهودية والمسيحية والإسلام)، تعتبر الكتب المقدسة هي: اليهودية: التوراة (العهد القديم)،... المسيحية: الكتاب المقدس المسيحي يتكون من العهد القديم (التوراة) والعهد الجديد ... الإسلام: القرآن الكريم ، وهو الكتاب المقدس للمسلمين ويعتقد أنه وحي من الله للنبي محمد ... بعض الأماكن المقدسة الشهيرة تشمل: الكعبة في مكة المكرمة (الإسلام)، الحائط الغربي في القدس (اليهودية)، الكنيسة القديمة العائدة في بيت لحم (المسيحية)، والمسجد الأقصى في القدس (الإسلام).

(... In the three monotheistic religions (Judaism, Christianity, and Islam), the holy books are: Judaism: The Torah (Old Testament) ... Christianity: The Christian Bible consists of the Old Testament (Torah) and the New Testament. ... Islam: The Holy Qur'an, which is the holy book of Muslims and is believed to be a revelation from God to the Prophet Muhammad.... the Kaaba in Mecca (Islam), the Western Wall in Jerusalem (Judaism) ... Bethlehem (Christianity), and Al-Aqsa Mosque in Jerusalem (Islam).)

open-source Arabic text 2022 [3], and refined from sources like Arabic Wikipedia, CC100, and OSCAR3. The English dataset is obtained from Slim Pajama (Soboleva et al., 2023) to avoid forgetting knowledge of English texts. Given LLaMA2's excellent adaptability to the English dataset, we sample a subset of data from Slim Pajama randomly.

Due to the limit of computing resources, we only train the LLaMA2-7B with 30B data (19.2B tokens in Arabic and 10.8B in English) and LLaMA2-13B with 10B data (6B tokens in Arabic and 4B in English), prioritizing a larger quantity of Arabic data than English data. We utilized the original vocabulary of LLaMA2 which contains all 53 Arabic letters; The reason why we did not expand the vocabulary as existing work is to save training costs.

2.2.2 Localized Supervised Fine-Tuning

To enable the model to follow Arabic user instructions and tackle realistic applications, we fine-tuned AceGPT with localized instructions and localized responses.

Localized instructions and localized responses The localized instructions are Arabic natural questions derived from real-world contexts, i.e. online question-answering platforms Quora [4], which can help models to capture what Arabs care in the wild. We can see from Table 3 that common entities in the popular open-source datasets such as Alpaca are mostly Western (e.g. 'John', 'Apple', and 'New York'), deviating from Arab's actual interest (e.g. 'Mohammed', 'Muslim Brotherhood', and 'Egypt') which can be addressed by Quora. The main idea of localized responses is to leverage the fact that GPT-4 produces culture- and value-relevant responses in the context of question language, which means responses to questions in English are different from those in Arabic. See an example in Table 4, GPT-4 produces culture-dependent responses based on the queried languages. Therefore, when incorporating open-source instruction-tuning data, we ask the GPT-4 to re-generate responses in Arabic (rather than translate) to produce localized responses.

Data In addition to Arabic Quora questions, we also incorporate some open-source instruction-tuning datasets to improve the overall performance. Specifically, we incorporate Alpaca (Taori et al., 2023; Peng et al., 2023) (the most classical instruction-tuning dataset), Evol-Instruct (Xu et al., 2023) (a complex instruction dataset), Code-Alpaca (Chaudhary, 2023) (a code-specific instruction dataset) [5], and ShareGPT [6] (a popular user-GPT dialogue dataset). For these open-source data except ShareGPT, an Arabic version is created by translating the English questions into Arabic and re-generating the responses using GPT-4. We reserve the original ShareGPT data because the original conversations will be destroyed with a re-generated different response.

Table 3: Top 5 names of individuals, organizations, and geopolitical entities (GPE) by frequency.

Dataset	Top-5 Person	Top-5 Organization	Top-5 GPE
Alpaca	John, John Smith, Alice, Mary, Harry Potter	Apple, Amazon, Google, Microsoft, ABC	United States, India, New York, France, China
Evol-Instruct	John, John Smith, Harry Potter, Alice, Bob	Apple, Amazon, quantum, Google, Microsoft	United States, New York, Los Angeles, San Francisco, Japan
ShareGPT	Di Maria, Messi, Beckhaus, Eco, Clara	Tribunal, Google, Council, Bing, Supreme Court	United States, Argentina, France, New York, Hong Kong
Quora	Prophet, Mohammed, Adam, Hijri, Ali	European Union, Google Muslim Brotherhood, Soviet Union, United Nations	Egypt, Turkey, Saudi Arabia, Morocco, America

Table 4: GPT-4 answers culture-relevant questions differently across languages. Questions here are the same in semantics but differ in languages. The Arabic response is translated into English (right).

Question in English: Is it forbidden for a woman to confess her love to a man?	**Question in Arabic**: هل من الحرام أن تعترف المرأة بحبها للرجل؟
GPT-4: No, it is not forbidden for a woman to confess her love to a man. Society and social norms have evolved greatly over the years, and it has become increasingly common and accepted for women to express their feelings and intentions toward men, just as it is for men to do so toward women...	**GPT-4**: (In Islam, it is not necessarily considered haram for a woman to express her feelings towards a man, but it must be done decently and respectfully and in accordance with Islamic teachings. Islam encourages modesty and chastity, and therefore both men and women must display decency and good morals in their dealings. If a woman wants to express her feelings, she can do so directly or through an intermediary, such as her family...)

2.2.3 Reinforcement Learning from AI Feedback

To further align AceGPT with values and cultures, we utilize reinforcement learning from AI feedback with a reward model trained with localized preference data. There are primarily two stages: (1) training the reward model using localized preference data, and (2) aligning AceGPT to value and culture preference patterns using the proximal policy optimization algorithm (Schulman et al., 2017).

Localized preference data To align AceGPT with Arabic culture and values, a reward model mimicking the preferences of native speakers is essential. To prepare the localized preference data for reward model training, we reuse 40K localized instructions, i.e. Quora questions, in the SFT stage and sample paired outputs from our fine-tuned 7B model. Given the resource-intensive nature of collecting human feedback, we utilized GPT-4 feedback, which has been shown to correlate highly with human preference labeling and achieves competitive performance in text summarization (Lee et al., 2023). However, due to observed position bias in GPT-4 (Zhang et al., 2023), we altered the order of sample answers and retained consistent preferences between two order-switched runs, resulting in 12K pairs. A small study with 800 examples verified the reliability of this preference data, revealing a correlation coefficient of 0.84 between GPT-4 and human evaluations. We also incorporate 12K open-source preference data for better generalization. See Appendix D for details.

Reward model The reward model operates within a 'binary' framework, determining preferences with an additional linear head post the final hidden states. The loss function is expressed as:

$$\mathcal{L}(\theta) = -\frac{1}{\|D\|}\mathbb{E}_{(x,y_c,y_r)\sim D}\left[\log(\sigma(r_\theta(x,y_c) - r_\theta(x,y_r)))\right]. \quad (1)$$

Here, x is the input, y_c is the chosen model output, y_r is the rejected model output of the pair, and r_θ is the reward model with the parameter θ.

Proximal policy optimization We crawl another 30K Quora questions different from Quora-40K for PPO training data. Proximal Policy Optimization (PPO) is an off-policy policy gradient method for reinforcement learning (Schulman et al., 2017). The policy $\pi_\theta(a|s)$ represents the probability distribution over the next token a given a sequence of previous tokens s, where θ are the model parameters. The primary objective is to maximize the preference signal from the reward model that

corresponds to the desired output behaviour. The objective can be shown as

$$\mathcal{L}(\theta) = \mathbb{E}_t \left[\min \left(\rho A_t, \text{clip} \left(\rho, 1-\epsilon, 1+\epsilon \right) A_t \right) \right], \quad (2)$$

where ρ is a factor defined by $\rho = \pi_\theta(a_t|s_t)/\pi_{\theta_{\text{old}}}(a_t|s_t)$, θ_{old} denotes the model parameter used for experience sampling. A_t refers to the advantage function that measures the relative value of generating a_t as the next token conditioned on the sequence $s_1 \cdots s_t$, and ϵ is a hyperparameter for stability.

3 Localization Evaluation

3.1 Evaluation Protocol

In this section, we delve into the 'Localized Evaluation' of our language model, focusing exclusively on the Arabic Cultural and Value Alignment (ACVA). ACVA serves as a critical benchmark to assess our model's performance in terms of its alignment with Arabic cultural nuances and values. This evaluation is particularly important for understanding how well the model adapts to the specific linguistic and cultural context of the Arabic language. We conduct this evaluation using our fine-tuned chat models, which have been specifically optimized for higher relevance and accuracy in culturally specific scenarios.

Arabic Cultural and Value Alignment (ACVA) ACVA is a Yes-No question dataset, comprising over 8000 questions, generated by GPT-3.5 Turbo from 50 designed Arabic topics to assess model alignment with Arabic values and cultures (see Appendix C for data construction details and show some examples in Table 19). A subset, revised by Arabic speakers for question quality and answer accuracy, forms the 2486-data 'Clean set'. The correlation between 'All set' and 'Clean set' evaluations is in Sec 3.2. Given our focus on localized solutions, we evaluate our final models (post-SFT and RLAIF) on this benchmark in a zero-shot setting with F1 score.

Baselines We compare the performance of our models against LLaMA2 (Touvron et al., 2023), Bloomz (Muennighoff et al., 2022), Phoenix (Chen et al., 2023a,b), and Jais (Sengupta et al., 2023) for this section and Sec 4.1. LLaMA2-chat models are excluded as they consistently respond in English when queried in Arabic. See details in Appendix F.1.

Table 5: Average F1 on ACVA in the zero-shot setting. The best performance is in **bold** and the second is underlined.

Model	All Set	Clean Set
Phoenix	41.86%	43.80%
Phoenix–multiple-langs	59.78%	59.15%
Jais-13B-chat	61.44%	66.83%
AceGPT-7B-chat	69.53%	70.03%
AceGPT-13B-chat	75.02%	74.62%
GPT-3.5 Turbo	**75.57%**	**79.03%**

Table 6: Average performance ratio of GPT-3.5 Turbo and the standard variation over three runs in Arabic Vicuna-80 and Arabic AlpacaEval. The best performance is in **bold** and the second is underlined.

Comparison	Arabic Vicuna-80	Arabic AlpacaEval
Phoenix	71.92% ± 0.2	65.62% ± 0.3
Phoenix (multi-langs)	71.67% ± 0.7	65.36% ± 0.1
Jais-13B-chat	75.40% ± 1.6	74.95% ± 0.2
AceGPT-7B-chat	94.82% ± 0.2	93.81% ± 0.1
AceGPT-13B-chat	**100.88**% ± 0.4	**97.95**% ± 0.1

3.2 Experiment Results

ACVA benchmark We present the results of AceGPT and other chat models on ACVA in Table 5. The Pearson correlation of accuracy on 'All set' and 'Clean set' is 0.9825, indicating a high reliability of ACVA all set evaluation. Notably, our AceGPT-chat models (both 7B and 13B) consistently outperform other open-source LLMs, and AceGPT-13B-chat only trails GPT-3.5 Turbo by a marginal of -0.55% on all set. Since the Jais-30B-chat does not follow instructions and cannot return answers for multiple-choice questions, we suspect that this is due to overly stringent safety measures. Therefore, we did not include Jais-30B-chat in the zero-shot comparison.

4 Overall Evaluation

4.1 Evaluation Protocol

Evaluation of language models is multifaceted and typically involves multiple metrics and benchmarks to assess various aspects of model performance. Moving beyond the scope of localization, the 'Overall evaluation' section presents a comprehensive analysis of our language model across a spectrum of benchmarks. This includes assessing instruction-following ability, knowledge retention, and Natural Language Understanding (NLU). For evaluating instruction-following ability, we employ our

fine-tuned chat models, which are designed to excel in interactive and directive tasks. In contrast, knowledge retention and NLU are evaluated using our base models, focusing on the core strengths of the model's pre-training. While we utilize both automated and manual methods for assessing instruction-following ability, other benchmarks in this section are evaluated solely through automated methods.

Instruction-following capability We specifically assess the models' instruction-following capabilities using the Arabic versions of Vicuna-80 (Chiang et al., 2023) and AlpacaEval (Dubois et al., 2023), translated by GPT-4 and refined by native speakers. In accordance with (Chiang et al., 2023), we adopt the GPT-4 evaluation, which prompts GPT-4 to score the performance of models on each question, contrasting them with GPT-3.5 Turbo. The details can be found in Appendix F.2. While GPT-4 evaluation is efficient and scalable, it may overlook the subtle inconsistencies between model responses (Wang et al., 2023a) and human interactions in real-world scenarios. Therefore, we further conduct human evaluation on these benchmarks to evaluate the performance of AceGPT from the perspective of human rather than GPT-4 preferences. To ensure cultural relevance in manual evaluations, we engaged a diverse group of educated, native Arabic speakers. Each model's response was assessed independently by three assessors. We present more details in Table 17 and the UI for evaluation in Figure 2.

Knowledge benchmark We have two knowledge benchmarks, including Arabic MMLU and EXAMs. MMLU (Hendrycks et al., 2021) consists of diverse multiple-choice questions across 57 tasks, spanning various educational levels. We employed GPT-3.5 Turbo to translate this dataset from English to Arabic. Additionally, Arabic questions from the EXAMs (Hardalov et al., 2020), a resource specialized in multilingual high school exam questions, were also incorporated. Both datasets were evaluated in a few-shot setting, as per the methodology in (Huang et al., 2023), to assess the innate capabilities of LLMs, aiming at potential applications with minimal adaptations.

ALUE [7] is a popular online benchmark, which is similar to the GLUE benchmark but has a main focus on **A**rabic **L**anguage **U**nderstanding **E**valuation. It includes traditional NLP tasks such as sentiment analysis, semantic matching, text relation classification, and dialect identification. It comprises 9 tasks as illustrated in Table 21. More details of task illustration, experiment setting, and results can be found in Appendix G.2.

[7] https://www.alue.org/home

4.2 Experiment Results

Instruction-following benchmark We present each model's performance ratio against GPT-3.5 Turbo, scored by GPT-4, in Table 6. The result shows that AceGPTs are superior in both Arabic Vicuna-80 and Arabic AlpacaEval. Notably, AceGPT-7B-chat surpasses Jais-13B by about 20% points with smaller model size. Moreover, AceGPT-13B-chat attains a 100.88% performance ratio of GPT-3.5 Turbo in Arabic Vicuna-80.

Human evaluation Table 7 shows the human evaluation results on Arabic Vicuna-80 and Arabic AlpacaEval. We calculated the percentages of wins, ties, and losses of the results from three Arabic speakers. We observe that AceGPT-chat (both 7B and 13B) significantly surpasses Jais-13B-chat and even Jais-30B-chat, but lags behind GPT-3.5 Turbo. Moreover, the AceGPT-13B-chat is significantly better than the AceGPT-7B-chat, indicating the importance of model size.

Knowledge benchmark Table 8 shows the few-shot evaluation results on Arabic MMLU and EXAMs. We can see that AceGPT-13B-base attains the best performance in Arabic MMLU (37.26%) among open-source LLMs, and AceGPT-7B-base also surpasses other open-source models, including 13B models, in Humanities and Others (Business, Health, Misc) domains in Arabic MMLU. In EXAMs, the Jias-30B-base model achieves the best performance among open-source models.

5 Experimental Analysis

5.1 On Pre-Training

Localization of pre-training AceGPT-base uses LLaMA2 as the backbone, the only difference it is further pre-trained with some local Arabic texts. We compare AceGPT-base to LLaMA2 on ACVA with the few-shot setting to demonstrate the benefits of localized pre-training on Arabic culture and values. The results in Table 9 show the superiority of localized pre-training: after localized pre-training, AceGPT-7B-base surpasses LLaMA2-13B, which has a larger size.

Table 7: Human evaluations on Vicuna-80 and AlpacaEval. The winners are in **bold**.

Dataset	Comparison	Win	Tie	Lose	Win or Tie
Arabic Vicuna-80	**AceGPT-7B-chat** vs. Jais-13B-chat	82.5%	6.7%	10.8%	89.2%
	AceGPT-7B-chat vs. **GPT-3.5 Turbo**	27.5%	32.9%	39.6%	60.4%
	AceGPT-13B-chat vs. Jais-13B-chat	82.9%	6.7%	10.4%	89.6%
	AceGPT-13B-chat vs. **GPT-3.5 Turbo**	16.3%	57.1%	26.6%	73.4%
	AceGPT-7B-chat vs. Jais-30B-chat	67.5%	15.0%	17.5%	82.5%
	AceGPT-13B-chat vs. Jais-30B-chat	64.6%	15.0%	20.4%	79.6%
Arabic AlpacaEval	**AceGPT-7B-chat** vs. Jais-13B-chat	53.0%	36.5%	10.5%	89.5%
	AceGPT-7B-chat vs. **GPT-3.5 Turbo**	20.2%	46.5%	33.3%	66.7%
	AceGPT-13B-chat vs. Jais-13B-chat	49.4%	42.8%	7.8%	92.2%
	AceGPT-13B-chat vs. **GPT-3.5 Turbo**	25.2%	44.5%	30.3%	69.7%

Table 8: Accuracy on Arabic MMLU and EXAMs. The best is **bold** and the second is underlined.

Model	Arabic MMLU					EXAMs
	Average	STEM	Humanities	Social Sciences	Others	
Bloomz	33.69	33.35	29.29	37.58	34.53	33.89
LLaMA2-7B	29.47	30.30	29.33	27.46	30.78	23.48
LLaMA2-13B	33.76	32.94	32.30	33.42	37.27	25.45
Jais-13B-base	32.23	30.51	31.25	33.74	33.43	35.67
Jais-30B-base	36.27	32.67	30.67	42.13	39.60	39.91
AceGPT-7B-base	32.14	29.73	30.95	33.45	34.42	31.96
AceGPT-13B-base	40.45	36.60	38.74	43.76	42.72	36.63
GPT-3.5 Turbo	**49.07**	**43.38**	**44.12**	**55.57**	**53.21**	**45.63**

Table 9: Ablation of pre-training.

Size	Model	F1 on ACVA
7B	LLaMA2	51.44%
	AceGPT-base	68.28%
13B	LLaMA2	65.67%
	AceGPT-base	**76.23%**

Table 10: Effects of different datasets on ACVA, Arabic Vicuna-80 and Arabic AlpacaEval.

Comparison	ACVA	Arabic Vicuna-80	Arabic AlpacaEval
Alpaca-Arabic	50.52%	87.15% ± 0.5	82.97% ± 0.4
+ ShareGPT	38.64%	88.01% ± 0.03	84.89% ± 0.3
+ Evol-Instruct	61.72%	**90.39%** ± 0.4	**86.87%** ± 0.1
+ Quora	**65.53%**	89.74% ± 0.8	85.71% ± 0.03

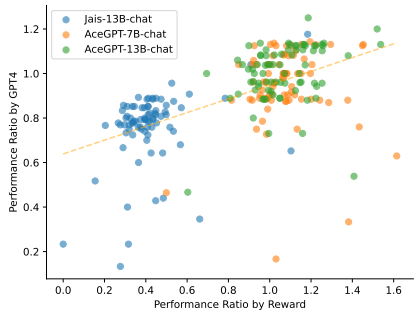
5.2 On Supervised Fine-Tuning

In this analysis, we primarily assess the impact of both localized and open-source instructions on localization and overall performance. Each dataset has been sampled with 40,000 data points, respectively. The results are shown in Table 10. It can be observed that Evol-Instruct highly contributes to the overall performance in the instruction-following benchmark, while Quora is most beneficial for Arabic culture and values. Note that incorporating ShareGPT largely harms the performance of ACVA; this may be because ShareGPT is almost aligned with Western culture and values.

5.3 On RLAIF

5.3.1 Reward Model

To evaluate the sensitivity of the reward model to the overall performance, we measure the correlations between reward scoring and GPT-4 scoring (described in section 4.1) on Arabic Vicuna-80. Following the pairwise comparison setting in GPT-4 scoring, we also calculate the performance ratio for normalized (to [0, 10] as GPT-4 scoring) reward scores on model-chatbot pairs. The Pearson correlation and Spearman correlation are 0.57 and 0.61 respectively, and the results are shown in Figure 1a. We conclude that the reward model shows a positive correlation with GPT-4 evaluation on Arabic Vicuna, which indicates it can offer an effective signal on overall performance.



Localization of reward model Then we evaluate the Arabic culture sensitivity of the reward model on the ACVA benchmark. Prompting with 'Give me a fact about Arab culture, values, and laws' in Arabic, we calculate the reward scores

Table 11: Experiments with/without RLAIF on Arabic Vicuna-80, Arabic AlpacaEval and ACVA.

	Automatic Evaluation			Human Evaluation (vs. GPT-3.5 Turbo)			
Comparison	ACVA	Arabic Vicuna-80	Arabic AlpacaEval	Win	Tie	Loss	Win or Tie
AceGPT-7B-chat (w/o RLAIF)	42.48%	92.01% ± 1.3%	91.35% ± 0.08%	27.5%	29.2%	43.3%	56.7%
AceGPT-7B-chat	**69.53%**	**94.82%** ± 0.2%	**93.81%** ± 0.1%	27.5%	32.9%	39.6%	60.4%
AceGPT-13B-chat (w/o RLAIF)	74.18%	95.14% ± 1.0%	93.05% ± 0.2%	19.6%	37.5%	42.9%	57.1%
AceGPT-13B-chat	**75.02%**	**100.88%** ± 0.4%	**97.95%** ± 0.1%	16.3%	57.1%	26.7%	73.3%

Table 12: Ratio of the frequency of "yes" to "no" of Reward.

Reward interval	(-∞,0)	(0, 0.5)	(0.5, 1)	(1,∞)
Ratio of Yes/No	81.7%	86.4%	110.8%	208.2%

(a) Correlations between reward model scoring and GPT-4 scoring on Arabic Vicuna-80.

(b) Reward score distribution on ACVA.

Figure 1: (a) Correlations between the reward model and GPT-4 and (b) reward distribution.

of prompt-statement pairs for all statements from ACVA. The distribution of reward scores for yes/no statements is shown in Figure 1b, and the ratio of the frequency of "yes" to "no" is shown in Table 12. It demonstrates that reward scores for 'yes' statements are higher than 'no' statements overall, which suggests that our reward model has a cultural sensitivity.

5.3.2 Ablation

To empirically validate the contribution of RLAIF on overall performance and localization to our AceGPT models, we conduct ablation studies across ACVA benchmarks, Arabic Vicuna-80 and Arabic AlpacaEval, results are outlined in Table 11.

RLAIF improves localization RLAIF results in performance gains of 27.05% and 0.84% for AceGPT-7B and AceGPT-13B in ACVA respectively, despite not being explicitly trained for them. This suggests that RLAIF enhances alignment with Arabic culture and values. Notably, the improvement from RLAIF on the 7B model is much larger than that of 13B, partially because the 7b model is weaker and therefore has more space for improvement, while it may be in saturation in the 13B model. Another reason could be that the preference data in RLAIF are generated from AceGPT-7b and therefore the learned reward model fits better AceGPT-7b than AceGPT-13b.

RLAIF improves instruction-following The results show that RLAIF significantly enhances overall model performance on both Arabic Vicuna-80 and Arabic AlpacaEval, increasing AceGPT-7B's performance by 2.81% and 2.46%, while AceGPT-13B shows an improvement of 5.74% and 4.90%, respectively. By examining the 'win or tie' metric, the 7B model shows an enhancement of 3.7% through RLAIF, while the 13B model shows a significant boost of 16.2%. This narrows the gap with GPT-3.5 Turbo. These enhancements across datasets underscore RLAIF's efficacy.

6 Conclusion

AceGPT addresses the 'localization issue' in large language models by specifically catering to the distinct linguistic and cultural contexts of Arabic environments, leveraging further pre-training, instruction tuning, and RLAIF. It excels in multiple benchmarks including instruction-following and natural language understanding, setting a new standard among Arabic LLMs. We contribute high-quality datasets and evaluation resources, highlighting the need for localizing large language models and introducing AceGPT as a pioneering solution for Arabic linguistic and cultural adaptation.

Limitation

Our AceGPT model exhibits several limitations. Its vocabulary, is primarily focused on Arabic letters, lacking further expansion, affecting Arabic text encoding efficiency. Limited machine resources during pre-training restricted token allocation, suggesting untapped potential in Arabic content processing. We omitted reasoning/misinformation and bias testing in our evaluation, raising concerns about the model's safety alignment and currently limiting its use to academic research rather than online deployment. Additionally, despite manual checks, the cultural dataset requires enhancement in both quality and quantity, which may affect the model's practicality and adoption.

Ethical Statement

We mainly use public data to train our models. For the newly-collected data (e.g., Quora), we use ChatGPT to filter the questions with any ethical issues. Additionally, we have adopted RL to aligned with human values.

A Related Work

Our work mainly lies in two topics: democratization of ChatGPT to low-resource language and localization and cultural alignment.

Democratization of ChatGPT to low-resource language Recent trends have focused on developing open-source LLMs as an alternative to the proprietary GPT-3.5 Turbo and GPT-4 models (Taori et al., 2023; Chiang et al., 2023; Conover et al., 2023; Chen et al., 2023a; Sengupta et al., 2023). These efforts have expanded to include LLMs designed for languages beyond English (Chen et al., 2023a; Sengupta et al., 2023). However, these models rely heavily on large-scale datasets translated from English in the supervised fine-tuning stage, inadvertently embedding English-centric cultural biases and values (Chen et al., 2023a; Sengupta et al., 2023). This practice risks undermining the models' capacity to align with the cultural contexts and values specific to their target linguistic communities. To mitigate this "localization issue", our work proposes a culture-aware framework that encompasses the pretraining, supervised fine-tuning, and reinforcement learning phases, to enhance the value and cultural alignment of AceGPT with Arabic.

Localization and cultural alignment Cultural diversity varies significantly by region and language. Yet, pre-trained language models primarily incorporate Western cultural biases (Palta and Rudinger, 2023; Ramezani and Xu, 2023; CH-Wang et al., 2023; Naous et al., 2023). These biases are attributed to the reliance on training corpora such as C4 (Dodge et al., 2021) and Wikipedia (Callahan and Herring, 2011), which are inherently skewed towards Western culture, leading to English-centric models. Moreover, the emphasis on translating English data in low-resource language NLP research exacerbates the "localization issue", failing to adequately represent the non-English culture and values (Conneau et al., 2018; Chen et al., 2023a; Sengupta et al., 2023). To address this, it is recommended to develop culture-aware models for non-English languages by gathering and annotating culture-specific data (Hershcovich et al., 2022). However, assembling comprehensive datasets for low-resource languages is challenging and expensive. Previous research has either concentrated on collecting unsupervised data for pre-training (Sengupta et al., 2023) or embarked on task-specific supervised fine-tuning (Wang et al., 2023b; Conneau et al., 2018; Huang and Yang, 2023; Palta and Rudinger, 2023). In this paper, we present a novel and comprehensive culture-aware pipeline that goes beyond the previous approaches, by integrating general culture-aware supervised fine-tuning and culture-aware reinforcement learning.

B Localization Issues

B.1 Sample Questions for Localization

The sample questions for Arabic name entity comparison in Table 1 and 2 are as follows Table 13.

Table 13: 20 sample questions

ما هي الأسماء العشرة الأكثر شيوعاً؟
What are the ten most common names?
ما هي القصص التاريخية العشرة الأكثر شهرة؟
What are the ten most famous historical stories?
أسماء المدن العشرة الأكثر شيوعاً
Names of the ten most common cities
ما هي أكثر عشر مدن يسمع عنها الناس أكثر؟
What are the top ten cities people hear about the most?
ما هي أهم عشر منظمات اجتماعية عربية؟
What are the ten most important Arab social organizations?
أفضل عشرة أشخاص لهذا العام
Top Ten People of the Year
كيف يحتفل الناس بالعام الجديد؟
How do people celebrate the New Year?
لماذا يؤمن الناس بالدين؟
Why do people believe in religion?
من هم العلماء المشهورون الجدد في الوطن العربي؟
Who are the new famous scholars in the Arab world?
ما هي بعض المعالم السياحية الشهيرة؟ ما هي الأحداث المحلية؟
What are some famous tourist attractions? What are local events?
من هم الكتاب والشعراء المشهورين في التاريخ؟
Who are the famous writers and poets in history?
ما هي بعض الأطباق الشهية التي لا يتم الاستمتاع بها إلا خلال المهرجانات الكبرى؟
What are some of the delicacies that are only enjoyed during major festivals?
ما هو تقاليدنا الأدبية؟
What is our literary tradition?
ما هي العادات والأنشطة الأساسية المهمة في حفل الزفاف؟
What are the basic customs and activities that are important at a wedding?
ما هي الكتب المقدسة والقديسين والأماكن المقدسة؟
What are the Holy Books, Saints, and Holy Places?
ما هي بعض الحكايات الشعبية؟
What are some folk tales?
كيف نشأت لغتنا؟
How did our language originate?
ما هي أهم المهرجانات؟ لماذا توجد هذه المهرجانات؟
What are the most important festivals? Why do these festivals exist?
من هم الأشخاص الذين يجب أن نتذكرهم؟
Who are the people we should remember?
من هم بعض الفنانين المتميزين؟
Who are some of the distinguished artists?

B.2 Case Study

In this subsection, we analyze the performance of AceGPT by conducting a comparative analysis of its localization ability via case studies on the sampled 20 localization questions. Illustrated in Table 24, we observed a larger proportion of Arabic events in AceGPT. The first example in Table 24 aligns with the instance illustrated in Table 2. Both AceGPT and GPT-3.5 Turbo exhibit superior responses to the given query, significantly surpassing the answer provided by Jais. Specifically, AceGPT's understanding of a 'holy book' is not solely confined to the Bible; it demonstrates a nuanced acknowledgment that different regions, especially Arabic, have their respective sacred texts, reflecting a broad and inclusive comprehension of diverse religious traditions. This illustrates the advanced capability of AceGPT, akin to GPT-3.5 Turbo, in response generation for Arabic-speaking areas.

The second example exemplifies the capability of AceGPT to incorporate more Arabic elements when responding to historical questions. Specifically, AceGPT allocates a significant proportion of its responses, 4 out of 10, to Arabic historical figures. In contrast, GPT-3.5 Turbo only attributes 1 out of 10 responses to Arabs, while Jais exclusively presents choices associated with Western figures. This demonstrates that AceGPT has an inclination towards Arabic culture, emphasizing its capability to offer more Arabic culture-relevant responses in an Arabic context.

C Construction of ACVA

We employ a top-down approach for the construction of the Arabic Cultural and Value Alignment benchmark. First, we gathered over 50 topic keywords (see Table 14) representing various aspects of Arabic culture, including humanity, art, science, geography, history, manners, religion, and the influence between civilizations, sourced from several books on Arabic culture and values. Then, we query GPT-3.5 Turbo to generate 8000 data based on the given topic using the prompt shown below, where `topic` is the placeholder for the topic.

We further sample 50% topics to verify the relevance of questions to Arabic cultures and values and the accuracy of the Yes-No labels, which were reviewed by Arabic speakers, leading to a 'Clean set'.

I am collecting some supervised fine-tuning (sft) data about Arabic culture. It is about the knowledge of Arabic culture and manners. The data is some questions in the Arabic language with an id in the form of {'id': '1','label':'xx' 'query':'xx'}. I will give you a topic in Arabic culture. The 'id' is the index of the data. 'label' is the topic I give you. 'query' is some question statement about Arabic culture under that topic. The Data should be of no repetition with a balanced proportion of true and false. Now please generate 200 sft data in json in Arabic with the format under the topic of `topic`

D Preference Data for RLAIF

The data comprises two parts: Arabic preference data and open-source English preference data. Outputs for Arabic preference data are sampled from our fine-tuned 7B model with a temperature of 1. The open-source English preference data is incorporated to improve the generalization capability of the reward model and alleviate GPT4-preference hacking. We randomly sample 12K from three public human-annotated datasets - Anthropic helpfulness and harmlessness (Bai et al., 2022), OpenAI Summarize (Stiennon et al., 2020), and OpenAssistant Conversations (OASST1) (Köpf et al., 2023).

The core idea of preference labeling for Arabic preference data is to use a GPT-4 model with prompts as an automatic annotator to assess two responses generated by the same model for a given question. However, a significant challenge emerges as GPT-4 often shows a marked preference for the first response, around 80% of the time, with the exact percentage varying based on the specific prompt design. To counter this, we utilize an order-switch mechanism to ensure consistent preference data across two separate runs of GPT-4. In one run, two responses are placed arbitrarily, and in the other, their orders are switched. The prompt for labeling is shown below. `instruction`, `response 1`, and `response 2` are the placeholders for the input instructions and the two generated responses.

Table 14: Topics for ACVA construction

Country	Algeria, Bahrain, Comoros, Egypt modern, Iraq, Jordan, Kuwait, Lebanon, Libya, Mauritania, Morocco, Oman, Palestine, Qatar, Saudi Arabia, Somalia, Sudan, Syria, Tunisia, United Arab Emirates, Yemen
Civilization Relation	Influence from ancient Egypt, Influence from Byzantium, Influence from China, Influence from Greece, Influence from Persia, Influence from Rome, Mesopotamia civilization
Science and Humanity	Arabic Astronomy, Arabic Math, Arabic Medicine, Arabic Physics and Chemistry, Arabic Literature, Arabic Music, Arabic Philosophy, Arab Empire, Arabic Architecture, Arabic Art, Arabic Calligraphy, Arabic Geography, Arabic History, Arabic Language Origin
Manners and Religion	Arabic Ceremony, Arabic Clothing, Arabic Culture, Arabic Food, Arabic Funeral, Arabic Ornament, Arabic Wedding, Mindset, Special Expression, Daily Life, Influence from Islam, Islam Branches and Schools, Islam Education, Islamic Law System

[Instruction]
`instruction`

[Response1]
`response 1`

[Response2]
`response 2`

[System]
A good response should be relevant, accurate, helpful, and have enough details. Also, it should follow Arabic culture, customs, beliefs, and laws.
Which is better, Response1 or Response2?
Do not explain your answer, just output Response1 or Response2.

E Implementation of Training

E.1 Pre-Training

We employ the LLaMA2 framework for the pre-training process, capitalizing on a computational setup furnished with 24 Nvidia A100 80G GPUs. We configure the context length at 2048 tokens and adopt the AdamW optimizer, paired with a cosine learning rate scheduler. The learning rate is set at 1e-4. Given a gradient accumulation setting of 128, the total batch size amounts to 3072. Additionally, a warm-up phase is integrated, constituting 5% of the total training duration.

E.2 Supervised Fine-Tuning

We train for one epoch using a variety of datasets in Table 15. Native Arabic data like Alpaca-Arabic-GPT4 and Quora-Arabic-GPT4 are included thrice in the mixture, while datasets like ShareGPT and Alpaca-Chinese-GPT4 are once to minimize the non-Arabic data ratio, totaling 629,293 data.

Following LLaMA2, we use the following form of system prompt:

`[INST] ⟨⟨SYS⟩⟩`
أنت مساعد مفيد ومحترم وصادق. أجب دائما بأكبر قدر ممكن من المساعدة بينما تكون آمنا. يجب ألا تتضمن إجاباتك أي محتوى ضار أو غير أخلاقي أو عنصري أو جنسي أو سام أو خطير أو غير قانوني. يرجى التأكد من أن ردودك غير متحيزة اجتماعيا وإيجابية بطبيعتها.

إذا كان السؤال لا معنى له أو لم يكن متماسكا من الناحية الواقعية، اشرح السبب بدلا من الإجابة على شيء غير صحيح. إذا كنت لا تعرف إجابة سؤال ما، فيرجى عدم مشاركة معلومات خاطئة.

`⟨⟨SYS⟩⟩`

`[question] [INST]`

The corresponding meaning in English is:

`[INST] ⟨⟨SYS⟩⟩`

You are a helpful, respectful, and honest assistant. Always answer with the utmost assistance while being safe. Your answers should not include any harmful, unethical, racist, gender discriminatory, toxic, dangerous, or illegal content. Please ensure that your responses are not socially biased and are positive.

If the question is meaningless or isn't coherent in a realistic sense, explain the reason instead of answering something incorrectly. If you do not know the answer to a question, please refrain from sharing.

`⟨⟨SYS⟩⟩`

`[question] [INST]`

Both AceGPT-7B and AceGPT-13B are fine-tuned with 8 Nvidia A100 80G GPUs. We employ

Table 15: Instruction tuning datasets; Datasets constructed in this work are highlighted in **bold**.

Dataset	Resources	Responses	Size
Quora-Arabic-40K	Collected from Quora	GPT-4	43,050
Alpaca (Peng et al., 2023)	Self-instruct (Taori et al., 2023)		49,969
Alpaca-Chinese (Peng et al., 2023)	GPT-3.5 Turbo translated (Peng et al., 2023)	GPT-4	49,969
Alpaca-Arabic	GPT-4 translated from (Taori et al., 2023)		49,969
Code-Alpaca-Arabic	GPT-4 translated from (Chaudhary, 2023)	GPT-4	20,022
Evol-Instruct-Arabic	GPT-4 translated from (Xu et al., 2023)	GPT-4	69,997
ShareGPT	humans	GPT 3.5 Turbo	80,179

the AdamW optimizer, with each batch consisting of 128 samples. We adopt different configurations for the learning rate based on the model architecture. For AceGPT-7B, the maximum learning rate is set to 5×10^{-5}, and for AceGPT-13B, it is 1×10^{-5}. A cosine scheduler is employed for learning rate adjustment, with a warmup rate of 0.03.

E.3 Reward Model Training

The reward model is initialized with Ziya, an open-source 7B reward model [8]. We use 8 Nvidia A100 80G GPUs for training. Each batch consists of 128 samples. We take two epochs with the AdamW optimizer. The maximum learning rate is set to 8e-6 and the warmup rate is set to 0.03 with cosine scheduler.

E.4 PPO

We implement PPO with DeepSpeed-Chat [9]. The actor parameters are initialized with our fine-tuned models and the critic parameters are initialized with our trained 7B reward model. We sample 448 experiences with the mini-batch size of 224 [10], which is updated in only one epoch. The maximum learning rate for the actor is set to 5e-7 while that for the critic is set to 5e-6. A cosine scheduler is used for learning rate adjustment with a warmup step of 100. We set the KL penalty as 0.01. The policy gradient loss is clipped with the threshold as 0.2 while that for the value loss is 0.3. The reward is clipped to be [-5, 5]. The gamma and lambda for the generalized advantage estimation are 1 and 0.95 respectively.

Notably, both AceGPT-7B and AceGPT-13B are trained with the 7B reward model whose preference data only comprises outputs from the 7B policy model (post-SFT).

[8]https://huggingface.co/IDEA-CCNL/Ziya-LLaMA-7B-Reward

[9]https://github.com/microsoft/DeepSpeedExamples

[10]We use 7 GPUs, where there are 64 experiences and 32 samples in each mini-batch on each GPU.

F Implementation of Evaluation

F.1 Baselines and Benchmarks

We use the following baselines :

- **LLaMA2** (Touvron et al., 2023), developed by Meta AI, are the most popular open-source large language models ranging in scale from 7 billion to 70 billion parameters. Our AceGPT models are also built upon LLaMA2-7B and -13B. We compare our AceGPT-base models to the corresponding size of LLaMA2.
- **Bloomz** (Muennighoff et al., 2022) and **Phoenix** (Chen et al., 2023a,b). **Bloomz** is a classical family of multilingual models fine-tuned with multiple traditional NLP tasks. **Phoenix** are multilingual instruction following models using Bloomz as the backbone. We compare AceGPT-base models to Bloomz and AceGPT-chat models to Phoenix.
- **Jais** (Sengupta et al., 2023) are concurrent open-source 13B Arabic-centric LLMs, including a foundation base model and an instruction-tuned model. We compare AceGPT-base and AceGPT-chat to their base and chat models respectively.
- **GPT-3.5 Turbo** is the most popular and powerful closed-source multilingual LLM, second only to GPT-4. We compare both AceGPT-base and AceGPT-chat to it.

We use Arabic Vicuda-80, Arabic AlpacaEval, Arabic MMLU, Exams, ALUE, ACVA as our benchmarks, see Table 16.

In the scoring method for the Arabic MMLU dataset, the process begins by calculating the average score within each subcategory, this average

represents the mean score for that particular subcategory. Subsequently, the average scores of all subcategories within a main category are aggregated and averaged again to yield the overall average score for that main category. Following this, the average scores of all main categories are collated and averaged to determine the overall average score for that category within the entire Arabic MMLU dataset. Finally, the aggregate average scores of all categories in the dataset are combined and averaged to arrive at the comprehensive average score across the entire Arabic MMLU dataset.

F.2 Evaluation on Instruction Following

We apply greedy decoding strategies for all models evaluated on Arabic Vicuna-80 and Arabic AlpacaEval benchmarks.

GPT-4 evaluation The temperature of the GPT-4 evaluator is set to 0.2, with the scoring conducted independently three times. We calculate the average performance ratio of the evaluated model relative to GPT-3.5 Turbo. Specifically, for each question, GPT-4 is queried to assign scores to responses from the evaluated model and GPT-3.5 Turbo respectively. We obtain the evaluated model's score for each question, and these scores are averaged to determine the evaluated model's overall score. Similarly, we derive an overall score for GPT-3.5 Turbo. The performance ratio is obtained by dividing the overall score of the evaluated model by that of GPT-3.5 Turbo. Averaging the performance ratios from three separate experiments yields the final performance ratio. The evaluation prompt is shown below. `question`, `response 1`, and `response 2` are the placeholders for the input questions and the two generated responses. To mitigate position bias (Wang et al., 2023a), we vary the order in which the model pair is presented in the prompt.

[Question]
`question`

[Assistant 1]
`response 1`

[End of Assistant 1]

[Assistant 2]

`response 2`

[End of Assistant 2]

[System]

We would like to request your feedback on the two AI assistants in response to the user question displayed above.

Requirements: The response should be helpful, relevant, accurate, and have enough details. The response should follow Arabic culture, customs, beliefs, and laws.

Please rate the performance of their responses. Each assistant receives an overall score on a scale of 1 to 10, where a higher score indicates better performance.

Please first output a single line containing only two values indicating the scores for Assistant 1 and 2, respectively. The two scores are separated by a space. You should consider which response is more in line with the given requirements.

In the subsequent line, please provide a comprehensive explanation of your evaluation.

Human evaluation We recruited 11 native people for annotation, including verification of the localization dataset, calibration of translation results, and human evaluation, the backgrounds of these people can be found in Table 17. The evaluation interface is illustrated in Figure 2. The results of the human evaluation corresponding to Table 7 for each annotator are shown in Table 23.

Table 16: Evaluation Benchmarks.

Benchmark	Evaluation Aspects	Type of Evaluation	Size	Types of Examples
Arabic Vicuna-80 Arabic AlpacaEval	Instruction following	Human & Automated	80 805	Freely-answered questions
Arabic MMLU EXAMs	Knowledge ability	Automated	14k 0.5k	Multiple-choice questions
ALUE(see Appendix G.2)	Language understanding	Automated	18k	Classification & regression
ACVA-all ACVA-clean	Arabic cultural and value alignment	Automated	9k 2.4k	Yes/No binary questions

Figure 2: User interface of human annotation. Response positions are randomized to alleviate biases.

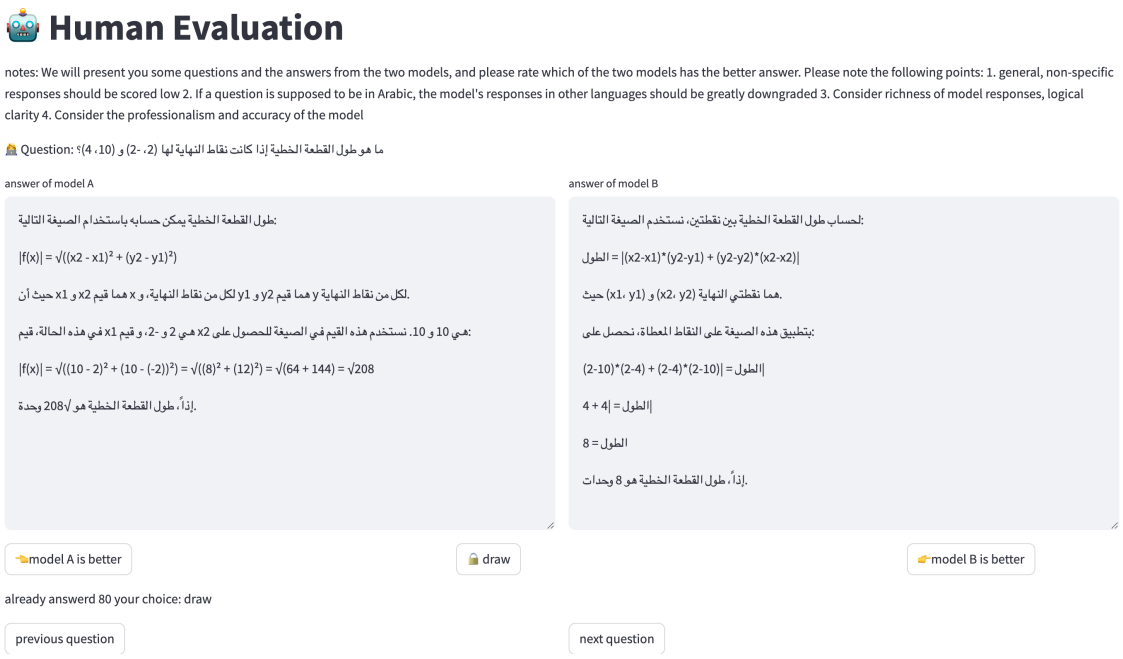

Table 17: Information of participants involved in the AceGPT testing

Name	Gender	Education	Language
Participant 1	female	PGDip	Arabic-Native
Participant 2	male	PhD	Arabic-Native
Participant 3	female	PGDip	Arabic-Native
Participant 4	female	PGDip	Arabic-Native
Participant 5	female	PGDip	Arabic-Native
Participant 6	male	PGDip	Arabic-Native
Participant 7	male	Master	Arabic-Native
Participant 8	female	PGDip	Arabic-Native
Participant 9	female	Master	Arabic-Native
Participant 10	female	PGDip	Arabic-Native
Participant 11	male	PhD	Arabic-Native

F.3 Evaluation on Knowledge

There are two main differences in the MMLU evaluation between (Sengupta et al., 2023) and ours: (1) we translate MMLU into Arabic differently. The machine-translated version in (Sengupta et al., 2023) is facilitated through their in-house translation model while we leverage GPT-3.5 Turbo. Additionally, (Sengupta et al., 2023) further creates a human-translated version. Unfortunately, both the human-translated and machine-translated versions are not publicly available, which prevents us from evaluating on the same benchmark; (2) we adopt the widely accepted few-shot prompting setting commonly found in related literature for base models, while (Sengupta et al., 2023) opts the zero-shot setting. Due to these differences in translation methods and evaluation settings, the performance metrics between the two works are not directly comparable.

We benchmark Jais-13B-base and Jais-30B-base using our GPT-3.5 Turbo-translated MMLU dataset under the standard few-shot setting in Table 8. Moreover, we also benchmark Jais-13B-chat using the zero-shot setting in Table 20.

The evaluating template is shown below:

سؤال: في اختبار جيني لرضيع حديث الولادة، يتم العثور على اضطراب جيني نادر ينتقل بشكل متنحي على قاعدة الصلة بالصبغي خ. أي من العبارات التالية تعتبر صحيحة بشكل محتمل بخصوص مخطط هذا الاضطراب الجيني؟

A. سيكون لدى جميع الأحفاد على الجانب الأمريكي المصابين بالاضطراب

B. سيكون الإناث على مقربة من ضعف الذكور المصابين في هذه العائلة

C. سيكون جميع البنات من ذوي الآباء المصابين مصابين بالمرض

D. ستكون هناك توزيع متساوٍ للذكور والإناث المتأثرين بالمرض.

إجابة: C

سؤال: يملأ مدرس العلوم في المدرسة الثانوية زجاجة سعتها ١ لتر بالنيتروجين النقي ويغلق الغطاء. الضغط هو ٧٠٠١ جوي، ودرجة حرارة الغرفة هي ٢٥ درجة مئوية. ما هما المتغيران اللذان سيزيدان ضغط النظام مع الحفاظ على كل المتغيرات الأخرى ثابتة؟

A. زيادة درجة الحرارة، زيادة مولات الغاز

B. زيادة درجة الحرارة، زيادة الحجم

C. تقليل الحجم، تقليل درجة الحرارة

D. تقليل مولات الغاز، زيادة الحجم

إجابة: A

سؤال: ما هو الآثر الجانبي المتوقع لتكملة الكرياتين؟

A. ضعف العضلات.

B. زيادة في كتلة الجسم.

C. تشنجات العضلات.

D. فقدان الكهرليتات.

إجابة: B

سؤال: ما هي الجينوم؟

A. هو عدد الكروموسومات الموجودة في الخلايا الجسدية للكائن الحي.

B. هو تسلسل الحمض النووي الكامل لكائن حي.

C. هي القائمة الكاملة للبروتينات التي يمكن للكائن الحي إنتاجها.

D. هي تسلسل الحمض النووي الخاص بكروموسوم كامل.

إجابة:

A specific example of zero-shot prompting is:

فيما يلي أسئلة الاختيار من متعدد حول المعرفة السريرية

A. ١٨ جيجا.

B. ٢٠ جيجا.

C. ٢٢ جيجا.

D. ٢٤ جيجا.

من فضلك اختر إجابة واحدة من بين 'A, B, C, D' دون شرح.

- Few-shot

فيما يلي أسئلة الاختيار من متعدد (مع الإجابات) حول طب جامعي

سؤال: كيف يتم نقل الجلوكوز إلى خلية العضلات؟

A. عبر ناقلات البروتين المسماة جلوت٤.

B. فقط في وجود الأنسولين.

C. عبر الهكسوكيناز.

D. عبر ناقلات حمض المونوكاربيليك.

إجابة: A

B. يحتوي عدد كبير من عضلات الساق لدى العدائين المتحمسين للتحمل على ألياف من النوع اي

C. جليكوجين الكبد مهم للحفاظ على تركيز الجلوكوز في الدم

D. الأنسولين يعزز امتصاص الجلوكوز من جميع الأنسجة في الجسم

إجابة: D

F.4 Evaluation on ACVA

The evaluation prompt for ACVA is

- Few-shot

فيما يلي أسئلة نعم أو لا (مع الإجابات) حول [category]

[exemplars]

سؤال: [question]
إجابة:

- Zero-shot

»الرجاء التحكم في ما إذا كانت الجملة التالية صحيحة أم لا. إذا كانت صحيحة، فالرجاء الرد بـ »نعم». إذا كانت غير صحيحة، فالرجاء الرد بـ »لا

سؤال: [question]

The corresponding meaning in English is:

- Few-shot

Below are multiple choice questions (with answers) about [category]

[exemplars]
Question: [question]
Answer:

- Zero-shot

Please determine whether the following sentence is true or not. If it is true, please respond with 'Yes'. If it is not true, please respond with 'No'.

Question: [question]

A specific example of five-shot prompting is:

فيما يلي أسئلة نعم أو لا (مع الإجابات) حول الجزائر

سؤال: الجزائر تعتبر جزءًا من الاتحاد العربي.
إجابة: نعم

سؤال: العربية هي اللغة الرسمية في الجزائر.
إجابة: نعم

سؤال: ثورة الجزائر نجحت في استعادة استقلالها من الاستعمار الإسباني.
إجابة: لا

سؤال: اللغة الرسمية في الجزائر هي الأمازيغية.
إجابة: لا

سؤال: اللغة الرسمية في الجزائر هي الأمازيغية.
إجابة: لا

سؤال: الاقتصاد الجزائري يعتمد بشكل رئيسي على الصناعات التحويلية.
إجابة:

A specific example of zero-shot prompting is:

»الرجاء التحكم في ما إذا كانت الجملة التالية صحيحة أم لا. إذا كانت صحيحة، فالرجاء الرد بـ »نعم». إذا كانت غير صحيحة، فالرجاء الرد بـ »لا

سؤال: كان لديهم طقوس دينية لتنظيم الفصول الأربعة والمواسم.

G More Experiments of AceGPT Evaluation

G.1 Supplementary Experimental Results

ACVA evaluation under the few-shot setting. Table 18 demonstrates the performance of base models on ACVA. AceGPT-30B-base outperforms Jais-30B-base by 4.81% in 'All set', but fails slightly 1.83% behind it in 'Clean set'.

Table 18: Average F1-score on ACVA in the few shot setting. The best performance is in **bold** and the second best is underlined.

Model	All set	Clean set
Bloomz	58.94%	60.91%
Jais-13B-base	73.96%	75.80%
Jais-30B-base	73.81%	77.44%
AceGPT-7B-base	74.72%	70.32%
AceGPT-13B-base	78.62%	75.61%
GPT-3.5 Turbo	**80.12%**	**81.99%**

Knowledge evaluation on the chat models. We evaluate chat models in the zero-shot setting on Arabic MMLU and EXAMs. As illustrated in Table 20, GPT-3.5 Turbo consistently outperforms other models in both MMLU and EXAMs benchmarks. Notably, Jais-13B-chat showcases superior performance, which is consistent with the results in (Sengupta et al., 2023). Specifically, its MMLU score stands at 41.06, trailing ChatGPT's score of 49.07 by a mere 8.01 points. On the EXAMs benchmark, Jais-13B-chat scored only 4.79 points lower than GPT-3.5 Turbo. One possible reason for

Jais's good performance may be attributed to traditional NLP task datasets in their SFT dataset such as Super-NaturalInstructions (Wang et al., 2022), which contains multiple-choice questions akin to the MMLU and EXAMs. Our model, in contrast, hasn't been trained on such data.

G.2 Evaluation on Arabic NLU Tasks

ALUE Details of the evaluation of ALUE will be included in this section, the introduction of ALUE can be found in Sec 4.1.

Experiment setting We train our AceGPT-13B-base on each task independently in a fully supervised manner, resembling the approach of the top models on the leaderboard. Moreover, high-ranking models on the leaderboard adopt the grid search method on validation sets to select hyper-parameters. Similarly, we employ a Bayesian approach for hyperparameter adjustment. For tasks providing predefined validation split, we utilize the given validation sets. Otherwise, we allocate 10% of the data from the training set for validation purposes. For the DIAG task, which does not provide training data, we use the model trained on XNLI to evaluate it.

Experiment results and analysis Table 22 presents our performance on the ALUE benchmark. AceGPT ranks second in terms of the average score in these nine datasets, right behind AraMUS (Alghamdi et al., 2023), which has conducted extensive pre-training in Arabic data. In future endeavors, we plan to incorporate a richer set of Arabic pre-training corpora and supervised data to enhance the model's NLU capabilities.

H Relationship between Arabic Culture and Arabic Language

The English language can reflect multiple cultures and vice versa (Hershcovich et al., 2022). This demonstrates that language and culture, although intertwined, are not inherently synonymous. In contrast, among Arabs, there exists a significant correlation between the Arabic language and Arab culture for several reasons. Primarily, Arabic is predominantly spoken by native speakers deeply embedded in Arab culture, in stark contrast to English, which is more commonly spoken by second-language speakers. [11] Furthermore, most second-language learners of Arabic pursue the language to connect with Islamic culture, a pivotal element of Arab culture, because all Islamic terminologies are expressed in Arabic. [12]

Therefore, in this paper, we assume that the Arabic language effectively captures Arab culture. Despite the presence of diverse sub-cultures within the Arab world, our paper primarily focuses on the Arab community as a whole, overlooking the distinctions among its sub-groups.

ما هي الكتب المقدسة والقديسين والأماكن المقدسة؟

(What are the holy books, saints, and holy places?)

AceGPT-7B-chat:

الكتب المقدسة هي الكتب التي تعتبر مقدسة أو من الله أو من الآلهة في الديانات المختلفة. تعتبر هذه الكتب المصدر الرئيسي للتعاليم والمعتقدات والشعائر في العديد من الديانات. تشمل الكتب المقدسة مثل الكتاب المقدس في المسيحية، القرآن في الإسلام، التوراة في اليهودية، والفيدا في الهندوسية. القديسين هم أشخاص يعتبرون من المؤمنين بأنهم قد حققوا مستوى عالٍ من القداسة أو الإلهية، وفي بعض الأحيان يعتبرون أنهم وصلوا إلى حالة من النعمة الإلهية أو الوحدة مع الله. يعتبر القديسين شخصيات مقدسة ومحترمة في الديانات المسيحية والإسلامية واليهودية. الأماكن المقدسة هي المواقع التي تعتبر مقدسة أو مكرسة في الديانات المختلفة. تشمل هذه الأماكن المعابد، الكنائس، المساجد، الأديرة، المواقع الدينية، والأماكن التي يعتقد أن الأحداث الدينية المهمة قد وقعت فيها. مثل القدس في فلسطين، ومكة في المملكة العربية السعودية، والفاتيكان في إيطاليا، ومصر والهند ولندن ونيويورك وغيرها من المواقع الدينية الهامة في جميع أنحاء العالم.

(Holy books are books that are considered sacred or from God or the gods in different religions. These books are considered the main source of teachings, beliefs, and rituals in many religions. It includes sacred books such as the Bible in Christianity, the Qur'an in Islam, the Torah in Judaism, and the Vedas in Hinduism. Saints are people who are considered by believers to have achieved a high level of holiness or divinity and are sometimes considered to have reached a state of grace. Divinity or unity with God. Saints are considered sacred and respected figures in the Christian, Islamic, and Jewish religions. Holy places are sites that are considered sacred or consecrated in different religions. These places include temples, churches, mosques, monasteries, religious sites, and places where important religious events are believed to have occurred. Such as Jerusalem in Palestine, Mecca in Saudi Arabia, the Vatican in Italy, Egypt, India, London, New York and other important sites in the world.)

Jais-13B-chat:

الكتاب المقدس هو مجموعة من النصوص الدينية التي تعتبر مقدسة لدى المسيحيين. القديسون هم الأشخاص المقدسون الذين يعتبرون أنهم عاشوا حياة فاضلة بشكل استثنائي ويتم تبجيلهم كقديسين من قبل بعض الأديان. الأماكن المقدسة هي مواقع تعتبر مقدسة أو مكرسة من قبل بعض الأديان ، مثل الكنائس والمعابد والمساجد

(The Bible is a collection of religious texts that are considered sacred by Christians. Saints are holy people who are considered to have lived exceptionally virtuous lives and are venerated as saints by some religions. Holy places are sites considered sacred or consecrated by some religions, such as churches and temples And mosques.)

GPT-3.5 Turbo:

الكتب المقدسة هي الكتب التي يعتقد أنها موحى بها من قبل الله وتحمل رسالته للبشرية. في الديانات السماوية الثلاث (اليهودية والمسيحية والإسلام)، تعتبر الكتب المقدسة هي: اليهودية: التوراة (العهد القديم)، وهي تتضمن الكتب الخمسة الأولى من الكتاب المقدس اليهودي وتشمل التكوين والخروج واللاويين والعدد والتثنية. المسيحية: الكتاب المقدس المسيحي يتكون من العهد القديم (التوراة) والعهد الجديد. العهد الجديد يتضمن الأناجيل الأربعة (متى ومرقس ولوقا ويوحنا) ورسائل الرسل وسفر الرؤيا. الإسلام: القرآن الكريم ، وهو الكتاب المقدس للمسلمين ويعتقد أنه وحي من الله للنبي محمد. أما القديسين، فهم الأشخاص الذين يعتقد أنهم قد تحققوا درجة عالية من التقوى والقداسة في الحياة الدنيا ويعتبرون مثالاً يحتذى به للمؤمنين. في المسيحية، يتم تكريم القديسين والقديسات الذين يعتقد أنهم قد حققوا هذه الدرجة من القداسة ويعتبرون وسطاء بين الله والبشر. أما الأماكن المقدسة، فهي الأماكن التي تحمل قدسية وتاريخاً دينياً مهماً للمؤمنين. بعض الأماكن المقدسة الشهيرة تشمل: الكعبة في مكة المكرمة (الإسلام)، الحائط الغربي في القدس (اليهودية)، الكنيسة القديسة العائدة في بيت لحم (المسيحية)، والمسجد الأقصى في القدس (الإسلام).

(The Holy Scriptures are books that are believed to be inspired by God and carry His message to humanity. In the three monotheistic religions (Judaism, Christianity, and Islam), the holy books are: Judaism: The Torah (Old Testament), which includes the first five books of the Jewish Bible and includes Genesis, Exodus, Leviticus, Numbers, and Deuteronomy. Christianity: The Christian Bible consists of the Old Testament (Torah) and the New Testament. The New Testament includes the four Gospels (Matthew, Mark, Luke, and John), the Epistles of the Apostles, and the Book of Revelation. Islam: The Holy Qur'an, which is the holy book of Muslims and is believed to be a revelation from God to the Prophet Muhammad. As for the saints, they are people who are believed to have achieved a high degree of piety and holiness in this world's life and who are considered an example for believers to follow. In Christianity, male and female saints who are believed to have achieved this degree of holiness are honored and considered mediators between God and humans. As for the holy places, they are places that carry sanctity and important religious history for believers. Some famous holy sites include: the Kaaba in Mecca (Islam), the Western Wall in Jerusalem (Judaism), the Holy Returning Church in Bethlehem (Christianity), and Al-Aqsa Mosque in Jerusalem (Islam).)

Abstract

Insufficient modeling of human preferences within the reward model is a major obstacle for leveraging human feedback to improve translation quality. Fortunately, quality estimation (QE), which predicts the quality of a given translation without reference, has achieved impressive alignment with human evaluations in the last two years. In this work, we investigate the potential of employing the QE model as the reward model to predict human preferences for feedback training. We first identify the *overoptimization* problem during QE-based feedback training, manifested as an increase in reward while translation quality declines. We examine the problem and argue that the vulnerability of the QE model might lead to high rewards for incorrect translations, resulting in overoptimization and error propagation. To address the problem, we adopt a simple yet effective method that uses heuristic rules to detect the incorrect translations and assigns a penalty term to the reward scores of them. Experimental results show that the proposed QE-based feedback training achieves consistent and significant improvements across various settings, further verified through human preference studies. Our subsequent analysis demonstrates the high data efficiency of the proposed QE-based feedback training: it outperforms systems using larger parallel corpora by a small amount of monolingual data. Our code is available at: https://github.com/zwhe99/FeedbackMT

1 Introduction

Human feedback has greatly contributed to recent advances in large language models (LLMs), aligning model behavior with human preferences and thereby enhancing the helpfulness and harmlessness of LLMs (Dong et al., 2023; Yuan et al., 2023; Zhao et al., 2023; Rafailov et al., 2023). The common practice involves using human evaluation data to train a reward model as a proxy for human preferences, followed by feedback training to fine-tune the LLM and maximize the reward score.

Early efforts in neural machine translation (NMT) also attempted to integrate feedback to improve translation quality. Most works used similarity scores (such as sentence-level BLEU; Papineni et al. 2002) between the predicted translation and a reference translation to simulate feedback rather than employing feedback from humans (Sokolov et al., 2016a,b; Kreutzer et al., 2017; Sokolov et al., 2017; Lawrence et al., 2017; Nguyen et al., 2017; Wu et al., 2018; Wieting et al., 2019). Few attempts to use real human feedback have been made, and these efforts either used implicit feedback in limited scenarios (e.g., e-commerce; Kreutzer et al. 2018a) or relied only on a minimal amount of human feedback data (Kreutzer et al., 2018b). Therefore, the integration of real human feedback in NMT has been constrained by inadequate modeling of human preferences.

Fortunately, the field of MT has seen substantial advancements in quality estimation (QE; Rei et al. 2021, 2022b; Wan et al. 2022). A QE model offers a reference-free estimation of translation quality and has been facilitated by the growing availability of human evaluation data (Specia et al., 2020, 2021; Zerva et al., 2022) and the development of pre-trained language models (Devlin et al., 2019; Conneau et al., 2020). Typically, given a source sentence and its translation, a sentence-level QE model can provide a numerical score to indicate the quality of the translation. The most advanced QE models to date have achieved impressive alignment with human evaluations (Freitag et al., 2022) and have been used to guide the decoding process (Fernandes et al., 2022; He et al., 2024).

In light of this progress, we explore the potential of utilizing QE models as proxies of human preferences and functioning them as reward models in feedback training for the first time. Firstly, we

[*]Work was done when Zhiwei He were interning at Tencent AI Lab.

Proceedings of the 2024 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies (Volume 1: Long Papers), pages 8164–8180
June 16-21, 2024 ©2024 Association for Computational Linguistics

identify the *overoptimization* problem in feedback training, manifested as an increase in reward while translation quality declines. Our analysis reveals that the underlying issue lies in the vulnerability of QE-based reward models, which, in rare instances, assign high scores to patently incorrect translations. As a result, these flawed patterns spread through subsequent training, leading to divergence from human preferences and a training collapse. However, the reward keeps rising throughout the whole process. This phenomenon aligns with the observation from Fernandes et al. (2023) that "overoptimizing" against an imperfect reward model can lead to systems "that receive good feedback from the model, but not humans".

Through manual examination of these flawed patterns, we categorize the most prevalent errors into two groups: length ratio errors and off-target errors (i.e., not the desired target language). Guided by this observation, we propose a simple yet effective solution to mitigate overoptimization. We first detect these errors and then add a negative penalty to the reward for these erroneous translations. We show that this approach significantly alleviates the overoptimization problem and results in notable improvements across various settings, which are further verified by human preference studies[1]

In summary, the contributions of this work are detailed as follows:

• We identify the *overoptimization* problem when using QE-based reward models for feedback training and verify the ubiquity of this phenomenon across comprehensive settings (12 in total): 3 QE models $\times$ 2 model architectures (decoder-only LLM and encoder-decoder NMT models) $\times$ 2 resource settings (high-resource and low-resource).

• By addressing the overoptimization with a simple yet effective method, we successfully integrate the QE model into feedback training for the first time, achieving remarkable improvements across various settings.

• Through further analysis, we demonstrate the high data efficiency of using the QE-based reward model for feedback training, showing that it can outperform systems using larger parallel corpora by only a small amount of monolingual data.

• We investigate the influence of the base model on feedback training, finding that stronger base models (larger in size and pretrained) yield greater improvements after feedback training. We also examine the effect of crucial hyperparameters.

[1]Automatic metrics and human judgement might be not consistent under feedback training as discussed in Limitations.

2 Feedback Training

2.1 Formulation

We denote an MT model as $M = P(y|x;\theta)$, with model parameters θ. It takes a source sentence x (or a prompt) as input and generates a target sentence y according to the distribution $P_T(y|x;\theta)$, where T is a temperature parameter to control the diversity. We consider the QE-based reward model as $r(x, y)$ whose value indicates the quality of y as the translation of x. Taken $\mathcal{D}$ as the training distribution of x, the optimization objective is:

$$\max_{\theta} \mathbb{E}_{x\sim\mathcal{D}, y\sim P(y|x;\theta)} r(x, y). \quad (1)$$

We adopt the local ranking version of Reward rAnked FineTuning (RAFT; Dong et al. 2023) to train the model M. The basic idea of RAFT is to rate the generated candidates from a prompt using the reward model and just learn from the best one of them. It has been proved to be more stable and efficient than Proximal Policy Optimization (PPO; Schulman et al. 2017). Algorithm 1 shows the details of RAFT.

Algorithm 1 RAFT

Require: Training set $\mathcal{X}$, reward function $r(x, y)$, initial model $M_0 = P(y|x;\theta_0)$, batch size b, temperature T, the number of candidate k

1: **for** iteration i in $0, 1, \ldots, N-1$ **do**
2: $\quad D_i \leftarrow \text{SampleBatch}(\mathcal{X}, b)$
3: $\quad \mathcal{B} = \emptyset$
4: $\quad$ **for** $x \in D_i$ **do**
5: $\quad\quad y_1, \ldots, y_k \sim P_T(y|x;\theta_i)$
6: $\quad\quad y^* = \arg\max_{y_j \in \{y_1,\ldots,y_k\}} r(x, y_j)$
7: $\quad\quad \mathcal{B} = \mathcal{B} \cup \{(x, y^*)\}$
8: $\quad$ Fine-tune θ_i on $\mathcal{B}$ to obtain $M_{i+1} = P(y|x;\theta_{i+1})$.

2.2 Addressing Overoptimization Problem

Overoptimization Our preliminary experiment observed *that as the reward increases, the translation performance deteriorates* (shown in Figure 1). This phenomenon is dubbed as *overoptimization* by Gao et al. (2023). The underlying reason for overoptimization is that the reward model does not serve as a perfect proxy for human preferences. Hence, overoptimizing rewards could steer

the model's behavior away from human preferences. This aligns with Goodhart's Law, which states, "When a measure becomes a target, it ceases to be a good measure."

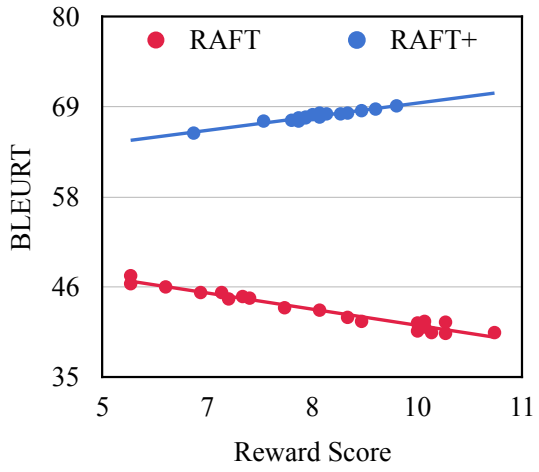

Figure 1: The relationship between reward score and translation quality. Each point represents the average performance of a checkpoint on the development sets. COMET-QE-DA is used as QE-based reward model. BLEURT is a translation quality metric that strongly correlates with human preferences (Freitag et al., 2022).

Causes We further found that the reward model may assign high scores to erroneous translations in some cases (as shown in Table 1). These errors encompass common error patterns in MT, such as length-ratio, off-target errors, and hallucinations[2]. While these errors may not be severe initially, they

Error type	Translation	Reward
None	The rule of drinking Red Label Whisky:	2.84
Len-ratio (too long/short translation)	The rule of drinking Red Label Whisky: 1. Always drink responsibly.2. Never drink alone.3. Avoid drinking on an empty stomach.4. Set limits and stick to them.5. Drink in moderation.	5.60
Off-target (wrong target language)	So trinkt man Red-Label-Whisky:	4.58

Table 1: A case of Chinese⇒English translation where the QE model (COMET-QE-DA) assigns higher scores to length-ratio and off-target errors than an error-free translation. Error spans are highlighted.

can rapidly propagate to subsequent training stages (see Figure 2) once they are accorded high reward scores, which can lead to disruption of the entire training process. Yan et al. (2023) also observed a similar phenomenon when optimizing BLEURT.

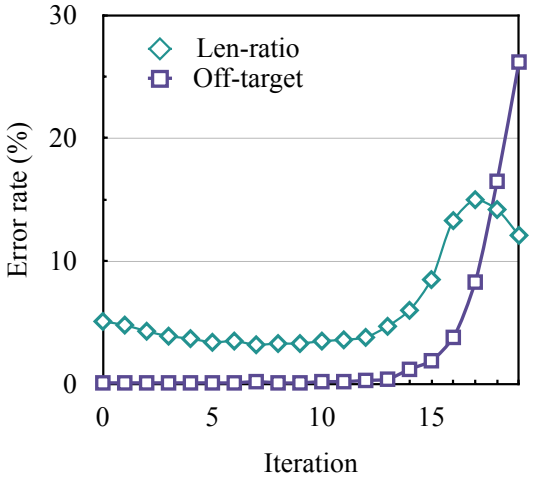

Figure 2: Trends in length-ratio and off-target error rates with the training process. Even though these errors do not manifest significantly during the early and middle phases of training, they may still surge in later stages.

Solution To alleviate overoptimization, we monitor length-ratio and off-target errors during training and assign negative, punitive rewards for these errors. Let $C(x, y)$ be true if $\frac{|y|}{|x|} \notin [L, U]$ or $\text{lang}(y) \neq$ target language, where $[L, U]$ is an acceptable length ratio interval and $\text{lang}(\cdot)$ is a language identification function (detailed in Appendix A). Then the reward modification can be expressed as:

$$r^+(x, y) = \begin{cases} r(x, y) - P & \text{if } C(x, y) \\ r(x, y) & \text{otherwise,} \end{cases} \quad (2)$$

where P is the penalty term that we simply set to $-\infty$ since RAFT is an algorithm based on data selection. We refer to this approach as RAFT+. As depicted in Figure 1, RAFT+ facilitates a trend of concurrent improvement in reward and translation quality. Notably, the relationship between reward and translation quality approximates a linear correlation. This suggests that optimizing QE-based reward can be an effective strategy in instances devoid of overoptimization.

3 Experiments

3.1 Experimental Setup

Pipeline We adopt the pipeline of reinforcement learning with human feedback (RLHF; Ouyang et al. 2022). Starting with the pretrained base

[2]For simplicity, we categorize repeating errors as length-ratio errors, and consider copying-source errors under the category of off-target errors.

model, we carry out the following steps: (1) Supervised fine-tuning (SFT), where we utilize parallel data to fine-tune the pretrained base model, thereby obtaining an initial MT model. (2) Feedback training, where we train the model using RAFT/RAFT+ to maximize the reward from a QE model. Note that this stage only uses monolingual data.

Model For the base models, we adopt:

- LLAMA-2-7B (Touvron et al., 2023): a decoder-only LLM primarily trained in English, with the objective to predict the next token.
- NLLB-200-1.3B (Costa-jussà et al., 2022): an encoder-decoder model that trained for multilingual translation across 200 languages. After SFT, it will be adapted to the language pairs we considered.

For QE models, we use:

- COMET-QE-DA (Rei et al., 2021): A QE model trained on *Direct Assessments* data.
- COMET-QE-MQM (Rei et al., 2021): Fine-tuned COMET-QE-DA model using *Multidimensional Quality Metric* (MQM) data.
- UNITE-MUP (Wan et al., 2022): A unified translation evaluation framework that is jointly trained for reference-only, source-only, and source-reference-combined evaluation. We only use its source-only evaluation.

Data We consider the settings for both high- and low-resource language pairs. In the high-resource setting, we focus on English⇔Chinese and English⇔German. In the low-resource setting, our focus is on English⇔Ukrainian and Ukrainian⇔Czech. It is important to note that both settings are multilingual, where all four translation directions are trained concurrently within one model, and we ensure the balance of all directions to avoid introducing other factors. That is, every direction has an equal number of training samples. We adopt WMT22 (Kocmi et al., 2022; He et al., 2022a) as the test sets for all language pairs, which is latest enough to avoid data contamination (Zhu et al., 2023b,a). For development sets, high resource setting uses WMT21, and low resource setting uses Flores200 (Goyal et al., 2022). Table 2 lists the detail of the data we used.

[4] https://github.com/facebookresearch/LASER/tree/main/tasks/WikiMatrix

		High-res	Low-res
Train	SFT (para)	WMT (2M)	Wiki (200K)
	FB (mono)	CC (85K)	Wiki (84K)
	Dev	WMT21	Flores200
	Test	WMT22	WMT22

Table 2: Data used in the different phases of our pipeline. SFT uses parallel data, while FB uses monolingual data. Numbers indicate the number of samples. "FB" denotes feedback training. "CC" and "Wiki" denote CCMatrix (Schwenk et al., 2021b)[3]and WikiMatrix (Schwenk et al., 2021a)[4]. WMT and CC are both general domain.

Training details For SFT, we conducted training for one epoch. For RAFT/RAFT+, we trained LLAMA-2-7B for 10 iterations using a learning rate of 2e-6, and for NLLB-200-1.3B, we trained for 20 iterations with a learning rate of 2e-5. We set the batch size b to 1024, the number of candidates k to 8, and the temperature T to 0.85.

Evaluation We use COMET (Rei et al., 2022a) and BLEURT (Sellam et al., 2020) to assess translation quality. These neural metrics show superiority over string-based metrics like BLEU (Freitag et al., 2022; Kocmi et al., 2021; Bawden and Yvon, 2023). We use `Unbabel/wmt22-comet-da` and `BLEURT-20` checkpoints for these two metrics. It is worth noting that we also observe the overoptimization problem on COMET, that is, COMET increased but the actual translation quality decreased (see § 3.2). Therefore, we use BLEURT as the main metric, but still report COMET as a reference and conduct human evaluation in § 4.1. We select the best checkpoint based on the performance on the dev sets, and report the final results on test sets using beam search (beam size = 4).

3.2 Results

Training curves Figure 3 illustrates the training curves of reward and BLEURT on the development sets when using COMET-QE-DA as the QE-based reward model. Our observations are:

• **Overoptimization is a phenomenon of high frequency when using vanilla RAFT.** Three out of the four settings (Figure 3a, c, d) have the situation that the reward shows an increase while the BLEURT declines. We further verify this phenomenon in Appendix C when using COMET-QE-MQM or UNITE-MUP as the reward model.

• **The severity of overoptimization varies under different settings.** Figure 3d represents the most severe overoptimization, where the BLEURT

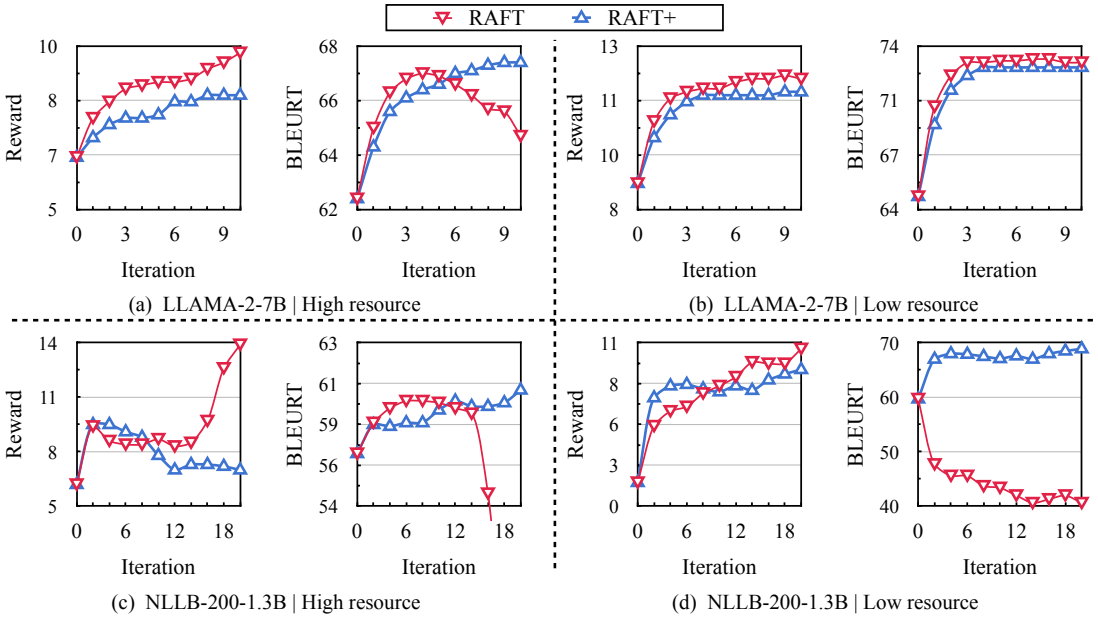

Figure 3: Training curves under various settings. The metrics are average values for all language pairs on the development set. The QE-based reward model is COMET-QE-DA.

score starts decreasing from the onset of the training process. Figure 3a and Figure 3c exhibit a trend of initial increase followed by a decrease. In such scenarios, a relatively good checkpoint can be chosen based on the performance on the development set. Conversely, Figure 3b does not display overoptimization. We conjecture that the severity of overoptimization could be related to multiple factors, including language pairs, the reward model, and the SFT model.

• **RAFT+ alleviates overoptimization effectively.** The BLEURT scores of RAFT+ in the four settings consistently increase as the training progresses. At the same time, the growth rate of the reward scores in RAFT+ is significantly slower than that in RAFT. We even witness a situation where the reward decreases in Figure 3c. Moreover, in Figure 3b where overoptimization did not occur originally, RAFT+ can still achieve a performance close to that of RAFT. However, it is worth noting that the overoptimization problem has not been completely solved, as some errors, like hallucinations, are challenging to identify. Furthermore, we cannot guarantee generalization to all other language pairs since language identification is not reliable for extremely low-resource language (Aji et al., 2022), indicating room for improvement. We leave a more comprehensive study to future work.

Main results Table 3 shows the main results on test sets when using COMET-QE-DA or COMET-QE-MQM as the QE-based reward model. We present the results of UNITE-MUP in Appendix D and use chrF as the evaluation metric in Appendix E.

• **Feedback training brings significant improvements in general.** Regardless of whether the resource setting is high or low and irrespective of the variation in base models, RAFT+ tends to deliver notable enhancements (though still underperforms the WMT22 Best systems), particularly pronounced in the low resource setting. This suggests that current QE models are already equipped with the capability to function as reward models after addressing the overoptimization problem. In contrast, while achieving good gains in most settings, RAFT can suffer from severe overoptimization that might lead to failed training.

• **The performance of the reward model varies under different resource settings.** In the high-resource setting, COMET-QE-MQM outperforms COMET-QE-DA, while the opposite is true in the low-resource setting, which suggests that QE models still have a lot of room for improvement.

• **Remarkably, even COMET, a reference-based metric, can be overoptimized.** In RAFT training of NLLB-200-1.3B under low-resource setting (bottom of Table 3b), there is a marginal increase in COMET scores, yet a significant drop in BLEURT, which is unusual. By inspecting the outputs, we found that severe off-target errors significantly hamper the model's performance. One plau-

(b) Low-resource language pairs

Table 3: Translation performance on the test sets under various settings, using COMET-QE-DA and COMET-QE-MQM as reward models. Results when UNITE-MUP is used as the reward model are presented in Appendix D. Bold indicates that the average performance of the method exceeds that of SFT and RAFT/RAFT+ within the same QE model. The subscripts indicate the change in performance relative to the SFT. "WMT22 Best" means competition winners for each direction as reported in WMT22 correspond to those used by Hendy et al. (2023).

sible reason might be the similarities between the COMET and COMET-QE models, both of which may be susceptible to these off-target errors. This finding underscores the necessity of treating automatic metrics with caution and the importance of employing multiple metrics simultaneously for a more comprehensive evaluation. Especially for feedback training using a reward model, the increasement of automatic metrics might not indicate true translation quality improvement. We therefore

conducted a human evaluation in § 4.1 and have a discussion in Limitations. It also stresses the significance of recognizing a metric's vulnerabilities during its development, including adjustments for prevalent translation inaccuracies such as length-ratio, off-target errors, hallucinations.

4 Analysis

4.1 Human evaluation

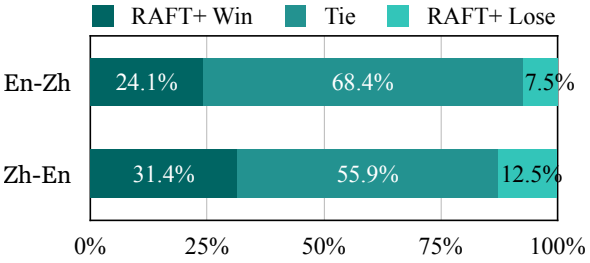

Figure 4: Human preference evaluation, comparing RAFT+ to SFT model on En⇔Zh test sets.

As discussed in § 3.2, automatic metrics may not correlate perfectly with actual translation quality. Therefore, we perform human preference studies on En⇔Zh test sets. For each test sample, our annotators (professional translators) were presented with a source sentence and two possible translations generated by either the SFT or RAFT+ model (based on LLAMA-2-7B). They were then tasked with selecting the superior translation or determining that neither translation was better than the other. Figure 4 shows the results of human preference studies. We find that RAFT+ achieves better or equal translations in 92.5% of the cases for En-Zh and 87.3% for Zh-En, compared to SFT, confirming the effectiveness of feedback training.

4.2 Data Efficiency of Feedback Training

Data efficiency refers to the capacity to achieve good performance with less training data. For low-resource language pairs, data efficiency is important since it is costly to annotate high-quality parallel data (He et al., 2022b). Feedback training provides an alternative path where humans only need to evaluate rather than generate translations.

We examine the data efficiency of feedback training in the low-resource setting. We collected an extra 3M of parallel data from WikiMatrix (Schwenk et al., 2021a) and continued training the SFT model (based on LLAMA-2-7B) using data of different sizes. We adopted two continued training strategies: full parameter fine-tuning and parameter-efficient

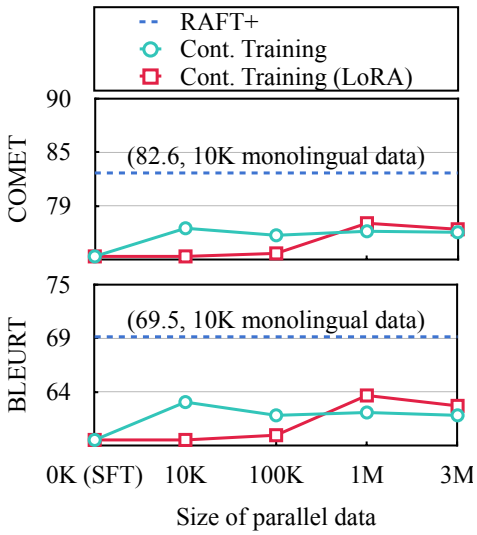

Figure 5: Comparison between RAFT+ and continuous training in the low-resource setting.

fine-tuning, specifically employing LoRA (Hu et al., 2022). To be fair, we filtered samples with length-ratio and off-target errors in the parallel data. On the other hand, RAFT+ only consumes 10K monolingual data (1024 batch size × 10 iterations). Figure 5 depicts their average performance on test sets. Unexpectedly, the continuous training with increasing amounts of parallel data fails to yield consistent improvements. This observation aligns with a similar phenomenon reported by Zhou et al. (2023). A plausible explanation could be the low quality of the crawled data for low-resource languages. Conversely, RAFT+ performs markedly better using merely 10K monolingual data, exhibiting high data efficiency. It is also worth noting that in RAFT+ the model is only trained on self-generated translations. Therefore, we conjecture that the SFT model already has strong translation potential inherently, and RAFT+ can bring this potential to fruition.

4.3 Effects of Scaling Model Size and Pretraining

In this section, we examine the effects of two dimensions of the base model on feedback training: model size and the presence of pretraining. We conduct experiments under the high-resource setting, using COMET-QE-MQM as the reward model. For model size, we consider NLLB-200-(600M, 1.3B, 3.3B) as base models; for pretraining, we randomly initialize NLLB-200-600M and perform the SFT from scratch with 80M parallel data, which we call Random-600M. From Figure 6, we have

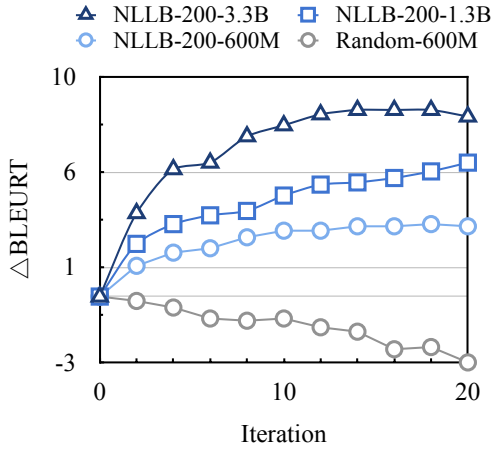

Figure 6: Training curves of RAFT+ (high-resource, COMET-QE-MQM) under different base models. We report the change in BLEURT score for each checkpoint relative to the SFT model.

two obvious phenomena: (1) a larger base model size results in a more significant enhancement from feedback training; (2) feedback training is effective only when the base model has undergone pretraining. Combining the two, we deduce that a stronger base model results in more significant improvements from feedback training. A plausible rationale for this could be that a well-established base model inherently possesses great potential, which can be further unlocked by suitable feedback.

4.4 Effects of Hyperparameters

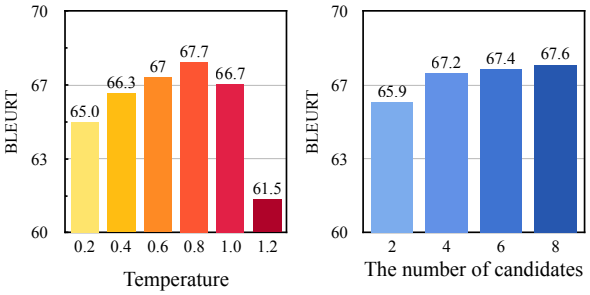

Figure 7: Effects of temperature T and the number of candidates k on the final performance (high-resource setting, LLAMA-2-7B, COMET-QE-DA).

The sampling temperature and the number of candidates are two crucial hyperparameters for RAFT+. Both influence the diversity of the candidates. Intuitively, having more diverse candidates may provide richer feedback signals, potentially leading to better final performance. However, as illustrated in Figure 7, (1) continuously increasing the temperature leads to performance degradation; (2) the boost from continuously increasing the number of candidates approaches saturation. This means that the increase in candidate diversity has reached its upper limit.

5 Related Work

5.1 Feedback Training in MT

Many early works have attempted to use various forms of feedback to improve MT, where the model has no access to the gold references but receives partial feedback on its output. Depending on the source of the feedback, they can be categorized into simulated or human feedback.

Simulated feedback This type of work utilizes a measure of similarity between the model's output and the reference translation to simulate feedback, e.g., sentence-BLEU and cross-entropy loss (Sokolov et al., 2016a,b). Kreutzer et al. (2017) lifts linear bandit learning to neural sequence-to-sequence learning. Lawrence et al. (2017) demonstrates the possibility of counterfactual learning from deterministic bandit logs. Nguyen et al. (2017) propose a training algorithm combining the advantage actor-critic algorithm with the attention-based neural encoder-decoder architecture. Wieting et al. (2019) proposes to use semantic similarity rather than BLEU as simulated feedback. Wu et al. (2018) discusses how to train the MT model using feedback effectively. The main drawback of simulated feedback is that there is no real human involvement, so the metrics being optimized, such as BLEU, do not correlate well with human preferences (Freitag et al., 2022). In addition, the need for references presents a challenge for low-resource language pairs.

Human feedback Kreutzer et al. (2018a) utilizes implicit human feedback in a constrained e-commerce scenario, which cannot be applied to general MT. Kreutzer et al. (2018b) investigates how to improve translation using human evaluation data but is limited by the small data size (1K). Concurrently with this work, Finkelstein and Freitag (2023); Ramos et al. (2023) and Gulcehre et al. (2023) also consider using QE models to provide reward signals in the training of MT models. Xu et al. (2024) points out that the references of training data might be worse than model outputs in quality, which aligns with our findings in § 4.2.

5.2 Aligning LLMs with Human

Pretrained on raw text from the internet, LLMs might generate toxic, inaccurate, and unhelpful content (Fernandes et al., 2023). To mitigate these issues, researchers have employed human feedback to better align the behavior of LLMs with human preferences, thereby enhancing their helpfulness and reducing potential harm (Ouyang et al., 2022; Stiennon et al., 2020; Bai et al., 2022). The basic idea involves learning a reward function that captures human preferences and optimizing the LLM using proximal policy optimization (PPO; Schulman et al. 2017) to maximize the reward. Lighter weight training strategies, such as RAFT (Dong et al., 2023), RRHF (Yuan et al., 2023) and DPO (Rafailov et al., 2024), use training data ranking based on rewards or human annotations to align the LLM. LIMA (Zhou et al., 2023) underscores the importance of high-quality supervised data for effective alignment. For a comprehensive understanding of alignment, we recommend readers refer to survey papers: Fernandes et al. (2023) and Wang et al. (2023).

6 Conclusion

We explore the potential of using the current QE model as a reward model. By identifying, analyzing, and mitigating the overoptimization problem, we successfully integrate the QE model into feedback training to refine translation quality. We validate its effectiveness across various settings, including human evaluation. Further analysis demonstrates the high data efficiency of feedback training using the QE-based reward model. Lastly, we delve into the impact of the base model and hyperparameters on feedback training.

Limitations

An increase in automatic metrics do not necessarily indicate a true improvement in translation quality. When we conducting feedback training, we need a QE model to provide reward score and a metric model to evaluate the final performance. Though they play different roles in the whole pipeline, they share the same function of assessing translation quality. Unfortunately, current open-sourcing QE and metric models that show strong correlation with human mostly rely on human evaluation data in WMT, which indicating the overlap between their training data. Therefore, overoptimizing the QE model might lead to unconsciously overoptimizing the metric model, as we observed in § 3.2. This is the reason why we conducted a human preference study to double check the improvement. However, human annotation is always costly and not scalable, and we only conduct it on En⇔Zh.

Training Algorithm This work only considers a simple yet stable training algorithm, RAFT, in favor of its ease of use and reduced computational requirements. We also implemented the Minimum Risk Training (MRT) algorithm (Shen et al., 2016) in Appendix B, but found it difficult to train stably. While other more commonly used reinforcement learning (RL) algorithms such as PPO exist, their training stability can be influenced by a variety of factors and often demands substantial GPU memory (Dong et al., 2023; Zheng et al., 2023). Hyperparameters, stability, and computational constraints led us to consciously limit our exploration to RAFT, thereby not investigating other potentially effective but more complex training algorithms. This choice simplifies the training process but might limit the general applicability of the approach in different contexts. Future work may explore these alternative algorithms, acknowledging the trade-offs between complexity, stability, and performance.

Granularity of Quality Estimation This work exclusively focuses on sentence-level QE, neglecting other granularities, such as word-level or document-level QE. The choice of granularity inherently limits the scope of our insights and applications. Understanding how word-level QE feedback might be utilized, or how QE could be employed to enhance document translation quality, presents exciting avenues for future research.

Imbalance in Multilingual NMT - Data This work does not consider the imbalances present in multilingual NMT. In real-world scenarios, the quantity of available corpora varies significantly across different languages, which might lead to biased or suboptimal results. However, considering unbalanced scenarios introduces many additional factors, such as different ways of sampling training data. Therefore, we constrain our focus to the balanced situation in this work, recognizing the need for future research to address this complexity and explore methods that can better handle the imbalances inherent in multilingual contexts.

Imbalance in Multilingual NMT - Reward Although we kept the amount of data the same for different language pairs, we still observed training imbalance problems due to "uneven" distribution of rewards. Specifically, in Table 3a, neither RAFT nor RAFT+ consistently improves NLLB in En→De and En→Zh (both are *from-English* direction) at the high resource setting. On the other hand, the performance of the other two *to-English* directions (De→En and Zh→En) has been significantly improved by notable margins (BLEURT | De→En: 53.5→71.3, Zh→En: 48.4→62.9). This means that during training, the model allocates more "capacity" to the *to-English* directions than to the *from-English* directions, i.e., they are not balanced. The intuitive reason is that the model "finds" optimizing the *to-English* directions offers a quick boost in reward, thereby "ignoring" the *from-English* directions which have less room for improvement. This involves *how the reward can be reasonably distributed among different language pairs*, which is less discussed in this work, but a meaningful and underexplored future direction.

Applicability of the Method to Mitigate Overoptimization The current method for mitigating overoptimization focuses on detecting relatively easy-to-identify errors such as len-ratio and off-target errors. More elusive mistakes, such as hallucinations, remain unaddressed and might potentially lead to overoptimization as well (Guerreiro et al., 2023). In addition, current language detectors are not reliable for extremely low-resource languages (Aji et al., 2022), limiting the applicability in these contexts.

A Error Detection and Penalty

We penalize for len-ratio errors and off-target errors. We consider translations whose length ratios do not belong to $[L, U]$ as len-ratio errors. We computed the distribution of length ratios of the SFT training data for each language pair (using the tokenizer of the corresponding model), taking $[L, U]$ so that it covers the top 50% of the most frequent length ratios. We adopt language detector from Stahl (2023) to detect off-target errors.

B MRT Implementation

MRT (Shen et al., 2016) is designed to directly optimize the model with respect to evaluation metrics. However, we failed to get meaningful improvements when using MRT.

The *risk* of MRT can be formulate as:

$$\mathcal{R}(\theta) = \sum_{(x,y^*)\in\mathcal{D}} \mathbb{E}_{y\sim P(y|x;\theta)} \left[\Delta\left(y, y^*\right)\right], \quad (3)$$

where y^* represents the ground-truth translation. The Δ function serves as the loss function and can be instantiated using various evaluation metrics, for example, $1 - \mathrm{BLEU}(y, y^*)$. The objective or MRT is to minimize $\mathcal{R}(\theta)$.

In out setting, $\mathcal{D}$ is the training distribution of x, i.e., monolingual data, and we use QE-based reward $r(x, y)$ to indicate the quality of y as the translation of x. Therefore, we modify the *risk* as:

$$\mathcal{R}(\theta) = \sum_{x\in\mathcal{D}} \mathbb{E}_{y\sim P(y|x;\theta)} \left[1 - r(x, y)\right]. \quad (4)$$

In practice, we sample k candidates and normalize the probabilities to approximate the expectation. Let S_k denote a set containing k candidates drawn from the distribution $P_T(y|x;\theta)$, where T is the sampling temperature. $R(\theta)$ is approximated as:

$$\tilde{R}(\theta) = \sum_{x\in D} \sum_{y\in S_k} \tilde{P}(y|x;\theta)[1 - r(x, y)], \quad (5)$$

where

$$\tilde{P}(y|x;\theta) = \frac{P(y|x;\theta)^\alpha}{\sum_{y'\in S_k} P(y'|x;\theta)^\alpha}, \quad (6)$$

and α is a hyperparameter. Algorithm 2 shows the details of MRT. Similar to RAFT+, when adding a penalty term to reward, we call it MRT+. We set the penalty term $P = 1$ and $\alpha = 0.005$[5], and leave other hyperparameters the same as RAFT.

Algorithm 2 MRT

Require: Training set $\mathcal{X}$, reward function $r(x, y)$, initial model $M_0 = P(y|x;\theta_0)$, batch size b, temperature T, the number of candidate k

for iteration i in $0, 1, \ldots, N-1$ **do**
  $D_i \leftarrow \mathrm{SampleBatch}(\mathcal{X}, b)$
  $\mathcal{B} = \emptyset$
  for $x \in D_i$ **do**
    $y_1, \ldots, y_k \sim P_T(y|x;\theta_i)$
    $S_k = \{y_1, \ldots, y_k\}$
    $\mathcal{B} = \mathcal{B} \cup \{(x, S_k)\}$
  Fine-tune θ_i on $\mathcal{B}$ to obtain $M_{i+1} = P(y|x;\theta_{i+1})$ using MRT risk: $\tilde{R}(\theta_i)$.

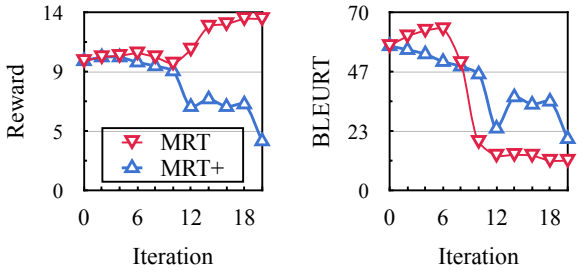

Figure 8: Training curves of MRT and MRT+ under high-resource setting. NLLB-200-1.3B and COMET-QE-MQM are used as base model and QE-based reward model, respectively.

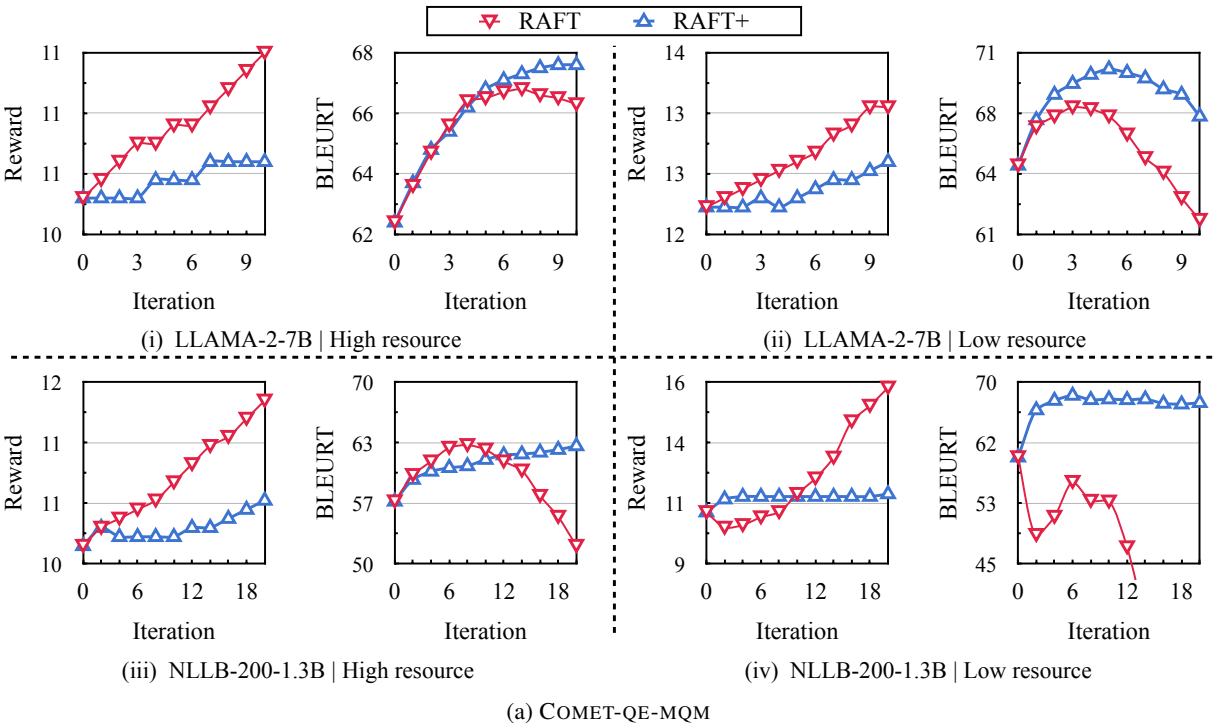
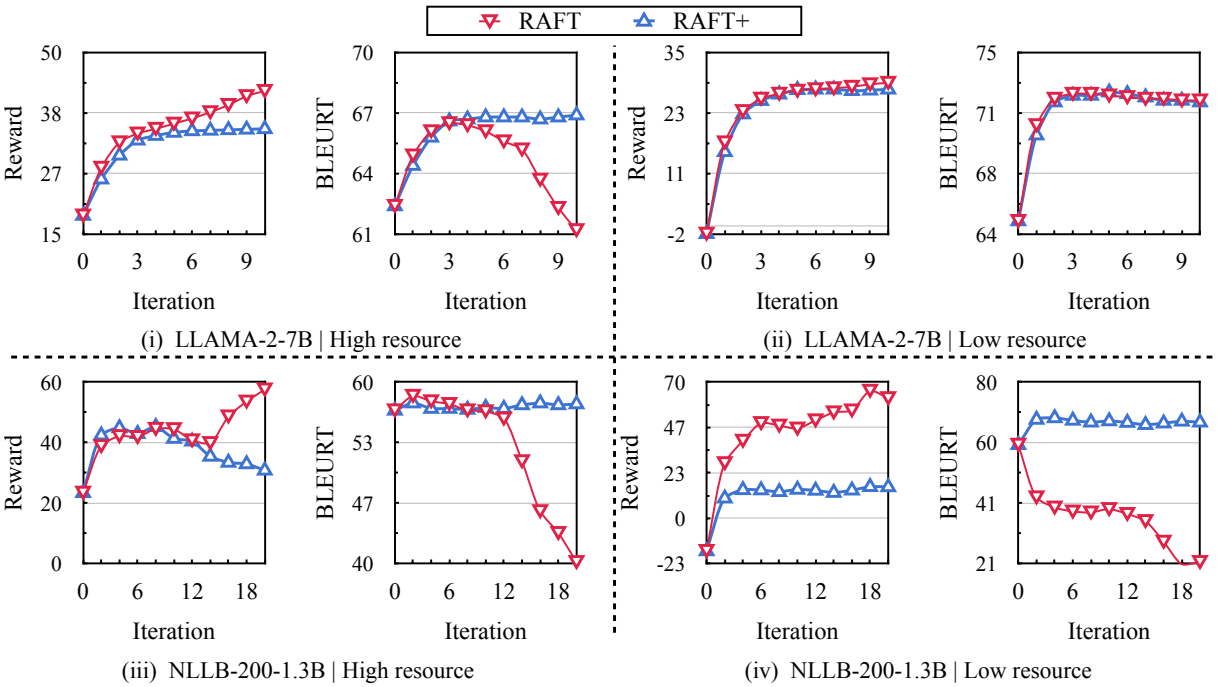
Figure 8 shows that vanilla MRT suffers from the overoptimization problem, manifested as an increase in reward while translation quality declines. Additionally, MRT+ also poses challenges in achieving stable convergence.



C More Training Curves

Figure 9 shows the training curves when using COMET-QE-MQM and UNITE-MUP as the reward models. Consistent with Figure 3, vanilla RAFT suffers from severe overoptimization problems in most cases, which are greatly alleviated by RAFT+.



D UNITE-MUP as the Reward Model

Table 4 presents the test results when UNITE-MUP functions as the reward model. The main trends are consistent with those shown in Table 3. We also observe that neither RAFT nor RAFT+ achieves positive improvement in high-resource language pairs when NLLB-200-1.3B is the base model. We speculate that this lack of improvement

[5]We follow the default setting in Sennrich et al. (2017).

(a) COMET-QE-MQM

(b) UNITE-MUP

Figure 9: Training curves under various settings when using COMET-QE-MQM and UNITE-MUP as reward models. The metrics are average values for all language pairs on the development set.

is due to overoptimization problems caused by the presence of errors that are not related to length ratio and off-target errors.

E chrF as the Evaluation Metric

Table 5 shows the chrF values for main results.

Abstract

Depression is a widespread mental health disorder affecting millions globally. Clinical interviews are the gold standard for assessing depression, but they heavily rely on scarce professional clinicians, highlighting the need for automated detection systems. However, existing methods only capture part of the relevant elements in clinical interviews, unable to incorporate all depressive cues. Moreover, the scarcity of participant data, due to privacy concerns and collection challenges, intrinsically constrains interview modeling. To address these limitations, in this paper, we propose a structural element graph (SEGA), which transforms the clinical interview into an expertise-inspired directed acyclic graph for comprehensive modeling. Additionally, we further empower SEGA by devising novel principle-guided data augmentation with large language models (LLMs) to supplement high-quality synthetic data and enable graph contrastive learning. Extensive evaluations on two real-world clinical datasets, in both English and Chinese, show that SEGA significantly outperforms baseline methods and powerful LLMs like GPT-3.5 and GPT-4.

1 Introduction

Depression is a pervasive mental health disorder that affects a significant portion of the global population. According to the World Health Organization (WHO)[1], over 300 million people suffer from depression, casting a profound shadow on individuals, families, and society. Furthermore, in many communities, limited awareness and stigmatization surrounding mental health can lead to under-diagnosis and under-treatment, which underscores the imperative for effective depression screening.

To date, clinical interviews remain the standard method for assessing depression severity (He et al., 2022). In Figure 1, we present an example interview from DAIC-WOZ (Gratch et al., 2014), a widely-used corpus for clinical depression detection. As can be seen, clinical interviews typically take the form of semi-structured multi-round question-answering dialogues. The interviewer follows an outline while flexibly posing questions relevant to personal experience and mental states, and the participant answers are recorded to assess the state of depression. Currently, conducting clinical interviews has become relatively feasible, by either an "Wizard-of-Oz" virtual interviewer (Kelley, 1983) or a fully autonomous scripted agent (DeVault et al., 2014). However, analyzing clinical interviews for depression assessment remains a domain reserved for highly specialized clinicians.

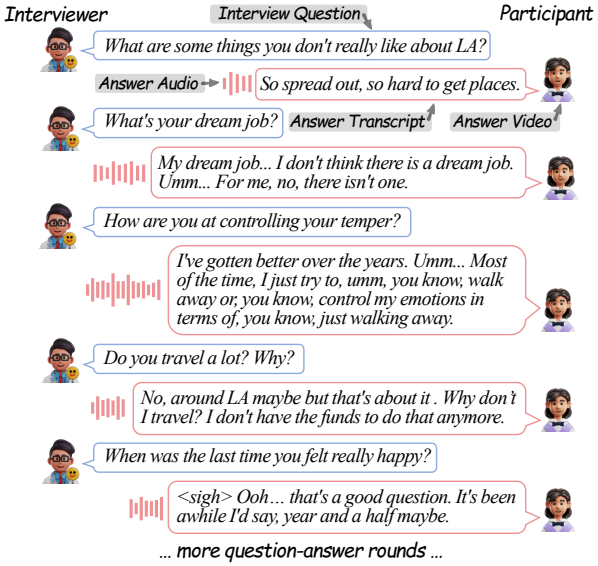

Figure 1: A clinical interview for assessing depression.

As an alternative, automatic assessment of clinical interviews has emerged as a promising assistance for depression detection (Valstar et al., 2016). Clinical interviews mainly encapsulate four types of elements: the *interview questions*[2] and the *answer transcripts/audios/videos*, enabling super-

vised learning for automatic depression assessment. However, existing studies still face two major challenges. **1)** As can be seen from Table 1, existing methods only capture part of the four elements in clinical interviews, unable to incorporate all relevant cues for depression detection. The main reasons are twofold. One is that the background noise in audio and video modalities poses difficulties for interaction among different elements, which may even degrade performance (Baltrušaitis et al., 2018; Hazarika et al., 2022). Moreover, the interview questions are usually overlooked since they contain no participant information. The other is the potential complexity of interviews, which can include up to 50 rounds, leading to a compromise in using only partial elements for efficient aggregation (Al Hanai et al., 2018). **2)** The scarcity of participant data, arising from privacy concerns and collection costs, directly constrains the quality of interview modeling. Commonly available datasets like DAIC-WOZ contain only $\sim$100 training samples with $\leq$30 depressed participants. Hereby, training a sophisticated depression detection model becomes an intrinsical demanding task.

To address the above limitations, we propose an LLM-empowered **S**tructural **E**lement **GrA**ph (SEGA) for comprehensive interview modeling under limited resources. **1)** To make full use of all four types of elements, we transform the clinical interview into SEGA, a directed acyclic graph. We first gather expertise about processing interview elements in depression assessment, then align SEGA's structure with this human experience to facilitate representation learning. Specifically, within each round, we predefine the information flow between elements with noise suppression, allowing for element interaction while avoiding interference. Across multiple rounds, we specify simple yet efficient information propagation and aggregation approaches, so as to preserve the complete element features for predicting depressive status. **2)** To alleviate the negative impact of data scarcity on interview modeling, we introduce a novel LLM-based data augmentation approach guided by principles of *integrity*, *authenticity*, *respectfulness*, *consistency*, and *informality*. Along with the graph contrastive learning with real and synthetic data, we further advance the performance of SEGA under limited resources. We conduct experiments on two real-world clinical interview datasets in English and Chinese, respectively. The results demonstrate that SEGA significantly surpasses existing baseline methods and powerful LLMs like GPT-4 for depression detection in clinical interviews.

2 Related Work

2.1 Depression Detection

Depression is a debilitating mental condition that affects a person's thoughts, feelings, and behavior. The automatic analysis of clinical interviews has been recognized as a promising assistant for psychologists and psychiatrists to improve the time efficiency and diagnostic consistency of depression detection (Valstar et al., 2016; Zou et al., 2022).

Most studies leverage the participant answers for depressive assessment, which can be categorized into three types: 1) Uni-modal methods typically model either transcripts or audios. For transcripts, existing work focuses on aggregating word representations for prediction (Mallol-Ragolta et al., 2019; Burdisso et al., 2023), or further incorporates affective and mental health lexicons (Xezonaki et al., 2020; Villatoro-Tello et al., 2021). For audios, existing studies have investigated the utility of shallow acoustic features like MFCCs (Taguchi et al., 2018; Huang et al., 2022) and deep audio representations from neural networks like CNN (Ma et al., 2016; Zhang et al., 2021; Sardari et al., 2022; Sun et al., 2022) . 2) Bi-modal methods typically combine transcripts and audios as the two most informative modalities via feature fusion (Al Hanai et al., 2018; Wu et al., 2022; Guo et al., 2022; Seneviratne and Espy-Wilson, 2022) or prediction ensembling (Niu et al., 2021; Shen et al., 2022). Yoon et al. (2022) model both audio and video modalities with a cross-attention transformer, but the performance is relatively limited without transcripts. 3) Tri-modal methods consider the answer transcripts, audios, and videos via multimodal fusion conducted at word-level (Rohanian et al., 2019) or utterance-level (Guohou et al., 2020; Zhang et al., 2020; Zheng et al., 2020; Fang et al., 2022; Prabhu et al., 2022).

In addition to the three modalities of the answers, a few studies (Niu et al., 2021; Flores et al., 2022) have incorporated the interview questions as supplementary context to better extract salient cues from participant answers. Different from the above methods, we resort to human experience in depression assessment to construct the structural element graph, so as to effectively model all four types of interview elements under limited resources.

2.2 LLMs Application in Healthcare

Recent years have witnessed the rapid development and powerful capability of large language models (LLMs), such as OpenAI's ChatGPT (Ouyang et al., 2022), Anthropic's Claude (Bai et al., 2022), Google's LaMDA (Thoppilan et al., 2022), and Meta's LLaMA (Touvron et al., 2023). LLMs have shown promising potential in powering the healthcare domain. Wang et al. (2023) and Chen et al. (2023) use LLMs to play doctor and patient roles, respectively, to generate medical dialogue data. Yang et al. (2023), Bisercic et al. (2023), and Jo et al. (2023) leverage LLMs to assist diagnosis via medical report generation, tabular data extraction, and emotional support deployment, respectively. Sarker et al. (2023) and Liyanage et al. (2023) conduct data augmentation via LLMs to enhance medication event identification and wellness dimension classification.

Despite these advances, LLMs remain underexplored in the realm of depression detection in clinical interviews. In this work, we meticulously craft principle-based prompts to direct LLMs in generating high-quality data for depression detection, complemented by responsible quality verification and ethical consideration.

3 Methodology

3.1 Task Definition

In a clinical interview I from the corpus $\mathcal{C}$, the interviewer asks the participant a series of m questions (recorded as text) $Q = \{q_1, ..., q_m\}$, typically probing into their feelings, experiences and mental states. The participant's responses are recorded in three modalities - transcripts $T = \{t_1, ..., t_m\}$ capturing the textual content, audios $A = \{a_1, ..., a_m\}$ capturing tone and prosody, and videos $V = \{v_1, ..., v_m\}$ capturing facial expressions and body movements. Each question (q_i) and transcript (t_i) comprises a word sequence, while each audio (a_i) and video (v_i) comprises a frame sequence sampled with a certain frequency. The goal is to analyze these elements and predict a label $y \in \{1, 0\}$ denoting whether the participant is depressed or not.

3.2 Structural Element Graph

For depression detection in clinical interviews, we propose the structural element graph ($\mathbb{SEGA}$) based on human experience for comprehensive interview modeling. Figure 2 presents the architecture of $\mathbb{SEGA}$, which comprises three main components: element feature extraction, graph construction with expertise, and graph learning and prediction.

3.2.1 Element Feature Extraction

In clinical interviews, each element serves as a unique indicator of the depressive state. Interview questions may probe for negative emotions, shedding light on underlying feelings of hopelessness or worthlessness. Answer transcripts may reveal a higher frequency of negative words, reflecting a depressed mindset. Answer audios can hint at depression through a flatter affect, slower speech rates, or prolonged pauses. Answer videos capture visual cues like reduced facial expressivity or subdued reactions. Together, these elements form a rich tapestry of information that helps in assessing an individual's depressive state.

Below we show how to extract element features. Within a question-answer round, the question (q_i)/ transcript (t_i) is an utterance involving the text modality. We first map every word in the utterance using a pre-trained word embedder, then compute the mean of word vectors to obtain the utterance representation $\boldsymbol{q_i}$ / $\boldsymbol{t_i}$. For the audio (a_i) and video (v_i) modalities of the answer utterance, they are already processed into frames at a certain frequency, where the raw features are specified by the used dataset. We then process those frames according to the timestamps in the corresponding transcript. Specifically, we look at the start and end timestamps of the utterance in the transcript, then average the frames spanning the duration of this utterance to derive audio and video representations $\boldsymbol{a_i}$ / $\boldsymbol{v_i}$ for the answer utterance. By this means, we ensure that all element features are strictly aligned at the granularity of a question-answer round.

3.2.2 Graph Construction with Expertise

Based on the element features, we follow specific expertise for depression assessment to derive the graph structure and facilitate interview modeling.

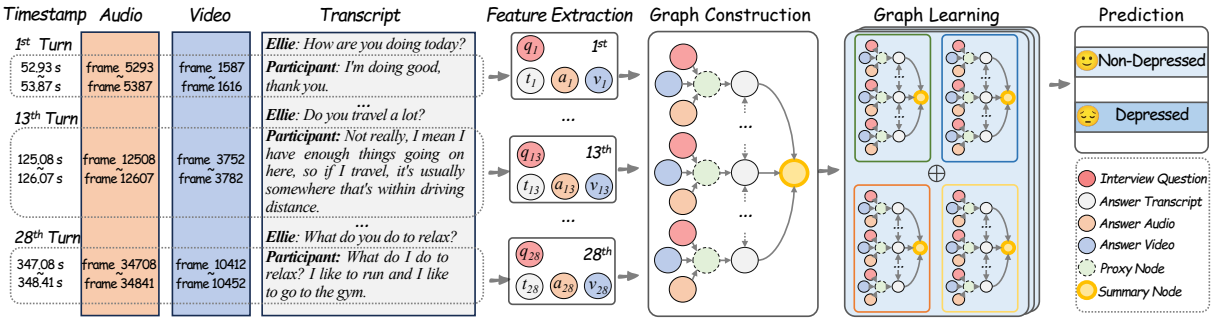

Figure 2: The architecture of SEGA. We first extract element features according to timestamps and frame index, then construct and learn a structural element graph for depression detection in clinical interviews.

Expertise within Each Round: 1) Element Importance. Studies on multi-modal learning have demonstrated that texts contain the richest semantics (Rohanian et al., 2019; Hazarika et al., 2022). Therefore, for each round, we anchor the transcript t_i as the central node, and treat the audio a_i and video v_i as auxiliary nodes. The question q_i is also recognized as a supplementary node since it completes the contextual information of the answer. 2) Information Flow. To reflect the status of nodes, we build a directed acyclic graph (Shen et al., 2021) where information is passed unidirectionally from the auxiliary nodes to the central node. 3) Noise Suppression. To avoid direct interference from the background noise in audio and video elements (Baltrušaitis et al., 2018), we additionally insert a proxy node p_i within each round. It aims to first distill evidence from the audio and video, transform it into the text vector space, and then let the transcript node selectively absorb useful information. The representation of p_i is initialized with the representation of t_i. Besides, each element node has a self-loop edge to preserve its own information.

Expertise across Multiple Rounds: 1) Information Propagation. Since an interview topic (e.g., querying family relationships) may span multiple rounds, we link adjacent central nodes (t_i) for capturing temporal dependencies. 2) Information Aggregation. To represent the semantics of the entire clinical interview, we introduce an additional virtual "summary" node (s). We then pass information unidirectionally from all central nodes (t_i) to the summary node s. The representation of s is initialized by averaging all t_i representations.

The structural element graph is a simple yet effective architecture. On the one hand, it fully utilizes the evidence in four types of elements embedded in clinical interviews. On the other hand, it benefits from prior human experience and sets a good starting point for interview modeling.

3.2.3 Graph Learning and Prediction

Based on the constructed structural element graph, we employ Graph Attention Network (GAT) (Velickovic et al., 2018) to capture the interactions among elements and accordingly update representations. For node i and its neighborhood nodes $\mathcal{N}(i)$, we iteratively updates the node representation $\boldsymbol{h_i} \in \mathbb{R}^{d_h}$ by aggregating neighborhood node representations using multi-head attention:

$$r_{ij}^{(k)} = \text{LeakyReLU}(\boldsymbol{w}^\top [\mathbf{W}^{(k)}\boldsymbol{h_i} || \mathbf{W}^{(k)}\boldsymbol{h_j}]), \quad (1)$$

$$\alpha_{ij}^{(k)} = \text{softmax}_j(r_{ij}^{(k)}) = \frac{\exp(r_{ij}^{(k)})}{\sum_{m\in\mathcal{N}i}\exp(r_{im}^{(k)})}, \quad (2)$$

$$\boldsymbol{h}_i^{(k)} = \text{ELU}\left(\sum_{j\in\mathcal{N}_i} \alpha_{ij}^{(k)}\mathbf{W}^{(k)}\boldsymbol{h}_j\right), \quad (3)$$

$$\boldsymbol{h}_i = ||_{k=1}^{K}\boldsymbol{h}_i^{(k)}, \quad (4)$$

where k denotes an attention head, $\mathbf{W}^{(k)}$ is the weight matrix, $\boldsymbol{w}$ is the weight vector, $\alpha_{ij}^{(k)}$ is the attention weight, $\boldsymbol{h}_i^{(k)}$ is the output feature vector for head k, $||$ denotes vector concatenation. After the computation of L GAT layers, we collect the representation $\boldsymbol{s}$ of the summary node after propagation as the final feature of the interview. We then feed it into a feed-forward layer to predict the depressive status $\hat{y}$ and compute the cross-entropy loss $\mathcal{L}_{ce}$ for detection:

$$\hat{y} = \text{softmax}(\mathbf{W}_y(\boldsymbol{s})), \quad (5)$$

$$\mathcal{L}_{ce} = -\left(y\log(\hat{y}) + (1-y)\log(1-\hat{y})\right). \quad (6)$$

3.3 A Helping Hand from LLMs

While SEGA intrinsically aligns with the expertise of processing interviews, its learning capability is still constrained by the limited clinical resources. Due to collection difficulties and privacy concerns, the training set size of commonly-used public clinical depression detection corpora is only about 100. Nevertheless, large language models (LLMs) possess an extremely strong human-like

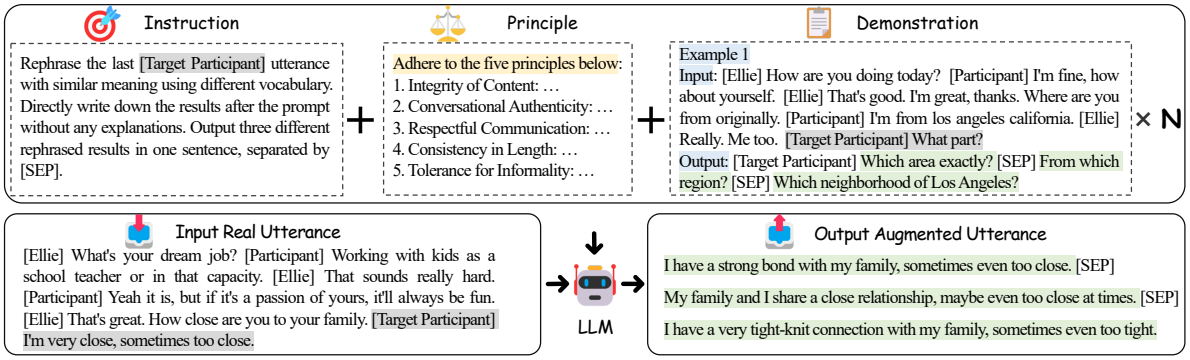

Figure 3: Guided by principles, LLMs synthesize augmentation data by rephrasing the answer utterances.

text generation capability, offering immense potential for generating synthetic data to alleviate data scarcity. Hereby, we propose to design a principle-based prompt to carefully control the LLM for data augmentation. The goal is to simulate diverse participant responses by rephrasing transcripts with the same meanings but different vocabularies.

3.3.1 Principle-based Augmentation

While LLMs are capable of generating fluent and coherent text, their outputs can sometimes deviate from the original meaning or contain inappropriate content if not properly constrained. This presents challenges when utilizing them for data augmentation in sensitive domains like mental healthcare. Therefore, to ensure LLMs rephrase transcripts faithfully without altering semantics or tones, we guide the synthesizing process with explicit principles. The five principles serve as "guard rails" to steer the model toward making edits that introduce diversity while preserving *integrity*, *authenticity*, *respectfulness*, *consistency*, and *informality*.

We list the principles as follows. 1) Integrity of Content: Retain the original meaning and sentiment. Do not change the substance. 2) Conversational Authenticity: Use natural, casual language. Avoid overly formal styles. 3) Respectful Communication: Maintain a respectful tone. Do not make inappropriate/offensive alterations. 4) Consistency in Length: Keep similar length to the original. Avoid excessive shortening/lengthening. 5) Tolerance for Informality: Tolerate some irregularities (omissions, repetitions, filler words) given the conversational context.

We rephrase transcripts in a sliding window with a size of three, applying LLMs with context awareness. In other words, when rephrasing each answer transcript, we use the last three rounds of question-answers as input. Besides, we also provide N hand-crafted demonstrations to facilitate task understanding. As shown in Figure 3, the final input prompt is composed of task instruction, rephrasing principles, and manual demonstrations. After prompting, we collect the outputs of LLMs as the augmented data. For the accompanying audios and videos, due to the untouchability of raw recordings and the lack of LLM-level synthesis tools, we adopt a simple random frame-swapping method. We sample $a_j \neq a_i$, $v_j \neq v_i$ in the same interview as augmentation features, capturing feasible variance. We do not augment interview questions as their content is predefined.

After synthesizing augmentation data via rephrasing, we manually inspect samples for quality verification. We verify that: 1) The rephrased sentences express the same semantic content as the originals, without introducing factual inconsistencies or changes in meaning. 2) The tone and sentiment remain consistent between the original and augmented versions. 3) No offensive, unethical, or otherwise inappropriate language is generated. 4) Personal details and identifiers are not altered or exposed. Ultimately, steered by the guiding principles, only very few (less than 1%) of the augmented data is filtered out and regenerated.

3.3.2 Empowerment of SEGA

After obtaining the synthetic data $\hat{\mathcal{C}}$, we mix it with the original corpus $\mathcal{C}$ to obtain the augmented training data. Furthermore, owing to the improved size and diversity with synthetic data, we introduce the self-supervised contrastive learning with InfoNCE (Oord et al., 2018) loss to encourage distinct representations for depressed and control participants:

$$\mathcal{L}_{cl} = -\sum_{c}^{\mathcal{C}||\hat{\mathcal{C}}} \log \frac{\exp(\boldsymbol{s}_c^\top \boldsymbol{s}_c^+/\tau)}{\exp(\boldsymbol{s}_c^\top \boldsymbol{s}_c^+/\tau) + \sum_{j=1}^{J} \exp(\boldsymbol{s}_c^\top \boldsymbol{s}_{c,j}^-/\tau)} \tag{7}$$

where τ denotes a temperature parameter, $\boldsymbol{s}_c^+$ is a certain positive sample with the same label , $\boldsymbol{s}_c^-$ denotes several negative samples with the opposite

label. By update the final training loss as $\mathcal{L} = \mathcal{L}_{ce} + \mathcal{L}_{cl}$, we obtain the empowered model SEGA^{++}.

4 Experiment

4.1 Experimental Setup

Datasets We conduct experiments on two available corpora for clinical depression detection: DAIC-WOZ (Gratch et al., 2014) and EATD (Shen et al., 2022). DAIC-WOZ is a widely-used English dataset that collects interviews from 189 participants, recorded in transcripts, audios, and videos. Each participant is accompanied by a PHQ-8 score (Kroenke et al., 2009), and those with scores >= 10 are labeled as depressed ([D]), while the others are labeled as control ([C]). DAIC-WOZ has a fixed data split, and we follow previous studies by using the development set for evaluation since the labels of the test set are unavailable. EATD is a newly released Chinese dataset that consists of interviews conducted with 162 student volunteers, recorded in transcripts and audios. Each participant is accompanied by an SDS score (Zung, 1965), and those with scores >= 53 are labeled as depressed. EATD is split into training and development sets via 3-fold cross-validation with train:dev = 2:1. The detailed statistics of datasets are shown in Table 2. The details of interview recordings and pre-processing methods can be found in Appendix A.

Dataset	Size	Category	Round	Token	Duration
DAIC-WOZ train	107	[D] 30 [C] 77	6,069 ($\bar{x}$=57)	149,149 ($\bar{x}$=1,394)	26h53m ($\bar{x}$=15m04s)
DAIC-WOZ dev	35	[D] 12 [C] 23	1,909 ($\bar{x}$=55)	53,588 ($\bar{x}$=1,531)	10h01m ($\bar{x}$=17m09s)
EATD train	108	[D] 23/20/24 [C] 85/88/84	324 ($\bar{x}$=3)	19,994 ($\bar{x}$=181)	1h22m ($\bar{x}$=47s)
EATD dev	54	[D] 7/10/6 [C] 47/44/48	162 ($\bar{x}$=3)	9,968 ($\bar{x}$=177)	1h1m ($\bar{x}$=49s)

Table 2: Detailed statistics of DAIC-WOZ and EATD.

Settings We first discuss feature pre-processing. For DAIC-WOZ, we use the GloVe.840B.300d embeddings (Pennington et al., 2014) to vectorize interview questions and answer transcripts. The videos and audios have already been processed by COVAREP (Degottex et al., 2014) and OpenFace (Baltrušaitis et al., 2016), respectively. For EATD, we use the pre-trained Chinese BERT (Cui et al., 2020) as the word embedder. EATD only provides unprocessed raw audios, so we extract the extended Geneva Minimalistic Acoustic Parameter Set (eGeMAPS) (Eyben et al., 2016) via OpenSMILE (Eyben et al., 2010) as acoustic features.

For the implementation of SEGA, the dimension of all hidden states is d_h=256. The layer number of GAT is L=2. The number of attention head K=8. We use `gpt-3.5-turbo-0613` for principle-guided data augmentation. In the prompt, we include N=2 manually written samples as the demonstration. We collect three rephrased results for each transcript, but only use the first one since no significant performance difference is observed, resulting in 2x training samples. We perform contrastive learning within a single batch with τ=0.05. For DAIC-WOZ/EATD, we train the models for 300/100 epochs using Adam optimizer (Kingma and Ba, 2015) with a learning rate 1e-4/2e-5 and batch size 8. We run all experiments on a single Tesla V100 32G GPU in Ubuntu 16.04. SEGA contains 2.6M trainable parameters and requires 0.33 GPU hours for training. The hyperparameter ranges can be found in Appendix B.

Following previous studies (Burdisso et al., 2023), we use depressed, control (i.e., non-depressed), and macro F1-scores as the metrics. We select the checkpoint for evaluation based on macro F1-scores. The final results for comparison are the average scores of 3 runs with random seeds (for DAIC-WOZ) or folds (for EATD)[3].

4.2 Compared Methods

After reviewing the literature on depression detection, we find that the pre-processing of clinical interviews in different methods varies considerably, making it inaccurate to compare their reported results directly. For instance, Niu et al. (2021) employ manual cleaning of transcripts, while Shen et al. (2022) group every ten participant answers as one sample. Additionally, there are hardly any reported results on the recently released EATD dataset. Therefore, we select the four latest top-performing methods involving participant transcripts, audios, videos, and interview questions used in SEGA. Since most models are not open-sourced, we carefully replicate them following the original papers. Our implementation may serve as a basis for fair comparison in future research.

ω-GCN (Burdisso et al., 2023) is a uni-modal model that leverages answer transcripts. **EATD-Fusion** (Shen et al., 2022) is a bi-modal model that leverages answer transcripts and audios. **MFM-Att** (Fang et al., 2022) is a tri-modal model that lever-
