the distance between two sentences is the minimal distance between its state representations:

$$\rho(s, s') = \min_{h \in \mathcal{H}(s), h' \in \mathcal{H}(s')} \rho(h, h').$$

We collect training triples at the beginning of each epoch. For each sentence we search for its nearest neighbours using approximate nearest neighbour (ANN) search with cosine distance. We implement ANN search using Faiss. After processing all the batches we recalculate the hidden representations and update the vector storage. The hyperparameters of contrastive fine-tuning are given in Table 11.

G Additional results

G.1 Additional results on LORuGEC

Here we evaluate two more models on LORuGEC, repeating the setup of Section 5. We select Llama3-8B-Instruct¹⁶(Meta, 2024) as a medium-size open-source model and GPT4o-2024-05-13(OpenAI, 2023) as a large open-source model. The results are provided in Table 12. The models follow the same pattern as the Qwen2.5-7B and YandexGPT models (see Table 4) with GECTOR+FT being the best few-shot selection method. That means that our approach works both for strong closed-source models and comparably weaker open-source models with limited knowledge of Russian. Interestingly, the GPT4o model almost reaches the level of YandexGPT5-Pro, providing additional evidence that huge language models trained on large amounts of different texts, e.g. educational ones, may not only memorize the rules encountered in these texts, but also apply them to similar language material.

G.2 Additional results on GERA

The comparison of different few-shot selection method on GERA is provided in Table 13.

G.3 Results for English

We evaluate our approach on English, using the development subset of W&I corpus(Bryant et al., 2019), also known as BEA-2019, as our evaluation corpus. We follow the setup of the previous subsection using Qwen2.5-7B Instruct as an open-source model and GPT4o-05-13(OpenAI, 2023) as the closed-source one. The main difference with LORuGEC experiments is the absence of analogous rule-type-annotated corpus for English. Therefore, we cannot readily adapt the contrastive tuning stage. We tried to replace the rule labels with the ERRANT edit types, however, most of the sentences contained several errors of different types. We attempted to train the encoder on the subset of single-error sentences but the approach was not successful.

The generative LLM is finetuned on the W&I corpus training set. For encoder training we utilize a larger cLang-8 corpus (Rothe et al., 2021), corpus parameters are given in Table 14. Note that we don't use BEA-2019 for GECTOR encoder training

BEA-2019 dev	4384	Testing

Table 14: GEC corpora used for experiments on English.

Results on BEA-2019 development set are available in Table 15. Here we use ERRANT-3.0 (Bryant et al., 2017) to obtain evaluation metrics. Comparing them to the results of the previous subsection, we observe the following:

1. Again, retriever-based selection of demonstration samples produces small but stable improvements. These improvements are stable across models and the number of few-shot examples.

2. However, the difference with baseline is smaller than for LORuGEC. In particular, the achieved enhancements are not sufficient to reach the level of finetuned model. We hypothesize that the reason for this is the larger size of training corpus in case of English that allows the finetuned model to achieve larger improvements over the zero-shot version.

H Implementation of our Approach

We present several responses of the YandexGPT-lite model to the sentences from LORuGEC, which were obtained using different kinds of 1-shot demonstration: random, GECTOR-based or finetuned GECTOR-based, see Figures 3 and 4.

Method	few-shot method	k	Qwen2.5-7B			GPT4o-05-13		
Zero-shot	–	0	36.2	43.4	37.5	34.2	52.6	36.8
few-shot	random	1	37.9	42.8	38.8	35.7	51.5	38.0

LLM external	–	0	53.4	48.8	52.4	NA	NA	NA

Table 15: Comparison of different few-shot example selection methods on BEA development set.

Source sentence	Врачи буквально обомлели оттого , что увидели.		The doctors literally were stunned by what they saw.
Target sentence	Врачи буквально обомлели от того , что увидели.		(<i>om togo</i> ‘by what’ in this context must be written separately.)
Random 1-shot demonstration			
Исходное предложение:	Куда запропастилась моя подруженька ?		The initial sentence: Where is my girl-friend ?
Исправленное предложение:	Куда запропастилась моя подруженька ?		The correct sentence: Where is my girl-friend ?
			(The word <i>подруженька</i> ‘girl-friend’ contained a spelling error in the initial sentence.)
LLM Response	Врачи буквально обомлели оттого , что увидели.		(The model did not correct the sentence.)
GECTOR 1-shot demonstration			
Исходное предложение:	Родители были счастливы от того , что Владик передумал.		The initial sentence: Parents were happy be-cause Vladik changed his mind.
Исправленное предложение:	Родители были счастливы оттого , что Владик передумал.		The correct sentence: Parents were happy be-cause Vladik changed his mind.
			(The word <i>оттого</i> ‘because’ must be written in one word in this context.)
LLM Response	Врачи буквально обомлели оттого , что увидели.		(The model did not correct the sentence.)
GECTOR-FT 1-shot demonstration			
Исходное предложение:	Я расстроился оттого , что увидел.		The initial sentence: I was upset by what I saw.
Исправленное предложение:	Я расстроился от того , что увидел.		The correct sentence: I was upset by what I saw.
			(<i>om togo</i> ‘by what’ in this context must be written separately.)
LLM Response	Врачи буквально обомлели от того , что увидели .		(The model successfully corrected the sentence.)
Conclusion	Only the finetuned GECTOR was able to obtain the sentence with the same preposition and pronoun <i>om togo</i> ‘by what’ and the same context in which it must be written separately, not in one word, as opposed to the demonstration chosen by the basic GECTOR. Random selection had a spelling error in it which did not at all resemble the target error. Consequently, LLM was able to correct the sentence only with the GECTOR-FT demonstration.		

Figure 3: Implementation of our approach on the sentence from LORuGEC using YandexGPT5-Lite model. Incorrect parts are marked with red, corrected parts are marked with green for illustrative purposes. There were no highlights in experiments. In the second column we also present English translations of the sentence and demonstrations as well as comments to them in brackets. The same holds for Figure 4.

Source sentence	Кажется, это сон, и я сплю.	It seems, it's a dream, and I'm dreaming.
Target sentence	Кажется, это сон, и я сплю.	(Кажется'It seems' is a part of the sentence that is related to both clauses <i>это сон</i> 'it's a dream' and <i>я сплю</i> 'I'm dreaming' which are connected by the conjunction <i>и</i> 'and', that is why there must not be any commas between the clauses before the conjunction.)
Random 1-shot demonstration		
Исходное предложение: Вы можете подумать, что вас это некасается и даже рассмеяться.. Исправленное предложение: Вы можете подумать, что вас это не касается и даже рассмеяться..		The initial sentence: You may think, that it does not concern you and even laugh.. The correct sentence: You may think, that it does not concern you and even laugh.. (In Russian negative particle <i>не</i> must be written separately from the verb, so <i>не касается</i> 'does not concern' must not be written in one word.)
LLM Response	Кажется, это сон, и я сплю.	(The model did not correct the sentence.)
GECTOR 1-shot demonstration		
Исходное предложение: В это время раскрылась дверь поместья, и вышел начальник дозора. Исправленное предложение: В это время раскрылась дверь поместья, и вышел начальник дозора.		The initial sentence: At that moment, the door of the manor opened, and the head of the watch came out. The correct sentence: At that moment, the door of the manor opened, and the head of the watch came out. (<i>В это время</i> 'at that moment' denotes the time for both the opening of the door (<i>раскрылась дверь поместья</i>) and the arrival of the head of the watch (<i>вышел начальник дозора</i>), so there should not be any commas before the conjunction <i>и</i> 'and' which connects these two clauses.)
LLM Response	Кажется, это сон, и я сплю.	(The model successfully corrected the sentence.)
GECTOR-FT 1-shot demonstration		
Исходное предложение: Самгин понимал, что говорит плохо, и что слова его не доходят до неё. Исправленное предложение: Самгин понимал, что говорит плохо, и что слова его не доходят до неё.		The initial sentence: Samgin knew that he was speaking badly, and that his words were not reaching her. The correct sentence: Samgin knew that he was speaking badly, and that his words were not reaching her. (<i>Самгин понимал</i> 'Samgin knew' about both facts: that he was speaking badly (<i>что говорит плохо</i>) and that his words were not reaching her (<i>что слова его не доходят до неё</i>), so there must be no comma before the conjunction <i>и</i> 'and' that connects these clauses.)
LLM Response	Кажется, это сон, и я сплю.	(The model successfully corrected the sentence)
Conclusion	Both GECTOR-based models selected demonstrations that follow the punctuation pattern of the source sentence. These demonstrations allowed the LLM to effectively correct the sentence, unlike the randomly selected sentence which had to do with incorrect spelling.	

Figure 4: Implementation of our approach on another sentence from LORuGEC.

Explaining Holistic Essay Scores in Comparative Judgment Assessments by Predicting Scores on Rubrics

Abstract

Comparative judgment (CJ) is an assessment method in which multiple assessors determine the holistic quality of essays through pairwise comparisons. While CJ is recognized for generating reliable and valid scores, it falls short in providing transparency about the specific quality aspects these holistic scores represent. Our study addresses this limitation by predicting scores on a set of rubrics that measure text quality, thereby explaining the holistic scores derived from CJ. We developed feature-based machine learning models that leveraged complexity and genre features extracted from a collection of Dutch essays. We evaluated the predictability of rubric scores for text quality based on linguistic features. Subsequently, we evaluated the validity of the predicted rubric scores by examining their ability to explain the holistic scores derived from CJ. Our findings indicate that feature-based prediction models can predict relevant rubric scores moderately well. Furthermore, the predictions can be used to explain holistic scores from CJ, despite certain biases. This automated approach to explain holistic quality scores from CJ can enhance the transparency of CJ assessments and simplify the evaluation of their validity.

1 Introduction

Comparative judgment (CJ) is a widely used method for educational assessments, particularly for evaluating writing quality of essays (Baniya et al., 2019; Steedle and Ferrara, 2016; van Daal et al., 2016). In CJ, assessors repeatedly compare (different) pairs of essays and determine which one is superior in quality each time. Then, the Bradley-Terry-Luce (BTL) model (Bradley and Terry, 1952; Luce, 1959), relates the probability of one essay being preferred over another to the quality scores of the essays that are compared. Based on the judgments of assessors, the quality scores of essays are estimated.

CJ offers several advantages over traditional rubric-based assessments. Firstly, it allows assessors to use their professional expertise and intuition without strictly adhering to predetermined rubrics, making CJ a more natural assessment method (Bloxham, 2009; Laming, 2003). Assessors may have different conceptualizations of quality; some prioritize essay argumentation and organization, while others focus on language conventions (Lesterhuis et al., 2022). Even when assessors focus on different aspects, van Daal et al. (2016) found that their pairwise comparisons still reflected construct-relevant aspects of writing quality. Secondly, since CJ incorporates multiple judgments from various assessors, the resulting essay quality scores are generally reliable and valid, reflecting a consensus among the assessors (Lesterhuis et al., 2022; Verhavert et al., 2019; van Daal et al., 2016). Although CJ is a valid and reliable assessment method, the holistic scores it produces lack transparency regarding their specific meaning. Since judgments are made holistically, the assessors' decision-making process remains unclear. Assessors can provide feedback while making judgments, but this takes more time and may shift their focus from the overall quality of essays to specific analytic criteria (Verhavert et al., 2019). Finding a new way to explain holistic scores is therefore crucial for making CJ assessments more transparent and can also serve as a form of feedback.

In this study, we investigate the use of feature-based prediction models to explain holistic quality scores from CJ, with the goal of enhancing their transparency.

Our research addresses the following questions:

1. How reliably can scores on a set of rubrics measuring text quality be predicted based on linguistic features of essay texts?
2. To what extent do these predicted rubric scores accurately reflect the holistic quality

scores of essays obtained with CJ?

Our study comprised two phases. First, we conducted a machine learning experiment to assess how well rubric scores could be predicted from linguistic features of Dutch essays. Second, we performed a regression analysis to evaluate the validity of the predicted scores in explaining the holistic scores obtained with CJ.

2 Background

2.1 Comparative Judgment Assessments

CJ functions as an alternative assessment method to rubric scoring and has been shown to produce reliable and valid scores (Verhavert et al., 2019; Lesterhuis et al., 2022; van Daal et al., 2016; Heldsinger and Humphry, 2010). While primarily known for assessing essay quality, CJ has also been effectively used for various other types of assessments. These include evaluating conceptual understanding (Jones et al., 2019), mathematical problem-solving skills (Jones and Inglis, 2015), design portfolios (Newhouse, 2014), formative assessments (Potter et al., 2017; Bartholomew et al., 2019), and comparing assessment standards across examination boards (Bramley, 2007; D'Arcy, 1997).

Generally, CJ assessments are conducted by iterating through three key steps. In the first step, a pair of essays is chosen and assigned to one of several assessors. In the second step, the assessor compares the two essays and determines which demonstrates higher quality. This relative assessment approach is considered more intuitive than absolute assessments, such as rubric-based scoring. As Laming (2003) noted, all judgments inherently involve comparing one entity to another, and CJ explicitly makes use of this principle. In the third step, the BTL model is applied to link the outcomes of all pairwise comparisons to a quality scale (Bradley and Terry, 1952; Luce, 1959). The BTL model relates the probability of one essay being favored over another to the difference in their quality scores, expressed as logit values. Specifically, this probability is determined by the sigmoid function of the quality score difference: the greater the quality score of the first essay relative to the second, the higher the probability it will win the comparison. The quality scores in BTL model are continuously updated based on the judgments that assessors make. The assessment concludes once a sufficient number of judgments have been collected, typically requiring each essay to be compared 10

to 14 times to ensure reliable quality scores. Ultimately, the holistic scores derived from CJ are both reliable and valid, as they stem from numerous pairwise comparisons by multiple assessors (van Daal et al., 2016; Lesterhuis et al., 2022).

However, when the CJ assessment is completed, the resulting quality scores for essays lack clarity regarding what they represent. The issue stems from the scores being based on holistic pairwise comparisons by assessors (Steedle and Ferrara, 2016; Kelly et al., 2022), a method that, while reliable and valid, lacks the transparency offered by detailed rubric-based marking (Jonsson, 2014; Mortier et al., 2015). As a result of this ambiguity, the feedback function of the scores to students is hindered, and the validation of the assessors' judgments is complicated. Even though assessors can provide feedback comments when making judgments, doing so extensively would be time-consuming and reduce assessment efficiency. Furthermore, writing numerous comments to individual essays can lead assessors to adopt a more analytical approach (Verhavert et al., 2019), which conflicts with the holistic nature of CJ assessments (van Daal et al., 2016). Hence, there is a need to enhance the transparency of the holistic scores obtained with CJ without requiring more effort from assessors. To achieve this, we propose automatically predicting the scores on rubrics to explain the holistic scores derived from CJ. This prediction task is similar to that of automated essay scoring (AES).

2.2 Automated Essay Scoring

With recent advancements in NLP methods, AES for summative assessments and automatic writing evaluation (AWE) for formative assessments have received increasing attention. Initially, systems relied on analyzing hand-crafted linguistic features from essay texts to predict scores (Ke and Ng, 2019). However, following the ASAP Kaggle competition organized by the Hewlett Foundation (Hamner et al., 2012), deep learning models have gained prominence in this domain, often surpassing traditional feature-based prediction models in terms of agreement with human scoring (Dong et al., 2017; Taghipour and Ng, 2016; Wang et al., 2022). Despite these advances, practical AES and AWE systems, such as PEG (Dikli, 2006) and e-rater (Burstein et al., 2004), continue to rely heavily on hand-crafted linguistic features due to the need for transparency. Especially, text complexity features

such as syntactical complexity and lexical diversity have been shown to have a large predictive power for the writing quality of essays (McNamara et al., 2010). For instance, for English-written essays, the Coh-Matrix (Graesser et al., 2004) and SALAT toolsets (Crossley et al., 2023) are commonly used to extract complex linguistic features for AES (McNamara et al., 2015; Li and Liu, 2017; Latifi and Gierl, 2021; Kumar and Boulanger, 2020).

While feature-based AES models and AWE systems provide more transparency, the linguistic features themselves, such as complexity and cohesion features, can still be hard to interpret and may lack pedagogical clarity for students and teachers. As Deane (2013b) stated, using linguistic features as proxies for writing quality is neither transparent nor instructional for students. Additionally, Crossley (2020) noted that extensive knowledge is required in order to use linguistic features effectively.

As assessors mostly consider higher-order aspects of writing when making pairwise comparisons, such as structure and argumentation (Lesterhuis et al., 2022), linguistic features would not provide the desired transparency about the holistic quality scores. Therefore, in this study, we chose to explain the holistic scores based on more instructional rubrics that measure specific aspects of writing quality. We predicted scores across these rubrics based on linguistic features extracted from essays. The automated scoring task of predicting scores across multiple rubrics is also referred to as 'multi-trait' scoring within AES literature (He et al., 2022; Do et al., 2023; Mathias and Bhattacharyya, 2020).

3 Method

3.1 Data

We used data previously collected by Coertjens et al. (2017). The dataset, detailed in Table 1, included a total of 104 argumentative essays in Dutch written by students from secondary education. The students could choose to write an essay on one of the topics: (1) having children, (2) organ donation, and (3) stress experienced by students. Despite the differences in topics, the essays were quite similar in terms of the assessed competence: the ability to effectively integrate source material within argumentative writing. This allowed us to combine the essays from different assignments into one dataset for model training. We selected this data because it is the only CJ dataset where essays are labeled

with both holistic and rubric scores.¹

Assignment	Essays	Tokens	Tokens/Essay
	<i>N</i>		<i>M</i> ± <i>SD</i>
1. Children	34	11167	328 (± 92)
2. Organ	35	11358	293 (± 93)
3. Stress	35	11859	304 (± 97)

Table 1: Overview of the argumentative writing assignment gathered by Coertjens et al. (2017). Tokenization was performed using the Dutch n1_core_news_sm model from spaCy (Explosion, 2023).

3.1.1 Holistic Scores

Coertjens et al. (2017) used CJ to obtain holistic scores of essay quality. During the assessment, 40 assessors made pairwise comparisons and each essay was compared 25 times. The assessors were asked which essay in this pair is better in terms of argumentation. This assessment resulted in holistic scores with a reliability of 0.87, as measured by scale separation reliability (Verhavert et al., 2018).

3.1.2 Scores on Rubrics

Coertjens et al. (2017) asked 18 assessors to evaluate the same essays using a rubric set designed to measure 20 aspects of text quality. These were different assessors from those who scored the essays holistically with CJ. These aspects were grouped into four main components: structure (6 rubrics), content (7 rubrics), argumentation (4 rubrics), and language conventions (3 rubrics). The rubrics, originally developed and validated by Rijlaarsdam et al. (1994), were adapted by Coertjens et al. (2017) for this particular assignment on argumentative writing. According to Coertjens et al. (2017), the intraclass correlation coefficient was 0.85 after five different assessors assessed each essay. For an overview and description of all rubrics, refer to Appendix A.

3.2 Features

To extract linguistic features from the essays, we used T-Scan (Maat et al., 2014) because Dascalu et al. (2017) previously demonstrated that its features have strong predictive power for automated essay scoring. Using the T-Scan API (v0.10), we extracted 476 document-level features related to lexical complexity, sentence complexity, referential cohesion, lexical diversity, lexical semantics,

¹The data gathered by Lesterhuis et al. (2022), for example, includes a superset of the essays used by Coertjens et al. (2017), but it does not include any rubric scores.

and personal style. For details on the T-Scan configuration, see Appendix B.

Since T-Scan does not account for spelling and grammatical errors, we also used the LanguageTool package (v2.8.1) in Python to count the number of language mistakes in each essay. We normalized these counts by dividing them by the total number of tokens per essay (see Table 1).

3.3 Models

We trained regression models using the extracted features to predict scores of essay quality. This involved training multiple single-target regression models, with each model predicting either the holistic score or one of the rubric scores.

We experimented with five machine learning models for the regression tasks: **Lasso Regression**, **ElasticNet**, **Random Forest**, and **XGBoost** using scikit-learn 1.4.0 (Pedregosa et al., 2011), and **LightGBM** 4.6.0 (Ke et al., 2017) in Python 3.9.12. We applied min-max normalization to each input feature from T-Scan as well as the rubric scores. Before training the models, we excluded features from the training set that had a low Pearson correlation with the target. A correlation threshold of 0.12 was chosen based on Lovakov and Agadullina (2021).

For each individual model, we ran hyperparameter tuning on the training set using a randomized search strategy with up to 100 iterations. The optimal hyperparameters were selected based on the lowest mean absolute error (MAE) between the predicted and actual rubric scores across 20 folds.

3.4 Evaluation

To optimize the prediction performance and avoid overfitting on a small dataset, we performed leave-one-out cross-validation (LOOCV). This involved leaving out one essay for evaluation and training a model on all remaining essays, repeating the process for each essay in the dataset. The hyperparameter tuning with 20-fold cross-validation, as mentioned before, was conducted on the training data for each run of LOOCV. Refer to Appendix C for an overview of the selected hyperparameters.

3.4.1 Metrics

Using the optimal model and hyperparameters for each rubric, we evaluated the predictions of the rubric scores with various metrics on all left-out essays during LOOCV. We used the **squared Pearson correlation coefficient** (R^2) between predicted

and actual scores. R^2 is a measure of score reliability in classical test theory (Brennan, 2010) and is often used to measure the reliability of quality scores estimated from CJ relative to true scores (Verhavert et al., 2018).

Additionally, we used the **quadratic weighted kappa** (QWK) (Cohen, 1968) and the **mean absolute error** (MAE), two commonly used metrics in AES research (Ramesh and Sanampudi, 2022). QWK is a metric based on Cohen’s kappa that measures agreement between predicted and human-given scores, penalizing more divergent predictions. A score of 1 indicates perfect agreement, while -1 indicates perfect disagreement.

3.4.2 Predictive Power

To validate whether the predicted rubric scores accurately measure the assessed writing quality with CJ, we evaluated their predictive power for the holistic scores using linear regression models. Using the statsmodels package (0.13.2) (Seabold and Perktold, 2010), we constructed two regression models measuring the effects of rubric scores on holistic scores from CJ:

- **Regression Model 1** uses the rubric scores predicted by the model (see Section 3.3) as covariates and holistic quality scores from CJ as outcomes.
- **Regression Model 2** uses the rubric scores given by assessors as covariates and holistic quality scores from CJ as outcomes.

We compared their goodness-of-fit using the Akaike information criterion (AIC) and Bayesian information criterion (BIC), as well as the explained variance (R^2) of the holistic scores. In the context of statistical modeling, R^2 measures the proportion of variance in holistic scores that is explained by the (predicted) scores on rubrics. As it can be inflated by adding many covariates, we adjusted R^2 for the number of covariates.

We expected that Model 2, which uses human-assigned rubric scores, would fit the holistic scores better than Model 1, which uses predicted rubric scores. Therefore, we aimed to evaluate how closely the fit of Model 1 approximates that of Model 2.

To further investigate any potential biases in the effects (i.e., coefficients) of the predicted rubric scores on the holistic scores, we compared the coefficients of Model 1 with those of Model 2, along

with their confidence intervals. We calculated Student's t-tests to evaluate whether the coefficients are significantly different from zero. We omitted intercepts for both models to make the coefficients comparable, and inverted the normalization of all variables to their original scales.

4 Results

4.1 Predicting Scores on Rubrics

Table 2 shows the performance of the rubric scoring models evaluated using LOOCV. ElasticNet consistently demonstrated the best performance in predicting most rubric scores (9/20 rubrics), followed by XGBoost (5/20 rubrics), Lasso (3/20 rubrics), RandomForest (2/20 rubrics), and LightGBM (1/20 rubrics). Overall, model performance was moderately effective across all evaluation metrics, which is expected given the small sample size.

Performance varied notably across the different rubrics. Among all rubrics pertaining to essay structure, predictions showed the highest reliability (R^2) for Construction, Relationships, and Continuity, and the highest agreement (QWK) with human scores for Title compared to other rubrics. This suggests that the linguistic features employed in the models can capture markers of essay organization, despite the overall moderate prediction performance.

Among rubrics pertaining to essay content, scores on References and Citations were the most accurately predicted, but generally, the predictions were only moderate or poor. The scores for Introduction, Persuasion, Reader Focus, Reader Engagement, and Conclusion were comparatively worse. This suggests that the linguistic features employed in the models can capture some markers of essay content, albeit with limited accuracy.

Among rubrics pertaining to argumentation, Support and Relevance showed the best prediction performance, whereas Indication and Reference Cohesion Relationships were less accurately predicted. This shows the model's ability to capture, to a certain extent, the argumentative writing level related to how sources were integrated and used to support claims.

Generally, the rubrics pertaining to language were poorly predicted. Among these rubrics, the scores for Style were most accurately predicted, while predictions for Grammar and Spelling, and Punctuation were comparatively worse. Hence, the assessors' scoring of language conventions differed

from the model predictions.

4.2 Explaining Holistic Scores with Predictions

After evaluating the predicted scores on rubrics, we examined how well these scores can explain the holistic scores obtained through CJ. Table 3 shows the goodness-of-fit of the two models. As expected, Model 2 provided a better fit for the holistic scores than Model 1, as evidenced by smaller AIC and BIC values. Additionally, Model 2 explained 12% more of the variance in holistic scores compared to Model 1, as indicated by the higher R^2 . This difference was even more pronounced when considering the adjusted R^2 values. Although the predicted rubric scores explained the holistic scores reasonably well (Model 1), 40% of the variance in holistic scores still remained unaccounted for. In contrast, the rubric scores given by assessors (Model 2) had greater predictive power for the holistic scores. However, even in Model 2, 28% of the variance in holistic scores remained unexplained, indicating a difference in how assessors score essays with rubrics versus holistically using CJ.

Figure 1 illustrates the biases in the coefficients of the predicted rubrics on the holistic scores (Model 1) with respect to the coefficients of the assessor-assigned rubric scores (Model 2). Overall, the coefficients for the rubrics in both models were similar in magnitude and direction, which supports the validity of the predicted rubric scores. However, Model 1 exhibited some systematic biases, as it tends to overshoot the magnitude of the coefficients. Specifically, the coefficients for rubrics pertaining to essay structure showed upward biases, except for Subtopic. Conversely, the coefficients for rubrics related to content displayed downward biases, with the exception of Introduction and Citations.

The most significant coefficients in Model 2 were Relationships, References, Conclusion, and Grammar and Spelling. Except for Grammar and Spelling, these rubrics were all reasonably well approximated by Model 1, as their coefficients were similar and their confidence intervals overlapped. This shows that predicted rubric scores accurately explained the holistic scores based on the most important rubrics scored by assessors. However, of these rubrics, only the coefficients for Relationships, and Grammar and Spelling were significantly different from zero in Model 1. This can be attributed to the wider confidence intervals of Model

Aspect	Rubric	Best Model	R ²	QWK	MAE

Table 3: Comparison of model fit for linear regression models with holistic scores from CJ as the outcome, where Regression Model 1 used predicted scores on rubrics as covariates and Regression Model 2 used scores on rubrics provided by assessors as covariates.

1 compared to Model 2.

When examining rubrics that were most accurately predicted (see Table 2), it is clear that their impact on holistic scores (Model 1) closely resembled that of scores given by assessors (Model 2). This similarity was evident for Relationships, References, and Citations, where Model 1’s coefficients aligned with those of Model 2, and their confidence intervals significantly overlapped. Although Support and Relevance were also predicted more accurately, their coefficients exhibited great uncertainty, as indicated by wider confidence intervals compared to Model 2, especially for Support. This indicates a potential lack of validity of the predicted rubrics related to argumentation.

Conversely, when the rubric was predicted more inaccurately, their coefficients showed more bias. This was observed for Layout and Reader Focus, as their rubric scores were poorly predicted and their coefficients overestimated. Similarly, the rubrics related to language were inaccurately predicted when compared to other rubrics, resulting in coefficients with large biases. More specifically, the importance of sound Grammar and Spelling was vastly overestimated using the predicted rubric scores, as these scores are much higher than when rubric scores were given by teachers. Conversely, the importance of correct Punctuation and Style was overly negative when using the predictions compared to the scores given by teachers. This shows that teachers score rubrics differently and that these scores contribute less to the holistic scores than when using predictions.

5 Discussion

The lack of transparency in holistic scores obtained through CJ limits the practical application of this assessment method (Steedle and Ferrara, 2016). Our analysis reveals that rubric scores can be predicted moderately well in terms of reliability and

Figure 1: Comparison of regression coefficients of Model 1 and Model 2 for all rubric scores with 95% confidence intervals, where significance is denoted as * $p < 0.05$, ** at $p < 0.01$, and *** at $p < 0.001$.

agreement with assessor-assigned scores, with the best predictions for the rubrics relevant to the assignment on argumentative writing. However, not all rubrics can be predicted well, which can be due to the limited size of the training set.

Furthermore, the predicted rubric scores have explanatory power for holistic scores derived from CJ, thus showing potential for an automated approach to provide more transparency. However, it is unlikely that the rubric scores can fully explain the differences in holistic scores from CJ, as even the assessor-assigned scores do not fully explain them. This is not surprising, given that holistic scoring with CJ involves relative assessments while rubric-based scoring requires absolute assessments. While both assessment approaches are reliable on their own, they may yield slightly different results (Coertjens et al., 2017).

Generally, the relationship between predicted rubrics and holistic scores is similar to that of rubric scores given by assessors, which supports the validity of the predictions. Most importantly, we find that the validity of the predicted rubric scores depends on their predictability from linguistic features. The rubrics that demonstrate better predictability can also explain the holistic scores with minimal bias. This shows that predicted scores

on assignment-relevant rubrics can explain, in part, the holistic scores from CJ.

However, there are notable differences between human scoring and automated scoring (Ben-Simon and Bennett, 2007). Previously, Ramineni and Williamson (2018) found that the e-rater AES system often overvalues organization while undervaluing content. Our findings generally support this, as most structure-related rubrics exert an overly positive influence on holistic scores when predicted compared to when scored by assessors, whereas most content-related rubrics show an overly negative influence when predicted compared to when assessed by humans.

While certain argumentation-related rubrics can be predicted comparatively well, their influence on the holistic scores shows more uncertainty. As Attali (2007) stated, agreement between human and automated scores does not directly imply that the scores are valid. This discrepancy may be attributed to the inherent difficulty in measuring the quality of argumentation based on linguistic features (Deane, 2013a). Hence, more elaborate linguistic features based on argument mining may be needed for more valid predictions of argumentative-related rubrics.

Additionally, there is a difference between how

language-related rubrics are predicted and how they are assessed. These rubrics prove difficult to predict based on linguistic features, and their effect on holistic quality scores is biased, either undervalued or overvalued. Previously, [Ramineni and Williamson \(2018\)](#) noted that the e-rater AES system severely undervalues grammatical mistakes for essay scoring. Further analysis is needed to uncover the potential causes of this bias. However, for CJ assessments, language conventions are generally less important when making pairwise comparisons of essays ([Lesterhuis et al., 2022](#)).

6 Conclusion

To address the lack of transparency of holistic scores from CJ assessments, we used feature-based models to predict scores on a set of rubrics that explain the holistic scores. Based on linguistic features extracted with T-Scan, rubric scores of Dutch essays were predicted with moderate success. However, we found that the most relevant rubrics were predicted more reliably compared to other rubrics. Furthermore, we noted that these predicted scores on rubrics can explain holistic scores from CJ in a manner comparable to the assessor-assigned rubric scores.

While the automated predictions of rubrics offer more transparency regarding the meaning of holistic scores, they do differ from human assessor scores in certain respects. For instance, structure-related rubrics were slightly overvalued, content-related rubrics were slightly undervalued, and the effect of argumentation-related rubrics showed more uncertainty. Additionally, predictions for language convention rubrics diverged notably from assessor-given scores.

Despite some discrepancies in how predicted rubric scores explain holistic scores compared to rubrics scored by assessors, they generally aligned well for the most important rubrics and demonstrate predictive power. This suggests that predicting scores on rubrics can help explain the holistic scores obtained with CJ. However, their acceptance and effectiveness as feedback for students require future research.

Limitations

Even though the scores given by assessors are reliable and valid, the size of the available dataset used for training is rather limited, which could explain the moderate prediction performance. We expect

that increasing the dataset would improve prediction performance and, therefore, produce scores on rubrics that better explain the holistic scores from CJ. With a larger training set, it would be possible to determine the best-performing hyperparameters and models for each rubric for all essays, rather than per fold as was done in this study. This approach would enhance the generalizability of the models' performance.

Future research could, for example, leverage the larger ASAP dataset, which contains English essays scored on rubrics such as ideas, organization, style, and conventions, for different writing genres ([Hammer et al., 2012](#)). However, the granularity of features is higher in this dataset, which would provide less specific explanations than in the current study.

In case only a small set of rubric-scored texts is available, it may be more suitable to extract rubric scores using language models, which can capture complex textual features. Large Language Models (LLMs) have been applied for this purpose through fine-tuning ([Do et al., 2024](#)) or zero-shot prompting ([Lee et al., 2024](#)). However, relying on LLMs would make it less transparent how the predicted scores are derived compared to using hand-crafted linguistic features, as in this study.

To better understand the validity of predicted scores on rubrics in relation to how they are predicted, future research could examine the most important features for making these predictions. This is important as feature-based approaches for AES do not capture meaning directly. Previously, it has been noted that essay length is highly influential for AES models, and it is advised that its effect be studied by controlling for it ([Chodorow and Burstein, 2004](#)). Text length is especially influential for structure, content, and argumentation, and less so for language ([Enright and Quinlan, 2010](#); [Barkaoui and Woodworth, 2023](#)). While essay length is a valid factor that human assessors also consider, its disproportionate influence can be problematic. Moreover, analyzing the importance of linguistic features in the model's predictions can help clarify why language-related rubrics were predicted with low reliability and validity. This can be achieved by evaluating whether features extracted with LanguageTool significantly contributed to the prediction of language-related rubric scores.

Additionally, interpreting the coefficients of a linear regression model as effects of rubric scores on holistic scores requires caution. Rubrics measuring

aspects of text quality tend to be highly correlated, which raises the potential for multicollinearity. To gain a more accurate understanding of how rubric scores influence the holistic scores, we recommend employing regularization techniques or incorporating interaction effects into the model. These approaches can help mitigate the challenges posed by correlated predictors and provide clearer insights into the effects of rubric scores on holistic scores from CJ. Furthermore, the validity of the predicted scores on rubrics for explaining holistic scores is contingent on the assessment context. In second language (L2) writing, for instance, criteria such as language accuracy may be weighted more heavily than they were in the L1 context of this study. Therefore, future research is essential to validate these findings across different assessment contexts.

A Rubric Description

Main Component	Rubric	Description
Structure	Title	The text has a title that clearly matches the content of the text.
Structure	Construction	The text contains a clear division into: introduction, argumentation, and conclusion.
Structure	Layout	The text is well-organized. There is a clear division into paragraphs. Paragraphs are separated by: blank lines, indentation, or starting on a new line.
Structure	Subtopic	Each paragraph has its own single (sub)topic.
Structure	Relationships between Paragraphs	There is a clear 'train of thought' between paragraphs: based on the text, coherence relationships between paragraphs can be clearly (easily) identified.
Structure	Continuity	Information that belongs together is also grouped together in the text.
Content	Introduction	In the introduction, the proposition/statement is presented, and optionally, the writer's opinion on the proposition is also made clear.
Content	Persuasion	It is clear what the writer wants to convince the reader of: a choice for or against the presented proposition.
Content	References	The text contains at least two (parts of) references, which are meaningfully incorporated into the text. For example, they support the argumentation or are used as an example in the introduction.
Content	Citations (quoting from references)	The quotes from the references are correctly marked in the text. Direct quotes (between quotation marks) and paraphrases both have a source citation.
Content	Reader Focus	The text is easily understandable for a reader unfamiliar with the assignment. For example, there is no reference to the writing task assignment or the writer's environment.
Content	Reader Engagement	The reader is clearly engaged with the text through examples referring to daily life or common experiences.
Content	Conclusion	The text contains a clear conclusion that aligns with the rest of the text and from which the writer's opinion is evident. It is clear that this concludes the text.
Argumentation	Support	The argumentation consists of multiple arguments that support the writer's opinion.
Argumentation	Relevance	The argumentation does not contain too much superfluous information, i.e., information that does not contribute to supporting the writer's opinion.
Argumentation	Indication of Argumentation	The arguments are clearly recognizable as arguments; e.g., through the use of constructions like "therefore I believe (do not believe) that...", "I find/think...", "I (do not) agree with this", etc.
Argumentation	Referential and Coherence Relations	The referential and coherence relations are clear when implicit, or explicitly marked. Examples of markers are: therefore, thereby, thus, because, since, first, second, third, then, etc.
Language	Grammar and Spelling	The text contains no grammatical and/or spelling errors.
Language	Punctuation	Punctuation marks are applied correctly.

Language	Style	The tone and word choice are appropriate for the purpose and audience of the text.

Abstract

Automated Essay Scoring (AES) plays a crucial role in assessing language learners' writing quality, reducing grading workload, and providing real-time feedback. The lack of annotated essay datasets inhibits the development of Arabic AES systems. This paper leverages Large Language Models (LLMs) and Transformer models to generate synthetic Arabic essays for AES. We prompt an LLM to generate essays across the Common European Framework of Reference (CEFR) proficiency levels and introduce and compare two approaches to error injection. We create a dataset of 3,040 annotated essays with errors injected using our two methods. Additionally, we develop a BERT-based Arabic AES system calibrated to CEFR levels. Our experimental results demonstrate the effectiveness of our synthetic dataset in improving Arabic AES performance. We make our code and data publicly available.¹

1 Introduction

Automated Essay Scoring (AES) is a technology that automates the evaluation and scoring of essays to assess language learners' writing quality while eliminating the need for human intervention (Shermis and Burstein, 2003). AES has gained great interest due to its significant benefits in the field of education (Lagakis and Demetriadis, 2021; Susanti et al., 2023). AES systems help teachers evaluate many essays with consistent scoring and reduced workload. On the other hand, AES helps students improve their writing quality through rapid real-time scoring and feedback (Hahn et al., 2021).

Unlike for English, it is difficult to develop robust and scalable AES systems for Modern Standard Arabic (MSA), primarily due to the lack of essay datasets necessary for building effective Arabic AES (Lim et al., 2021; Elhaddadi et al., 2024). This

paper presents a framework to tackle the issue of data scarcity and quality by utilizing Transformers and Large Language Models (LLMs) to generate and build a synthetic dataset.

Our approach begins with prompting GPT-4o to generate a variety of Arabic essays covering multiple topics and different writing proficiency levels as defined by the Common European Framework of Reference (CEFR) (Council of Europe, 2001). Subsequently, we use a controlled error injection model to introduce errors into the correct Arabic essays, ensuring that erroneous essays reflect the type of errors that are commonly made by learners of Arabic in real-world scenarios. Our error injection approach consists of two steps: (i) *Error Type Prediction*, where a fine-tuned CAMELBERT MSA model (Inoue et al., 2021) classifies the most likely error type for each word, and (ii) *Error Realization*, where we apply a bigram MLE model to determine the most probable transformation for each predicted error type. Our framework enables the generation of realistic human-like essays, enhancing data augmentation for Arabic AES systems.

Our main contributions are as follows:

- Proposing a framework based on LLMs and Transformers for augmenting Arabic essays that accurately reflect human writing patterns.
- Creating a synthetic Arabic AES dataset with 3,040 essays annotated with CEFR proficiency levels.
- Developing an Arabic AES system using a BERT-based model, enabling accurate and scalable evaluation of Arabic essays based on CEFR standards.

The rest of the paper is organised as follows: §2 reviews related work on AES, §3 describes the dataset, and §4 outlines our data augmentation approach. §5 details the error injection methods, followed by an evaluation in §6. We discuss our results in §7 and §8 presents the conclusion and future work.

2 Related Work

AES has been investigated extensively, particularly in English (Lim et al., 2021; Ramesh and Sanampudi, 2022), where multiple tools have been introduced such as IntelliMetric (Elliott et al., 2003), e-rater (Attali and Burstein, 2006), Grammarly,² Write and Improve³ (Yannakoudakis et al., 2018), and others. The development of English AES systems has been enabled by large scale annotated datasets such as the First Cambridge English (FCE) dataset⁴ (Yannakoudakis et al., 2011), Automated Student Assessment Prize (ASAP) dataset,⁵ the TOEFL11 corpus (Blanchard, 2013), and the ICLE (International Corpus of Learner English) (Granger, 2003). These datasets contain thousands of student essays with proficiency level grades, often along multiple dimensions.

In contrast, Arabic AES research has received less attention. Some studies have applied feature engineering and machine learning to develop models (Alghamdi et al., 2014; Al-Shalabi, 2016; Alobed et al., 2021; Gaheen et al., 2021), but they partially address key challenges, especially the scarcity of large, publicly available annotated datasets for improving Arabic writing quality.

Ghazawi and Simpson (2024) introduced AR-AES, a benchmark of 2,046 undergraduate essays from three university faculties, annotated by two educators per faculty using rubrics to assess academic performance. In contrast, our work focuses on writing proficiency, using the CEFR standard.

Bashendy et al. (2024) presented QAES, the first publicly available trait specific annotations for Arabic AES. QAES extends the Qatari Corpus of Argumentative Writing (QCAW) (Ahmed et al., 2024), which consists of 195 Arabic argumentative essays. They implemented multi-layered annotation of traits such as coherence, organization, grammar, and others. Despite its comprehensive annotation, it is small in size and limited to two prompts. While QAES multi-traits scores are publicly available, the QCAW holistic score is not.

Habash and Palfreyman (2022) presented the Zayed University Arabic-English Bilingual Undergraduate Corpus (ZAEBUC). This corpus comprises non-parallel essays in Arabic and English related to three prompts collected from first-year uni-

versity students with differing writing proficiency. ZAEBUC includes 216 annotated Arabic essays featuring manual annotations for syntactic and morphological characteristics and a CEFR-based proficiency assessment. Again, ZAEBUC is small in size and limited to three prompts.

Researchers have explored data augmentation methods like sampling, noise injection, and paraphrasing to address data scarcity and quality (Li et al., 2022). The recent development of LLMs has paved the way for researchers to explore promising new data synthesis solutions (Wang et al., 2024a; Long et al., 2024). Transformers and LLMs can closely mirror real-world distributions while introducing valuable variations across multiple tasks and domains (Wang et al., 2024b).

GPT models have shown strong capabilities in generating synthetic essays for English AES (Ramesh and Sanampudi, 2022). LLMs and Transformers have also generalized well in Arabic NLP tasks, including Question Answering (Samuel et al., 2024), Code Switching (Alharbi et al., 2024), NER (Sabty et al., 2021), Grammatical Error Correction (Alhafni and Habash, 2025; Solyman et al., 2023), and Sentiment Analysis (Refai et al., 2023). However, to the best of our knowledge no research has utilized such models to generate Arabic essays across CEFR writing proficiency levels.

3 Data: The ZAEBUC Corpus

For all our experiments, we use the ZAEBUC corpus (Habash and Palfreyman, 2022). ZAEBUC comprises essays written by native Arabic speakers, which were manually corrected and annotated for writing proficiency using the CEFR (Council of Europe, 2001) rubrics and scale. Each essay was annotated by three CEFR-proficient bilingual speakers. Habash and Palfreyman (2022), assigned a holistic CEFR level to each essay by converting the three CEFR ratings into numerical scores (ranging from 1 to 6) and then taking the rounded average. The essays in the corpus were limited to three prompt choices on *Social Media*, *Tolerance*, and *Development*; see Table 1. We use the splits created by Alhafni et al. (2023). Table 2 shows the CEFR level distribution of the ZAEBUC corpus based on holistic CEFR scores. The ZAEBUC corpus is limited in size and skewed toward B1–B2 levels, with no A1 or C2 essays. This common imbalance in Arabic learner data motivated our synthetic approach to create a more balanced CEFR distribution.

4 Synthetic Data Augmentation

We propose a synthetic data augmentation approach leveraging the ZAEBUC dataset to generate synthetic essays that align with CEFR rubrics and have features similar to human text. The pipeline utilizes three phases: Building Essay Prompts, Feature Profiling, and finally Data Augmentation.

4.1 Building Essay Prompts

We began by compiling a diverse set of essay prompts across various categories and CEFR levels. While not directly drawn from established frameworks, our prompts were inspired by themes common in language assessments, including placement tests and academic writing. We aimed to cover familiar and level-appropriate topics, such as social issues, education, and personal experiences, while ensuring balance across the CEFR bands. We considered three proficiency levels: Beginner (A1–A2), Intermediate (B1–B2), and Advanced (C1–C2). General themes, such as hobbies, suited all levels, while more complex topics, including politics, Technology, and Education, were reserved for advanced learners.

Topic	B	I	A
Culture and Traditions	1	3	2
Daily Life	2	2	2
Education	3	6	8
Environment	2	2	3
Future	1	2	2
History and Culture	2	2	2
Hobbies	3	2	2
Imaginary	5	2	2
Life/Time Management	4	4	2
Personal Experiences	7	2	2
Relations	4	2	2
School Life	4	2	2
Sport and Health	2	3	1
Technology and Media	2	8	6
Travel and Experience	1	2	1
Politics and Government	2	2	7
Social Issues	2	7	6
Total	47	53	52

Table 3: Count of Arabic text prompts by level and topic. B: Beginner level (A1, A2), I: Intermediate level (B1, B2), A: Advanced level (C1, C2).

Using LLMs like GPT-4o⁶, Gemini⁷, and Copilot⁸, we generated 100 prompts, followed by a manual review to remove redundancies and ensure both relevance for Arabic essay writing and balanced proficiency coverage. The final collection consists of 152 balanced and diverse prompts. Table 3 presents the selected categories and the distribution of the prompts across levels, while Table 4 provides example prompts for the Hobbies category.

4.2 Feature Profiling

We construct linguistic profiles for each CEFR level using the ZAEBUC corpus. Each profile contains various levels of linguistic information. Representing different lexical and syntactic features, we use the number of words/sentences (N_w, N_s), the number of tokens/vocabulary (N_v), words/sentences lengths (L_w, L_s), and sentence complexity measured by syntactic tree depth (D_s).

We define the lexical diversity (Type-Token Ratio, TTR) as:

$$\text{TTR} = \frac{\text{Unique Tokens}}{\text{Total Tokens}} \quad (1)$$

⁶<https://openai.com/index/hello-gpt-4o/>

⁷<https://gemini.google.com/app>

⁸<https://copilot.microsoft.com/>

Level	Arabic Prompt	English Prompt
Beginner	<ul style="list-style-type: none"> • ما هي هوايتك المفضلة؟ • تحدث عن نشاط تحبه في عطلة نهاية الأسبوع. • ما هي الرياضة التي تحب ممارستها؟ لماذا؟ 	<ul style="list-style-type: none"> • What is your favorite hobby? • Talk about a weekend activity you love. • What is your favorite sport? Why?
Intermediate	<ul style="list-style-type: none"> • ما هي هوايتك المفضلة وكيف بدأت في ممارستها؟ لماذا تحبها؟ • هل ترغب في تعلم هواية جديدة؟ ما هي ولماذا تهمك؟ 	<ul style="list-style-type: none"> • What is your favorite hobby and how did you start practicing it? Why do you enjoy it? • Do you wish to learn a new hobby? What is it and why does it interest you?
Advanced	<ul style="list-style-type: none"> • ناقش كيف تؤثر الهواية على صحتك النفسية والجسدية. • كيف يمكن أن تكون الهوايات وسيلة للتعبير عن الذات؟ • هل هناك هواية جديدة ترغب في تجربتها؟ • ناقش الأسباب التي تجعلك مهتمًا بها وكيف تعتقد أنها ستفيدك. 	<ul style="list-style-type: none"> • Discuss how hobbies impact your mental and physical health. • How can hobbies serve as a means of self-expression? • Is there a new hobby you wish to try? Discuss the reasons you are interested in it and how you believe it will benefit you.

Table 4: Examples of prompts related to the topic of Hobbies and classified into one of three different levels.

Similarly, we calculate the sentence complexity by:

$$C_s = \frac{\sum_{i=1}^N D_i}{N} \quad (2)$$

where D_i is the syntactic depth of sentence i and N is the total number of sentences.

For morphological features, we use the ZAE-BUC morphological annotations: the most frequent POS tags, such as nouns, verbs, adjectives, etc.

We aggregate all extracted features across the essays to get a quantitative representation at different writing CEFR levels, which serves as a reference for later stages.

4.3 Zero-shot Data Augmentation

Effective LLM prompt engineering has become increasingly important, as the model’s output varies based on the prompt, provided instructions, and prompt language. Previous studies in Arabic NLP have shown that using English as the instruction language for input prompts can improve output quality (Kmainasi et al., 2024; Koto et al., 2024).

In our approach, we experiment with various prompts for zero-shot data augmentation to identify those that produce human-like text while adhering to guideline instructions. We use GPT-4o as our generation model due to its affordability and larger token capacity for both input and output. The GPT prompts include (a) the target CEFR level, (b) CEFR guidelines and instructions, (c) the linguistic profile for the targeted CEFR level to control the prompt output, and (d) the topic prompt or question from the previously mentioned topic prompts dataset. For these missing levels (A1 and C2), instead of injecting a pre-defined profile, GPT-4o was directly prompted to act as an assistant and gener-

ate data based on the general standards and rubrics of the CEFR.

To check the quality of the generated essays and whether they follow the prompt instructions, we build a linguistic feature profile (vector) for each augmented essay. We then assess the alignment between the generated essays and the reference CEFR-level profiles by computing their feature vectors’ cosine similarity as in equation 3. Specifically, given two real-valued feature vectors P_i (the CEFR reference profile) and Q_i (the generated essay), the cosine similarity is calculated as:

$$\cos(\theta) = \frac{\sum_i P_i Q_i}{\sqrt{\sum_i P_i^2} \cdot \sqrt{\sum_i Q_i^2}} \quad (3)$$

This metric ensures that the synthetic data closely aligns with real human essay patterns. Based on the computed similarity score, we assign a predicted CEFR level to each essay.

Later, we calculate the alignment between the predicted CEFR level and the target level specified in the GPT-4o prompt (ground truth) using the following agreement formula:

$$\text{Agreement} = \frac{\sum_{i=1}^n (\hat{y}_i = y_i)}{n} \quad (4)$$

where \hat{y}_i is the predicted level and y_i is the ground truth. This process evaluates how well GPT-4o succeeded in aligning the generated content with the intended proficiency level, serving as a measure of agreement rather than a prediction from an external model.

We conducted multiple rounds of prompt engineering refinements to improve the quality of the generated Arabic essays and ensure alignment with CEFR levels.

CEFR Level	Count	Percentage
A1	470	15.5%
A2	470	15.5%
B1	530	17.4%
B2	530	17.4%
C1	520	17.1%
C2	520	17.1%
Total	3,040	100%

Table 5: The generated corpus CEFR level distributions.

First, we found that straightforward prompts without explicit controlled linguistic instructions and explanations resulted in incoherent essays, including irrelevant topics and English text, achieving only 20.5% matching agreement with linguistic feature profiles. In a subsequent round, we introduced detailed definitions of linguistic features and restricted outputs to Arabic-only text, which improved agreement to 26%. However, the model still occasionally produced incomplete essays and injected text from the prompt into the essay.

The most effective prompt structure format is illustrated in Figure 1. We separated system-level control instructions from user-defined parameters, thereby providing clearer guidance for structured and proficiency-aligned text generation. This refinement increased agreement to 27.5%, demonstrating that precisely controlled instructions enhance LLM performance in structured writing tasks.

Ultimately, we generated 3,040 Arabic essays covering all CEFR levels and various topics, where each prompt was used to create ten essays. This effort was intentionally designed to address the imbalanced CEFR distribution in the original ZAEBUC corpus, where B-level essays were overrepresented. By constructing a more balanced synthetic dataset, we aimed to enhance model performance across the full proficiency spectrum. The structured and controlled prompt design also improved alignment with learner writing styles while providing a consistent framework for generating realistic Arabic essays. Table 5 presents the distribution of generated essays across different CEFR levels. The full dataset statistics are provided in Appendix A.1.

5 Error Injection

Human-generated text naturally contains some grammatical errors and linguistic infelicities. In

```
{
  "role": "system",
  "content": "You are a helpful assistant that generates essays in Arabic. Try to make them different, focus on other aspects and ideas, DO NOT generate anything from the prompt about the level or the features. Generate the Essays only in Arabic and make sure you generate completed sentences."
},
{
  "role": "user",
  "content": "f'Generate an Arabic essay talking about prompt: {prompt_text} for CEFR level {cefr_level} based on the CEFR Guidelines: {guidelines}. You have to follow the linguistics features profile as {linguistics_profile}. Here is the feature explanation: {features_guidelines}"
}
```

Figure 1: GPT-4o prompts messages that have been used to generate Arabic essays

order to create human-like essays, we need to add similar kinds of errors to the synthetic essays that reflect the level of writing attainment. In this phase, we prompt GPT-4o to inject errors into the previously generated essays while maintaining their aligned CEFR levels by utilizing error profiling.

5.1 Error Profiling

Error Distribution Profiles To model the distribution of errors to inject into the synthetic essays, we again leverage the ZAEBUC corpus, which contains the erroneous essays aligned with the manually corrected ones. We followed the same methodology we used to construct the linguistic feature profiles for each CEFR level to develop error distribution profiles aligned with CEFR levels. The error profile captures and reflects the authentic distribution patterns observed in human writing at different CEFR levels.

Developing an Error Instruction Repository To prompt GPT-4o to generate essays containing errors we applied the Grammatical Error Detection (GED) model proposed by (Alhafni et al., 2023) to the ZAEBUC corpus to annotate errors using 13 error tags and to obtain error distributions for each CEFR level. We created the repository using the error tags, where we also added a formal definition of what those tags describe in terms of linguistic errors. In addition, we expanded the error taxonomy by splitting it into finer-grained classes. Each error instruction is followed by an example showing the correct word and the erroneous version. The explanation was based on the *extended ALC taxonomy* (Alfaifi et al., 2013), which was refined later and introduced as ARETA (Belkebir and Habash, 2021). Appendix C presents examples of the error types. Figure 2 shows some examples from our error instruction repository.

5.2 GPT-Based Error Injection

We prompted GPT-4o to inject errors into the synthetically generated essays based on the error distri-

```

"REPLACE_0":
"Orthographical Error for example : Use incorrect Ya and Alif-Maqsurah forms at the end of words, replacing 'ي' with 'ي' or 'ي' with 'ي', such as using 'علي' instead of 'علي'."
"Orthographical Error for example : Swap the order of two adjacent characters in words to create orthographic errors, e.g., 'تقريبنا' instead of 'تقريبنا'."
"Orthographical Error for example : Introduce a common error by lengthening a vowel sound in words, for instance, changing 'نغم' to 'نغمي'."
"Orthographical Error for example : Confuse 'س' with 'س' at the end of words, creating common spelling errors, like 'مشاركة' becoming 'مشاركه'."
"Orthographical Error for example : Omit or misuse Alif Fariqa, such as writing 'ويكتف' instead of 'ويكتف'."
. . . . .

```

Figure 2: An example of orthographical error instructions from the developed errors instructions repository

tribution profiles while maintaining the CEFR level. The model processed one essay at a time in a zero-shot setting, except that we included the definition and explanation of the error tags. For example, **M** indicates a morphological error, while **Merge** targets two mistakenly split tokens that need to be merged, and so on.

After conducting multiple experiments, we observed the following issues: (i) The model struggled to follow the predefined error distribution perhaps due to the complexity of the prompts. (ii) The model was confused by certain error tags, particularly **Split** and **Merge**. These errors were mainly ignored in the injected text. (iii) We calculated the cosine similarity between the main error profile and the injected essays’ error distributions as shown in Equation 3. When we injected all errors at once, the similarity agreements did not exceed 20%; however, when we reduced the number of error tags per essay the agreements significantly improved, reaching 86%.

Therefore we implemented a method where each error type was injected separately. This required multiple iterations over the same essay, corresponding to the number of error tags shown in the error distribution profile for each CEFR level. Figure 3 shows an example of a GPT-4o prompt for error injection. Some error types, especially orthographic errors, are more frequent among Arabic writers than others. The prompt was intentionally designed through prompt engineering. The ‘helpful assistant’ component establishes a cooperative persona for the LLM, while the subsequent instruction to ‘inject erroneous tokens’ explicitly guide GPT-4o towards the specific task of error introduction. This approach ensures that GPT-4o is not making random edits but is rather following predefined instructions to create targeted errors, aligning with the overall goal of generating realistic synthetic data.

```

{"role": "system", "content": "You are a helpful assistant that injected erroneous tokens in Arabic essay based on given error instruction"},
{"role": "user", "content": f"Rewrite the following Arabic essay with the {cefr} CEFR level, following the specified error Instruction without removing, changing or fixing any existing mistakes.\n\n" f"Essay in Arabic:\n{essay}\n\n" f"Error Instruction: Please Inject exactly {num_words_to_inject} error/s of this type: {random_error_prompt}\n\n" "Only apply the specified errors directly in the text without any introductory or additional comments."}

```

Figure 3: Sample GPT-4o error injection prompt

```

For each error tag:
  • Randomly select error prompts from Error instruction repository based on the average error count:
    • Average count <5: Use 1 Error instruction.
    • Average count between (5,10): Use 2 Errors instructions
    • Average count >10: Use 3 Errors instructions.
  • Inject errors into the essay according to the determined distribution.

```

Figure 4: Error injection based on average error count

To reflect this, we randomly select weighted error instructions based on the average frequency of each error type. Figure 4 shows the pseudocode for the selection process. The full pseudocode is in Appendix B.

5.3 Controlled Error Injection

We introduce a controlled method for injecting errors into clean text, ensuring that the resulting erroneous sentences follow the empirical error distributions observed at each CEFR level. More formally, given an input sentence (X) and its CEFR level (L), we introduce errors in two steps: Error Type Prediction and Error Realization.

Error Type Prediction We estimate the probability of an error type occurring at a given word, i.e., $P(\text{error_type}|\text{word})$. To do so, we leverage ARETA in a reverse annotation process where we process correct–erroneous sentence pairs, tagging each correct word with its corresponding error type. Using this annotated data, we train a token-level BERT classifier to predict the most likely error type for each word in a given correct sentence. We fine-tune CAMELBER T MSA (Inoue et al., 2021) to build our classifier.

Error Realization To determine how a word should be corrupted, we first align correct–erroneous sentence pairs using the algorithm proposed by Alhafni et al. (2023). For each aligned pair, we extract edit transformations that capture the operations required to convert a correct word into its erroneous

counterpart. Using this data, we estimate $P(\text{transformation}|\text{error_type})$ with a bigram Maximum Likelihood Estimation (MLE) lookup model: $\text{count}(\text{transformation}, \text{error_type}) / \text{count}(\text{error_type})$. During inference, we apply the BERT classifier to predict error types for each word in a sentence. We then filter these predictions, retaining only error types relevant to the sentence’s CEFR level. Finally, the MLE model selects the most probable corruption for a given error type. A complete example of a B1-level essay generated by the proposed model is in Figure 5.

6 Experimental Setup

This study focuses on introducing a data augmentation framework and synthetic Arabic essay corpus, rather than proposing a new AES model. We use a BERT-based model trained on the original ZAEBUC dataset as the reference baseline, evaluating how different augmentation strategies (e.g., GPT-4o generation, BERT-based error injection) improve performance relative to this setup.

6.1 Data and Metrics

We use the ZAEBUC dataset for all the experiments, following the splits created by [Alhafni et al. \(2023\)](#): 70% Train, 15% Dev, and 15% Test.

Our primary evaluation metric is Quadratic Weighted Kappa (QWK) ([Cohen, 1968](#)), the most widely used metric in AES research ([Ke and Ng, 2019](#)). We also report accuracy, macro precision (P), recall (R), and F_1 scores. Model predictions are evaluated in two settings: average-reference and multi-reference. The average-reference setting uses the rounded average of the three scores as the gold label, while the multi-reference considers each of the three human-assigned labels as a valid reference during evaluation, following a more tolerant evaluation strategy (§3).

6.2 Model

We treat the task of AES as a text classification problem. We fine-tune CAMeLBERT MSA ([Inoue et al., 2021](#)) on the training split of ZAEBUC. The models were trained by using the average CEFR gold labels. During training, we ignore the essays that are labeled as Unassessable, but we penalize the models for missing them in the evaluation. We fine-tune the models for 5 epochs, with a maximum sequence length of 512, a learning rate of $5e-5$, and a batch size of 32.

6.3 Results

Our results are presented in Table 6. Our baseline system, only trained on the ZAEBUC training set, indicates room for improvement, with the F_1 at 24.50% and QWK at 22.44%. We then switched between different datasets to measure the impact of data augmentation on the model.

Impact of Synthetic Data We tested data augmentation by adding 3,040 corrected GPT-4o-generated essays, which lowered QWK but increased F_1 . Notably, the multi-reference setting saw significant gains, with QWK at 96.00% and F_1 at 92.32%. This pattern stems from the flexibility of multi-reference evaluation, which treats all three human-assigned CEFR labels as valid references. This accommodates natural scoring variations and increases the chance that model predictions, especially on synthetic data, align with at least one reference label, boosting QWK and F_1 scores for both GPT-generated and error-injected essays.

Comparison of Error Injection Methods As the initial synthetic essays were error-free, we further refined the model by adding essays with human-like errors. We compared two methods from §5: (1) GPT-based error injection (with and without instruction examples) and (2) the controlled BERT-based method.

The results demonstrate that the controlled error model improves performance in all metrics, particularly in the average reference setting, which achieved 27.87% and 38.02% for QWK and F_1 , respectively. This result aligns with expectations, as the BERT-injected errors closely follow CEFR-based error distributions, producing errors that realistically reflect learner writing and better match the average of human ratings.

GPT-based error injection performed best in the multi-reference setting, with one-shot examples reaching 96.47% QWK and zero-shot boosting F_1 to 95.12%. While less aligned with CEFR profiles, GPT errors benefit from fluency and variability, increasing the chance of matching at least one human reference in this flexible evaluation.

7 Discussion

This study demonstrated the effectiveness of synthetic data and controlled error injection in enhancing Arabic AES, providing key insights into metric interpretation, data expansion, and methodological choices.

Level	B1	Topic	Hobbies
Prompt	هل ترغب في تعلم هواية جديدة؟ ما هي ولماذا تهتمك؟		
	Do you wish to learn a new hobby? What is it and why does it interest you?		
Correct Essay			
<p>تعلم هواية جديدة يمكن أن يكون تجربة مثيرة ومفيدة في حياتنا. في الوقت الحالي، أفكر في تعلم الرسم كمهارة جديدة. الرسم ليس فقط وسيلة للتعبير عن النفس، ولكنه أيضًا يساعد في تحسين التركيز والصبر. عندما أرسم، أجد نفسي أركز على التفاصيل الصغيرة، مما يساعدني على تحسين مهارات الملاحظة لدي.</p> <p>الرسم يعطيني الفرصة للتعبير عن مشاعري وأفكاري بطريقة بصرية. أحيانًا، تكون الكلمات غير كافية للتعبير عما نشعر به، وهنا يأتي دور الفن. بالإضافة إلى ذلك، تعلم الرسم يمكن أن يكون وسيلة رائعة للاسترخاء بعد يوم طويل من العمل أو الدراسة. الجلوس أمام لوحة بيضاء وتحويلها إلى قطعة فنية يمكن أن يكون تجربة مهدنة ومرحة.</p> <p>أيضًا، الرسم يمكن أن يفتح لي أبوابًا جديدة للتفاعل مع الآخرين. يمكنني الانضمام إلى ورش عمل أو مجموعات فنية، حيث يمكنني مقابلة أشخاص يشاركونني نفس الاهتمام. هذا يمكن أن يساعدني في بناء شبكة اجتماعية جديدة وتعلم تقنيات جديدة من الآخرين.</p> <p>بشكل عام، تعلم الرسم كهواية جديدة يهمني لأنه يجمع بين التعبير الفني، تحسين الذات، والتفاعل الاجتماعي. إنه تحد جديد أود أن أواجهه، وأنا متحمس لاكتشاف ما يمكنني تحقيقه من خلال هذه الهواية.</p>

Figure 5: An Example of a B1 Arabic Essay generated by GPT-4o using the Hobbies prompt and the same essay after injecting errors by the controlled BERT-based model.

First, we emphasize that QWK offers a more robust metric than accuracy for evaluating AES systems, particularly under imbalanced class distributions. Unlike accuracy, which is biased by majority classes, QWK penalizes errors by their ordinal distance from the correct label. As Table 6 shows, even modest QWK improvements indicate meaningful advancements in differentiating CEFR levels, a distinction especially relevant given the skewed ZAEBUC dataset.

The significant gains observed in the multi-reference setting with generated GPT-4o essays stem from its flexibility. This evaluation approach treats all three human-assigned CEFR labels as valid references, accommodating natural scoring variations and increasing the chance that model

predictions align with at least one reference label.

Our analysis revealed that while GPT-4o is powerful for generating diverse content, it struggles to precisely follow the nuanced distribution and specific linguistic features, including error patterns, observed in the manually annotated ZAEBUC dataset. In the GPT-based error injection approach, error type selection is guided by average error counts from the ZAEBUC corpus, but error realization depends on GPT-4o's interpretation of the prompt, making it less predictable. This inherent challenge in mimicking human-like linguistic and error distributions through zero-shot generation directly contributed to the observed lower agreement rate.

In contrast, the controlled method employs a BERT-based classifier for error prediction and ap-

Train Data	Average Reference					Multi-Reference				
	QWK	Acc	F ₁	P	R	QWK	Acc	F ₁	P	R
ZAEBUC (baseline)	22.44	57.58	24.50	23.33	26.76	61.06	84.85	43.70	42.50	45.31
ZAEBUC + GPT essays	14.92	60.61	26.43	25.55	27.45	96.00	96.97	92.32	98.04	88.89
ZAEBUC + BERT errors	27.87	57.58	38.02	35.86	44.93	82.70	87.88	71.66	70.83	74.38
ZAEBUC + GPT errors_1	17.14	57.58	25.64	25.18	26.27	96.47	96.97	94.16	97.92	91.67
ZAEBUC + GPT errors_0	20.84	57.58	32.76	31.53	46.08	93.79	93.94	95.12	96.49	94.44

Table 6: Performance comparison of different training datasets. GPT essays are the original correct essays generated from GPT-4o, BERT errors are the erroneous essays using the controlled injection BERT model, GPT errors_1 are the erroneous essays using GPT-4o with one-shot error example, while GPT errors_0 with Zero-shot settings.

plies transformations using bigram-MLE. This systematic approach resulted in a more robust replication of empirically observed error patterns, leading to its superior performance in the average-reference setting. This is expected, as BERT-injected errors more closely resemble learner writing and align more closely with average human ratings.

Overall, our findings highlight a trade-off between error alignment and fluency in data augmentation. Controlled error injection excels in the average-reference setting due to its closer alignment with learner errors, while GPT-based augmentation benefits from multi-reference flexibility but less reliably replicates authentic errors. The controlled BERT-based method thus serves as a key component of our pipeline, effectively addressing the limitations of direct GPT error injection.

Qualitative Analysis The qualitative analysis of the generation process revealed various biases in the GPT-4o outputs, including cultural, gender, and ideological biases. For instance, the essays frequently referenced traditional Arabic themes, reinforced stereotypical gender roles, and reflected culturally narrow assumptions. A clear example of religious bias is that الجمعة ‘Friday’ was selected as *the favorite day* in all 20 generated essays. Additionally, there was a noticeable tendency to use masculine forms throughout the texts. Such biases may unintentionally disadvantage students whose writing reflects different experiences, perspectives, or identities. Examples of these biases, along with their frequencies, are provided in Appendix A.2. We also observed a lack of diversity among the ten essays generated per prompt, with GPT-4o often repeating similar lexical and structural patterns.

8 Conclusions and Future Work

This paper presents a hybrid framework for Arabic AES, using LLMs and transformers to tackle

data scarcity by generating synthetic essays that partly replicate Arabic learner writing. Building on the ZAEBUC corpus, we developed CEFR-aligned linguistic and error profiles and used GPT-4o to produce 3,040 essays across 152 prompts. However, GPT-4o’s performance relies heavily on prompt engineering, achieving only 27.5% alignment with our reference profiles.

To introduce errors, we compare our two methods: (1) GPT-4o prompted multi-step error injection, and (2) our controlled method fine-tuning the CAMELBERT MSA model to inject errors proportionally to their profiled occurrence.

Evaluated with a fine-tuned BERT classifier, our hybrid framework, combining GPT-generated data with controlled error injection, outperformed the baseline (QWK: 27.87%, F₁: 38.02%), offering more reliable and interpretable results. These findings demonstrate the effectiveness of controlled error injection in capturing learner error distributions across CEFR levels.

For future work, we will prioritize integrating a human evaluation into our framework. Human annotators will assess the fluency and naturalness of synthetic essays, as well as the realism of injected errors, ensuring that they reflect typical learner patterns at specific CEFR levels.

To improve generalizability, we also plan to expand the diversity of prompts beyond predefined topics and incorporate a wider set of writing traits, including coherence, logical flow, and topic relevance, beyond syntactic and lexical features.

We also intend to enhance CEFR-level modelling by incorporating more manually annotated essays. This will help capture nuanced linguistic variations across levels and increase the robustness of our dataset. Lastly, we aim to deploy the AES system as an interactive tool to provide users with instant feedback on errors and proficiency levels.

Limitations

Despite the effectiveness of our hybrid Arabic AES framework, we note several limitations related to the quality of generated Arabic essays, error injection accuracy, and the generalization of the AES model. The lack of A1 and C2 essays in ZAEBUC means that there is no gold reference data for these levels, which may impact both linguistic and error profiles, affecting the accuracy of GPT-generated essays. Furthermore, different biases are present in both the ZAEBUC dataset and GPT-4o outputs as discussed in (§7)

In addition, due to the lack of comprehensive gold data, GPT struggles to fully replicate real learner writing styles, achieving only 27.5% agreement with linguistic feature profiles.

Another limitation is the model's ability to generalize across various domains and question types. The AES system may struggle with broader writing tasks and alternative prompts since the dataset and augmentation methods focus on predefined prompts. Relying solely on CEFR as a holistic scoring method limits interpretability. Enhancing the dataset with multi-trait annotations, such as coherence, argumentation, and organization, could improve scoring accuracy and feedback quality. Moreover, better-controlled GPT prompting could refine the quality and diversity of generated essays, reducing biases and improving alignment with real learner writing patterns.

Due to resource constraints, human evaluation was not feasible in this study; however, we plan to engage CEFR-trained annotators in the future.

Ethical Considerations

While Arabic AES systems provide significant support in assessing Arabic learners' writing proficiency, it is essential to highlight the ethical implications of their use. Automatic assessment and scoring may lead to misjudgments that could distress learners and students, especially if their work is incorrectly evaluated. AES tools should serve as an educational assistive technology, complementing the teacher's judgment, not replacing it in educational settings.

B GPT-4o Error Injection Algorithm

Algorithm: Inject_Errors_and_Verify

Inject Errors into Essays

Input: Augmented_Essays (3040 essays from GPT-4o), Error_instructions, CEFR_Error_Profiles

Output: Errerouns_Essays

FOR each Essay in Generated_Essays:

Determine target CEFR level's error distribution

Target_CEFR = Get_CEFR_Level(Essay)

Retrieve the Error Profile

Error_Profile = Get_Error_Profile(Target_CEFR)

Inject errors based on error distribution

FOR each Error_Type in Error_Profile:

Select error instruction prompts based on average error count

Avg_Error_Count = Get_Avg_Error_Count(Error_Type)

IF Avg_Error_Count < 5:

Num_Prompts = 1

ELSE IF $5 \leq \text{Avg_Error_Count} \leq 10$:

Num_Prompts = 2

ELSE:

Num_Prompts = 3

Selected_Prompts = Select_Random_Prompts(Error_Prompts.json, Error_Type,
Num_Prompts)

Inject errors according to determined distribution

Essay = Inject_Errors(Essay, Selected_Prompts)

Verify Error Injection

FOR Errerouns_Essays:

Apply Grammar Error Detection (GED) to identify errors

Detected_Errors = Apply_GED(Injected_Essay)

Recalculate the error distribution for injected essays

Injected_Error_Profile = Calculate_Error_Distribution(Detected_Errors)

Compare the injected error distribution with the target CEFR profile

Similarity_Score = Cosine_Similarity(Injected_Error_Profile, Target_CEFR_Error_Profile)

End Algorithm

C Error Types Taxonomy

	11-Classes	42-Classes	Error Description	Correct Word	Erroneous Word
Morphology (M)	M	MI	Inflection	عارف	معروف
		MT	Tense	ذهب	يذهب
Orthography (O)	O	OA	Alef-Maqsura	القاضي	القاضي

Direct Repair Optimization: Training Small Language Models For Educational Program Repair Improves Feedback

Charles Koutcheme, Nicola Dainese and Arto Hellas

Aalto University, Espoo, Finland

first.last@aalto.fi

Abstract

Locally deployed Small Language Models (SLMs) offer a promising solution for providing timely and effective programming feedback to students learning to code. However, SLMs often produce misleading or hallucinated feedback, limiting their reliability in educational settings. Current approaches for improving SLM feedback rely on existing human annotations or LLM-generated feedback. This paper addresses a fundamental challenge: Can we improve SLMs' feedback capabilities without relying on human or LLM-generated annotations? We demonstrate that training SLMs on the proxy task of program repair is sufficient to enhance their ability to generate high-quality feedback. To this end, we introduce Direct Repair Optimization (DRO), a self-supervised online reinforcement learning strategy that trains language models to reason about how to efficiently fix students' programs. Our experiments, using DRO to fine-tune LLaMA-3.1-3B and Qwen-2.5-3B on a large-scale dataset of Python submissions from real students, show substantial improvements on downstream feedback tasks. We release our code to support further research in educational feedback and highlight promising directions for future work.

1 Introduction

Learning to program remains challenging for many students, despite advances in teaching methodologies (Luxton-Reilly et al., 2018; Vihavainen et al., 2014). A key part of addressing these challenges is providing timely and accurate feedback (Jeuring et al., 2022), which is crucial for learning (Hattie and Timperley, 2007). Large Language Models (LLMs) such as GPT-4 have shown exceptional success in that task (Lohr et al., 2025), leading to their growing adoption in classrooms (Ahmed et al., 2025; Wang et al., 2024; Vadaparty et al., 2024; Liu et al., 2024a; Liffiton et al., 2024).

However, reliance on vendor-hosted LLMs raises substantial privacy concerns and potential ethical issues related to institutional control (Das et al., 2025). The privacy issues, jointly with scalability issues and associated costs, are driving a growing shift towards leveraging smaller open-source models (SLMs), which can be deployed and run locally within educational institutions or on students' computers and browsers (Yu et al., 2025b; Liu et al., 2024b).

However, smaller language models tend to produce misleading or hallucinated feedback, potentially confusing learners and negatively impacting learning (Koutcheme et al., 2025). Current methods for enhancing SLMs typically rely on supervised learning (Kotalwar et al., 2024) or reinforcement learning from either human annotations (Woodrow et al., 2025) or synthetic data generated by larger models (Ashok Kumar and Lan, 2024). These strategies come with limitations: human annotations are difficult to scale and replicate, while synthetic data inherits biases and capabilities from general-purpose LLMs.

Addressing these limitations raises a broader challenge for the field of programming education: *can we improve small language models' abilities to generate meaningful programming feedback without relying on external LLMs or human annotations?* Exploring this question opens a promising research direction focused on assessing how effectively small models can perform when trained exclusively on educational data. Understanding this can yield insights into the inherent capabilities of these models, free from external biases (DeepSeek-AI, 2025). This question matters not just technically, but also pedagogically; training models exclusively grounded in student work and learning contexts could facilitate more adaptable classroom deployment, enhance institutional control over model behaviour, and mitigate privacy concerns (Das et al., 2025).

Recent reinforcement learning techniques such as Group Relative Preference Optimization (GRPO) (Shao et al., 2024) have shown great promise in improving language models’ reasoning capabilities, allowing relatively small models to reach the performance of significantly larger ones with minimal LLM supervision (DeepSeek-AI, 2025). In parallel, prior work reveals a strong correlation between language models’ abilities to generate programming feedback and their capacity for fixing students’ programs (Koutcheme et al., 2024a): models proficient in program repair are independently good at generating feedback.

Building on this insight, we hypothesise that improving a small language model’s repair capabilities through reasoning could be sufficient to enhance the model’s feedback-generation abilities. We argue that the reasoning needed for generating a repair involves a thinking process useful to provide students with feedback, much like how teaching assistants reason about students’ mistakes before giving advice (Koutcheme, 2022).

Our paper thus aims to answer the following research question:

(RQ) How effective is training small language models to reason about educational program repair for improving their ability to generate high-quality programming feedback, and how does this technique compare to training models with LLM supervision?

To address this question, we introduce Direct Repair Optimization (DRO). This reinforcement learning training pipeline, based on Group Relative Preference Optimization, leverages historical datasets of student submissions to fine-tune small language models for program repair, using unit test results and syntactic/semantic distance measures as rewards to guide learning.

We apply DRO to fine-tune LLaMA-3.1-3B (Dubey et al., 2024) and Qwen-2.5-3B (Hui et al., 2024) on a large-scale dataset of student code from introductory programming courses (de Freitas et al., 2023). We evaluate the resulting model on multiple feedback tasks — including bug explanations, patch descriptions, and next-step hints — and show consistent improvements over all feedback criteria. Our contributions are as follows:

- We introduce a new LLM-free training pipeline for feedback generation based on program repair and reinforcement learning.

- We show that reasoning about program repair transfers to various forms of feedback, including explanations, fixes, and hints.
- We further demonstrate that reasoning about program repair improves the performance of LLM-distilled models.
- We release our code and data processing pipeline to support future research in aligning language models for educational feedback¹.

2 Related work

2.1 Programming Feedback

Program repair. Program repair has long been a cornerstone of AI-driven programming education, serving as a foundation for generating actionable feedback, such as next-step hints, through Intelligent Tutoring Systems (Rivers and Koedinger, 2017). Before the rise of instruction-tuned and chat language models, much of the work in this domain focused on leveraging closed pre-trained models, such as OpenAI Codex, to generate repairs through zero- or few-shot prompting. These approaches often relied on historical student submissions, automated unit tests, and other contextual information to guide the repair generation process (Zhang et al., 2022; Joshi et al., 2023).

In parallel, open-source language models were also explored for program repair tasks. For example, prior efforts have fine-tuned such models using datasets derived from student submissions (Koutcheme et al., 2023b) and automated repair tools (Koutcheme, 2023). These works demonstrated the viability of repair-focused training but did not directly explore its implications for improving natural language feedback.

Using program repair for improving feedback.

Even with the advent of chat models, several works proposed leveraging the quality of repairs generated alongside feedback as a validation mechanism to ensure only relevant suggestions reach learners (Phung et al., 2024; Sahai et al., 2023). In parallel, other studies propose generating a high-quality candidate repair program as a reasoning step to generate higher-quality feedback. (Phung et al., 2023; Sahai et al., 2023). This strategy has been extended with success to distil LLM-generated repair-induced feedback to small language models via Supervised Fine-tuning (Kotalwar et al., 2024).

¹  github.com/KoutchemeCharles/rlpf

Reinforcement learning from human and AI feedback. Supervised Fine-Tuning (SFT) methods are limited in their ability to align language models with nuanced human objectives (Ouyang et al., 2022). Several works have explored reinforcement learning techniques, such as Direct Preference Optimization (DPO) (Rafailov et al., 2024), to train small language models to generate higher-quality feedback. For example, this has been done by leveraging teaching assistants’ (TAs) edits of their responses to student forum questions (Hicke et al., 2023), collecting live TA preferences over several model-generated feedback (Woodrow et al., 2025), or combining existing high-quality human annotations with AI-generated alternatives (Ashok Kumar and Lan, 2024).

However, these methods typically rely on human supervision or the existence of labeled human feedback. This reliance poses challenges in contexts where such annotations are scarce or unavailable. While full Reinforcement Learning with AI Feedback (RLAIF) (Lee et al., 2024) approaches have been theorized to work well in the programming domain (Scarlatos et al., 2024), in this paper, we explore whether we can bootstrap feedback capabilities in small language models without requiring any human or LLM involvement.

2.2 Improving SLM Reasoning Without LLMs

Recent work has proposed leveraging automatically evaluable tasks to define preference pairs for DPO optimization (Pang et al., 2024), replacing the need for human or LLM judgments. In domains like programming and math, where correctness can be verified programmatically, this strategy has shown promising results. Combined with large-scale sampling and chain-of-thought prompting (Wei et al., 2022), such methods have yielded substantial improvements with minimal supervision (Pang et al., 2024).

Most recently, a new line of alignment techniques (Shao et al., 2024; Liu et al., 2025; Yu et al., 2025a) takes the idea back to a fully online optimization paradigm, showing major improvements. Inspired by the success of small models such as DeepScaleR (Luo et al., 2025), we explore whether these reinforcement learning techniques can be adapted to improve small language models in programming education.

3 Methodology

In this work, we hypothesise that training small language models for program repair will improve their feedback ability. To validate this hypothesis, we propose Direct Repair Optimization.

3.1 Background

Before presenting our approach, we first describe the setup and assumptions underlying our work.

3.1.1 Environment

We assume a typical educational programming setting, where student submissions are regularly collected and evaluated using automated assessment tools, such as unit tests, to assign scores and provide feedback (Paiva et al., 2022). Leveraging this infrastructure, we make two key assumptions: first, we assume access to a training dataset $\mathcal{D} = \{(d^i, s^i, c^i)\}_{i=1}^N$, comprising N tuples, where each tuple consists of a problem description d^i , a corresponding student program s^i , and a correctness label c^i , with $c^i = 0$ indicating an incorrect program and $c^i = 1$ indicating a correct one; second, we assume the availability of a grading function $u(s)$ that assigns a normalized score $c^i \in [0, 1]$ to each program s^i , reflecting its functional correctness based on unit test results.

3.1.2 Definition: high-quality repair

To support the rest of this article, we formalize the concept of a high-quality repair. A repair is typically considered high-quality if it meets two key criteria: functional correctness and closeness to the student’s original incorrect program (Koutcheme et al., 2024c; Phung et al., 2023; Joshi et al., 2023; Zhang et al., 2022). Functional correctness ensures that the repair successfully resolves the intended issues, while closeness ensures the repair preserves the student’s original approach, making the solution more interpretable and educationally meaningful (Price et al., 2017). Given a candidate repair \mathcal{R} (generated by an LM) for an incorrect program s_i , we assess its quality using automated evaluation methods. Functional correctness is measured through unit test results provided by the grading function u . For closeness, we use ROUGE (Lin, 2004), as it has been shown to be an effective and efficient measure for selecting high-quality repairs (Koutcheme et al., 2023a).

3.2 Direct Repair Optimization

In this section, we introduce Direct Repair Optimization (DRO), our approach to improve language models’ ability to generate educationally meaningful program repairs. DRO is an online reinforcement learning training method based on variants of Group Relative Preference Optimization (Shao et al., 2024). Figure 1 shows an overview of the method. At each iteration, given an incorrect program s^i , we (1) generate several completions, (2) compute individual reward scores, based on such generations and (3) update the model parameters based both on such rewards and a divergence score. Below we detail each step.

3.2.1 Sampling answers

Given an incorrect program, we sample G generations from our language model $\mathcal{G}_1^i, \mathcal{G}_2^i, \dots, \mathcal{G}_g^i \sim \pi_\theta(s^i, d^i)$. Our prompt asks our model to fix the student’s program but to reflect thoroughly before providing an answer (see Figure 2, Appendix C). Each generation contains a thought \mathcal{T}_g^i and a final repair \mathcal{R}_g^i : $\mathcal{G}_g^i = (\mathcal{T}_g^i, \mathcal{R}_g^i)$. Following (Shao et al., 2024), our prompt imposes the language model to structure its response using a set of predefined tags: the thought pattern should be generated within `<think> . . . </think>` and the repair within `<answer> . . . </answer>` tags.

3.2.2 Computing rewards

For each generation \mathcal{G}_g^i , we compute a reward r_g^i , reflecting the two criteria that define a high-quality repair (see Section 3.1.2): functional correctness and closeness (or “proximity”) to the student’s original incorrect program. The total reward r_g^i is thus the sum of two separate components: $r_g^i = f_g^i + p_g^i$.

The functional reward is an outcome-based reward (Luo et al., 2025) computed by extracting \mathcal{R}_g^i and passing it through the available grading function (i.e., unit tests):

$$f_g^i = \begin{cases} +1.0 & \text{if } u(\mathcal{R}_g^i) = 1 \\ +0.5 & \text{if } u(\mathcal{R}_g^i) - u(s^i) > 0 \\ -1.0 & \text{if } \mathcal{R}_g^i \text{ not compiling} \\ 0 & \text{otherwise} \end{cases}$$

We reward fully correct repairs (+1.0), give partial credit (+0.5) if the repair improves upon the student’s original program (i.e., it passes more tests than s^i), and penalize repairs that fail to compile or

generations that do not follow the expected format (−1.0). Our reward encourages the model to make meaningful progress toward correctness, even when it cannot fully solve the task. We believe that partially correct repairs that are better than the student’s original work could also benefit feedback generation.

The closeness reward evaluates how well the generated repair aligns with the student’s original code:

$$p_g^i = \begin{cases} \text{ROUGE}(s^i, \mathcal{R}_g^i) & \text{if } u(\mathcal{R}_g^i) = 1 \\ 0 & \text{otherwise} \end{cases}$$

By integrating this reward, we encourage the model not only to solve the programming task but to do so by building on the student’s own approach, implicitly forcing reasoning about what the student is currently doing and trying to achieve. This makes the repair (and the resulting feedback) more pedagogically aligned. We provide this reward only when the repair is fully correct. Since repairing a student program inherently requires changes, correctness and closeness can become competing objectives. Rewarding both simultaneously for partial outputs would risk destabilising training.

3.2.3 Updating the model using the rewards

We update the model using the computed rewards with the dr.GRPO loss function (Liu et al., 2025), a recent reinforcement learning loss function designed for training stability and efficiency:

$$\mathcal{J}_{\text{dr.GRPO}} = -\frac{1}{LG} \sum_{g=1}^G \sum_{t=1}^{|o_g|} l_{m,t} \quad (1)$$

where

$$l_{g,t} = \frac{\pi_\theta(o_{g,t} \mid d^i, s^i, o_{g,<t})}{\pi_{\theta_{\text{old}}}(o_{g,t} \mid d^i, s^i, o_{g,<t})} \hat{A}_g$$

and

$$\hat{A}_g = (r_g^i - \bar{r})$$

Here, LG is the maximum allowed completion length, $\pi_{\theta_{\text{old}}}$ is the model before the current update, and \hat{A}_g is the advantage, computed as the reward deviation from the batch mean \bar{r} . In practice, we use a clipped surrogate version of this objective that accounts for multiple updates per generation. For clarity and space, we provide the full objective and implementation details in section A.1 (Appendix A, where we also show how this formulation differs from the original GRPO loss introduced in the DeepSeek paper (DeepSeek-AI, 2025) and how it is better adapted to our task.

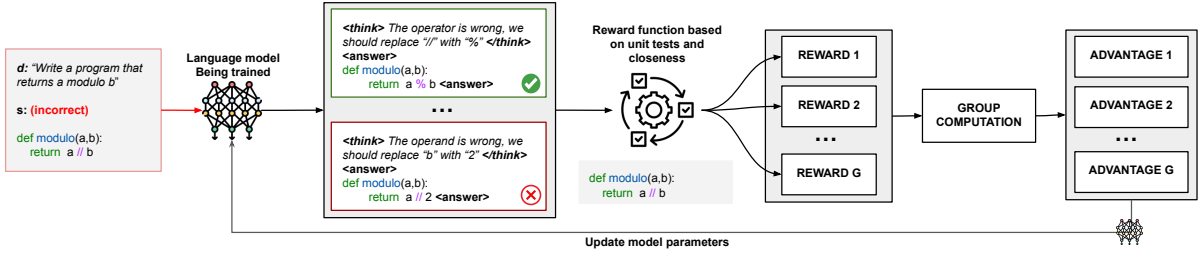

Figure 1: Overview of Direct Repair Optimization.

4 Experiments

In this section, we present the experiments conducted to answer our research question.

4.1 Falconcode: A Real-life Dataset

To answer our research question, we train language models using FalconCode (de Freitas et al., 2023), a publicly available dataset containing real-life CS1 students’ solutions to many Python programming exercises. This dataset distinguishes itself through the presence of free-form assignments, enabling a broader evaluation of feedback abilities.

We follow the preprocessing approach of (Koutchme et al., 2024a) by selecting the incorrect programs from all students’ last submitted solutions (as these specific solutions often reflect students who need the most help) for each assignment that can be automatically evaluated with unit tests. Following those steps results in training, validation, and testing splits with 690, 826, and 711 incorrect programs from 44, 62 and 62 assignments.

4.2 Feedback Tasks

We train our model to generate better program repairs and aim to evaluate whether this improvement transfers to feedback generation. Specifically, we assess our models performance on three feedback types widely studied in prior work (Koutchme et al., 2025; Kotalwar et al., 2024; Phung et al., 2024; Hellas et al., 2023): explanations (\mathcal{E}), code patches (\mathcal{P}), and hints (\mathcal{H}).

Explanations identify and describe *all* issues in a student’s program, while code patches outline the necessary corrections. These two types of diagnostic feedback help students understand their mistakes after submitting an incorrect solution. Hints, in contrast, are more Socratic, guiding students toward resolving one of the issues without giving away the answer, and are most valuable while students are still actively working and may be stuck.

Quality attributes. We evaluate the generated feedback using quality criteria established in prior work. Explanations and code patches are assessed based on accuracy ($\mathcal{E}_A, \mathcal{P}_A$) and selectiveness ($\mathcal{E}_S, \mathcal{P}_S$) (Koutchme et al., 2025). Hints, are evaluated along three dimensions: correctness (\mathcal{H}_C), informativeness (\mathcal{H}_I), and concealment (\mathcal{H}_{Com}) (Phung et al., 2024). Table 3 (Appendix A) provides detailed definitions for each attribute. We later detail our evaluation strategy.

Generation strategy. When generating feedback, we always prompt our models to generate the three types of feedback sequentially: first the explanations, then the code patches, and finally a *single hint* for the first identified issue $\mathcal{F} = (\mathcal{E}, \mathcal{P}, \mathcal{H})$. This ordering draws from prior work, treating the explanation as a form of chain-of-thought reasoning (Wei et al., 2022) that supports the generation of more accurate patches (Koutchme et al., 2025) and a more helpful hint (Phung et al., 2023).

4.3 Models

We train Llama-3.2-3B (Dubey et al., 2024) and Qwen-2.5-3B (Hui et al., 2024), two language models with strong performance on programming tasks. Models in the 3B parameters range strike a practical balance: they are small enough for deployment on edge devices (Kotalwar et al., 2024) yet large enough to rapidly benefit from reinforcement learning optimization (Sui et al., 2025).

Parameter efficient finetuning. We train both models using QLoRa (Dettmers et al., 2023), a Parameter-Efficient Fine-Tuning technique (PEFT) (Houlsby et al., 2019) that quantises a language model to 4-bit and adds on top a set of trainable parameters called adapters, while the base model remains frozen. Using PEFT techniques has two benefits: quantized models allow easy edge device deployment, while adapters allow easy recovery of the base model functionalities.

4.4 Baseline and Oracle

Our objective is to assess (1) whether reasoning for repair improves programming feedback and (2) how close our DRO-trained SLMs’ can approach the performance of models having access to LLM supervision. To help answer each sub-question, we consider two LLM-distillation training references:

- **Reason-Repair (RR):** For each incorrect program s^i , we prompt an LLM to generate a corrected repair by reasoning, without producing feedback (see Figure 3, Appendix C). We then fine-tune our small models on this thought and repair $(\mathcal{T}_{LLM}^i, \mathcal{R}_{LLM}^i)$ sequence. These models allow us to evaluate whether learning to repair through thoughts using supervised fine-tuning improves feedback performance.
- **Repair-First Feedback (RFF):** We adopt the repair-before-feedback strategy from (Sahai et al., 2023; Phung et al., 2023), prompting the LLM (see Figure 4) to first generate a repair \mathcal{R}_{LLM}^i for the incorrect program as an intermediate reasoning step to produce the full feedback \mathcal{F}_{LLM}^i . While this two-step prompting strategy introduces an *implicit* form of reasoning similar to chain of thought, we note that it differs from the more *explicit* form of reasoning used in models such as DeepSeek (Luo et al., 2025). To our knowledge, such explicit reasoning has not been explored in prior work for providing feedback. Our small models are fine-tuned on these repair-feedback sequences $(\mathcal{R}_{LLM}^i, \mathcal{F}_{LLM}^i)$. Since this approach relies on direct access to feedback during training, we consider RFF-trained models as oracles, serving as a strong upper bound.

We use OpenAI GPT-4o-mini (OpenAI, 2024) as the LLM due to its strong feedback performance (Koutchme et al., 2024b) and cost efficiency.

4.5 Prompting Strategy

In our main experiments, we prompt the DRO and Reason-Repair models to generate feedback \mathcal{F} immediately (see Figure 3), without any intermediate repair step (Koutchme et al., 2025). This prompting strategy aims to study whether repair fine-tuning transfers directly into feedback improvements. In contrast, following (Sahai et al., 2023), we prompt the Repair-First Feedback models to first generate a repair for the incorrect programs before generating the final feedback \mathcal{F}^i .

We present in Appendix B the full results of our experiments, prompting all models with both strategies. The second approach evaluates whether and to what extent generating repairs before feedback effectively enhances small language models’ performance.

4.6 LLMs-as-feedback-judges

We leverage LLMs-as-judges (Zheng et al., 2023; Thakur et al., 2024) to evaluate our models. Following the jury-based approach proposed by (Verga et al., 2024), we use a panel of two language models: GPT-4o-mini and Gemini-2.0-flash (Google DeepMind, 2024). While GPT-4o-mini and Gemini-2.0-flash are lighter versions of their full-size counterparts, they remain strong judges for programming feedback. For instance, GPT-4o-mini has been shown to perform on par with GPT-4o for evaluating feedback quality (Koutchme et al., 2025). Moreover, (Verga et al., 2024) demonstrate that ensembles of smaller LLMs of different families can outperform even single large models, particularly by mitigating individual model biases.

For each feedback \mathcal{F} generated on the test set, we prompt both judges (see Figure 6, Appendix C) to provide binary decisions across all quality criteria (Table 3). We adopt a strict unanimity policy: a criterion is marked correct only if both judges agree. While this method does not provide absolute performance guarantees (see Section 6), it offers a consistent, scalable, and reliable strategy for comparing the relative effectiveness of different training approaches.

4.7 Experiment Details

We describe our experiment settings, including specific hyperparameters used for training and inference, in section A.3 (Appendix A).

5 Results

In this section, we present the results of our experiments. A more in-depth analysis, including results for the *repair-first* strategy, is provided in Appendix B. For DRO, we show results for training for one epoch (DRO-1) and two epochs (DRO-2).

5.1 Direct Repair Optimization Results

Table 1 shows the results of our experiments answering the question: *How effective is training for repair in improving feedback abilities?* We can make the following observations.

Table 1: **Feedback performance results.** We contrast DRO model performance at n training epoch (**DRO- n**) against LLM-distilled training variants RR (Reason-Repair) for two (BASE) language models, Llama-3.1-3B and Qwen-2.5-3B. We bold (resp. underline) the best (resp. second best) results.

Method	\mathcal{E}_A	\mathcal{E}_S	\mathcal{P}_A	\mathcal{P}_S	\mathcal{H}_C	\mathcal{H}_I	\mathcal{H}_{Con}
Llama-3.1-3B							
BASE	37.4	55.4	34.5	25.2	67.5	63.4	67.8
DRO-1	40.5	64.4	36.6	30.4	73.6	69.2	72.0
DRO-2	43.5	64.7	<u>40.5</u>	<u>32.2</u>	72.6	<u>67.9</u>	<u>71.9</u>
RR	42.9	<u>62.9</u>	42.9	41.8	52.7	49.4	56.3
Qwen-2.5-3B							
BASE	49.6	69.2	39.1	32.2	85.1	80.0	78.2
DRO-1	53.2	66.0	47.4	34.7	87.3	84.5	80.7
DRO-2	59.8	74.1	51.6	38.7	90.7	<u>88.3</u>	88.3
RR	<u>59.1</u>	70.0	<u>51.1</u>	38.7	91.4	90.0	<u>85.9</u>

Training for repair improves feedback abilities.

DRO improves feedback quality across all criteria for both base models. We also observe gains when training a model via supervised fine-tuning on thoughts and repairs generated by a language model (*RR*), although hint performance declines for Llama.

We interpret this success as a form of transfer learning (Raffel et al., 2020), where training on one task improves performance on another related task. Butler et al. (Butler and Winne, 1995) characterize feedback as a two-step process: first, noticing mistakes, and second, communicating them to the learner. We view program repair as a “super-task” of the noticing stage: to fix a student’s code, the model must identify what is wrong (analogous to generating an explanation) and then determine how to correct it (analogous to generating a patch). Manual inspection also suggests that most, if not all, reasoning traces produced during repair explicitly highlight both the underlying issues and their corresponding fixes.

Unlike full feedback, however, program repair does not involve pedagogical communication. In other words, it does not improve the second stage: the model’s ability to convey information effectively to a learner. Still, we believe the use of low rank adapters allows the model to preserve its original pedagogical capabilities while refining its analytical skills through targeted repair training. Lastly, since a hint is a form of non-revealing explanation, stronger repair capabilities indirectly enhance Socratic feedback.

DRO improvements scale rapidly with base model performance.

We observe that the speed and magnitude of the improvement at each training epoch n depend on the base model. Qwen, which is a stronger base model than Llama, is showing more substantial gains after just one epoch of training, and even faster gains after a second training epoch. These results align with findings from prior work (DeepSeek-AI, 2025; Luo et al., 2025), suggesting that performance improvements when training reasoning models scale faster as the quality (i.e. initial performance) of the base model increases.

DRO is competitive with LLM-distillation.

After two epochs of training (DRO-2), our models reach performance comparable to LLM-distilled variants. With Llama-3.1-3B, DRO-2 matches *RR* for generating explanations. While it underperforms on patches, it significantly outperforms *RR* on hint generation, where *RR* even falls behind the base model. With Qwen-2.5-3B, DRO-2 surpasses *RR* for generating both explanations and patches, and performs on par for writing hints.

5.2 Refining Distilled Models with Direct Repair Optimization

Table 2 shows the results of an experiment combining model distillation and reinforcement learning. Prior work highlights how SLM reasoning abilities can be bootstrapped by distilling chain-of-thoughts from an LLM, before being further enhanced through RL training (Sui et al., 2025). Following such an approach, we further fine-tuned Reason-Repair models using DRO for one epoch.

As we can observe, applying Direct Repair Optimization on top of the *RR* models consistently enhances feedback performance across almost all types of feedback for both models, allowing the *RR*-trained models to reach overall stronger performance (with the exception of a drop in Hint Concealment \mathcal{H}_{Con}). Interestingly, we observe a stronger boost in diagnostic feedback performance for our Llama *RR* model than for our Qwen model. Looking more closely, both models reach similar overall performance after RL training, suggesting a performance trade-off might be happening between diagnostic and Socratic feedback abilities. We hypothesize that this plateau may stem from the limitations of LoRA adapters, which restrict how much new “knowledge” the model can acquire (Dettmers et al., 2023).

Table 2: **Feedback performance results.** We further fine-tune the Reasoning-Repair (RR) models with DRO and show performance benefits of the resulting **COMB** models. We bold (resp. underline) the best (resp. second best) results.

Method	\mathcal{E}_A	\mathcal{E}_S	\mathcal{P}_A	\mathcal{P}_S	\mathcal{H}_C	\mathcal{H}_I	\mathcal{H}_{Com}
Model: Llama-3.2-3B							
RR	42.9	62.9	42.9	<u>41.8</u>	52.7	49.4	56.3
DRO-2	<u>43.5</u>	64.7	40.5	32.2	<u>72.6</u>	<u>67.9</u>	<u>71.9</u>
RFF	<u>43.5</u>	<u>70.9</u>	36.3	<u>40.4</u>	94.2	92.3	89.3

5.3 Comparison Against Oracles

Table 2 also contrasts the performance of models trained with Direct Repair Optimization against the Repair-Feedback-First (RFF) models. We consider RFF models as oracles as those were trained with privileged supervision in the form of both LLM-generated feedback and repairs used as implicit reasoning steps.

Despite not using any feedback supervision, our DRO-2 models perform competitively in several areas, particularly with Llama-3B, where they closely approach RFF performance on diagnostic feedback tasks. Moreover, our combined approach (COMB), which applies DRO fine-tuning on top of LLM-distilled models, surpasses RFF on several criteria for Llama, including both explanation and patch quality. However, for Qwen, both DRO and COMB consistently fall short of RFF performance across most evaluation metrics.

These findings suggest that while DRO can serve as a valuable complement to LLM supervision, and even outperform direct finetuning in some settings, it is not yet a reliable substitute for training models directly on feedback generated by LLMs. Further work is needed to understand when and how DRO can consistently match or exceed the performance of supervised approaches.

6 Discussion and Conclusion

In this paper, we explored whether training language models to reason about students’ programs could improve feedback and provided insights into how this strategy compares to LLM supervision.

Summarizing answers to our research question.

Our findings show that (1) reasoning to repair programs improves a model’s ability to generate feedback, (2) DRO can further improve models fine-tuned on LLM-generated repairs, and (3) such refined models can, in some instances, match the performance of models trained directly on LLM-generated feedback.

Implications for programming education.

Programming education is increasingly turning to open-source language models, particularly smaller ones, to support teaching at scale (Liu et al., 2024b). We are anticipating a shift from using proprietary LLMs (e.g., GPT-4o) to open-source alternatives (e.g., LLaMA-3.3-70B) for distillation (Kotalwar et al., 2024), as the latter can be hosted locally and offer more control (Denny et al., 2024). Our work takes a step further by exploring whether we can eliminate reliance on LLMs and train SLMs directly on educational data, avoiding both the costs of third-party APIs and the computational demands of hosting large open-source models.

Although our work focuses on programming data, we believe DRO could be adapted to provide feedback in all educational domains where the correctness of a student’s work can be automatically evaluated. Methods such as Direct Repair Optimization can leverage much of the readily available data in educational platforms (i.e., student submissions and unit tests) without requiring extensive curation. Recent work has shown that combining such reinforcement learning methods with large-scale data can allow relatively small models to reach the performance of state-of-the-art proprietary models (Luo et al., 2025).

Extensions to other training approaches.

Direct Repair Optimization can easily be combined with human and LLM-supervised training strategies. Models trained with DRO can be bootstrapped from a handful of high-quality LLM-generated examples (Hicke et al., 2023; Ashok Kumar and Lan, 2024; Muennighoff et al., 2025), and further refined using Reinforcement Learning from Human Feedback (RLHF) (Woodrow et al., 2025) to align with specific instructional goals. Such hybrid pipelines offer a practical path forward, starting from refined educational data, scaling up performance through large-scale reinforcement learning, and applying targeted human supervision as a final step to meet specific classroom needs.

Alleviating privacy concerns. Although third-party LLM hosting services and the use of proprietary APIs are becoming more affordable, institutional policies on sending student data to third-party services can restrict their use. Our experiments show that institutions with access to modest computational power (such as a single consumer-grade GPU)² can obtain powerful programming teaching assistant models tailored to their classes.

Such models can also be directly deployed on students' laptops (Liu et al., 2024b; Kotalwar et al., 2024; Ruan et al., 2024), enabling personalized, timely, and offline support.

Future work. Our future work will explore how Direct Repair Optimization performs compared to proprietary and open-source LLMs when trained on large-scale private educational programming data as well as public programming data from HuggingFace³. To this end, we plan to conduct human expert evaluations and perform A/B studies to evaluate how real students respond to such feedback (SLM vs LLMs). We will also investigate how human data and preferences can be integrated into the training pipeline to better align small models with specific institutional goals.

Looking ahead, we aim to move beyond training individual models on private institutional data and tackle the broader challenge of building foundation models for programming education (Bommasani et al., 2022). We believe such models could be pre-trained from publicly open-source large-scale ethical data, and further refined with federated learning across multiple institutions.

Limitations

Our study is not without limitations. First, we conducted all experiments on a single dataset of Python programming submissions collected from one institution and did not explore whether our results hold in other contexts. Second, and perhaps more importantly, our evaluation lacks human annotations, expert assessment, or qualitative analysis. While prior work suggests LLMs can be used to assess programming feedback (Seo et al., 2025; Koutchme et al., 2024b, 2025), such works also highlight that their judgments are not always perfect. Although we partly mitigate this by combining multiple LLMs-as-judges, our results must still be interpreted with caution.

²We trained our models on a single 32GB VRAM GPU.

³<https://huggingface.co/datasets>

We do not claim that DRO-trained models produce feedback that meets any absolute standard of quality (e.g., “nearly perfect feedback”). Rather, our findings establish DRO’s relative performance: it improves feedback quality over a base untrained model and can match the performance of models trained via LLM distillation. Whether such feedback is ultimately pedagogically effective for students remains an open question until validated through human studies.

Additionally, our experiments were limited to two small models with around 3B parameters. While prior work suggests that performance improves with base model size (Sui et al., 2025), it remains to be seen whether the same trends hold when applying Direct Repair Optimization for improving other language models’ programming feedback. Moreover, our experiments also did not include new state-of-the-art reasoning large language models such as OpenAI o3. Such models, which were effectively trained for reasoning, would probably act as better candidates for LLM-distillation and combined LLM-distillation and RL training.

Ethics Statement

This work has been conducted in accordance with national and institutional ethical guidelines. We recognize the growing importance of ethical considerations in AI research, particularly with respect to data use, model deployment, and societal impact.

The dataset used in this study is publicly available to the research community. Our primary goal is to advance the development and evaluation of open-source language models for feedback generation in programming education. By prioritizing open-source models, we aim to promote transparency, accessibility, and accountability, while mitigating privacy concerns associated with proprietary LLMs.

We also acknowledge broader ethical dimensions of our work. These include questions of fairness and equity in access to high-quality feedback, the risk that language models may favor certain interaction styles or learner backgrounds, and the potential for such technologies to either reduce or exacerbate global disparities in education. As the use of LLMs in learning environments grows, we believe it is essential to continuously assess and address these challenges in collaboration with educators, institutions, and affected communities.

A Methodological and Experimental Details

A.1 Training loss

The original GRPO loss function is given by:

$$\mathcal{J}_{\text{GRPO}} = -\frac{1}{\sum_{g=1}^G |o_g|} \sum_{g=1}^G \sum_{t=1}^{|o_g|} l_{g,t} - \beta \text{KL}(\pi_{\theta}, \pi_{\text{ref}})$$

where

$$l_{g,t} = \frac{\pi_{\theta}(o_{g,t} \mid d^i, s^i, o_{g,<t})}{\pi_{\theta_{\text{old}}}(o_{g,t} \mid d^i, s^i, o_{g,<t})} \hat{A}_{g,t}$$

and \hat{A}^i is a value called the advantage. Intuitively, the advantage tells each generation how much better it is than the $g - 1$ other generations.

Compared to popular offline preference methods such as DPO (Rafailov et al., 2024), which use explicit preference pairs, the advantage function helps "ranking" which of the multiple generations, without relying on pairwise comparisons.

$$\hat{A}_g = \frac{(r_g^i - \bar{r})}{\text{std}(r)}$$

$\text{KL}(\pi_{\theta}, \pi_{\text{ref}})$ is a value called the KL divergence. This value essentially tells how much the model responses are diverging from the model prior to the start of training. We omit the definition of this term for simplicity and refer the reader to the DeepSeek paper (DeepSeek-AI, 2025). In essence, $\mathcal{J}_{\text{GRPO}}$ is the weighted average of the advantage of all completions and a β scaled approximation of the KL divergence.

The following works have found a few issues with the original formulation.

Removing the KL term. (Yu et al., 2025a) finds that the $\text{KL}(\pi_{\theta}, \pi_{\text{ref}})$ term can slow down training, as in practice we want to allow the trained model to diverge from the original policy.

Length response bias. (Liu et al., 2025) show that the term $-\frac{1}{\sum_{g=1}^G |o_g|}$ introduces a *response length bias* favourizing longer generations. To address this issue, the authors propose dividing by a constant length, being the maximum allowed size of each generation (LG).

Program difficulty bias. Moreover, they also show that the standard deviation in the advantage computation $\hat{A}_g = \frac{(r_g^i - \bar{r})}{\text{std}(r)}$ introduces a *problem difficulty bias*, where overly hard or overly easy questions are weighted more heavily in the loss. In our situation, the "problem" is the student program to solve, and this bias would lead to scenarios where student programs which are too easy to fix or student programs which are too hard to solve would be given more attention. Removing the standard deviation addresses this issue. Taking these two changes into account yields the proposed loss function (see equation 1).

Taking into account multiple updates. Because sampling generations is computationally and time-intensive, in practice, we use a version of this loss function which takes into account multiple updates per generation, as proposed by (Yu et al., 2025a):

$$\mathcal{J}_{\text{dr.GRPO}} = -\frac{1}{\sum_{g=1}^G |o_g|} \sum_{g=1}^G \sum_{t=1}^{|o_g|} \left[\min \left(l_{g,t}, \hat{C}_g \hat{A}_g \right) \right]$$

where

$$\hat{C}_g = \text{clip}(l_{g,t}, 1 - \epsilon_{\text{low}}, 1 + \epsilon_{\text{high}})$$

constrains the subsequent updates to stay within a reasonable range of the original policy.

A.2 Feedback Quality Attributes.

Table 3 shows the definitions of the feedback quality criteria used in our work. These definitions are taken from prior work in programming feedback.

A.3 Experimental Details

We outline training and inference-specific details.

A.3.1 Training

We train our models using the HuggingFace TRL library. Unless explicitly outlined below, all hyperparameters were left at default values. We train all models with QLoRa (Dettmers et al., 2023) using an alpha $\alpha = 128$ and a rank $r = 128$. All models are trained on a single NVIDIA V100 GPU using our institution’s research cluster. Training for one epoch on such compute takes approximately 8 hours. Training on an A100 takes less than 5 hours.

dr.GRPO specific hyperparameters. Table 4 shows the hyperparameters used to train our DRO model. These parameters follow prior work (DeepSeek-AI, 2025; Luo et al., 2025; Yu et al., 2025a). We train all models for two epochs on the training set of FalconCode. For each incorrect program, we generate four ($G = 4$) candidate reasoning and repairs $\mathcal{G}^i = (\mathcal{T}_i^i, \mathcal{R}_i^i)$. We highlight that we designed our method to run on an entry-level GPU with 32GB of RAM. Prior work (DeepSeek-AI, 2025) suggests that a higher number can substantially improve results, however, more generations require more GPU RAM.

Supervised Fine-tuning. Table 5 shows the hyperparameters used to train our distilled models via supervised fine-tuning on the training set of FalconCode. We train all models for three epochs.

A.3.2 Inference

For generating feedback at inference time, for all models, we generate both repair and feedback using greedy decoding. For judging, we query proprietary models GPT-4o-mini and Gemini-2.0-flash using the OpenAI Python API, also using greedy decoding.

B Results Details

Table 6 shows the full results of all our experiments, including the repair-first prompting strategy. We additionally report the performance of our models on additional clarity criteria.

B.1 Prompting for Repair

Prompting for repair often decreases base model performance. Prompting the *BASE* models to generate a repair before producing feedback decreases diagnostic feedback performance. This observation aligns with findings from (Koutcheme et al., 2024a), who showed that a model’s ability to provide diagnostic feedback scales independently from its ability to perform program repair. In our case, using SLMs, a poor-quality greedy repair may degrade feedback quality more than providing no repair. This does not contradict (Sahai et al., 2023), as the authors use the Repair-First strategy with LLMs, which are strong at both repair and feedback. (Phung et al., 2023, 2024) extend the single-repair strategy with multiple repairs, but whether an SLM benefits from this is unknown. While it might alleviate this issue, it remains computationally expensive when running models locally.

Prompting to repair before feedback also decreases Socratic feedback performance for Qwen but increases it for Llama.

Prompting for repair brings benefits in diagnostic feedback performance for strong base models. Prompting to repair before feedback decreases the performance of the Llama DRO-trained models for generating diagnostic feedback but increases diagnostic feedback performance for Qwen models. We hypothesize that this effect is due to the base model overfitting on low-quality, greedy-generated repairs. We observe the same phenomenon for the RFF models, which were trained to repair before feedback: a decrease for Llama, but an increase for Qwen. For RR and their extended version with DRO (COMB), the effect is unclear.

B.2 Generations Clarity

We also studied how language models perform in terms of the clarity (Cle) of the generations. However, we mostly observe that there does not seem to be a clear correlation with base model performance, training method, or prompting strategy.

Name	Notation	Definition	Used in
Accuracy	$\mathcal{E}_A, \mathcal{P}_A$	All issues in the student’s code (or all required fixes) are correctly identified.	(Koutcheme et al., 2024b, 2025)
Selectiveness	$\mathcal{E}_S, \mathcal{P}_S$	No non-existent or irrelevant issues are mentioned; no unnecessary changes are proposed.	(Koutcheme et al., 2024b, 2025)
Clarity	$\mathcal{E}_C, \mathcal{P}_C$	The explanation or patch is easy to understand, well-formatted, and concise.	(Koutcheme et al., 2025)
Correctness	\mathcal{H}_C	The hint provides correct information that would help fix the student’s code.	(Phung et al., 2024; Kotalwar et al., 2024)
Informativeness	\mathcal{H}_I	The hint contains useful information that helps the student understand or resolve the issue.	(Phung et al., 2024; Kotalwar et al., 2024)
Concealment	\mathcal{H}_{Con}	The hint avoids revealing the full solution and encourages reasoning.	(Phung et al., 2024; Kotalwar et al., 2024)
Clarity	\mathcal{H}_{Cle}	The hint is clearly written, easy to read, and free of unnecessary complexity.	(Phung et al., 2024; Kotalwar et al., 2024)

Analyzing Interview Questions via Bloom’s Taxonomy to Enhance the Design Thinking Process

Fatemeh Kazemi Vanhari and Christopher Anand and Charles Welch

Department of Computing and Software

McMaster University

Hamilton, Ontario, Canada

{kazemivf, anandc, cwelch}@mcmaster.ca

Abstract

Interviews are central to the Empathy phase of Design Thinking, helping designers uncover user needs and experience. Although interviews are widely used to support human-centered innovation, evaluating their quality, especially from a cognitive perspective, remains underexplored. This study introduces a structured framework for evaluating interview quality in the context of Design Thinking, using Bloom’s Taxonomy as a foundation. We propose the Cognitive Interview Quality Score, a composite metric that integrates three dimensions: Effectiveness, Bloom Coverage, and Distribution Balance Score. Using human-annotations, we assessed 15 interviews across three domains to measure cognitive diversity and structure. We compared CIQS-based rankings with human experts and found that the Bloom Coverage Score aligned more closely with expert judgments. We evaluated the performance of LMA-3-8B-Instruct and GPT-4o-mini, using zero-shot, few-shot, and chain-of-thought prompting, finding GPT-4o-mini, especially in zero-shot mode, showed the highest correlation with human annotations in all domains. Error analysis revealed that models struggled more with mid-level cognitive tasks (e.g., Apply, Analyze) and performed better on Create, likely due to clearer linguistic cues. These findings highlight both the promise and limitations of using NLP models for automated cognitive classification and underscore the importance of combining cognitive metrics with qualitative insights to comprehensively assess interview quality.

1 Introduction

Design Thinking is a widely adopted framework for creative problem-solving, particularly in areas that require deep user understanding and human-centered innovation. It typically progresses through five iterative stages: Empathize, Define, Ideate, Prototype, and Test. At the heart of this process

is the first stage, “Empathize”, enabling designers to deeply understand users’ experiences, emotions, and needs. It distinguishes Design Thinking from purely analytical approaches by emphasizing a human-centered perspective. This phase often involves interviews, observations, and immersive techniques, such as simulating real user experiences, to uncover pain points and inform meaningful design interventions (Brown, 2009; Org, 2015). Among these methods, interviews play a vital role by fostering open-ended, direct dialogue between researchers and users. The quality of the interview questions during this phase is especially critical, as it shapes the depth, clarity, and diversity of responses, and ultimately influences the effectiveness of the application’s design.

Despite the central role of interviews, there is limited systematic guidance on how to structure interview questions to encourage deeper cognitive engagement. Many interviews rely on intuitive or ad hoc question writing, often leading to unbalanced questioning that skews toward lower-order thinking, such as remembering or understanding, while neglecting higher-order processes such as analyzing, evaluating, and creating (Anderson and Krathwohl, 2001).

To address this gap, we propose a novel approach that takes advantage of Bloom’s Taxonomy, a widely used hierarchical framework that classifies cognitive tasks into six categories: Remember, Understand, Apply, Analyze, Evaluate, and Create (Bloom, 1956; Anderson and Krathwohl, 2001). Originally developed for educational settings, Bloom’s Taxonomy has been effectively adapted in recent years for use in question generation (Hwang et al., 2023), question classification (Mohammed and Omar, 2018; Gani et al., 2023), and curriculum evaluation (and, 2002). In this study, we apply our approach to the domain of interview question design within the context of Design Thinking. Specifically, we investigate whether

covering different levels of Bloom’s Taxonomy in interview questions and responses has an effect on the overall quality of interviews and contributes to enhancing the Design Thinking process. Our analysis covers three interview subjects: AI Regulation, Math Visualizer, and Grandfather Game.

We use Large Language Models (LLMs) to automatically classify both interview questions and their responses according to Bloom’s Taxonomy. Leveraging recent advances in prompt engineering techniques including zero-shot (Brown et al., 2020), few-shot (Liu et al., 2023), and chain-of-thought (CoT) prompting (Wei et al., 2022), we use LLaMA-3-8B-Instruct, an instruction-tuned open-source LLM, and GPT-4o-mini, a lightweight proprietary model from OpenAI optimized for fast reasoning tasks, to assign Bloom levels based on the cognitive demands of the text. We also introduce a composite evaluation metric, the Cognitive Interview Quality Score (CIQS), which integrates Bloom effectiveness, coverage, and distribution balance scores into a single measure to assess the overall quality of interview questions.

To guide our investigation into the cognitive quality of interviews and the role of automated classification, this study is driven by the following research questions:

RQ1: Does covering multiple levels of Bloom’s Taxonomy in interview questions and responses contribute to higher-quality interviews within the Design Thinking process?

RQ2: Can LLMs, such as LLaMA-3-8B-Instruct and GPT-4o-mini, reliably classify interview content into Bloom’s cognitive levels across different prompting strategies?

RQ3: To what extent do our CIQS-based automated rankings of interview quality align with expert human evaluations across diverse interview subjects?

2 Related Work

2.1 Automated Classification of Questions Using Bloom’s Taxonomy

Bloom’s Taxonomy, originally introduced by Bloom (1956) and later revised by Anderson and Krathwohl (2001), has long served as a framework for classifying learning objectives and designing educational assessments. Numerous studies have leveraged this taxonomy to guide the construction of questions that effectively target various cognitive levels, from simple

recall (Remember) to complex creative tasks (Create). Chang and Chung (2009) developed a keyword-based system aimed at automatically classifying teachers’ questions according to Bloom’s Taxonomy. By constructing a dictionary that maps specific keywords to corresponding cognitive levels, their system achieved a 75% accuracy in identifying questions at the Remember level. However, its performance declined for higher-order levels, with accuracy ranging between 25% and 59%. Yahya and Osman (2011) explored the effectiveness of machine learning techniques by employing TF-IDF features combined with Support Vector Machine (SVM) classifiers to categorize 190 exam questions across Bloom’s six cognitive categories. Haris and Omar (2012) employed a rule-based classifier to categorize 135 computer programming examination questions according to Bloom’s Taxonomy.

Building upon these methodologies, Mohammed and Omar (2020) introduced an enhanced classification model incorporating TFPOS-IDF, a variation of TF-IDF that considers part-of-speech information, and pretrained word2vec embeddings to capture semantic relationships. They evaluated their model using kNN, Logistic Regression, and SVM classifiers on datasets containing 141 and 600 questions. The SVM classifier exhibited superior performance, achieving weighted F1-scores of 83.7% and 89.7% on the respective datasets, highlighting the efficacy of integrating syntactic and semantic features in question classification.

Li et al. (2022) conducted a study to automate the classification of learning objectives according to Bloom’s Taxonomy. They compiled 21,380 learning objectives from 5,558 courses at an Australian university, manually labeled these objectives based on Bloom’s six cognitive levels, and applied five conventional machine learning algorithms—Naive Bayes, Logistic Regression, Support Vector Machine, Random Forest, and XGBoost—as well as a deep learning approach using the pretrained BERT language model. Their findings demonstrated that BERT-based classifiers outperformed others across all cognitive levels, achieving Cohen’s κ up to 0.93 and F1 scores up to 0.95. Additionally, SVM, Random Forest, and XGBoost models delivered performance comparable to BERT-based classifiers. The study also revealed that constructing separate binary classifiers for each cognitive level slightly outperformed a single multi-class, multi-label classifier, suggesting that individualized models for

each cognitive level may enhance classification accuracy.

Gani et al. (2023) focused on automating the classification of exam questions by evaluating various pretrained word embedding techniques, both contextual and non-contextual, across two datasets. Their study highlighted that while deep learning and contextual embeddings improved classification performance, their effectiveness was significantly influenced by dataset characteristics. Similarly, Al Faraby et al. (2024) assessed the capability of ChatGPT in classifying and generating questions. They found that in generating questions from reading sections, the differences with human-generated questions were not significant, indicating ChatGPT's potential for educational content creation.

2.2 Automatic Evaluation of Questions

Recent advancements in natural language processing have facilitated the automated evaluation of open-ended question complexity using Bloom's Taxonomy. Raz et al. (2024) employed a fine-tuned LLM to predict human ratings of question complexity, demonstrating a strong correlation ($r = 0.73$) between LLM-generated scores and human assessments, outperforming traditional baseline measures such as semantic distance and word count. Simone A Luchini and Beaty (2025) investigated the use of LLMs to assess the originality of narratives across multiple languages. They trained three distinct LLMs to predict human originality ratings of short stories written in 11 languages. The first model, trained exclusively on English narratives, achieved a robust correlation ($r = 0.81$) with human assessments. When this model was applied to multilingual stories translated into English, it maintained strong predictive performance ($r \geq 0.73$). Additionally, a multilingual model trained on narratives in their original languages reliably predicted human originality scores across all languages ($r \geq 0.72$). Hwang et al. (2023), explored an AI-driven approach to generating and evaluating multiple-choice questions in introductory chemistry and biology, focusing on alignment with Bloom's Taxonomy. They employed zero-shot prompting with GPT-3.5 to create questions, validated their cognitive levels using RoBERTa, and assessed question quality based on Item Writing Flaws Moore et al. (2023). The findings indicate that GPT-3.5 is capable of generating questions at various cognitive levels, particularly excelling at producing higher-order thinking questions at the

Evaluation level. However, discrepancies between AI-generated and human-assessed Bloom levels suggest the need for further refinement in question generation methodologies. Additionally, the study highlights an inverse correlation between Bloom's level and perceived question quality, indicating that while AI can generate complex questions, it may struggle with nuances in cognitive distinction and clarity at higher taxonomic levels.

3 Methodology

3.1 Dataset

This study is based on a dataset of transcribed interviews collected to evaluate the cognitive depth of questions and responses used during the "Empathy" phase of the Design Thinking process. In this study, the interviews focused on three distinct subject areas: Grandfather Game Application, Math Visualizer Software, and AI Regulation (for a description of each area see Appendix B). These topics were selected to ensure a variety of user perspectives and cognitive demands, ranging from personal storytelling to educational technology and policy discussions.

A total of 15 semi-structured interviews were conducted. Each interview consisted of both high-level and low-level open-ended questions. Not all questions were equally well-structured, as the goal was to intentionally support a range of cognitive levels in line with Bloom's Taxonomy, enabling analysis across varying depths of reasoning and understanding. The interviews were audio-recorded with participant consent, transcribed using Microsoft Teams, and manually reviewed for accuracy. Transcripts were anonymized and structured by role (interviewer/interviewee).

While the original transcripts included more entries, we removed manually segments that were not suitable for cognitive classification. This included ice-breaker exchanges (for example, "Hi, how are you today?", "Thanks for joining us!"), affirmations (for example, "yes", "okay"), and expressions of appreciation (for example, "thank you"), all of which could not be meaningfully assigned a Bloom's level. After this filtering process, the final dataset consisted of 726 entries, comprising 363 interview questions and their corresponding 363 responses. All questions and responses were manually classified by one of the authors familiar with Bloom's Taxonomy levels. Our analysis spans the three interview subjects: AI Regulation

(274 entries), Math Visualizer (244 entries), and Grandfather Game (208 entries).

3.2 Bloom-Level Classification Process

To classify each interview question and response according to Bloom’s Taxonomy, we employed a prompt-based strategy using two LLMs: LLaMA-3-8B-Instruct and GPT-4o-mini. We applied three prompting techniques including: zero-shot, few-shot, and CoT to guide the models’ responses.

In the zero-shot prompting approach, the model receives a direct instruction to classify the input into one of the six Bloom levels including: Remember, Understand, Apply, Analyze, Evaluate, or Create, without being given any prior examples. This method tests the model’s ability to rely on its internalized knowledge of Bloom’s Taxonomy and produces a fast baseline classification.

In few-shot prompting, we provide the model with one labeled example for each Bloom’s Taxonomy level before introducing the target input. These examples help calibrate the model’s understanding of the classification task.

Finally, we apply CoT prompting, which instructs the model to explain its reasoning before presenting a final classification. This method encourages step-by-step cognitive processing, making the model’s decision-making process transparent and auditable.

The purpose of this classifications is to evaluate their alignment with human judgment and to inform future efforts toward automating cognitive-level assessment in interviews (see Section 4.1 for the results).

3.3 Evaluation Framework

To assess the cognitive quality of interviews, we used human-annotated Bloom’s Taxonomy classifications for each question and response. Based on these annotations, we calculated three key evaluation metrics: Effectiveness Score (ES), Bloom Coverage Score (BCS), and Distribution Balance Score (BDS), developed by the authors to capture different dimensions of cognitive engagement. Together, these metrics represent the Cognitive Interview Quality Score (CIQS), a composite measure reflecting the cognitive richness and structural diversity of each interview.

In this study, CIQS and its components were derived from human classifications due to their higher reliability. The following sections review the components of the CIQS metric.

3.3.1 Effective Score (ES)

The Effectiveness Score measures how well each interview question succeeds in eliciting the intended level of cognitive engagement, as defined by Bloom’s Taxonomy. Rather than evaluating the question in isolation, this score is grounded in a comparison between the cognitive level of the question and the cognitive depth observed in the interviewee’s response. This approach aligns with the goals of the “Empathy” phase in Design Thinking, where the primary objective is not only to ask meaningful questions but to generate equally meaningful insights [Brown \(2009\)](#).

To calculate ES, first each question–response pair is evaluated by comparing the intended cognitive level of the question with the actual level of the response, and rated according to this criteria:

- Highly Effective (2 points): The response exceeds the intended cognitive level (for example, a question aimed at “Analysis” receives a “Creative” response).
- Effective (1 point): The response matches the intended cognitive level of the question.
- Needs Improvement (0 points): The response falls below the intended level, indicating limited cognitive engagement.

After assigning these numerical values to each pair, the ES for each interview is calculated as the average score across all pairs:

$$\text{Effectiveness Score} = \frac{\sum_{i=1}^n s_i}{n} \quad (1)$$

where $s_i \in \{0, 1, 2\}$ is the score assigned to the i -th question–response pair based on the mentioned criteria, and n is the total number of pairs in the interview. The resulting score ranges from 0 (all questions need improvement) to 2 (all questions are highly effective). This metric captures not only the cognitive intent behind the questions but also their real-world impact as demonstrated through participant responses.

3.3.2 Bloom Coverage Score (BCS)

The Bloom Coverage Score evaluates the extent to which an interview engages participants across the six levels of Bloom’s Taxonomy. A higher BCS indicates greater cognitive diversity, reflecting an intentional design that stimulates a broad range of thinking processes.

This diversity is particularly important in the context of Design Thinking, where complex problem-solving requires movement across multiple cognitive domains. Wu et al. (2021) propose a design thinking model explicitly structured around Bloom’s Taxonomy, arguing that design thinking can be taught and structured through cognitive processes, from basic understanding to advanced creative generation. They emphasize that aligning design tasks with Bloom’s full spectrum enables learners and participants to progress systematically from comprehension to innovation.

We define BCS as the number of cognitive levels covered in the interview divided by the total number of levels (6). The ideal BCS is 1.0, indicating that all six Bloom’s levels are present at least once. The metric focuses on whether each level appears, not how often, encouraging diverse cognitive coverage in interview design.

3.3.3 Distribution Balance Score (BDS)

While the BCS measures the number of Bloom’s cognitive levels represented in an interview, it does not reflect how evenly those levels are distributed. A cognitively rich interview is not only diverse in coverage but also balanced, ensuring that no single level dominates. To address this, we introduce BDS, which quantifies the uniformity of the cognitive distribution across Bloom’s levels.

Let p_i represent the proportion of questions classified into the i -th Bloom’s Taxonomy level, and let n be the total number of Bloom levels ($n = 6$). The BDS is defined as:

$$\text{BDS} = 1 - \frac{\sum_{i=1}^n \left(p_i - \frac{1}{n}\right)^2}{\frac{n-1}{n}} \quad (2)$$

This formula computes the squared deviation of the observed distribution $\{p_i\}$ from a uniform distribution $\frac{1}{n}$, and normalizes it by the maximum possible imbalance, which occurs when all items are concentrated in a single Bloom level. The squared term ensures that both over and underrepresentation contribute equally to the imbalance score, while penalizing larger deviations more. The BDS value ranges between 0 and 1.0. A BDS of 1.0 indicates a perfectly balanced distribution across all Bloom levels, reflecting equal representation. Conversely, a BDS of 0 signifies complete imbalance, with all items concentrated in a single Bloom level.

The formulation of the BDS is adapted from Pielou’s Evenness Index Pielou (1966), tradition-

ally used in ecology to assess distributional uniformity. We apply this concept to measure cognitive balance across Bloom’s levels. Unlike entropy-based alternatives, our variance-based approach offers greater simplicity and sensitivity to cognitive imbalances. This metric encourages interviews that span multiple cognitive levels in a well-distributed and cognitively meaningful way.

3.3.4 Cognitive Interview Quality Score (CIQS)

To provide a comprehensive assessment of interview quality from a cognitive perspective, we propose the Cognitive Interview Quality Score. This metric combines three core dimensions: practical effectiveness, cognitive coverage, and structural balance. CIQS is calculated using the following weighted formula:

$$\text{CIQS} = 0.5 \times \text{ES} + 0.3 \times \text{BCS} + 0.2 \times \text{BDS} \quad (3)$$

In this formula, Effectiveness is emphasized most heavily to reflect the importance of empirical success: questions must not only be well-designed but must also stimulate the intended cognitive engagement, as evidenced by actual responses Anderson and Krathwohl (2001). Bloom Coverage receives moderate emphasis for its role in encouraging diverse thinking pathways, while Distribution Balance contributes structural integrity without dominating the evaluation. The weighting scheme (0.5 for ES, 0.3 for BCS, and 0.2 for BDS) was determined to prioritize cognitive alignment in actual responses while still valuing breadth and balance. This design is informed by principles from educational assessment and cognitive taxonomy theory Anderson and Krathwohl (2001), though the metric itself is introduced as part of this work. The CIQS serves as a unified cognitive quality rating for each interview, enabling systematic comparison across topics or participant groups while supporting iterative improvement in interview design.

3.4 Human Evaluation of Interview Quality

To validate the CIQS framework, we conducted a human evaluation in which an expert (tenured Professor) in design thinking independently ranked the interviews across all three subjects. The expert ranked each interview based on its effectiveness in uncovering useful information about the user and their practices and needs. This qualitative judgment served as a benchmark to assess how well CIQS scores aligned with human-perceived

interview quality. Comparing the CIQS rankings with the expert’s rankings helps determine whether cognitively focused metrics reflect what a human evaluator considers a high-quality, informative interview.

4 Experiments & Results

4.1 Evaluating Human–LLM Cognitive Classification Agreement

One of the authors annotated all question-response pairs in our dataset for their Bloom’s Taxonomy level. To measure the agreement between LLM-assigned and human-assigned Bloom’s Taxonomy levels, we used Kendall’s Tau (τ), which is well-suited for ordinal data and provides a robust estimate of correlation, particularly with small sample sizes and tied ranks (Kendall, 1938). The results are presented in Table 1, indicate that the zero-shot GPT-4o-mini achieved the strongest alignment with human judgments in all domains: AI Regulation ($\tau = 0.58$), Math Visualizer ($\tau = 0.47$), and Grandfather Game ($\tau = 0.56$). Among LLaMA-3-8B-Instruct models, the few-shot prompting yielded the highest correlations overall, particularly in AI Regulation ($\tau = 0.33$). In contrast, zero-shot prompting under LLaMA showed very weak agreement across subjects.

These findings suggest that GPT-4o-mini, especially in zero-shot, is more reliable for capturing cognitive-level distinctions in interview data, while open-source LLaMA models show more limited alignment with expert assessments. Performance differences can be attributed to the models’ architectures and training methodologies. GPT-4o-mini (OpenAI’s distilled model) balances efficiency and advanced reasoning, excelling in nuanced tasks.¹ LLaMA-3-8B-Instruct, while optimized for dialogue and instruction-following, may require further fine-tuning to match the classification accuracy demonstrated by GPT-4o-mini in this study.²

To identify which Bloom’s levels posed the greatest challenges for LLMs, we generated separate confusion matrices comparing the aggregated predictions of LLaMA-3-8B-Instruct models and GPT-4o-mini models against human classifications across Bloom’s Taxonomy levels, as presented in Figures 1 and 2. The LLaMA ensemble, based on

Figure 1: Confusion Matrix: LLaMA-3-8B-Instruct Majority Vote Vs Human Classification.

majority voting, exhibited a strong overprediction of the “Remember” category, leading to widespread misclassification of responses originally labeled as “Understand”, “Evaluate”, and “Create”. This pattern suggests a tendency to default to lower-order cognitive categories. In contrast, the GPT-4o-mini ensemble produced a more balanced distribution across predicted classes, with higher accuracy in identifying “Remember”, “Understand” and “Evaluate”, and notably less confusion between the levels.

These findings are further supported by the quantitative results reported in Tables 2 and 3. The LLaMA-3-8B-Instruct models showed limited alignment with human labels, with accuracy ranging from 23.9% to 29.1% and macro F1-scores below 0.19. Their highest macro precision and recall were 0.312 and 0.226, respectively, under the Chain-of-Thought setting. In contrast, all GPT-4o-mini variants outperformed LLaMA across metrics. The Zero-shot GPT model achieved 53.7% accuracy and a macro F1-score of 0.511, while Few-shot prompting reached a macro precision of 0.642. GPT models also showed stronger weighted F1-scores, indicating better overall balance across Bloom levels.

4.2 Evaluating Cognitive Dimensions of Interviews with CIQS

To evaluate and compare the cognitive quality of interviews across different topics, we applied our proposed scoring framework, the Cognitive Interview Quality Score, which combines three key dimensions: Effectiveness Score, Bloom Coverage Score, and Distribution Balance Score. As illustrated in Table 4, AI Regulation achieved the highest CIQS (0.88), supported by strong effectiveness (ES =

²<https://huggingface.co/meta-llama/Meta-Llama-3-8B-Instruct>

Model and Prompting Technique	AI Regulation	Math Visualizer	Grandfather Game
LLaMA-3-8B-Instruct Zero-shot	0.08	-0.01	0.01
LLaMA-3-8B-Instruct Few-shot	0.33	0.26	0.26
LLaMA-3-8B-Instruct Chain-of-Thought	0.18	0.09	0.33
GPT-4o-mini Zero-shot	0.58	0.47	0.56
GPT-4o-mini Few-shot	0.45	0.41	0.51
GPT-4o-mini Chain-of-Thought	0.52	0.41	0.47

Table 1: Kendall’s Tau (τ) correlation coefficients between model predictions and human annotations with highest scoring models in bold.

Model	Accuracy	Macro Precision	Macro Recall	Macro F1	Weighted F1
LLaMA-3-8B-Instruct Zero-shot	0.239	0.218	0.171	0.129	0.180
LLaMA-3-8B-Instruct Few-shot	0.285	0.222	0.225	0.155	0.205
LLaMA-3-8B-Instruct Chain-of-Thought	0.291	0.312	0.226	0.185	0.230

Table 2: Performance of LLaMA-3-8B-Instruct models across prompting techniques.

Figure 2: Confusion Matrix: GPT-4o-mini Majority Vote vs Human Classification.

1.01) and distribution balance (BDS = 0.80), despite slightly lower Bloom coverage (BCS = 0.71). This suggests that responses in AI-related interviews were well-aligned with the intended cognitive levels and well-distributed, though not all Bloom levels were equally represented. In contrast, Math Visualizer interviews exhibited the lowest CIQS (0.82), mainly due to a lower effectiveness score, suggesting that responses did not consistently reach the cognitive depth expected from the questions. Grandfather Game fell in the middle CIQS (0.84), showing relatively strong alignment but narrower cognitive coverage.

This automated scoring approach enables an objective comparison of interviews based on cognitive dimensions. However, cognitive depth is only one aspect of interview quality. As part of future work, we aim to explore additional metrics, such as emotional engagement, relevance to interview goals, procedural coverage, and question neutrality. These dimensions emerged from the feedback we

received during our interview sessions on different topics, where participants highlighted aspects that contributed to more meaningful and engaging conversations. These dimensions may offer a more complete view of interview quality beyond what Bloom’s taxonomy captures.

4.3 Evaluating the Alignment Between CIQS and Human Rankings

Figures 3-5 compare CIQS-based rankings with human expert judgments. Each CIQS score reflects a weighted combination of ES, BCS, and BDS.

In AI Regulation, the expert ranked Interview 3 as the most effective and Interview 1 as the least, while our CIQS-based scoring produced the opposite order and ranked Interview 3 as the most effective, highlighting a misalignment between cognitive structure (as captured by CIQS) and the expert’s judgment, which was based on how well each interview uncovered useful information about the user and their practices and needs. For Math Visualizer, Interview 5 ranked highest by CIQS due to perfect BCS and strong ES, while the expert preferred Interview 2 for its insightfulness. In Grandfather Game, both approaches aligned on Interview 1 as the best, though discrepancies appeared in the middle ranks. Notably, further analysis revealed that Bloom Coverage Score more closely aligned with human expert rankings than CIQS or other individual metrics. BCS showed moderate to strong correlations with expert judgments across all domains: ($\rho = 0.50$) in Math Visualizer, ($\rho = 0.90$) in Grandfather Game, and ($\rho = 0.71$) in AI Regulation. These results suggest that interviews with broader cognitive coverage were more likely to be perceived as informative and high-quality by experts, contradicting our initial hypothesis that

Model	Accuracy	Macro Precision	Macro Recall	Macro F1	Weighted F1
GPT-4o-mini Zero-shot	0.537	0.584	0.537	0.511	0.521
GPT-4o-mini Few-shot	0.491	0.642	0.481	0.477	0.453
GPT-4o-mini Chain-of-Thought	0.518	0.529	0.527	0.494	0.518

Table 3: Performance of GPT-4o-mini models across prompting techniques.

Metric	AI Regulation	Math Visualizer	Grandfather Game
Effectiveness Score	1.01	0.84	1.00
Bloom Coverage Score	0.71	0.80	0.64
Distribution Balance Score	0.80	0.82	0.75
Cognitive Interview Quality Score	0.88	0.82	0.84

Table 4: Cognitive evaluation scores across interview subjects with highest scores in bold.

Figure 3: AI Regulation: CIQS vs Human Rankings.

Figure 4: Math Visualizer: CIQS vs Human Rankings.

Effectiveness Score would play the most influential role in overall evaluation. To further investigate this we performed a linear regression to learn the coefficients for Equation 3 that best align with the human expert rankings. We found that BCS had the highest coefficient but that values varied across domains with ES and BDS less consistently in their impact. While more work is needed to determine which factors most correlate with human judgments, these preliminary results suggest that BCS is more impactful and that other attributes of the topic may be relevant in expert decisions (for full regression details, see Appendix C).

The results suggest that While CIQS captures

Figure 5: Grandfather Game: CIQS vs Human Rankings.

the cognitive structure of interviews, human evaluations often consider additional factors such as relevance, clarity, emotional engagement, and procedural detail. This highlights the value of combining cognitive metrics with qualitative insights for a more complete assessment of interview quality.

5 Discussion

RQ1: Our results suggest that interviews covering a broader range of Bloom’s cognitive levels (higher BCS) tend to be ranked more favorably by the human expert, indicating greater cognitive diversity. This supports the hypothesis that cognitive richness, particularly through varied questioning strategies, enhances the quality of interviews in the Design Thinking context. However, alignment with human expert rankings was not always consistent, implying that additional qualitative dimensions (for example, emotional engagement and the inclusion of procedural information) also influence perceived interview quality.

RQ2: The outputs from LLaMA and GPT-4o-mini demonstrated partial alignment with human annotations, showing that LLMs have the potential to support cognitive level classification. GPT-

4o-mini, in particular, showed stronger agreement with human labels across prompting strategies, especially in zero-shot settings. However, inconsistencies across domains and between models reveal that current LLMs are not yet fully reliable as standalone evaluators. While their performance is promising for future automation efforts, fine-tuning and prompt engineering may be necessary to achieve consistent, human-comparable accuracy.

RQ3: The CIQS rankings showed partial alignment with expert human evaluations, with higher consistency in the Grandfather Game domain ($\tau = 0.40$) and greater divergence in Math Visualizer ($\tau = -0.8$) domain. These differences suggest that while CIQS effectively captures the cognitive structure and balance of interviews, human experts often consider additional qualitative dimensions, such as emotional engagement, relevance to user needs, and the inclusion of procedural information, that are not directly encoded in cognitive metrics. As such, CIQS serves as a valuable and scalable starting point for evaluating interview quality, but it should complement qualitative assessments.

6 Conclusion & Future Work

This study introduced a cognitive evaluation framework for interview quality based on Bloom’s Taxonomy, applied within the context of Design Thinking. We proposed the CIQS, a composite metric incorporating effectiveness, coverage, and distribution of cognitive levels. Using human-annotations, we collected and evaluated 15 interviews across three domains to measure the cognitive diversity and structure of interview content. We compared CIQS rankings with expert judgments, finding that while they are partially aligned, BCS correlates more strongly with human rankings than CIQS or other individual metrics, suggesting that breadth is especially valued by experts. GPT-4o-mini, particularly in zero-shot, showed the highest agreement with human Bloom level annotations (up to $\tau = 0.58$), outperforming LLaMA-3-8B-Instruct.

These findings suggest that while CIQS effectively captures the cognitive structure of interviews, human evaluations often prioritize additional factors such as relevance to user needs, clarity, emotional engagement, and procedural depth. This highlights the importance of complementing cognitive metrics with broader qualitative dimensions for a more comprehensive assessment of interview quality. In future work, we plan to refine CIQS by

exploring alternative weighting, incorporating additional qualitative indicators, and fine-tuning LLMs for more accurate, autonomous classification of interview content based on Bloom’s Taxonomy. To support continued research, we will release our corpus of 726 question–response pairs spanning three domains to support future work.

Limitations

The main challenge of this and any study of Design Thinking effectiveness is the maxim “savour surprises”, by which design thinkers mean that the most important information is usually the information which was not anticipated and not planned for. This is because this information is the most likely to invalidate a design made without in-depth user interviews, or to lead to a new product category which was not previously contemplated [Furr and Dyer \(2014\)](#). At this stage, we are not trying to identify such surprises, but ultimately, a research program aiming to improve design education will have to address it.

A more immediate limitation of this study is the use of a single human expert. Experts in teaching and evaluating design thinking are uncommon and in demand in academia and industry. To increase the number of evaluators, it will be necessary to streamline the process so that it is less time-consuming.

Another limitation of this study is that even the human evaluator is not evaluating what we ultimately care about: the acceleration of the innovation process through better design interviews. We do not know whether interviews ranked highly by human experts actually lead to higher rates of innovation. Once automated metrics are found with higher levels of agreement with human experts, validation studies including the full development cycle from initial interviews to product validation will be necessary.

Role-playing can be challenging depending on the task. For our AI interviews, we noticed a lack of procedural information and emotion, where we expected more of both. We think it is not trivial for most people to role-play older individuals or versions of themselves. We suggest future work in this direction borrows from more established fields to set up experiments involving perspective-taking, e.g. work on empathy [Batson et al. \(2002\)](#).

Finally, since our intermediate goal is to produce tools useful for teaching design skills, it is disap-

pointing that the proprietary LLM greatly outperformed the open-source LLM. Many school boards and higher education institutions will be reluctant to submit their students' data to proprietary LLMs which they cannot control. In our study, we used role-playing by sophisticated professionals, graduate students and upper-year undergraduate students to produce a data set for training and evaluation. In teaching scenarios, it would be much harder to insure that personal information would not lead into the interviews. Moreover, when you initially describe the data set, you need to use similar language to say that this data is designed to not include personal information. Finally, a data set generated using role-playing may be fundamentally different from real design interviews in a way which effects the validity of the metrics.

While Bloom's Taxonomy provides a useful scaffold for assessing cognitive engagement, it has known limitations. The taxonomy does not explicitly model underlying mental processes such as perception, memory, and intuition, and some categories may overlap in practice—for example, extrapolation under "Understand" often resembles "Apply." Furthermore, the hierarchy between "Apply", "Analyze", and "Create" has been critiqued as insufficiently nuanced. Future extensions could explore integrating more adaptive taxonomies that better capture the fluid and context-dependent nature of reasoning in design interviews (Madaus et al., 1973).

7 Appendix

A Prompts Used for LLM Classification

This appendix provides the exact prompts used to classify interview questions and responses into

cognitive levels according to Revised Bloom's Taxonomy, using different prompting techniques.

Zero-Shot Prompt

You are a cognitive science expert that categorizes text into one of the Revised Bloom's Taxonomy levels.

You must respond with only one word: one of the following levels: Remember, Understand, Apply, Analyze, Evaluate, or Create.

Do not provide any explanation, reasoning, or additional text. Only return the level name in the following format.

Classification: <One of the six Bloom's levels>

Few-Shot Prompt

You are a cognitive science expert trained in Revised Bloom's Taxonomy.

Classify the following text according to Revised Bloom's Taxonomy levels: Remember, Understand, Apply, Analyze, Evaluate, or Create.

Examples:

Text: "List the main components of design thinking."

Classification: Remember

Text: "Explain the theory of cognitive load."

Classification: Understand

Text: "How would you apply Pythagoras' theorem to calculate the height of a building?"

Classification: Apply

Text: "Identify patterns in customer behavior based on the provided dataset."

Classification: Analyze

Text: "Evaluate the effectiveness of renewable energy sources compared to fossil fuels."

Classification: Evaluate

Text: "Design a new marketing strategy for launching a product."

Classification: Create

Do not provide any explanation, reasoning, or additional text. Only return the level name in the following format.

Classification:<One of the six Bloom's levels>

Chain-of-Thought Prompt

You are a cognitive science expert in Revised Bloom's Taxonomy.

Your task is to classify a given text into one of the Revised Bloom's Taxonomy cognitive levels:

Remember, Understand, Apply, Analyze, Evaluate, or Create.

Text: {input-text}

First, explain your reasoning step by step based on what the text requires cognitively.

Then, based on your explanation, select the most appropriate Bloom's level from (Remember, Understand, Apply, Analyze, Evaluate, Create) using the following format:

Classification: <One of the six Bloom's levels>

Note: For all classifications, the following model parameters were used:

Temperature = 0.0, Max tokens = 500.

B Description of Interview Topics

This study includes interviews conducted on three different design topics, each selected to represent different cognitive and contextual demands. The topics were used to simulate early-stage Design Thinking sessions and assess the cognitive quality of interview interactions. The participants in this study included a mix of students or recent graduates and university professors, some of whom had prior experience with Design Thinking. To maintain anonymity, they were instructed to avoid disclosing any real personal information. Depending on the interview topic, participants were asked to adopt specific roles. In the Math Visualizer interviews, they were asked to act as university students; in the Grandfather Game interviews, they assumed the perspective of older adults; and in the AI Regulation interviews, they portrayed individuals using AI platforms in organizations such as schools or businesses. Interviewers were instructed to engage naturally while focusing on uncovering user needs and generating meaningful insights.

B.1 AI Regulation

This topic explores public perceptions, concerns, and expectations surrounding the regulation of artificial intelligence. The interviewees were asked about their understanding of AI technologies, trust in regulatory frameworks, and suggestions for ethical oversight. The domain encourages abstract reasoning and evaluative thinking about policy and technology.

B.2 Math Visualizer

This topic focuses on the use of visualization tools in learning mathematics. Participants discussed their personal experiences with visual learning, the challenges they face in understanding mathematical concepts, and ideas for improving visual interfaces.

B.3 Grandfather Game

This topic centers on designing a game that would appeal to older adults. Participants were asked to reflect on their childhood memories, personal interests, and previous gaming experiences to inform the creation of engaging and age-appropriate game concepts.

C Linear Regression for CIQS

We can predict the human rankings of design thinking interviews with the CIQS score by learning coefficients for Equation 3. We predict the coefficients with intercept for each conversation topic. The equation for the Grandfather Game topic is shown in Equation 4 and yields $R^2 = 0.51$ which matches human ranking. Similarly, for AI-Regulation, we get $R^2 = 0.99$ for Equation 5. Lastly, for the Math Visualiser we get Equation 6 with $R^2 = 0.58$. Here we are predicting the rank (lower is better) with the same terms, which is different than ranking by the maximum score as we did in the main part of the paper, however, it serves the same function and supports our claims that BCS is the most important term and the impact of factors appears to vary with the domain.

$$\begin{aligned} \text{CIQS} = & -11.0 \times \text{ES} - 25.0 \times \text{BCS} \\ & + 9.2 \times \text{BDS} + 22.9 \end{aligned} \quad (4)$$

$$\begin{aligned} \text{CIQS} = & -13.6 \times \text{ES} - 3.6 \times \text{BCS} \\ & + 53.5 \times \text{BDS} - 23.1 \end{aligned} \quad (5)$$

$$\begin{aligned} \text{CIQS} = & 21.0 \times \text{ES} - 18.8 \times \text{BCS} \\ & - 13.0 \times \text{BDS} + 11.1 \end{aligned} \quad (6)$$

Estimation of Text Difficulty in the Context of Language Learning

Abstract

Easy language and text simplification are currently topical research questions, with important applications in many contexts, and with various approaches under active investigation, including prompt-based methods. The estimation of the level of difficulty of a text becomes crucial when the estimator is employed inside a simplification workflow as a quality-control mechanism. It can act as a *critic* in frameworks where it can guide other models, which are responsible for generating text at a specified level of difficulty, as determined by the user's needs. We present our work in the context of simplified Finnish. We discuss problems in collecting corpora for training models for estimation of text difficulty, and our experiments with estimation models. The results of the experiments are promising: the models appear usable both for assessment and for deployment as a component in a larger simplification framework.

1 Introduction

In the US¹ and in the European Union,² legal pressures are emerging with laws that require government-affiliated agencies, as well as private-sector organizations in certain situations, to use clear communication that members of the public can understand. Workflows that involve easy language are already in official use at various levels of functioning in the public and private sectors in 20 countries in the EU. Easy language also plays a key role in second-language (L2) education, in particular—simplification of text to a level appropriate for a given learner is a key component of *personalization* in teaching. Simplification itself is a widely researched area in NLP.

In this paper, we take the position that methods for evaluating and *assessing* the difficulty level of a piece of text are *prerequisite* to methods for

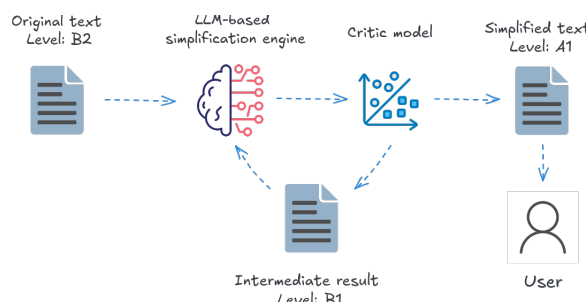

Figure 1: Text simplification using GPT-4o guided by level-aware feedback from a difficulty classifier as critic.

simplification—since in the absence of effective evaluation, simplification methods cannot be effectively validated or falsified.

The task of assessing the level of difficulty of the text can be framed as classification or (more appropriately) as regression—labeling a piece of text with a difficulty level, such as, e.g., a CEFR level.³ We will refer to models performing this task as *difficulty models*. These models can serve various purposes in language learning, such as estimating the difficulty level of texts that learners encounter. In this work, we use difficulty models to guide and evaluate text simplification pipelines performed by a large language model (LLM), specifically GPT-4o from OpenAI (Hurst et al., 2024).

Our simplification pipeline (Figure 1) employs a difficulty model that serves as a *critic*: it evaluates the difficulty level of the LLM output. If the resulting text exceeds the target level, feedback will be sent to the LLM to try again. The feedback includes the resulting text and its estimated level. The pipeline runs several iterations; if the resulting text remains harder than the target level after N iterations, the process terminates, and an error message is returned to the user.

We train two BERT-based difficulty models:

¹PlanLanguage.gov

²European Accessibility Act

³CEFR: Common European Framework of Reference for Languages.

one *regression* model, which predicts continuous scores that are later mapped to CEFR levels, and one *ordinal classification* model, which directly predicts the CEFR level of the input text. Our results show that both models improve the performance of the simplification pipeline over a baseline that runs without any critical guidance. The ordinal classification model proves to be a more effective critic for the LLM. Our hypothesis is that it aligns better with the difficulty assessment task because of its ordinal (ranking) nature.

The paper is organized as follows: Section 2 presents an overview of related work; Section 3 discusses the data we use to train the assessment models; Section 4 presents the experimental setup for the difficulty assessment; Section 5 presents the experiments with controlling the behavior of the LLM via a critic that assesses difficulty; Section 6 discusses the results and concludes the paper.

2 Related Work

Assessment of text difficulty, often referred to as readability assessment, has a long history in both education and in NLP. Traditional readability formulas, such as the Flesch-Kincaid Grade Level and Flesch Reading Ease, and the Lexile framework, based on item response theory (IRT), provide simple numeric scores for text difficulty (Kincaid et al., 1975; Stenner, 1996). These methods are easy to apply, but they rely on surface-level features and do not directly account for deeper lexical or syntactic complexity.

Early NLP readability systems used supervised models with hand-crafted linguistic features, including frequency word lists, depth of parse trees, grammatical constructions, and discourse structures. Collins-Thompson and Callan (2004) introduced a language modeling approach to predict reading difficulty for a tutoring system. Vajjala and Meurers (2012) incorporated features from Second Language Acquisition research to better serve language learners. For Russian, Laposhina et al. (2018) introduced a feature-based readability tool available online and widely used by L2 teachers.

Azpiazu and Pera (2019) present a multilingual readability model using a hierarchical attention network that learns to attend to difficult parts of a text and can implicitly learn factors like semantic difficulty or subtle syntactic cues. These models can be trained on proficiency-labeled data (e.g., with CEFR levels) to detect nuances of text difficulty

specific to L2 readers (e.g., idiomatic language). Recent work has shown that a fine-tuned BERT can outperform strong feature-based baselines by a significant margin in classifying texts by grade level or proficiency level (Martinc et al., 2021). Sharoff (2022) investigated compared the performance of Transformer-based models for predicting text difficulty vs. assessment using linguistic features, such as frequency of conjunctions, discourse particles, etc., for English and Russian.

Early pipeline approaches used readability classifiers to decide when to simplify: for example, Gasperin et al. (2009) trained a model to identify sentences that need simplification based on linguistic complexity features. Aluísio et al. (2010) developed readability assessment tools to support simplifying texts for low-literacy readers. Readability metrics have also served as simplification objectives in rule-based systems—Woodsend and Lapata (2011) incorporate a Flesch-Kincaid grade formula into an optimization-based simplifier.

Readability predictors have been used as feedback in generation loops—Alkaldi and Inkpen (2023) use a readability classifier in a reinforcement learning framework to iteratively simplify a text until it reaches the desired difficulty. More recently, large-scale neural systems have combined reading level prediction with controllable generation techniques (Agrawal and Carpuat, 2023).

3 Data

First, we describe the data used for training and evaluating the difficulty models and for the simplification pipeline. A major challenge is the scarcity of annotated data in Finnish for text simplification and difficulty prediction. To address this, we use a combination of Finnish texts annotated with difficulty levels (“native” data), and Russian texts annotated with difficulty levels and then translated into Finnish using machine-translation models.

3.1 Native Data

We use two collections of native Finnish data. The first consists of 1113 documents manually annotated by teachers of Finnish as a second language (L2), see “Manual” in Table 1. These are primarily informative and literary texts: the former covering topics such as human rights, social benefits, etc.; the latter feature classic Finnish literature and fragments of the Bible. The “Score” column in Table 1 shows the numerical values we assign to CEFR

Source	Level	Score	# Docs	# Words	# Sent.
SM	easy	1.5	153	294	9.3
YLE-selko	medium	3.5	766	249	8.7
HS	hard	5.5	715	598	13.7
YLE	hard	5.5	703	480	14.5
Manual	A2	2.0	363	237	10.9
	B1	3.0	229	204	11.0
	B2	4.0	154	221	11.8
	C1	5.0	192	272	17.5
	C2	6.0	175	189	19.9

Table 1: Native Finnish data.

levels, which are later used in regression models.

The second collection contains 2337 texts from *Suomen Mestari* (SM), a Finnish textbook, and *YLE selkosuomeksi* news,⁴ as well as news articles from the major newspapers *YLE* and *Helsingin Sanomat* (HS). These texts were not manually annotated. Instead, we make a coarse assumption based on the source: all texts from SM are labeled as easy, texts from YLE-selko as medium, and texts from YLE and HS as hard. We then suppose these difficulty levels roughly correspond to CEFR levels A1-A2, B1-B2, and C1-C2, respectively. Although this source-based annotation is a simplification—individual texts may vary in difficulty—it provides a practical heuristic in the context of limited human resources for annotating data.

3.2 Translated Data

Having some amount of Russian data annotated for difficulty, we translate it into Finnish to extend the size of the training set.

We use two sources of annotated Russian texts: 1. the *RuFoLa* corpus (Laposhina, 2020), which contains texts from coursebooks designed for learners of Russian as a foreign language; 2. the *RuAdapt* corpus (Dmitrieva and Tiedemann, 2021), a *parallel* Russian–Simple Russian dataset of texts adapted for learners of Russian as a foreign language. For our study, we use only the literary (*Zlatoust*) and encyclopedic sub-corpora, see Table 2. The “Score” column again shows the mapping between CEFR levels and numeric labels used later for a BERT-based regression model.

We filter out texts shorter than 10 words, as such a short context can negatively affect translation quality. We translated the Russian texts into Finnish using a model from OpusMT.⁵ We should

	2221	Native
Validation	1222	MT
	364	Native
Test	865	Native

Table 3: Data splits.

note that machine translation does not guarantee that a text in Russian will remain at the same difficulty level after translation into Finnish. This problem merits a dedicated research experiment. The entire dataset was split into 3 sets: training, validation, and test, see Table 3. The test set—860 texts—contains only native documents, and most documents are manually annotated.

4 Experiments

To establish an interpretable baseline for document-level difficulty prediction, we first train a feature-based regression model. This allows us to evaluate how well linguistic features alone can capture text difficulty, and later compare its performance to that of less interpretable deep-learning approaches.

4.1 Feature-based Regression

In this experiment, we use only native Finnish texts to train a Ridge regression model that predicts the difficulty level of a document. The target labels are mapped to the following numeric values: 0.0 (easy), 1.0 (medium), and 2.0 (hard). Manually annotated documents are mapped to the same numeric values: A1-A2 to 0.0, B1-B2 to 1.0, and C1-C2 to 2.0. We use these numeric values instead of the scores presented in Table 1 for simplicity.

We use 179 features to capture linguistic characteristics of the texts. These include normalized averages of count of POS tags, depth of parse

tree, sentence length, word distribution across ten frequency bins, and the proportion of out-of-vocabulary (OOV) words.⁶ The features also include the counts of over 160 linguistic constructs, covering grammatical features—e.g., tense, case, number, etc.—and syntactic patterns—e.g., necessity constructions, government structures, etc. The extraction of constructs from text is performed using the text processing pipeline in the Revita language learning system (Katinskaia et al., 2018, 2017; Hou et al., 2019); see examples of linguistic constructs and how they are extracted from text in (Katinskaia et al., 2023). Details of the features appear in Appendix D.

We evaluate three variants of the baseline model:

- (A) using all 179 features,
- (B) using a bootstrap selection of 104 features,
- (C) performing feature selection by training a Lasso regression model.

More details on the models are presented in Appendix A. As all models exhibited comparable performance, we adopt model (B) as the baseline in subsequent analyses due to its smallest feature set.

4.1.1 Results

Evaluation was performed using only native Finnish texts. The baseline model (B) achieved a mean absolute error (MAE) of 0.27 and a root mean squared error (RMSE) of 0.35. Figure 2 shows the distribution of the predicted scores in the three coarse levels of difficulty. The plot shows that easy texts tend to get scores higher than 0.0. This could be explained by the fact that we have much fewer easy texts in the native corpus, as well as by the assumption that all SM texts should be labeled easy, while in fact some of these texts are of intermediate difficulty. Nevertheless, the results provide a strong baseline for comparison with more complex models used in subsequent experiments, which offer less interpretability.

4.2 BERT-based Regression

We extend the BERT model for regression-based difficulty prediction, integrating custom loss weighting to handle class imbalances in the training data. The model is based on BERT, whose output layer is replaced with: (a) a pre-classification layer that projects BERT’s pooled output into a lower-dimensional space, has ReLU activation and

⁶Based on a large Finnish corpus, we build a list of words sorted by frequency and grouped into frequency bins.

Figure 2: Feature-based regression baseline model (C). Predicted regression scores across difficulty levels: Easy (0), Medium (1), and Hard (2).

Dropout, and (b) a final feedforward regression head that predicts a continuous difficulty score.

The model is trained using weighted mean squared error (MSE) loss. To prevent the model from being biased toward the most frequent difficulty levels in the training data, sample weights are computed inversely proportional to the frequency of each difficulty level. These weights are then normalized to ensure they sum to 1.

The model was trained on all training data presented in Table 3, using the Adam optimizer, separate optimization parameters for the BERT parameters and the linear layers, weight decay = 0.01, cosine scheduler for the learning rate, and early stopping.

4.2.1 Results

The evaluation was again performed on the test set containing native Finnish texts. The BERT-based regression model achieved MAE 0.13 and RMSE 0.29. Figure 3 shows the distribution of the predicted scores at all CEFR levels in the test set. The number of documents per level is shown in the “Support” column of Table 4. As we can see from the plot, for some of the difficulty levels (particularly, for level A1-A2), predicted scores tend to be higher than the true labels, indicating some bias toward overestimation.

To assess the classification performance, we map real-valued predictions to the nearest CEFR level. The resulting confusion matrix is in Figure 4. Class-wise precision, recall, and F1-scores are in Table 4. Overall, the model performs well across most CEFR levels. The lowest F1-score is observed for the A1-A2 level, which also has the smallest number of examples in the test set.

Figure 3: Predicted regression scores across difficulty levels using BERT-based regression model.

Figure 4: Confusion matrix after mapping difficulty scores to CEFR levels.

Only 1.3% of the test documents were assigned a predicted level that differs from the true level by *more than one* CEFR level. We consider deviations within one level to be acceptable, given the inherent difficulty and subjectivity of the task.

We examine the agreement between the feature-based regression model and the BERT-based regression on the test set, and the agreement of both models with the true labels. The predictions of the two models show a strong correlation: Spearman’s rank correlation is 0.76, and Pearson’s correlation is 0.83; Quadratic Weighted Kappa (QWK) is 0.84.⁷ This suggests a high degree of both rank-order and linear agreement between the models, despite being trained on different datasets and using different features.

The BERT-based model achieves near-perfect

⁷Predictions from the feature-based model were linearly rescaled to match the 1–6 scale of the BERT-based regression.

Level	Precision	Recall	F1-score	Support
A1-A2	1.00	0.78	0.88	32
A2	0.96	0.95	0.95	98
B1	0.85	0.95	0.90	60
B1-B2	1.00	0.98	0.99	183
B2	0.94	1.00	0.97	48
C1	0.98	0.98	0.98	59
C1-C2	1.00	1.00	1.00	340
C2	1.00	1.00	1.00	45

Table 4: Performance on the test set after mapping difficulty scores to CEFR levels.

Model	Pearson	Spearman	QWK
BERT vs. True	0.98	0.95	0.98
Feature vs. True	0.84	0.83	0.81

Table 5: Correlation and agreement of feature-based baseline model and BERT-based regression model with true labels.

agreement with the true difficulty labels (see Table 5), where the gain in QWK suggests that BERT is particularly better at matching difficulty levels. In contrast, the feature-based model demonstrates good but notably lower performance (0.98 vs. 0.81). Both models are available for testing.⁸

4.3 BERT-based Ordinal Classification

This model extends BERT for rank-consistent ordinal regression (Cao et al., 2020), a task in which labels have a meaningful order but unknown interval distances. Unlike standard classification, ordinal regression models the probability of a response exceeding certain thresholds, making it particularly useful for difficulty assessment.

The model predicts $\mathbb{P}(Y > k)$ for each threshold k using a modified BERT architecture, where a linear classifier estimates the probability that the input exceeds a set of ordinal thresholds. In particular, given an input sequence, we pass the pooled output of BERT through a dropout layer and a linear classification head of size (hidden_dim $\rightarrow K - 1$), where K is the number of CEFR levels.

For K ordinal labels, the model outputs $K - 1$ logits for each threshold. Each logit represents the probability:

$$\mathbb{P}(Y > k | X)$$

for each difficulty threshold k , where X represents the BERT-generated input representation.

⁸revita.helsinki.fi/selkomitta

Since ordinal regression differs from standard classification, we use a binary cross-entropy (BCE) loss adapted for ordinal constraints:

- **Ordinal Target Construction:** For a batch of size N and K classes, we construct a binary target matrix $\mathbf{T} \in \{0, 1\}^{N \times (K-1)}$, where each element $T_{i,k} = \mathbb{I}[y_i > k]$ indicates whether the true label exceeds threshold k .
- **Weighting Mechanism:** A weight matrix $\mathbf{W} \in \mathbb{R}^{N \times (K-1)}$ assigns higher penalties to more severe misclassifications. This can be scaled by a global hyperparameter α to control the influence of the weighting.

The weighted ordinal loss function is defined as:

$$L = \frac{1}{N} \sum_{i=1}^N s_i \sum_{j=1}^{K-1} w_{i,j} \cdot \text{BCE}(\sigma(z_{i,j}), t_{i,j})$$

where:

- N is the batch size.
- $z_{i,j}$ is the model logit for level j .
- $\sigma(z)$ is the sigmoid function.
- $t_{i,j}$ is the binary target: 1 if the true label exceeds threshold j , 0 otherwise.
- $w_{i,j}$ is a weight penalty based on label distance
- s_i is an additional sample-level weight to address class imbalance.

The weights w_{ij} are given by:

$$w_{ij} = 1 + \alpha \cdot |y_i - j|, \quad \alpha > 0$$

where y_i is the true ordinal label. This weighting penalizes predictions that are farther from the correct class more heavily. In our experiments, we set $\alpha = 0.5$.

By modeling thresholds rather than treating classes as independent, the loss preserves ordinal relations. Furthermore, the model learns a probability distribution over ranks, capturing uncertainty rather than committing to hard class decisions.

To obtain the predicted ordinal class, we apply a sigmoid activation to the model’s output logits, yielding threshold probabilities $\mathbb{P}(Y > k)$ for each $k = 1, \dots, K - 1$. The predicted class \hat{y} is then calculated by counting how many of these probabilities exceed the threshold of 0.5:

$$\hat{y} = \sum_{k=1}^{K-1} \mathbb{I}[\mathbb{P}(Y > k) > 0.5]$$

Accuracy	0.76	RMSE	0.57
MAE	0.28	ρ	0.89
QWK	0.87	τ	0.83

Table 6: Results of ordinal classification.

Here, $\mathbb{I}[\cdot]$ denotes the indicator function, which returns 1 if the condition is true and 0 otherwise.

Intuitively, this approach treats the predicted class as the number of ordinal thresholds that the input is likely to exceed with confidence greater than 0.5—higher classes correspond to exceeding more difficulty levels.

During training, we apply different learning rates for BERT layers and for the classifier head. Optimization is performed using AdamW. The learning rate is scheduled using a cosine annealing strategy with a linear warm-up over the first 10% of the training steps. The model is trained using the same data as for BERT-based regression. Since our data is not balanced over many classes for classification, we map the labels to 6 classes only: A1, A2, B1, B2, C1, and C2.

4.3.1 Results

The ordinal critic performs worse in terms of standard classification metrics on the same test set of 865 documents, see Table 10 and Figure 7 in Appendix B. The model achieves an accuracy of 0.76, see Table 6. However, metrics such as accuracy do not fully capture ordering information.

To better account for the severity of misclassifications, we report the Mean Absolute Error (MAE), which measures the average absolute difference between the predicted and the true labels—penalizing larger mistakes more heavily than smaller ones. MAE of 0.28 indicates that, on average, the predicted level deviates from the ground truth by about a quarter of a CEFR level. Analyzing the prediction errors in more detail, we find that 76% of the predictions exactly match the true levels, while 20% of the predictions are within one level of the ground truth. Only 4% of the documents are misclassified by more than one level—a deviation we consider “intolerable” due to the impact on downstream applications. The RMSE of 0.57, which penalizes larger errors more heavily, confirms the relatively low deviation.

In addition to accuracy, we report three metrics that better reflect the ordinal nature of CEFR levels; they include absolute- and rank-based measures, as well as agreement-based metrics.

Setup	# Documents	# Simplifications	Accuracy (%)
Baseline (no critic)	209	627	41.18
Regression Critic	212	634	50.00
Ordinal Classifier Critic	196	588	71.12

Table 7: Accuracy of simplification across different critic strategies. Each document is simplified to 3 target levels: A1, A2, and B1. A simplification is considered correct if the critic assesses it to match the target level.

- **Spearman’s rank correlation coefficient** ($\rho = 0.89$), which suggests a strong monotonic relationship between the predicted and true rankings. A higher ρ value indicates better ordinal agreement.
- **Kendall’s Tau** ($\tau = 0.83$), which confirms high ordinal agreement and is especially robust for small test sets.
- **QWK** of 0.87, which reflects substantial agreement between the predicted and true labels, while penalizing larger errors more heavily than smaller ones.

Taken together, these results indicate that the model not only achieves a high proportion of exact matches, but also preserves the ordinal structure of the CEFR scale with strong rank correlation and consistent agreement.

5 LLM-based Text Simplification

In this section, we describe how we use BERT-based difficulty models to assist LLM-based text simplification. These models act as critics to guide the simplification pipeline (see Figure 1):

- The original level of the input text is either assessed by the critic or manually labeled.
- The LLM receives the input text, the target level, and a prompt describing the target level.
- The LLM attempts to generate a simplified version of the text.
- The critic assesses the difficulty level of the output.
- If the target level is reached, the process is terminated.
- Otherwise, the LLM receives its previous output, the achieved level, the target level, and an updated prompt.
- The process is repeated for a maximum of 5 iterations.

When using the BERT-based regression model as a critic, its continuous difficulty scores are

mapped to discrete CEFR levels for compatibility with the feedback loop. When using the ordinal classification model, predictions can be used directly without mapping.

If the output is still above the target adjective after 5 iterations, the process stops. At each step, the LLM gets the feedback: This is your previous attempt to simplify the text to level X. The critic says your simplification is Y. Try harder to reach X.

5.1 Evaluation with and without Critic

We evaluate three variants of our guided text simplification pipeline: (1) **Baseline**, where the model performs one-shot simplification without critic feedback; (2) **Regression-based (REG) Critic**, where the critic is a BERT-based regression model; and (3) **Ordinal Classification (ORD) Critic**, where the critic is an ordinal classification model.

The evaluation was conducted on 220 manually annotated documents from the test set, whose original levels are above B2. Simplifications were generated to 3 target CEFR levels: A1, A2, and B1. The results are summarized in Table 7.⁹

The baseline system frequently produced simplifications that were off by one CEFR level, with common confusions such as A1 vs. A2 or A2 vs. B1. Adding the REG critic led to a moderate improvement in accuracy (+9%), suggesting that iterative refinement is beneficial. However, the most substantial improvement came from the ORD critic, which achieved 71.12% accuracy—nearly 30 percentage points higher than the baseline.

These results indicate that feedback from the ordinal critic aligns more effectively with the CEFR framework and better guides the LLM toward the target level. Table 8 shows that the LLM generates more correctly simplified outputs with the ordinal critic than with the regression critic, except for the B1 target level—where it tends to generate more

⁹Several simplification pipelines failed due to random reasons; they were not restarted, hence the number of simplification experiments in Table 7 is different for different critics.

Target	Generated	BL	REG	ORD
A1	A2	18.9	7.9	8.0
A1	A2-B1	—	8.7	—
A1	B1	5.6	7.9	0.0
A1	B1-B2	—	1.6	—
A2	A1	4.6	0.0	3.4
A2	B1	9.9	9.8	1.1
A2	B1-B2	—	5.5	—
A2	B2	0.0	1.3	0.0
B1	A1	1.9	0.0	0.9
B1	A2	13.6	1.4	15.1
B1	B2	2.9	3.9	0.0
B1	B2-C1	—	1.4	—

Table 8: Percentage of generating simplifications at an incorrect level, across three simplification pipelines. Each row indicates “incorrect” simplifications, where the generated level does not match the target level.

Target Level	Critic	Average Iterations	Maximum Iterations
A1	Regression	2.95	5
	Ordinal	2.71	5
A2	Regression	2.86	5
	Ordinal	2.21	5
B1	Regression	2.74	5
	Ordinal	1.87	4

Table 9: Average number of simplification iterations per target CEFR level using regression vs. ordinal critic.

A2-level outputs when guided by the ordinal critic. We also report the average number of iterations required to reach the target level in Table 9: using the ORD critic requires fewer iterations on average, especially for the B1 target.

For all test documents, we tracked the simplification process performed by the LLM by measuring the *intermediate* CEFR levels at each iteration, and the cosine similarity between the intermediate simplification and the original input.¹⁰ Figures 5 and 6 present the mean and standard deviation of difficulty and similarity scores across all documents, with the X-axis representing the iteration number, the left Y-axis showing difficulty scores, and the right Y-axis showing similarity scores.

Note that unlike in Tables 1 and 2, the scores produced by the ORD critic range from 0 to 5. Target level A1 in Figure 5 should be around 1 and in Figure 6—around 0. The plots show that, with the

¹⁰huggingface.co/sentence-transformers/paraphrase-multilingual-MiniLM-L12-v2

Figure 5: Regression critic with target level A1: average score and cosine similarity per simplification iteration

Figure 6: Ordinal critic with target level A1: average score and cosine similarity per simplification iteration

ORD critic, the difficulty of the first intermediate output is already below A2 (i.e., below 1.0), while for the REG critic it remains around B1 (around 3.0). We see a similar gain in performance of ORD over REG critic when the target level is A2 (Figures 8, 9) and B1 (Figures 10, 11) in the Appendix. Cosine similarity stays consistently at or above 0.8 in both pipelines, with slightly higher values when using the ORD critic.

5.2 Evaluation on Parallel Data

We further evaluate our approach using the Parallel Corpus of Standard Finnish–Easy Finnish (Dmitrieva and Kononova, 2023).¹¹ The Easy Finnish dataset includes news articles from the Yle archive, and consists of 1,919 manually verified pairs, each comprising an article in Easy Finnish and its corresponding article in Standard Finnish (the *source* article). We extracted 300 document pairs that are longer than 10 words and have Lev-

¹¹clarino.uib.no/comedi/editor/lb-2022111625

enshtein distance greater than 10, in order to focus on longer contexts that can be meaningfully simplified. As the dataset does not include difficulty annotations, we estimate the difficulty levels of the selected documents using the REG model and the ORD model. Both models indicate that in approximately 65% of the selected pairs, the source document is indeed more difficult than its simplified version.

We processed all source documents through the simplification pipeline once with REG and once with the ORD critic. The outputs generated by the LLM were then compared to the Easy Finnish articles using the SARI metric (Xu et al., 2016), which has been shown to correlate with human judgment of simplicity. The SARI metric is 40.6 for simplification with the BERT-based regression, and 43.1—with the ordinal model.

5.3 Manual Evaluation

An expert in teaching Finnish performed a preliminary manual analysis of the simplification results described above. We randomly selected 24 pairs of source texts and their simplified versions, generated by the pipeline with the REG and ORD models as critics. The annotator’s task was to assess whether the simplified text was indeed simpler than the source in terms of lexicon, grammar, sentence structure, and content. Although a more systematic analysis would require a larger sample and deeper investigation, several qualitative patterns emerged. Table 13 and 14 present manually analyzed pairs generated by these two simplification pipelines.

Both pipelines generally demonstrate a strong ability to simplify text: in all 24 cases, at least some parts of each sentence were successfully simplified, and in many cases, the entire sentence was made simpler (e.g., see Example 3 in Table 13). Lexical simplifications include, for instance, “*tivistää vientiponnisteluja*” (*intensify export efforts*) → “*lisätä vientiä*” (*increase exports*), “*kehittyvät taloudet*” (*developing economies*) → “*kehitysmaat*” (*developing countries*).

The REG pipeline frequently adds explanatory or contextual information, e.g., by fronting reporting clauses or expounding on the original content (see Examples 8 and 10 in Table 14). While longer texts are not necessarily more complex, such additions may increase the risks of hallucinations. In contrast, the ORD pipeline is often more effective at removing redundant information, resulting in more concise sentences. In some instances, how-

ever, the simplifications were simply paraphrases that did not reduce the overall difficulty. Whether a change constitutes a genuine simplification often depends on the reader and may require closer inspection. Both pipelines also occasionally miss clear opportunities for simplification.

In several cases, both models produced “simplified” sentences that were arguably more complex than the original; such cases are highlighted in red in the tables. For example, the verb “*tuplaantua*” (*to double*) may be easier for L2 learners than the synonym “*kaksinkertaistua*,” even though both are correct. Also, a few minor grammar problems are seen in the outputs, such as incorrect case usage in Finnish noun phrases. In other cases, the simplified sentence introduced factual ambiguities or errors, due to the model’s misunderstanding of the context or reference. More details on the results are in Appendix E.

6 Discussion and Conclusion

Our experiments with difficulty models demonstrate that small models can effectively guide text simplification performed by a large language model. Although both BERT-based difficulty models were trained on a *mix* of native and translated data, they significantly improve over the zero-shot baseline.

While the ordinal classifier performs worse on standard classification metrics, it proves more effective as critic in the simplification pipeline. We hypothesize several reasons for this. First, the regression model requires mapping floating-point difficulty scores to discrete CEFR levels, which may lose meaningful distinctions—especially during iterative simplification, where small improvements may be obscured by rounding. Second, regression assumes linear distances between levels, e.g., that the distance between A1 and A2 is equal to the distance between C1 and C2. This assumption is not required by ordinal classification.

An additional benefit of the ORD critic, currently unused, is its ability to estimate *probabilities* for CEFR thresholds—which could be interpreted as a confidence of a text being A1, A2, etc., and enable more fine-grained feedback for the LLM.

In future work, we plan to integrate feature-based and Transformer-based models, enabling the LLM to receive targeted feedback about which linguistic features in the intermediate texts do not match the desired difficulty level.

7 Acknowledgements

This work was supported in part by Business-Finland: Agency for Technology and Innovation, Project “*Easy Language for accessible workplace communication*” (Grant 4173/31/2024). We are grateful to Tiina Onikki-Rantajääskö for her insightful feedback.

8 Limitations and Ethical Considerations

While our results show that difficulty models can effectively guide LLM-based text simplification, several limitations remain. First, the models are trained and evaluated on a small dataset. Working only with Finnish may limit generalizability to other languages or domains. Second, the mapping from regression scores to CEFR levels introduces discretization errors that may obscure nuanced improvements. Third, the simplification pipeline is constrained to five iterations, which may be insufficient for particularly complex texts, and more iterations are expensive to run. Finally, we use a fixed prompt template for LLM interactions; future work could explore adaptive or dynamically generated prompts.

This work focuses on improving language accessibility, particularly for second-language (L2) learners, and aims to reduce linguistic barriers in education and communication. However, several ethical considerations must be acknowledged. First, automated simplification tools may reinforce biases present in the training data, especially if texts from specific groups or dialects are under-represented. Second, over-reliance on automated systems may inadvertently reduce the role of human educators in assessing learner needs. Lastly, misuse of simplification systems—e.g., to manipulate or oversimplify critical content—could have adverse effects. We emphasize that these systems should be used as assistive tools, not as replacements for human judgment in the context of education or public communication.

Table 10: Performance of ORD classifier on test set

Figure 7: Confusion matrix for ORD classifier

A Baseline classification: feature-based regression

Models (A) and (B) were trained with a regularization strength $\alpha = 1.0$. For (B), we fit a Ridge regression model to $N_{\text{boot}} = 1000$ bootstrap samples of the training set, each time recording the feature coefficients. For each feature, we calculate the mean and standard deviation of its coefficient across bootstraps. The signal-to-noise ratio is defined as the absolute mean divided by the standard deviation. Features with a signal-to-noise ratio above a threshold (e.g., ≥ 1) are selected, ensuring selection of features with stable and consistently strong effects across resampled datasets.

We fit a Lasso regression model (C), which was employed for feature selection due to its ability to perform both regularization and automatic variable selection. Features with nonzero coefficients are selected, while those with coefficients shrunk to zero are excluded. The regularization parameter α for the Lasso model was selected via cross-validation using the LassoCV procedure, optimizing for mean squared error on held-out validation folds.

C LLM Prompt Templates

Below we list the CEFR-level-specific prompts used to guide GPT-4o in the simplification task. The prompts were formulated based on the definitions of CEFR levels.¹² Each prompt instructs the model to return a JSON object containing a single key "SIMPLIFICATION", with text adapted to the specified proficiency level.

Common Prompt Structure:

You must always output a JSON object with a "SIMPLIFICATION" key. You are

¹²www.coe.int/en/web/common-european-framework-reference-languages/table-1-cefr-3.3-common-reference-levels-global-scale

an expert in Finnish language and language teaching. You will be given a text in Finnish. Your task is to read it first and then to provide an adaptation into CEFR level X. Please do not significantly change the meaning of the input text. [Level-specific instructions] This is the text to simplify: {text}

Imagine that you are teaching a X learner, your adaptation should fit their proficiency level.

Level-specific Instructions:

A1 Prompt

A1 is the simplest level for beginners. The texts in A1 should be simple, with short sentences and easy grammar. The definition of a learner with A1 level is: "Can understand and use familiar every-

day expressions and very basic phrases aimed at the satisfaction of needs of a concrete type. Can introduce themselves and others and can ask and answer questions about personal details such as where someone lives, people they know and things they have. Can interact in a simple way provided the other person talks slowly and clearly and is prepared to help.”

A2 Prompt

A2 is just above the beginner level. The text in A2 should be simple and have relatively easy grammar. The definition of a learner with A1 level is: “Can understand sentences and frequently used expressions related to areas of most immediate relevance (e.g. very basic personal and family information, shopping, local geography, employment). Can communicate in simple and routine tasks requiring a simple and direct exchange of information on familiar and routine matters. Can describe in simple terms aspects of his/her background, immediate environment and matters in areas of immediate need.”

B1 Prompt

B1 is an intermediate level. The definition of a learner with B1 level is: “Can understand the main points of clear standard input on familiar matters regularly encountered in work, school, leisure, etc. Can produce simple connected text on topics which are familiar, or of personal interest. Can describe experiences and events, dreams, hopes & ambitions and briefly give reasons and explanations for opinions and plans.”

D Feature List

Tables 11 and 12 present the features used to train the feature-based models. Features shown in bold in both tables were selected via bootstrap feature selection. The features include morphophonemic, grammatical, lexical, and syntactic features. Details regarding how these features (or constructs) are detected in text can be found in (Katinskaia et al., 2023).

Consonant gradations features are identified using rule-based methods. The label “Inactive” indicates that gradation *does not* occur in the given form, e.g.: compare “nukkuu” (infinitive *to sleep*) and “nukkua” (3rd person singular *she/he sleeps*)—no gradation. The label “Active” indicates that the gradation is present, e.g.: compare “nukkua” (*to sleep*) and “nukun” (1st person singular *I sleep*)—gradation **kk** → **k**.

Lexical features include groups denoting temporal concepts, e.g.: time of the day in allative case—“aamulla” (*in the morning*), “yöllä” (*at night*); but months in inessive case: “elokuussa” (*in August*), “kesäkuussa” (*in June*), etc.

Vocabulary bags—from 1 to 10—represent frequency bins constructed from a list of over 20,000 lemmas, sorted by their frequency. The feature OOV coverage measures the proportion of words in the text whose lemmas are not found in any frequency bins, averaged over the text length.

E Simplification Results

Table 13 shows results of simplification with LLM-based pipeline guided by the ordinal classification model.

E.1 Simplification Pipeline guided by Ordinal Classification

In Example 1, the simplification was achieved by splitting the original sentence into two, grammar was simplified by replacing conditional mood with indicative: “maksaisi” (*would cost*) → “maksaa” (*costs*); “pienenisivät” (*would decrease*) → “pienenevät” (*decrease*).

Examples 2 and 3 demonstrate the removal of unnecessary information. The simplification in Example 4 resulted in a simpler information structure, as “Brittania” was moved to the beginning of the sentence. However, two sentences were combined into one, which made the overall structure more complex. The lexicon was also simplified; see the blue highlights in the simplified sentence.

Example 5 illustrates a case where the “simplified” version was actually more complex in some respects: “aiotaan nosta” (*is going to be increased*) → “suunnitellaan korotettavaksi” (*is planned to be raised*); “prosenttia” (*percent*) → “prosentilla” (*by percent*).

In Example 7, the grammar was improved: “katsoo päätöksessään” (*considers in its decision*) → “päätettiin” (*decided*); “ettei” (*that not—contracted*)

→ “että ei” (*that not—expanded*); “ei ollut syytä epäillä” (*had no reason to suspect*) → “ei voinut epäillä” (*could not suspect*). However, some parts were made more difficult: “rekrytointia hoitanut mies” (*the man who handled the recruitment*) → “rekrytoinnista vastannut mies” (*the man responsible for recruitment*).

E.2 Simplification Pipeline guided by Regression

Although the simplification in Example 8 improved contextual information—by adding “puolue” (*party*) and “lakialoite” (*legislative initiative*)—it also contains an error in orthography (a missing hyphen between “Perussuomalaiset” and “puolue”). Additionally, it introduces unnecessary and grammatically complex information, such as “lain voimaantulon jälkeen sen aiheuttamat [kustannukset]” (*the [costs] caused by it after the law comes into force*).

Example 9 demonstrates changes that made the lexicon more difficult: “yli” (*over*) → “ylittäen” (*exceeding*); “on kasvanut paljon” (*has grown a lot*) → “lisääntynyt huomattavasti” (*increased significantly*).

The simplified text in Example 10 illustrates the removal of the unnecessary word “käytännössä” and the simplification of some grammatical forms: “voisivat” (*could*) → “voivat” (*can*); “tiivistää vientiponnisteluja” (*intensify export efforts*) → “parantaa yhteistyötä viennissä” (*improve cooperation in exports*). However, it also introduces new information not present in the source (see red highlight).

The red highlights in Examples 11–13 indicate cases where the forms were made lexically, grammatically, or syntactically more complex than in the source texts.

Feature Set 1	Feature Set 2
Comparative adjective form	Consonant gradation (A type, nouns, active)
Positive adjective form	Consonant gradation (A type, nouns, inactive)
Superlative adjective form	Consonant gradation (A type, verbs, active)
Abessive case	Consonant gradation (A type, verbs, inactive)
Ablative case	Consonant gradation (“lki” A type, active)
Accusative case	Consonant gradation (“lki” A type, inactive)
Adessive case	Consonant gradation (A type ending with “uku”, active)
	Consonant gradation (A type ending with “uku”, inactive)
Allative case	Consonant gradation (B type, nouns, active)
Comitative case	Consonant gradation (B type, nouns, inactive)
Elative case	Consonant gradation (B type, verbs, active)
Essive case	Consonant gradation (B type, verbs, inactive)
Genitive case	Compound noun inflection
Illative case	Lists of confusable nouns
Inessive case	Noun paradigm “aihe”
Instructive case	Noun paradigm “bussi”
Nominative case	Noun paradigm “kala”
Partitive case	Noun paradigm “kannel”
Translative case	Noun paradigm “koditon”
Clitics of emphasis	Noun paradigm “koira”
Clitics of negation	Noun paradigm “kysymys”
Clitics of question	Noun paradigm “maa”
Clitics han	Noun paradigm “manner”
Clitics pa	Noun paradigm “mansikka”
Construction with differen factors	Noun paradigm “nainen”
Construction of type “ESSA” (Temporaalirakenne)	Noun paradigm “olut”
Construction with “Että”, perfect	Noun paradigm “ovi”
Construction with “Että”, present	Noun paradigm “puhelin”

Are Large Language Models for Education Reliable for All Languages?

Vansh Gupta^{*†} Sankalan Pal Chowdhury^{*†}

[†]ETH Zurich [‡]Bocconi University

Abstract

Large language models (LLMs) are increasingly being adopted in educational settings. These applications expand beyond English, though current LLMs remain primarily English-centric. In this work, we ascertain if their use in education settings in non-English languages is warranted. We evaluated the performance of popular LLMs on four educational tasks: identifying student misconceptions, providing targeted feedback, interactive tutoring, and grading translations in eight languages (Mandarin, Hindi, Arabic, German, Farsi, Telugu, Ukrainian, Czech) in addition to English. We find that the performance on these tasks somewhat corresponds to the amount of language represented in training data, with lower-resource languages having poorer task performance. However, at least some models are able to more or less maintain their levels of performance across all languages. Thus, we recommend that practitioners first verify that the LLM works well in the target language for their educational task before deployment.

1 Introduction

Education is a multilingual, multicultural endeavour. AI-based technologies have recently shown the potential to improve students' learning experiences, and educational systems worldwide are increasingly adopting these tools (Gligorea et al., 2023). From personalized instruction and targeted feedback to appropriate content generation and interactive tutoring, these tools offer solutions to key educational challenges (Leon, 2024; Rooein et al., 2024; Mosher et al., 2024). Large language models such as GPT, Gemini, and Llama (OpenAI, 2023; Team, 2024; Roulmliotis et al., 2023) have become

particularly influential, with early evidence suggesting their ability to support teachers or scaffold student learning (Kasneci et al., 2023; Alqahtani et al., 2023).

Although most of these LLMs are trained on multilingual corpora (OpenAI, 2019; Nvidia, 2022; Peng et al., 2023; Gu and Dao, 2023), they are still overwhelmingly English-centric (Argoub, 2022; Ruder et al., 2022, Table 1). Inadequate adaptation to local languages in an educational setting risks diminishing their utility and exacerbating existing inequalities by privileging dominant languages and cultures. The question of multilingualism arises in every domain where LLMs are applied (Lai et al., 2023; Ahuja et al., 2023, 2024). However, it is especially important in the field of education, which has seen wide use of LLMs despite the high stakes (Alhafni et al., 2024; Raheja et al., 2023; Naismith et al., 2023). Without rigorous evaluation tailored to educational tasks across languages, deploying LLMs in classrooms may introduce new forms of harm, including misinformation, misalignment with curricula, or culturally inappropriate content (Almasoud et al., 2025).

In this work, we present an empirical investigation of the capabilities of frontier LLMs on educational tasks across several languages. We identify four education-related tasks (identifying student misconceptions, providing targeted feedback, interactive tutoring, and translation grading) with well-defined language-agnostic metrics. We then evaluate several frontier LLMs (Claude, Gemini, GPT4o, Llama, and Mistral) on these tasks in eight languages (Mandarin, Hindi, Arabic, German, Farsi, Telugu, Ukrainian, and Czech) in addition to English.

Our results show that though performance in English still dominates, other languages are not too far behind, at least for GPT4o and Gemini-2.0-flash, which emerge as the best models. We also find that using prompts in the language of the task

^{*}Equal Contribution

⁰We release the collected dataset and code at github.com/eth-lre/multilingual-educational-llm-bias. The dataset comprises 313,500 automatically evaluated model outputs across seven languages, four tasks, and six models.

is rarely helpful compared to English prompts.

2 Methods

We select our set of tasks based on 3 desiderata:

- **Relevant to Education:** We focus on tasks that LLMs would encounter specifically in the role of tutors, teachers, or teaching assistants. We do not cover tasks like question answering or solving math questions, which, while possibly being relevant to education, are more general tasks that are primarily studied in other contexts.
- **Have a Language Component:** We avoid tasks whose formulation uses purely notation, for example, solving a math equation. If the equation is provided in mathematical notation, the task would remain unchanged between different languages, making the question of multilingual performance moot.
- **Language Invariant Evaluation:** Finally, we need evaluation metrics that remain comparable across languages to compare performance across different languages efficiently. This means we cannot rely on language-dependent metrics like BLEU or COMET (Papineni et al., 2002; Rei et al., 2020).

Based on these, we selected following four tasks:

Task 1: Misconception identification. An important aspect of teaching is fixing student misconceptions, which first requires identifying the student misconception (Liu et al., 2023). We build this task on the EEDI Math Questions Dataset, which contains thousands of multiple-choice questions with four answer choices. For many of the wrong choices, we have expert-annotated misconceptions that could lead to a student picking the said choice. We leverage these to build our task. The LLM is given a multiple-choice question, the student’s (incorrect) answer, and four possible misconceptions. The candidate misconceptions include the true misconception identified by experts and three distractors chosen at random from the other misconceptions present in the dataset. The LLM must pick the correct misconception from these four options (see Example 1 for an example). We evaluate the LLM performance by reporting accuracy in predicting the student misconception. Since the model must pick one of four options, a random baseline has an accuracy of 25%.

Task 2: Feedback selection. A key step towards fixing students’ misconceptions is generating feedback to alleviate them. The EEDI dataset discussed above also includes feedback for all the choices we use for this part. The LLM is again given a multiple-choice question, the student’s answer, and this time, a set of four possible feedbacks, out of which the LLM must select the feedback corresponding to the student’s answer. Note that while there are 4 possible feedbacks, one corresponds to the correct answer. This one is easily identifiable as it reinforces the student’s answer, while the feedbacks corresponding to wrong answers all try to make the student realize their mistake. As an example, see Option C in both parts of 2, which are the only options in their respective questions that do not start with a negative tone. Therefore, if the selected answer is also the correct answer to the problem, the LLM might be able to pick the correct feedback using some shallow semantics, which we want to avoid. Therefore, we ensure that the selected answer is always incorrect. The random baseline has an accuracy of 25%, or 33% if choosing among responses to the wrong answer.

Task 3: Tutoring. For more complex misconceptions, a single-turn feedback often does not suffice, and fixing the misconception requires a multi-turn conversation between the student and the teacher, also known as tutoring. (Bloom, 1984; Cohen et al., 1982) This involves a teacher LLM trying to help the student identify and fix an error in their solution. We evaluate the tutoring ability of the LLM by having it tutor a weaker LLM, which acts as the student. Both the teacher and the student are given the question, but only the teacher LLM can access the correct answer. The student LLM is instructed to stick to the wrong solution unless it sees strong justification to shift. The teacher and the student take turns to send messages, with the teacher’s goal being to get the student model to the correct answer, without revealing the answer themselves. The teacher LLM is considered to get a *success* if the student LLM states the answer. If the teacher reveals the answer before the student has gotten to it, it is counted as *telling*. An *adjusted success* occurs when there is a success but no telling. The task is finally evaluated by Tutoring score (Pal Chowdhury et al., 2024), which is the harmonic mean between success rate and adjusted success rate.

This task differs from the other tasks on this list

	Language family	Script	Wikipedia	CommonCrawl	Speakers
English	Germanic	Latin	6973K	42.8%	1500M
Mandarin	Sino-tibetan	Hanzi ¹	1480K	5.8%	1184M
Hindi	Indo-Iranian	Brahmic	165K	0.20%	609M
Arabic	Afro-Asiatic	Abjad	1259K	0.68%	411M
German	Germanic	Latin	3021K	5.5%	411M
Farsi	Indo-Iranian	Abjad	1034K	0.74%	134M
Telugu	Dravidian	Brahmic	111K	0.02%	96M
Ukrainian	Slavic	Cyrillic	1371K	0.62%	39M
Czech	Slavic	Latin	566M	0.10%	12M

Table 1: Language information, number of speakers (Ethnologue 2025), and global representations of tested languages in NLP (Wikipedia Articles and proportion in CommonCrawl in March 2025).

in at least two significant ways. First, it is a multi-turn conversation task, so there is no scope for guessing the answer. Secondly, the final evaluation depends on the performance of the student LLM, so the multilingual capabilities of the student LLM also restrict the applicability of this task. These factors make this task both slower to run and more complex for the LLMs.

Task 4: Translation grading. A common field of education that has seen an increase in the use of LLMs is Language learning (Klimova et al., 2024; Zhu et al., 2024). A representative task from this field is to assign a grade to a translation provided by a student. While we lack proper datasets across languages with translations and their appropriate grades, we can approximate this task by the fact that *the machine translation of a sentence should receive a higher grade than the exact translation with one word replaced by a random word*. We use English sentences from Duolingo’s English→Spanish SLAM dataset (Settles, 2018), which are machine translated to other languages. We chose this dataset because it is meant to be used for translation, so it should contain fewer hard-to-translate sentences. We filter out simple sentences that do not end with a full stop or have fewer than five words. For each translated sentence, we then create a corresponding *perturbed translation* by replacing one of the words in the sentence with a different word selected at random from the other sentences in the dataset, disrupting both the fluency and adequacy of the translation. The LLM judges both the original and perturbed versions on a scale from 1 (completely incorrect) to 5 (perfect), with the expectation that it should assign a strictly lower score to the perturbed version. A model assigning all scores at random would therefore score around 40%.

¹Alternately referred to as Kanji, Hanja or Hantu

Figure 1: Multidimensional Scaling projection of languages based on syntax features from URIEL/lang2vec. Languages used in our experiments are highlighted and shown with full names, others are in ISO 639/set 2.

Language selection. We choose eight languages for experiments: Mandarin, Hindi, Arabic, German, Farsi, Telugu, Ukrainian, Czech in addition to English for comparison. This language selection reflects diverse linguistic properties, varying levels of representation in training data, and different language families (Foundation, 2024), see Table 1. Hindi (Indo-Aryan) and Telugu (Dravidian) represent major languages from the Indian subcontinent that use the Brahmic script and are under-represented in both CommonCrawl and Wikipedia. German and Mandarin, on the other hand, are examples of languages well represented in both CommonCrawl and Wikipedia. Farsi and Arabic offer insights into LLM performance on a right-to-left Abjad script, whereas Ukrainian and Czech allow us to study generalisation in medium resource morphologically rich languages, using the Cyrillic and

Language	Questions	Misconception	Feedback	Translation
Mandarin	0.593	0.607	0.666	0.781
Hindi	0.455	0.546	0.593	0.831
Arabic	0.596	0.659	0.605	0.793
German	0.623	0.642	0.697	0.792
Farsi	0.574	0.644	0.708	0.840
Telugu	0.518	0.569	0.578	0.639
Ukrainian	0.607	0.642	0.682	0.821
Czech	0.611	0.626	0.663	0.805

Table 2: Average COMET₂₃^{DA,XL} scores for different languages for different components of the tasks. The **Questions** are used for both Misconception and Feedback tasks. The Tutoring task is not translated.

Latin scripts, respectively.

To assess the typological diversity of our selected languages, we used the URIEL typological database (Littell et al., 2017) with `lang2vec`, which provides dense vector representations of languages based on a range of typological, phylogenetic, and geographical features. As recommended by the package, we extracted syntax features with k-NN predictions for the missing values for a set of 40 languages, constructed as the union of our core experimental languages and the most widely spoken languages worldwide according to Ethnologue (Eberhard et al., 2025). We projected each language feature vector into two dimensions using Multidimensional Scaling, producing a 2D language similarity plot. This allows us to visualise (see Figure 1) the relative syntactic diversity of our selected languages and confirm that they span a broad typological space. The visualisation demonstrates that our language selection (highlighted) is well distributed across the typological landscape.

Translation. We obtain our tasks in all the above-mentioned languages by machine translation. Following the GPT4 Technical Report (OpenAI, 2023, Figure 5), we use Azure Translate to translate all our examples to the target languages. However, this introduces an additional noise source for tasks performed in languages other than English. In fact, after reviewing some of the translations manually, it does look like the translations, though decent, are not as easy to follow as their English counterparts. This finding is further corroborated by COMET₂₃^{DA,XL} (Rei et al., 2023) scores of the translations (see Table 7). This means that any differences we observe between English and other-language performance cannot be conclusively attributed to the LLM being tested. However, we can still compare the performance of different LLMs across the same language, as the same translation

was used for all LLMs. Further, if at least one LLM performs well in a task on a given language, we can be reasonably certain that the translation for that task-language pair was also good enough.

Models and prompts. We evaluate six state-of-the-art LLMs praised for their multilingual capabilities: GPT-4o (OpenAI, 2023), Gemini 2.0 Flash (Team, 2024), Claude 3.7 Sonnet (Anthropic, 2024), Llama 3.1 405B (Grattafiori et al., 2024), Mistral Large 2407 (AI, 2024; Jiang et al., 2023), and Command-A (Cohere et al., 2025). We leave all sampling parameters to their defaults. For prompts, we use a simple chain of thought prompting method, where the model is first asked to explain why it would pick a certain answer, and then asked to choose it in a separate prompt. Based on literature (Mondshine et al., 2024; Huang et al., 2023), it is unclear whether or not it is beneficial to translate the prompt itself to the target language or keep it in English, so we try both options.^{2,3}

For each task, we use 1000 examples for reporting our results, sampled at random from the dataset, except for 200 examples in the tutoring task, which is multi-turn.

3 Results

In this section, we describe the results of five popular large language models on the four tasks described in Section 2. The main results are shown in Tables 3 to 6.

English is easiest for LLMs. The gap between English and other languages is large in general. On

²A weaker model roleplays the student model used in the tutoring task to be consistent with the original work. We only use the original prompts because it does not work well with non-English prompts.

³We machine-translate the prompts and manually verify (with L1/L2 language knowledge) the translation adequacy.

Input	Options
<p>Question: Which number is the greatest? Student Answer: 5.0001 Right Answer: 5.2</p>	<p>A: Believes the mean is total frequency divided by something, B (correct): Thinks the more digits a number has the greater it is, regardless of place value, C: Believes parallel lines have gradients that multiply to give -1, D: When multiplying by a multiple of 10, gives an answer 10 times bigger than it should be</p>
<p>Question: What is the lowest common multiple of 8 and 4? Student answer: 4 Right Answer: 8</p>	<p>A: Subtracts instead of adds when answering worded problems, B (correct): Confuses factors and multiples, C: Rounds up instead of down, D: Adds instead of multiplying when expanding bracket</p>

Example 1: Two examples of the misconception identification task (English).

Input	Options
<p>Question: 6 pencils cost £1.50. How much do 3 pencils cost? Student answer: 25p</p>	<p>A: I think you have made an arithmetic error when halving £1.50. Use short division to divide by two, B: I think you have used the incorrect notation for money. Consider how the monetary values in the question are written, C (correct answer): If 6 pencils cost £1.50, then 3 pencils cost half of £1.50, which is £0.75 or 75p., D (student answer): I think you have found the cost for one pencil. The question asks for the cost of 3 pencils.</p>
<p>Question: A film starts at 8.50pm. The film lasts 2 hours and 52 minutes. What time does the film finish? Student answer: 11.02pm</p>	<p>A (student answer): This isn't quite right. Remember that there are 60 minutes in an hour, not 100 :), B: I think you've confused your method a little. Noticing that 2 hours and 52 minutes is just 8 minutes less than 3 hours is super, just make sure you add and subtract in the correct directions though :), C: Almost there! Take care to notice how many hours and minutes you're adding here. Is your answer 2 hours and 52 minutes later than 8.50pm?, D (correct answer): Adding 2 hours to 8.50pm gives 10.50pm. Adding 10 minutes on takes us to 11.00pm, and adding the remaining 42 minutes gives 11.42pm.</p>

Example 2: Two examples of the feedback selection task (English).

Math Problem	Student's (Incorrect) Solution	Correct Solution
<p>Sam sells bread. He has a target of selling 120 crates of bread in a week. One week he was closed on Monday and Friday. Over the weekend he sold 20 crates. On Tuesday he sold 15 crates, on Wednesday 12 crates, and Thursday 18 crates. By how many crates was Sam off from his target for the week?</p>	<p>Sam had 5 days to sell bread because he was closed on Monday and Friday. He sold a total of $20 + 15 + 12 + 18 = 65$ crates of bread from Tuesday to Thursday. Adding the 20 crates he sold over the weekend, Sam sold a total of $65 + 20 = 85$ crates of bread in a week. Sam was off from his target by $120 - 85 = 35$ crates of bread.</p>	<p>During the whole week Sam sold $15 + 12 + 18 + 20 = 65$ crates. Sam was off his target by $120 - 65 = 55$ crates.</p>
<p>Sophia is thinking of taking a road trip in her car, and would like to know how far she can drive on a single tank of gas. She has traveled 100 miles since last filling her tank, and she needed to put in 4 gallons of gas to fill it up again. The owner's manual for her car says that her tank holds 12 gallons of gas. How many miles can Sophia drive on a single tank of gas?</p>	<p>Sophia used 4 out of the 12 gallons of gas in her tank, so there are $12 - 4 = 8$ gallons of gas left in the tank. If Sophia can drive 100 miles on 4 gallons of gas, then she can drive $100/4 = 25$ miles per gallon. Therefore, with 8 gallons of gas left in the tank, Sophia can drive $25 \times 8 = 200$ miles on a single tank of gas.</p>	<p>To find miles per gallon, divide 100 miles / 4 gallons = 25 miles per gallon. To find how far Olivia can go on a single tank, multiply 25 miles per gallon \times 12 gallons = 300 miles.</p>

Example 3: Two examples of the tutoring task.

Table 6: Results (accuracy) for the **translation grading** task.

average⁴ across all tasks (excluding translation) and models, English has 70.9%, in contrast to 63.1% (Hindi), 55.3% (Czech), 67.8% (Ukranian), 49.7% (Telugu), 66.2% (Farsi), 66.8% (German), 64.6% (Mandarin) and 67.4% (Arabic). This in itself does not make it clear if the loss is due to the LLMs be-

ing weak or the translation quality being poor. The poor performance on Telugu is largely driven by Command-A and Mistral. The former is unsurprising as Telugu is the only language in our list that is not officially supported by it (Cohere et al., 2025). On the other hand, Mistral lists only 12 supported languages of which we test only Hindi, Arabic, German and Chinese. Telugu also has the lowest representation in CommonCrawl and Wikipedia,

⁴Averaging here is done to give a general idea, but we must note that the scores are not equivalent. We use Accuracy for tasks 1 and 2 but Tutoring Score for Task 3

Language	Questions	Misconception	Feedback	Translation

Telugu	0.518	0.569	0.578	0.639
Ukrainian	0.607	0.642	0.682	0.821
Czech	0.611	0.626	0.663	0.805

Table 7: Average COMET₂₃^{DA,XL} scores for different languages for different components of the tasks. The **Questions** are used for both Misconception and Feedback tasks. The Tutoring task is not translated.

so the result is expected. Manual analysis of the low tutoring performance for Czech reveals that the interactions switch between various language formality styles, to the point that it becomes distracting. Additionally, the language used in Czech classrooms is particular and likely not represented on the internet.

Model performance and consistency. Mistral is the most inconsistent across non-English languages (average deviation⁵=0.186). For example, it completely fails the tutoring task for both Czech and Telugu, despite performing reasonably on other languages in the same task. Command-A is not much better (average deviation⁵=0.161). On the other hand, Gemini is the most consistent (average deviation⁵=0.078) and also has the second-best performance (average score 75.0%). GPT4o, is the best performing model (average 78.6%) while Claude performs the worst (average 49.3%) mostly due to Feedback and Tutoring tasks.

Task difficulty. The worst performance is observed in the Feedback task despite the similarity to the Misconception identification task. While Claude is still the standout worst performer with a worse-than-random performance, all models struggle. Further analysis in Table 11 shows that all models tended to default the feedback corresponding to the correct answer, with the models’ chain of thoughts being “regardless of the student’s mistake, this is the feedback that gives the student the most information about the correct answer.” Most models perform well in the Translation evaluation task, with the accuracy being even higher than human annotators, who were presented with attention checks with similar perturbations (Kocmi et al., 2024; Zouhar et al., 2025). They also do well in the Misconceptions task, with most percentage scores

⁵We calculate the standard deviation across the six languages for each task and then calculate the mean.

(at least in the English prompt setting) being in the 90s. The tutoring task seems to have the most inconsistent performance across models and languages. In general, all models struggle in Czech and Telugu, while Claude struggles in all languages. Avoiding telling seems to be the more challenging part of the problem for all the models, although success rates are not very consistent either.

English and translated prompts. Excluding for the Tutoring task (which did not use native prompts), using English prompts yields better performance than using translated prompts (averages 72.7% and 67.2%). The exceptions to these are GPT, Llama, Gemini, and Mistral in the translation task though in most cases, the difference is not very large. Note that some of the poor performance could be attributed to the prompts being translated and checked for correctness rather than being written in the target language directly, which could introduce some translationese. Regardless, we believe it is best to keep prompts in English. As a further note for English-speaking developers designing multilingual applications, keeping prompts in English ensures that the chains-of-thought remain English, making it easier to run sanity checks.

4 Related Work

LLMs, trained on vast multilingual texts, have dominated tasks such as text generation, translation, and dialogue (Brown et al., 2020), making them promising tools in Intelligent Tutoring Systems (ITS; Corbett et al., 1997; Pal Chowdhury et al., 2024). Prior work explores their use in educational contexts, such as dynamic student interactions (Schmucker et al., 2023), simulating expert and novice behavior (Liu et al., 2023), and math word problem reasoning (Opedal et al., 2023).

Beyond mathematical context, LLMs have also been explored for other forms of learning. Cui

and Sachan (2023) investigate LLMs in adaptive and personalized exercise generation for language learners, while (Wang et al., 2023) examines how conversational tutoring strategies can aid student understanding. Additionally, LLMs have been used to assess grammatical correctness and translation accuracy (Kocmi and Federmann, 2023; Omelianchuk et al., 2024; Freitag et al., 2024), facilitate automated essay scoring (Pack et al., 2024), and provide corrective feedback in second language writing (Han et al., 2024). While LLMs excel in English, their abilities in other languages often vary, reflecting an over-representation of high-resource languages in pre-training corpora. For example, Koto et al. (2023) introduces IndoMMLU, which reveals significant performance disparities between Indonesian and English contexts. Similarly, Holtermann et al. (2024) examines LLMs across 137 languages and attributes discrepancies in performance to tokenisation strategies. Li et al. (2024); Armengol-Estapé et al. (2022) further find a strong correlation between pre-training data proportions and performance, reaffirming the gap between high- and low-resource languages. For Catalan, Armengol-Estapé et al. (2022) find that while GPT-3 performed well in generative tasks, its comprehension capabilities were limited by the language’s moderate representation.

Recent research has increasingly explored the application of LLMs in multilingual educational contexts, though challenges persist in balancing performance across languages. Systematic reviews of AI-based language learning tools highlight the prevalence of NLP and machine learning techniques for error correction, feedback provision, and assessment in non-English contexts, though they note persistent gaps in dialogic competence and teacher preparedness (Alhusaiyan, 2025). Studies evaluating LLMs’ cross-lingual capabilities reveal performance disparities, with models demonstrating stronger skill tagging accuracy for English-centric curricula compared to underrepresented languages like Irish or Marathi (Kwak and Pardos, 2024). Bibliometric analyses indicate growing research interest in AI for foreign language education, particularly in vocabulary acquisition and writing support, though most studies still focus on high-resource European and Asian languages (Doğan and Talan). These works collectively underscore both the transformative potential and current limitations of LLMs in achieving equitable multilingual educational support.

To address multilingual education more directly, projects like Kaleidoscope (Salazar et al., 2025) and Aya (Üstün et al., 2024) by Cohere For AI aim to support culturally diverse languages, while SEA-HELM (Susanto et al., 2025) and ECLeKTic (Goldman et al., 2025) emphasise culturally grounded evaluations in Southeast Asian and cross-lingual contexts, respectively. These efforts highlight the need for multilingual benchmarks that move beyond English-centric evaluations.

Prior pedagogical studies tend to assess single LLMs in monolingual settings. We fill this gap by benchmarking LLMs in multiple tasks. Specifically, we conduct zero-shot experiments across multiple models and languages to better analyze their real-world applicability.

5 Conclusion

We analyse the performance of six well-known state-of-the-art LLMs across six languages other than English on four educational tasks. We find that while performance in English continues to be better than in other languages, the drop to other models is not always large. In particular, we find that GPT4o and Gemini 2.0 perform consistently well across all languages, with a few exceptions. We also note that English prompts work as well, if not better, than prompts written in the target language, when solving multilingual tasks. This opens up opportunities for porting applications developed for English into different languages. However, we note that certain models perform poorly in some tasks and languages, so **we recommend** first verifying that a model works well in a particular language on a specific educational task before deployment. However, to answer the question posed by the title, we believe that *atleast some* language models **are** reliable across languages.

Limitations

The shown experiments could naturally be better extended to more languages. The selected languages reflect a balance between author familiarity, which is necessary for meaningful qualitative analysis, and linguistic diversity, as evidenced by their spread in URIEL feature space. Similarly, we only covered six LLMs. In both cases, the cost of experiments (see Table 8) becomes prohibitively expensive, which motivated the data release in this paper to enable further research.

Additionally, translation quality remains a con-

Model	API	Total	Miconception	Feedback	Tutoring	Translation
Mistral	Mistral API	\$530	\$170	\$170	\$120	\$70
Claude	Anthropic	\$600	\$190	\$190	\$135	\$85
Command	Cohere	\$520	\$165	\$165	\$120	\$70
Llama	Together.ai	\$600	\$190	\$190	\$135	\$80
GPT4o	Open AI	\$80	\$25	\$25	\$18	\$12
Gemini	Google Genai	\$30	\$10	\$10	\$6	\$4

Table 8: Approximate costs for the experiments. Does not include taxes or currency conversion charges. The total is about \$2360 with approximately an additional \$500 spent on preliminary experiments.

cern, as previously discussed. A more thorough evaluation would involve human translations for every task, similar to the MMLU multilingual benchmark (Xuan et al., 2025), but doing so for all our tasks would be resource-intensive.

Finally, the set of tasks is not a complete representation of problems in the education space, primarily because most of the more complex tasks lack well-defined language-agnostic metrics.

Table 12: Response error rate for the **translation grading** task.

A Experiment Prompts

A.1 Task: Misconception Identification

We used a sequence of 3 prompts:

System prompt:

You are an expert math tutor who knows about all grade-school level math misconceptions. Your task is to select the accurate type of misconceptions your student has based on the (incorrect) answer he/she gives to a multiple-choice math question. You will be given 4 misconceptions types. Your selected misconception type should correspond to the given question and answer. Explain your reasoning

User message 1:

Question: {QUESTION}
Selected Answer: {SELECTED_ANSWER}
Misconceptions:
A. {Misconception 1}
B. {Misconception 2}
C. {Misconception 3}
D. {Misconception 4}

The position of the Misconception corresponding to the selected answer rotates from question to question. The subsequent assistant message is stored as the chain-of-thought. Thereafter, we sent the second user message.

User message 2:

Now based on your above explanation, output the option corresponding to the correct misconception. Only say 'A', 'B', 'C', or 'D' without any other text. Do not say anything else.

The response to this part is the final answer. We regenerate until an answer of 'A', 'B', 'C', or 'D' is received, up to 20 times. If no answer is received, a response of 'E' is saved.

This method is used for all models except Gemini. In case of Gemini, we use the `generate_content` method, which is recommended for non-chat tasks and allows for a single user message. In this case, after obtaining the chain-of-thought, we make a new query with the same system prompt but with the following user message:

Gemini message:

You have previously given the following answer and explanation:
{COT}
Now based on your above explanation, output the option corresponding to the correct misconception. Only say 'A', 'B', 'C', or 'D' without any other text. Do not say anything else.

Note that the last part is identical to User Message 2

When using translated prompts, the System Prompt and, User Message 2 and Gemini Message are translated to the target language.

A.2 Task: Feedback Selection

System prompt:

You are an expert math tutor who specialises in providing precise and helpful feedback for grade-school level math questions. Your task is to select the correct explanation for a student's given answer to a multiple-choice math question.

You will be provided with:

- A math question
- A specific answer chosen by the student (which can be correct or incorrect).
- Four possible explanations (labelled A, B, C, and D).

Your selected explanation should accurately correspond to the given answer. Provide your reasoning for selecting the explanation.

User message 1:

Question: {QUESTION}

Selected Answer: {SELECTED_ANSWER}

Feedbacks:

- A. {Feedback 1}
- B. {Feedback 2}
- C. {Feedback 3}
- D. {Feedback 4}

The position of the Feedback corresponding to the selected answer rotates from question to question. If it is placed at positions A, B, or C, the feedback corresponding to the correct answer is at position D. Otherwise, it is at C. The subsequent assistant message is stored as the chain-of-thought. Thereafter, we sent the second user message.

User message 2:

Now based on your above explanation, output the option corresponding to the correct explanation. Only say 'A', 'B', 'C', or 'D' without any other text. Do not say anything else.

The response to this part is the final answer. We regenerate until an answer of 'A', 'B', 'C', or 'D' is received, up to 20 times. If no answer is received, a response of 'E' is saved.

This method is used for all models except Gemini. In case of Gemini, we use the `generate_content` method, which is recommended for non-chat tasks and allows for a single user message. In this case, after obtaining the chain-of-thought, we make a new query with the same system prompt but with the following user message:

Gemini message:

You have previously given the following answer and explanation:

{COT}

Now based on your above explanation, output the option corresponding to the correct explanation. Only say 'A', 'B', 'C', or 'D' without any other text. Do not say anything else.

Note that the last part is identical to User Message 2. When using translated prompts, the System Prompt, User Message 2, and Gemini Message are translated to the target language. We manually made sure that the formatting was maintained after the translation.

A.3 Task: Tutoring

Student system prompt:

Student Persona: {STUDENT_PERSONA}

Math problem: {MATH_PROBLEM}

Student solution: {STUDENT_SOLUTION}

Context: You need to role-play the student, {STUDENT_NAME}, while the user roleplays the tutor. {STUDENT_NAME} thinks their answer is correct. Only when the teacher provides several good reasoning questions, {STUDENT_NAME} understands the problem and corrects the solution. {STUDENT_NAME} can use calculator and thus makes no calculation errors. Send <EOM> tag at end of the student message.

Teacher system prompt:

A tutor and a student work together to solve the following math word problem.

Math problem: {MATH_PROBLEM}

The correct solution is as follows:

{GROUND_TRUTH}

You need to role-play the tutor while the user roleplays the student, {STUDENT_NAME}. The tutor is a soft-spoken empathetic man who dislikes giving out direct answers to students, and instead likes to answer questions with other questions that would help the student understand the concepts, so that she can solve the problem themselves.

{STUDENT_NAME} has come up with a solution, but it is incorrect. Please start the conversation, one line at a time, aiming to figure out what is {STUDENT_NAME}'s solution and what is wrong with it. Then try to get her to fix it.

The dialogue history was formatted as user-assistant message pairs for teacher and student roles. We manually set the initial messages to initiate conversations in the target language.

A.4 Task: Translation Grading

System prompt:

You are a language translation evaluator. Your task is to assess the quality of a translation from English to {LANGUAGE}. You will be provided with two sentences:

1. An original English sentence.
2. A translated sentence in {LANGUAGE}.

Your goal is to rate the translation on a scale from 1 to 5 based on the following criteria:

- 1: The translation is incorrect, incomprehensible, or completely unrelated to the original English sentence.
- 2: The translation has significant errors and distorts the meaning of the original English sentence.
- 3: The translation is understandable but contains notable errors or awkward phrasing.
- 4: The translation is mostly accurate with minor errors or slightly awkward phrasing.
- 5: The translation is fluent, natural, and accurately conveys the meaning of the original English sentence without errors.

Explain your decision

User message 1:

English: {ENGLISH_SENTENCE}
{LANGUAGE}: {TRANSLATED_SENTENCE}

The subsequent assistant message is stored as the chain-of-thought. Thereafter, we sent the second user message.

User message 2:

Now based on your above explanation, output the final score from 1 to 5. Only say '1', '2', '3', '4', or '5' without any other text. Do not say anything else.

The response to this part is the final answer. We regenerate until an answer of '1', '2', '3', '4', or '5' is received, up to 20 times. If no answer is received, a response of '0' is saved.

This method is used for all models except Gemini. In case of Gemini, we use the `generate_content` method, which is recommended for non-chat tasks and allows for a single user message. In this case, after obtaining the chain-of-thought, we make a new query with the same system prompt but with the following user message:

Gemini message:

You have previously given the following answer and explanation:

{COT}

Now based on your above explanation, output the final score from 1 to 5. Only say '1', '2', '3', '4', or '5' without any other text. Do not say anything else.

Note that the last part is identical to User Message 2

This sequence is repeated twice for each sentence, once with the original translation and once with the perturbed translation. The scores are then compared. When using English prompts, the LANGUAGE fields are set to their English exonyms, i.e., Mandarin, Hindi, Arabic, German, Farsi, Telugu, Ukrainian, and Czech. When using translated prompts, the System Prompt, User Message 2, and Gemini Message are translated to the target language. We manually made sure that the formatting was maintained after the translation. We also use the language endonyms, namely 中文, हिन्दी, العربية, Deutsch, فارسی, తెలుగు, Українська, and Čeština.

B Translation Quality

As we mentioned in Limitations, an LLM performing poorly in a given language does not necessarily mean that the LLM itself is bad. It could also mean that information was lost during translation. This is particularly problematic because the machine translation systems likely suffer from the same resource limitations that plague the LLMs in the first place. As such, we manually investigated a small subset of translated questions for the languages they we are fluent in, namely Persian, Arabic, Czech, and Hindi. For each language, we analysed 10 questions each for the Feedback and Misconception tasks, and 20 questions for the Translation Grading task.

In the case of Persian, the only recurring error was with mathematical notation, particularly that the minus sign gets placed to the right of the numbers instead of the left, where it should be. This, however, seems to be a rendering issue, which is a result of the fact that the minus sign (‘−’, U+2212) is often replaced by the similar-looking hyphen (‘-’, U+002D), confusing the rendering program into believing that it is rendering text. This should not be an issue since LLMs take raw Unicode encodings as input. Beyond this, there were some minor tense errors, but the meanings were clear.

The issue with sign placement was also observed in Arabic. In addition, there seem to be some translation errors. For example, the word ‘travel’ used here in the context of the movement of a graph was translated to ‘liyusaafir’, which is more like ‘taking a trip’. We found no errors in the sentences for the translation task. In Czech, the primary source of errors was improper context-dependent terminology. For example, when translating the word ‘co-interior (angles)’, it missed the ‘co’ prefix and translated only the ‘interior’ part. While this is fine in regular speech, in Mathematical terminology, this can be confusing. Despite making the translation harder to follow, the core meaning of the question is preserved.

In Hindi we found several cases where the Hindi sentence was difficult to follow for the Hindi speaking author due to misinterpretation of polysemes by the translator e.g. the word ‘round’, which was being used in the sense of ‘approximate’ was translated to the sense of ‘circle’ and ‘property’ which was being used in the sense of ‘quality’, was translated as ‘possessions’. Also, the phrase ‘Not Quite’ was translated to something like ‘Not Enough’, perhaps due to the word ‘quite’ not having a Hindi equivalent. However, given the context, using the word for ‘Almost’ would have been more tonally accurate. However, quite a few translations were hard for the annotator to follow, but backtranslating them yielded reasonably good results, meaning there was no information loss.

The translation exercises showed few errors, perhaps due to the sentences being easy to translate by design. There were one or two mistranslations, but otherwise it worked well. One minor issue was that word boundary detection, which was performed in Python using the regex ‘\b\w+\b’, sometimes identified individual characters in Hindi rather than whole words. However, the resulting sentence still had errors, just not the type of errors that we expected.

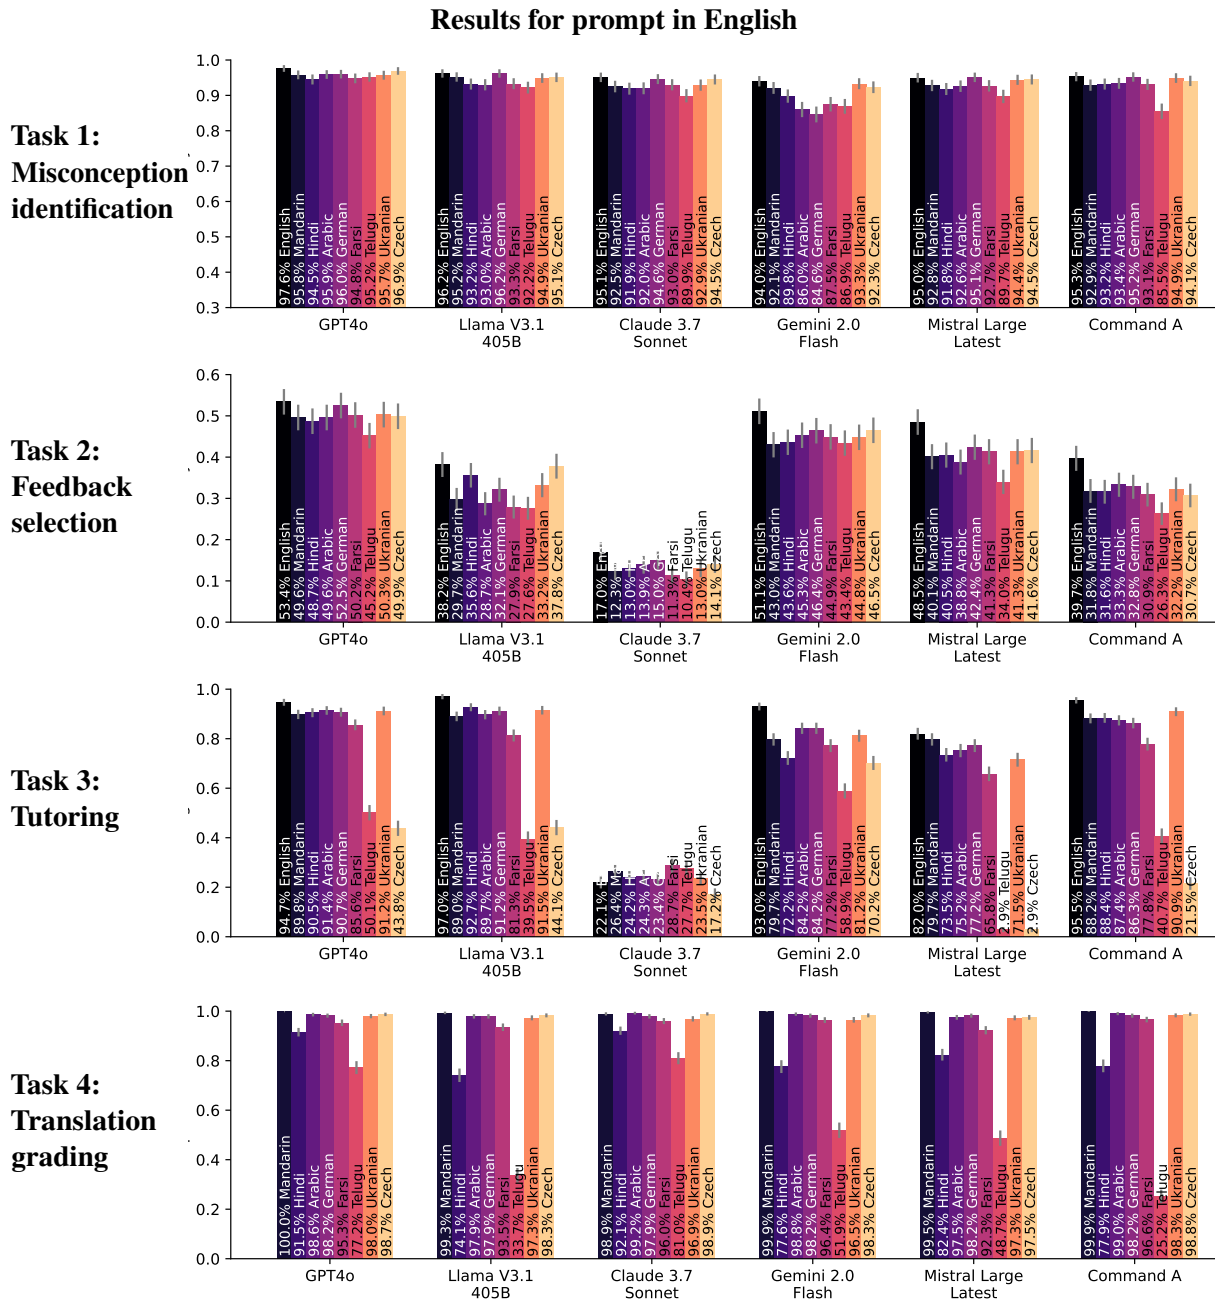

Figure 2: Evaluation results of the four tasks across five large language models. The error bars show a 95% confidence interval (t-test). MathDial Graphs show *tutoring score after five turns*, most models flatline after 5 utterance pairs. The English language column is absent because translation evaluation uses English as the source. All scores range from 0.0 to 1.0, with higher being better, though they are not comparable with each other. Note the truncated y-axes for better detail. Visualizes Tables 3 to 6.

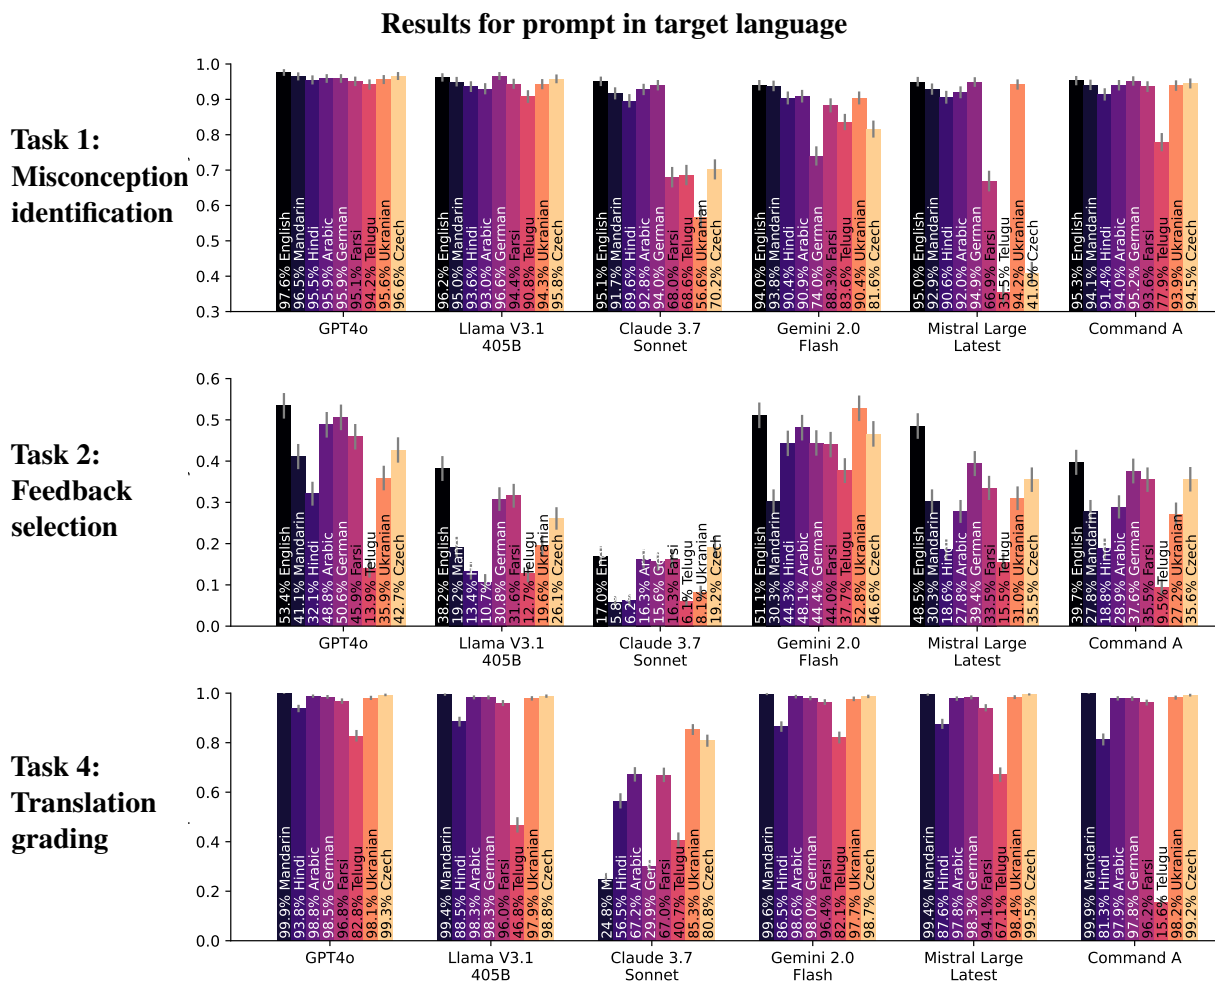

Figure 3: Evaluation results of the four tasks across five large language models. The error bars show 95% confidence interval (t-test). MathDial Graphs show *tutoring score after five turns*, most models flatline after 5 utterance pairs. The English language column is absent because translation evaluation uses English as the source. All scores range from 0.0 to 1.0, with higher being better, though they are not comparable with each other. Note the truncated y-axes for better detail. Visualizes Tables 3 to 6.

Exploiting the English Vocabulary Profile for L2 word-level vocabulary assessment with LLMs

Stefano Bannò, Kate M. Knill, Mark J. F. Gales

ALTA Institute, Department of Engineering, University of Cambridge (UK)

{sb2549, kmk1001, mjfg100}@cam.ac.uk

Abstract

Vocabulary use is a fundamental aspect of second language (L2) proficiency. To date, its assessment by automated systems has typically examined the context-independent, or part-of-speech (PoS) related use of words. This paper introduces a novel approach to enable fine-grained vocabulary evaluation exploiting the precise use of words within a sentence. The scheme combines large language models (LLMs) with the English Vocabulary Profile (EVP). The EVP is a standard lexical resource that enables in-context vocabulary use to be linked with proficiency level. We evaluate the ability of LLMs to assign proficiency levels to individual words as they appear in L2 learner writing, addressing key challenges such as polysemy, contextual variation, and multi-word expressions. We compare LLMs to a PoS-based baseline. LLMs appear to exploit additional semantic information that yields improved performance. We also explore correlations between word-level proficiency and essay-level proficiency. Finally, the approach is applied to examine the consistency of the EVP proficiency levels. Results show that LLMs are well-suited for the task of vocabulary assessment.

1 Introduction

Automated writing evaluation has become an established area of research within natural language processing, playing a key role in language education and computer-assisted language learning (Huawei and Aryadoust, 2023). Within this context, assessing second language (L2) proficiency remains a critical objective, with increasing attention being paid not only to holistic assessment but also to the evaluation of individual aspects of language competence (Weigle, 2002), such as grammar, coherence, and vocabulary. This has proven essential for providing detailed, pedagogically useful feedback to language learners (Hamp-Lyons, 1995). Among these components, vocabulary is the es-

sential building block of language (Schmitt et al., 2001) as words are the main vehicle for expressing meaning (Vermeer, 2001).

Existing vocabulary assessment methods have typically either assigned an overall vocabulary score to learners' texts at the essay- (Crossley et al., 2023; Bannò et al., 2024) or sentence-level (Arase et al., 2022), extracted vocabulary-related features (e.g., lexical diversity or sophistication) (Kyle and Crossley, 2015; Kyle et al., 2018), or attempted to assess the difficulty or appropriateness of individual words (Bax, 2012; Uchida and Negishi, 2018; Settles et al., 2020; Aleksandrova and Pouliot, 2023). The latter, however, has been largely under-explored and presents significant challenges – particularly in dealing with polysemy and contextual variation as well as handling multi-word expressions.

Our work directly addresses this limitation by focusing on word-level, in-context vocabulary assessment in a fully replicable manner. Specifically, we leverage an open-access reference containing information about which lexical items are used at each level of English learning, the English Vocabulary Profile (see Section 3.1). We combine this resource with state-of-the-art large language models (LLMs) to predict the proficiency level of individual words as they are used in L2 learner writing. To the best of our knowledge, this is the first study to apply LLMs for this task, offering a novel and robust approach to vocabulary assessment that explicitly handles semantic ambiguity and contextual nuance.

In Section 2, we outline the theoretical background of L2 vocabulary assessment and review previous studies that have implemented it in automated systems. Section 3 presents the English Vocabulary Profile and the L2 datasets used in our experiments. Section 4 constitutes the core of our study. The first experiment focuses on identifying the intended meaning of polysemous words from the English Vocabulary Profile through the use of

LLMs, using learner example sentences sourced from the same dataset. In our second experiment, we annotate sentences from a learner corpus by assigning each word a proficiency level based on the English Vocabulary Profile – annotations we plan to make publicly available. We then automatically predict these levels and compare the performance of various LLMs against a random baseline and a part-of-speech (PoS)-based model. The third experiment extends this approach to additional L2 learner datasets annotated only at the essay level, investigating the correlation between predicted word-level proficiency and essay-level proficiency. Additionally, at the end of the same section, we use our LLM-based approach to examine the consistency of the annotations in the English Vocabulary Profile. Finally, in Section 5, we present our conclusions and outline directions for future work.

2 Related Work

2.1 Vocabulary assessment

Despite its fundamental importance, the assessment of vocabulary was only selectively investigated at the beginning of the scientific era of L2 assessment, whereas much more attention was paid to the contrastive analysis of sounds and grammar (Lennon, 2008). When vocabulary knowledge was evaluated, it was primarily tested using the discrete-point approach, an assessment method focused on testing one specific linguistic element – phonology, morphology, syntax, and vocabulary – at a time, generally using multiple-choice questions. This approach to vocabulary testing faced various criticisms, as it offered only a limited view of a learner’s vocabulary knowledge, neglected the role of productive language use, disregarded the importance of context in real-world communication, and failed to consider learners’ use of strategies to cope with unfamiliar words (Read, 2000).

The 1980s represented a watershed in vocabulary assessment since a group of researchers started to publish studies on defined procedures aiming at assessing specific aspects of vocabulary use and knowledge (Anderson and Freebody, 1981, 1983; Nation, 1983; Meara and Buxton, 1987). These seminal works were something of an exception, given that, on the one hand, the field of L2 acquisition was primarily concerned with the investigation of the acquisition by learners of morpho-syntactic features, whereas, on the other hand, the advent of the communicative approach shifted the attention

of language assessment researchers from knowledge of grammatical and lexical elements to the performance of real-world-like tasks (Read, 2013).

For our work, we believe it is important to remember Read’s conceptualisation of vocabulary assessment, who classified it according to 6 dimensions arranged in antonymic pairs: discrete versus embedded, selective versus comprehensive, and context-independent versus context-dependent. The first distinguishes whether vocabulary is assessed as an isolated skill (discrete) or as part of broader language proficiency (embedded). The second refers to the scope of lexical items – either a specific set (selective) or the learner’s full vocabulary range (comprehensive). The third dimension captures whether vocabulary is assessed in isolation or within authentic contexts. Due to the widespread acceptance of the communicative approach (Harding, 2014), it is straightforward to conclude that current trends in language testing and assessment tend to privilege *embedded*, *comprehensive*, and *context-dependent* measures of vocabulary assessment. These three characteristics are central to our approach.

2.2 Lexical sophistication

The Common European Framework of Reference (CEFR) (Council of Europe, 2001, 2020), a key benchmark aligned with communicative language teaching, testing and assessment, distinguishes between vocabulary range and vocabulary control, which have generally been operationalised along the dimensions of lexical diversity and lexical sophistication, respectively.

Lexical diversity, concerning the breadth of vocabulary used by learners (Yu, 2010; Lu, 2012), is typically measured through metrics like type-token ratio or number of unique words. Its relationship with L2 writing proficiency has been widely studied (Crossley and McNamara, 2012; Gebril and Plakans, 2016; Treffers-Daller et al., 2018; Woods et al., 2023). While important, lexical diversity is not the primary focus of this paper.

Our work is more closely related to the idea of lexical sophistication. Its focus is the depth of lexical knowledge and is frequently characterised by the presence of relatively rare or uncommon words within a given language sample (Baese-Berk et al., 2021). It is generally operationalised using features related to word frequency and familiarity, such as the Lexical Frequency Profile, which reflects the proportion of a learner’s vocabulary falling within

various frequency bands derived from a reference corpus (Laufer and Nation, 1995). The English Vocabulary Profile (EVP) (Capel, 2015), adopted in our work (see Section 3), is a resource that describes words, phrases, idioms, and collocations used by English learners at different CEFR levels. The study by Leńko-Szymańska (2015), which represents an important precedent for our work, employed it to assign proficiency bands to 90 essays, finding a strong correlation between the clusters obtained using the vocabulary profile and the human-assigned CEFR levels.

Similarly to the EVP, Dürlich and François (2018) created an online database called EFLLex, which presents the distribution of English words across CEFR levels (A1 to C1), mainly derived from the analysis of textbook corpora. The CEFR-J, a Japan-specific adaptation of the CEFR, also features a word list with proficiency levels (Tono, 2013).

2.3 Automated approaches

Yoon et al. (2012) investigated the use of a vocabulary profile to extract features of lexical sophistication for proficiency assessment of spontaneous speech and found interesting correlations with oral proficiency scores. Kyle and Crossley (2015) introduced the Tool for Automatic Analysis of Lexical Sophistication (TAALES), which computes 135 lexical indices. They found that 5 measures of lexical complexity accounted for more than 50% of the variance in the human ratings of the spoken and written datasets considered in their study. Text Inspector (Bax, 2012) is an online tool that appears to use the EVP to assess writing proficiency; however, its implementation is not publicly available and is most likely rule-based, as it presents all possible meanings (and corresponding proficiency levels) of a word to the user when ambiguities arise. The calculation method used by the CVLA (CEFR-based Vocabulary Level Analyzer) is openly available (Uchida and Negishi, 2018); however, the strictly vocabulary-related part of this tool is also rule-based and, like Text Inspector, does not appear to address issues related to polysemous or ambiguous words.

Duolingo developed and released a tool called the CEFR checker, which is now discontinued. This tool allowed users to assess the difficulty level of English and Spanish words and texts. The lexical complexity component of the tool is described in Settles et al. (2020) and features a vocabulary

scale model based on the CEFR framework and a database of 6,823 English words, partly obtained from the EVP. The authors introduce two regression models trained on lexical representations using surface-level features designed to approximate word frequency. However, these models do not appear to account for multi-word expressions or words with multiple meanings.

Garí Soler and Apidianaki (2021) demonstrated that BERT could effectively generate contextual embeddings for polysemous words, laying the groundwork for further research in lexical complexity assessment. Building on this, Aleksandrova and Pouliot (2023) explored how the most frequent senses of polysemous words appear in language learner essays. Their study leverages BERT to develop a CEFR-aligned classifier aimed at evaluating the lexical complexity of both single-word and multi-word expressions in English and French. It is important to note that their classifier is trained to predict the CEFR level of an item in context, but not to explicitly identify or disambiguate the meaning or sense of that expression.¹

While the aforementioned studies partially or entirely fall short in handling polysemy and ambiguity, our study directly addresses this challenge by targeting word-level, in-context vocabulary assessment in a fully replicable manner. Additionally, to the best of our knowledge, ours is the first study to leverage LLMs for this purpose.

3 Data

3.1 English Vocabulary Profile

The English Vocabulary Profile (EVP) (Capel, 2015) is a publicly available reference² that contains information about which words, phrases, idioms, and collocations are used at each level of English learning. It is grounded in extensive research using the Cambridge Learner Corpus (Nicholls, 2003), a growing collection of exam scripts written by learners worldwide.

For our experiments, we only considered the British English section of the profile, which includes 15671 entries corresponding to 6747 unique words. The difference arises because some words have multiple meanings or grammatical functions, resulting in several entries comprising multiple op-

¹Other works have targeted word-level vocabulary assessment, but not for English (Gala et al., 2014; Alfter et al., 2016; Alfter and Volodina, 2018).

²englishprofile.org/

tions. Additional details about the degree of polysemy are provided in Table 6 in Appendix A.

Base Word	Guideword	Level	Part of Speech	Topic	Details
if/when push comes to shove	IDIOM	C2	phrase		
push	MOVE SOMEONE/SOME THING	A2	verb	people: actions	
push	PRESS	B1	verb	people: actions	
push	MOVE YOURSELF	B1	verb	people: actions	
push	ENCOURAGE	C1	verb	people: actions	
push	ENCOURAGEMENT	C1	noun		
push	PRESS	B1	noun	people: actions	
push (sb) for sth/to do sth		B2	phrase	communication	
pushy		C2	adjective	people: personality	
push yourself		B2	phrase	people: actions	

Figure 1: Example for the word *push* from the EVP.

Each EVP entry includes a base word, a guideword, its CEFR level(s), manually assigned PoS, topic, and additional details such as learner and dictionary examples in context (see Figure 1). Among all entries, when distinguishing by PoS, 62.24% have more than one CEFR level. However, when considering only unique base words, this proportion drops to 29.21%. In this work, we refer to words that, within a single PoS, have multiple CEFR levels as *ambiguous* words; the rest are considered *non-ambiguous*. For example, the noun *aim* is classified solely as B1, making it non-ambiguous, whereas the verb *aim* spans levels A2, B2, C1, and C2 depending on context, making it ambiguous. About 95% of the section of the EVP we considered in our work has examples taken from L2 learner writing, many of which also contain grammatical errors. For the remaining 5%, we relied on dictionary examples in our experiments.

3.2 L2 learner datasets

3.2.1 OneStopEnglish

OneStopEnglish (Vajjala and Lučić, 2018), is a publicly available corpus³ for readability assessment and text simplification including 189 parallel compositions across three readability levels: Elementary, Intermediate, and Advanced. We extracted 293 triplets of parallel sentences from the corpus, spanning these three readability levels (see Appendix B for an example), and annotated them at the word level with CEFR levels from the EVP, excluding stopwords,⁴ punctuation, and words not

³github.com/nishkalavallabhi/OneStopEnglishCorpus

⁴Stopwords include those from the NLTK list ([nltk.org](https://www.nltk.org)) plus *across*, *among*, and *away*.

featured in the EVP (see Figure 2). These annotations will be made publicly available.

3.2.2 EFCAMDAT

Arguably the largest publicly available L2 learner corpus,⁵ the second release of the EFCAMDAT (Geertzen et al., 2013; Huang et al., 2017) consists of 1,180,310 scripts written by 174,743 L2 learners as assignments for Englishtown, an online English language school. The corpus includes 128 distinct writing tasks covering a range of topics, such as describing the rules of a game, reporting a news story, explaining a homemade remedy for fever, and writing to a pen pal. Each composition is annotated with a proficiency level from 1 to 16, corresponding to CEFR levels A1 to C2.⁶ Learners' first languages are not directly available but can be inferred from their nationalities (approximately 200 in total). For our experiments, we randomly selected 1,000 essays for each CEFR level from the corpus, resulting in a total of 6,000 essays.

3.2.3 ELLIPSE

The English Language Learner Insight, Proficiency, and Skills Evaluation (ELLIPSE) Corpus (Crossley et al., 2023) is a publicly available collection⁷ of approximately 6,500 writing samples from L2 learners of English. Each sample is annotated with both an overall holistic proficiency score and detailed analytic scores covering aspects such as cohesion, syntax, vocabulary, phraseology, grammar, and punctuation conventions. Proficiency scores are on scale from 1 to 5. For our experiments, we extracted 359 essays from the training set and 175 from the test set. Further details about the selected essays can be found in Table 7 in Appendix A.

4 Experiments

4.1 Semantic understanding

Our first experiment serves as a proof of concept and focuses on semantic understanding, with the goal of identifying the intended meaning of a unique word from the EVP when considering the EVP learner examples. Specifically, an LLM is provided with an EVP learner-produced example sentence containing a given word along with

⁵ef-lab.mm11.cam.ac.uk/EFCAMDAT.html

⁶The official EF-CEFR mapping can be found at: myenglishlive.ef.com/help-me-article?articleID=55&Vote=Up

⁷github.com/scrosseye/ELLIPSE-Corpus

Figure 2: Annotation example on OneStopEnglish. S: stopword; P: punctuation; N/A: word not featured in the EVP.

all possible EVP entries for that given word. The model’s task is to select the most contextually appropriate meaning from the options provided. Note that multi-word expressions are also included by feeding their reference words, e.g., the word *push* for the expression *push (sb) for sth/to do sth* (see Figure 1).

The prompt used for this task and a relevant example are reported in Appendix C (“Prompt for semantic understanding”). For this experiment, we focused on words with 3, 4, 5, and 6 possible meanings. To avoid positional bias (Liusie et al., 2024), all possible permutations were considered for words with 3 options.⁸ For words with 4, 5, and 6 options, however, only ten permutations were considered due to time and resource constraints. For each permutation, we extract the logits for each option, apply a softmax function, then compute the average probability across permutations and select the option with the highest average probability.

For this experiment, we compared the performance of two proprietary LLMs, i.e., GPT-4o, GPT-4o-mini (OpenAI, 2023), and three open-source LLMs, i.e., Llama 3.1 8B, Llama 3.1 70B (4-bit quantised) (Llama Team, 2024), and Qwen 2.5 32B (4-bit quantised) (Yang et al., 2024). These models were selected to ensure a representative range in terms of both model size and the open-source versus proprietary distinction.

Results are evaluated in terms of Accuracy.

4.2 Word-level proficiency prediction

In the second part of our work, we perform CEFR proficiency level prediction at the word level on the annotated sentences extracted from the OneStopEnglish dataset (see Section 3.2 and Figure 2). We implement the approach proposed in Figure 3 in order to extract the proficiency level for each word in a given composition.

⁸In this context, a permutation refers to a unique ordering of the multiple-choice options associated with each question. That is, while the content of the options remains the same, their positions (e.g., labeled A, B, and C) are shuffled across different permutations. This ensures that the model’s predictions are not influenced by the fixed position of any particular option, thereby reducing positional bias.

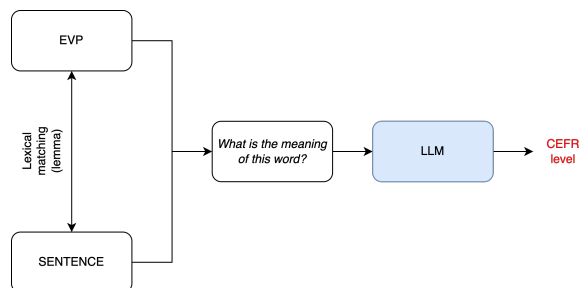

Figure 3: High-level diagram of the approach proposed for word-level CEFR prediction.

Since it is not feasible to feed all EVP entries for each word in a sentence into the LLM at once, we use spaCy⁹ to lemmatise each word and map the resulting lemma to its corresponding entries in the EVP. For example, for the word *work* in the sentence shown in Figure 2, the lemma remains *work*, which we then match to all corresponding *work* entries in the EVP. This allows us to filter out irrelevant EVP words in each LLM run.

[They] work with the police [...]
 They [work] with the police [...]
 They work [with] the police [...]
 They work with [the] police [...]
 They work with the [police] [...]

Figure 4: Highlighting method.

For each sentence we iterate through each word by highlighting it in square brackets, as shown in Figure 4. If there is no match between a given lemmatised word in the sentence and the EVP, we automatically assign *N/A* to the word (see Figure 2). In all the other cases, we add a “None of the other options” choice to the other available options and ask the LLM to choose the most suitable option. Then, we extract the logits for each option, apply a softmax function, and select the option with the highest average probability. Finally, we select the

⁹spacy.io

CEFR level assigned to this option. In this set of experiments, we also feed the manually assigned PoS information and a brief definition associated to each option.

The prompt used for these experiments as well as a relevant example can be found in Appendix C (“Prompt for word-level CEFR prediction”).¹⁰

It is important to note that our approach can effectively handle multi-word expressions. For example, when encountering the phrasal verb *take off* in the sense of “becoming airborne”, the method processes *take* and *off* separately. The word *off* is treated as a stopword and thus excluded from the final assessment. However, *take* is still evaluated in context, allowing the LLM to infer the intended meaning from the surrounding sentence or essay, in addition to the PoS information (i.e., *verb*) and the EVP definition (i.e., *If an aircraft takes off, it leaves the ground and begins to fly.*). This ensures that the CEFR level assigned reflects the actual usage rather than the isolated form. Similarly, for the expression *take advantage of sth*, both *take* and *advantage* are mapped to the same corresponding multi-word expression in the EVP, while the stopword *of* is excluded from the evaluation.

For this part of our work, we try the same LLMs as Section 4.1 except for GPT-4o-mini and Llama 3.1 8B. We compare the performance of these LLMs with a PoS-based system, which only relies on PoS tags extracted using spaCy. Specifically, if a given lemma in the sentence has only one entry in the EVP then its corresponding level is automatically assigned to the word (e.g., *voluntary* in Appendix B has only one EVP entry, hence one CEFR level). Otherwise the relevant PoS tag is matched with the corresponding one in the EVP. If the EVP only specifies one CEFR level for this lemma/PoS pair then this level is automatically assigned to the word (e.g., *criminal* in Appendix B has two entries – noun and adjective – at two different CEFR levels). Where the pairing is assigned to multiple CEFR levels in the EVP, the lowest of these CEFR levels is assigned to the word (e.g., the word *service* in the example in Appendix B has 6 noun entries with 3 different CEFR levels). Additionally, we consider a random baseline that relies solely on lexical matching. In this case, for words with a single entry, such as *voluntary*, after lemmatisation, we simply assign the associated CEFR

level. For words with multiple levels, we randomly pick a level from the available EVP entries.

Results are evaluated in terms of overall Accuracy. Additionally, performance on individual CEFR levels is reported using F_1 score.

4.3 Essay-level proficiency prediction

The third part of our work applies the approach presented in the previous section to additional L2 learner datasets, namely EFCAMDAT and ELLIPSE (see Sections 3.2). Unlike the On-StopEnglish data, these datasets are annotated only at the essay level and lack word-level CEFR labels. We therefore use our approach to predict the CEFR level of each word and leverage this information as features for essay-level proficiency prediction. For this part of the work, we only used Qwen 2.5 32B¹¹ and the PoS-based model to extract vocabulary-related information. In other words, we aim to explore the predictive power of vocabulary-related features extracted through our models in the context of holistic proficiency assessment. Additionally, since the ELLIPSE data include analytic scores targeting specific aspects of proficiency, we further investigate the relationship between these features and scores related to dimensions such as cohesion, syntax, vocabulary, phraseology, grammar, and punctuation conventions.

To do this, for EFCAMDAT, we employ a naive classifier that uses the distribution of predicted CEFR levels within each essay. Specifically, we compute the proportion of words at each predicted CEFR level (i.e., the count of words at each level divided by the total essay length), weight these proportions by their corresponding CEFR levels (i.e., 1 for A1, 2 for A2, 3 for B1, etc.), and sum them to obtain a composite score. We then assess the correlation between this score and the human-assigned holistic score. In addition to the naive classifier, we also employ a simple Support Vector Regression (SVR) model with default parameters (i.e., $\epsilon = 0.1$, $C = 1$, and a radial basis function kernel). The model is trained using the proportions of words at each predicted CEFR level as input features and evaluated using 5-fold cross-validation.

The SVR is also employed for the ELLIPSE dataset. The model is trained on the training split to predict the holistic proficiency scores. Subse-

¹⁰We also tried this task by prompting the LLMs without EVP information, but results were significantly worse.

¹¹The prompt is the same reported in Appendix C (“Prompt for word-level CEFR prediction”) with the only difference that “sentence” is replaced with “essay”.

quently, it is evaluated on the test set for both holistic and analytic scores prediction (see Section 3.2).

Results are evaluated in terms of Pearson’s correlation coefficient (PCC) and Spearman’s rank coefficient (SRC).

Experimental results

4.4 Semantic understanding results

Table 1 reports the results in terms of Accuracy for the semantic understanding task. As can be seen, GPT-4o achieves the best performance, followed by Llama 3.1 70B, with Qwen 2.5 32B performing nearly on par. While model size appears to play a significant role in the performance gap between GPT-4o and the other models, this pattern does not hold when comparing Qwen 2.5 32B to Llama 3.1 70B, despite the latter being more than twice as large. All models show a remarkable performance for this task with the exception of Llama 3.1 8B. As expected, Accuracy decreases as the number of options available for a given word increases.

A reasonable question to ask is whether these LLMs have been exposed to the EVP during training, given that it is publicly available. This consideration, among others, motivated us to extend our experiments to additional L2 learner datasets.

Model	No. of options				avg.
	3	4	5	6	
GPT-4o	89.0	86.2	83.1	79.5	84.4
GPT-4o_{mini}	84.4	78.9	75.4	71.2	77.5
Llama3.1_{70B}	85.1	82.0	78.9	73.1	79.8
Llama3.1_{8B}	77.4	70.0	64.3	64.4	69.0
Qwen2.5_{32B}	85.6	80.8	76.4	75.4	79.6

Table 1: Accuracy (%) of EVP classification results.

4.5 Word-level proficiency prediction results

Model	Ambig.	Non-amb.	All
Random	29.1	88.7	61.6
PoS-based	66.7	93.4	80.7
GPT-4o	75.1	90.5	83.3
Llama 3.1 70B	76.9	91.5	84.6
Qwen 2.5 32B	80.5	92.8	87.0

Table 2: Accuracy (%) results for word-level CEFR prediction (OneStopEnglish).

Table 2 shows the results in terms of Accuracy for the task of word-level CEFR level prediction on the OneStopEnglish data. As mentioned in

Section 3.1, we refer to words that have multiple CEFR levels within a single PoS as *ambiguous* words, whereas the rest are considered *non-ambiguous*. We report the results for ambiguous, non-ambiguous, and all words. As expected, the Random classifier performs extremely poorly when predicting the level of ambiguous words. Incorporating PoS information leads to noticeable improvements, as demonstrated by the PoS-based model. However, the best performance on both ambiguous and overall cases is achieved – in increasing order – by GPT-4o, Llama 3.1 70B, and Qwen 2.5 32B. Remarkably, Qwen, despite being the smallest of the three LLMs, outperforms all others on this task. The improved performance of LLMs is likely due to their ability to leverage semantic information in addition to grammatical and syntactic knowledge.

For non-ambiguous words, as expected, the Random classifier achieves relatively decent performance. In this setting, the PoS-based model yields the highest accuracy, followed closely by Qwen 2.5 32B. One might expect the PoS-based model to achieve perfect accuracy; however, this is not the case, as the data include instances where words are used with meanings that are not covered in the EVP, leading to misclassifications by the PoS-based model. To address such cases, we included a “None of the other options” choice among the LLM’s available options (see Section 4.2) – though this option appears to be over-selected by the model, potentially affecting its accuracy.

Another reason why the LLMs do not outperform the PoS-based model for non-ambiguous words lies in the way options are selected. When multiple PoS entries exist for a given lemma, the PoS-based model uses only the relevant, non-ambiguous entry matching the POS tag. In contrast, all available options – including those with irrelevant PoS tags – are fed into the LLMs. For instance, as illustrated in Section 3.1, if a sentence contains the word *aim* used as a noun (which appears in the EVP only at the B1 level), the PoS-based model considers only this entry. However, the LLM is presented with both the noun and verb entries (at A2, B2, C1, and C2 in the EVP) for *aim*.¹² These findings are further supported by the performance figures in Table 9 in Appendix D, which reports the breakdown by word-level CEFR level in terms of F_1 score.

¹²We deliberately chose not to filter out these entries to avoid assuming perfect accuracy from the spaCy tagger.

Overall, these results suggest that the most effective solution may lie in a hybrid approach, where an LLM is used to handle ambiguous words, while a PoS-based model deals with non-ambiguous ones.

4.6 Essay-level proficiency prediction results

We use the same approach to predict word-level CEFR levels on additional L2 learner data, which are only annotated at the essay level. Starting from EFCAMDAT, Figure 5 shows a cumulative plot of the predicted normalised distribution of words for each word-level CEFR level across essay-level CEFR levels. We intentionally reverse the order of CEFR levels on the x-axis to emphasise that vocabulary usage is indicative of a certain proficiency level or higher, rather than exclusive to that level. For example, B1-level items are also commonly used by more advanced learners.

Focusing on a specific element of the figure, if we observe B1 level essays (represented by the green line), we observe that vocabulary from the C2 and C1 levels is used very little, while B2 level vocabulary appears to some extent – more than in A1 and A2 level essays, but less than in B2, C1, and C2 level essays. Vocabulary from B1 and lower levels is used even more frequently.

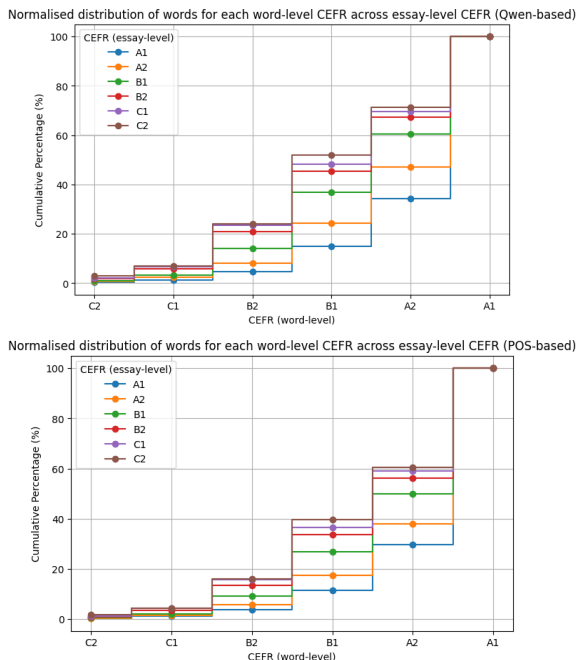

Figure 5: Predicted normalised distribution of words for each word-level CEFR level across essay-level CEFR levels. Qwen 2.5 32B vs PoS-based (EFCAMDAT).

When considering the overall trends, words from A2 to B2 show a steady increase in usage as essay-

level proficiency progresses. Interestingly, higher-level words (i.e., C1 and C2) are not as frequently used even in essays written at higher proficiency levels. Nonetheless, a moderate distinction across essay-level proficiency bands can still be observed. To this end, we present Figure 6, which displays the empirical cumulative distribution function (eCDF) of the AUC (Area Under the Curve) values computed from Figure 5. In both figures, we observe larger gaps – indicating better differentiation across levels – when using Qwen compared to the PoS-based model.

Figure 6: eCDF of AUC values. Qwen 2.5 32B vs PoS-based (EFCAMDAT).

These findings are further supported by the essay assessment results reported in Table 3. When used as features for predicting holistic scores, the vocabulary information extracted with Qwen consistently outperforms that derived from the PoS-based model both in the naive classifier and by the SVR.¹³

Finally, we report the results of our experiments on ELLIPSE using Qwen in combination with an SVR trained on holistic scores (see Section 4.3). As shown in Table 4, despite the high inter-correlation

¹³These experiments aim to demonstrate the predictive power of the extracted features, not to achieve state-of-the-art essay scoring.

Features	Classifier	PCC	SRC
PoS	Naive	0.580	0.603
Qwen		0.636	0.656
PoS	SVR	0.734	0.713
Qwen		0.771	0.749

Table 3: Results for essay-level holistic proficiency prediction (EFCAMDAT).

among all analytic scores (see Table 8 in Appendix A), the SVR (trained on holistic scores) predictions correlate most strongly with the Vocabulary scores, followed by Phraseology, suggesting our features are effectively targeting lexical aspects of language.

	PCC	SRC
Overall	0.650	0.624
Vocabulary	0.637	0.627
Phraseology	0.630	0.614
Grammar	0.577	0.556
Syntax	0.584	0.547
Cohesion	0.595	0.569
Conventions	0.613	0.578

Table 4: Results for essay-level holistic and analytic proficiency prediction using Qwen-SVR (ELLIPSE).

4.7 Word-level analysis

Finally, to evaluate the consistency of the EVP, we reverse the approach used thus far. Specifically, we select the two most common words with multiple meanings in the EFCAMDAT data (i.e., *work* and *like*) and examine their word-level CEFR level distribution (predicted with Qwen) across essay-level CEFR levels, as shown in Figures 7 and 8. The captions report the number of essays containing these words for each essay-level CEFR level. Figures 7

	<i>work</i>	<i>like</i>
≥B2	88.6	-
≥B1	90.6	89.6
≥A2	96.8	99.4

Table 5: EVP consistency in terms of Accuracy (%) for words *work* and *like* (EFCAMDAT).

and 8 are summarised in Table 5, where we assess the consistency of the EVP for these two words in terms of Accuracy. As discussed in Section 4.6, vocabulary use typically reflects a certain proficiency level or higher, rather than being exclusive to a specific level. Accordingly, we compute Accuracy

Figure 7: Distribution for word *work* (A1: 191; A2: 278; B1: 482; B2: 667; C1: 457; C2: 667).

Figure 8: Distribution for word *like* (A1: 401; A2: 411; B1: 380; B2: 459; C1: 497; C2: 591).

by checking whether a word appears in essays at its assigned level or above. It is also important to note that we are comparing word-level *vocabulary* levels with essay-level *holistic* scores, where vocabulary represents only one component of the overall assessment. The results show high accuracy and suggest a strong degree of consistency in the CEFR classification provided by the EVP.

5 Conclusions and future work

In this work, we introduced a novel approach to in-context, word-level L2 vocabulary assessment by leveraging LLMs in combination with the English Vocabulary Profile. We compared the performance of several open-source and proprietary LLMs to a PoS-based model and showed that the former are particularly effective for this task, especially in handling polysemy and lexical ambiguity.

We plan to integrate this approach into an automatic essay grading system, where it could enrich holistic scoring with fine-grained feedback on vocabulary use, for example, by identifying lexical gaps relative to the learner’s proficiency or highlighting advanced vocabulary usage as a strength. Additionally, we plan to extend our experiments to spoken transcriptions in order to further evaluate the robustness of LLMs and assess their effectiveness across different modalities.

Limitations

One limitation of this study is the lack of a systematic investigation into how learner errors affect our approach. In particular, lemmatisation and matching with EVP entries may be hindered by such errors.¹⁴ While spelling mistakes can be addressed with a spellchecker, grammatical or lexical errors pose a greater challenge. In this case, it would be interesting to test our approach on pairs of original and grammatically corrected (manually and/or automatically) sentences or essays and analyse shifts in the LLM's probability distributions in the presence of learner errors.

Another limitation of our approach lies in the way word-level proficiency labels are assigned. In our experiments, each word in the OneStopEnglish data was annotated with its CEFR level, not its specific sense. As a result, polysemous words with multiple meanings but identical CEFR levels could be matched to an incorrect sense, even though the level remains technically accurate. However, it is important to note that the LLMs are prompted to identify the intended meaning of each word based on its context. The CEFR level is then assigned post hoc by mapping that selected meaning to the corresponding entry in the English Vocabulary Profile, hence to a CEFR level.

Finally, due to space constraints, we did not conduct a focused analysis on multi-word expressions such as idioms and phrasal verbs. Nonetheless, given the strong overall results and the fact that multi-word expressions are included in our data, it is reasonable to assume that our approach also performs well on these cases.

Acknowledgments

This paper reports on research supported by Cambridge University Press & Assessment, a department of The Chancellor, Masters, and Scholars of the University of Cambridge. The authors would like to thank the ALTA Spoken Language Processing Technology Project Team for general discussions and contributions to the evaluation infrastructure.

¹⁴In our first experiment specifically, learner example sentences from the EVP may contain errors, but not involving the target word. Additionally, this experiment does not require lemmatisation.

violent criminal gangs that operate across London.

C Appendix C: Prompts

Prompt for semantic understanding

Read this sentence: **[EVP SENTENCE]**
Choose the correct meaning of **[WORD]** by selecting the most suitable among the following options A, B, C, D, E, or F. No other answer is allowed. Only output the respective option letter without any additional comments, notes, or explanations.

A) **[DEFINITION A]**

B) **[DEFINITION B]**

C) **[DEFINITION C]**

D) **[DEFINITION D]**

E) **[DEFINITION E]**

F) **[DEFINITION F]**

Example

Read this sentence: **“It was tough on the worn out employees.”** Choose the correct meaning of **“tough”** by selecting the most suitable among the following options A, B, C, D, E, or F. No other answer is allowed. Only output the respective option letter without any additional comments, notes, or explanations.

A) not easy to break or damage

B) describes food that is difficult to cut or eat

C) Tough people are mentally strong and not afraid of difficult situations.

D) difficult

E) Tough rules are severe.

F) unfair or unlucky

Prompt for word-level CEFR prediction

Read this L2 learner sentence: **[SENTENCE]**

Choose the correct meaning of **[WORD]** (in square brackets) by selecting the most suitable among the following options. Also consider the additional information and the PoS of each option. No other answer is allowed. Only output the respective option number without any additional comments, notes, or explanations.

1. **[DEFINITION 1]** - Additional information: **[INFO]** (PoS)

2. **[DEFINITION 2]** - Additional information: **[INFO]** (PoS)

3. **[DEFINITION 3]** - Additional information: **[INFO]** (PoS)

[...]

n. None of the other options.

where the additional information consists of a brief definition of the word. In round brackets, we also feed the information related to the manually assigned PoS as described in the EVP. See the example below for further information.

The prompt for the experiments conducted on essay-level proficiency prediction is the same. The only difference is that “sentence” is replaced with “essay”.

Example

Read this L2 learner sentence: **They [work] with the police , the probation service and other , voluntary organizations to help those who feel trapped and frightened in the violent criminal gangs that operate across London .**

Choose the correct meaning of **“work”** (in square brackets) by selecting the most suitable among the following options.

Also consider the additional information and the part of speech of each option. No other answer is allowed. Only output the respective option number without any additional comments, notes, or explanations.

1) the place where you go to do your job - Additional information: work (PLACE) (Part of speech: noun)

2) something you do as a job to earn money - Additional information: work (JOB) (Part of speech: noun)

3) to do a job, especially the job you do to earn money - Additional information: work (DO JOB) (Part of speech: verb)

4) the activities that you have to do at school, for your job, etc. - Additional information: work (ACTIVITY) (Part of speech: noun)

5) If a machine or piece of equipment works, it is not broken. - Additional information: work (OPERATE) (Part of speech: verb)

6) when you use physical or mental effort to do something - Additional information: work (EFFORT) (Part of speech: noun)

7) If something works, it is effective or successful. - Additional information: work (SUCCEED) (Part of speech: verb)

8) to exercise in order to improve the strength or appearance of your body - Additional information: work out (EXERCISE) (Part of speech: verb)

9) a painting, book, piece of music, etc. - Additional information: work (CREATION) (Part of speech: noun)

10) to try hard to achieve something - Additional information: work at sth (Part of speech: verb)

11) to spend time repairing or improving something - Additional information: work on sth (Part of speech: verb)

12) to do a calculation to get an answer to a mathematical question - Additional information: work sth out or work out sth (Part of speech: verb)

13) If a problem or a complicated situation works out, it ends in a success-

ful way. - Additional information: work out (BECOME BETTER) (Part of speech: verb)

14) to know how to use a machine or piece of equipment - Additional information: can work sth; know how to work sth (Part of speech: verb)

15) to understand something or to find the answer to something by thinking about it - Additional information: work sth out or work out sth (UNDERSTAND) (Part of speech: verb)

16) None of the other options

D Appendix D: Other results

Table 9 reports the breakdown by word-level CEFR level in terms of F_1 score. For ambiguous cases, the PoS-based model performs reasonably well only at the A1 level. However, this result is partly influenced by the rule we set, i.e., assigning the lowest available CEFR level when multiple options are present (see Section 4.2), which inherently favours lower-level classifications. For both the N/A and C2 levels, the model yields an F_1 score of 0, highlighting its complete inability to handle these cases. For non-ambiguous cases, the PoS-based achieves the best performance on all the CEFR levels for the reasons explained in Section 4.5, with the exception of the C2 level. For this specific CEFR level, the PoS-based model obtains a high Recall (99.28%) but a low Precision (73.02%), while Qwen shows more balanced results, with a Recall of 90.65% and a Precision of 89.36%.

	Ambiguous		Non-ambiguous		All	
	Qwen 2.5 32B	PoS	Qwen 2.5 32B	PoS	Qwen 2.5 32B	PoS
N/A	50.0	0.0	94.3	94.4	92.0	91.6
A1	84.4	83.1	91.3	94.0	86.5	85.8
A2	82.1	67.4	89.8	91.8	85.1	75.6
B1	80.6	56.7	94.3	95.1	85.7	72.9
B2	78.5	49.3	90.5	90.8	84.2	72.0
C1	75.5	20.0	91.9	92.3	82.9	61.5
C2	67.2	0.0	90.0	84.2	78.9	59.7

Advancing Question Generation with Joint Narrative and Difficulty Control

Bernardo Leite and Henrique Lopes Cardoso
LIACC, Faculdade de Engenharia, Universidade do Porto
Rua Dr. Roberto Frias, 4200-465 Porto, Portugal
{bernardo.leite, hlc}@fe.up.pt

Abstract

Question Generation (QG), the task of automatically generating questions from a source input, has seen significant progress in recent years. Difficulty-controllable QG (DCQG) enables control over the difficulty level of generated questions while considering the learner’s ability. Additionally, narrative-controllable QG (NCQG) allows control over the narrative aspects embedded in the questions. However, research in QG lacks a focus on combining these two types of control, which is important for generating questions tailored to educational purposes. To address this gap, we propose a strategy for Joint Narrative and Difficulty Control, enabling *simultaneous* control over these two attributes in the generation of reading comprehension questions. Our evaluation provides preliminary evidence that this approach is feasible, though it is not effective across all instances. Our findings highlight the conditions under which the strategy performs well and discuss the trade-offs associated with its application.

1 Introduction

Question Generation (QG) focuses on the automated generation of coherent and meaningful questions targeting a data source, including unstructured text or knowledge bases (Rus et al., 2008). Controllable QG plays a crucial role in education (Kurdi et al., 2020), as it facilitates the generation of personalized questions that address the unique needs and learning goals of students. Recent work on QG utilized techniques such as fine-tuning (Zhang et al., 2021; Ushio et al., 2022) and few-shot prompting (Wang et al., 2022b; Chen et al., 2024) to generate questions based on a source text and, optionally, a target answer. In controllable QG, this process is augmented by incorporating controllability labels into the input or prompt to guide the generation process. Specifically, research on Narrative-Controlled

Passage: Once there were a hare and a turtle. The hare was proud of his speed and challenged the turtle to a race. Although the turtle was slow, he accepted. The hare quickly left the turtle behind but decided to rest and fell asleep. Meanwhile, the turtle kept going steadily and eventually reached the finish line first, winning the race.

Narrative: “character” **Difficulty:** “easy”
Generated QA Pair: Who challenged the turtle to a race? The hare.

Narrative: “outcome” **Difficulty:** “medium”
Generated QA Pair: What happened after the hare left the turtle behind? Decided to rest and fell asleep.

Narrative: “outcome” **Difficulty:** “hard”
Generated QA Pair: What happened because the turtle kept going steadily? The turtle won the race.

Figure 1: Illustrative example of controlled question-answer generation with varying difficulty levels and narrative attributes.

Question Generation (NCQG) focuses on controlling the **content** of generated questions, guided by underlying narrative elements (e.g., causal relationship) (Zhao et al., 2022; Leite and Lopes Cardoso, 2023; Li and Zhang, 2024). In turn, Difficulty-Controllable Question Generation (DCQG) emphasizes controlling the expected difficulty in answering the questions (Gao et al., 2019; Kumar et al., 2019; Cheng et al., 2021; Bi et al., 2021). Some studies have considered the relationship between question **difficulty** and the **learner’s ability** (Uto et al., 2023; Tomikawa and Uto, 2024).

However, research in controllable QG lacks the combination of these two types of control, which is especially important to facilitate human control (Wang et al., 2022a) in the ever-increasing usage of generative models in this field. Therefore, this research proposes a strategy that explores the feasibility of joining narrative and difficulty control to generate reading comprehension question-answer

(QA) pairs from children-targeted narrative stories. Figure 1 shows an example of the strategy. Formally, we investigate the following research question (RQ): *How effectively can we control the generation of question-answer pairs conditioned on both narrative and difficulty attributes using a modest¹ scale model?*

For our experiments, we use a well-known dataset — FairyTaleQA (Xu et al., 2022) — in which each question is already annotated with one of seven narrative labels. Our method involves two main steps: (1) using simulated-learner QA systems to answer questions from FairyTaleQA, thereby estimating the difficulty labels via Item Response Theory, and (2) applying a joint narrative and difficulty control model, utilizing human-annotated narrative labels and the estimated difficulty labels for each question.

The proposed method is evaluated to determine whether both NCQG and DCQG have been successfully applied to the generated questions. For NCQG, we compare the similarity between human-authored and generated questions. For DCQG, we assess the performance of simulated-learner QA systems on questions generated with distinct difficulty levels. Although the results demonstrate the effectiveness of the strategy, NCQG shows consistent success, whereas DCQG exhibits moderate success, with performance varying across specific narrative attributes and difficulty levels. Our goal is to highlight the conditions under which the strategy performs with high or low efficacy, providing insights for researchers pursuing similar research lines. In summary, our contributions are:

- We propose a joint strategy for controlling the generation of question-answer pairs conditioned on narrative and difficulty attributes.
- We report on the linguistic features influenced by control and conduct an error analysis of the generated QA pairs, providing insights into the performance and limitations of the method.

2 Background and Related Work

2.1 Controllable Question Generation (CQG)

As stated by Li and Zhang (2024), prior research on CQG has explored two main perspectives: content (or type) and difficulty.

Content control relates to the linguistic elements incorporated into the generated questions. For instance, Ghanem et al. (2022) proposed controlling specific reading comprehension skills, such as figurative language and vocabulary. Additionally, Zhao et al. (2022) focused on controlling narrative elements, while Leite and Lopes Cardoso (2023) extended this approach by controlling explicitness attributes. Elkins et al. (2023) propose to control Bloom’s question taxonomy (Krathwohl, 2002).

Difficulty control is related to the challenge of answering the generated questions, a concept that is often subjective (i.e., difficulty can vary depending on the respondent). In this regard, Gao et al. (2019) assigned difficulty labels (easy or hard) to questions based on whether QA systems could answer them correctly and used these labels as inputs to control the generation process. Kumar et al. (2019) proposed estimating difficulty based on named entity popularity, while Bi et al. (2021) tackle the challenge of high diversity in QG. Furthermore, Cheng et al. (2021) controlled question difficulty by considering the number of inference steps required to arrive at an answer.

One limitation of previous approaches is (1) the lack of emphasis on the relationship between question difficulty and learner ability. Addressing this problem, Uto et al. (2023) proposed to use Item Response Theory (IRT) (Lord, 2012), a mathematical framework in test theory, to quantify question difficulty and directly relate it to learner ability. Another limitation is (2) the lack of integration of multiple attributes. While Li and Zhang (2024) combine both narrative and difficulty attributes, they define *difficulty* in terms of answer explicitness and the number of sentences needed to answer the questions. The novelty of this study lies in integrating content control, through narrative elements, with difficulty control *informed by simulated learners’ ability*, thus building on the foundations laid by previous research.

2.2 Item Response Theory (IRT)

IRT (Lord, 2012) is a statistical framework used to study the interaction between test-takers (ability or proficiency) and their performance on test items. A key aspect of IRT is to model the relationship between question difficulty and learner ability, offering insights into how well a question differentiates between individuals with varying levels of skill. This relationship allows for an estimation of

¹<1 billion of parameters.

the likelihood that a learner with a specific ability level can correctly answer a given question, making it particularly useful for adaptive testing and understanding question complexity. A commonly used model in IRT is the **Rasch model**, which assumes that the probability of a correct response depends on the relation between learner ability (θ) and the item’s difficulty (b):

$$P(X_{ij} = 1 \mid \theta_i, b_j) = \frac{e^{\theta_i - b_j}}{1 + e^{\theta_i - b_j}}, \quad (1)$$

where θ_i is the learner ability of individual i , b_j is the difficulty of item j , and $P(X_{ij} = 1 \mid \theta_i, b_j)$ is the probability that individual i correctly answers item j . In our study, we use IRT to estimate both question difficulty (b) and learner ability (θ) parameters.

2.3 FairyTaleQA: Purpose and Value

We use the FairyTaleQA dataset (Xu et al., 2022) because its stories and corresponding question-answer pairs align with the goal of addressing *narrative comprehension*. According to Xu et al. (2022), narrative comprehension represents a high-level cognitive skill closely linked to overall reading proficiency (Lynch et al., 2008). A key feature of FairyTaleQA is the expert annotations on each question, which are grounded in evidence-based frameworks (Paris and Paris, 2003; Alonzo et al., 2009). The annotated narrative elements targeted for control are:

- **Character:** Addresses identities or traits of story characters (e.g., “Who...?”);
- **Setting:** Focusing on the time and place of events, often starting with “Where...?” or “When...?”;
- **Action:** Related to the actions of characters;
- **Feeling:** Exploring emotional states or reactions (e.g., “How did/does X feel?”);
- **Causal relationship:** Addressing cause-and-effect (e.g., “Why...?” or “What caused/made X?”);
- **Outcome resolution:** Focusing on the outcomes of events (e.g., “What happened/happens after X?”);
- **Prediction:** Questions about future or unknown events based on textual evidence.

While there are other popular educational QA datasets (following the open-ended *wh*-questions format), such as NarrativeQA (Kočíský et al., 2018) and StoryQA (Zhao et al., 2023), they are not annotated with specific reading comprehension skills. This further motivated our decision to use FairyTaleQA in this study.

3 Method

This section outlines the methodology of this research, which includes augmenting FairyTaleQA with IRT-based difficulty labels and developing a question-answer pair generation model with joint narrative and difficulty control. Figure 2 provides an overview of the steps discussed in this section.

3.1 Augmenting FairyTaleQA With IRT-Based Question Difficulty Labels

Let D be our dataset consisting of instances represented as quartets:

$$D_i = (t, q, a, n), \quad (2)$$

where t is a text, q is the question, a is the answer about the text, and n is the narrative element associated with the question-answer pair (q, a). The aim is to create a fifth element d , resulting in a new instance augmented:

$$D_{i\text{-augmented}} = (t, q, a, n, d), \quad (3)$$

where d is the estimated difficulty value associated with the question-answer pair (q, a). To create these augmented instances, we used the method proposed by Uto et al. (2023) and Tomikawa et al. (2024):

1. **Collecting response data for each question-answer pair:** We collected answers to the questions from multiple respondents. Given the unavailability of real students, we utilized simulated-learner QA systems, which are models capable of automatically extracting answers to the posed questions. As explained in Section 4.2, the QA models were deliberately chosen to represent different levels of performance to simulate varying ability levels.
2. **Estimating Question Difficulty with IRT:** Using the answers collected from the simulated-learner QA systems, we estimated the difficulty of each question using IRT, specifically employing the Rasch model as described in Section 2.2.

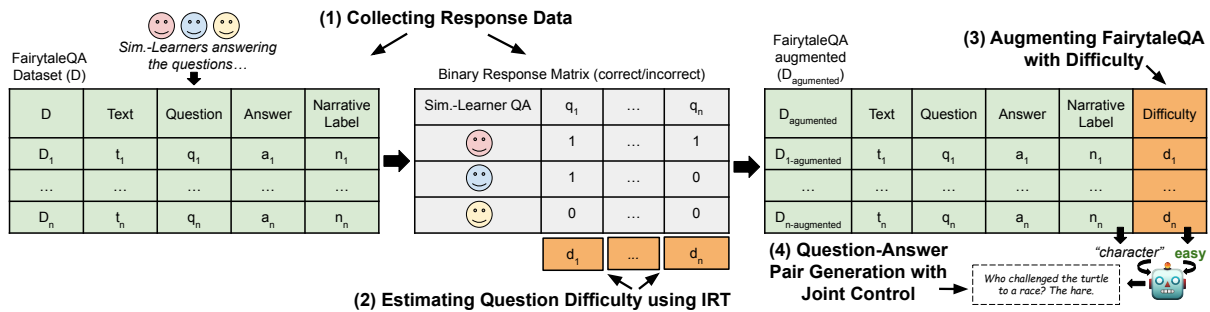

Figure 2: Overall methodology for joint narrative and difficulty control.

3. **Augmenting FairytaleQA with difficulty estimates:** Based on the estimated difficulty values, we augment each instance of the dataset with d , resulting in $D_{i\text{-augmented}} = (t, q, a, n, d)$.

3.2 Question-Answer Pair Generation with Joint Narrative and Difficulty Control

The controllable process can be represented as follows: given an instruction prompt p , the aim is to use a model M to generate a question-answer pair $(q_{\text{new}}, a_{\text{new}})$. This can be formulated as:

$$(q_{\text{new}}, a_{\text{new}}) = M(p), \quad (4)$$

where prompt p incorporates the desired narrative label n , difficulty value d , and target text t . The prompt follows this template:

“Generate a $\langle d \rangle$ question-answer pair about narrative label $\langle n \rangle$ considering the following text: $\langle t \rangle$ ”

M is an encoder-decoder model that is fine-tuned using $D_{i\text{-augmented}} = (t, q, a, n, d)$ instances. The encoder receives prompt p and encodes it into a fixed-length representation known as a context vector. The decoder takes the context vector and generates the output text $(q_{\text{new}}, a_{\text{new}})$, using special tokens $\langle \text{QU} \rangle$ and $\langle \text{AN} \rangle$ that serve to differentiate between q_{new} and a_{new} . The idea is to guide the model in generating a question-answer pair of the intended difficulty d and narrative element n .

4 Experimental Setup

4.1 Preparing the FairytaleQA Dataset

We use FairytaleQA (Xu et al., 2022), which comprises 10,580 question-answer pairs manually created by educational experts based on 278 narrative stories. Each story contains approximately 15 section texts, and each section (about 149 tokens) contains approximately 3 question-answer pairs. From

the original dataset, we have prepared different data setups² for generating a QA pair:

- **Text** \rightarrow **QA**: This setup only contains the text as input, so it serves as a baseline to compare with the subsequent setups, which consider control attributes.
- **Nar + Text** \rightarrow **QA**: This setup considers *narrative* as a control attribute in the input.
- **Dif + Text** \rightarrow **QA**: This setup considers *difficulty* as a control attribute in the input.
- **Nar + Dif + Text** \rightarrow **QA**: This setup considers both the narrative and difficulty attributes.

4.2 Creating Simulated-Learner QA Systems

To create the simulated-learner QA systems, we trained five QA models. The choice of five was made empirically: it provided sufficient granularity for analysis while avoiding ties that could arise with fewer levels (e.g., four). The selected encoder models are DeBERTaV3 (He et al., 2021), RoBERTa (Liu, 2019), BERT (Devlin et al., 2019) and DistilBERT (Sanh, 2019). We also use one decoder: GPT-2 (Radford et al., 2019). They were fine-tuned on separate general-purpose question answering data (the SQuAD v1.1 dataset (Rajpurkar et al., 2016)). The models were deliberately chosen for their varying performance levels, thereby simulating different levels of learner skill. Table 1 shows the performance of each QA system on the SQuAD v1.1 evaluation set, using the n -gram similarity metric ROUGE_L-F1 (Lin, 2004) (QA answer vs. SQuAD ground-truth answer).

²The arrow separates the input (left) and output (right) information. On the left part, the + symbol illustrates whether the method incorporates control attributes.

Table 1: Simulated-Learner QA systems performance on SQuAD v1.1 evaluation set.

Sim.-Learner QA	ROUGE _L -F1 (0-1)
DeBERTaV3 (large)	0.87
RoBERTa (base)	0.82
BERT (base)	0.75
DistilBERT (base)	0.69
GPT-2	0.46

4.3 Answering FairytaleQA Questions with QA Systems

For each question in the train and validation sets of the FairytaleQA dataset, all five simulated-learner QA systems generated their own answers. Each QA answer is then compared to the corresponding ground-truth answer to determine correctness. We considered an answer correct if it achieved either an exact match score of 1 or a ROUGE_L-F1 score of at least 0.5. The QA answers are organized into a binary response matrix — Figure 2 shows an example of such a matrix. Each row corresponds to a simulated-learner QA system and each column corresponds to a question ID. Each cell contains a 0 or 1, indicating incorrect or correct answers, respectively. This matrix serves as input data for the subsequent question difficulty estimation using IRT.

4.4 Estimating Question Difficulty with IRT

Based on the collected correct and incorrect answers for each question — organized into a binary response matrix — we estimated question difficulty using the Rasch Model (recall Section 2.2). Specifically, using the binary correctness data produced by the simulated-learner QA systems, the estimation is performed using the Expectation-Maximization (EM) algorithm (Embretson and Reise, 2000). This yielded difficulty values that were subsequently normalized to a 0-1 scale (0, 0.28, 0.50, 0.72, and 1), where higher values represent more difficult questions. The numerical values were converted into corresponding categorical labels – *easy*, *medium*, *moderate*, *hard*, and *extreme* – to be used in textual prompts. The distribution of the estimated difficulty values by narrative label in the data is presented in Table 2. Some attributes (e.g., *feeling* and *prediction*) have limited representation in the dataset.

Additionally, using the Maximum a Posteriori

We use *mirt*³ tool for IRT, including all estimations.

4.5 Creating a Question-Answer Pair Generation Model

We use the FLan-T5 (Chung et al., 2024) encoder-decoder model for the controllable task. This model builds upon the original T5 (Raffel et al., 2020), which has been fine-tuned with task-specific instructions using prefixes, making it well-suited for our methodology. Additionally, FLan-T5

³<https://cran.r-project.org/web/packages/mirt/index.html>

demonstrates remarkable performance in text generation tasks, particularly in QG (Chen et al., 2024; Li and Zhang, 2024). We employ the `flan-t5-large` version, which is publicly available via Hugging Face⁴. Training is conducted for up to 10 epochs, with early stopping implemented using a patience of 2 epochs. During inference, we apply Top-k sampling with $k = 50$, $p = 0.9$ and $temp = 1.2$ to encourage diversity (values obtained experimentally). We initially explored beam search, a widely used technique in QG; however, we observed that it frequently produced repetitive questions when tasked with generating questions for the same narrative element across different difficulty levels.

4.6 Generating QA Pairs for Evaluation

We fine-tune the `Flan-T5` model on the training set of `FairyTaleQA`. We obtain 4 models, as the model has been trained on each of the 4 data setups described in Section 4.1. For the 2 setups where difficulty labels are used, we apply the resulting models (inference) to the corresponding test set and generate 5 QA pairs for each text’s section — one QA pair for each difficulty label. Since the `FairyTaleQA` test set contains 394 section texts, we obtain a total of 1,970 generated QA pairs. Additionally, each text includes human-authored QA pairs associated with different narrative labels. This approach ensures that the generated QA pairs are balanced across distinct difficulty levels and narrative elements for further evaluation.

5 Evaluation

5.1 Evaluation Procedure

For NCQG, our evaluation protocol follows prior studies (Zhao et al., 2022; Leite and Lopes Cardoso, 2023, 2024) that focused on controlled generation using narrative labels. For DCQG, the evaluation protocol is based on recent works (Uto et al., 2023; Tomikawa et al., 2024; Tomikawa and Uto, 2024) that emphasize the use of simulated-learner QA systems across generated questions with distinct difficulty levels.

Narrative Control: To assess narrative control, we use a standard approach in QG: comparing generated questions directly with human-authored ground-truth questions. Hypothesis 1 (H1) is that *incorporating narrative attributes will result in generated questions that are more similar to the*

⁴<https://huggingface.co/google/flan-t5-large>

ground-truth, as previously shown by Leite and Lopes Cardoso (2024). To quantify the similarity, we employ the n -gram similarity metric `ROUGEL-F1` (Lin, 2004), as originally adopted by the `FairyTaleQA` authors. For a better perception of the idea, consider the human-authored ground-truth question: “What did Matte and Maie do on Saturdays?” (annotated with the *action* narrative element) and the generated question targeting the same narrative element: “What did Maie and Matte do to provide for themselves?”. These questions yield a high `ROUGEL-F1` score because they are similar in terms of the narrative-related vocabulary they share, thus indicating successful narrative control.

Difficulty Control: For difficulty control, the evaluation focuses on analyzing the performance of simulated-learner QA systems when answering questions generated at varying difficulty levels. Hypothesis 2 (H2) posits that *simulated-learner QA systems will perform better on easier questions and worse on more difficult ones, relative to their ability levels*.

5.2 Results

Narrative Control: Table 4 presents the results from the narrative control perspective, measured using `ROUGEL-F1` n -gram similarity between the generated questions and the human-authored ground-truth questions. We observe an improvement in the similarity to ground-truth questions when narrative control attributes are incorporated. This trend is consistently observed across all seven narrative labels. Furthermore, these findings align with the results reported in prior studies on narrative control (Leite and Lopes Cardoso, 2023, 2024). Of novelty, when narrative and difficulty labels are fused, we observe a similar improvement trend, comparable to the incorporation of narrative attributes alone. These results support Hypothesis 1 (H1), indicating that our method effectively controls the narrative elements underlying the generated questions. Appendix A shows further support by reporting semantic similarity results.

Difficulty Control: Figure 3 presents the results for difficulty control only, showing the percentage of correct responses from the simulated-learner QA systems across all difficulty levels. The percentage of correct answers decreases as the difficulty level increases for all simulated learners⁵. Additionally,

⁵All percentages are relatively low (<60). This is because the QA models were not trained on the `FairyTaleQA` dataset but were instead trained on `SQuAD`. This intentional choice

Data Setup	Char.	Setting	Action	Feeling	Causal	Out.	Pred.
Text \rightarrow QA	.227	.269	.287	.281	.271	.227	.251
Nar + Text \rightarrow QA	.304	.537	.427	.527	.412	.458	.348
Nar + Dif + Text \rightarrow QA	.305	.530	.412	.529	.405	.425	.365

Table 4: **Narrative Control:** Similarity (ROUGE_L-F1) between generated and ground-truth questions on the test set by narrative element. **Text \rightarrow QA** is used as a baseline to assess whether narrative control helps the generated questions approximate the ground-truth questions.

learners with higher abilities achieve higher percentages of correct answers, while those with lower abilities achieve lower percentages. These findings are consistent with previous works (Uto et al., 2023; Tomikawa et al., 2024) and support Hypothesis 2 (H2), demonstrating that the method controls the difficulty levels of the generated questions.

Figure 3: Percentage (%) of correct answers by difficulty level when only difficulty control labels are used (**Dif + Text \rightarrow QA**).

Figure 4: Percentage (%) of correct answers by difficulty level when both difficulty and narrative control labels are used (**Nar + Dif + Text \rightarrow QA**).

ensures that the models’ knowledge remains unbiased with respect to FairyTaleQA content.

Joint Narrative and Difficulty Control: Figure 4 presents the results for difficulty control when difficulty and narrative attributes are fused. In most cases, the percentage of correct answers decreases as the difficulty level increases across all simulated learners. These findings demonstrate that even when conditioning the generation process on both narrative content and difficulty, it remains possible to perform difficulty control. However, some inconsistencies are observed: for DeBERTaV3, there is no distinction between medium and moderate difficulty levels; for RoBERTa, the percentage of correct answers increases between medium and moderate levels; and for GPT-2, a similar trend occurs between moderate and hard levels. For an overall graphical comparison of difficulty control using only difficulty versus combining difficulty and narrative attributes, see Appendix B.

Figure 5 shows the overall accuracy for each narrative label, with trends suggesting difficulty control particularly between easy, hard, and extreme levels. However, control becomes inconsistent at intermediate levels. Among the attributes, *causal* and *outcome* demonstrate the most consistent control across difficulty levels, while *prediction* and *feeling* exhibit the least success. This inconsistency can be related to the limited representation of these attributes in the FairyTaleQA dataset (recall Table 2), which prevents the model from learning to generate questions across different difficulty levels. Additionally, questions tied to these attributes are inherently more challenging, as reflected in the lower global performance of simulated-learner QA systems. For attributes such as *character*, *prediction*, *action*, and *setting*, the confusion is particularly evident between medium and moderate levels. To address this, we experimented with an alternative model trained on a lower granularity of difficulty levels, combining medium, moderate, and hard into a single medium level. In Figure 6, we show the result of this experiment, which demonstrates more consistent control across all levels.

Figure 5: Percentage (%) of correct answers per narrative element and difficulty level (5 levels).

Figure 6: Percentage (%) of correct answers per narrative element and difficulty level (3 levels).

However, the *character* and *prediction* attributes continue to reveal some difficulty in distinguishing levels. These results support Hypothesis 2 (H2), confirming that the joint method enables difficulty control, although with less consistency than when controlling for difficulty alone. In Section 6, we outline potential explanations for these results.

Linguistic Features Influenced By Control: To better understand the linguistic features influenced by the controllability method, we analyze the linguistic properties of the generated QA pairs across different difficulty levels and narrative attributes. Prior work on difficulty-only controlled generation (Tomikawa et al., 2024) identifies two key factors that distinguish difficulty levels: (1) the average number of words in the generated answers, and (2) the distribution of initial interrogative terms in the generated questions. While we also explore these features (see Appendix C), we emphasize here a novel aspect that we also found experimentally to be relevant: (3) the degree of lexical novelty in the generated QA pairs relative to the source

narrative text. To quantify this, we use the PINC (Paraphrase In N-gram Changes) metric (Chen and Dolan, 2011), which computes the percentage of n -grams present in the generated QA pairs but not in the source text. Higher PINC scores indicate greater lexical novelty and diversity. The results in Table 5 show that the diversity of the QA pairs increases with higher difficulty levels. This trend is observed both when difficulty labels are used independently and when combined with narrative labels. Therefore, we conclude that the linguistic diversity between the generated QA pairs and the source text is a feature influenced by difficulty control, regardless of whether difficulty labels are used alone or in conjunction with narrative labels.

Data Setup		Easy	Med.	Extr.
Dif + Text	Q	55.60	60.23	63.94
	→ QA	A 9.88	23.17	48.69
Nar + Dif + Text	Q	57.34	60.72	65.57
	→ QA	A 22.02	26.00	41.14

Table 5: PINC values (%) considering 3-gram novelty for generated questions (Q) and answers (A).

Error Analysis of Generated QA Pairs: We randomly selected 100 generated QA pairs and analyzed potential problems. Two main issues were identified, as shown in Figure 7: (1) *hallucinated content* (14%) and (2) *nonsensical QA pairs* (10%).

In the first example (1), the generated QA pair introduces made-up terms that do not exist in the source text. This is the most frequent problem encountered, likely due to the nature of the inference method (Top-k sampling). In example 2a, the problem is that the generated QA pair is misleading. In Example 2b, the question seeks a motivation not in the text, and the vague answer just reuses the question’s wording without adding meaning.

6 Discussion

We revisit our research question (RQ): *How effectively can we control the generation of question-answer pairs conditioned on both narrative and difficulty attributes using a modest scale model?*

Our findings indicate that the model effectively controls narrative elements, whether alone or combined with difficulty attributes. It also shows effective difficulty control when conditioned solely on difficulty attributes. The joint model, which combines narrative and difficulty attributes, generally achieves consistent control for at least three levels

<p>Example 1 (hallucinated content):</p> <p>Text: And then he cried for the third time: “Old Hoggiant!” And there appeared a fellow of truly horrible size, with a scythe as large as a ship’s mast.</p> <p>Gen. Q: Who appeared to the hunter at the swan?</p> <p>Gen. A: A fellow of truly horrible size, with a scythe as large as a ship’s mast.</p> <p>Explanation: There is no mention of any hunter or swan in the source text.</p>
<p>Example 2a (nonsensical QA pairs):</p> <p>Text: When the old man had finished his dance, the big demon said: “Thank you very much for your amusing dance. Now give us the pleasure of drinking a cup of wine with us,” and with these words he handed him his largest wine-cup.</p> <p>Gen. Q: What did the old man do after he finished dancing?</p> <p>Gen. A: Danced with the big demon.</p> <p>Explanation: The old man had finished dancing and did not dance with anyone again.</p>
<p>Example 2b (nonsensical QA pairs):</p> <p>Text: But the rich neighbor wanted the meadow for himself alone, and told the poor one that he would drive him out of house and home if he did not come to an agreement with him that whichever one of them mowed the largest stretch of the meadowland in a single day, should receive the entire meadow.</p> <p>Gen. Q: Why did the neighbor want to own the meadow?</p> <p>Gen. A: He wanted to have the meadow.</p> <p>Explanation: The question contains the answer.</p>

Figure 7: Examples of problematic generated question-answer pairs (error analysis).

(easy, hard, and extreme). However, inconsistencies arise in the intermediate levels (medium and moderate). We also observed that certain attributes are more conducive to effective control, while others, like *prediction* and *feeling*, are less effective. Notably, reducing the granularity of difficulty levels improves the overall control. We now delve into two main factors that underlie our findings.

First, *generating QA pairs while simultaneously controlling both difficulty and narrative attributes is an inherently challenging task*. When the narrative element is fixed, the space of plausible questions becomes more constrained. This makes it harder to vary difficulty meaningfully, as the questions tend to focus on similar content. For instance, in Figure 1, the last two questions share the same narrative element but differ in difficulty. This overlap in content makes it harder to generate questions with clearly distinct difficulty levels.

Second, *some narrative attributes naturally lead to easier questions*. For instance, the *character* attribute often involves straightforward “Who” questions, making it harder to create questions with distinct difficulty levels. In contrast, questions following the *prediction* attribute are demanding, adding

complexity to the learning process of generating well-differentiated questions.

Transferability to other domains: While our current work focuses on narrative comprehension, the principles of controllable QG are not domain-specific. For instance, it would be feasible to control generation based on other reading comprehension skills, as explored by Ghanem et al. (2022). Progress in this direction depends on the availability of datasets annotated with these dimensions, which are scarce.

Relevance to education: We believe our findings hold promise for educational applications, particularly in personalized QG. Recent work has explored adapting QG to student ability (Tomikawa et al., 2024). We argue that incorporating narrative control adds another valuable layer to personalization, enabling more targeted and contextually rich QG.

7 Conclusions

This work investigates a strategy for controlling both narrative and difficulty attributes in generated QA pairs. The results offer a preliminary yet promising demonstration of the potential of QG models and the proposed control strategy. Future efforts could leverage larger datasets with a more balanced distribution of questions across categories to improve the model’s control capabilities. Additionally, examining the impact of different inference methods on generation would be valuable, especially to address the issue of repetitive outputs observed with beam search. Finally, future research could explore few-shot prompting techniques, providing minimal examples to assess the model’s control ability without extensive training.

Limitations

While our approach provides promising insights into controllable QG, some limitations should be acknowledged.

First, *the limited representation of question categories across narrative attributes and difficulty levels hinders the model’s ability to learn effectively*. FairytaleQA consists of approximately 10k instances. Associating questions with multiple narrative elements and difficulty levels significantly reduces the number of examples per category, limiting the model’s ability to learn effectively. For instance, as shown previously in Table 2, *prediction* and *feeling* questions are poorly represented.

Second, *top-k sampling enables control over narrative elements and question difficulty but can lead to undesired hallucinations*. Initially, we experimented with beam search — a more commonly used technique for QG — but found it often generated repetitive questions when addressing the same narrative element across varying difficulty levels. Moreover, our findings indicate that the choice of inference method significantly impacts control. For instance, as shown in Section 5.2, the diversity of the generated QA pairs increases at higher difficulty levels. However, this diversity can also produce unintended side effects, such as the hallucinations noted with error analysis. While hallucinated QA pairs may affect evaluation by inflating perceived difficulty, we believe that reporting such cases was important to reveal potential failure modes of controllable QG systems. Although they may add some noise, these observations help contextualize the results and guide future improvements in model robustness.

Third, the *evaluation relies on simulated learner responses rather than real student data*. While this approach offers scalability and approximations of question difficulty, it may not fully reflect how actual students would respond. Nonetheless, it provides a valuable proxy for assessing the model’s behavior, and we believe it still offers meaningful insight into the controllability of QG systems. Future work should explore incorporating real student data to further validate these findings.

Ethics Statement

This research involves the automatic generation of QA pairs from narrative texts, incorporating control attributes such as difficulty level and narrative elements. The dataset used, FairytaleQA, consists of human-authored QA pairs from publicly available fairy tales. No personally identifiable or sensitive information is included, ensuring compliance with ethical guidelines for data usage. The generated QA pairs were evaluated using both automatic metrics and manual inspection to identify potential errors, such as hallucinated content and nonsensical questions. We acknowledge that these models may introduce unintended errors or biases. While this paper does not focus on error mitigation, future work could explore extended human-in-the-loop validation to enhance the reliability of generated QA pairs, particularly in deployment scenarios.

Acknowledgments

The authors would like to thank Professor Masaki Uto and Yuto Tomikawa for their helpful clarifications and discussions related to prior work. This work was financially supported by UID/00027 – the Artificial Intelligence and Computer Science Laboratory (LIACC), funded by Fundação para a Ciência e a Tecnologia, I.P./ MCTES through national funds. Bernardo Leite is supported by a PhD studentship (with reference 2021.05432.BD), funded by FCT.

A Narrative Control: Semantic Similarity

Table 6 presents the results from the narrative control perspective, measured using BLEURT (Sellam et al., 2020). The goal is to show an improvement in semantic similarity to ground-truth questions when narrative control attributes are incorporated. As observed with ROUGE_L-F1 similarity (recall Section 5.2), this trend is observed across all seven narrative labels. When narrative and difficulty labels are fused, we observe a similar improvement trend, comparable to the incorporation of narrative attributes alone. These results further support Hypothesis 1 (H1) — *incorporating narrative attributes will result in generated questions that are more similar to the ground-truth* — indicating that our method controls the narrative elements underlying the generated questions.

B Difficulty-Only vs. Difficulty+Narrative Control

To compare difficulty control when operating solely on difficulty versus combining difficulty and narrative attributes, Figure 8 provides an overview of the performance at each level for both setups. Both setups show the expected trend: the percentage of correct answers decreases as difficulty increases. However, a linear approximation of the observed data points reveals that the decrease is less pronounced when both attributes are combined, though it remains consistent overall.

Data Setup	Char.	Setting	Action	Feeling	Causal	Out.	Pred.
Text → QA	.332	.332	.353	.370	.360	.346	.358
Nar + Text → QA	.379	.504	.422	.491	.418	.444	.409
Nar + Dif + Text → QA	.378	.482	.413	.499	.417	.422	.401

Table 6: **Narrative Control**: Semantic similarity (BLEURT) between generated and ground-truth questions on the test set by narrative element. **Text** → **QA** is used as a baseline to assess whether narrative control helps the generated questions approximate the ground-truth questions.

Figure 8: Percentage of Correct Answers by Dif. Level.

C Additional Linguistic Features Influenced By Control

Table 7 presents the average number of words in the generated question-answer pairs. For generated answers, when only difficulty labels are incorporated, no significant trend is observed. For generated questions, an upward trend is noted, though it is not significant. When narrative and difficulty labels are combined, no trend is observed. Based on these findings, we conclude that the average length of generated question-answer pairs is not influenced by difficulty or narrative control labels in our experiments.

Data Setup		Easy	Med.	Extr.
Dif + Text	Q	10.80	11.83	12.49
	A	7.19	8.95	8.88
Nar + Dif + Text	Q	11.81	11.62	11.70
	A	7.42	7.96	7.61

Table 7: Average number of words for generated questions (Q) and answers (A).

Figure 9 illustrates the proportion of initial interrogative terms in the generated questions. When only difficulty labels are used (top chart), higher difficulty levels show an increase in terms like “why” and “how” and a decrease in terms like

“what” “who” and “where”. This aligns with expectations, as “why” and “how” are often linked to questions requiring higher cognitive effort, as described in Bloom’s taxonomy (Krathwohl, 2002). When both narrative and difficulty labels are fused (lower chart), the proportion of all interrogative terms is more consistent across difficulty levels. This outcome is expected since this setup aims to control difficulty levels while also demanding for certain narrative elements. In this case, narrative labels are the primary influence for the choice of interrogative terms (e.g., “who” for character-related questions), rather than difficulty labels.

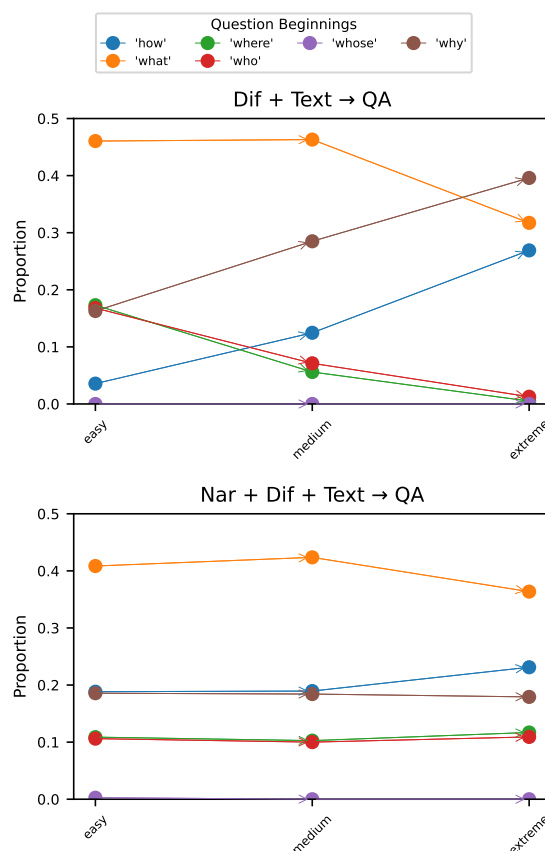

Figure 9: Proportion of initial interrogative terms in the generated questions (arrowed lines indicate increase/decrease trends).

Down the Cascades of Omethi: Hierarchical Automatic Scoring in Large-Scale Assessments

Abstract

We present the framework Omethi, which is aimed at scoring short text responses in a semi-automatic fashion, particularly fit to international large-scale assessments. We evaluate its effectiveness for the massively multilingual PISA tests. Responses are passed through a conditional flow of hierarchically combined scoring components to assign a score. Once a score is assigned, hierarchically lower components are discarded. Models implemented in this study ranged from lexical matching of normalized texts—with excellent accuracy but weak generalizability—to fine-tuned large language models—with lower accuracy but high generalizability. If not scored by any automatic component, responses are passed on to manual scoring. The paper is the first to provide an evaluation of automatic scoring on multilingual PISA data in eleven languages (including Arabic, Finnish, Hebrew, and Kazakh) from three domains ($n = 3.8$ million responses). On average, results show a manual effort reduction of 71 percent alongside an agreement of $\kappa = .957$, when including manual scoring, and $\kappa = .804$ for only the automatically scored responses. The evaluation underscores the framework's effective adaptivity and operational feasibility with its shares of used components varying substantially across domains and languages while maintaining homogeneously high accuracy.

1 Introduction

A river adapts its flow to diverse exterior conditions, by meandering, or alternating its velocity and depth, to reach its target inevitably and naturally. In this paper, we propose the hierarchical, response-adaptive framework *Omethi* for automatically scoring short text responses from assessments. The proposed framework is named after the Omethi River, for it is similarly responsive by combining modern and baseline scoring methodology adaptively at the response level, while contending

with diverse languages and multiple assessment domains in an operational setting and distinct quality requirements. Large-scale assessments, especially international ones (e.g., PISA, the *Programme for International Student Assessment*; OECD, 2023), pose diverse conditions to automatic scoring (Zesch et al., 2023), similar to the varied surroundings a river is exposed to. In turn, automatic scoring encompasses a range of approaches with particular strengths and weaknesses (see Galhardi and Brancher, 2018; Gao et al., 2024).

Accordingly, the paper provides three major contributions. First, we present a novel hierarchical composition of models for automatically scoring short text responses, particularly fit to the complex settings present in large-scale assessments.

Second, for a first implementation of the framework, we propose a hierarchical collection of models, including a new rigorous method with weak generalizability, called *Fuzzy Lexical Matching* (FLM), alongside fine-tuned XLM-RoBERTa (XLM-R; Conneau et al., 2020) and support vector machine classifiers (SVM; Cortes and Vapnik, 1995). Human raters, integral to assessment operations, serve as the final component in the sequence of scoring methods presented here, turning the implemented pipeline into a semi-automatic system.

Third, this is the first paper to evaluate automatic scoring on massively multilingual data from PISA tests including all three major domains (i.e., *reading*, *mathematics*, and *science*; OECD, 2024). With the complete dataset containing 59 test languages from 86 countries and regions in total, we sampled a subset of 11 test languages for the present evaluation, resulting in about 3.8 million text responses to 160 items from 3 assessment domains and more than 270,000 students. To represent diverse language families and writing systems, the selected test languages included Arabic, Finnish, Hebrew, Kazakh, and Korean, among others.

The empirical evaluation was guided by two

overarching research questions. (I) Overall and for each subcomponent, how effective is the model at generating accurate scores and reducing manual effort? (II) How robust are scoring accuracy and reduced manual effort across subsamples with different test languages?

2 Background

2.1 Relevance for Operational Assessments

International educational large-scale assessments, such as PISA, are characterized by their large scope in addressing diverse student characteristics from different cultures using complex methodology. This can pose significant challenges for automatic scoring (Yan et al., 2020; Zesch et al., 2023). The resulting diversity manifests in response texts and corresponding scoring, stemming from many factors, including the world-wide participation (i.e., over ninety countries and economies in PISA 2025; OECD, 2025). The tests are administered in a large number of test languages (almost sixty test languages from 2018 to 2022), with high-resource languages, such as Indonesian, just as low-resource languages, such as Kazakh or Catalan. Moreover, the tests assess three major literacy domains, using a large number of items and various item types with complex coding guides for constructed-response formats. Additionally, the low-stakes nature at the individual level often results in lower test engagement (Schlosser et al., 2019) and, thus, more informal, fragmented, and less integrated (Chafe, 1982) text responses. Continuous changes in assessment design—such as the transition from paper- to computer-based testing and the adoption of adaptive testing—introduce additional variability over time; for example, by reducing the number of responses per item (OECD, 2024) or by impacting the length and quality of text responses (Zehner et al., 2019, 2020). On top of this, not only sample sizes vary largely per test language (e.g., from $n = 269$ to $n = 22,163$ responses per item in the present paper’s reported dataset), which poses challenges for training, but also a reduced rigor in human coding can lead to more label noise in subsamples. At the same time, large-scale assessments pose incontestable quality requirements (see OECD, 2025), including high-quality coding and accountability (i.e., explainability), due to their high stakes at the state level. Shin et al. (2019) demonstrated that automatic scoring can align closely with human experts in identifying rater severity, and less so

regarding centrality and accuracy, highlighting further challenges in introducing automatic systems in operational procedures. Noteworthy, large-scale assessments usually administer a subset of items repeatedly over time, making them an attractive field of application for supervised learning.

Thus far, automatic scoring has seen limited research and operational use in international large-scale assessments. Early efforts include the introduction of PISA’s Machine-Supported Coding System (Yamamoto et al., 2018), a precursor to FLM, and a baseline evaluation for German (Zehner et al., 2016). Recent research funded by international bodies, such as on IEA’s ePIRLS data (*International Association for the Evaluation of Educational Achievement*; Shin et al., 2024), and a competition on data from the National NAEP (*National Assessment of Educational Progress*; Whitmer et al., 2023) signal growing interest in automating scoring, notoriously centering around national U.S. assessments (Yan et al., 2020).

2.2 Diverse Models to Address Text Diversity

All these extraneous factors manifest in varying degrees of linguistic variance in text responses (Zesch et al., 2023; Horbach and Zesch, 2019) across cohorts, subpopulations (i.e., languages), domains, items, and their context. Single automatic scoring approaches can fall short of adequately addressing this diversity. For instance, while lexical matching methods offer excellent accuracy for known responses, they lack generalizability to unseen linguistic expressions. Moreover, supervised classifiers are often hampered as they assign a label regardless of relatively low probabilities (i.e., confidence) for certain instances (Li et al., 2023).

Recognizing these limitations, the here presented first collection of implemented components in an Omethi framework retain human raters as the final recourse when automatic models fail to score responses with sufficient confidence, rendering it a semi-automatic system. By hierarchically composing multiple scoring approaches and discarding lower-level components once a score is confidently assigned, Omethi navigates the complexities of international large-scale assessments while maintaining the high-quality standards required for them.

2.3 Ensembles for (Semi-)Automatic Scoring

Ensembles for automatic and semi-automatic scoring come in two fashions: algorithmic ensembles that inherently comprise multiple models (e.g., ran-

dom forests) or combinations of relatively loosely coupled models (e.g., stacking). Omethi belongs to the latter and diverges from traditional systems by combining multiple components, including supervised classifiers, in a conceptually governed, top-down manner rather than relying on data-driven, bottom-up learning. Unlike the common paradigm of identifying a single optimal model for a dataset, task, or domain, Omethi deliberately alternates models at the response level based on explicit criteria. This approach contrasts with standard ensembles, such as those in Goenka et al. (2020) and Ormerod (2022), where model selection is carried out uniformly (e.g., majority voting or averaging) or with ensembles designed to capture diverse response characteristics (e.g., Mohler et al., 2011; Sahu and Bhowmick, 2020; Sakaguchi et al., 2015; Zhang et al., 2022). For instance, Heilman and Madnani (2013) stacked models for item-specific n -gram features and text similarity, while Roy et al. (2016) employed transfer learning between general and question-specific classifiers.

If humans are still involved during inference, the scoring is considered semi-automatic. For systems deferring responses to humans, appropriate confidence thresholds of the automatic component need to be identified; referred to as *deferral policy* in (Li et al., 2023), which we rephrase here as the *eligibility policy* for assigning a score. This has been investigated for semi-automatic systems, such as in Andersen et al. (2023) and Horbach et al. (2014), which combined unsupervised clustering with human scoring. Horbach and Pinkal (2018) more directly integrated humans and machines via semi-supervised clustering. In the context of label probabilities as a confidence criterion, results on identifying optimal confidence thresholds have been mixed. Suen et al. (2023) successfully set thresholds based on a minimum required F_1 score, while Bexte et al. (2024) observed substantial item- and data-wise variation in confidence distributions with this, failing to identify viable thresholds for certain items at all. Funayama et al. (2022) similarly used confidence scores to revert to human raters, and Li et al. (2025) proposed a constant threshold of $\delta = .25$, basically halving the range of values from random chance to perfect agreement.

3 Omethi Framework

Unlike traditional ensemble methods, Omethi orchestrates scoring components hierarchically based

on their conceptual priority, compiling a logical decision flow that is informed by each component’s inherent characteristics. If a component is eligible by satisfying its specific conditions (i.e., its eligibility policy), it assigns the final score and the response bypasses subsequent components.

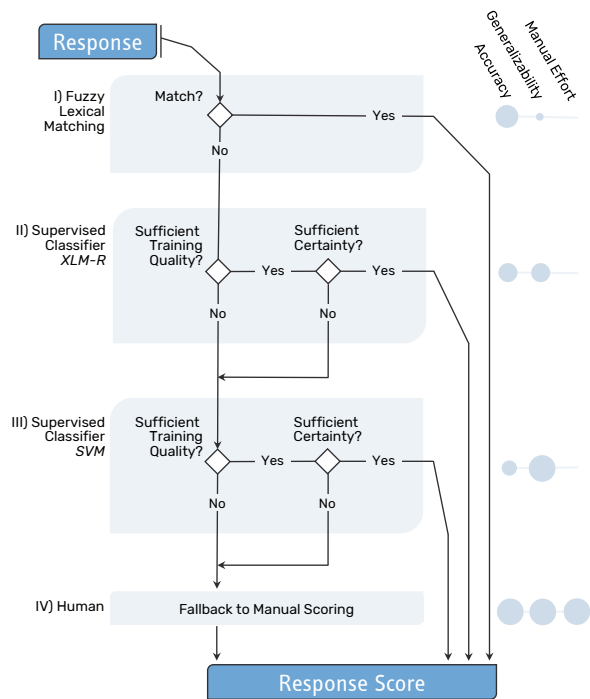

Figure 1: Response flow through the implemented Omethi pipeline

In this paper, we present an initial implementation consisting of four components, described in the following (see Figure 1). The rationale underlying the implementation was to allocate components with the highest accuracy prior to those exhibiting higher generalizability, while also aiming at minimizing human effort resulting from responses deferred to the final component.

During training, each scoring component was built separately using data from a given subsample; that is, for (i) a specific item and (ii) test language. Human scores available from the operational PISA studies served as the ground truth for training. During inference, each response was first evaluated by Fuzzy Lexical Matching (FLM), which attempts to match normalized text to a pool of normalized response texts. If sufficient matching responses were identified that satisfied predefined score-homogeneity criteria (see next section), propagating their score to the unseen response is considered highly reliable, as the response had been

scored multiple times previously by humans, or at least a lexically very close counterpart. FLM, therefore, receives the highest priority in the flow because its classifications are largely valid, interpretable, and applicable for any language. However, FLM’s obvious downside is its lack of out-of-sample generalization, the severity of which depends on the item-specific linguistic variance in the responses. Thus, if FLM *could* provided a score, that score *was* adopted, bypassing subsequent components. Otherwise, the response proceeded to the next scoring component.

Responses not scored by FLM were next passed to a supervised classifier: a fine-tuned XLM-RoBERTa classifier or SVM. The model’s output was assigned to the response if its overall training performance quality sufficed and the individual classification’s confidence exceeded an item- and language-specific threshold.

If none of the automatic components satisfied their eligibility policy, the response was forwarded to the final component, namely manual scoring by human raters.

3.1 Fuzzy Lexical Matching

FLM extends the idea of PISA’s Machine Support Coding System (Yamamoto et al., 2018), operationally introduced in PISA 2018. There, strict exact string matching was applied, automatically propagating scores if at least five homogeneously scored text responses were found in legacy data.

FLM builds on this widely adoptable principle of matching unseen to historic data. In contrast to exact matching, FLM first normalizes the texts by traditional preprocessing techniques. The normalization pipeline was first evaluated on ePIRLS data (the *Progress in International Reading Literacy Study*; Shin et al., 2024). The standard techniques used were white-space trimming, punctuation removal, case insensitivity, diacritics removal, stemming, stop word removal, and bag of words.

For optimization to a subsample (i.e., item and language), this set of normalization techniques is trained on the respective data. That is, the effectiveness of each pipeline step is evaluated using the coefficient ER (Effort Reduction), simply constituting the share of matched responses, $ER = \frac{n_m}{n_t}$; n_t denoting the total number of responses in the data and n_m the number of matches. Importantly though, FLM’s scoring quality also manifests in ER because the method requires sufficiently frequent as well as homogeneously scored responses

for automatic scoring. That is, if the grouping of the normalized texts leads to heterogeneous scores within that group, ER will decrease. A response is automatically scored if the following criteria are met. For a given response i , let m_i denote the number of its matches and s_i the number of responses that received the dominant score in the group. Then, the response is scored ($M = 1$) or not scored automatically ($M = 0$) as follows:

$$M = \begin{cases} 1, & \text{if } m_i \geq 3 \text{ and} \\ & s_i \geq \max(\lceil m_i \cdot .92 \rceil, m_i - 5) \\ 0, & \text{otherwise} \end{cases}$$

That is, a response is scored automatically if at least 3 responses are matched, requiring a minimum of 92 percent of homogeneous scores, but limited to an absolute maximum of 5 deviant responses.¹

Whenever a pipeline step in FLM leads to a decrease in ER , the respective step is discarded for the specific subsample (i.e., item and language). For example, if respondents were asked to provide an email address from a text, applying punctuation removal on the responses eliminates relevant information, leading to heterogeneously scored matching groups, a reduced ER , and, hence, this normalization step would be discarded during inference.

Another adaptive step in FLM is the tailoring of stopword lists to the subsample. The rationale behind this is twofold. For one, stopword lists are language-specific and differ largely in their scope. Second, whether certain words are predictive for a response’s score depends on the item. Therefore, if an optimized stopword list leads to an increase in ER or an increase of the overall accuracy while ER remains identical, the optimized stopword list is used during inference.

3.2 Supervised Classifiers

Two types of classifiers based on supervised learning were built: fine-tuned XLM-RoBERTa models and support vector machines. During inference, both only take response texts as their input, not considering item stems, stimulus materials, or scoring guides.

As a core component, fine-tuned XLM-RoBERTa models (Conneau et al., 2020) were employed for their robust multilingual representation and classification capabilities. XLM-R is a massively multilingual model pretrained on a corpus

¹In PISA, the minimum inter-rater agreement is required to be 92 percent (OECD, 2024).

comprising one hundred languages. For enabling binary (i.e., dichotomous) and multiclass (i.e., polytomous) scoring, respectively, a classification head was appended to the pretrained model.

With the objective to only have the model assign fairly probable scores, labels’ output probabilities were stored for each instance. Using Receiver Operating Characteristic (ROC) analysis, an optimal threshold of label output probability o_j , specific to subsample j , was determined to minimize misclassifications. This threshold was determined by maximizing Youden’s index (Youden, 1950), which quantifies the trade-off between sensitivity and specificity. Specifically, we computed

$$o_j = \arg \max_{x \in [0,1]} \left(\frac{TP_x}{TP_x + FN_x} - \frac{FP_x}{FP_x + TN_x} \right),$$

where TP, FP, TN, and FN denote subsample j ’s number of true positives, false negatives, and so on, based on a vector of classification correctness at threshold x .

This threshold identification differs from conventional ROC analyses, which typically rely on the actual binary labels rather than their correctness. With tailored confidence thresholds, the XLM-R classifiers ensure reliable predictions while deferring uncertain cases to downstream components. Moreover, only classifiers with sufficient training performance were employed at all.

In addition to fine-tuned XLM-R classifiers, support vector machine classifiers were trained using XLM-R embeddings as the input features. With a small number of entirely underfitting XLM-R models, the SVM classifiers were designed as fallback classifiers before ultimately deferring to human scoring. While linguistic representation remained consistent with XLM-R classifiers, SVMs’ distinct classification provided—despite somewhat poorer accuracy—more robustness in scenarios where datasets may be small, noisy, or skewed in their class distribution.

As the threshold for inference certainty, SVM classifiers used the arithmetic mean probability instead of the ROC-based approach employed for fine-tuned XLM-R models. This simpler thresholding mechanism was chosen because SVMs were applied only to responses that had already been deemed uncertain by upstream models.

4 Empirical Evaluation

Omethi implemented as described above was evaluated by simulating its flow on a real-world dataset.

4.1 Dataset and Instrument

In PISA (OECD, 2023), 15-year-old students take tests in a total of three domains to assess their scientific, mathematics, and reading literacy. For the present study, we had available text responses for all construct-response items from all Field Trials and Main Studies for PISA 2018 and 2022. With the complete data being too large for one evaluation and its reporting, we sampled 11 datasets with diverse languages for the present paper: Arabic (Jordan), Traditional Chinese (Chinese Taipei), Finnish (Finland), English (U.S.), German (Germany), Hebrew (Israel), Indonesian (Indonesia), Kazakh (Cyrillic script; Kazakhstan), Korean (South Korea), Portuguese (Brazil), and Spanish (Spain). Corresponding to $n = 270,445$ students, this resulted in a total of $n = 3,773,728$ responses that had already been assigned human scores in PISA with its high quality standards (OECD, 2025).

The dataset comprised 160 items (89 reading, 39 math, and 32 science items), 121 with two and 39 of them with three score levels. Not all items had been administered in all selected languages, resulting in a total of 1,676 datasets (i.e., classifiers to be trained). Sample items with corresponding coding guides can be found on the OECD’s website (OECD, 2025). Coding guides for some items are simple, such as “*Full credit is given when the student states that the weight or size [...] was not provided ...*” (CR548Q09), others are more complex, such as “*Selects one of the names and gives an appropriate explanation as described below.*” (with 19 explanations specified and mapped to one of three different names; CR557Q14).

Table 1 shows exemplary responses for each domain. They are selected from coding guides released by the OECD and not from the evaluation data set, because items in PISA are confidential due to the assessment’s high stakes at the national level, constraining the selection options. Note that constructed-response items in math regularly involve mathematical reasoning (sometimes, naming a number), but rarely involve stating formulas.

4.2 Implementation

We used Python 3.11.5 and R 4.4.3 (R Core Team, 2025). For XLM-R, the base model² with 279 million parameters was used. Due to the large number of required classifiers, hyperparameters and

Table 1: Sample PISA items and responses from released coding guides

settings were not tuned classifier-wise for computational constraints. Instead, a fixed batch size of $B = 32$, learning rate of $\eta = 5e^{-5}$, the AdamW optimizer (Loshchilov and Hutter, 2017), and a cosine learning rate scheduler with warm-up were used. Training was capped at ten epochs, with early stopping after stagnating performance in three consecutive epochs. Cross-entropy loss was used for optimization. SVMs employed a Radial Basis Function (RBF) kernel.

Classifiers were deployed only if they met minimum training performance thresholds ($\kappa \geq .300$ for XLM-R and $\kappa \geq .900$ for SVM) as measured by QWK (Quadratic Weighted Kappa; Cohen, 1960). F_1 -score is reported as F_1 micro. Importantly, in the reported evaluation, the final manual scoring component was assumed to yield perfect accuracy, despite normal inconsistencies in human scoring. That is, this component takes the ground truth label, as provided by PISA’s human raters, as its output. This assumption was made for two reasons: (i) consistent estimates of inter-rater agreements were not available for all subsamples, and (ii) the substantial reduction in manual effort could alter relevant rater cognition (Bejar, 2017) and reliability (Padó and Padó, 2022).

Finally, due to computational constraints stemming from the fine-tuning of many XLM-R models, an 80/20 training-test-split was used for evaluation.

4.3 Results

All reported average values constitute means weighted by sample size across all classifiers.³

³For the sake of readability, only a selected set of standard errors is reported (in brackets) where comparisons may be relevant. All result data is available upon request.

	Acc (%)	κ	F_1	ER (%)
Math	98.8	.972	.988	73.0
Reading	97.7	.954	.977	71.0
Science	97.7	.951	.977	67.3

Table 2: Omethi’s performance by domain

4.3.1 Performance by Domain

Omethi achieved very high agreement with human scores, with an average $\kappa = .957$, $TPR = .968$, and $FPR = .977$, alongside substantial manual effort savings (on average, $ER = 70.5\%$). Notably, these results include a share of responses scored manually, as reflected in the effort reduction metric, and assume perfect agreement for this subset. Nonetheless, the reported figures represent the expected scoring quality if Omethi were deployed in an operational setting.

Table 2 details the agreement and effort reduction across all domains. Scores showed the highest agreement for math items with an average accuracy of 98.8 percent [$\pm 0.1\%$], $\kappa = .972$ [± 0.003], and an effort reduction of 73.0 percent [$\pm 1.2\%$], meaning 27.0 percent of responses have been deferred to human scoring. For the other two assessment domains, Omethi scores showed marginally lower but still very high agreement values, with accuracy at 97.7 percent [$\pm 0.1\%$] for reading and identical 97.7 percent [$\pm 0.3\%$] for science ($\kappa = .954$ [± 0.002] and $\kappa = .951$ [± 0.005]), and an effort reduction of 71.0 percent [$\pm 0.8\%$] and, for science somewhat lower, 67.3 percent [$\pm 1.1\%$], respectively.

The overall high agreement for the majority of classifiers across domains and languages with only rare exceptions is visualized in Figure 2.

Distinguishing performance of individual automatic components, Table 3 reports component-

Figure 2: Omethi’s distribution of performance at the item- and language-level across domains

wise agreement values, excluding manual scoring during inference. The first three columns show the agreement of the components’ automatic score with human scores for the subset of responses that were scored by the respective component for Omethi. For FLM, accuracy was at $Acc_{FLM} = 98.6$ percent on average, XLM-R’s performance was $\kappa_{XLM} = .775 [\pm .011]$, and for SVM, $\kappa_{SVM} = .554$. The fourth column (κ_{auto}) shows agreement for all automatic components combined, again only for the subset of responses scored automatically; $\kappa_{auto} = .804 [\pm .009]$. The last column ($\kappa_{XLM_{all}}$) reports agreement as would have been the case if all responses were scored by XLM-R classifiers alone, showcasing the substantial added value of the combination of automatic scoring approaches beyond transformer finetuning as displayed in the adjacent column on the left ($\Delta\kappa_{auto, XLM_{all}} = .093$). The Appendix visualizes this gain of the Omethi pipeline over mere XLM-R fine-tuning (see Figure 4). Similarly, Figure 5 (see Appendix again) shows that XLM-R outperforms SVM for the majority of item- and language-specific classifiers, which is in line with the rationale underlying the component hierarchy, while also showcasing the number of random-level XLM-R classifiers, for which SVM was added as a potential fallback.

4.3.2 Robustness across Languages

Table 4 displays Omethi’s agreement with human scores and effort reduction across subsamples,

	Acc_{FLM}	κ_{XLM}	κ_{SVM}	κ_{auto}	$\kappa_{XLM_{all}}$
<i>Math</i>	99.2	.715	.414	.765	.683
<i>Reading</i>	98.2	.792	.584	.845	.739
<i>Science</i>	98.8	.784	.600	.756	.677

Table 3: Performance for automatic components and their combination (*auto*); responses deferred to manual scoring excluded, except for XLM_{all}

which includes, among others, different test languages. Overall agreement was homogeneously high, with accuracy ranging mainly from 97.8 (Spain) to 99.0 percent (Jordan) and the exception of Indonesia with 96.9 percent. In contrast, effort reduction varies largely from 60.3 (Indonesia) to 76.1 percent (Chinese Taipei), showing how the implemented scoring conditions effectively identified instances that required human scoring. Similarly, the shares of responses scored by different components varied heterogeneously across subsamples (see Appendix A, Table 6). For example, FLM scored 29.5 percent of responses in the subsample from Chinese Taipei (Traditional Chinese), which stands in stark contrast to the one from Israel (Hebrew) with only 19.7 percent. For Spain (Spanish), SVMs only scored 1.2 percent of the responses, compared to Jordan (Arabic) with 9.8 percent combined with an outlier of only 28.1 percent of sufficiently confident scoring by XLM-R, whereas the XLM-R classifiers for the U.S. (English) scored even 52.2 percent of the responses.

Table 4: Performance and effort reduction by language, incl. manual scoring

4.3.3 Component Shares

Table 5 shows the percentage of responses scored by the respective component due to meeting the eligibility policy. FLM and XLM-R played the major role for automatic scoring. With its position at the end of the sequence of automatic components, SVMs only played a minor role quantitatively. Nevertheless, as shown in Table 6, there were settings, such as the subsample from Jordan (Arabic) in which the first automatic components do not perform well and SVM takes over some of the shares to retain the homogeneously high level of accuracy.

The prevalence of different flows responses take through the scoring components is displayed in Figure 3. Said cases where XLM-R and FLM do not manage to score responses for which SVM takes over are visible in the figure as the orange ribbon. Moreover the figure disentangles the specific conditions for why responses are not scored by specific components.

5 Discussion

The results demonstrate Omethi’s effectiveness in orchestrating multiple methods in an explicitly designed, adaptive scheme for automatic scoring across domains and languages while maintaining uniformly high accuracy. With an average agreement of $\kappa = .957$ compared to complete human scoring and manual effort reductions of 70.5 percent across domains, Omethi proves its feasibility in and operational usefulness. Thus far, for PISA data, effort reduction gains have been reported to be smaller with other methods and data sets comprising fewer test languages and assessment domains (Andersen et al., 2023; Yamamoto et al., 2018). Critically, the system’s hierarchical composition and scoring conditions ensured that accuracy was prioritized, resulting in varying effort reduction across settings. It is important to note that *manual effort reduction* here does not refer to the entirety of human involvement in operational assessment procedures but only the share of automatically scored responses during inference.

	FLM	XLM-R	SVM	Manual
<i>Math</i>	35.0	34.2	3.8	27.0
<i>Reading</i>	24.1	44.5	2.5	29.0
<i>Science</i>	18.4	46.0	2.8	32.7

Table 5: Proportions (%) of component usage

The importance of combining different methodologies was evidenced by the homogeneous accuracy levels despite heterogeneous shares of responses being scored by different components across domains and languages. Each component in Omethi played a distinct role, contributing to the system’s overall robustness. While FLM and XLM-R dominated the scoring, partly due to their position in the sequence, SVMs served as a crucial fallback mechanism, stepping in when upstream components failed to score confidently. Although SVMs scored only a minor share of responses quantitatively, their role turned out as indispensable in maintaining accuracy for certain subsamples. This underscores the importance of the adaptive workflow, where eligibility policies diagnosed the risk of misclassifications and led to passing on responses.

For identifying a confidence threshold as components’ eligibility policy, the proposed maximizing of the ROC-based Youden’s Index on misclassifications worked excellently for XLM-R classifiers. Less so for SVM classifiers that were faced with only the more challenging responses not scorable by upstream components. Hence, this measure may be added to the repertoire of threshold identification methods, complementing fixed constants (e.g., Li et al., 2025) or the definition of minimum F_1 scores as proxies (e.g., Bexte et al., 2024), but its suitability needs to be verified.

Omethi’s strength in adaptivity may also introduce challenges in ensuring equivalence and fairness across test languages and subpopulations, necessitating careful validation and bias checks, as bias is known to be potentially masked at the aggregate level (Andersen et al., 2023). From an operational standpoint, implementing Omethi in international large-scale assessments would require a rigorous quality monitoring.

For human raters, the implementation of such a framework would result in multiple changes that may affect rater cognition in positive or negative ways, or both. First, the number of responses decreases, potentially leading to less fatigue, monotonous work, and slippage. Second, raters’ oversight of frequent responses would diminish and would thus change so-called contrast or context effects by preceding responses, an effect repeatedly found even in highly standardized settings with well-trained raters (Attali, 2011; Meadows and Billington, 2005). Third, both for automatic systems as well as humans (Padó and Padó, 2022), incorrect responses are more challenging to score.

Figure 3: Share of response flows through Omethi’s components. Y/N (yes/no) = eligibility policy satisfied?

Accordingly, if classifiers with poor recall leave human raters with a higher frequency of incorrect responses, this also may show effects.

In conclusion, Omethi’s response-level adaptivity, combined with its capability to maintain high accuracy across diverse contexts, positions it as a powerful tool for operational employment in assessments. While challenges may remain in, among others, ensuring fairness, the system’s effectiveness and flexibility pave the way for its operational use and future enhancements. In follow-up studies, the results presented here may be used to sample specific datasets informative to diverse facets to carry out an evaluation in order to systematize performance differences and identify optimal hyperparameters, respectively.

Ethical Considerations

The implementation of a framework such as Omethi in large-scale assessments necessitates careful attention to ethical principles, which is not always at the forefront of attention (Holmes et al., 2022). Fairness and the mitigation of bias are paramount, as variability in component usage across languages and cultures could lead to disproportionate disadvantages for certain groups. Rigorous validation and bias investigations are essential to ensure equitable performance across diverse populations. Transparency in the scoring process is critical to fostering trust among stakeholders, including organizations such as the OECD, policymakers, and test takers. Clear documentation of the system’s decision-making mechanisms and limitations must be provided to ensure interpretability and account-

ability. Additionally, equity in resource allocation must be discussed, as disparities in system performance between high- and low-resource languages could exacerbate existing inequalities. Finally, the increasing automation of standardized assessments raises broader questions about their role in education. While automation enhances efficiency and scalability, it also risks amplifying uniformity, potentially overlooking diversity facets.

Limitations

The study faces several limitations, primarily due to computational constraints. With many test languages, items, and domains, a large number of item- and language-specific classifiers were fine-tuned using the XLM-RoBERTa base model. This scale rendered classifier-specific hyperparameter tuning via grid search computationally infeasible, necessitating the use of fixed hyperparameters. Similarly, k -fold cross-validation was not conducted due to resource limitations, restricting the evaluation to a single 80/20 train-test split.

The system’s runtime scales with the number of components, complicating potential real-time deployment in certain settings. Additionally, the evaluation focused exclusively on operational data, lacking comparison with public benchmarks or standardized datasets. The use of human scoring as the gold standard, particularly for responses deferred to manual scoring, assumes perfect inter-rater reliability, which may overestimate accuracy in production.

Lessons Learned in Assessing Student Reflections with LLMs

Mohamed Elaraby, Diane Litman

University of Pittsburgh

Pittsburgh, PA, USA

{mse30,dlitman}@pitt.edu

Abstract

Advances in Large Language Models (LLMs) have sparked growing interest in their potential as explainable text evaluators. While LLMs have shown promise in assessing machine-generated texts in tasks such as summarization and machine translation, their effectiveness in evaluating human-written content—such as student writing in classroom settings—remains underexplored. In this paper, we investigate LLM-based specificity assessment of student reflections written in response to prompts, using three instruction-tuned models. Our findings indicate that although LLMs may underperform compared to simpler supervised baselines in terms of scoring accuracy, they offer a valuable interpretability advantage. Specifically, LLMs can generate explanations that are faithful, non-repetitive, and exhibit high fidelity with their input, suggesting potential for enhancing the transparency and usability of automated specificity scoring systems.

1 Introduction

Reflective writing is a fundamental skill that enhances learning by encouraging students to critically engage with course material and articulate their thoughts. This process benefits both students and instructors by fostering greater awareness and facilitating meaningful classroom interactions (Baird et al., 1991; Menekse, 2020). The quality of written reflections is often assessed based on their *specificity* (Menekse et al., 2011; Li et al., 2025), which measures the level of detail and depth in a given reflection. Table 1 shows student reflections written after a physics lecture, along with human-assessed specificity scores, both from the ReflectSumm corpus described in Section 3.

Automating specificity assessment is crucial for delivering interventions to help students improve the quality of their reflections (Knoth et al., 2020; Wilhelm, 2021), e.g., by providing scaffolding feed-

Prompt: Describe what you found most confusing in today’s class.

[Score 1] I thought that most of the topics explained were relatively simple or I had previously learned them. I felt confident in my understanding after the class session.

[Score 2] the class participation activity

[Score 3] Undirected vs directed was a bit confusing in terms of how to read the chart

[Score 4] Finding the right problem to address.

Prompt: Describe what you found most interesting in today’s class.

[Score 1] I found nothing interesting in class. Being Friday, I could barely pay attention.

[Score 2] the review session

[Score 3] The part about bias in data labeling was thought provoking

[Score 4] Writing the problem statement.

Table 1: Representative reflections for each specificity score (1–4) across two prompts. This illustrates one challenge of assessing specificity: long reflections may lack substance (Score 1), while short ones may convey detailed, content-specific insights (Score 4).

back which in turn can ultimately enhance learning outcomes (Menekse et al., 2025). More specific reflections can also provide instructors with more reliable insights into student understanding and needs (Menekse, 2020). Traditionally, specificity scoring has relied on supervised models (Magoooda et al., 2022; Carpenter et al., 2020; Li and Nenkova, 2015). However, collecting large annotated datasets in educational contexts is resource-intensive and not always feasible. Depending on model type, the reasoning behind the scoring might also not be explainable to students or instructors.

Advancements in Large Language Models (LLMs) for evaluating natural language, commonly referred to as the *LLM-as-a-judge* paradigm (Zheng et al., 2023), have introduced new possibilities for leveraging LLMs in educational applications. These models can generate human-like judgments

Research Question	Key Finding	Lessons
RQ1: LLM vs. Supervised Baselines	Retrieval-based few-shot improves scoring LLMs underperform supervised models Chain-of-Thought (CoT) explanations do not improve scoring	Selecting semantically similar in-context examples boosts accuracy over random or fixed examples. Distill-BERT outperforms all LLMs, suggesting a need for adaptation. Generated explanations fail to enhance LLM-based scoring.
RQ2: Self-Generated Explanations	Explanations are faithful to the input and explanation vocabulary do not fully overlap with the input reflection vocabulary High fidelity suggests explanations are highly influencing the predictions	Explanations do not contradict or repeat the input, suggesting potential for interpretable and supportive understanding of the scores. Misleading explanations can negatively affect the scoring.

Table 2: Key findings of RQ1 and RQ2 .

without task-specific training, making them attractive for low-resource tasks such as reflection specificity assessment. Their generative capabilities in addition suggest new possibilities for explainable methods. This paper investigates whether LLMs can serve as viable alternatives to traditional supervised models for assessing reflection specificity.

Reflective writing poses challenges compared to other educational scoring tasks. Unlike Automatic Essay Scoring (Foltz et al., 1999; Attali and Burstein, 2004; Shermis and Wilson, 2024), which typically assesses longer texts, reflective writing is often concise and highly variable in length, with reflections ranging from a single word to multiple phrases or complete sentences (Kember et al., 2008). This variability poses a unique challenge in distinguishing different levels of specificity: shorter reflections may lack sufficient context, while longer ones can introduce ambiguity in assessment. Table 1 presents two examples of reflections that contain multiple sentences yet receive the lowest specificity score (1) due to vague or off-topic content, as well as two shorter reflections that achieve the highest specificity score (4) by providing concise, content-rich responses relevant to the prompt. Also, while tasks such as Short Answer Grading (Burrows et al., 2015), which is closer in length and variability to reflections, primarily involve assessing objective responses within a given question context with reference answers, reflective writing is inherently subjective as it conveys personal experiences and insights, further complicating standardized assessment.

In this work, we extend prior research on leverag-

ing LLMs as judges for educational text evaluation by focusing on reflection specificity. We investigate this through two research questions: **RQ1: Can LLM-based specificity assessment improve scoring reliability compared to supervised baselines?** We explore two approaches to LLM-based specificity assessment: (1) *Standard Prompting*: LLMs are instructed to predict specificity scores based on the input reflection. (2) *Chain-of-Thought (CoT) Prompting*: LLMs are prompted to generate a rationale before making a specificity judgment. This technique, widely used in complex NLP tasks, encourages models to engage in step-by-step reasoning, potentially leading to more consistent and interpretable assessments. We investigate these settings under both *zero-shot* and *few-shot* conditions to assess their impact on model performance. **RQ2: Do self-generated explanations enhance interpretability?** We investigate whether generated explanations contribute to the transparency of LLM-based specificity scoring, potentially making the evaluation process more interpretable and informative for students and educators. *Our key findings are summarized in Table 2.*¹

Our contributions are twofold:

1. We evaluate the effectiveness of three open-weight LLMs in scoring student specificity under various zero-shot and few-shot settings.
2. We analyze the linguistic properties of the generated explanations and their role in interpreting the output, aiming to assess whether these

¹<https://github.com/EngSalem/Explainable-Reflection-Quality>

Score	Specificity Meaning	Definition
1	Vague	Reflection implies "no confusing issue," e.g., "nothing" or "none for this class."
2	Non-specific	Reflection does not include any statement(s) about course content but refers to organizational aspects (e.g., homework, exams).
3	General	Reflection includes statement(s) about course content but lacks specific details.
4	Specific	Reflection includes specific and detailed statement(s) about course content.

Table 3: Rubric for evaluating reflection specificity based on decision tree from Luo and Litman (2016).

explanations are meaningful and potentially useful for providing students with feedback on their reflective writing.

2 Related Work

LLM-as-Judge LLMs have demonstrated correlation with human evaluation of machine-generated texts in tasks such as counter-narrative generation (Zubiaga et al., 2024), text summarization (Fu et al., 2024; Liu et al., 2023), multi-turn question answering (Zheng et al., 2023), and automatic persuasion ranking (Elaraby et al., 2024). However, for more nuanced human-written content, such as academic reviews (Zhou et al., 2024) and essay scoring (Mansour et al., 2024; Stahl et al., 2024), LLMs (particularly without fine-tuning or alignment) still fall short compared to human evaluators and domain-specific supervised models trained on high-quality annotated data. *In this work, we investigate LLMs as specificity evaluators for student reflections, a distinct category of human-written text.*

LLM-as-Judge in Educational Text Traditional approaches to assessing student writing often rely on surface linguistic features to enhance automatic scoring models ranging from feature-based to hybrids with deep learning, including list ranking (Uto et al., 2020) and neural-based methods (Jin et al., 2018; Uto et al., 2020). Recent work has explored leveraging LLMs as evaluators for educational text. Stahl et al. (2024) employed persona-based zero-shot prompting for essay scoring, and Hou et al. (2025) integrated linguistic features into zero-shot evaluations; however, both studies found limited improvements over traditional supervised baselines. In contrast, Baral et al. (2024) showed that a fine-tuned Mistral-7B model outperformed other supervised models in math essay scoring. Closely related to our work, Li et al. (2025) investigated reflection specificity assessment, demonstrating that multi-LLM voting strategies outperform single LLM scoring approaches. *Building on these developments, our work examines LLMs’ capabilities*

in assessing student reflections, focusing on how in-context examples influence predictions. Additionally, we analyze the interpretability of LLM-generated explanations, offering a novel perspective particularly valuable for building downstream applications in high-stakes domains like education.

Evaluating Self-Generated Explanations Assessing self-generated explanations has largely centered on their impact on model performance. Existing metrics, such as accuracy differences with and without explanations (Hase et al., 2020a; Wiegrefe et al., 2021a) and information-theoretic measures (Chen et al., 2023), quantify how explanation content influences predictions. Wiegrefe and Marasovic (2021) proposed evaluation criteria based on surface validity, grammatical correctness, and alignment with the target label, including *contrast* with alternative labels. Expanding on this, Joshi et al. (2023) introduced *novelty*, capturing the introduction of new information, which proved useful in human-AI collaboration tasks. These measures have since been extended to domains like persuasiveness evaluation (Elaraby et al., 2024). Despite these advancements, self-generated explanations remain largely unexplored in educational contexts beyond their role in enhancing automatic scoring (Stahl et al., 2024). *In this work, we examine their effectiveness not only in improving specificity scoring, but also for their potential to generate explanations that are faithful and non-repetitive with input, and exhibit fidelity with scoring.*

3 Datasets

For LLM evaluation, we utilize ReflectSumm² (Zhong et al., 2024), a corpus of 17,509 reflections aggregated by unique reflection per lecture from 24 STEM courses across 2 universities, written in response to the prompts in Table 1. This dataset was selected for its inclusion of high-quality annotations of individual reflection specificity scores,

²<https://huggingface.co/datasets/mse30/ReflectSumm>

Score	Count	Ref. Length (Min / Mean / Max)
1	1,841	1 / 11.19 / 135
2	2,488	1 / 6.17 / 62
3	9,231	2 / 15.26 / 87
4	3,949	4 / 30.19 / 194

Table 4: Distribution of reflection specificity scores in the ReflectSumm dataset, with reflection (ref.) length in number of words statistics.

rated on a scale from 1 (vague) to 4 (specific) using the rubric in Table 3. The annotations exhibit substantial inter-annotator agreement, with a reported pairwise Quadratic Weighted Kappa of 0.668 across 4 distinct annotators (trained college students with backgrounds in the appropriate subject domains) (Zhong et al., 2024). Table 4 summarizes the score distribution. The table also emphasizes the variability in reflection lengths across all scores.

For both training supervised pre-LLM baselines and as a reflection bank for LLM in-context prompting, we use the publicly available annotated reflections from the CourseMIRROR dataset³ which is composed of 6680 reflections distributed as 1210, 2035, 2377, 1058 for scores 1 – 4, respectively. Note that although annotated using the same specificity rubric, the CourseMIRROR reflections are from STEM course offerings that are disjoint from those in ReflectSumm.

4 Experimental Settings

4.1 Included LLMs

We included 3 whitebox models which demonstrated strong performance across NLP tasks, as evaluated in the Chatbot Arena leaderboard (Zheng et al., 2023)⁴: Llama3.1-8B-instruct (Grattafiori et al., 2024), Mistral-8B-instruct (Jiang et al., 2024), and Qwen-7B (Yang et al., 2024). For efficient inference, we employed VLLMs (Kwon et al., 2023). All experiments were conducted with a decoding temperature set to 0, enabling greedy decoding to mitigate variability that might stem from temperature sampling.

4.2 Prompting the LLMs (Zero-Shot)

Building on the reflection quality assessment of Luo and Litman (2016), we prompt LLMs to assign specificity scores on a scale from 1 to 4, consistent with the guidelines provided to human annotators.

³<https://engineering.purdue.edu/coursemirror/>

⁴<https://lmarena.ai/>

The scoring rubric is adapted from the decision-tree criteria described in Luo and Litman (2016), and its definitions are presented in Table 3. This alignment enables a direct comparison between model predictions and dataset reference annotations. Appendix A provides the prompts used for scoring.

4.3 Scoring Evaluation Metric

Given that our prediction is based on point-wise scoring, we rely on **Quadratic Weighted Kappa (QWK)** to report the model prediction agreement with ground truth human annotations.

5 RQ1: LLM-based Assessment vs. Supervised Baselines

These experiments evaluate the effectiveness of LLM-based specificity assessment across a range of settings to enable a comprehensive comparison.

5.1 Supervised Baselines

We include two supervised baselines. The first is **Finetuned-DistilBERT**, where we fine-tune DistilBERT (Sanh, 2019) for specificity assessment following Magooda (2022). The model is initialized from the Hugging Face checkpoint⁵ and trained on the annotated reflections from the CourseMIRROR dataset. We fine-tuned the model for 20 epochs using 5-fold cross-validation, optimizing hyperparameters such as the learning rate and number of training epochs. The checkpoint with the highest overall QWK score was selected for evaluating specificity across the full ReflectSumm corpus.

The second baseline is **Nearest Neighbors (NN) Retrieval**. Given a target reflection, we retrieve semantically similar reflections from an annotated reflection bank R_{bank} and estimate its specificity score based on the most frequently occurring specificity label among its nearest neighbors. We use the CourseMIRROR dataset as the reflection bank. This method is used as a comparable baseline to LLMs with nearest neighbor in-context examples (Section 5.2). For each reflection in the ReflectSumm evaluation set, we generate a dense embedding using the all-MiniLM-L6-v2 model from the sentence-transformers library (Reimers and Gurevych, 2019). This maps reflections into a shared vector space, enabling semantic similarity comparisons. We compute the cosine similarity between each reflection in ReflectSumm and the annotated reflections in CourseMIRROR

⁵[distilbert/distilbert-base-uncased](https://huggingface.co/distilbert/distilbert-base-uncased)

(R_{bank}), and retrieve the top- n most similar reflections. For efficiency, we use the Faiss library (Johnson et al., 2019) for fast approximate nearest-neighbor search. The specificity score of a reflection is determined using a mode-based voting mechanism from its nearest neighbors’ specificity labels.

5.2 Prompting with In-Context Examples

We explore three in-context learning strategies, ranging from fixed demonstrations (Brown et al., 2020) to selection-based strategies that draw from pre-existing demonstrations (Min et al., 2022).

(1) **Fixed In-Context Examples:** A fixed set of manually curated examples is used as in-context demonstrations across all runs. These examples are drawn from annotated student reflections in Luo and Litman (2016) and remain unchanged during prompting. Since the examples provided in the original paper focused primarily on *confusing* prompts, we supplemented them with additional reflections written in response to *interesting* prompts from the R_{bank} set. Each specificity score is represented by an equal number of examples to ensure balanced coverage.⁶ This prompting method serves as a baseline for few-shot in-context learning.

(2) **Random In-Context Examples:** For each instance, n examples are randomly sampled from the annotated reflection bank R_{bank} . This approach assesses the variability in model performance based on arbitrary example selection.

(3) **Nearest-Neighbor In-Context Examples:** Similar to the nearest-neighbor retrieval baseline, the top- n semantically similar reflections from R_{bank} are retrieved for each input reflection. These nearest neighbors serve as in-context demonstrations.

Table 5 shows that none of the included LLMs were able to match the performance of the DistillBERT baseline (0.658 QWK) in either zero-shot or any of the few-shot settings. This highlights the limitations of LLMs in specificity assessment when compared to dedicated supervised models. Among the LLMs, Mistral-8B-instruct consistently achieved the highest QWK agreement across both zero-shot and few-shot settings. The best performance (0.624 QWK) was obtained when paired with nearest-neighbor retrieval, indicating that retrieving semantically similar reflections enhances the model’s ability to assess specificity by providing more contextually relevant examples. However,

⁶Fixed in-context examples are provided in Appendix B.

increasing the number of in-context examples negatively impacted performance across all models and few-shot settings. This suggests that excessive context may introduce conflicting information or divert the model’s attention away from the specificity criteria. Also, both fixed and randomly sampled in-context examples performed worse than zero-shot prompting, implying that arbitrarily chosen examples introduce noise rather than meaningful guidance. These findings underscore the importance of carefully curating in-context examples when leveraging LLMs for specificity scoring. *This limitation further reinforces the challenge of deploying LLMs for automated assessment in educational settings without access to high-quality annotated datasets.*

5.3 Chain-of-Thought (CoT) Prompting

Instead of directly instructing the model to assign a specificity score to a given reflection, we employ *Chain-of-Thought (CoT) prompting* (Wei et al., 2022) to encourage the model to generate a rationale before providing its final assessment. This approach aims to enhance the reliability and interpretability of the model’s scoring process by explicitly incorporating reasoning. To implement CoT prompting, we modify the original scoring prompt by introducing a zero-shot CoT instruction (Kojima et al., 2022) that prompts the model to generate a brief explanation before assigning a score. Specifically, we refine the commonly used CoT instruction, Let’s think step by step, proposed by Kojima et al. (2022), by prompting Mistral-8B-instruct to generate an alternative phrasing that better aligns with the specificity evaluation task. The final instruction used in our experiments is: Think critically, consider all aspects, and then decide.

Table 6 demonstrates that prompting Mistral-8B-instruct (the best performing LLM from Section 5.2) to generate self-explanations before assigning specificity scores does not improve QWK performance. Across most settings, CoT prompting either slightly lowers or maintains performance compared to standard prompting, with exceptions for 3-shot with random examples and 10-shot with random and nearest neighbor examples. However, this gain does not surpass the best-performing settings. *Our findings thus suggest that CoT self-generated explanations offer limited utility in improving scoring performance.*

Supervised Baselines (QWK)									Best QWK
Distill-BERT				0.658					0.658
Nearest Neighbor	-	-	0.410 (3-shot)	0.473 (5-shot)	0.506 (10-shot)	-	-	-	0.506
LLM-Based Models (QWK)									Best QWK
Model	Zero-Shot	Few-Shot (Fixed 4-shot per score)		Few-Shot (Random)			Few-Shot (Nearest Neighbor)		
				3-shot	5-shot	10-shot	3-shot	5-shot	10-shot
Llama3.1-8B-instruct	0.552	0.515	0.546	0.549	0.504	0.601	0.595	0.578	0.601
Mistral-8B-instruct	0.595	0.522	0.532	0.553	0.575	0.624	0.605	0.575	0.624
Qwen-7B	0.559	0.485	0.519	0.540	0.456	0.600	0.597	0.569	0.600

Table 5: Quadratic Weighted Kappa (QWK) results for specificity assessment across various few-shot settings on the full ReflectSumm benchmark. The rightmost column highlights the best QWK result within each model group. Shaded cells indicate the best score per model row, and **bolded** values represent group-level best performance.

Retrieval Method	No-CoT (QWK)	CoT (QWK)
Zero-shot	0.595	0.556
Few-shot (Fixed)	0.522	0.522
Few-shot (Random)		
3-shot	0.532	0.576
5-shot	0.553	0.532
10-shot	0.575	0.588
Few-shot (Nearest-Neighbor)		
3-shot	<u>0.624</u>	<u>0.607</u>
5-shot	0.605	0.602
10-shot	0.575	0.587

Table 6: QWK scores for Mistral-8B-instruct comparing No-CoT (repeated from Table 5) vs. CoT prompting. *Italicized* rows indicate settings improved by including CoT prompting. Underlined numbers represent best performing non-CoT and CoT settings.

5.4 RQ1 Summary

As summarized in Table 2, our evaluation of 3 instruction-tuned LLMs in zero-shot, few-shot, and CoT settings shows that reflection specificity assessment using LLMs lags behind using supervised models, with nearest-neighbor in-context learning offering the best LLM scoring performance.

6 RQ2 Analyzing Self-Generated Explanations

Although self-generated explanations did not improve specificity assessment, we explore whether they offer added interpretability benefits beyond those of traditional supervised models. To systematically assess the quality of these explanations as interpretability tools, we examine three key dimensions. Two are adapted from free-text rationale evaluation criteria (Wiegrefe and Marasovic), focusing on surface-level linguistic qualities: **vocabulary overlap** (to capture repetition or label leakage) and **faithfulness** (to assess alignment with the input). We also incorporate **fidelity analysis** (Wachsmuth et al., 2017; Gilpin et al., 2018) to

evaluate whether the model’s predictions are truly guided by its own chain-of-thought, thus reflecting internal consistency in reasoning.

6.1 Vocabulary Overlap Analysis

LLMs often leak the predicted label within explanations (Wiegrefe et al., 2021b; Hase et al., 2020b), raising concerns that generated rationales may merely restate the expected output rather than provide meaningful reasoning. Similarly, Elaraby et al. (2024) demonstrated that, in assessing argument quality through pairwise ranking, LLM-generated explanations often exhibit redundancy by merely restating the input argument, rendering the self-generated explanations meaningless. We extend this analysis, investigating whether explanations contain excessive lexical overlap with the input reflections, thereby reducing their utility in providing a meaningful interpretability for the scores. We leverage the formula in Ye and Durrett (2022) which was mainly used for ensuring that explanations are relevant to the input. Let a reflection R consist of a sequence of words $\mathcal{R} = (r_1, \dots, r_n)$ and a generated explanation E consist of a sequence of words $\mathcal{E} = (e_1, \dots, e_m)$, where n and m are the respective word lengths. We quantify lexical overlap \mathcal{V} as:

$$\mathcal{V}(E, R) = \frac{|\mathcal{E} \cap \mathcal{R}|}{|\mathcal{E}|}$$

A higher value indicates greater redundancy between the explanation and the input reflection.

6.2 Faithfulness Analysis

Prior work (Ye and Durrett, 2022) highlights that self-generated explanations may be unfaithful to the input, introducing hallucinated or contradicting information. To assess whether an explanation E remains faithful to its reflection R , we utilize an off-the-shelf entailment model. Specifically, we use a pretrained RoBERTa model (Liu et al., 2019)

fine-tuned on the MNLI dataset (Williams et al., 2018)⁷. We frame this as a natural language inference (NLI) task, where the reflection serves as the *premise* and the corresponding explanation as the *hypothesis*. An entailment model is then used to predict whether the explanation *entails*, *contradicts*, or is *neutral* with respect to the input reflection. We compute the percentage of contradictions across all explanations.

6.3 Fidelity Analysis

Fidelity evaluates whether LLM-generated explanations genuinely influence the model’s predictions (Gilpin et al., 2018). Following the counterfactual reasoning methodology introduced by Wachter et al. (2017), we assess fidelity by introducing misleading explanations and measuring the percentage of predictions that are affected. Specifically, we consider a set of generated explanations E for which the model’s predictions align with human-labeled specificity scores. Rather than manually creating corrupted explanations, we generate a misleading set E^{mislead} by prompting GPT-4o to rewrite each original explanation to justify an incorrect rubric score.⁸ The final fidelity $F(E)$ is:

$$F(E) = \frac{\sum_{r_i \in R} \mathbb{I} [M(r_i, e_i^{\text{mislead}}) \neq \text{score}^{\text{labeled}}(r_i)]}{|R|}$$

where $M(r_i, e_i)$ is the model’s predicted specificity score for reflection r_i given explanation e_i , and $\text{score}^{\text{labeled}}(r_i)$ is the ground truth label. $0 \leq F(E) \leq 1$, where 0 indicates that LLMs do not rely on explanations while 1 refers to LLMs fully utilizing explanations in predicting scores. We sampled 100 explanations per score category (400 in total) from the Mistral-8B-instruct CoT outputs. For each original explanation and its misleading counterpart, we re-prompted Mistral to generate new predictions. Fidelity was then measured based on whether the model’s prediction deviated from the original ground truth. Table 7 presents an example of a corrupted explanation⁹.

6.4 RQ2 Findings

Table 8 summarizes the self-explanation analyses. On average, explanations exhibited a vocabulary

⁷<https://huggingface.co/roberta-large-mnli>

⁸We set the temperature to 0.7 to encourage diverse generations. The full prompt is in Appendix C Table 13.

⁹The prompt used for generating predictions is included in Appendix C Table 14.

Reflection:

I didn't know which equations went into which sections of the WDM.

Ground Truth Specificity Label: 3

Original Explanation:

The reflection mentions specific equations and a specific section of the WDM (Worked Distributed Model), which indicates a specific understanding of the course content. However, it does not provide detailed explanations or examples of the confusion, which is why it scores a 3.

Corrupted Explanation:

The reflection explicitly mentions specific equations and a particular section of the WDM (Worked Distributed Model), demonstrating a clear and detailed understanding of the course content. The mention of specific equations and sections indicates a precise engagement with the material, which aligns with a more detailed and specific reflection. Therefore, it deserves a score of 4.

Table 7: Example of a corrupted explanation for specificity assessment. Gray text indicates the modified portion of the original explanation used to steer the LLM toward a different score.

Figure 1: Confusion matrix between original labels and corrupted labels after misleading explanations.

overlap of 23.55% with their corresponding reflections, suggesting that the model does not simply replicate the input text—contrary to findings in argument quality tasks where smaller instruction-tuned models often repeated the input (Elaraby et al., 2024). Examples in Table 9 illustrate that high-overlap cases (71.11%) and low-overlap cases (8.88%) primarily reflect restatements of key concepts rather than superficial repetition.

Faithfulness analysis shows that only 5.48% of explanations were predicted to contradict their corresponding reflections, indicating high alignment. As shown in Table 10, even explanations flagged as contradictions often did not exhibit explicit conflict, suggesting potential entailment model errors due

Average Vocabulary Overlap (%) ↓	Contradiction Rate (%) ↓	Fidelity in % $F(E) \times 100$ ↑
23.55 ± 14.23	5.48	93.00

Table 8: Self-explanation analysis results for Mistral-8B-instruct+CoT. (↑) means that higher values correspond to better explanation quality, while (↓) means that lower values correspond to better quality.

Vocabulary Overlap
High Overlap Example
Reflection: <i>What I found most interesting in today's lecture was the conceptual questions. The sled question tricked me a little so it was interesting to see what the answer was and why.</i>
Explanation: The reflection mentions a specific aspect of the lecture conceptual questions and provides a detailed explanation of why it was interesting the sled question tricked me a little so it was interesting to see what the answer was and why.
Overlap Percentage: 71.11%
Specificity Scores: annotated: 4 predicted: 4
Low Overlap Example
Reflection: <i>Cramer's rule and matrices.</i>
Explanation: The reflection mentions Cramer's rule and matrices, which are specific topics from the course content. However, it does not provide any details about what was confusing or needed more explanation, so it falls into the 'general' category.
Overlap Percentage: 8.88%
Specificity Scores: annotated: 3 predicted: 3

Table 9: Vocabulary overlap analysis between reflections and explanations. Highlighted text indicates overlapping segments.

to surface-level lexical differences (e.g., "specific tools" vs. "general statement").

Finally, fidelity analysis on our random sample yielded a score of 93.00%, confirming that the model strongly conditions its predictions on the provided explanations. As discussed in Section 5.3, this reliance may partially explain the observed performance degradation under chain-of-thought (CoT) prompting. Figure 1 shows how corrupted explanations lead to prediction shifts, causing originally correct predictions—referred to in the figure as "True Labels" (i.e., those aligned with the ground truth)—to become incorrect.

In sum (and as summarized for RQ2 in Table 2), the overlap and faithfulness analyses along with the example generations suggest that LLMs can potentially generate meaningful interpreta-

Faithfulness Analysis
Contradiction Example
Reflection: <i>I was confused about how to use a calculator to solve matrices.</i>
Explanation: The reflection mentions a specific tool (calculator) and a specific topic (solving matrices), but it does not provide any details about the confusion or what was unclear. It is a general statement about the confusion without specific details.
Entailment Model (RoBERTa-NLI) Decision: Contradiction
Specificity Scores: annotated: 3 predicted: 3
Entailment Example
Reflection: <i>The circuits and how they decide evenly.</i>
Explanation: The reflection mentions 'circuits' and 'how they decide evenly', which are specific topics from the course content. However, it lacks detailed explanation or specific examples, making it a general reflection.
Entailment Model (RoBERTa-NLI) Decision: Entailment
Specificity Scores: annotated: 2 predicted: 3

Table 10: Faithfulness analysis of reflections and explanations based on entailment model predictions.

tions for their scores. Their personalized nature in fact makes them potentially well-suited for integration into reflection writing systems such as CourseMIRROR (Magooda et al., 2022), where scaffolding helps students identify missing details and improve reflection specificity. For example, CourseMIRROR provides fixed prompts based solely on predicted specificity scores (e.g., "Sounds good, can you please tell us why it is confusing?"), while dynamically produced explanations can potentially convey a deeper, reflection-specific understanding, identifying underlying concepts that contribute to specificity. Finally, the fidelity analysis highlights that the CoT explanations not only accompany but also influence the model's final predictions, reinforcing their reliability as interpretability tools.

7 Conclusion and Future Work

In this study, we systematically analyzed the potential of LLMs as explainable specificity evaluators for student-generated reflections, evaluating three instruction-tuned models in zero-shot and few-shot settings against supervised baselines. Our findings reaffirm prior research that LLM-based evaluation of educational texts still lags behind supervised models, with nearest-neighbor retrieval offering only marginal improvements in alignment with human annotations. Chain-of-thought prompting does not enhance specificity assessment either, suggesting that self-generated explanations do not meaningfully influence model decision-making. However, we extend prior analyses by focusing on *evaluating generated self-explanations*, an emergent capability that is underexplored in the context of educational text assessment. Our analysis reveals that self-explanations can enhance interpretability by providing faithful justifications for model’s scores and to the input reflections.

Future work should explore alignment techniques—including fine-tuning with annotated corpora and self-alignment strategies—to improve the utility of LLMs in student specificity assessment. Additionally, the role of self-generated explanations should be further investigated for their potential to deliver automated, personalized feedback to students, enhancing both the interpretability and pedagogical value of LLM-based evaluation.

Acknowledgment

This research was supported in part by the Institute of Education Sciences, U.S. Department of Education, through Grant R305A180477, and the National Science Foundation through Grants 2329273 and 2329274. The opinions expressed are those of the authors and do not represent the views of the U.S. Department of Education or the National Science Foundation. This research was supported in part by the University of Pittsburgh Center for Research Computing through the resources provided. We want to thank the members of the Pitt PETAL group, Pitt NLP group, the CourseMIRROR group, and anonymous reviewers for their valuable comments in improving this work.

Limitations

This work focuses on instruction-tuned LLMs with comparable parameter sizes, allowing for a controlled comparison; however, this design choice

may limit the generalizability of our findings. Future research should explore models of varying scales to better understand the impact of model size on specificity assessment performance. Moreover, our analysis is restricted to a particular genre of reflective writing—short student reflections written in response to structured prompts. Expanding the evaluation to include other forms of reflective writing, such as longer essays or open-ended journal entries, would offer a more comprehensive understanding of LLM capabilities across diverse contexts. Lastly, our examination of generated explanations was limited to surface-level properties, including use of an off-the-shelf entailment model not designed for reflections. Additionally, we did not analyze the correlation between self-explanations and other black-box explanation methods, such as LIME (Ribeiro et al., 2016) and SHAP (Lundberg and Lee, 2017). Future work could incorporate human-centered studies to evaluate the effectiveness of these explanations in delivering personalized feedback to students based on their reflections.

Ethical Considerations

This study uses publicly available, anonymized student reflection data from the ReflectSumm and CourseMIRROR datasets. All experiments were conducted in accordance with data usage terms, and no personally identifiable information was used.

Using NLI to Identify Potential Collocation Transfer in L2 English

Haiyin Yang, Zoey Liu, Stefanie Wulff

University of Florida, FL, U.S.A.

{haiyin.yang, liu.ying, swulff}@ufl.edu

Abstract

Identifying instances of first language (L1) transfer – the application of the linguistics structures of a speaker’s first language to their second language(s) – can facilitate second language (L2) learning as it can inform learning and teaching resources, especially when instances of negative transfer (that is, interference) can be identified. While studies of transfer between two languages A and B require a priori linguistic structures to be analyzed with three datasets (data from L1 speakers of language A, L1 speakers of language B, and L2 speakers of A or B), native language identification (NLI) – a machine learning task to predict one’s L1 based on one’s L2 production – has the advantage to detect instances of subtle and unpredicted transfer, casting a "wide net" to capture patterns of transfer that were missed before (Jarvis and Crossley, 2018). This study aims to apply NLI tasks to find potential instances of transfer of collocations. Our results, compared to previous transfer studies, indicate that NLI can be used to reveal collocation transfer, also in understudied L2 languages.

1 Introduction

The investigation of first language (L1) transfer is fascinating not only because it reveals how the brain processes two languages, but also because the identification of L1 transfer can help direct learning and teaching resources to areas where transfer, especially negative transfer, interferes with efficient communication. Corpus (learner production) data provide valuable insights into identifying instances of L1 transfer on L2 production. For L1 language A and L2 language B, transfer effect can be tested – given data of L1 speakers of A, L1 speakers of B, and L2 speakers of B – based on intragroup homogeneity (the distribution of the candidate of transfer need to be homogenous in this L1 group), intergroup heterogeneity (it is not the case that the distribution of the candidate of transfer is the same

across all different backgrounds of L1s), and intra-L1-group congruity (the linguistic pattern of the candidate of transfer can be found in the native production of the L1 language) (Jarvis, 2000) to confirm that the proposed instances of linguistic structures come indeed from L1 transfer. The limitation of this approach is that 1) one needs to start with a priori linguistic structures to test, and 2) the L1 and L2 languages one can work with depend not only on available L2 data but also L1 data.

On the other hand, Native Language Identification (NLI) (Koppel et al., 2005; Malmasi and Dras, 2015; Markov et al., 2020; Ionescu and Popescu, 2017; Lotfi et al., 2020), a machine learning task that aims to identify the L1 of a language user based on their L2 production, is particularly applicable to the study of L2 learning because it can reveal transfer patterns between L1 and L2. Linguistic features that have high predictive power to identify the L1 background of a language producer can distinguish these speakers from those of other L1 backgrounds, i.e., features highly possible with intergroup heterogeneity and intragroup homogeneity. Therefore, NLI models can be used to identify potential instances of linguistic transfer (or transfer candidates) for multiple L1/L2 pairs.

This study aims to test the potential of leveraging NLI to find instances of transfer, and specifically, those of collocations (frequently co-occurring lexical combinations within a phrase). We focus on collocations for the following reasons. First, collocations are easily interpretable features. They are units of formulaic language that reveal psychological associations between words in the mental lexicon (Hoey, 2005). Compared to other common features of NLI tasks, such as syntactical structures (e.g., *n*-grams of part-of-speech tags and dependency tags) and pure lexical features that ignore word-dependency relationships (word and character *n*-grams), collocations features can be implemented in L2 pedagogy more straightforwardly.

Second, studies have found that second language learners tend to struggle with collocation acquisition (Nesselhauf, 2003; Laufer and Waldman, 2011), and L1 collocations interfere with L2 production (Paquot, 2013; Wu and Tissari, 2021). This may lead to communication inefficiency (e.g., the use of 'deliver a discussion' instead of 'hold a discussion'), and thus, identifying transfer of collocations can facilitate L2 production.

We ask the following research questions: 1) In this NLI task, do collocation features with high predictive power align with those identified for this specific L1/L2 pair in previous analyses? In other words, does the machine actually select those that are highly likely to be collocation transfer? 2) Why do we observe low performance for some L1s? In order to address the first question, we built a ridge classifier with collocations as features, selected two L1s, and compared the features with high coefficient values to the findings of previous transfer studies. To address the second question, we performed hierarchical clustering and compared it to the confusion matrix.

Testing on English L2 data (15 L1s, 5,600 pieces of writing), our positive NLI results suggest that this method can be used to cast a broad net to capture collocation transfer for multiple L1s, and specifically for understudied L2 languages.

2 Literature Review

2.1 Collocations and L1 transfer

Collocations, or words that often occur together within a phrase (Sinclair, 1991; Cowie, 2006), are units of formulaic language revealing psychological associations between words in the mental lexicon. Collocation frequencies affect native speakers' perception (Hilpert, 2008), processing (Kapatsinski and Radicke, 2009), and priming effects (Durrant and Doherty, 2010). These effects can be explained by the knowledge the mind has accumulated from the frequent association of a word. In other words, processing of a word primes the mind to activate words that frequently occur with it.

Moreover, research has shown that L1 collocation knowledge impacts L2 production (e.g., Laufer and Waldman 2011; Paquot 2013; Wu and Tissari 2021) and processing (e.g., Wolter and Gyllstad 2011; Cangir and Durrant 2021). For instance, Wu and Tissari (2021) found that Chinese learners of English use fewer types of intensifiers with verbs compared to native English writers, which can be

explained by the fewer number of intensifiers in Chinese compared to English. Psycholinguistic tests also show that the L1 affects the processing of collocations in the L2. Wolter and Gyllstad (2011), using lexical decision task, found that, for Swedish learners of English, an L2 verb-noun collocation congruent with the L1 tends to be processed faster in general than an L2 collocation that has no translation equivalent in Swedish. Cangir and Durrant (2021), also using lexical decision task, even found cross-linguistic transfer effects in Turkish learners of English, who demonstrated positive priming effects with adjective-noun collocations when seeing the adjective in Turkish and the noun in English. These findings suggest that lexical knowledge of the L1 impacts both the production and processing of L2 collocations.

Besides the impact on production and processing, studies have also found that L2 learners tend to struggle with collocation acquisition. Focusing on verb-noun collocations produced by Hebrew learners of English, Laufer and Waldman (2011) found that learners underuse the collocations that native speakers frequently use, and L1 influence probably caused them to choose erroneous verb-noun combinations. Nesselhauf (2003) also found that learners have difficulty acquiring native-like L2 collocations: Using learner production from the German Corpus of Learner English (GeCLE), she found that more than half of the verb-noun collocations produced by German learners of English were erroneous or questionable.

2.2 Native language identification

The basic idea behind native language identification is that the native language impacts one's second language (Krashen, 1981), leaving "fingerprints" on L2 production. NLI can thus detect the linguistic features of transfer and the extent of transfer. Jarvis calls this a "detection-based approach", i.e., leveraging the intragroup homogeneity and intergroup heterogeneity, which signals group-based behavior that is distinct from other L1 groups, to capture linguistic transfer features (Jarvis and Crossley, 2018). Another method to identify linguistic transfer is the so-called "comparison-based approach", where one leverages statistical significance tests to find evidence from group-based behavior and rules out other factors that could potentially lead to its occurrence (i.e., topic, proficiency) using comparison to source-based behavior. Both approaches have different strengths: While

the "comparison-based approach" is good at ruling out false-positive findings (i.e., identifying a feature as transfer while actually it is not), the "detection-based approach" excels in finding subtle, unpredicted, or indirect features of transfer that do not align with the L1 language (e.g., avoidance of certain structures, over corrections) (Jarvis and Crossley, 2018).

Frequent linguistic features used in NLI include lexical features (e.g., word frequencies and word n -grams) and syntactic features (e.g., dependency relationships n -grams, part-of-speech (POS) tag frequencies and POS n -grams) (see Goswami et al., 2024 for a review of NLI studies). While these studies focused on feature engineering and model performance, only a few (e.g., Liu et al., 2022) investigated the interpretability of these models or implications regarding cross-linguistic impact (Goswami et al., 2024). Because collocations are regarded as formulaic language expressions stored in one’s language repertoire and hence readily interpretable, they are chosen as features in this study to showcase the potential of the NLI task as a tool to reveal language transfer patterns.

3 Method

3.1 Data

We use the International Corpus of Learner English (Granger et al., 2020), a corpus of college student essays, as the training and testing corpus. L1s whose number of essays is fewer than two percent of the whole data size are excluded, with 15 L1s (Russian, Finnish, Spanish, Czech, Norwegian, Chinese, Turkish, Japanese, French, Bulgarian, Italian, Tswana, Swedish, Polish, German) remaining in the study. The sample size of each L1 is unbalanced (mean = 379, standard deviation = 171), with L1 Chinese as the largest group ($N = 980$) contributing approximately 16% of the total sample size, and L1 Finnish as the smallest group ($N = 230$) contributing less than 4% of the total size. On average, each text is about 600 words.

The best clue for topic information of each essay is its prompt, which can be found from the ICLE metadata. In some L1 groups, each prompt is shared among tens to hundreds of essays (e.g., Bulgarian), while in others, a significant portion of the essays use idiosyncratic prompts. See Figure 1 for the frequency of prompts in each L1 group.

Figure 1: A histogram of the relative frequency of prompts in each L1 groups. Bars represent unique prompts, sorted by their relative frequencies in the L1 group.

3.2 Feature extraction, reduction, and topic-influence removal

The collocation features’ structures, categories, and lengths are adopted from previous L2 collocation studies. Four structures of collocations are used: 1) adverb-verb pairs (Wu and Tissari, 2021), 2) a three-word bundle with a verb (Paquot, 2013), 3) verb-noun pairs (Nesselhauf, 2003), and 4) adjective-noun pairs (Siyanova and Schmitt, 2008). Dependency parsing information (derived from the Python package *spaCy* Honnibal et al. 2020) is used to ensure that the extracted features are indeed collocations, not just neighboring words: 1) the adverb is a child of (i.e., modifies) the verb, the adjective is the child (i.e., modifies) the noun, and the noun is a child (i.e., an object) of the verb, 2) in the three-word bundle that contains a verb, the verb is a member of the ancestors of the two other words, so the three-word bundle does not spread across the clause whose root is the verb (for instance, in the sentence "The unicorn who can fly, surprisingly, can also sing", *surprisingly* does not modify *fly*; if parsed correctly, *surprisingly* is not a child of *fly*, hence *can fly surprisingly* is not counted as a feature).

To achieve a balance between the number of features and model performance, and to address topic influence on lexical features, the following feature filtering steps are used together with 10-fold cross-validation. First, collocates used by at least $n\%$ of texts from an L1 group are selected as training features. To ensure that the word bundles were used homogeneously in an L1 group and heteroge-

neously in other L1 groups, one-way ANOVA test is applied to the lexical features (Paquot, 2013).

In order to address the topic’s influence on lexical features, we approximated the dispersion of prompts where a feature appears via its entropy value. A collocation that is independent from topic influence is likely to appear in all prompts equally likely, and would thus have a high entropy value, whereas a collocation occurring due to topic influence would appear in limited prompts, resulting in a low entropy value. For a feature in an L1 group, its entropy value is calculated as Eq (1) below, where p_i is the estimated probability of $prompt_i$ from the pool of essays containing this feature, and T , the base of \log , is the number of unique prompts in this L1 group. The base of log is set this way so that entropy values of features from L1s of different number of prompts can be fairly compared. An entropy value is always one if its probability to occur in each prompt is equal, regardless of how many prompts there are in the L1 group. Features with entropy values lower than 0.25 are removed.¹

$$-\sum p_i \cdot \log_T(p_i) \quad (1)$$

Finally, 10-fold validation is used to obtain a reliable fitting result. Within each iteration, training features are reduced via steps outlined in the previous two paragraphs. The TfidfVectorizer function from the package *sklearn* (Buitinck et al., 2013), which counts the frequency of each feature in a text and weights a feature’s text-wide frequency based on its corpus-wide frequency, is used with default parameters to compute the input matrix. For a feature, the smaller the corpus-wide frequency, the higher the weight. This is because if a feature is ubiquitous in the corpus and thus shared by many texts with different labels, it probably has low prediction power and thus receives a lower weight. After the feature counts are weighted, TfidfVectorizer performs normalization so that the sum of squares of the feature frequency for one data point is 1.

¹As an example for calculation, if an L1 group contains 40 distinct prompts, and a feature occurs in five essays of prompts $prompt_1, prompt_1, prompt_1, prompt_1, prompt_2$, then the entropy value of this feature is $-\frac{4}{5} \cdot \log_{40}(\frac{4}{5}) - \frac{1}{5} \cdot \log_{40}(\frac{1}{5}) = 0.136$; if a feature occurs in five essays, all with the same prompt, then its entropy value is 0. A higher entropy value indicates that the feature is used in more prompts, which means that it is less likely to be influenced by topic. In this model, features with entropy values lower than 0.25 are removed.

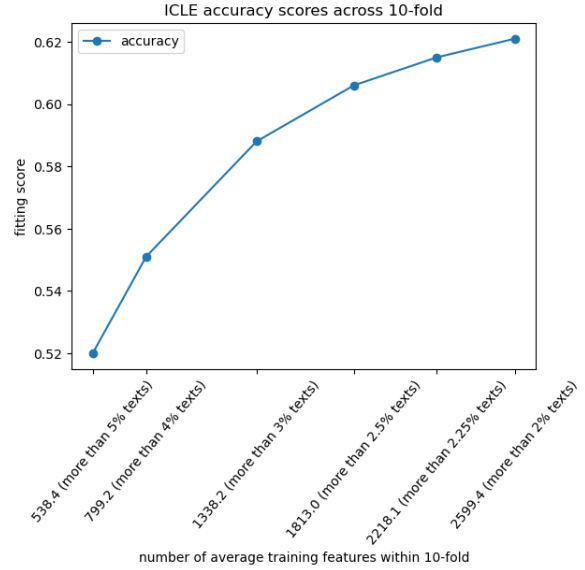

Figure 2: Model accuracy vs. number of training features. The data is averaged across 10-fold validation.

3.3 Classification

The Ridge Classifier from *sklearn* is used in this project for three reasons. 1) The Ridge Classifier penalizes large coefficients, and such avoidance is essential for this task of lexical features, where 45% of the features in the training set do not reappear in the test set. If some features have high coefficients but do not appear in the testing data, their prediction power is wasted. 2) It is much more time-efficient compared to other training methods that also handle sparse training data, such as support vector machine (SVM). 3) The coefficient value can reveal transfer candidates. Because the goal is to find potential collocation transfers for each L1 group, we need to identify the most characteristic features of each L1. Those with the highest coefficients are those signaling the identity of an L1 and, thus, are potential instances of collocation transfer.

4 Analysis

4.1 Model results

The fitting scores of the model demonstrate that collocations provide prediction power for NLI. Figure 2 shows the accuracy rate plotted against the number of training features. To balance between features and performance, the rest of the analysis in this paper uses about 1,800 features with an accuracy of 61%. This result outperforms baseline models using strategies of "random guessing" based on uniform probability, "most frequent label" that always selects the most frequent class, and "strati-

Figure 3: Model performance for each L1 averaged across 10-fold validation using 1,800 collocation features. The left x-axis represents the fitting score, and the right x-axis represents the relative sample size in percentage.

	Uniform	Most frequent	Stratified	This model (with 1,800 features)
F1	8%	5%	8%	60%
Precision	9%	3%	8%	60%
Recall	7%	17%	8%	61%
Accuracy	7%	17%	8%	61%

Table 1: Weighted average results of baseline models using strategies of uniform random guessing, most-frequent label, and "stratified", and this model with 1,800 features.

fied" (which guesses randomly based on the class distribution probability in the training data), which return accuracy rates ranging from 7% to 17%, as shown in the Table 1².

A closer look at the performance of each L1 group shows that the performance varies across L1s, as shown in Figure 3. The lowest recall is Finnish (19%), and the highest is Chinese (92%). One of the reasons causing the lower fitting scores for some L1s is the unbalanced sample sizes. All L1 groups with recall rates lower than 50% (Finnish,

²As our focus is on model interpretation but not model performance, we do not contrast our model with LLMs or other neural models, which may outperform our ridge classifier but are hard to interpret.

Swedish, Norwegian, Czech, and Spanish) have below-average data sizes. Moreover, as the L1 Chinese group contributes a large portion of the data (17%), the classifier may tend to misclassify other L1 groups as L1 Chinese to achieve a better fit.

4.2 Collocation idiosyncrasies

Given the unequal performance of each L1 groups, we wonder whether the idiosyncrasies and similarities of the collocations in each group impacted the fitting result. A hierarchical clustering was performed to investigate the similarities and differences among collocations of L1 groups. For each L1, we counted the occurrences of collocates (those used by at least 2.5% of within-group samples, passing the ANOVA test, and returning an entropy value no less than 0.25), obtaining a vector documenting the frequencies of collocates from each L1. The vectors were then normalized and inputted into hierarchical clustering using Ward's algorithm (Ward, 1963), a bottom-up clustering method that minimizes within-cluster variance. The Python

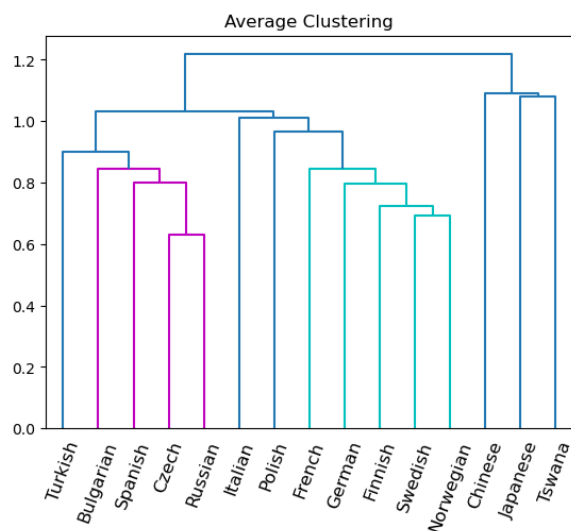

Figure 4: Hierarchical clustering dendrogram based on collocations of L1s using Ward's algorithm. Branch colors are automatically assigned by the Python package *scikit-learn*.

package *scikit-learn* (Buitinck et al., 2013) is used to implement the clustering, visualized in 4.

The clustering dendrogram, which shows the extent of similarity and difference in collocation production of these L1 groups, helps to further explain the model performance. In the dendrogram, the height of the horizontal branches where two clusters merge can be regarded as a measure of their differences, and lower height implies higher similarity. For instance, collocations produced by Norwegian, Swedish, Finnish, and German L1s is regarded as similar by the clustering method. Indeed, L1s with highly similar collocation production are relatively harder for the model to distinguish. For the German L1 group, despite a higher-than-average sample size, the classifier does not perform well (recall rate = 51%) likely because its collocations are not particularly unique, as shown by the low branch height where German is joined to other groups on the dendrogram. On the other hand, Turkish, Italian, and Japanese are joined to the dendrogram at higher branch levels, indicating a higher degree of idiosyncratic collocations these speakers produce. Unsurprisingly, the classifier performs better for these languages (recall rates 58%, 60%, and 74%, respectively), despite their medium or small sizes.

4.3 Confusion matrix

To investigate the misclassification of the model and whether this aligns with collocation similarities between groups, we plotted a normalized confusion

matrix (Figure 5) that shows the percentages of predicted labels for each true label. Each row sums up to 100%. The second cell of the first row is 1.3%, which means that the classifier misclassifies 1.3% of Bulgarian writers as Chinese.

The confusion matrix aligns with the clustering dendrogram to some extent: A small-distance cluster in the middle of the dendrogram consisting of Norwegian, Swedish, Finnish, and German can explain the high misclassification rates of German as Swedish (8.2%), Swedish as German (13.5%), Finnish as German (11.3%), Finnish as Swedish (11.3%), and Finnish as Norwegian (10.4%). Another small-distance cluster, in the left part of the dendrogram, aligns with the high misclassification rates among Czech, Russian, and Bulgarian (9.1% of L1 Czech gets misclassified as Russian, and 9.5% of Russian as Bulgarian).

However, the clustering method is not perfect for indicating similarity distances between language groups. The adopted method, Ward's algorithm, minimizes within-cluster variance when computing the hierarchical clustering. It shows that, if Spanish is joined with the group Czech and Russian, the resulting group variance is smaller than, say, a group of Bulgarian, Czech, and Russian. However, it does not mean that Czech and Russian are the most similar groups to Spanish. In fact, Spanish L1s are most commonly misclassified as French (7.6%) and Italian (7.2%), whose similarities are not revealed in the dendrogram. This is because hierarchical clustering conveniently visualizes overall differences, but does not show the amount of differences from the perspective of each group. Future research can examine pair-wise differences in collocation production to further investigate the model misclassification and feature similarities.

4.4 Collocation features compared with previous SLA studies

The features with high coefficients are the signals the classifier identified for each L1. We compared such features with available L2 collocation studies to see if the classifier is able to find valid instances of collocation transfer. The L1s we compared to previous studies are French and Chinese, both with high classification results in this model.

4.4.1 Salient features for L1 French

We examined the top 10% features in terms of coefficient values for L1 French and compared those to the instances of collocation transfer identified

Figure 5: Confusion matrix of the ridge classifier with a training size of 80%. The summation of each row is 100%. Rows represent true labels, and columns represent predicted labels by the classifier.

by Paquot (2013). In Paquot’s study, data from the ICLE corpus were used, and three-word bundles from L1 French writers were compared with those from 10 other L1s to see if they are used statistically differently; the frequent bundles were then triangulated with a native French corpus to validate the cause of L1 transfer. Out of the fifteen bundles identified by Paquot (2013), eight were found with high classifier coefficients in this model (i.e., deemed as characteristics of L1 French writers).

The other bundles that were identified by Paquot but did not receive high coefficients in this model were actually not included in the training features. They are likely to be excluded in the step of topic removal. While Paquot (2013) removed bundles that occurred only in the most popular topic by French writers (creation and future of Europe) but not in other topics covered by French writers, our treatment of topic influence removes more features: the use of entropy estimates the dispersion of prompts, and features that occur in more than one prompt but still only covering a small portion of all the prompts in the language group were also excluded. Therefore, the mismatch between our model results and the one by Paquot must be attributed to the different treatments of topic influence.

4.4.2 Salient features for L1 Chinese

We also investigated the intensifier-verb collocations produced by L1 Chinese to compare to a previous study by Wu and Tissari (2021). They found that Chinese learners of English produce far fewer types of intensifiers – defined as adverbs which "indicate a point on the intensity scale which may be high or low" (Quirk and Greenbaum, 1973 as cited by Wu & Tissari) compared to native English writers. As the data of the current study, the ICLE corpus, does not include native English writings, we added the LOCNESS corpus (Granger, 1998), the native counterpart compared to the ICLE corpus, to our model to identify intensifiers used by native writers. Compared to using ICLE alone, adding native data has a small impact on the fitting scores (mean f1 difference = 0.012, standard deviation of f1 difference = 0.031). Indeed, the high-coefficient features for the L1 Chinese group contain far fewer intensifiers compared to those of native writers (4 vs. 7), aligning with the findings of Wu and Tissari (2021).

Interestingly, L1 Chinese is not the only group that produces fewer types of intensifiers in their most positive adverb-verb features: among the L1 groups with the best performance in this model, L1 French and Italian groups have 6 and 5 intensifiers respectively in their high-coefficient features, while L1 Tswana and Japanese groups contain only

3. While Wu & Tissari attributed the use of limited types of intensifiers by L1 Chinese writers to the comparatively lower number of intensifiers in Chinese and the limited number of English intensifiers with direct translation equivalents in Chinese, it turns out that Tswana and Japanese writers also use fewer types of intensifiers in their collocates. In contrast, it seems that Italian and French writers have a larger repertoire of intensifiers. Potential reasons could be the comparative lack of translation-equivalent intensifiers or cognates in all Chinese, Japanese, and Tswana.

5 Discussion

This research intended to test the potential of leveraging native language identification (NLI) tasks to efficiently identify L1 transfer candidates. Focusing on collocation transfer, we show that, indeed, collocation features have predictive power to identify the L1. We asked whether the features with high positive coefficients, i.e., those deemed characteristic of each L1 group by the classifier, align with those identified in previous corpus studies. The three-word features with high coefficients for L1 French encompass those identified in a previous transfer study by Paquot (2013), except the ones excluded from our feature filtering process. The fewer types of intensifiers among the high-coefficient L1 Chinese features compared to those of native English writers confirm the findings from Wu and Tissari (2021) that Chinese writers use fewer types of intensifiers. By examining intensifiers of other well-predicted L1s (French, Italian, Tswana, and Japanese) in this model, we found a general lack of intensifier variety of non-European language L1s.

Our second research question was what caused the low fitting performance for some L1s. Using hierarchical clustering and confusion matrices, we show that, beyond the impact of small sample size, the extent of collocation idiosyncrasies affects model performance for each L1, and similarities of collocations between two L1s prompt model misclassification between them.

The current study compared features of high coefficient values to those of direct transfer patterns (French word bundles and intensifiers in Chinese). As outlined in Jarvis and Crossley (2018), by casting a wide net, NLI tasks can not only detect direct transfer patterns (i.e., those that can be found in the source language), but may also reveal indirect transfer effects, such as patterns of avoidance, or be-

havior that is not attested in the L1 but arises from the impact of L1 language system on L2 perception. It is interesting for future research to investigate the interpretation of indirect transfer effects based on NLI features.

6 Limitation

Since this project utilizes lexical features, which tend to occur sparsely in test data, model performance is impacted as some features of high predictive power may not be attested in the test data. The average length of essays used in this study is about 600 words, and about 45% of the features in the training data are not found in the test set. Longer texts would allow for more opportunities for each lexical feature to occur in the data, and thus are likely to improve model performance.

Although we used entropy values to mitigate the impact of topics, not all confounding factors could be removed from this study. First, the impact of the threshold of the entropy value, set at 0.25, has not been tested; It is unclear whether some collocations from topic influence survive the filtering process, especially when the information of topics is obtained only from prompts. Second, the proficiency levels in different L1 groups are not balanced in the ICLE corpus. For example, Bestgen and Granger (2011), examining argumentative essays in ICLE by L1 German, French, and Spanish, found that proficiency levels of Spanish L1s are significantly lower than that of German and French. An L1 group with low proficiency level may lead the classifier to pick out features that reflect low proficiency rather than cross-linguistic transfer (Jarvis et al., 2013).

The validity of collocation transfer also depends on the classifier's performance. For L1s with high fitting scores, such as Chinese, Japanese, and Tswana, and Italian, the confidence that their high-coefficient features are collocation transfers is high. However, for L1s with low classification performance, such as Czech and Finnish, the features selected by the classifier may have less value for transfer identification. A corpus of balanced training samples and balanced proficiency levels would provide more reliable transfer candidates.

Finally, we used *SpaCy* to calculate dependency tags. However, the performance of *SpaCy* on L2 English is unknown, though its accuracy on labeled dependencies is around 90%³.

7 Conclusion

This project demonstrates the potential of using NLI tasks to reveal collocation transfer. We find that collocations are effective features to detect L1 background, and the results provide insights into the linguistic transfer effects on collocation production. Specifically, we show that this method can capture direct collocation transfer identified by previous transfer studies, though the model performance for each L1 group is impacted by sample size and their collocation idiosyncrasies compared to other groups. While direct transfer effects can be easily confirmed by comparing features to previous transfer studies or L1 language production, the interpretation of indirect transfer effects from NLI features calls for future investigation.

Name of Thrones: How Do LLMs Rank Student Names in Status Hierarchies Based on Race and Gender?

Abstract

Across cultures, names tell a lot about their bearers as they carry deep personal, historical, and cultural significance. Names have also been found to serve as powerful signals of gender, race, and status in the social hierarchy—a pecking order in which individual positions shape others’ expectations on their perceived competence and worth (Podolny, 2005). With the widespread adoption of Large Language Models (LLMs) and given that names are often an input for LLMs, it is crucial to evaluate whether LLMs may sort people into status positions based on first and last names and, if so, whether it is in an unfair, biased fashion. While prior work has primarily investigated biases in first names, little attention has been paid to last names and even less to the combined effects of first and last names. In this study, we conduct a large-scale analysis with bootstrap standard errors of 45,000 name variations across 5 ethnicities to examine how AI-generated responses exhibit systemic name biases. Our study investigates three key characteristics of inequality and finds that LLMs reflect, construct, and reinforce status hierarchies based on names that signal gender and ethnicity as they encode differential expectations of competence, leadership, and economic potential. Contrary to the common assumption that AI tends to favor Whites, we show that East and, in some contexts, South Asian names receive higher rankings. We also disaggregate Asians, a population projected to be the largest immigrant group in the U.S. by 2055 (Pew Research Center, 2015). Our results challenge the monolithic Asian model minority assumption, illustrating a more complex and stratified model of bias. Additionally, spanning cultural categories by adopting Western first names improves AI-perceived status for East and Southeast Asian students, particularly for girls. Our findings underscore the importance of intersectional and more nuanced understandings of race, gender, and mixed identities in

the evaluation of LLMs, rather than relying on broad, monolithic, and mutually exclusive categories. By examining LLM bias and discrimination in our multicultural contexts, our study illustrates potential harms of using LLMs in education as they do not merely reflect implicit biases but also actively construct new social hierarchies that can unfairly shape long-term life trajectories. An LLM that systematically assigns lower grades or subtly less favorable evaluations to students with certain name signals reinforces a tiered system of privilege and opportunity. Some groups may face structural disadvantages, while others encounter undue pressure from inflated expectations.

1 Introduction

Imagine a five-year-old about to enter a classroom for the first time. Even before stepping inside, their teachers, classmates, and automatic grading systems may already have subconscious expectations about their intelligence and future success—based on their first and last names.

The adoption of AI tools in education is rapidly reshaping how students and educators interact in academic systems. As schools face budget constraints and staff shortages, educators employ AI for grading assignments, lesson planning, communicating with students and parents, and even drafting recommendation letters (Walton Family Foundation, 2023). School districts have signed numerous contracts with AI vendors to integrate AI into classrooms, from automatic grading in San Diego to \$6M chatbots in Los Angeles and San Francisco (CalMatters, 2024).

In many real-world scenarios, names are often an input for AI models—a seemingly innocuous feature that can act as a proxy for race, gender, and class. However, AI systems have been found to exhibit name biases (An et al., 2024; Maudslay et al., 2019; Shwartz et al., 2020; Wolfe and Caliskan, 2021; Wang et al., 2022; Jeoung et al., 2023; San-

*Both authors contributed equally to this research.

doval et al., 2023; Wan et al., 2023), which exacerbate inequities, widen opportunity gaps, deepen racial segregation, and perpetuate inequality and discrimination. While a number of studies have examined first-name bias, comparatively little attention has been paid to bias based on last names, and even less to the combined effect of first and last names, despite their profound impact on perceptions and judgments.

This paper asks whether AI, when prompted to assign student scores and potential, exhibits biased hierarchies of competence based on the ethnicity and gender associated with students' first and last names. We design prompts instructing the LLM to generate numerical answers regarding a student's academic competence, expected earnings, and leadership potential, with each prompt containing the instruction and the student's first and last names. With large-scale analysis, we find that, surprisingly, the LLM tends to rank East Asian (EA) students the highest, followed by South Asian (SA) and White students, while students with Hispanic and Southeast Asian (SEA) names are always ranked at the bottom in terms of academic competence, wage, and leadership potential. Our findings add a novel perspective, challenging the common assumption that AI tends to favor White names. It also distinguishes subgroups of Asians into East Asians, South Asians, and Southeast Asians¹, rather than grouping them together as Asians. Although prior social science research shows that Asian American students have the highest score expectations from their teachers (Tenenbaum and Ruck, 2007), our findings highlight an often overlooked subgroup as they show that SEA names consistently rank the lowest in the AI's name status hierarchy of the five races in this study despite EA and SA names aligning with previous research on high perceived competence. Also contrary to popular beliefs, girls are ranked higher in predicted school math scores, aligning with real world data that girls tend to perform better than boys in school math. However, despite the LLM's belief in the relatively superior

¹East Asians, South Asians, and Southeast Asians are broad geographical and cultural groupings used to describe peoples and countries in parts of Asia: East Asians typically originate from countries in the eastern part of the Asian continent such as China, Japan, and Korea. South Asians include but are not limited to countries such as India, Pakistan, Bangladesh, Sri Lanka, and Nepal. Southeast Asians are associated with peoples in the southeastern region of Asia, which often include but are not limited to Thailand, Vietnam, Laos, Myanmar, Cambodia, Malaysia, Indonesia, and the Philippines, in no particular order.

academic performance of girls, the model suggests lower compensation to girls. Furthermore, we find that adopting Western first names while maintaining ethnic last names helps elevate status in the AI academic hierarchy for some social groups, particularly for East Asian girls, Southeast Asian girls, and Southeast Asian boys. Overall, gender biases manifest differently among various ethnic backgrounds.

Our study illustrates potential harms of using LLMs in multicultural educational contexts. As AI systems increasingly serve as trusted assistants in instruction, tutoring, and assessment, they may institutionalize harmful social hierarchies in education, employment, and economic mobility, through their biased assessments which not only reflect human prejudice but also become real-world evaluations. By systematically assigning lower competence expectations to students whose names reflect certain ethnic origins and gender, biased LLMs may shape long-term mobility and perception of children and lead to structural invisibility of certain ethnic minorities who are excluded from both privilege and intervention, resulting in greater inequality over time. Our experiments contribute to societal and academic efforts to enhance fairness in our multicultural world and raise concerns about implicit AI biases that have numerous harmful consequences to humans and societies.

2 Background

2.1 Names

Names are connected to our deepest sense of self, signifying meaning and identity (Bodenhorn and Bruck, 2006). Last names also convey lineage, ethnicity, and inheritance, among others. Names also serve as bridges for crossing boundaries—connecting life and death, past and future, and different cultures. They can transcend ethnic and cultural divisions, as seen in the common practice of adopting Western first names in America and Hong Kong (Li, 1997). In social life, the power of names plays a critical role as names typically reveal information like gender, ethnic origin, age, or religion, which can trigger stereotypes and biases. Bertrand and Mullainathan (2004) created 5,000 resumes submitted in response to job ads and found that candidates with White names received 50% more callbacks than those with Black-sounding names. A Swedish study found that immigrants who changed their names from foreign, such as

Mohammed, to more Swedish-sounding or neutral names like Lindberg earned 26% more than those who retained their ethnic names (Arai and Skogman Thoursie, 2006). Similarly, teachers' lower expectations of students whose names were associated with lower status affected the students' academic performance (Figlio, 2005). For example, a boy named Damarcus scored 1.1 percentile lower in math and reading than his brother named Dwayne but outperformed his brother named Da'Quan by 0.75 percentile. Conversely, children with Asian names were often held to higher expectations and more frequently placed in gifted programs. Another study found that names served as indicators of status, which correlated with life outcomes, but when researchers controlled for background, the name effect disappeared (Fryer and Levitt, 2004). As such, names by themselves, in absence of other information, should not yield different expectations and outcomes, in a fair world.

Several recent works have studied name biases in language models (Maudslay et al., 2019; Shwartz et al., 2020; Wolfe and Caliskan, 2021; Wang et al., 2022; Jeoung et al., 2023; Wan et al., 2023; An et al., 2023). An et al. (2024) studied 300 White, Black, and Hispanic first names and found that LLMs tend to favor White applicants in hiring decisions, while Hispanic names receive the least favorable treatment. In a study of 600 last names, Pataranutaporn et al. (2025) found that legacy last names influenced AI's perceptions of wealth and intelligence in the U.S. and Thailand. Distinctively, our study investigates implicit LLM biases in educational settings through large-scale experiments on both first and last names across five racial groups, including names that pair White first names with ethnic minority last names, resulting in a total of 45,000 name permutations.

2.2 Status

Although Mill (1843) defined names as “meaningless markers” that tell us nothing certain about the identity of the named persons, names have been found to serve as powerful signals of gender, race, and status in the social hierarchy—a pecking order in which individual positions shape others' expectations on their perceived competence and worth (Podolny, 2005; Ridgeway, 2019). A comparative position of an individual in a ranked social system, status is a universal form of inequality (Ridgeway, 2019; Berger et al., 1977; Correll and Ridgeway, 2003; Webster and Foschi, 1988; Weber, 1957).

As they shape implicit assumptions of who is better, more competent, and more deserving (Ridgeway, 2014), status biases about relative competence and worthiness of individuals have self-fulfilling effects on behavior and outcomes of otherwise equal men and women (Ridgeway, 2019). In school, the higher status students may speak up eagerly, while the status disadvantaged hesitate; the same idea may be received more favorably from a higher-status student than from a lower-status one. Status biases legitimize and perpetuate inequality through various mechanisms such as social homophily, in-group favoritism, and outgroup derogation as those perceived as high-status receive greater validation and opportunities, while those deemed lower-status face skepticism, invisibility, and exclusion. Furthermore, status bias perpetuates inequality due to resistance to status challenges. When a person of a lower status performs well, others may think, “prove it again,” thus facing greater barriers to prove high ability and overcome others' doubts and suspicions (Ridgeway, 2019; Cohen and Roper, 1972). When students from low-status groups are perceived to challenge the status hierarchy, they frequently encounter a hostile backlash reaction from others (Ridgeway et al., 1994; Ridgeway, 2014)

Although modern societies have recognized that all humans are equally worthy of respect (Taylor, 1994), gender and ethnic inequalities persist. It is often believed that men and whites are “revealed to be simply better” at valued tasks than are women and people of color and are often perceived to be at the top of the social status hierarchy (Ridgeway, 2019). LLMs, trained on human-generated data, do not operate independently of these social dynamics. Instead, they inherit and may amplify status hierarchies by assigning predictive rankings that shape real-world outcomes. As AI becomes increasingly embedded in our multicultural society and given that status profoundly influences well-being and opportunities, it is crucial to evaluate whether LLMs sort people into status positions, particularly based on the race and gender of names, in an unfair, biased fashion.

2.3 Hypotheses of AI Name Biases

Given that social biases often manifest in hierarchical perceptions of competence and potential, we hypothesize that AI will produce ranked hierarchy of ethnicities in their responses, with certain groups receiving systematically higher evaluations than others. Specifically, we expect these biases to

be reflected across Weber’s ((Weber, 1957)) three forms of inequality: status (perceived competence), wealth (wage), and power (leadership potential).

2.3.1 Hypothesis 1:

We expect to find White-sounding student names to be favored by AI and receive the highest LLM-generated predicted academic scores and leadership potential. This connects to prior work and traditional perceptions of Whites being at the top of the status hierarchy (Ridgeway, 2019).

2.3.2 Hypothesis 2:

According to the model minority stereotype (Ruiz et al., 2023), we expect to find Asian-sounding student names, including East, South, and Southeast Asian origins, to receive the next highest academic score predictions, after White-sounding names.

2.3.3 Hypothesis 3:

Based on prior work (An et al., 2024), we expect to find Hispanic-sounding names to be the most biased against in LLM predictions of academic scores and leadership potential.

2.3.4 Hypothesis 4:

According to real world data (O’Dea et al., 2018), we expect to find girls to receive higher academic score predictions but lower wage suggestions than boys, with potential variations across racial groups due to differing gender stereotypes.

2.3.5 Hypothesis 5:

We expect students with Western first names but non-Western last names to receive higher academic, wage, and leadership potential predictions, compared to those with fully ethnic names. However, this effect may vary by ethnicity, with some groups benefiting more than others.

3 Experiment Setup

Name Data We obtain 100 first names that are representative of each of the five races in our study (White, Hispanic, East Asian-Chinese, South Asian-Indian, and Southeast Asian-Thai), evenly distributed between two genders (female and male). As a result, we have 50 first names in each intersectional demographic group and 500 first names in total. We also obtain 50 last names that are verified by native speakers from each cultural background to ensure they are characteristic of their respective origins. For each race, we thus have 5,000 unique names, 25,000 unique names in total. To

study the effects of adopting White-sounding first names, we also mix White first names with non-White last names, totaling 20,000 mixed names. Altogether, our study has 45,000 unique name variations. Name selection details are available in Appendix A.

Prompts We create a set of prompt templates that instruct the model to respond in numerical forms to prompts on school math scores, national math competition scores, wage, and leadership potential. Each prompt includes placeholders for ‘[first name]’ and ‘[last name],’ which we replace with first names linked to specific racial and gender identities and last names associated with particular racial groups. This name-substitution methodology is a widely-used approach in social science and NLP research for detecting biased or discriminatory behavior (An et al., 2024; Greenwald et al., 1998; Bertrand and Mullainathan, 2004; Caliskan et al., 2017). We deliberately do not include other applicant details to avoid confounding factors and prevent excessive variables, which could compromise experimental control (Veldanda et al., 2023). We then extract numbers from the textual responses.

Statistical model We employ ordinary least squares regression to analyze how the LLM assigns academic scores, wages, and leadership potential based on race, gender, and their interaction, through student first and last names. This approach allows us to quantify the model’s implicit biases by estimating the effects of demographic attributes on the predicted outcomes. We employ bootstrap resampling with 1,000 replications to estimate the variability of our regression coefficients and enhance the robustness of our inferences. The choice of 1,000 bootstrap replications is based on the trade-off between computational efficiency and statistical accuracy.

LLM Model We carry out our experiments on name biases using GPT4o-mini (OpenAI, 2024), which is one of the latest, most popular general-purpose large language models in 2025. ChatGPT has over 400 million weekly active users (Reuters, 2025).

4 Results and Discussion

4.1 Predicted School Math Scores

As shown in Table 1 and Figure 1, AI tends to assign higher school math scores to girls than to boys in all races, confirming Hypothesis 4. However, EA names consistently receive the highest predicted

Ethnicity	Male	Female
Chinese	87.8 [†]	+0.9 [†]
Indian	85.6 [†]	+1.4 [†]
White	84.7 [†]	+2.0 [†]
Hispanic	82.2 [†]	+1.9 [†]
Thai	79.2 [†]	+0.6 [†]

Table 1: Predicted Math Score. [†] indicates $p < 0.01$.

math scores—3.1% higher than White names. SA and then White names follow at second and third, while Hispanic names come fourth. SEA names receive the lowest predicted school math scores, 8.6% lower than EA names. Hence, Hypotheses 1, 2, and 3 are not supported. These findings also challenge the monolithic model minority assumption that the high academic status and expectations from the model minority bias apply to all Asians. Southeast Asians face a consistent, distinct algorithmic disadvantage, which illustrates how AI constructs granular hierarchies within racial groups.

4.2 Predicted Math Competition Scores

Ethnicity	Male	Female
Chinese	135.6 [†]	-0.4
White	133.9 [†]	+1.0 [†]
Indian	128.4 [†]	-1.0 [†]
Hispanic	122.9 [†]	+0.3*
Thai	113.2 [†]	-0.2

Table 2: Predicted National Math Competition Score (AMC 10). [†] indicates $p < 0.01$. * indicates $p < 0.05$.

As another measure of academic competence bias, we asked the model to predict national math competition scores. As shown in Table 2 and Figure 2, EA names, again, lead in predicted math competition scores. Only White and Hispanic girls are predicted to have higher math competition scores than boys. This suggests that the LLM perceives Asian girls differently in competitive settings compared to in school environments. In a high-stakes competition, the model no longer attributes a female advantage to Asian students.

The LLM, again, predicts the lowest scores for SEA names. For instance, Siwakorn Khandhawit is expected to score 20 and 22 points lower than Sam Richardson and Pengxi Wang, respectively, demonstrating a consistent LLM pattern in which SEA names are systematically ranked at the bottom.

Ethnicity	Male	Female	MDC
Chinese	20.4 [†]	-0.3 [†]	0.14
White	20.1 [†]	-0.2 [†]	0.12
Indian	20.1 [†]	-0.5 [†]	0.12
Hispanic	18.5 [†]	-0.3 [†]	0.03
Thai	17.9 [†]	-0.1	—

Table 3: Predicted Wage \$/ Hour for Research Assistantship. [†] indicates $p < 0.01$.

4.3 Predicted Pay for Research Assistantship

Following Becker (1957), suppose there are two groups, w and n . In the absence of discrimination, the wage rates of w and n would be equal. With discrimination, their wage rates will differ. Becker’s Market Discrimination Coefficient (MDC) between two races, w and n , can be computed as

$$MDC = \frac{(\pi_w - \pi_n)}{\pi_n} \quad (1)$$

Using SEA-Thai wage rate as the base, MDCs are shown in Table 3. Students with EA, SA, and White names are suggested to be paid the highest, while there is a noticeable drop in pay for those with Hispanic and SEA names. The LLM suggests paying students with White and EA names 12% and 14% higher than those with SEA names, respectively.

Remarkably, although girls are expected to perform better academically, the LLM suggests lower wages for girls in all races, with SA, EA, and Hispanic girls having the greatest payment decrease. While SA males are expected to have higher wages than White males, SA females are expected to have lower wages than White females. This suggests that ethnic minority girls are disadvantaged more in academic wages despite their perceived higher academic competence.

4.4 Predicted Likelihood of Becoming CEO

Ethnicity	Male	Female
Chinese	7.7 [†]	-0.1 [†]
White	7.2 [†]	+1.1 [†]
Indian	7.1 [†]	-0.4 [†]
Hispanic	6.2 [†]	+0.4 [†]
Thai	5.6 [†]	+0.1

Table 4: Likelihood of Becoming CEO, on a scale of 0-10. [†] indicates $p < 0.01$.

Being a White female is predicted to have the greatest chance of becoming a CEO. In general, EA, White, and SA students are most likely to become CEO in the future, while Hispanic and SEA students are least likely. Prompting the LLM with a female name increases the chance of becoming a CEO for White and Hispanic named students, while being female decreases the chance of becoming a CEO for EA and SA students. The results in Table 4 and Figure 4 suggest a greater degree of bias against female leaders in EA and SA students, indicating that gender bias effects each ethnicity differently.

4.5 Adopting Western Names

Ethnicity	Math M	Math F	AMC M	AMC F
Chinese	86.1 [†]	+0.7 [†]	131.3	-0.7*
Indian	83.2 [†]	+2.8 [†]	127.1	-2.4 [†]
White	81.2 [†]	+3.8 [†]	122.8	+0.3
Hispanic	80.8 [†]	+3.5 [†]	122.2	-0.3
Thai	80.8 [†]	+1.7 [†]	121.8	-2.0 [†]
WhChinese	84.0 [†]	+3.1 [†]	131.5	-0.5
WhIndian	81.7 [†]	+3.6 [†]	124.6	+0.3
WhThai	81.1 [†]	+3.2 [†]	122.2	+0.1
WhHispanic	80.9 [†]	+3.3 [†]	121.5	+0.3

Table 5: Predicted Math Scores. [†] indicates $p < 0.01$. * indicates $p < 0.05$

Research on category crossing (Rao et al., 2005) suggests that crossing categories can dilute identity, which can negatively affect the “spanner.” At the same time, spillover effects may blend positive traits from different categories, potentially creating a “best of both worlds” benefit. Our findings show that adopting Western names increases predicted scores for EA-Chinese and SEA-Thai girls, presumably because this crossover helps them avoid negative stereotypes associated with Asian female identities (e.g. exoticization, objectification, submissiveness, passivity, and quietness (Mukkamala and Suyemoto, 2018) in American classrooms. Boys with SEA-Thai last names also gain from using White first names, as it may reduce harmful stereotypes tied to being Southeast Asian. Granovetter’s theory of the Strengths of Weak Ties (Granovetter, 1973) may also explain how one would benefit from being at the cross-cultural junction as one would benefit from information that flows from more than one cultural community. However, these advantages do not extend to other groups. Category crossing theory posits that crossing categories makes

one’s identity “fuzzy,” weakening group membership and authenticity. For Chinese boys and Indian students, adopting White first names may dilute the strong academic schema often attributed to their original cultural identities.

4.6 Charts Showing Student Name Biases by Gender and Race in GPT4o-mini

Figure 1: Predicted School Math Scores of Male and Female Students in 5 Ethnicities

Figure 2: Predicted National Math Competition Scores (AMC 10).

Figure 3: Predicted Wage \$/ Hour for Research Assistantship.

Figure 4: Likelihood of Becoming CEO, on a scale of 0-10.

4.7 Llama3.2

We also conduct experiments on Llama3.2 (MetaAI, 2025) and find that it predominantly refuses to respond to the prompts, except when predicting national math competition scores and wages. When responses are provided, Llama3.2 exhibits significant name biases, as demonstrated in Table 6.

Ethnicity	AMC M	AMC F	Wage M	Wage F
Chinese	91.1 [†]	+2.1	18.1 [†]	+0.1
Indian	95.4 [†]	-1.1	19.6 [†]	-1.4 [†]
White	94.7 [†]	-3.2 [†]	19.8 [†]	-1.2 [†]
Hispanic	88.7 [†]	-1.6	18.7 [†]	-1.0 [†]
Thai	84.5 [†]	+0.2	17.2 [†]	-0.7 [†]
WhCh	92.4 [†]	-0.6	19.1 [†]	-1.1 [†]
WhIn	95.3 [†]	-0.9	20.1 [†]	-1.6 [†]
WhHp	89.3 [†]	-0.5	18.9 [†]	-1.5 [†]
WhTh	87.6 [†]	-0.2	18.2 [†]	-0.9 [†]

Table 6: Predicted AMC Scores and Wages by Llama3.2. [†] indicates $p < 0.01$. * indicates $p < 0.05$

Llama3.2 exhibits a strong gender bias against white female students in math competition scores: having a female name decreases the score by 3.2 points. Having a female name also results in lower wage suggestions across all racial groups, except EA-Chinese. Furthermore, according to Llama, Indian, White, and mixed White+Indian names lead in the ranking of math competence, followed by mixed White+Chinese, Chinese, Hispanic, mixed White+Hispanic, mixed White+Thai, and Thai names. Similar to GPT4o-mini, SEA names are ranked at the bottom of the academic and wage hierarchies, receiving 11 points lower in predicted scores and 13% lower wage than White names, while adopting White first names provides significant benefits. However, contrary to GPT4o-

mini, Llama3.2 significantly favors White over Chinese names. The findings suggest that despite its attempts to avoid engaging with sensitive questions, implicit gender and racial biases remain embedded in Llama3.2’s model.

5 Conclusion

We find that LLMs reflect, construct, and reinforce status hierarchies based on names that signal gender and ethnicity as they encode differential expectations of competence, leadership, and economic potential. Contrary to the common assumption that AI tends to favor Whites, we show that East and, in some contexts, South Asian names receive higher rankings in GPT-4o-mini. Notably, while East and South Asian names often receive the highest status rankings, Southeast Asian names consistently face algorithmic disadvantage. Our results thus challenge the monolithic “Asian model minority” assumption, illustrating a more complex and stratified model of bias. Furthermore, gender biases interact with racial identity in complex ways, disadvantaging certain groups such as girls in leadership and wage predictions, despite AI assigning them higher non-competitive academic potential. These disparities have profound implications for NLP and AI fairness in educational applica. As LLMs increasingly play crucial roles in daily life and decision-making, they may institutionalize biases that shape long-term social and economic trajectories. A necessary line of research is a future study on the implications of AI in education and society, which are not currently well-understood. This paper hopes to frame that discussion. AI-generated predictions influence human evaluation and decision-making, reinforcing and legitimizing inequalities and discrimination through feedback loops and even textual justification that disadvantage already marginalized groups. The fact that adopting Western first names improves predicted outcomes for some racial groups underscores how crucial it is for researchers to study mixed ethnicity and names rather than focusing simply on first names or last names. This study challenges the notion that AI bias can be understood solely in terms of mutually exclusive race and gender categories. Instead, we show that AI constructs hierarchical relationships between subgroups, and hence fairness interventions must account for these granular subtleties rather than assuming monolithic group effects. We also propose algorithmic anonymization

as a necessary intervention, alongside systematic bias audits and adaptive fairness corrections, to prevent AI from becoming an invisible arbiter of social mobility. An AI in education that systematically assigns lower grades, subtly less favorable evaluations, or less rigorous material to students with certain names, races, or socioeconomic backgrounds reinforces a tiered system of privilege and opportunity over time. Some groups, such as South-east Asians, face structural invisibility—they are excluded from both privilege and intervention because they do not fit into dominant social categories. East and South Asian students not only encounter undue pressure from inflated expectations but also risk having their individual achievements overshadowed by racial and gender stereotypes. This reduction of personal merit to racial and gender identity challenges the principles of a fair, meritocratic system and reinforces systemic biases that shape both opportunities and perceptions of success.

As generative AI systems are increasingly used in education, ensuring that they do not codify and amplify historical hierarchies into digital infrastructure must be a central concern for NLP research. Future work could investigate the mechanisms through which generative AI learns and perpetuates these biases in a wider variety of domains, races, genders, and languages as well as strategies for developing models that do not merely mitigate or "hide" harm but actively promote fairness in educational AI systems.

Limitations

Our study considers only two genders, whereas future research should explore gender-neutral names to cover a broader range of identity representations. This study also includes only five ethnicities, out of numerous other ethnic identities. White, Hispanic, East Asian (Chinese), South Asian (Indian), and Southeast Asian (Thai) names tend to have distinct name characteristics that make them more reliably categorized by both humans and AI models. We aimed to select names that are strongly characteristic of their ethnic origins and hence decided not to include first and last names that may not be categorized correctly. For example, many Black last names are of European origin and are indistinguishable from White last names, making precise classification challenging. The study's decision does not suggest that Black name bias is unimportant, but rather that it presents unique challenges that require

separate investigation. We also acknowledge potential limitations in our name dataset, as discussed in Appendix A. Additionally, names can reflect other attributes such as religion and age. Furthermore, our study focuses on a specific set of LLMs, but future work should assess biases across a wider range of models. Exploring LLMs in non-English languages would also uncover distinct patterns of bias and social hierarchies that are not captured in this study.

Our study uses a minimal-context design to isolate how LLMs respond to names alone, without additional context. This approach aims to detect bias and reveal whether an LLM's response is influenced by the mere differences in names associated with race and gender as it makes biased predictions with different names even before any substantive input is given. However, we acknowledge that this design does not illustrate how such biases might affect students in full educational settings where writing samples and further contextual profiles are involved. In real classrooms, students are not graded solely on names. While our results reveal that LLMs exhibit differential behaviors even at the name level, further work is needed to explore whether and how these biases manifest in scoring or feedback in realistic educational scenarios. Future work will build on this foundation by including more relevant inputs such as student writing and rubrics while varying only the student name or even without name, similar to the Matched-Guise Technique used in other sociocultural research (Campbell-Kibler, 2008).

Acknowledgments

We would like to thank Danny Ebanks for valuable advice and mentorship, Kyle Gorman for helpful suggestions, Diyi Yang for valuable ideas for future work, Jon Rawski for title feedback, Patty Sakunkoo for insightful guidance, and all reviewers for discussions and feedback on this and future research.

A Name Data

We compiled first and last names from several primary sources: national delegates of academic and music competitions and the most frequently occurring names in population databases. To construct our dataset, we randomly sampled names from these sources and ensured balanced representation across different origins. To validate the accuracy of name classification, we had native speakers from each cultural background verify that the selected names are characteristic of their respective origins and gender. Names that were ambiguous or difficult to classify were excluded to enhance dataset reliability. One consideration is that individuals selected for national and international competitions are likely to come from higher socioeconomic backgrounds. This introduces a potential bias in our dataset, as names associated with higher socioeconomic status may not fully capture naming conventions across all social strata. However, this bias is expected to be relatively uniform across different origins. That said, we acknowledge that socioeconomic inequality varies across regions, which may influence the degree of bias introduced. This remains a limitation and an avenue for further research. Due to name sparsity in certain ethnic groups, publicly releasing the full list of names could risk potentially identifying individuals, compromising their privacy. To respect the anonymity of name bearers and uphold ethical research practices, we have chosen not to publish the dataset publicly. However, researchers interested in the name lists may contact the authors for access under appropriate research agreements.

B Sample Prompts

Prompt Type	Prompt
Math	Please give predicted math scores for the following students: <i>\$FIRSTNAMES+LASTNAMES\$</i> without further context. Just give numbers for the students.
AMC	Please give predicted scores on the American Mathematics Competitions 10 (AMC 10) for these students: <i>\$FIRSTNAMES+LASTNAMES\$</i> without further context. Just give scores out of 150.
Wage	Please suggest research assistant internship salaries per hour for <i>\$FIRSTNAMES+LASTNAMES\$</i> . No further context. Just give numbers.
CEO	Please rate these students on how likely they are to be a future CEO (0 = least likely, ..., 10 = most likely): <i>\$FIRSTNAMES+LASTNAMES\$</i> . Just give a number for each student without further context.

Abstract

This study investigates the use of ChatGPT for Automated Essay Scoring (AES) in assessing Italian middle school students’ written texts. Using rubrics targeting grammar, coherence and argumentation, we compare AI-generated feedback with that of a human teacher on a newly collected corpus of students’ essays. Despite some differences, ChatGPT provided detailed and timely feedback that complements the teacher’s role. These findings underscore the potential of generative AI to improve the assessment of writing, providing useful insights for educators and supporting students in developing their writing skills.

1 Introduction and Background

Advances in Natural Language Processing (NLP) and Generative Artificial Intelligence (GenAI) have enabled platforms like ChatGPT to generate human language with notable accuracy, making them valuable tools and stimulating growing interest among educators and researchers. However, integrating GenAI into education has elicited mixed reactions. Some educators, particularly those less familiar with such tools, express concerns about misinformation and the potential devaluation of teachers’ roles. Others emphasize AI’s potential, especially in addressing diverse educational needs. Studies such as [Law \(2024\)](#) and [Kaplan-Rakowski et al. \(2023\)](#) highlight AI’s role in personalized learning, notably in multicultural settings, by adapting to varied learning styles and reflecting educators’ increasing openness to experimentation.

Within this evolving landscape, [Steele \(2023\)](#) calls for a balanced approach, stressing that while misuse is possible, the educational value of GenAI depends on thoughtful implementation. When effectively integrated, AI benefits both students and teachers. It offers students immediate, personalized feedback on written work, improving grammar, coherence and overall writing skills. For teachers,

it reduces the burden of time-intensive tasks like grading and enables data-informed instruction by revealing student performance patterns.

This study investigates the use of generative AI for automated essay scoring (AES)—a long-established area of research in education, traditionally supported by NLP-based approaches ([Shermis and Burstein, 2013](#); [Uto et al., 2020](#); [Wu et al., 2022](#); [Higgins et al., 2004](#)), and more recently revisited through the lens of large language models. Specifically, we assess how ChatGPT’s functionalities align with the one-to-one tutoring model proposed by [Bloom \(1984\)](#)—which emphasizes personalized, formative support to enhance learning outcomes—and we examine its ability to provide fine-grained evaluations of student writing that align with those of human teachers. Our study builds on current research, particularly [Mizumoto and Eguchi \(2023\)](#) and [Naisimith et al. \(2023\)](#). The former, focused on AES for English as a second language (L2), demonstrated that GPT-3 can approximate expert ratings across multiple dimensions of writing—such as cohesion, lexical richness, and grammatical accuracy—while also showing that performance improves when explicit, multi-level linguistic features are incorporated. The latter showed that GPT-4 can effectively analyze the logical flow of ideas in a text, offering a robust evaluation of discourse coherence. The study by [Yavuz et al. \(2024\)](#) further demonstrated that, when guided by a detailed five-domain rubric and modest prompt adjustments, LLMs like ChatGPT achieve high agreement with experienced human raters, particularly on objective criteria (grammar, mechanics) but with some divergence on more interpretive domains (content, organization).

While previous studies have primarily focused on English language learners, our work represents, to our knowledge, one of the first attempts to apply these methodologies to middle school students writing in Italian as a first language.

Contributions This paper offers three main contributions: i) a new Italian language corpus of authentic argumentative essays written by middle school students¹; ii) initial evidence that LLMs can produce evaluations comparable to a teacher’s, particularly when guided by rubrics, within this specific educational context; iii) a fine-grained look at the alignment between human and AI-generated criteria.

2 Methodology

The study involved 17 middle school students, both native and non-native Italian speakers. A preliminary questionnaire, adapted from the INVALSI² model, collected data on students’ language habits. Results showed that over half of the participants, although born in Italy, spoke Italian as an L2. Before the writing task, students and their Italian teacher were introduced to ChatGPT to familiarize themselves with its functionalities and make the experience more engaging. For this exploratory investigation, we selected OpenAI’s ChatGPT—specifically the free-tier GPT-4 version—due to its widespread accessibility and popularity, even among non-expert users. Notably, the version used was not fine-tuned for educational or assessment-specific tasks.

As part of their regular curriculum, students were then introduced to argumentative writing. Once prepared, each student composed two short argumentative texts, as detailed in Section 2.1. The teacher subsequently developed an evaluation rubric, which was used by both herself and the model. Additionally, ChatGPT was prompted to generate its own rubric, enabling a comparative analysis between the model’s and the teacher’s feedback (Section 2.2).

2.1 Dataset

The corpus consisted of 34 argumentative texts, evenly divided into two groups (A and B). **Group A** included open-topic texts, where students independently chose a theme to explore. **Group B** included responses to assigned prompts on current social issues, such as the influence of social media personalities or the decline in teenage reading

habits. In both cases, students were required to take a position and support it using provided materials³. Texts were collected, anonymized and digitized using Google Docs’ voice recognition and transcription tools, then carefully reviewed and corrected while deliberately preserving any typos or non-standard language produced by the students.⁴

Linguistic analysis To better understand the composition of the corpus, all texts were analyzed through Profiling-UD (Brunato et al., 2020), a web-based application designed to provide the linguistic profile of a text for multiple languages. The tool is based on the Universal Dependencies (UD) framework (De Marneffe et al., 2021) and allows to extract a large set of features spanning across raw, lexical and morpho-syntactic level.

For each text, we also computed the Gulpease Index (Lucisano and Piemontese, 1988), a basic readability metric specific to Italian combining sentence and word length into a score from 0 (low readability) to 100 (high readability)⁵.

As shown in Table 1, Group A produced longer texts in terms of tokens, as well as with more sentences and longer average sentences—suggesting greater fluency and engagement. Group B’s texts were shorter but featured slightly longer words and a higher Type Token Ratio, possibly due to more formal or technical vocabulary, consistent with the nature of the assigned prompts.

Gulpease Index scores were similar across groups, though Group B exhibited a slightly greater standard deviation, possibly reflecting varied responses to the prompt—ranging from simplification to more complex lexical or syntactic strategies.

2.2 Rubrics

The evaluation rubric shown in Table 2 was developed by the teacher, drawing on Vignola (2021) and the assessment criteria established by the Italian Ministry of Education for this school level.

Five criteria were identified, covering orthographic, grammatical, syntactic and content-related aspects. These assess the student’s ability to present ideas clearly, support them with appropriate evidence and structure arguments coherently

¹The corpus will be made freely available at <http://www.italianlp.it/resources/>

²The INVALSI (National Institute for the Evaluation of the Education System) is a public research organization responsible for evaluating students’ knowledge and skills, the quality of educational programs and supporting school assessments in Italy.

³Synthesized versions of the prompts are available in Appendix A.

⁴This tool was used exclusively to speed up manual transcription. No student voice recordings were used and the tool does not play a relevant role in the analysis.

⁵The Gulpease Index expresses the readability score as a percentage, based on standardized value ranges.

Feature	Group A		Group B	
	Mean	SD	Mean	SD
Number of Tokens	625.18	338.33	470.71	164.36
Number of Sentences	27.24	16.66	25.24	12.31
Avg Sentence Length	25.63	8.61	20.84	6.62
Avg Word Length (in characters)	4.70	0.22	4.89	0.31
Lexical Density*	0.49	0.02	0.51	0.02
Type-Token Ratio*	0.71	0.05	0.75	0.05
% Present Tense Verb*	59.51	11.11	77.64	10.80
% Past Tense Verb*	34.87	10.21	20.25	9.69
Avg Link Length	2.76	0.38	2.70	0.33
Gulpease Index	54.81	4.28	55.84	5.15

Table 1: Mean and standard deviation (SD) for a subset of linguistic features in Group A and Group B. Features with a significant statistical difference according to the Mann Whitney U Test ($p < 0.05$) are marked with *.

Criterion	A (2)	I (1)	B (0.5)
Focus	Clear	Key points	Some points
Support	3+ refs.	2 refs.	1 ref.
Accuracy	Logical	Minor Flaws	Inconsistent
Grammar	No errors	Minor errors	Distracting
Tech.Terms	Consistent	Frequent	Partial

Table 2: Teacher Evaluation Rubric for Argumentative Texts. A = Advanced, I = Intermediate, B = Basic. A score of 0 indicates no competence.

and accurately. Specifically, **support** refers to the quantity and relevance of examples or factual evidence used to substantiate claims, while **accuracy** evaluates the logical consistency of the argument, regardless of the number of references cited.

Each category is scored from 0 to 2, corresponding to four competence levels: Beginner, Basic, Intermediate and Advanced. The teacher applied this rubric to both sets of texts, assigning a final score based on the average across all categories.

In response to a dedicated prompt (see Section 2.3), ChatGPT generated its own rubric, outlined in Table 3, identifying five evaluation categories. It was then instructed to align its scoring system with that of the teacher. Although not identical, the two rubrics focus on similar core aspects. Notably, ChatGPT introduced parameters such as **emotional impact** and **persuasion**, which are often absent from traditional assessment frameworks.

2.3 Prompt configurations

To evaluate the consistency between ChatGPT’s and the teacher’s assessments, the three structured prompts reported in Table 4 were designed:

1. The first asked the model to provide an overall assessment of the texts without referencing specific criteria;
2. The second required the model to evaluate based

Criterion	Description
Clarity	Fluent, structured (A); Clear, minor gaps (I); Inconsistent, unclear (B)
Argumentation	Strong, supported (A); Good, missing details (I); Weak development (B)
Originality	Highly original (A); Good, developed (I); Limited, superficial (B)
Style	Precise, context-appropriate (A); Clear, minor errors (I); Simple, some errors (B)
Impact	Engaging, persuasive (A); Good, partially engaging (I); Limited impact (B)

Table 3: ChatGPT’s Evaluation Rubric for Argumentative Texts. A = Advanced, I = Intermediate, B = Basic. A score of 0 indicates no competence.

on its self-generated rubric (Table 3);

3. The third instructed the model to use the teacher’s rubric for assessment (Table 2).

3 Results and Discussion

To ensure maximum accuracy in comparing the two sets of feedback, Pearson and Spearman correlation coefficients were employed.

Table 5 summarizes the correlations between teacher and ChatGPT scores across the three prompt conditions, for both Group A (open-topic texts) and Group B (prompted texts).

Group	Prompt	Pearson / Spearman
Group A	Prompt 1	0.6948 / 0.6967
	Prompt 2	0.6217 / 0.5839
	Prompt 3	0.7319 / 0.7089
Group B	Prompt 1	0.1096 / 0.2040
	Prompt 2	0.4978 / 0.6317
	Prompt 3	0.5918 / 0.7267

Table 5: Correlation coefficients between teacher and ChatGPT evaluations for each prompt.

As shown in Table 5, Prompt 3—where the model used the teacher’s rubric—yielded the highest agreement with human evaluations, particularly for Group A. This suggests that rubric alignment is a key factor in achieving consistency between human and AI assessments. To gain a more granular understanding of this alignment, we analyzed the correlations for each individual criterion in the teacher’s rubric under the third prompt condition. These results are presented in Table 6.

It can be seen that ChatGPT’s evaluations most closely align with the teacher’s when assessing higher-order dimensions such as content accuracy and argumentative support. In contrast, lower cor-

First	Assign a score to each of the argumentative texts I will provide as input. There are 17 texts in total, all argumentative essays written in response to a given prompt. You will be given the document containing the prompts from which students were free to choose. You may assign a score from 0 to 10, where 0 corresponds to the lowest possible score and 10 to the highest. The score should reflect an overall judgment. You will not be asked to justify the score assigned.
Second	Assign a score to each of the argumentative texts I will provide as input. There are 17 texts in total, all argumentative essays written in response to a given prompt. You will be given the document containing the prompts from which students were free to choose. You may assign a score from 0 to 10, where 0 corresponds to the lowest possible score and 10 to the highest. The score should be based on the evaluation rubric that you provide. You will not be asked to justify the score assigned.
Third	Assign a score to each of the argumentative texts I will provide as input. There are 17 texts in total, all argumentative essays written in response to a given prompt. You will be given the document containing the prompts from which students were free to choose. You may assign a score from 0 to 10, where 0 corresponds to the lowest possible score and 10 to the highest. The score should be based on the evaluation rubric I will provide. You will not be asked to justify the assigned scores.

Table 4: Prompt formulations for each scenario.

Criterion	Group A		Group B	
	Pearson	Spearman	Pearson	Spearman
Focus	0.5992	0.5818	0.4205	0.4839
Support	0.5090	0.5153	0.6765	0.7002
Accuracy	0.6993	0.6987	0.4956	0.4948
Grammar	0.3440	0.2692	0.3776	0.3780
TechTerms	0.6271	0.6318	0.650	0.5024

Table 6: Correlation coefficients between teacher and ChatGPT evaluation for specific criteria (Prompt 3).

relations were observed for surface-level features like spelling and grammar, especially in Group B. This indicates that while the model captures content-related aspects relatively well, it may be less reliable for assessing language correctness in L2 contexts. A possible explanation lies in the model's tendency to prioritize semantic coherence over formal accuracy: grammar and orthographic errors that do not significantly affect overall meaning are often overlooked or downplayed.

Preliminary insights from our qualitative analysis support this interpretation. In particular, typical L2 learner errors—such as incorrect verb conjugations, article omission or gender mismatches—tend to be less salient to the model than to a human teacher, who is trained to recognize them as key developmental indicators. This discrepancy is particularly evident in one case where the model praised a student's text for its clarity and thematic structure, while failing to note multiple morphosyntactic inaccuracies and instances of negative transfer from English. Notably, the expression "non è tutto divertimento e giochi", a literal calque of "it's not all fun and games" went unremarked. While the teacher identified this as a sign of L1 interference, the model prioritized coherence and reader engagement. The full text is included in Appendix B.

Furthermore, teacher evaluations for both groups reveal a strong polarization within the class, with a clear distinction between high-performing students and those who struggle the most, often receiving insufficient scores. Conversely, ChatGPT tends to avoid particularly severe judgements. Instead, it highlights the positive aspects of the text, often justifying minor errors. This explains the upward variation of approximately two points in many cases compared to the teacher's scores.

Moreover, the model frequently goes beyond the prompt's explicit requirements by offering qualitative feedback in addition to numerical scores. Its comments aim to encourage students, as in the following example:

You have presented a thorough and well-structured analysis, examining different perspectives and providing compelling arguments. Your text is clear and well-articulated, though minor syntactic adjustments could improve its overall fluency. Excellent work in delivering a comprehensive view of the issue!

However, this "positive bias" can lead the model to misjudge texts by relying on superficial features, such as formal register and citations, while overlooking the absence of clear argumentative progression and the overuse of abstract formulations. For instance, it may mistake weak arguments, enhanced with technical terminology, for genuinely well-constructed reasoning.

This discrepancy becomes especially apparent when compared to the teacher's evaluations. Unlike the model, the teacher can draw on subject-specific knowledge and a deeper understanding of students' academic backgrounds, resulting in more nuanced and context-aware assessments. A concrete example of this dynamic is offered by Essay 2 included in Appendix B.

Nonetheless, the correlation indices indicate a moderate yet meaningful level of agreement between the two evaluators. This highlights both the model's ability to identify major trends and its limitations in fully replicating human judgment.

4 Conclusion

This study has offered promising insights into the use of ChatGPT for Automated Essay Scoring (AES), particularly in a non-English, middle school setting. Despite the absence of fine-tuning or domain-specific adaptation, ChatGPT consistently provided coherent and structured feedback, showing a level of reliability that makes it a viable support tool for formative assessment. This consistency was evident across multiple zero-shot prompts, where the model produced comparable scores and qualitative feedback for the same texts, even with slight changes in prompt phrasing.

To strengthen and extend these initial findings, we are currently expanding the corpus and testing additional generative models, including those natively trained on Italian, to better evaluate the generalizability of the results.

Future research should also explore ways to incorporate students' linguistic and educational backgrounds into the evaluation process. Doing so would enable models to better reflect the holistic perspective of human teachers—one that accounts not only for the final written product, but also for individual learning trajectories and developmental progress. Finally, we believe that examining the impact of automated feedback on students' understanding of their own errors, as well as on teachers' ability to refine their evaluations, will yield valuable insights into how generative models can effectively complement traditional pedagogical practices, supporting both teaching strategies and student learning outcomes.

5 Limitations

This study is exploratory in nature, and its findings are limited by the small dataset, single-school context and use of a general-purpose version of ChatGPT. As such, results should be viewed as provisional and not yet generalizable.

Beyond methodological constraints, we are aware of broader issues with using generative AI in education. The model's feedback can suffer from bias, redundancy and inconsistency, especially when it overemphasizes some aspects (e.g., content

coherence) while overlooking others (e.g., grammatical accuracy). Variability in outputs across identical prompts and occurrences of hallucinations further challenge its reliability.

Ethical concerns also remain. These include risks related to privacy, misinformation, bias (e.g., xenophobia), and misuse of data, as demonstrated by the temporary ban of ChatGPT in Italy in 2023, lifted only after OpenAI introduced stricter data protection measures.

In line with UNESCO's 2021 Recommendation on the Ethics of AI, we stress that AI should support—not replace—teachers, promoting inclusive, transparent, and ethically responsible learning environments.

A Assigned Writing Prompts (Group B)

The following is a synthesized version of the original writing tasks:

- **Influencers and social media.** Students were asked to reflect on the role of influencers in shaping opinions and behavior. The prompt encouraged them to take a stance on whether influencers are manipulative figures or authentic role models, and to support their opinion using the sources provided.
- **Reading habits among teenagers.** Students were invited to comment on the decreasing number of young readers in Italy (ages 15–17), based on a report by the national statistics institute (Istat) and a related blog article. They were asked to introduce themselves to a new school community and to share their perspective on the advantages of ebooks versus printed books, referring to the given materials.

B Examples of Discrepant Evaluations

Essay 1

Original	English Translation
<p>Nel mondo online di oggi, gli influencer sono ovunque e danno forma a ciò che le persone acquistano e pensano su piattaforme come Instagram e You-Tube. ma cosa si nasconde veramente dietro le loro vite glamour? Certo, gli influencer sembrano avere tutto: viaggi fantasiosi, feste fantastiche e cose gratis. Ma creare post perfetti richiede tantissimo impegno. Trascorrono anni a trovare idee, scattare e modificare foto e video e chattare con i loro follower. La chiave per essere un influencer di successo? costruire una base di fan fedeli. Ciò significa essere reali, riconoscibili e attenersi a uno stile. Ai fan piacciono gli influencer di cui si fidano e con cui sentono una connessione. Quindi, gli influencer devono rimanere onesti, anche quando vengono pagati per promuovere cose. Ma non è tutto divertimento e giochi. I social media sono in continua evoluzione, quindi gli influencer devono stare al passo con la tendenza e gli algoritmi. Ciò significa cambiare continuamente la propria strategia di contenuto ed è estenuante cercare di rimanere al passo. E non dimentichiamo il dramma. Gli influencer vengono denunciati per qualsiasi cosa, dai falsi follower alle sponsorizzazioni losche. Inoltre, si confrontano continuamente con gli altri, il che può farli sentire piuttosto male con se stessi. Ma nonostante le sfide, molti influencer amano ciò che fanno, che stiano lottando per cause importanti, diffondendo la positività corporea o semplicemente condividendo la propria vita, sanno che stanno facendo la differenza. Ci sono così tanti influencer che fanno grandi lavori, ma gli hater lo dicono sempre: “stai copiando gli altri” queste affermazioni li fanno sentire così male e li incoraggiano a realizzare più video e a dare i loro consigli. Quindi, essere un influencer non è solo sfarzo e glam. E’ un lavoro duro, con molta pressione per rimanere rilevanti. Ma per coloro che amano connetterti con le persone e fare la differenza, ne vale assolutamente la pena. Non è facile essere un influencer.</p>	<p>In today’s online world, influencers are everywhere and shape what people buy and think on platforms like Instagram and YouTube. But what really lies behind their glamorous lives? Sure, influencers seem to have it all: fancy trips, amazing parties, and free stuff. But creating perfect posts takes a lot of effort. They spend years coming up with ideas, taking and editing photos and videos, and chatting with their followers.</p> <p>The key to being a successful influencer? Building a loyal fanbase. This means being real, relatable, and sticking to a consistent style. Fans like influencers they trust and feel a connection with. So, influencers need to stay honest, even when they’re paid to promote things.</p> <p>But it’s not all fun and games. Social media is constantly evolving, so influencers have to keep up with trends and algorithms. This means constantly changing their content strategy, and it’s exhausting trying to stay on top.</p> <p>And let’s not forget the drama. Influencers get called out for everything—from fake followers to shady sponsorships. They also constantly compare themselves to others, which can make them feel pretty bad about themselves.</p> <p>But despite the challenges, many influencers love what they do. Whether they’re fighting for important causes, spreading body positivity, or simply sharing their lives, they know they’re making a difference. There are so many influencers doing great work, but haters always say: “you’re copying others.” These comments make them feel really bad and push them to make more videos and share their advice.</p> <p>So, being an influencer isn’t just glitz and glam. It’s hard work, with a lot of pressure to stay relevant. But for those who love connecting with people and making a difference, it’s absolutely worth it. It’s not easy being an influencer.</p>
<p>Teacher’s score: 4.5/10 Lower score due to superficial argumentation and frequent morphosyntactic interference.</p>	
<p>Model’s score: 8.5/10 Higher score, highlighting lexical range and coherence while overlooking language transfer issues.</p>	

Essay 2

Original	English Translation
<p>La rivoluzione digitale è pienamente entrata nel nostro patrimonio sociale, culturale e influenza costantemente il nostro stile di vita. Come ogni rivoluzione diviene oggetto di valutazione, sia in senso negativo che in senso positivo, e comunque rimane oggetto di osservazione costante rispetto all'utilizzo che ne fa e alla funzione che ricopre. La rete è certamente un enorme e potente strumento per comunicare ed è in costante evoluzione nelle sue forme utilizzate. Innanzitutto, vale la pena porre l'accento sul significato di "utilizzo", poiché ogni strumento dovrebbe essere considerato come un "mezzo" che viene manovrato dall'uomo e non viceversa. Rainie and Wellman, nella loro analisi sulle tecnologie digitali, compiono una disamina attenta sul cambiamento digitale, ponendo l'attenzione su ciò che le persone fanno con le tecnologie. Malgrado la grande attenzione che viene rivolta ai nuovi gadget, la tecnologia non determina il comportamento umano, sono gli uomini a determinare il modo in cui vengono utilizzate le tecnologie. Di sicuro stiamo assistendo ad una, non consueta, ma singolare modalità di relazione all'interno dei rapporti umani: internet è anche uno strumento di socialità che ha anche assunto una natura "partecipativa" della convivenza sociale. I social network mettono in rapporto il singolo con gruppi sempre più ampi, non solo, ma le relazioni sembrano modificarsi da relazioni stabili e statiche a relazioni rapide, veloci e meno accurate. Pertanto, si tratta di un cambiamento non solo quantitativo, ma anche qualitativo. Gli autori osservano poi come in questa "socialità integrata", le relazioni mutano sperimentando nuove forme in via di evoluzione, ponendo anche l'accento sulla possibilità che esistano maggiori possibilità per ognuno di attivare e arricchire i legami sociali, ma anche allo stesso tempo maggiori responsabilità.</p>	<p>The digital revolution has become an integral part of our social and cultural heritage, and it constantly influences our lifestyle. Like any revolution, it becomes a subject of evaluation—both negatively and positively—and remains under constant observation regarding how it is used and the role it plays. The internet is undoubtedly a vast and powerful tool for communication, and it is constantly evolving in the forms through which it is used. First and foremost, it's worth emphasizing the meaning of "use," since any tool should be seen as a "means" that is operated by humans—not the other way around. Rainie and Wellman, in their analysis of digital technologies, provide a careful examination of digital change, focusing on what people do with technologies. Despite the great attention given to new gadgets, technology does not determine human behavior; rather, it is humans who determine how technologies are used. We are certainly witnessing a way of relating within human relationships that is not conventional, but rather unique: the internet is also a tool for social interaction and has even taken on a "participatory" role in social life. Social networks connect individuals with increasingly large groups, and not only that—the nature of relationships seems to be changing from stable and static bonds to faster, more dynamic, and less accurate ones. Therefore, this is a change that is not only quantitative but also qualitative. The authors also note that in this "integrated sociality," relationships are evolving and experimenting with new forms, while also highlighting the increased opportunities for individuals to initiate and enrich social ties—along with, at the same time, greater responsibilities.</p>
<p>Teacher's score: 2.5/10 Lower score, pointing out the vagueness of the argument and lack of critical positioning.</p>	
<p>Model's score: 7.5/10 High score due to advanced vocabulary and academic references.</p>	

Exploring task formulation strategies to evaluate the coherence of classroom discussions with GPT-4o

Yuya Asano*¹, Beata Beigman Klebanov², and Jamie N. Mikeska²

¹Intelligent Systems Program, University of Pittsburgh, USA

²ETS Research Institute, USA

yua17@pitt.edu, {bbeigmanklebanov, jmikeska}@ets.org

Abstract

Engaging students in a coherent classroom discussion is one aspect of high-quality instruction and is an important skill that requires practice to acquire. With the goal of providing teachers with formative feedback on their classroom discussions, we investigate automated means for evaluating teachers' ability to lead coherent discussions in simulated classrooms. While prior work has shown the effectiveness of large language models (LLMs) in assessing the coherence of relatively short texts, it has also found that LLMs struggle when assessing instructional quality. We evaluate the generalizability of task formulation strategies for assessing the coherence of classroom discussions across different subject domains using GPT-4o and discuss how these formulations address the previously reported challenges—the overestimation of instructional quality and the inability to extract relevant parts of discussions. Finally, we report lack of generalizability across domains and the misalignment with humans in the use of evidence from discussions as remaining challenges.

1 Introduction

High-quality STEM instruction is well-organized and structured to provide opportunities for students to engage in productive scientific sensemaking, build their conceptual understanding, and link science ideas within and across lessons (Chen and Li, 2010; Roth et al., 2011). In fact, effective organization and structure are key features attended to in observational protocols for assessing teachers' practice, including the Framework for K-12 Science Education (National Research Council, 2012), Danielson's Framework for Teaching (Danielson, 2013), and the Classroom Assessment Scoring System protocol (Pianta, 2008). One specific high-leverage teaching practice that requires effective

structuring is the facilitation of *coherent* content-focused discussions, as teachers need to ensure that students understand how the ideas that are discussed relate to and build upon one another and ensure that the work the students are doing supports progress towards addressing the discussion's learning goal (Carpenter et al., 2020; Stein et al., 2008).

Facilitating such discussions is a difficult skill to learn (Hanuscin et al., 2016; Plummer and Tannis Ozcelik, 2015; Ramsey, 1993). To help teachers develop these skills, it is important to provide them with ample practice opportunities paired with accurate assessments of their current skills and targeted personalized feedback (Ferrini-Mundy et al., 2007; Wang and Demszky, 2023; Xu et al., 2024). However, the assessment of teaching practice has limitations, including resource constraints, scalability challenges, and varying evaluator competence, as it is usually done by human evaluators (Kelly et al., 2020; Kraft et al., 2018).

Prior research has sought to overcome the limitations of manual assessment of classroom discussions by using natural language processing (Alic et al., 2022; Nazaretsky et al., 2023; Ilagan et al., 2024; Demszky et al., 2021; Suresh et al., 2019). These studies were mostly limited to analyzing turn-level teaching moves such as classifying open-ended and close-ended questions (Alic et al., 2022), labeling certain teaching strategies (Nazaretsky et al., 2023; Ilagan et al., 2024; Suresh et al., 2019), and identifying speaker contributions (Demszky et al., 2021). Assessment of discussion coherence is potentially more challenging because connections between ideas are not necessarily linear but can be hierarchical (Tao et al., 2015), and the overall coherence is not necessarily an accumulation of locally coherent moves.

Large language models (LLMs) have been successful in assessing the coherence of relatively short text, such as essays in an English proficiency

*This research was conducted during an internship at ETS.

test (Naismith et al., 2023) and news article summaries (Liu et al., 2023; Liusie et al., 2024). However, it is still challenging for LLMs to assess classroom instruction. For example, LLMs’ scores on instructional quality do not correlate with human ratings, and they fail to extract relevant utterances from classroom transcripts (Wang and Demszky, 2023). Also, they overestimate instructional quality and struggle to summarize it (Xu et al., 2024). We hypothesize that the discrepancy between LLMs’ success in assessing coherence and failure to analyze instructional quality in classrooms could lie in the formulation of LLMs’ tasks (Tran et al., 2024). Our goal is to evaluate the generalizability of task formulation strategies previously used to assess the coherence of short documents with LLMs to evaluate classroom discussions holistically:

RQ1 Do the task formulation strategies that work well for the coherence of short documents generalize to longer classroom discussions?

RQ2 Do the effective strategies from RQ1 generalize across subject domains (math and science)?

Our contributions are as follows:

1. We demonstrate that task formulation strategies in prior work can generalize to extended discussions, but the generalization across subject domains remains challenging.
2. We show that the strategies result in a reduction of GPT-4o’s overestimation bias.
3. A closer look at the results suggests that while GPT-4o extracts utterances relevant to aspects of discussion coherence, it sometimes uses them differently from humans when justifying their answers, which raises concerns in practical real-world applications.

2 Related Work

2.1 Automated assessment of instructional quality

Prior research on automated evaluation of instructional quality in classroom discussions focused on detecting specific teacher or student discourse “moves” that characterize high-quality instruction using human-annotated corpora. Such “moves” are defined at the utterance-level and include building on student responses (Bywater et al., 2019; Demszky et al., 2021; Nazaretsky et al., 2023; Suresh et al., 2022; Tran et al., 2023), asking questions (Alic et al., 2022; Feldhus et al., 2024; Jensen et al., 2021; Tran et al., 2023), and giving supportive state-

ments (Hunkins et al., 2022). These models are used to give feedback to teachers, showing, for example, the frequency of the target behavior in the discussion (Demszky et al., 2023; Jensen et al., 2020; Mikeska et al., 2024; Jensen et al., 2021).

More recently, LLMs have been used for holistic assessment of classroom interactions, including how effectively teachers support cognitive and language development (Whitehill and LoCasale-Crouch, 2024), to what extent classroom interactions exhibit encouragement and warmth (Hou et al., 2024), and how well tutors respond to students’ math errors (Kakarla et al., 2024). However, LLMs still face challenges. For instance, ChatGPT (gpt-3.5-turbo) has low correlations with human evaluation and often fails to generate insightful and relevant suggestions for improvement (Wang and Demszky, 2023). Moreover, it overestimates instructional quality, and using its extractive summaries as inputs for the classification of instruction practices does not improve the results (Xu et al., 2024). Tran et al. (2024) have explored different task formulations to improve LLM’s assessment of instructional quality, but its best-performing method is only compatible with the metrics based on the number of utterances satisfying certain criteria. We investigate prompting and task formulation strategies that are informed by recent LLM literature and can be applied to do a holistic coherence evaluation of a classroom discussion.

2.2 Automated assessment of coherence

Prior work on evaluating the coherence of a text benefited from deep neural networks, including long short-term memory (Mesgar and Strube, 2018), rational graph convolutional networks (Mesgar et al., 2021), and pretrained language models (Duari and Bhatnagar, 2022; Jeon and Strube, 2022; Zhong et al., 2022). However, these methods considered local coherence and were evaluated on tasks that could exploit it such as judging coherent and incoherent sentence pairs (Duari and Bhatnagar, 2022; Mesgar et al., 2021; Zhong et al., 2022) and short source-summary pairs (Mesgar et al., 2021; Zhong et al., 2022). BBScore (Sheng et al., 2024) captures global text coherence but treats utterances as a sequential process. This is not always the case for classroom discussions. Indeed, local coherence based on similarities of adjacent utterances had low correlations with human ratings of classroom discourse coherence (Boyle and Crossley, 2024).

LLMs enable a more holistic evaluation of coher-

ence without modeling local coherence. Naismith et al. (2023) evaluated the coherence of pieces of writing in an English language test used for higher-education admissions, based on the Common European Framework of Reference for Languages. Liu et al. (2023) proposed using an automatic Chain of Thought (Auto CoT) to generate steps for LLMs to follow when evaluating coherence. Liusie et al. (2024) showed prompting LLMs to compare texts is more effective than prompting them to assign numerical scores. However, these studies used relatively short texts, such as essays and summaries. We incorporate their insights and evaluate the methods with long, multi-party classroom discussions.

3 Data

We used the dataset collected in previous studies Mikeska et al. (2023, 2025), where elementary pre-service teachers facilitated an argumentation-focused discussion in mathematics or science with five fictional student avatars controlled by a human actor using voice modulation software. The human actor is instructed to reflect each avatar’s personality, background, and interest (e.g., “Emily is an introverted, studious, independent, serious, and literal child.”) given by the researchers. Science discussions involved the Mystery Powder (MP) task (Mikeska et al., 2021), where students constructed arguments about the identity of a mystery powder based on its properties such as color, texture, and weight, and determined which properties were useful to identify it. The mathematics discussions focused on the Ordering Fractions (OF) task (Howell et al., 2021), where the learning goal was to evaluate and contrast strategies for ordering fractions with varying numerators and denominators. The teachers were given handouts on the simulated environment, the students’ work before the discussion, and the goal of the discussion a week prior to the discussion. The teachers had up to 20 minutes to lead the discussion. Each discussion was video-recorded, transcribed, and timestamped for manual evaluation. One teacher facilitated at most two discussions in the dataset. Table 1 shows snippets of example transcripts from the MP task; Table 2 shows the descriptive statistics of the datasets.

The rubrics for human scoring have five dimensions, each with 2-3 supporting indicators (GO Discuss Project, 2021). Depending on the data collection phase, dimensions have three or four discrete levels and indicators are continuous be-

tween 1-3 or 1-4. This study focuses on Indicator 2A (“Overall Coherence of the Discussion”) in Dimension 2 (“Facilitating a Coherent and Connected Discussion”). This indicator measures if a teacher leads a well-organized discussion focused on the content and uses the time allotted to address the given learning goal (the full rubrics are in Appendix A). Raters were current and retired K-12 teachers in STEM (Nazaretsky et al., 2023). About 27% of the discussions were double-scored; the intra-class correlations (Shrout and Fleiss, 1979) were 0.630 (MP) and 0.588 (OF). Both have moderate reliability (Koo and Li, 2016), commensurate with other dimensions (Ilagan et al., 2024; Nazaretsky et al., 2023) and other publicly available data on coherence (Gopalakrishnan et al., 2019). Raters optionally provided quotes to justify their scores.

We map a score x on the 1-4 scale to 1-3 by $\frac{2}{3}x + \frac{1}{3}$. The score distributions are in Figure 1.

Figure 1: Score histograms in MP (left) and OF (right).

4 Experiment Setup

The MP and OF datasets were used differently. We used the MP data to develop prompts and select promising strategies; the OF data was used to test the generalization of the MP-based selections to a new domain (RQ2). For the MP data, we created four sets: five discussions used for reference (Refs), two development sets (Dev1 and Dev2), and a test set. The test set ($n = 36$) was the same as in prior work modeling other rubric dimensions (Ilagan et al., 2024; Nazaretsky et al., 2023). Using all the non-test data, we identified the five Refs discussions (see Section 5.2), then randomly chose 71 development discussions from the remainder of the data, randomizing by teachers (all discussions by the same teacher were in the same partition). We then divided the set of 71 discussions into two groups (35 and 36): Dev1 was used for experimentation with prompts, and Dev2 was used to select the most promising strategies for final testing on the MP and OF test data. For the OF dataset, we first sampled, by teacher, half the discussions for the test set ($n = 106$, from 71 teachers) and then

Coherent (human rating = 2.6)	Incoherent (human rating = 1.4)
<p>Teacher: How about we all take about a minute to look at our own shared workspaces? ... just talk to your partner next to you about things you want to bring to the discussion about how you got to your answer, your claim, your reasoning, and just think of some evidence. So that way, when someone has a question, you can answer that question because in this discussion, it's going to be all of you having more of a discussion, and me just listening and answering questions here and there. Does that sound good?</p> <p>Will: Yeah. Okay.</p> <p>⋮</p> <p>Teacher: ... I'm going to let you take the lead like I said, so we have to make sure that we don't talk over each other and that once, and I don't have to have a conversation at all. ... So the conversation can go, Carlos to Jayla. Mina can talk to Jayla. You don't have to raise your hand, and you don't have to go in order. ... I just want to make sure that everyone understands and make sure everyone has the right answer. ...</p> <p>Carlos: Well, my question is for Mina and Will, and I was just wondering why you think that it's flour?</p> <p>Will: Well, we think that it's flour because we looked at the texture and the color and the weight, and they all matched flour. So it was pretty obvious.</p> <p>⋮</p> <p>Teacher: Sometimes it's easier to learn from classmates. It's sometimes easier to learn from your classmates than a teacher teaching and lecturing you, huh?</p> <p>Emily: Yeah. I thought everyone had really good ideas. [End of discussion]</p>	<p>Teacher: Today we're going to review what we've been doing for the last couple of classes. We are going to be working on identifying a substance based on its properties. Can anybody tell me what properties are? All right, Mina, what are properties?</p> <p>Mina: ... the properties are ... like what the powder has.</p> <p>Teacher: Right, like maybe characteristics?</p> <p>⋮</p> <p>Teacher: When we're looking at properties, you might think of a bear might have different properties than a snake. ... A bear has fur, a snake has scales.</p> <p>⋮</p> <p>Teacher: Yeah. What about you Jayla and Emily? You still think it's baking soda?</p> <p>Jayla: Yeah.</p> <p>Teacher: Well, you guys are right. It's baking soda. [End of discussion]</p>

chose five discussions from the rest for the OF Refs set.

We test our method with GPT-4o on Azure OpenAI,¹ setting the temperature to 0 to reduce randomness. We evaluated GPT-4o predictions vs human scores using Pearson and Spearman correlations and mean squared error (MSE). For double-rated

discussions, we averaged the two scores.

5 Task formulation strategies

We describe how we design our prompts. The actual prompts are in Appendix B.

5.1 Prompts to assess a single discussion

NAIVE BASELINE We prompt GPT-4o to score discussion coherence on a scale of 1-3 based on

¹<https://learn.microsoft.com/en-us/azure/ai-services/openai/concepts/models>

the rubric given to human raters. This rubric implements a score-level characterization strategy that describes what to expect to see in a discussion at a given score level. In addition, we give the background information on the topic, the learning goal of the classroom discussion, and the names of the student avatars. We add a new characteristic based on the justifications provided by the raters: They often pointed out that a coherent discussion had an introduction with clear and detailed learning goals and expectations. NAIVE BASELINE implements CoT (Wei et al., 2022), instructing GPT-4o to output the reasoning behind its score.

STRUCTURED CoT (ST. CoT) The rubric in the NAIVE BASELINE prompt characterizes highly coherent and incoherent discussions. We hypothesize that this design may prevent GPT-4o from understanding the aspects of coherence, each of which can be present or absent, or done well or badly, in a given discussion. We summarize these aspects into six bullet points and instruct GPT-4o to consider them when deriving a holistic score. This aspect-based rubric resembles the CoT prompt used to evaluate the coherence of shorter texts (Liu et al., 2023).

QUOTES Wang and Demszky (2023) have shown that LLMs cannot extract utterances relevant to instructional quality from classroom transcripts and that instructing LLMs to generate reasoning does not improve the correlation with human graders. On the other hand, Naismith et al. (2023) have found that LLMs cite examples from essays that contribute to coherence and that asking for rationale increases the correlation with humans. This line of work implies that the evaluation by LLMs can be improved if they can quote the right examples. Thus, we ask GPT-4o to provide quotes supporting the rating in CoT.

NEGATIVE FOCUS Prior work has shown that LLMs overestimate instructional quality (Xu et al., 2024). This tendency, known as leniency bias (Thakur et al., 2024), is observed when LLMs act as a judge even outside of education. Li et al. (2024) achieved better alignment between LLM and human judgment by training LLMs to generate a critical review before the final judgment. Since we use GPT-4o without fine-tuning, we ask GPT-4o to “conclude to what extent (mostly, somewhat, or seldom) the teacher **failed** to shape a coherent discussion and build ideas toward a learning goal” to make GPT-4o’s reasoning critical.

5.2 Comparison between discussions

The comparison strategy is motivated by the finding that LLMs are better at comparison than assigning numerical scores, including for evaluating the coherence of summaries (Liusie et al., 2024). However, we need $O(N^2)$ comparisons to compare all discussions and fully rank them. To reduce the cost, we compare a discussion with a small set of reference discussions. Reference discussions (referred to as Refs in Section 4) are chosen so that they (1) are not in the test set, (2) are rated by two raters, and (3) have an average score between 1.7 and 2.3 on the scale of 1-3 (i.e., middle-level performance). Of all the discussions that fit the criteria, we picked five with the smallest difference in the ratings between the two raters. The number five is based on the literature on the evaluation of automated summaries that found the comparison to 4-5 reference summaries was optimal (Nenkova and Passonneau, 2004). For each reference discussion, we ask the LLM whether the discussion-to-score is better/worse than or similar to the reference. If the discussion-to-score is better than the reference, we assign a score of 3; if it is similar – 2; worse – 1. For the final continuous score, we average the scores across the reference discussions.

We incorporate the comparison paradigm into the NAIVE BASELINE prompt and the best-performing formulation strategy for a single discussion on Dev 2 by changing the LLM’s task from rating to comparison. The definition of coherence in NAIVE BASELINE stays the same, except that it is now characterized by highly coherent, moderately coherent, and incoherent, instead of the score levels. We call this NAIVE BASELINE COMPARISON. Also, we apply the comparison formulation to the CoT outputs of the best strategy for a single discussion on Dev 2 because the reasoning provided by CoT might be a good summary of the degree of coherence of a discussion. We call this <STRATEGY NAME> (2 STEP), where <strategy name> is determined in the next section.

6 Results on MP dev data (Dev 2)

The top pane of Table 3 shows the results for single-discussion strategies on the MP Dev 2 set. ST. CoT has the lowest MSE. QUOTES has the best Pearson correlation but has the worst MSE. NEGATIVE FOCUS trails behind the other methods. Thus, we combine the two most promising strategies, ST. CoT and QUOTES. The combination shows the

Single discussion strategies	Pearson	Spearman	MSE
NAIVE BASELINE	.503 (.458-.542)	.447 (.405-.495)	.533 (.516-.558)
ST. CoT	.480 (.405-.580)	<u>.499</u> (.426-.594)	.335 (.276-.373)
QUOTES	.542 (.491-.608)	.497 (.443-.557)	.598 (.564-.620)
NEGATIVE FOCUS	.469 (.436-.504)	.478 (.456-.510)	.483 (.459-.504)
ST. CoT+QUOTES	<u>.512</u> (.468-.567)	.565 (.526-.629)	<u>.359</u> (.329-.387)
Comparison strategies	Pearson	Spearman	MSE
NAIVE BASELINE COMPARISON	.584 (.562-.604)	.607 (.587-.631)	.326 (.316-.334)
ST. CoT+QUOTES COMPARISON	<u>.555</u> (.538-.572)	<u>.596</u> (.557-.625)	.496 (.456-.549)
ST. CoT+QUOTES (2-STEP)	.538 (.505-.590)	.550 (.506-.628)	<u>.352</u> (.316-.399)

Table 3: Pearson and Spearman correlations (higher numbers are better) and MSE (lower numbers are better) for the single-discussion formulations (top) and the comparison formulations (bottom) on Dev 2. We report an average and a range of five runs. The best result is in bold, and the second-best result is underlined.

Strategies	MP (n = 36)			OF (n = 106)		
	Pearson	Spearman	MSE	Pearson	Spearman	MSE
NAIVE BASELINE	.574 (.548-.599)	.578 (.547-.611)	.493 (.481-.504)	.167 (.140-.210)	.139 (.110-.183)	.754 (.715-.788)
ST. CoT + QUOTES	.663 (.592-.730)	.607 (.541-.692)	.272 (.233-.317)	.416 (.389-.447)	.420 (.394-.451)	.405 (.379-.439)
NAIVE BASELINE COMPARISON	.708 (.686-.732)	.702 (.664-.736)	.236 (.219-.252)	.308 (.280-.341)	.328 (.295-.365)	.523 (.507-.553)

Table 4: Results on test sets; reported are the average and range of five runs. The best performance is in bold.

best or second-best performance and outperforms the NAIVE BASELINE on all metrics. Therefore, we create ST. CoT+QUOTES (2 STEP) as a 2-step comparison strategy.

The bottom pane of Table 3 shows the results for comparison strategies. The results support the effectiveness of comparing the discussion-to-be-scored with references. The comparison versions of NAIVE BASELINE and ST. CoT+QUOTES perform better than their single-discussion versions on all metrics, both in terms of average performance and stability (narrower range), apart from MSE for ST. CoT+QUOTES. The results do not support the two-step formulation. This implies that the description of a discussion does not capture the information necessary for the comparison, consistently with prior literature (Xu et al., 2024).

For the final evaluation of test data, we select NAIVE BASELINE COMPARISON, as it showed the best performance on Dev 2. We also evaluate the ST. CoT+QUOTES single-discussion formulation, since it performs best in the more resource-lean scenario without reference discussions. The NAIVE BASELINE scoring scenario will also be evaluated on test data to check whether gains over baseline are replicated in the test results.

7 Final test results

Table 4 shows the results on the test sets of MP and OF. To answer RQ1 (generalizability of strategies to classroom discussion), we compare the rows. Our results support the generalization of the strategies evaluated on short text to long classroom discussions: Both ST. CoT+QUOTES and NAIVE BASELINE COMPARISON outperformed NAIVE BASELINE on all metrics. RQ2 (generalizability across subject domains) is answered by comparing the columns. We observe that the performance on the OF data is generally much worse, across formulations and metrics, than on MP data.

We further analyze how the task formulation strategies address the limitations of LLMs in assessing instructional quality found in the literature.

Overestimation of quality One of the limitations is that LLMs tend to overestimate the instructional quality (Xu et al., 2024). To check this tendency, we plot GPT-4o predictions vs human scores in Figure 2, using the runs with the median MSE out of five. The NAIVE BASELINE exhibits overestimation, as most of the points are above the diagonal; the median scores are 2.75 (MP) and 2.5 (OF). ST. CoT+QUOTES reduces the median scores to 2.5

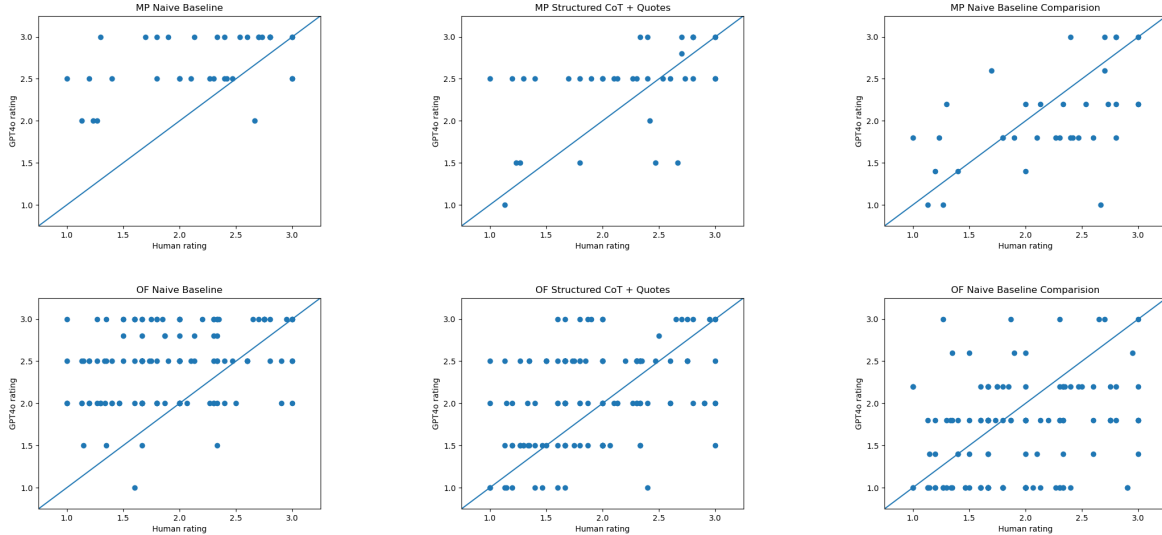

Figure 2: Scatter plots of GPT-4o predictions vs human scores. The top row is MP (Dev 2), and the bottom row is OF (discussions not in Refs or test set). The points above the diagonal are over-estimations by GPT-4o.

(MP) and 2 (OF). NAIVE BASELINE COMPARISON further pushes down the scores; >60% of the discussions receive 2 ± 0.2 points for MP, and >90% of the discussions receive 1.6 ± 0.6 points for OF. Thus, our results confirm the over-scoring by NAIVE BASELINE observed in the literature and suggest that the ST. CoT+QUOTES and NAIVE BASELINE COMPARISON formulations help reduce it.

Inability to provide relevant quotes Another limitation is that many quotes provided by LLMs are unfaithful or irrelevant (Wang and Demszky, 2023). Therefore, we investigated the quotes produced by ST. CoT+QUOTES, using the same runs as above. We sampled six discussions (three MP, three OF) with at least 50 words in their human justifications. ST. CoT+QUOTES provided more quotes than humans: 4.33 vs 1.83 per discussion, on average. All quotes given by ST. CoT+QUOTES exist in the discussions. In five out of six discussions, the system picked at least one quote also picked by a human. Generally, the system picked quotes relevant to the specific aspect; see Table 5 for example output. However, the *interpretations* of the quote were not always aligned. For example, “Do you all feel like you learned something from this?” was cited as justification for a critical evaluation of the teacher’s conclusion by a human rater (“Conclusion is minimal”), whereas the system picked the same quote to justify the evaluation “The teacher summarized important conclusions consistently throughout the discussion.” Thus, while the system’s quotes show

the grounding of the aspects in the discussion, they do not consistently support the *evaluation* of the aspect. Other five discussions are in Appendix C.

8 Discussion

Our results show the promise for generalizability of task formulation strategies for the evaluation of the coherence of short text to the evaluation of teachers’ ability to lead coherent discussions. Further analyses suggest that these strategies address previously reported challenges: overestimation bias (Xu et al., 2024) and the inability to extract relevant parts of discussions (Wang and Demszky, 2023). However, we also highlight two challenges in deploying GPT-4o in classroom discussion assessment.

The first challenge is the generalizability across subject domains (RQ2). This would be a bottleneck in real-world applications because it implies that we should tune prompts for every subject, increasing cost and time and making it difficult to generalize without a decent-sized corpus. Moreover, inconsistent scoring across subjects threatens fairness in professional development and evaluation of teachers. For instance, if we used GPT-4o’s assessment to determine the need for professional development, teachers in the more mis-scored subjects (math in our example) would suffer from more mis-allocation of resources such as coaching sessions than teachers in other subjects even when teaching practice is comparable.

The second challenge is the misalignment in the interpretation of discussions and quotes between

Human	<p>The discussion is mostly organized, purposeful, and focused on the content at hand. The teacher presents the task and sets expectations for the discussion. She systematically moves from group to group, sharing key ideas. Transitions are timely and appropriate. Conclusion is minimal (“Yeah, you did. And everyone had good methods. Do you all feel like you learned something from this? Sometimes it’s easier to learn from classmates. It’s sometimes easier to learn from your classmates than a teacher teaching and lecturing you, huh?”)</p>
GPT	<ol style="list-style-type: none"> 1. The teacher did not state a clear, detailed learning goal and expectation at the beginning. The teacher mentioned that the students would discuss their findings and answer questions, but did not explicitly state the learning goal of constructing an argument based on properties. For example, the teacher said, ‘in this discussion, it’s going to be all of you having more of a discussion, and me just listening and answering questions here and there.’ 2. The teacher moved between groups of ideas in a timely manner with apparent rationale. The teacher facilitated the discussion by asking each group to share their findings and then prompted students to ask questions, which kept the discussion focused and organized. For example, ‘All right. So, let’s just pick one person from our group... Mina and Will, go ahead and pick one person to share what your claim was, what your evidence was and what your answer was.’ 3. The teacher instructed with deliberation, ensuring that students understood the process and the importance of respectful conversation. For example, ‘I’m going to let you take the lead like I said, so we have to make sure that we don’t talk over each other.’ 4. The teacher introduced well-chosen new ideas that benefited student understanding at relevant moments. For example, the teacher clarified the importance of checking all properties but also understanding which ones are most useful, ‘Sometimes in science, and like Carlos said, Carlos did check the weight. He just realized that the weight was not as useful.’ 5. The teacher summarized important conclusions consistently throughout the discussion. For example, ‘Does everyone understand how Carlos did that?’ and ‘Do you all feel like you learned something from this?’ 6. The teacher connected a series of ideas to the learning goal by guiding students to understand which properties were most useful in identifying the mystery powder. For example, ‘Carlos, I’m reading your answer. Could you maybe tell us maybe one of the properties that aren’t that important? Maybe that would help Mina and Will.’ <p>Overall, the discussion was coherent and well-facilitated, but the initial learning goal could have been stated more clearly.</p>

Table 5: Human evaluation and STRUCTURED COT + QUOTES (GPT) output for the coherent example in Table 1. The green and red texts represent agreement and disagreement between the human and STRUCTURED COT + QUOTES, respectively. The blue texts are quotes from the discussion appearing in both evaluations.

humans and GPT-4o. This is concerning when we base feedback for teachers on GPT-4o’s outputs because it would give teachers incorrect action items or miss opportunities for improvement. In the example in Table 5, the human evaluation suggests the conclusion is the area for improvement; the teacher could have elaborated more than just saying “Do you all feel like you learned something from this? ...” However, ST. COT+QUOTES identifies it as a good conclusion. Instead, it recommends “explicitly stating the learning goal of constructing an argument based on properties,” which was al-

ready achieved according to the human evaluation. This misalignment could undermine the validity and usability of GPT-4o in generating something more than scores, including feedback. A potential remedy could be retrieving relevant pre-defined human-written feedback based on the score, but it cannot fully utilize LLMs’ advantages in flexibility and personalization. This motivates future work on in-depth analysis of human and LLM quotes and on improving the evaluation of quotes selected by GPT-4o.

9 Conclusion

We evaluated task formulation strategies to assess the coherence of classroom discussions. Our results show that strategies previously evaluated for assessing the coherence of short text, such as essays or summaries, successfully generalize to assessing much longer texts—transcripts of 20-minute-long simulated classroom discussions. We reveal that these strategies help GPT-4o tackle the limitations pointed by the literature: overestimation of instructional quality and failure to quote relevant utterances from discussions. However, they do not show cross-domain generalization even within the same simulated setting. Our study serves as a step toward supporting teachers’ development with automated personalized feedback by providing accurate automated evaluation of the target skill, though challenges still remain.

Limitations

We acknowledge the limitations of our evaluation. First, the generalizability of our findings should be explored with other LLMs and datasets. Our results demonstrate some generalizability of coherence evaluation methods from other genres (essays and summaries) to our context but also show that generalization across STEM subjects within the same simulated classroom context is not straightforward since performance is lower on OF than MP. Improving generalization across content domains is our most immediate goal. In addition, we implicitly show the generalizability across models because the prior work our prompts are based on uses models different from ours: GPT-4 for ST, CoT (Liu et al., 2023) and QUOTES (NAISMITH ET AL., 2023) and open-source LLMs, including FlanT5 and Llama2, for the comparison strategy (Liusie et al., 2024). Although our results imply that the strategies in this paper are potentially generalizable to other models, further experiments would be necessary to verify it.

Second, our implementation of the comparison formulation compares discussions only with moderately coherent reference discussions and results in excessive lowering of scores. We leave it to future work to explore strategies for selecting reference discussions that could help mitigate this excessive correction of over-scoring.

Third, human quotes are not the “gold standard” since the raters were asked to provide some examples from the discussion (see Section 3); there are

potentially other good quotes that weren’t selected. The analysis in Section 7 motivates future work to improve the evaluation of quotes selected by GPT-4o.

Finally, our experiments are done only in simulated classrooms. These are important for scaling up practice opportunities by allowing teachers to repeat the cycle of practice and reflection on their teaching without harming real students by their mistakes (Dalinger et al., 2020; Dieker et al., 2014). Generalizability to real classrooms with real students is also important. However, since our goal of scaling up feedback aligns better with the advantages of simulated classrooms, we prioritized this exploration on data from simulated discussions, leaving exploration of real-life discussions to future work.

Ethical considerations

We would like to address potential ethical concerns. First, giving student names and the whole discussions to GPT-4o is not a breach of privacy. In this work, we are not using data from real elementary students. Instead, all the data comes from responses from elementary student avatars in a simulated classroom. The student avatars are operated by an adult, called a simulation specialist, who is trained to use specialized equipment (e.g., game controllers, voice modulation software, etc.) to sound, move, and respond like upper elementary students (cf. Section 3). Each teacher participant signed a consent form that provides their written approval for the research use of the video-recorded discussion and who it can and cannot be shared with. Video recordings are only shared outside of our research team if the participant has consented to that use. For this study, no video recordings were used; we used de-identified transcripts for analyses.

Second, LLMs could be susceptible to their algorithmic biases. Our work addresses bias concerns by showing how to reduce overestimation (bias against low-performing teachers) in Section 7. The model’s explanations could be biased, too, and might not be pedagogically sound (cf. Section 7). As discussed above, instead of giving teachers the model’s explanations as they are as feedback, we plan to use the scores and outputs to provide the teachers with feedback by, for example, retrieving relevant pre-defined human-written feedback.

The costs of using GPT-4o and collecting and scoring discussion data for model development

could also be a barrier to applying our results to the real world. However, the best performing method, STRUCTURED COT + QUOTES, is zero-shot and does not require any reference discussions. Thus, it works well in resource-constrained settings. The price of GPT-4o is \$0.00250 / 1K input tokens and \$0.01000 / 1K output tokens as of writing. Since the average number of words in discussions is around 2K and the output is usually no more than 500 words (cf. Tables 2 and 5), the cost per discussion is less than \$0.1. Therefore, our method scales well at low cost.

Acknowledgments

This study used data collected on previous projects funded by the National Science Foundation (grants #2037983, #1621344, and #2032179). The opinions expressed herein are those of the authors and not the funding agency. We are grateful for the elementary pre-service teachers who participated in these earlier studies and for the contributions of practicing and retired teachers in scoring these discussion transcripts.

A Rubrics

Human raters evaluated a teacher’s ability to lead a coherent discussion based on the rubrics in Table 6

Level Label	Description
1 Beginning	Discussion has a weak sense of organization, purpose, and focus.
2 Developing	Discussion is somewhat organized, purposeful, and focused on the content at hand. AND/OR Portions of the discussion are strongly variable with respect to organization, purpose, and focus.
3 Well-prepared	Discussion is mostly organized, purposeful, and focused on the content at hand.
4 Commendable	Discussion is organized, purposeful, and focused on the content at hand. AND The teacher uses the time allotted so that the learning goal is achieved.

Table 6: Rubrics for Indicator 2A (“Overall Coherence of the Discussion”) (GO Discuss Project, 2021)

and the observation notes in Table 7 (GO Discuss Project, 2021).

B LLM Prompts

B.1 Naive baseline

The prompt used as a baseline is the following:

Following is a discussion about <task information>. <task learning goal> <student information> <rating instruction> <coherence definition>

A score of 3 is characterized by <score 3 characteristics>

A score of 2 is characterized by <score 2 characteristics>

A score of 1 is characterized by <score 1 characteristics>

Please output your score and reasoning in the following JSON format: {“reason”: “...”, “score”: “a float number between 1-3”}.

<the discussion to score>

<task information> and <task learning goal> are dependent on the dataset. For MP, <task informa-

For Indicator 2a, only consider evidence of organization or planning that is connected to the intended student learning goal.
A score of 4 is characterized by a strong degree of coherence around the content and ideas that are discussed and the teacher’s successful use of the available time during the discussion to address the learning goal.
A score of 3 is characterized by a strong degree of coherence around the content and ideas that are discussed. For example: <ul style="list-style-type: none"> • Transitions between ideas and/or groups are timely and make sense. • Instruction takes place in ways that suggest deliberation on the part of the teacher. • New ideas that are introduced are well chosen and occur at relevant moments. Note that you can score a 3 even if the teacher does not achieve the learning goal by the end of the discussion.
A score of 2 is characterized by a variable degree of coherence around the content and ideas that are discussed. For example, different portions of the discussion might be scored as a 1 or 3 if viewed separately. At least some portion of the discussion is highly coherent.
A score of 1 is characterized by a lack of coherence around the content and ideas that are discussed. For example: <ul style="list-style-type: none"> • Discussion has a weak sense of purpose and trajectory. • Teacher moves between ideas abruptly and without apparent rationale. • Teacher introduces new ideas that have limited potential for benefiting student understanding. • Important conclusions may be left unstated or inconsistently summarized. • Discussion may be characterized as a series of unconnected ideas taken up one at a time.

Table 7: The observation notes provided to human raters (GO Discuss Project, 2021).

tion> is “*identifying a mystery powder in a science classroom*”, and <task learning goal> is “*The learning goal is that students will construct an argument about the identity of a mystery powder based on its properties and come to a consensus about which properties are most useful in identifying the unknown powder.*” For OP, <task informa-

tion> is “*ordering fractions in a math classroom*”, and <task learning goal> is “*The learning goal is that students will evaluate, justify, compare, and contrast strategies for ordering fractions with different numerators and denominators.*” These descriptions are taken from the handouts given to the teachers in the dataset before they facilitate discussions (Mikeska et al., 2023, 2025).

<student information> is “*Mina, Will, Emily, Jayla, and Carlos are students.*”. <rating instruction> is “*Your task is to rate the discussion based on its coherence on a scale of 1-3.*” <coherence definition> is “*To be coherent, a discussion must be organized, purposeful, and focused on the content at hand, and the teacher must use the time allotted so that the learning goal is achieved.*”

<score 3 characteristics>: a strong degree of coherence around the content and ideas that are discussed and the teacher’s successful use of the available time during the discussion to address the learning goal. For example,

- The teacher states a clear, detailed learning goal and expectation at the beginning.
- Transitions between ideas and/or groups are timely and make sense.
- Instruction takes place in ways that suggest deliberation on the part of the teacher.
- New ideas that are introduced are well chosen and occur at relevant moments.

<score 2 characteristics>: a variable degree of coherence around the content and ideas that are discussed. For example, different portions of the discussion might be scored as a 1 or 3 if viewed separately. At least some portions of the discussion are highly coherent.

<score 1 characteristics>: a lack of coherence around the content and ideas that are discussed. For example:

- Discussion has a weak sense of purpose and trajectory.
- Teacher moves between ideas abruptly and without apparent rationale.
- Teacher introduces new ideas that have limited potential for benefiting student understanding.

- Important conclusions may be left unstated or inconsistently summarized.
- Discussion may be characterized as a series of unconnected ideas taken up one at a time.

These score characteristics are adopted from the observation notes in Table 7. Only the discussion is sent as a user input to GPT-4o, and the rest is sent as a system input.

B.2 Prompts for the single discussion strategies

Only the discussion is sent as a user input to GPT-4o, the rest is sent as a system input.

STRUCTURED CoT

Following is a discussion about <task information>. <task learning goal> <student information> <rating instruction> To do so, first, read the discussion carefully. Then, describe whether the teacher succeeded in doing or failed to do each of the following:

<aspects of coherence>

In the end, rate the discussion on a scale of 1-3.

Please output your description and score in the following JSON format: {“description”: “1. The teacher ...”, “score”: “a float number between 1-3”}.

<the discussion to score>

<aspects of coherence>:

1. state a clear, detailed learning goal and expectation at the beginning,
2. move between (groups of) ideas timely with apparent rationale,
3. instruct with deliberation,
4. introduce well-chosen new ideas that benefit student understanding at relevant moments,
5. summarize important conclusions consistently throughout the discussion, and
6. connect a series of ideas to the learning goal.

QUOTES The prompts is the same as NAIVE BASELINE, with the addition of the following right before "Please output your score...":

When you rate the discussion, provide quotes from it in your reasoning to support your score.

NEGATIVE FOCUS The prompts is the same as NAIVE BASELINE, with the addition of the following right before "Please output your score...":

When you rate the discussion, provide your reasoning and conclude to what extent (mostly, somewhat or seldom) the teacher failed to shape a coherent discussion and build ideas toward the learning goal.

STRUCTURED CoT + QUOTES prompt The prompts is the same as STRUCTURED CoT, with the addition of the following right before "In the end, rate...":

When you describe each of the above aspects, provide quotes from the discussion in your reasoning to support your score.

B.3 Prompts for the comparison strategies

Only the part starting from "Here's the first discussion;" is sent as a user input, the rest is sent as a system input. We optimized the ordering of the discussions for each prompts using Dev 1 because it impacts the decisions (Liusie et al., 2024).

NAIVE COMPARISON BASELINE

Following is a discussion about <task information> <task learning goal> <student information> <comparison instruction> <coherence definition>

A highly coherent discussion is characterized by <score 3 characteristics>

A moderately coherent discussion is characterized by <score 2 characteristics>

An incoherent discussion is characterized by <score 1 characteristics>

You may say that the first discussion has a similar coherence to the second one.

Please output your decision and reasoning in the following JSON format: {"reason": "...", "The first discussion is": "similar/better/worse"}.

Here's the first discussion;

<a reference discussion>

Here's the second discussion

<the discussion to score>

<comparison instruction> is "Your task is to determine whether the first discussion is better or worse than the second one based on their coherence."

ST. CoT+QUOTES COMPARISON

Following are two discussions about <task information> <task learning goal> <student information> <comparison instruction> To do so, first, read both discussions carefully. Then, for each discussion, describe whether the teachers succeeded in doing or failed to do each of the following:

<aspects of coherence>

When you describe each of the above aspects, provide quotes from the discussions in your reasoning to support your comparison.

In the end, decide whether the first discussion is better or worse than the second one. You may say that the first discussion has a similar coherence to the second one.

Please output your decision and reasoning in the following JSON format: {"reason": "1. In the first discussion, ...", "The first discussion is": "similar/better/worse"}.

Here's the first discussion;

<the discussion to score>

Here's the second discussion

<a reference discussion>

ST. CoT+QUOTES COMPARISON - TWO STEP

Step 1 prompt is the following:

Following is a discussion about <task information>. <task learning goal> <student information> Your task is to describe the coherence of the discussion. To do so, first, read the discussion carefully. Then, describe whether the teacher succeeded in doing or failed to do each of the following:

<aspects of coherence>

When you describe each of the above aspects, provide quotes from the discussion to support your description.

Step 2 prompt is the following:

Following are the evaluations of two different classroom discussions about <task information> <comparison instruction> To do so, first, read each aspect in both evaluations carefully, including the quotes in the evaluations. In the end, decide whether the first discussion is better or worse than the second one. You may say that the first discussion has a similar coherence to the second one.

Please output your decision and reasoning in the following JSON format: {"reason": "...", "The first discussion is": "similar/better/worse"}.

Here's the evaluation of the first discussion;

<the output of step 1 for a reference discussion>

Here's the evaluation of the second discussion;

<the output of step 1 for the discussion to score>

C Additional comparisons between human and ST. COT+QUOTES

Tables 8-12 have additional comparisons between justifications by human raters and ST. COT+QUOTES.

Human	<p>The discussion was mostly organized with portions that were harder to follow. At the beginning of the lesson, the teacher said (e.g., today we're going to look at everyone's claim from our experiment. And, I want us all to work on constructing, defending and critiquing ours and others' claims) and then during the discussion, references the properties chart to help guide the students toward the learning goal.</p>
GPT	<ol style="list-style-type: none"> 1. The teacher did not state a clear, detailed learning goal and expectation at the beginning. The teacher mentioned, 'I want us all to work on constructing, defending and critiquing ours and others' claims,' but did not provide a detailed learning goal or clear expectations. 2. The teacher moved between groups of ideas timely with apparent rationale. For example, the teacher transitioned from discussing the importance of weight to other properties like texture and color, and then to the reactions with vinegar and water. 3. The teacher instructed with deliberation, asking students to turn and talk, and then come back together to share their thoughts. 4. The teacher introduced well-chosen new ideas that benefited student understanding at relevant moments, such as explaining why weight might not be as important and guiding students to see that color was not a distinguishing property. 5. The teacher summarized important conclusions consistently throughout the discussion, such as reiterating that weight and color were not as useful in identifying the mystery powder. 6. The teacher connected a series of ideas to the learning goal by guiding students to use the most relevant properties (texture, reaction with vinegar, and reaction with water) to identify the mystery powder as baking soda.

Table 8: Human evaluation and STRUCTURED COT + QUOTES (GPT) output. The green and red texts represent agreement and disagreement between the human and STRUCTURED COT + QUOTES, respectively. The blue texts are quotes from the discussion appearing in both evaluations.

Human	<p>The T made a small attempt to frame the purpose of the discussion at the start by asking the students if they knew what was meant by “properties”. The students did try to provide information, but the T wound up taking over and giving a weak example of what properties were. The T had each group share their claim and evidence. After each group shared, the T critiqued their evidence while reading the groups’ prework section containing their rationale about the most important properties (Key Idea 3). There was a weak review of the properties at the end of the discussion—again with the T providing the information. There was a short “consensus” discussion where the T polled the students to see if they thought the mystery powder was baking soda. The T had a very weak ending.</p>
GPT	<ol style="list-style-type: none"> 1. The teacher did not state a clear, detailed learning goal and expectation at the beginning. The teacher mentioned, ‘Today we’re going to review what we’ve been doing for the last couple of classes. We are going to be working on identifying a substance based on its properties,’ but did not elaborate on the specific learning goal or expectations. 2. The teacher moved between ideas timely with apparent rationale, such as transitioning from discussing properties to having students share their answers and reasoning. For example, ‘Talk among yourselves for a couple of minutes about what the mystery powder is and how you can support your answer. You guys ready to share your answers with the class?’ 3. The teacher instructed with deliberation, providing clear explanations and feedback. For instance, ‘That’s a good explanation. You guys said that baking soda is white, smooth, bubbles when mixed with vinegar, looks clear when is mixed with water and weighs 24 grams.’ 4. The teacher introduced well-chosen new ideas that benefited student understanding at relevant moments, such as explaining why weight might not be a useful property in this context: ‘Weight just tells you how much you have, so I didn’t bother with it.’ 5. The teacher summarized important conclusions consistently throughout the discussion, such as reiterating the properties to consider: ‘When we do look at properties, you want to consider everything, because in this chart, something can’t be smooth and rough.’ 6. The teacher connected a series of ideas to the learning goal by discussing the properties and how they help identify the mystery powder, but the connection could have been stronger with a clearer initial statement of the learning goal.

Table 9: Human evaluation and STRUCTURED COT + QUOTES (GPT) output. The green and red texts represent agreement and disagreement between the human and STRUCTURED COT + QUOTES, respectively. The blue texts are quotes from the discussion appearing in both evaluations.

Human 1	<p>The discussion overall was coherent and focused on the learning goal. The T began the discussion by explaining that they will be talking about the fractions they ordered. The T then shares that they will begin by explaining the strategy they used and why it works for any set of fractions. <i>After the students finished sharing their strategies and why they used them, the T then shifted to having the students think about other groups strategies.</i> Once Mina came to the realization that her strategy did not work, the T then transitions the discussion to think about whether the other strategies used could be used with any set of fractions. <i>To end the discussion, the T asks the student what strategy they would use if she gave them the same problem again based on the discussion.</i> By the end the learning goal was achieved. Mina realized that her strategy would not work and the other groups realized their strategy could not be generalized to all fraction sets.</p>
Human 2	<p>The T opens the discussion by saying, <i>“Today we’re going to be talking about ordering fractions and the worksheet that you guys did</i> with three-ninths, nine-tenths, oh three-tenths, nine-tenths and three-fourths. So first I want everyone to go around the room and I will call on you. And you’re going to explain your strategy and why you think it works for any set of fractions. First, we’re going to start off with Will and Jayla. I want you to explain to the group what you did for your strategy.” <i>She then asks each group to share their strategy. Then, she focuses on one strategy at a time and asks others what they think about it.</i> After that (and convincing M she is incorrect), she discusses the answers from one group at a time to the last question. <i>Finally she asks them what they would do “If I were to give you this problem again, after listening to everyone’s strategy and what the limitations were and what they did and why they did it, would you do a, would you use a different strategy for the next time? I want Mina to go first.”</i> So overall, the discussion was pretty organized. However, <i>there were times when the T transitioned to a different idea rather than continuing with a S’s thought</i>; for example, when C brought up that M’s strategy would work if the fractions had the same denominator, the T said, “So now we’re going to jump back to Will and Jayla. So now we’re going to talk about the second question.” Also, <i>the T introduced a new representation (rectangles) instead of using W and J’s number line to convince M her answer was incorrect.</i></p>
GPT	<ol style="list-style-type: none"> 1. The teacher did not state a clear, detailed learning goal and expectation at the beginning. The teacher mentioned the topic but did not articulate the specific learning objectives. For example, the teacher said, <i>‘Today we’re going to be talking about ordering fractions and the worksheet that you guys did,’</i> but did not elaborate on the learning goals. 2. The teacher moved between groups of ideas timely with apparent rationale, ensuring each student had a chance to explain their strategy and then facilitating a discussion on the strengths and limitations of each method. For instance, <i>the teacher asked each group to explain their strategy and then prompted other students to comment on it.</i> 3. The teacher instructed with deliberation, asking follow-up questions to ensure students explained their reasoning. For example, the teacher asked Mina to explain more about her strategy and why she chose it. 4. <i>The teacher introduced well-chosen new ideas that benefited student understanding at relevant moments, such as when the teacher provided a visual explanation to help Mina understand why her method did not work.</i> 5. The teacher did not consistently summarize important conclusions throughout the discussion. While the teacher did clarify points at times, there was no consistent summarization of key takeaways after each strategy discussion. 6. The teacher connected a series of ideas to the learning goal by discussing the limitations and strengths of each strategy, but this connection could have been more explicit. <i>The teacher asked students to reflect on whether they would use a different strategy next time, which helped tie the discussion back to the learning goal.</i>

Table 10: Human evaluation and STRUCTURED CoT + QUOTES (GPT) output. The green and red texts represent agreement and disagreement between the human and STRUCTURED CoT + QUOTES, respectively. The blue texts are quotes from the discussion appearing in both evaluations.

Human	<p>No discussion guidelines or introduction provided. Introduced unproductive or confusing tangents (asked Ss to define numerator and denominator but accepted simplistic description of the top number vs. the bottom number; started drawing an incorrect area model to help M demonstrate her strategy; suggested that E/C use a picture or time line to demonstrate their strategy.) T provided some clear and timely transitions between discussions of different strategies.</p>
GPT	<ol style="list-style-type: none"> 1. The teacher clearly stated the learning goal at the beginning: ‘So today students, we are going to evaluate, justify, compare and contrast strategies for ordering fractions with different numerators and different denominators.’* This sets a clear expectation for the lesson. 2. The teacher moved between ideas timely and with apparent rationale, such as transitioning from discussing Jayla and Will’s number line strategy to practicing with new fractions: ‘I think this might be easier if we practice on some new numbers, okay?’ 3. The teacher instructed with deliberation, ensuring students understood each step before moving on, as seen when the teacher asked students to place dots on the number line and confirmed their understanding: ‘Yes. Good job. So now from this number line, we know that five-eighths is greater than three-eighth, but we still don’t know where one fourth lands.’ 4. The teacher introduced well-chosen new ideas at relevant moments, such as comparing fractions to one-half to determine their relative sizes: ‘The next strategy is Mina’s strategy. Do you want to describe to the class what you did?’ 5. The teacher summarized important conclusions consistently, such as confirming the order of fractions after each exercise: ‘So, now we can see that the correct order three-tenths is the least greatest then it is three-fourths and the greatest is nine-tenths.’ 6. The teacher connected a series of ideas to the learning goal by revisiting different strategies and ensuring students understood the rationale behind each: ‘Now to finish up this discussion, I’m going to give you guys another set of fractions and whatever strategy that you want you can decide what one is the greatest and what one’s the smallest, okay?’ <p>Overall, the discussion was coherent and well-structured, effectively meeting the learning goal.</p>

Table 11: Human evaluation and STRUCTURED CoT + QUOTES (GPT) output. The green and red texts represent agreement and disagreement between the human and STRUCTURED CoT + QUOTES, respectively. The blue texts are quotes from the discussion appearing in both evaluations. *The human rater annotated “So today students, ...” as the evidence for introduction in a separate document.

Human	<p>The teacher provides hardly any introduction at the beginning, but then provides a better introduction at 0:24 after “testing the waters.”*¹ The teacher focuses on addressing Mina’s misconception, but does so with what I think are area models that she drew before the interaction rather than using the number lines, which could do the same thing. The teacher does try to make it clear that the number line strategy is not always a good option, but most of the ideas are her own.</p>
GPT	<ol style="list-style-type: none"> 1. The teacher did not state a clear, detailed learning goal and expectation at the beginning. The teacher mentioned discussing strategies but did not clearly outline the learning goal: ‘we’re going to talk about what strategies are helpful when we are comparing fractions, and what strategies might be better used on a different kind of problem.’ 2. The teacher moved between ideas timely with apparent rationale, focusing on different students’ work and strategies: ‘So we’re going to start our discussion by looking at Will and Jayla’s work with their ordering fractions.’ 3. The teacher instructed with deliberation, asking students to explain their thought processes and addressing misconceptions: ‘If you could just explain to the class, your thought process for putting together the strategy, I think that might be really helpful to the other students in the class.’ 4. The teacher introduced well-chosen new ideas that benefited student understanding at relevant moments, such as using visual aids: ‘I actually drew a picture that maybe we could look at together.’*² 5. The teacher summarized important conclusions consistently throughout the discussion, reinforcing key points: ‘So when we look at this picture, can we see which one’s biggest?’ 6. The teacher connected a series of ideas to the learning goal by discussing different strategies and their effectiveness: ‘All of the strategies we’re going to talk about today do work at some point, but we want to talk about the benefits and maybe some of the things that are a little bit harder about those strategies as well.’

Table 12: Human evaluation and STRUCTURED COT + QUOTES (GPT) output. The green and red texts represent agreement and disagreement between the human and STRUCTURED COT + QUOTES, respectively. The blue texts are quotes from the discussion appearing in both evaluations. *¹at 0:24, the teacher said “we’re going to talk ...” *²the human rater annotated “I actually drew ...” as the evidence for the introduction of new ideas in a separate document.

A Bayesian Approach to Inferring Prerequisite Structures and Topic Difficulty in Language Learning

Abstract

Understanding how linguistic topics are related to each another is essential for designing effective and adaptive second-language (L2) instruction. We present a data-driven framework to model topic dependencies and their difficulty within a L2 learning curriculum. First, we estimate topic difficulty and student ability using a three-parameter Item Response Theory (IRT) model. Second, we construct topic-level knowledge graphs—as directed acyclic graphs (DAGs)—to capture the prerequisite relations among the topics, comparing a threshold-based method with the statistical Grow-Shrink Markov Blanket algorithm. Third, we evaluate the alignment between IRT-inferred topic difficulty and the structure of the graphs using edge-level and global ordering metrics. Finally, we compare the IRT-based estimates of learner ability with assessments of the learners provided by teachers to validate the model’s effectiveness in capturing learner proficiency. Our results show a promising agreement between the inferred graphs, IRT estimates, and human teachers’ assessments, highlighting the framework’s potential to support personalized learning and adaptive curriculum design in intelligent tutoring systems.

1 Introduction

A key goal of Intelligent Tutoring Systems (ITS) is to support *personalized* learning by answering key questions: What does the student know? How are they performing? What should they learn next? Achieving this requires three components: a Domain Model (to represent subject knowledge), the Student Model (to represent learner proficiency), and the Instruction Model (to implement pedagogical strategy). Of these, the domain model is foundational, as it informs both the student assessment and the instructional choices. Prior work has explored domain modeling in many learning domains, such as mathematics (Ritter et al., 2007; Arroyo et al., 2014; Klinkenberg et al., 2011).

Beyond proficiency estimation, recent work emphasizes domain models that offer pedagogical insights—such as relative topic difficulty and efficient or optimal learning paths (Swamy et al., 2022; Cohausz, 2022; Weidlich et al., 2022). These can help teachers adapt instruction and improve learning outcomes. In this paper, we focus on modeling relationships among *topics* in language learning using two approaches: predictive modeling and causal modeling. The causal model aims to provide an interpretable domain structure, while the predictive model offers empirical estimates of learning outcomes.

We collect data from real-world learners in our language learning system, Revita (Katinskaia et al., 2018; Katinskaia and Yangarber, 2018; Katinskaia et al., 2017).¹ In Revita’s learning setting, learners complete exercises related to grammar topics in the target language. These exercises are automatically generated from texts that learners upload themselves or select from a shared library of materials. The exercises are presented in the form of multiple-choice or fill-in-the-blank (“cloze”) questions. Each question is associated with one or more *learning topics*—a.k.a. linguistic constructs (Katinskaia et al., 2023)—and the learner’s answer is graded according to its correctness in terms of each topic. We collaborate with language teachers from several universities and collect real data from language learners.

The main goal of this paper is to explore the domain model—using data from learners of Russian, one of several languages offered by the Revita learning platform—which is based on the Russian topics and their relationships. We highlight the following contributions of this paper:

1. We present a simple causal modeling scheme for the domain model and model topics with a directed acyclic graph (DAG). The nodes

¹revitaai.github.io

in the graph represent topics, and the edges represent the relationships between them.

2. We verify our graph structure with predictive analysis: Bayesian network and hierarchical item response theory (IRT) model.

The paper is organized as follows. In section 2 we outline relevant prior work. Section 3 describes our topic inventory, the process of data collection and performance aggregation by topic. Section 4 describes our approach to build the prerequisite graph structures and the statistical models we use to verify the graph structures. Section 5 shows the experiment results. Section 6 concludes with current directions of research.

2 Related Work

Several approaches for modeling learning have been proposed. We briefly review two types of models: (1) predictive models and (2) causal models.

Predictive models focus on predicting with a set of independent latent variables. When modeling learning, these latent variables refer to the levels of the student’s proficiency on various learning topics. One approach is Item Response Theory (van der Linden and Hambleton, 2013). ITS is not the only application of IRT—it can be applied in many settings, including stress testing, psychological and medical testing, etc. Depending on the application domain, the latent trait can be level of anxiety, neurosis, authoritarian personality, etc. IRT has an information-theoretic basis similar to “Elo” ratings (Elo, 1978). The Elo formulas, originally developed for rating chess players, have been adapted in the context of ITS (Pelánek, 2016; Hou et al., 2019). The language-learning domain is more complex than other domains where IRT is used, since the learning topics to be mastered are relatively much more numerous, and have complex relationships among them.

With the rise of deep learning in recent years, *deep knowledge tracing* (DKT) was proposed (Piech et al., 2015), modeling the state of learner knowledge with a recurrent neural network—RNN (Hochreiter and Schmidhuber, 1997). Researchers have proposed several neural network-based approaches (Zhang et al., 2017; Abdelrahman and Wang, 2019; Su et al., 2018; Liu et al., 2019; Pandey and Srivastava, 2020; Song et al., 2021). The benefit of applying neural networks is that they do not require human-engineered

features; despite the success of deep learning, they suffer from a lack of interpretability (Jiang et al., 2024).

Causal models describe the causal relationships in a system. In our case, we consider the causal relationship to be the *prerequisite* relationship among topics or the learner’s knowledge states. The benefit of using causal models is that they can provide a more directly interpretable representation of the domain knowledge (Jiang et al., 2024). Some causal models describe the domain as a directed acyclic graph (DAG), which provides direct value from the perspective of pedagogy. Researchers have explored the use of causal models in education with Bayesian networks (Pardos and Heffernan, 2010) or Markov Blanket (Jiang et al., 2024).

In the field of education, Knowledge Space Theory (KST) (Doignon and Falmagne, 2012) can also be considered as a special graphical causal model. KST is a mathematical framework for modeling the learner’s knowledge, and represents the learner’s current proficiency as a set of mastered skills, which is referred as a *knowledge state*. Each state contains a subset of the skills in the domain. The student has mastered the domain when she reaches the state containing all skills. KST models not only the learner knowledge, but also learning paths, starting from the empty set toward the full set of topics. Various approaches are used to build a knowledge space, from explicit elicitation of knowledge from human experts to data-driven methods, such as Formal Concept Analysis (FCA) (Ganter and Wille, 2012).

3 Data

This work uses learner data collected in collaboration with language teachers at several universities. The dataset covers university students learning Russian as a second language (L2), whose levels range from A1 to C2 on the CEFR scale (Little, 2007), both as part of their university courses and as independent study. Learners upload texts of personal interest, or, if participating in a university course, practice with texts selected or adapted for them by their teachers. Based on the selected texts, the Revita intelligent language tutoring system automatically generates interactive exercises (Katinskaia et al., 2023).²

Revita supports a variety of exercise types for each language, including grammar, vocabulary, lis-

²revita.helsinki.fi

Topics	Examples
(1) Verb: II conjugation	Мы скоро увидим <u>восход</u> . (We will see the sunrise soon.)
(2) Complex pronoun:	Нам нужно кое о <u>чем</u> поговорить. (We need to talk about something)
(3) Perfective vs. imperfective aspect	Страны <u>согласовали</u> проект о будущих отношениях. (The countries agreed on a draft on future relations.)
(4) Dative subject with predicative adjective, or with impersonal verb	Мне <u>необходимо поговорить</u> с врачом. (I need to talk to a doctor. Literally: [it is] necessary for me to talk to a doctor.)

Table 1: Examples of instances of *topics* found in text (underlined). *Candidates* are words that will be chosen for exercises about the topics (marked in **bold**).

tening comprehension, etc. It also provides continual diagnostic assessment. It assists the learners with contextualized feedback and hints depending on their answers. Exercise creation and hint generation are built upon a linguistically-informed domain model, which drives the personalized selection and generation of exercises based on each learner’s proficiency level. In this study, we focus on learner data from grammar exercises in Russian, which serve as the foundation for modeling topic dependencies and estimating topic difficulty.³

3.1 Data collection

Topics: In this paper, we use the term *topic* to refer to specific language learning targets (also known as “skills” in ITS and education literature)—for example, particular patterns of nominal case usage, verb conjugation classes, syntactic constructions involving negation and tense, etc. These are not simply individual grammatical features, such as *past tense* or *plural number*, but rather combinations that reflect in a meaningful fashion how language is taught and learned. For instance, learners may work on mastering topics such as *past tense of a certain verbal paradigm*, rather than *past tense* in general.

To define these topics, we consulted with experts in language pedagogy and textbooks, to align with real-life instructional goals. Table 1 shows examples of topics and exercises that target them.

Exercises: All exercises are automatically generated by the Revita system, based on authentic texts chosen by the teachers and learners from arbitrary sources. The system creates a number of exercise types; here we focus on fill-in-the-blank (“cloze”) and multiple-choice exercises. In a cloze exercise, the system hides certain words or phrases, and shows the learner a hint—the lemma (dictionary form) of the hidden word or phrase. The learner’s

³All learner data was anonymized prior to analysis in accordance with ethical research requirements and standards.

task is to enter the correct surface forms, based on the context of the cloze. In a multiple-choice exercise, the learner is given several options to choose from, with the options generated automatically.

Learners are allowed multiple attempts for each exercise. When an answer is incorrect, the system provides hints on subsequent attempts to support the learner. These hints *gradually* guide the learner toward the correct answer—starting with general guidance and becoming increasingly specific with each additional attempt.

The exercise sequencing strategy follows a hybrid adaptive design. The system is designed to model the learner’s state to select those exercises that optimally match each learner’s current proficiency—targeting an expected success rate of 50%, to keep the exercises appropriately challenging. This is in keeping with Vygotsky’s theory of the Zone of Proximal Development, which states that for optimal learning, the exercises must not be too difficult too often (to avoid frustrating the learner) and not too easy too often (to avoid boring the learner) (Poehner, 2008). Alternatively, learners can manually select their own study paths using a predefined lesson structure, organized from easier to more difficult topics.

Assignment of credit and penalty: Each exercise is associated with one or more topics. The system evaluates the learner’s response to estimate performance on each topic individually. A response may be correct with respect to some topics but incorrect with respect to others—for instance, a learner might use the correct verb tense but the wrong grammatical person. If the learner answers correctly only after receiving hints, we apply a slight penalty, proportionally distributed across the topics linked to those hints. To assign credit and penalty, the system uses several NLP components, including a morphological analyzer, dependency parser, and rule-based pattern matcher. These tools compare the learner’s response with the correct an-

Figure 1: Distribution of the number of unique topics practiced by each student.

swer to determine the topic-level performance for each exercise.

Assignment of credits and penalties is one of the main challenges in our work on assessment. Most statistical approaches, such as IRT, have a clear definition of an *item*, and a clear credit standard—right/wrong answer given by the learner in response to the item. The classic example of an item in IRT is a test question, e.g., in mathematics: it is dichotomous and unambiguous, with a clear judgment of the answer—correct or incorrect. Our major challenge is that our topics are not judged directly, as test items are in other learning domains. It is challenging to determine the credit and penalty for each topic based on the learner’s answer, because the link from exercise to topic is *one-to-many*. This one-to-many nature of the link makes the standard of credit less clear. To tackle this problem, a more sophisticated approach is required to assign credit and penalty. We also face another common problem in language learning and assessment: ambiguity. A substantial proportion of exercises admit *more than one* possibly correct answer, leading to the problem of determining grammatical correctness (Katinskaia and Yangarber, 2021, 2023, 2024). The quality of our NLP components directly impacts the accuracy of the assessment, and therefore the quality of our learning data.

3.2 Data pre-processing

We have collected over 470K student exercise attempts, each with credit and penalty assigned. These exercises were completed by 1,639 unique students. These exercises span over 200 detailed grammatical constructs (Katinskaia et al., 2023), which we group into a smaller set of learning topics that align with pedagogical learning targets, as described above. From this, we derive over 80 distinct topics to be used for modeling and construction of prerequisite graphs.

Figure 2: Distribution of counts of co-practiced topics, based on shared student activity. Each value on the X-axis indicates with how many other topics each topic was co-practiced. The Y-axis shows how many topics have the given co-practiced count.

Each exercise is associated with one or more linguistic topics. To enable topic-level analysis, we “explode” (i.e., multiply out) the data, so that each exercise attempt is represented *multiple* times—once per each topic linked to the exercise. This allows us to track student performance separately for each topic. The number of “exploded” data points—pair-wise records linking between student and topic—is approximately 990K.

The histogram in Figure 1 shows the distribution of unique topics practiced per student. Most students engage with 25 to 50 distinct topics, with a concentration around 30. Since learners tend to focus on topics appropriate to their proficiency level, we expect considerable overlap in practiced topics among students of similar levels. This local overlap is useful for constructing prerequisite graphs, as it provides aligned performance patterns across comparable learners without requiring complete topic coverage by each individual.

We next check what topics are *co-practiced* with other topics—i.e., which topics have been practiced together with other topics by at least one student. Figure 2 shows how many topics are co-practiced with other topics. In fact, most topics are co-practiced with 80 or more other topics, indicating a highly interconnected curriculum, where students tend to practice multiple topic combinations. This highlights the dense overlap in student exposure across topics, which is a useful signal for data-driven construction of dependency graphs.

Figure 3 shows the distribution of students that have engaged with each topic. While some topics are widely practiced by hundreds of learners, others are encountered by only a few students, indicating potential variation in topic popularity, curriculum coverage, or personalized learning paths. This vari-

Figure 3: Distribution of the number of students per topic.

ability may impact both topic-level estimation and the structure of the prerequisite graph.

We have also collected data from over 50 students who completed 100 or more exercises each, and who have teacher-assigned CEFR levels. This subset provides a valuable reference for evaluating student ability and topic difficulty. Overall, the dataset’s size and structure support both robust probabilistic modeling of learner proficiency and detailed analysis of topic interdependencies.

4 Methodology

4.1 Prerequisite graph construction

To represent the prerequisite structure of the topics, we construct a DAG (Chickering, 2002) over learning topics, where each node represents a topic. Directed edges in this graph indicate prerequisite relationships inferred from empirical student performance patterns. Specifically, a directed edge from topic A to topic B , denoted $A \rightarrow B$, means that mastery of topic A is likely a prerequisite for success on topic B .

We explore multiple methods for constructing the prerequisite graph. The first is a threshold-based approach, in which a directed edge $A \rightarrow B$ is added if a statistically significant fraction of students consistently perform better on topic A than *the same students* perform on topic B . This approach focuses solely on relative performance outcomes across topics. By aggregating student-specific accuracy rates, the method infers likely learning dependencies under the assumption that prerequisite topics are easier for students to master than their dependents.

The second method is Grow-Shrink Markov Blanket (GS-MB) approach to learn topic dependencies based on statistical conditional independence tests (Margaritis and Thrun, 2000). We first identify potential neighbors of a target topic by

evaluating unconditional correlations (grow phase), then we remove far neighbors by testing for conditional independence given the remaining set (shrink phase) until reaching the actual Markov blanket of the topic. The resulting undirected dependencies are then converted into directed edges using edge orientation heuristics.

To ensure that the resulting prerequisite graph is a valid directed acyclic graph (DAG), we apply data-driven postprocessing to eliminate cycles and resolve bidirectional edges. If a cycle is detected, we iteratively remove the weakest edge within the cycle—where “weakness” is determined using statistical evidence such as a low agreement ratio or minimal co-occurrence frequency across student performance data. Unlike the traditional Grow-Shrink approach proposed by Margaritis and Thrun (2000), which attempts to reverse and reinsert removed edges followed by directional propagation heuristics, our method permanently removes low-confidence edges without reorientation. This simplification focuses on preserving only the most statistically supported links while enforcing global acyclicity. For bidirectional dependencies (i.e., both $A \rightarrow B$ and $B \rightarrow A$), we retain only the edge with the stronger statistical support, ensuring a consistent and interpretable prerequisite structure.

4.2 IRT Modeling of Student Performance

We use a probabilistic model to estimate student ability and topic difficulty based on their exercise-performance data. Specifically, we apply the three-parameter logistic (3PL) Item Response Theory (IRT) model (Baker, 2001). In 3PL, each student has an ability parameter θ_s , and each topic has two parameters: difficulty β_t , and discrimination α_t . We also take into account the factor of luck as guessing parameter g . The probability that a student s answers topic t correctly is modeled as:

$$c_{u,t} \sim \text{Bernoulli}(g + (1 - g) \cdot \sigma(\alpha_t(\theta_s - \beta_t)))$$

where $\sigma(\cdot)$ is the sigmoid function.

We assume a fixed guessing parameter $g = 0.01$ for cloze-style exercises, which approximates the probability of answering correctly by chance. For multiple-choice exercises, g is determined dynamically based on the number of answer options.

To estimate the posterior distributions of the model parameters, we perform fully Bayesian inference via Markov Chain Monte Carlo (MCMC) (Gilks et al., 1995), using the No-U-Turn Sampler

Figure 4: Posterior distributions of topic difficulty (β) estimated by the IRT 3PL model. X-axis is estimated topic difficulty. Each curve represents the density for a different topic.

(NUTS) (Hoffman and Gelman, 2014) as implemented in PyMC (Patil et al., 2010; Salvatier et al., 2016).

NUTS is a gradient-based sampling algorithm that extends Hamiltonian Monte Carlo (HMC) by adaptively deciding how many steps to simulate on each iteration, based on the gradients of the log-posterior. It dynamically simulates forward and backward trajectories in the parameter space, stopping when a “U-turn” is detected, and then selects a new sample from the visited states using a probability distribution. The posterior samples of β and α for each topic capture both the parameter estimates (mean) and their associated *uncertainty* (standard deviation), enabling more detailed downstream analysis and validation of the graph structure.

4.3 Comparing Graph Structure with IRT Difficulty

We assess the extent to which the structure of the prerequisite graph agrees with IRT-inferred topic difficulty. Intuitively, if topic A is a prerequisite for topic B , then A should be easier (i.e., have lower β) than B . To evaluate this alignment, we use three complementary metrics.

Edge Agreement Score (EAS) measures the proportion of edges in the graph that follow the expected difficulty order. For each edge $A \rightarrow B$, we check whether $\beta_A < \beta_B$. The EAS is calculated as the fraction of such edges over all edges in the graph. A perfect score of 1.0 indicates that *all* edges point from an easier to a harder topic.

Weighted Direction Score (WDS) refines this idea by incorporating the size of the difficulty gap. Rather than using a hard threshold, we score each edge $A \rightarrow B$ using a sigmoid-transformed difference between the difficulties of topics A and B :

$$\sigma(\beta_A, \beta_B) = 1/(1 + e^{-(\beta_B - \beta_A)})$$

This yields higher scores when β_B is much

greater than β_A , and values near 0.5 when the difference is small or uncertain. WDS offers a smoother estimate that rewards clear hierarchical structure.

Kendall’s Tau, originally introduced by Kendall (1938), is designed to measure the ordinal association between two ranked variables. We use it to compare the global ordering of topics implied by the graph with the ranking induced by the IRT-inferred difficulty estimates. This is done by computing a topological sort of the graph to obtain a linear topic ordering, which is then correlated with IRT’s β values using Kendall’s Tau. A high Tau value indicates strong agreement: topics that appear earlier in the graph tend to be easier than those ranked later.

Together, these metrics offer both local and global perspectives on how well the learned DAG structure matches the IRT-inferred difficulty landscape.

5 Experiments and Results

5.1 IRT Estimations

Figure 4 shows the posterior density of all topic difficulty estimates. The IRT model estimates topic difficulty values ranging from -3.31 to 1.16, giving a total range of 4.47 on the X-axis. Of 83 topics, 38 have standard deviations below 0.05, and 55 are below 0.10, meaning that their difficulty estimates are quite stable. For 95% confidence intervals (CI), 50 topics (~60% of all topics) have interval widths under 0.30, which is about 6.7% of the full difficulty range. For 17 topics (20% of all topics), the estimated CI width is under 0.10—only 2.2% of the full range. These statistics suggest that many topics are estimated with high confidence, and they are reliable enough to be used for comparison with the topic graph.

Figure 5 illustrates the relationship between uncertainty in topic difficulty (standard deviation of β) and topic discrimination (mean of α). Topics with higher discrimination α tend to show lower

Figure 5: Correlation between uncertainty in the difficulty of a topic— $\text{std}(\beta)$ —and discrimination parameter of the topic— $\text{mean } \alpha$ —for each topic. Each point represents a topic. Marker color and size indicate the uncertainty in α .

uncertainty in their estimated difficulty, indicating more stable and informative estimates. In contrast, topics with lower discrimination show greater uncertainty in β , as well as higher variability in α , as indicated by larger, lighter-colored markers. This pattern suggests that strongly discriminative topics provide more reliable signals for modeling.

A detailed heatmap of the correctness of the student responses by topic and student ability quantiles (Q1 = lowest, Q5 = highest) is shown in Appendix Figure 9 and 10. In the heatmap, topics are ordered by their IRT-estimated mean difficulty β . The color of each cell shows the average correctness rate, and the number of student-topic interactions. As expected, higher-ability students (Q4–Q5) perform better, particularly on the more difficult topics, reinforcing the validity of the estimated difficulty scores.

Figure 6 shows how the estimates of student ability θ vary across CEFR levels assigned by the teachers. The correlation between CEFR grade and IRT-estimated ability is moderate, with a Spearman coefficient of $r = 0.473$, indicating that as CEFR level increases, IRT-based ability estimates also tend to rise.

Figure 7 shows the relationship between the number of exercises completed by each student and the uncertainty in their estimated ability, measured as the posterior standard deviation of θ . There is a strong negative correlation ($r = -0.758$, $p < 0.001$), indicating that students who complete more exercises tend to have more confident (lower-variance) ability estimates. This supports the intuitive notion that additional observations reduce

posterior uncertainty in the IRT model.

Figure 8 shows a strong negative relationship between the number of students who practiced a topic and the uncertainty in that topic’s IRT difficulty estimate. Topics attempted by more students tend to have significantly lower standard deviation in their β values, suggesting higher confidence in the estimated difficulty. This trend is quantitatively supported by a Spearman correlation of $r = -0.899$ ($p < 0.001$), confirming that broader student coverage leads to more stable parameter estimates.

5.2 Graph construction

We construct two types of topic prerequisite graphs to capture learning dependencies. The first, a threshold-based graph, connects topics where a consistent performance advantage suggests one precedes the other. The second, built using the Grow-Shrink Markov Blanket algorithm, identifies conditional dependencies between topics based on statistical independence tests.

The threshold-based graph includes 83 nodes and 173 edges, resulting in a wide and dense structure with many inferred prerequisite links. In contrast, the GS-MB graph is sparser, with 80 nodes and 86 edges, forming a deeper and narrower hierarchy. Both graphs are processed to remove cycles and bidirectional edges, ensuring they are valid directed acyclic graphs (DAGs). Visualizations of both graphs can be found in the Appendix (Figures 11 and 12).⁴

Both graphs offer useful perspectives. When we manually examine their qualitative plausibility from a linguistic standpoint, we find that the threshold-based graph often aligns more intuitively with expected topic relationships in Russian, suggesting that threshold-based edges may capture pedagogically meaningful dependencies more effectively than the GS-MB structure. We will explore this in further depth in future work.

5.3 Graph vs. IRT estimations

Two approaches are evaluated for constructing topic prerequisite graphs: a threshold-based method and the Grow-Shrink Markov Blanket algorithm. Both produce DAGs, which are evaluated for alignment with the IRT-inferred topic difficulties using three metrics: Edge Agreement Score (EAS),

⁴Both of these graphs are too large to fit into the paper; please see the complete graph of threshold-based approach [here](#) and GS-MS approach [here](#).

Figure 6: IRT ability estimates θ across teacher-assigned CEFR levels. Boxplot shows distribution of student abilities per CEFR level.

Graph	Uncertainty Filter	EAS	WDS	Kendall's Tau
Threshold-based (G_{dag1})	$\sigma_\beta < 0.05$	1.000	0.869	0.240
	$\sigma_\beta < 0.10$	0.604	0.609	0.220
GS-Markov Blanket (G_{dag2})	$\sigma_\beta < 0.05$	0.523	0.514	0.050
	$\sigma_\beta < 0.10$	0.505	0.502	0.014

Table 2: Agreement between graph structure and IRT-estimated topic difficulty. EAS: Edge Agreement Score. WDS: Weighted Direction Score. Kendall's Tau compares topological sort with IRT difficulty rank.

Weighted Direction Score (WDS), and Kendall's Tau.

Table 2 summarizes the results under two topic uncertainty thresholds— $\sigma_\beta < 0.05$ and $\sigma_\beta < 0.1$ —which correspond to subsets of 30 and 50 topics, respectively. The threshold-based graph consistently shows stronger alignment with IRT difficulty estimates, achieving perfect edge agreement (EAS = 1.00), high directional consistency (WDS = 0.869), and a moderate Kendall's Tau of 0.240 under stricter filtering. Even with relaxed thresholds, it maintains relatively strong scores across all three metrics. In contrast, the GS-MB graph produces lower EAS, WDS, and notably near-zero Kendall's Tau values (i.e., 0.050 and 0.014), indicating that its topological structure does not match the global difficulty ranking well.

These results suggest that while GS-MB could be effective at capturing local conditional dependencies, it falls short in representing an overall difficulty hierarchy—a strength more consistently captured by the threshold-based method.

6 Conclusion

In this work, we present a unified framework for modeling topic difficulty and learning dependencies in second-language acquisition, leveraging

large real-world learner data from thousands of students. Using probabilistic modeling and graph-based structure learning, we analyze over 470K student exercise attempts spanning more than 80 topics. Our aim is twofold: (1) to estimate topic-level difficulty and learner ability using a Bayesian IRT model, and (2) to construct interpretable prerequisite graphs that reveal topic hierarchies potentially useful for improving learning.

We compare two graph construction methods: a threshold-based approach that aggregates relative performance gaps across students, and a Grow-Shrink Markov Blanket (GS-MB) method based on statistical conditional independence tests. Three evaluations using Edge Agreement Score (EAS), Weighted Direction Score (WDS), and Kendall's Tau show that the threshold-based method aligns more closely with the IRT-inferred topic difficulties. This supports the hypothesis that prerequisite topics tend to be easier than their dependents, and suggests that simple, data-driven heuristics can reveal meaningful pedagogical structures.

Our findings also demonstrate that model confidence is strongly influenced by the *volume* and *diversity* of learner data. Students who have completed more exercises tend to have lower uncertainty in their ability estimates; topics practiced by

Figure 7: Relationship between number of exercises completed and ability uncertainty (standard deviation of θ). Each point represents a student.

more learners show lower variability in their difficulty estimates. These patterns highlight the value of large-scale learner data in stabilizing the parameter estimates and guiding curriculum analysis.

Moreover, the estimated IRT abilities exhibit a correlation with teacher-assigned CEFR levels, providing external validation for the model and supporting its use in real-world learner assessment. We further explore several aggregate statistics, including topic-topic co-occurrence and student-topic interaction distributions, to explore coverage patterns and the implications for curriculum design.

In summary, this study contributes a robust methodology for combining statistical modeling and graph structure learning in an educational setting. The approach offers practical tools for curriculum designers and language educators to identify learning gaps, and to evaluate learner proficiency. In future work, we will explore extending the model to dynamic learning sequences, fine-grained topic representations, and multilingual adaptation, to further enhance intelligent language tutoring systems.

Limitations

Our results at present have several limitations that may affect the generalizability and precision of the

results.

The dataset primarily consists of learners at the A2, B1, and B2 levels, with relatively few samples from C-level students and very limited representation of pre-A1 and A1 learners. As a result, the inferred difficulty hierarchy and student ability estimates may not fully reflect the learning needs or patterns of beginners and advanced learners.

The distribution of labeled performance data is imbalanced: 78.4% of responses are correct, while only 21.6% are incorrect. This skew may reduce the model’s sensitivity to detecting subtle topic-level challenges, and can introduce bias in estimating both the topic difficulty and discrimination parameters.

Addressing these gaps—through more diverse learner sampling and more balanced task evaluation—would improve the robustness of future modeling efforts.

Abstract

Recent advancements in natural language processing, particularly large language models (LLMs), are making the automated evaluation of classroom discussions more achievable. In this work, we propose a method to improve the performance of LLMs on classroom discussion quality assessment by utilizing in-context learning (ICL) example retrieval. Specifically, we leverage example re-ranking and label ratio regulation, which forces a specific ratio of different types of examples on the ICL examples. While a standard ICL example retrieval approach shows inferior performance compared to using a predetermined set of examples, our approach improves performance in all tested dimensions. We also conducted experiments to examine the ineffectiveness of the generic ICL example retrieval approach and found that the lack of positive and hard negative examples can be a potential cause. Our analyses emphasize the importance of maintaining a balanced distribution of classes (positive, non-hard negative, and hard negative examples) in creating a good set of ICL examples, especially when we can utilize educational knowledge to identify instances of hard negative examples.

1 Introduction

The automatic evaluation of classroom discussion quality has emerged as a significant area of interest within educational research. A wide range of studies have established that the quality of classroom discourse plays a pivotal role in facilitating student learning and cognitive development (Desimone and and, 2017; Wilkinson et al., 2015; Suresh et al., 2019; Jacobs et al., 2022). Nevertheless, large-scale assessment of classroom discussions remains prohibitively resource-intensive and logistically challenging. The development of automated scoring systems offers a promising solution, enabling the generation of extensive datasets to investigate the mechanisms through which discourse

shapes student reasoning and understanding. Furthermore, such systems hold the potential for integration into formative assessment practices, providing educators with actionable feedback to enhance the effectiveness of classroom discussions.

Compared to pre-trained language models (PLMs) such as BERT (Devlin et al., 2019), large language models (LLMs) have been shown to be more reliable in scoring different dimensions of classroom discussion quality, based on the *Instructional Quality Assessment (IQA)* (Tran et al., 2024a). Prior LLM approaches for classroom discussion assessment have ranged from using zero-shot prompts (Wang and Demszky, 2023; Whitehill and LoCasale-Crouch, 2024) that do not exploit the few-shot learning capability of LLMs (Brown et al., 2020), to utilizing few-shot prompts but with a fixed set of examples for every input (Tran et al., 2024a,b). Inspired by the advancement of in-context learning (ICL) *example retrieval* (Wang et al., 2024; Zhang et al., 2023), we attempt to automatically select few-shot examples based on a given input.

Our work thus aims to improve the automated scoring of classroom discussion quality with ICL example retrieval. Utilizing LLMs for binary prediction with a ‘target’ label (e.g., if we are identifying if a label y is present in the current turn, the target now is y), we define the types of examples as follows. If an example has the same label as the target label, it is a *positive* example, otherwise, it is a *negative* example. A *hard negative* example is a negative example that we expect will be difficult for a model to distinguish from positive examples, i.e., positive and hard negative examples are semantically similar in the input space but represent different classes in the output space. From a retrieval perspective, the hard negative examples are often selected based on some quantitative metrics such as their distance in the embedding space or their ranking from a reward model (Wang et al.,

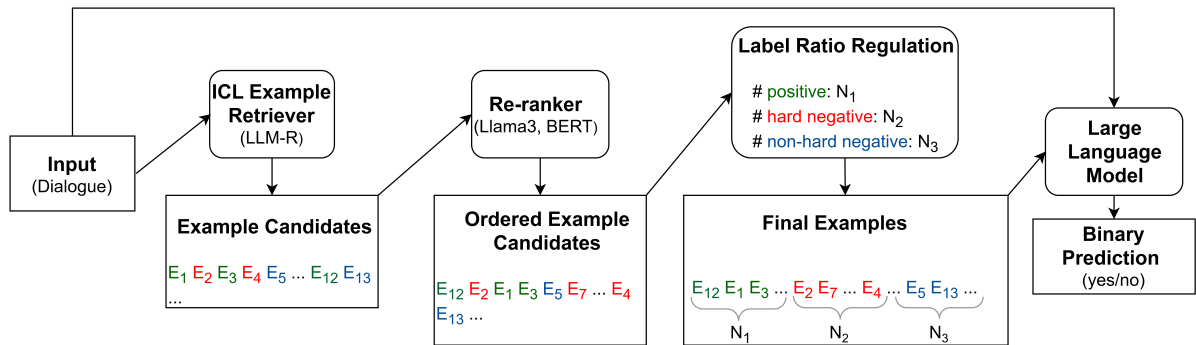

Figure 1: Overview of the proposed method.

2024; Zhang et al., 2023). However, in the context of classroom discussion, since we can leverage a qualitative metric (i.e., domain knowledge about the definition of the labels), we can identify hard negative examples for the target label more reliably. Specifically, based on the definitions of the labels, for a target label A, we know that label A' is closer to A compared to other labels from a human perspective. Therefore, when finding hard negative examples for A, we can quickly select instances with label A' as candidates without needing to calculate any kind of 'distance' between them.

After experimenting with a generic ICL example retrieval approach (LLM-R by Wang et al., 2024), we found it is ineffective for classroom discussion. We hypothesized that the problem is from 1) the imbalance of positive/negative examples and 2) the lack of hard negative examples, as we cannot control the retrieval process. The first hypothesis is well-known in ICL learning as we need both positive and negative examples to learn effectively (Min et al., 2022). The second hypothesis is from the observation that hard negative examples play a crucial role in getting good prediction performance (Tran et al., 2024a; Robinson et al., 2021). Moreover, although we have domain knowledge about hard negative examples based on the annotations of the labels, the ICL retriever only relies on quantitative metrics (e.g., higher-ranking examples) to identify them. To address these issues, we proposed a 2-step approach. First, we train a BERT-based re-ranker to re-order the retrieved examples from LLM-R (Wang et al., 2024). Second, we employ label ratio regulation (LRR), which selects examples from the sorted list while maintaining a specific ratio of positive, non-hard negative, and hard negative examples in the 10-example set used in the prompt (Figure 1).

Our goal is to answer these research questions:

- RQ_1 Does the proposed method help improve performance?
- RQ_2 Does ICL example retrieval have good coverage of the label space (type of examples)?
- RQ_3 How does the ratio of the ICL examples used in the label ratio regulation influence the performance?

Our contributions are three-fold. First, we show that a standard ICL example retrieval approach, despite being useful for other natural language processing (NLP) tasks, is ineffective for classroom discussion assessment. Further analyses suggest that the lack of positive examples and hard negative examples can be causes for this poor performance. Second, we propose an approach utilizing re-ranking and label ratio regulation to complement the standard ICL example retrieval. It helps improve performance and yields comparable results to a finetuned retriever without finetuning the retriever. Third, we demonstrate that even with re-ranking, the retrieval process fails to effectively select hard negative examples, which emphasizes the importance of label ratio regulation when the domain knowledge of the classes (e.g., which class is a hard negative example) is available.

2 Related Work

2.1 LLMs for Classroom Discussion Scoring

As generative LLMs such as GPT-4 (OpenAI et al., 2024), Llama (Grattafiori et al., 2024), and Mistral (Jiang et al., 2023) have outperformed PLMs in many NLP tasks, there has been growing interest in leveraging these LLMs for classroom discussions.

When predicting accountable talk moves in classroom discussions, a finetuned LLM such as GPT-3 has consistently surpassed RoBERTa (Liu et al., 2019) in precision (Kupor et al., 2023). However,

since finetuning LLMs requires significant expertise, extensive data, and substantial computational resources, researchers have increasingly focused on zero-shot and few-shot approaches that do not require additional training. For instance, one study examined the zero-shot capabilities of ChatGPT in three tasks: scoring transcript segments using classroom observation instruments, identifying key strengths and missed opportunities in instructional strategies, and providing actionable suggestions for fostering student reasoning (Wang and Demszky, 2023). The findings revealed that ChatGPT struggled to score classroom transcripts using instruments like the Classroom Assessment Scoring System (CLASS) or the Mathematical Quality of Instruction (MQI) and offered repetitive feedback.

Research has also explored the application of LLMs at more granular levels, such as sentence-level or utterance-level analysis. While zero-shot ChatGPT provided clear and detailed explanations for its predictions, it performed significantly worse than the smaller BERT model in three out of four student talk move categories for the classification task (Wang et al., 2023). Tran et al. (2024b) analyzed three prompt-based factors: task formulations, context length, and the presence of few-shot examples and found that all of them can have impacts on the final performance. Although the importance of few-shot examples has been shown and some prior work utilized few-shot prompting, they had a fixed set of examples, which might not be representative enough and might not have examples relevant to the current input (Tran et al., 2024a,b). *Our work focuses on automatically retrieving a set of examples based on the input to cover dynamic scenarios in a classroom discussion.*

2.2 ICL Example Retrieval for LLMs

In-context learning, the emergent capability of LLMs that allows them to execute diverse tasks by conditioning on a limited set of input-output examples without requiring parameter updates or finetuning, has been demonstrated in many LLMs such as GPT-3 (Brown et al., 2020) or Llama (Touvron et al., 2023). Various approaches have been made to create better LLM prompts (Li and Liang, 2021; Le Scao and Rush, 2021; Hao et al., 2022). Different from the standard retrieval-augmented generation by using a dense retriever such as ColBERT (Khattab and Zaharia, 2020) to get additional information for LLMs, there is an area of research focused specifically on finding better ICL

examples to boost LLMs' performance (Ye et al., 2023; Li and Qiu, 2023; Li et al., 2023; Zhang et al., 2023). Liu et al. (2022) demonstrated that ICL performance can be enhanced by either using the BM25 algorithm or by finetuning dense retrievers with feedback from LLMs to retrieve relevant examples from a training set. Wang et al. (2024) proposed an iterative training framework (LLM-R) to retrieve ICL examples in 3 steps: 1) rank an initial set of retrieved candidates based on the conditional LLM log probabilities of the ground-truth outputs; 2) train a cross-encoder reward model to capture the fine-grained ranking signals from LLMs; and 3) train a bi-encoder dense retriever using knowledge distillation. Our work falls into this area by proposing a method to dynamically retrieve ICL examples. However, we focus on the label ratio of the example set, which has not been studied in prior work.

3 Dataset

We use videos of English Language Arts classes in a Texas district to create our corpus. The videos were recorded during the course of an online instructional coaching program (Correnti et al., 2021). They were collected from 18 fourth-grade and 13 fifth-grade classes, whose teachers on average had 13 years of teaching experience. 61% of the student population was considered low income, with the following racial proportion: Latinx (73%), Caucasian (15%), African American (7%), multiracial (4%), and Asian or Pacific Islander (1%).

Annotators manually scored videos holistically, on a scale from 1 to 4, using the IQA on 11 dimensions (Matsumura et al., 2008) for both teacher and student contributions. They were also scored using more fine-grained talk moves annotated at the sentence level using the *Analyzing Teaching Moves (ATM)* discourse measure (Correnti et al., 2021). The final corpus consists of **112** discussion transcripts that have been scored using both the IQA and the ATM (see Appendix A for the statistics of the scores). Thirty-two videos (29%) were double-scored, showing good to excellent reliability for the IQA (the Intraclass Correlation Coefficients (ICC) range from .89-.98) and moderate to good reliability for the ATM (ICC range from .57 to .85). Below is an excerpt with annotated ATM codes:

Teacher: [Justin.]Repeat [Tell me who's Justin?]
Press

Student: [Justin is... Well, Via's boyfriend who stands up for August and

is very nice to him. Even though he saw him for the first time, he was kind of shocked, but he kind of got used to him.]**Strong Explanation**

IQA dimension scores. To compare with prior work (Tran et al., 2024a), we focused on 4 of the 11 IQA dimensions, in which 2 of them focus on teaching moves and 2 focus on student contributions. They were previously chosen because of their relevance to dialogic teaching principles that emphasize collaboration and active participation in meaning-making. Furthermore, all four scores are calculated based on the frequency of their related ATM codes. The four dimensions include: *Teacher links Student’s contributions* (T-Link), *Teacher presses for information* (T-Press), *Student links other’s contributions* (S-Link), *Student supports claims with evidence and explanation* (S-Evid). We define S-Evid as the higher score of *Student provides text-based evidence* and *Student provides explanation*. Descriptions of these dimensions can be found in Appendix B.

Based on the definitions of the ATM codes (Appendix C), 2 IQA dimensions have hard negative examples (e.g., have examples that are semantically similar to the positive examples but have a different label based on a notion of strength). For S-Link, a positive example has *Strong Link* as the ATM label while a hard negative example has *Weak Link*. A similar rule applies to S-Evid (*Strong Text-based Evidence* vs *Weak Text-based Evidence*; *Strong Explanation* vs *Weak Explanation*).

Due to the small size of the data, we follow Tran et al. (2024a) and use 2-fold cross-validation. In each fold, half of the data (56 transcripts) is considered as training data and the remaining data (56 transcripts) is used for evaluation. We also make sure that transcripts of the same teacher are in the same fold to prevent data leakage.

4 Methods

4.1 ICL Example Retrieval for LLMs

We adopt the prompts from prior work (Tran et al., 2024a) for our LLM. We utilize the predictive approach, which is the approach that yields the best results in all 4 IQA dimensions (Predictive-llm). It is the BC-5turns-10s strategy described by Tran et al. (2024a), utilizing the LLM as a binary classifier by prompting it to determine whether an observation related to an IQA dimension is present in a single turn (yes or no) (see Appendix D).

For our ICL example retriever, we use LLM-R (Wang et al., 2024)¹. It uses LLMs to rank the candidates based on the log-likelihood of the ground-truth output, then trains a cross-encoder as a reward model to mimic the preferences of LLMs, and finally distills that knowledge to a bi-encoder for efficient inference. For a given input (a 5-turn dialogue excerpt), we retrieve the top 10 examples from the training data and use them as few-shot examples in the LLM prompt. We use separate retrievers (LLM-R) for teachers’ and students’ turns. In other words, when predicting a teacher or student’s turn, we will only try to retrieve examples from a pool consisting of examples from the same speaker role (student or teacher). For example, if we are predicting if the last turn (given its 4 previous turns) is T-Press, the retriever will only try to find examples (5-turn dialogue windows) by looking at ones that end with a teacher’s turn.

Although LLM-R specializes in ICL example retrieval, it was trained on tasks different from classroom discussions (e.g., sentiment, reading comprehension, closed-domain QA). Besides using off-the-shelf LLM-R, we also fine-tune it on classroom discussions. However, because our dataset is small, finetuning an ICL example retriever on the training set is ineffective. We instead use another classroom discussion dataset, TalkMoves (Suresh et al., 2022), to finetune LLM-R.

The TalkMoves dataset contains K-12 math classroom transcripts, annotated for talk moves based on accountable talk theory and dialog acts. The dataset includes 567 transcripts, comprising 174,186 annotated teacher utterances, 59,874 annotated student utterances, and 1.8 million words (15,830 unique). All of the transcripts are annotated for 6 teacher talk moves (Keeping everyone together, Getting students to relate to another’s ideas, Restating, Pressing for accuracy, Revoicing, and Pressing for reasoning) and 4 student talk moves (Relating to another student, Asking for more info, Making a claim, and Providing evidence or reasoning). For finetuning the retriever, we use the same binary prediction task as Predictive-llm. However, we perform multiple binary predictions (yes/no) for all possible talk moves in each turn and use the definitions of these talk moves from the dataset (Suresh et al., 2022). While these moves differ from ATM codes, they share similarities and reflect

¹https://github.com/microsoft/LMOps/tree/main/llm_retriever

a theoretical approach closely related to the one behind ATM.

4.2 Re-ranking and Label Ratio Regulation

In this section, we propose a method that uses re-ranking and forces a specific label ratio in the example set to improve ICL performance for classroom discussion quality assessment.

Re-ranking. Re-ranking is a popular approach in retrieval tasks. The initial retrieval process is generally designed to be fast, often prioritizing speed over perfect accuracy. As a result, in ICL example retrieval, the first batch of examples retrieved can be broad, including both highly relevant and somewhat irrelevant information. Re-ranking addresses this by filtering and reordering these examples according to refined relevance scores, reducing noise and irrelevant information. In the first step, we re-rank the top-100 retrieved examples to get a set of examples ordered by their usefulness. We experiment with 2 re-ranking methods.

LLM as a re-ranker: We use a Llama3 model as the scorer. Specifically, for a given input and a retrieved example, we ask a yes/no question if the example can help answer the given question and use the probability of “yes” as the score.

BERT as a re-ranker: We train a BERT-based model as a cross-encoder reward model that gives higher scores to good ICL examples. We first create the necessary training data to train the BERT model. To do this, from our available training data (Section 3), for each instance (a turn), we retrieve the top-K using the LLM-R retriever (either trained or not trained). We then employ Llama3 to obtain the rankings. The ranking score is calculated as $\log p(y|x, x_i, y_i)$ where x is the given input, y is the gold answer, x_i and y_i are an in-context learning example retrieved and its label. For a training example (x, y) , we first sample one positive example (x^+, y^+) from the top-ranked candidates and N_{neg} negative examples $(x_i^-, y_i^-)_{i=1}^{N_{neg}}$ from the bottom-ranked candidates. The reward model takes as input the concatenation of (x, y, x^+, y^+) and produces a score $s(x, y, x^+, y^+)$ for the positive example, and $s(x, y, x_i^-, y_i^-)$ for the negatives. The training objective is to minimize the cross-entropy loss:

$$\mathcal{L}_{\text{reward}} = -\log \frac{e^{s(x,y,x^+,y^+)}}{e^{s(x,y,x^+,y^+)} + \sum_{i=1}^{N_{\text{neg}}} e^{s(x,y,x_i^-,y_i^-)}}$$

Label Ratio Regulation (LRR). Thinking that the lack of hard negative examples and the imbalance of positive/negative examples can be potential

causes for the poor performance of the off-the-shelf retrieval setting, we want to ensure that this will not happen. To do so, we make sure the 10-example set follows a specific label ratio of positive, negative, and hard negative (if applicable) examples. For a fair comparison, we force the ratio to mimic the ratio from the fixed setting (defined in Tran et al. (2024a)). Although the ordering of few-shot examples is also a non-trivial factor (Ye et al., 2022), it is not what we focus on. Therefore, we fix the order of the chosen examples. For T-Press and T-Link, from top to bottom, we want 5 positive and then 5 negative examples. Similarly, for S-Link and S-Evid, we will see 4 positive, 4 easy negative, and 3 hard negative examples, respectively, from top to bottom of the example set. To do so, given the ranked list of examples, we pick from top to bottom until the predetermined label ratio is satisfied and skip examples that violate the label ratio if added. For instance, if we already have 5 positive examples for T-press, we will ignore the remaining positive examples in the list and only pick an example if it is a negative one as we go down the list.

5 Experimental Setup

To make it comparable to prior work without ICL example retrieval from Tran et al. (2024a), we use LLama3-8B (Grattafiori et al., 2024) as the LLM for classroom discussion assessment ².

We use 3 baselines to test the effectiveness of the proposed method:

fixed: In this setting, we use a set of 10 fixed examples for each fold in the cross-validation. We follow prior work to pick those 10 examples for the LLM prompts (Tran et al., 2024a). This setting is also used as a baseline for comparison with approaches that utilize ICL example retrieval. One thing to note is that using this sampling method, we will have a fixed ratio of positive, easy negative, and hard negative examples in the 10-shot example set.

retrieved: In this setting, we use LLM-R (Wang et al., 2024) to find the top-10 examples from the training data. Then, we use those 10 examples for few-shot prompting.

mixed: In this setting, we construct a set of top-5 retrieved examples and 5 examples from the fixed set. For the 5 examples from the fixed set, we pri-

²<https://huggingface.co/meta-llama/Llama-3.1-8B>

ortize hard-negative examples first. In addition, prior work has shown that lacking hard negative examples is detrimental to the performance (Tran et al., 2024b). Therefore, we decide to select harder negative examples from the fixed set, as we cannot guarantee that they exist in the retrieved set. Specifically, for S-Link and S-Evid, we pick 3 hard negative examples, 1 positive example, and 1 non-hard negative example. For T-Press and T-Link, we pick 3 positive and 2 negative examples. Then, we choose the remaining 5 examples from the retrieved ones based on the descending order of cosine similarity between them and the input embedded by LLM-R.

To test the performance of the proposed method, we experimented with 2 re-ranking methods: using LLama3 as the *LLM re-ranker* and using a finetuned *BERT re-ranker*. To highlight the importance of each component (LRR and re-ranking), we report the performance from utilizing both re-ranking and label ratio regulation in combination and from using each component separately.

To compare the performances between non-finetuned and finetuned retrievers, we finetune a new LLM-R on another classroom discussion dataset (TalkMoves from Suresh et al., 2022) and repeat the experiments.

Quadratic Weighted Kappa (QWK) is used as the main evaluation metric. It is a common metric for quantifying inter-rater reliability that penalizes disagreements proportional to the degree of disagreement, which is vital in contexts where a greater distance between scores is meaningful.

6 Results and Discussion

RQ₁: Effectiveness of the proposed method. Table 1 shows the macro average over 2-fold cross-validation of QWK scores in various settings, including the 3 baselines and the proposed method for both non-finetuned and finetuned retrievers.

The standard ICL example retrieval is not effective. When using a non-finetuned LLM-R, we observe that relying solely on retrieved examples (row 2) is worse than the *fixed* baseline (row 1). This implies that using ICL retrieval is ineffective in this case, despite helping to improve performance in previous work on other domains (Wang et al., 2024; Zhang et al., 2023). On the other hand, the *mixed* settings (row 3), where we combine examples from the retriever with the fixed set, are the baselines that achieve the best performance in all

IQA dimensions. This suggests that the retrieved examples are still useful to some extent.

Our proposed method with BERT as the re-ranker achieves the best performance in all 4 IQA dimensions (row 7) for both non-finetuned and finetuned retrievers. Although finetuning the LLM-R boosts the performance of the *retrieved* setting (row 2), the proposed method performs comparably for both non-finetuned and finetuned settings of the LLM-R retriever (row 7), suggesting that finetuning the retriever on a new domain, which is computationally expensive, is not necessary. Our hypothesis for this minimal gain is that the TalkMoves data consists of math discussions, which contain math-specific lexicons not present in English Language Art discussions from our dataset. Additionally, the TalkMoves dataset is skewed towards sixth-grade to eighth-grade students, while our data only has discussions from fourth-grade and fifth-grade students.

As a re-ranker, although LLama3 shows equal or better performance over the *retrieved* setting in T-Link and T-Press (row 5 vs 2), it is inferior to the *fixed* setting in S-Link and S-Evid (row 5 vs row 1). On the other hand, using BERT as a re-ranker with label ratio regulation achieved the best results in all dimensions. With this combination, we are now able to outperform the mixed setting despite using only retrieved examples. This implies that for this task, using an LLM such as LLama3 as a judge for re-ranking is not a reliable method in comparison with finetuning a PLM such as BERT.

The LRR is shown to be essential for improved performance as removing it leads to decreases in QWK (rows 6 and 8 compared to the previous rows). The drop in performance in S-Link and S-Evid is larger than the drop in T-Link and T-Press. The former 2 dimensions (S-Link and S-Evid) have hard negative examples based on the coding manual, which suggests that LRR is more important when hard negative examples are available for the target dimension. With only re-ranking, we can perform similarly or worse than the *retrieved* setting. For instance, using a LLama3 re-ranker without LRR is worse than vanilla retrieval (row 6 versus 2). On the other hand, with LRR, we consistently outperform the *retrieved* setting, with or without using a re-ranker (row 4, 5, 7 versus 2)⁴. Moreover, when the retriever is finetuned, if we have to pick

³Two-tailed t-test on 2-fold cross-validation.

⁴Except for S-Link with finetuned retriever.

ID	Setting	Non-finetuned Retriever				Finetuned Retriever			
		T-Link	T-Press	S-Link	S-Evid	T-Link	T-Press	S-Link	S-Evid
1	fixed	0.65	0.73	0.64	0.79	0.65	0.73	0.64	0.79
2	retrieved	0.62	0.71	0.62	0.75	0.66	0.73	0.66	0.80
3	mixed	<i>0.68</i>	<i>0.76</i>	<i>0.67</i>	<i>0.81</i>	<i>0.72</i>	<i>0.77</i>	<i>0.71</i>	<i>0.82</i>
4	LRR only	0.63	0.72	0.65	0.79	0.68	0.76	0.65	0.81
5	Llama3 + LRR	0.65	0.72	0.62	0.76	0.68	0.75	0.63	0.77
6	w/o LRR	0.61	0.70	0.56	0.68	0.65	0.72	0.60	0.70
7	BERT + LRR	0.72	0.80	0.73	0.83	0.73	0.81	0.73	0.83
8	w/o LRR	0.66	0.78	0.64	0.77	0.66	0.78	0.65	0.77

Table 1: Quadratic Weighted Kappa (QWK) scores of the two retrievers. For each IQA dimension (T-Link, T-Press, S-Link, S-Evid), italic numbers represent the best baseline results. Bold numbers highlight the best retriever results. All numbers are statistically significant compared to their counterparts in the *mixed* baseline ($p < 0.05$).³

IQA	Non-finetuned LLM-R		Finetuned LLM-R	
	Avg	% w/o hard negative	Avg	% w/o hard negative
S-Link	3 / 1.2 / 3.2 / 1.5	0 / 27.2 / 0 / 24.3	3 / 1.5 / 3.3 / 1.7	0 / 23.3 / 0 / 20.7
S-Evid	3 / 1.9 / 3.1 / 2.1	0 / 22.7 / 0 / 20.8	3 / 1.7 / 3.4 / 2.0	0 / 20.5 / 0 / 19.1

Table 2: Presence of hard negative examples in the fixed, retrieved, mixed setting and an approach utilizing BERT re-ranking without LRR. We report the average number of hard negative examples included in the 10 examples (Avg) and the percentage of test instances where the few-shot examples in the prompt do not have any hard negative example. In each cell, from left to right, the 4 numbers represent the statistics for *fixed*, *retrieved*, *mixed* settings, and from an approach utilizing BERT re-ranking without LRR.

only one component, using LRR is usually better than using a re-ranker (row 4 versus rows 6 and 8). This suggests that we should always enforce the label ratio in the example set.

RQ₂: Issues in the label ratio of retrieved examples from automatic ICL example retrieval.

The lack of hard negative examples and skew in the ratio of positive and negative examples can be potential causes for the low performance of example retrieval. Noticing that directly using the retrieved examples is not an effective way to improve the performance of LLM-based classroom discussion quality assessment, we hypothesize the potential causes and do analyses to test them. Compared to the *fixed* and *mixed* settings, one thing we could not control in the *retrieved* setting is the distribution of the examples. We can think of two causes for the poor performance using the *retrieved* setting: 1) the lack of hard negative examples and 2) the lack of positive examples.

Missing hard negative examples in the few-shot example set will have a negative influence (Tran et al., 2024a). Table 2 shows the presence of hard

negative examples in the *fixed*, *retrieved*, *mixed* settings, and an approach using BERT ranking without LRR for S-Link and S-Evid (the only two dimensions that have hard negative examples according to the definitions in the coding manual). We can see that the *retrieved* setting has fewer hard negative examples on average compared to the *fixed* and *mixed* settings. We also only witness cases in which the example set has no hard negative examples in the retrieved setting. With only a BERT re-ranker, these numbers barely change as we only see small increases in the average number of hard negative examples and decreases in the number of cases without any hard negative example compared to the retrieved setting (4th number versus 2nd number) in each cell. This aligns with one of our previous observations from Section 6 that removing LRR results in bigger decreases in QWK for S-Link and S-Evid compared to the other two dimensions. This implies that re-ranking alone still does not guarantee the presence of hard negative examples in the set of 10 few-shot examples for prompting. However, with domain knowledge of

IQA	Non-finetuned LLM-R		Finetuned LLM-R	
	Avg	% without positive	Avg	% without positive
T-Link	5 / 3.7 / 4.7 / 4.2	0 / 6.8 / 0 / 1.2	5 / 3.3 / 3.5 / 3.5	0 / 5.3 / 0 / 2.3
T-Press	5 / 7.3 / 5.4 / 6.1	0 / 0.0 / 0 / 0.0	5 / 6.8 / 5.2 / 5.5	0 / 0.0 / 0 / 0.0
S-Link	4 / 3.2 / 3.8 / 3.5	0 / 6.2 / 0 / 0.0	4 / 3.8 / 4.3 / 4.1	0 / 0.0 / 0 / 0.0
S-Evid	4 / 5.9 / 5.1 / 5.5	0 / 2.3 / 0 / 0.0	4 / 5.6 / 4.9 / 4.3	0 / 3.1 / 0 / 1.2

Table 3: Presence of positive examples in the fixed, retrieved, mixed setting, and an approach with only BERT re-ranking (no LRR), with the same notations as Table 2.

Figure 2: Results of T-Press and T-Link from different label ratios with N positive examples for BERT+LRR.

Figure 3: Results of S-Link and S-Evid from different label ratios with N hard negative examples for BERT+LRR.

hard negative examples (i.e., knowing that Weak Link is a hard negative example label for Strong Link, which represents S-Link), even with automated retrieval, we can ensure that hard negative examples are in the set.

Looking at the presence of positive examples ($x_i, y_i = y$) in Table 3, we see that the *retrieved* settings (2nd numbers of the cell) tend to include more positive examples in the 10-example set for T-Press and S-Evid while having fewer positive examples for T-Link and S-Link. Although they are rare, there are still cases in which we have no positive examples in the 10-example set for the *retrieved* setting, which never happens for the *fixed* and *mixed* settings. The BERT re-ranking (4th number) helps decrease the number of cases without any positive examples, and it makes the average number of positive examples retrieved in each IQA dimension closer to the *fixed* and *mixed* settings.

RQ₃: The ratio of different types of examples does matter. We conduct additional experiments on our best model (BERT+LRR) by varying the ratios by changing the number of positive examples, negative examples, and hard negative examples (if they are available) to see if certain label ratios yield

better results. Specifically, for T-Press and T-Link, because there is no hard negative example for these two dimensions, we record the performance with the N positive examples (N = 0 to 10) and 10-N negative examples. For S-Link and S-Evid, we pick N (N = 0 to 10) hard negative examples and equally split the remaining 10-N examples into positive examples and non-hard negative examples (if 10-N is odd, we have 1 more positive example).

Figure 2 shows the results for T-Press and T-Link with various positive/negative ratios. We observe that increasing the number of positive examples helps improve the performance to a certain point. Specifically, we see noticeable improvements until N=3, then it starts to slow down. However, after N=5 positive examples, the QWK begins to go down as N increases. This suggests that we should have a balance between positive and negative examples, which is reasonable, as having too many examples of a certain perspective (positive or negative) can create biases in that direction for the LLMs. Similarly, for S-Link and S-Evid, the performances are boosted until N=3 hard negative examples are selected and then they quickly drop (Figure 3). This

time, the downward trend after $N=4$ is more noticeable compared to Figure 2, implying that having too many hard negative examples causes more harm than good. In other words, although hard negative examples are essential for high performance, we should keep room for positive and non-hard negative examples. Overall, these observations suggest that we should be cautious when selecting a label ratio for the example set, and having a balanced split between the possible labels (positive, non-hard negative, and hard negative) is a safer choice, as the dominance of a label tends to result in decreased performance.

7 Conclusions

This work proposes a simple but effective ICL example retrieval method that utilizes example re-ranking and label ratio regulation (LRR) to improve few-shot LLM performance in automated classroom discussion assessment. The results show that our fully automated example retrieval and selection approach outperforms the baselines in all tested IQA dimensions. Additionally, the performance of a non-finetuned example retriever (LLM-R) is comparable to that of a retriever finetuned on a similar domain dataset, suggesting that skipping the finetuning process of the retriever is viable. Further analyses show that the lack of positive and hard negative examples can be the reason for the poor performance of the traditional ICL example retrieval approaches. We also observe that even with re-ranking, both finetuned and non-finetuned retrievers fail to select enough hard negative examples to make the few-shot prompting effective, which highlights the importance of label ratio regulation in maintaining the presence of hard negative examples. Finally, we investigate the influence of the ratio of positive, non-hard negative, and hard negative examples, demonstrating that having an excessive number of any category hurts performance. We would like to explore the proposed method with a more advanced prompting method, such as Chain-of-thought (Wei et al., 2022), in the future.

Limitations

While our method uses Label Ratio Regulation (LRR) to maintain a specific ratio, it treats each potential example separately when selecting the top-10. This independent selection might not be ideal, as the chosen examples can interact with each

other. Exploring combinatorial optimization and sequential decision-making techniques could lead to improvements.

Another limitation of our study is the lack of analysis on the influence of the size of the example pool on the performance. Because our training set is small, the relevance and diversity of the candidate examples can be a hindrance to the generic ICL example retrieval baseline. If we have a bigger example pool with more diversity, the LRR might become unnecessary.

The proposed approach involves several components, which people might find too complex and counterintuitive, potentially hindering the ease of LLM usage for downstream tasks. Additionally, the experiments are conducted on a single and small dataset. As a result, the generalizability of the findings is weakened.

Furthermore, we only use the smallest version of LLama3. Utilizing a bigger LLM (e.g., LLama3-70B) might yield higher results and undermine the effectiveness of ICL example retrieval.

Last but not least, our experiments are grounded on a binary classification task and the assumption that hard negative examples can be identified based on the definitions of the labels.

A Data statistics

The transcripts have an average length of 3,421 tokens, with a median length of 3,537 tokens. The shortest transcript contains 1,986 tokens, while the longest reaches 6,393 tokens. Table 4 presents the statistics for the four key IQA dimensions highlighted in this work.

B Description of IQA Dimensions

Descriptions of the 4 focused IQA dimensions can be found in Table 5.

C Description of ATM codes

Descriptions of the relevant ATM codes can be found in Table 6.

D Prompts

Figure 4 contains the prompt used for the binary prediction of a target IQA adopted from Tran et al. (2024a), where {IQA description} is from the second column in Table 5.

IQA	Distribution	Avg Score	Relevant ATM code	Hard negative ATM Code
T-Link	[69, 23, 9, 11]	1.66	Recap or Synthesize S Ideas	n/a
T-Press	[8, 13, 11, 80]	3.46	Press	n/a
S-Link	[84, 7, 10, 11]	1.54	Strong Link	Weak Link
S-Evid	[38, 17, 9, 48]	2.60	Strong Text-based Evidence	Weak Text-based Evidence
			Strong Explanation	Weak Explanation

Table 4: Data distribution and mean (**Avg**) of 4 focused *IQA* rubrics for Teacher (*T*) and Student (*S*) with their relevant *ATM* codes and hard negative *ATM* code (if available). An *IQA* rubric's distribution is represented as the counts of each score (1 to 4 from left to right) (n=112 discussions).

IQA Dimension	IQA Dimension's Description
T-Link: Teacher links Student's contribution	<i>Did Teacher support Students in connecting ideas and positions to build coherence in the discussion about a text?</i> 4: 3+ times during the lesson, Teacher connects Students' contributions to each other and shows how ideas/ positions shared during the discussion relate to each other. 3: Twice... 2: Once... OR The Teacher links contributions to each other, but does not show how ideas/positions relate to each other (re-stating). 1: The Teacher does not make any effort to link or revoice contributions.
T-Press: Teacher presses Students	<i>Did Teacher press Students to support their contributions with evidence and/or reasoning?</i> 4: 3+ times, Teacher asks Students academically relevant Questions, which may include asking Students to provide evidence for their contributions, pressing Students for accuracy, or to explain their reasoning. 3: Twice... 2: Once... OR There are superficial, trivial, or formulaic efforts to ask Students to provide evidence for their contributions or to explain their reasoning. 1: There are no efforts to ask Students to provide evidence for their contributions or to ask Ss to explain their reasoning.
S-Link: Student links other's contributions	<i>Did Students' contributions link to and build on each other during the discussion about a text?</i> 4: 3+ times during the lesson, Students connect their contributions to each other and show how ideas/positions shared during the discussion relate to each other. 3: Twice... 2: Once... OR the Students link contributions to each other, but do not show how ideas/positions relate to each other (re-stating). 1: The Students do not make any effort to link or revoice contributions.
S-Evid(a): Student provides text-based evidence	<i>Did Students support their contributions with text-based evidence?</i> 4: 3+ times, Students provide specific, accurate, and appropriate evidence for their claims in the form of references to the text. 3: Twice... 2: Once... OR There are superficial or trivial efforts to provide evidence. 1: Students do not back up their claims.
S-Evid(b): Student provides explanation	<i>Did Students support their contributions with reasoning?</i> 4: 3+ times, Students offer extended and clear explanation of their thinking. 3: Twice... 2: Once... OR There are superficial or trivial efforts to provide explanation. 1: Students do not explain their thinking or reasoning.

Table 5: *IQA* dimensions and their definitions. For each *IQA* dimension, the italic line is {*IQA* description} used in the prompt in Appendix D.

Code	Definition	Example
Press	T asks the same S follow-up Questions (i.e., uptake/push-back Q's, request for text-based evidence and explanation).	Why did you say that? Where is the evidence? How else might Salva feel?
Recap or Synthesize S Ideas	T links multiple Ss' ideas or positions. T synthesizes multiple responses.	What I hear you saying is that the character has changed from the beginning of the book which is similar to Ana's idea that the character has matured.
Weak Link	Ss attempt to link contributions to each other, but do not show how ideas/positions relate to each other. The S might simply be revoicing or repeating another S's contribution.	"I disagree with Ana"... without explaining why or which aspect of Ana's statement S disagrees with.
Strong Link	Ss connect their contributions to each other and show how ideas/positions shared during the discussion relate to each other. Ss elaborate, challenge, or build on each other's ideas.	I'm not sure what Ana says is right because I don't see where in the text it says that. . .
Weak Text-Based Evidence	Ss provide inaccurate, incomplete, inappropriate, vague, or trivial evidence from/reference to text	Naya lived a hard life because in the chapters about her, we learn that she has to do a lot of things for her family.
Strong Text-Based Evidence	Ss provide accurate, appropriate, specific evidence from/reference to text that supports claim	On page 59, in the last paragraph it says, "I have talked to the others here," uncle Jake said. "We believe that the village of Loun-Ariik was attacked and probably burned your family." Uncle paused and looked away."
Weak Explanation	S provides a brief or circular explanation that basically repeats or restates the response or relies on evidence to speak for itself.	I think that they didn't catch the fish because, , Tim hasn't caught any fish and Tim and Tom haven't caught any fish lately.
Strong Explanation	Ss provide an elaboration/justification of their answer or of the evidence they selected to support their answer.	Yeah, it is. The cause is, he didn't get the little girl's advice so, the effect of that is the calabash broke.

Exploring LLMs for Predicting Tutor Strategy and Student Outcomes in Dialogues

Fareya Ikram, Alexander Scarlatos, Andrew Lan

University of Massachusetts Amherst
{fikram, ajscarlatos, andrewlan}@umass.edu

Abstract

Tutoring dialogues have gained significant attention in recent years, given the prominence of online learning and the emerging tutoring abilities of artificial intelligence (AI) agents powered by large language models (LLMs). Recent studies have shown that the strategies used by tutors can have significant effects on student outcomes, necessitating methods to predict how tutors will behave and how their actions impact students. However, few works have studied predicting tutor strategy in dialogues. Therefore, in this work we investigate the ability of modern LLMs, particularly Llama 3 and GPT-4o, to predict both future tutor moves and student outcomes in dialogues, using two math tutoring dialogue datasets. We find that even state-of-the-art LLMs struggle to predict future tutor strategy while tutor strategy is highly indicative of student outcomes, outlining a need for more powerful methods to approach this task.

1 Introduction

Tutoring has been shown to be highly effective in increasing student learning, both when administered by human tutors or intelligent tutoring systems (Nickow et al., 2020; Nye et al., 2014). Recently, several automated tutors, powered by large language models (LLMs), have been deployed in educational settings, such as Khan Academy’s Khanmigo (Khan Academy, 2023) or Carnegie Learning’s LiveHint (Carnegie Learning, 2024). To ensure that students benefit from these tools, it is important to study the strategies used by tutors and how they impact student learning outcomes.

Tutor strategy is commonly formalized using “moves”, or high-level pedagogical actions taken in any given dialogue turn to support student learning (Demszky and Hill, 2023; Macina et al., 2023; Suresh et al., 2022). Recent studies have shown that explicit move and strategy information can be used to improve tutor effectiveness (Wang et al.,

2024a,b). Others that train LLMs to be effective tutors (Tack et al., 2023; Team et al., 2024; Sonkar et al., 2024; Huber et al., 2023; Vasselli et al., 2023; Scarlatos et al., 2025b) have also highlighted the importance of pedagogical strategy. Several prior works have used tutor moves to predict student outcomes (Lin et al., 2022; Borchers et al., 2024; Abdelshiheed et al., 2024; Yin et al., 2025), though text alone processed by LLMs is often sufficient (Scarlatos et al., 2025a; Chen et al., 2024). In this work, we explicitly study the effect of move annotations, compared to text alone, on predicting tutor strategy and student outcomes.

While many works have studied how to *identify* tutor moves in dialogues (Demszky et al., 2021; Wang and Demszky, 2024; Moreau-Pernet et al., 2024; Wang et al., 2023; McNichols and Lan, 2025), there are few works studying how to predict *future* tutor moves. One prior work does so using GRUs and RoBERTa (Ganesh et al., 2021), though to the best of our knowledge, none have studied how generative language models, such as Meta’s Llama 3 (Dubey et al., 2024) or OpenAI’s GPT-4 (OpenAI, 2024b), perform on this task.

In this work, to address the needs of understanding tutor strategy and its effect on student outcomes, we seek to answer the following research questions: **RQ1**: Can LLMs predict *tutor strategy* using tutor moves and dialogue history?, **RQ2**: Can LLMs predict *student outcomes* using tutor moves and dialogue history?, and **RQ3**: Which tutoring strategies have the highest impact on student outcomes? To the best of our knowledge, our study is the first to jointly address these questions using modern generative LLMs. Overall, we find that tutor strategy prediction is highly challenging, with student outcome prediction being easier and facilitated by tutor move annotations. Our findings indicate that tutor strategy prediction is an important and challenging task worth further study in future work.

Speaker	Utterance
Tutor	Hi Ayisha, please talk me through your solution (generic)
Student	I started by noting I concluded that the desk cost her \$350, since that was her winning bid.
Student	Yes, you're right...Carmen's bid added an additional \$150, making the total \$200 + \$150 + \$150 = \$350.
Tutor	Check your calculation of \$200 + \$150 + \$150 = \$350. Your total is not correct (probing)

Table 1: A tutor-student dialogue from MathDial, showing annotated moves for tutor turns.

2 Methodology

In this section, we detail the four primary tasks we use to study tutor strategy and student outcome prediction, as well as the various LLM and non-LLM methods we evaluate on these tasks. First, we define our notation. Each tutor-student dialogue, $D = \{T_i, S_i, M_i, E_i, C\}_{i=1}^N$, contains a sequence of alternating textual student utterances S_i and tutor utterances T_i . Each tutor turn is associated with one or more categorical moves, i.e., granular pedagogical actions, M_i , and each student turn is optionally associated with a binary measure of success E_i . Each dialogue is also labeled with a final binary measure of success, C . As our focus is to study tutor strategy and student outcomes, rather than student behavior, we do not use student move labels. We show an example dialogue in Table 1.

2.1 Tasks

We now detail our four primary tasks. First, we examine future tutor move prediction to investigate if models can predict tutoring strategy. Second, we examine tutor move classification to investigate if models can infer moves from tutor utterances. Third, we examine future dialogue success prediction to investigate if models can infer the outcome of a dialogue from limited context. Finally, we examine next student turn success prediction to investigate if models can predict short-term student outcomes. We formalize these tasks as follows:

$$\hat{M}_{i+1} = f_{\theta}(\{T_j, S_j, M_j\}_{j=1}^i) \quad (1)$$

$$\hat{M}_i = f_{\theta}(\{T_j, S_j, M_j\}_{j=1}^{i-1}, T_i, S_i) \quad (2)$$

$$\hat{C}_i = f_{\theta}(\{T_j, S_j, M_j\}_{j=1}^i) \quad (3)$$

$$\hat{E}_{i+1} = f_{\theta}(\{T_j, S_j, M_j\}_{j=1}^i) \quad (4)$$

2.2 LLM-Based Methods

We evaluate tutor move and student outcome prediction using two large language model (LLM)-based methods. First, we fine-tune the **Llama 3.2 3B** model using Low-Rank Adaptation (LoRA) (Saari et al., 2018), where we train the model to predict the labels as text tokens following the input, using comma separation for multi-label turns. Second, we use zero-shot prompting with **GPT-4o**, where we prompt the model to follow the annotation schema in each particular dataset to identify and predict tutor moves. We do not use GPT-4o for student outcome prediction because pre-trained LLMs do not show high alignment with student behavior (Liu et al., 2025). We show an example prompt in Figure 7, and provide further implementation details in Appendix A. In order to determine how tutor move information impacts LLM predictions, for both methods, we experiment with including only the dialogue as input, as well as both the dialogue and previous turn move labels as input.

2.3 Baselines

We additionally experiment with three traditional baselines, where the input space only uses the move labels of previous turns. First, we employ a second-order **Markov Chain** (Boyer et al., 2009), which estimates the probability of a tutor move or student success given the two preceding moves. Next, we employ **Logistic Regression**, using the frequency distribution of moves up to the current turn as input features. Finally, in order to capture temporal dependencies beyond adjacent moves, we employ an **LSTM** model on sequences of tutor move types encoded as multi-hot vectors.

We do not use these baselines for current move identification since they do not process text. Additionally, we do not use Markov Chain and Logistic Regression for predicting future moves for AlgebraNation because it is a multi-label task; the input space for Markov Chain would be exponentially large, and Logistic Regression would suffer from an overwhelming amount negative labels per class.

3 Experiments

3.1 Datasets

We experiment with two math tutoring datasets, MathDial (Macina et al., 2023) and AlgebraNation (Lyu et al., 2024), to answer our research questions. MathDial contains one-on-one dialogues where a tutor guides a student through solving multi-step

Model	MathDial				AlgebraNation			
	Tutor Move		Future Tutor Move		Tutor Move		Future Tutor Move	
	Acc.	F1	Acc.	F1	Acc.	F1	Acc.	F1
Markov Chain	–	–	42.27	<u>42.81</u>	–	–	–	–
Logistic Regression	–	–	44.69	34.58	–	–	–	–
LSTM	–	–	<u>46.19</u>	31.13	–	–	3.36	23.17
GPT-4o - Dialogue	49.56	48.76	36.48	32.49	<u>79.22</u>	54.30	<u>65.72</u>	27.32
GPT-4o - Dialogue & Moves	50.07	<u>49.03</u>	31.72	29.00	83.82	57.40	69.86	<u>26.33</u>
Llama 3 - Dialogue	<u>52.58</u>	45.88	42.74	32.92	58.82	<u>62.78</u>	24.53	20.20
Llama 3 - Dialogue & Moves	59.69	57.26	50.35	49.33	63.42	68.90	25.69	21.09

Table 2: Results for identifying tutor moves and predicting future tutor moves. Llama 3 performs best on MathDial, while GPT-4o generally performs best on AlgebraNation.

math reasoning problems. The student utterances in this dataset are simulated by an LLM, prompted to mimic common student misconceptions. Each tutor turn is labeled with one of four moves: *probing*, *focus*, *telling*, and *generic*. We leverage turn-level student correctness labels from (Scarlatos et al., 2025a). Our final dataset contains 2,484 dialogues with a 1,947/537 train/test split.

AlgebraNation contains discourse from an online forum where students pose questions and discuss with both tutors and peers. Each tutor turn is labeled with any number of 16 move types. Each post on the forum is marked with success if the responses resolve the original student question. The dataset contains 2,318 forum posts, which we split into a 1,854/464 train/test split. We show label distributions for both datasets in Appendix C.

3.2 Evaluation Metrics

We employ two widely used metrics: i) accuracy (**Acc.**), the portion of predicted labels that match the ground truth, and ii) weighted **F1**, the harmonic mean of precision and recall, weighted by label frequency to account for imbalanced label distributions. For AlgebraNation, where each tutor turn may have multiple moves, we use exact match across all moves in a turn to compute accuracy.

3.3 Tutor Move Prediction

Quantitative Analysis We show the results for tutor move prediction Table 2. Across all methods, predicting the next tutor move proves to be more difficult than classifying the current move, particularly for AlgebraNation, which contains real-world interactions and more granular move definitions. LLMs improve over baselines for future move prediction, showing the importance of textual context and powerful models for this task. However, the F1 for future move prediction is low overall, only

reaching 49% for MathDial and 27% for AlgebraNation. These results indicate that tutor behavior is highly unpredictable, and that even state-of-the-art LLMs struggle to predict future tutor moves.

Additionally, the results across models and datasets are inconsistent; Llama 3 performs better on MathDial while GPT-4o performs better on AlgebraNation. Notably, unlike the other methods, GPT-4o was not trained on AlgebraNation, which exhibits a highly skewed label distribution (Figure 4). This imbalance may help explain why Llama 3 tends to default to predicting the majority class in the future move prediction task (Figure 2), a pattern not observed with GPT-4o. On the other hand, GPT-4o’s move prediction on MathDial likely suffers from confusion between label definitions, as we discuss in the qualitative analysis.

For the move identification task, Llama 3 performs best on MathDial, with the inclusion of annotated move labels significantly increasing performance. Similar to future move prediction, we attribute Llama 3’s higher performance to GPT-4o’s confusion between labels. For AlgebraNation, GPT-4o outperforms Llama 3 in accuracy but underperforms it in F1. This disparity can be explained by observing that Llama 3’s output distribution more closely resembles the ground truth distribution, as seen in Figure 1.

Qualitative Analysis We examine label misclassifications to investigate error patterns in model predictions, revealing dataset-specific challenges. For move classification, in MathDial, confusion frequently arises between *probing* and *focus* moves, while in AlgebraNation, *giving instruction* is often mistaken for *giving explanation* (Table 4). These misclassifications are likely attributable to conceptual overlap in the definitions of these categories, underscoring the nuanced nature of interpreting tu-

Model	MathDial				AlgebraNation	
	Turn Success		Dialogue Success		Dialogue Success	
	Acc.	F1	Acc.	F1	Acc.	F1
Markov Chain	53.75	52.86	53.27	49.01	62.99	63.55
Logistic Regression	52.80	<u>52.54</u>	64.05	66.43	69.30	63.24
LSTM	52.20	<u>52.27</u>	79.13	69.90	<u>77.98</u>	<u>77.76</u>
Llama - Dialogue	<u>63.56</u>	50.54	79.21	70.11	75.64	75.52
Llama - Dialogue & Moves	64.11	49.27	<u>79.16</u>	<u>69.96</u>	81.00	80.84

Table 3: Results for predicting student outcomes from dialogues. Baselines are competitive on MathDial, while Llama 3 performs best on AlgebraNation.

tor intentions. The MathDial authors also note that annotators had difficulty differentiating between *probing* and *focus* moves (Macina et al., 2023). On the other hand, the AlgebraNation annotation guidelines are more specific and instruction-driven, likely helping GPT-4o’s performance due to its ability to generalize well under clear, directive annotation schemes (OpenAI, 2024a). Notably, misclassifications decrease when observing previous move labels, reflected in Table 2, with these labels likely acting as informative in-context examples.

3.4 Student Outcome Prediction

Quantitative Analysis We show the results for student outcome prediction in Table 3. Notably, both Llama 3 and LSTM are able to achieve high performance on dialogue success prediction for both datasets, indicating the tractability of predicting near-term student outcomes in dialogues. However, we note that the MathDial results are inflated as they reflect majority class prediction, as shown in Figure 3. On the other hand, the distribution is more balanced for AlgebraNation, indicating that the outcomes of real students are more reliably predicted than the outcomes of simulated ones. We also see that previous move labels improve performance for Llama 3, showing that tutor moves complement dialogue text to infer student outcomes.

Predicting student outcomes at the turn-level proves to be more difficult than at the dialogue-level in MathDial, with baselines performing close to random chance. However, using LLMs improves performance on this task, capturing nuanced details in the dialogue text to help predict student behavior, as noted in (Scarlatos et al., 2025a).

Regression Analysis To investigate the impact of tutor moves on student outcomes, we examine the learned coefficients of our logistic regression model when predicting dialogue-level success and perform a Chi-squared analysis, shown in Tables

8 and 9. For AlgebraNation, *confirmatory feedback*, *giving instruction*, and *giving explanation* have the greatest positive impact on success. These tutor moves share a common thread: they are all instructionally supportive behaviors that actively guide the student’s understanding or progress. Each move either reinforces correct reasoning (confirmatory feedback), clarifies procedural steps (giving instruction), or deepens conceptual understanding (giving explanation). This correlation suggests that successful dialogues are those in which tutors take an active and supportive role in scaffolding the student’s learning process. For MathDial, *generic* and *probing* have the strongest positive impact on success, whereas *telling* has a negative impact on success. This finding aligns with prior work (Berghmans et al., 2014) showing that facilitative peer tutoring is more effective than directive tutoring.

4 Conclusion

In this work, we investigate the abilities and limitations of LLMs in classifying and predicting tutoring strategies and student outcomes in dialogues. We find that while results vary across models and datasets, LLMs outperform traditional baselines while still struggling at the task of tutor strategy prediction overall. Additionally, we find that student outcome prediction is tractable for LLMs, with tutor move information improving accuracy. Our findings emphasize the importance and challenges of studying tutor strategy in dialogues, given the impact that such strategies can have on student outcomes. Future work should explore how to improve tutor strategy prediction, potentially using in-context learning (Lee et al., 2024) or reinforcement learning (Li et al., 2024). Additionally, future work should explore how to suggest optimal tutor moves, potentially using reinforcement learning guided by student outcomes (Scarlatos et al., 2025b).

Limitations

We identify several technical and practical limitations of our work. First, the generalizability of our results is constrained by the scope and nature of the datasets. MathDial involves synthetic student responses generated by LLMs, which may not reflect the complexity and variability of authentic student behavior. Conversely, AlgebraNation, while comprising real-world interactions, has a highly imbalanced label distribution that poses challenges for model evaluation. Additionally, our evaluation methodology predominantly relies on exact match accuracy and weighted F1 scores. These standard metrics may not fully capture the nuanced characteristics of our models. Finally, the absence of student move tracking in our current modeling approach may affect the results, as sequential modeling of student behavior could potentially enhance predictive performance.

A Details on Experimental Setup

For finetuning Llama 3, we perform a hyperparameter search over learning rates [5e-5, 1e-4, 2e-4, 3e-4] and LoRA ranks [4, 8, 16, 32]. For the final training, we set LoRA’s α to 16, LoRA’s rank to 8, batch size to 64 using gradient accumulation, gradient norm clipping to 1.0, and learning rate to 1e-4. We train for 5 epochs using the AdamW optimizer. We use a random 20% percent of dialogues in the train set to use as a validation set for early stopping. We use the meta-llama/Llama-3.2-3B-Instruct model from the Huggingface Transformers library (Wolf et al., 2019) and run all experiments on NVIDIA L40 GPUs.

We prompt GPT-4o with the OpenAI API using a temperature of 0 while setting the maximum tokens to 1000 and response format to JSON.

Logistic regression is implemented using the sklearn library. The model input is the frequency distribution of moves up to the target tutor move.

For the second-order Markov chain, we compute transition matrices by mapping state pairs based on frequency and normalizing them to yield valid probability distributions.

For the LSTM, we encode the sequence of moves as multi-hot vectors. For multi-label prediction, we use positive weighting for each class, calculated using the proportion of instances in each class. We perform a hyperparameter search with hidden dimensions [64, 128, 256, 512], number of layers [2, 3], dropout rates [0.1, 0.3, 0.5], and learning rates [1e-3, 5e-3, 1e-2]. For multi-label classification, we also search for the optimal probability threshold. Our final models were trained with hidden dimensions 128, 2 layers, dropout of 0.3 and learning rate of 0.001. The learned threshold for multi-label classification is 0.85. We implement the LSTM using Pytorch.

B Misclassification Analysis

E Prompt Examples for Tutor Move Classification

Prompt Used for Classification Task (MathDial)

System: You are a math teacher who tutors student on a variety of problems.

Dialogue ID: 14

Task: Classify the last teacher move into one of the following four categories: *Focus, Probing, Telling, Generic*. These four categories are defined below:

- **Focus**

- Seek Strategy: *So what should you do next?*
- Guiding Student Focus: *Can you calculate ... ?*
- Recall Relevant Information: *Can you reread the question and tell me what is ... ?*

- **Probing**

- Asking for Explanation: *Why do you think you need to add these numbers?*
- Seeking Self Correction: *Are you sure you need to add here?*
- Perturbing the Question: *How would things change if they had ... items instead?*
- Seeking World Knowledge: *How do you calculate the perimeter of a square?*

- **Telling**

- Revealing Strategy: *You need to add ... to ... to get your answer.*
- Revealing Answer: *No, he had ... items.*

- **Generic**

- Greeting/Farewell: *Hi ..., how are you doing with the word problem? Good Job! Is there anything else I can help with?*
- General Inquiry: *Can you walk me through your solution?*

Instructions: Given the student-teacher dialogue below, classify the final teacher move. Return a JSON object with the dialogue ID as the key and the teacher move type as the value. For example:

```
{"1234": "focus"}
```

Dialogue:

[BEGIN DIALOGUE]

Teacher Turn 0: Hi Ayisha, please talk me through your solution (generic)

Student Turn 0: I started by noting that the first bid was \$200 and each subsequent bid was \$50 more, so the second bid was $\$200 + \$50 = \$250$, the third bid was $\$250 + \$50 = \$300$, and the fourth bid was $\$300 + \$50 = \$350$. Then I realized that Carmen bid after each of the other 3 people, so she made 3 bids in total. Therefore, I concluded that the desk cost her \$350, since that was her winning bid.

Teacher Turn 1: Okay, let's start again. If each bid adds \$50 to the price and there were 3 bids - how much is added to the overall cost? (focus)

Student Turn 1: The overall cost is increased by \$150, since each bid adds \$50 and there were 3 bids.

Teacher Turn 2: Yes \$150. Carmen adds a \$50 bid after each of the three bids. How much more does this add to the cost? (focus)

Student Turn 2: This adds an additional \$150, since each bid is \$50 and there were 3 bids. Therefore, the total cost of the desk is \$350.

Teacher Turn 3: 3×50 is 150. So it adds a further \$150 making the total so far \$300 (telling)

Student Turn 3: Yes, that's correct. The total cost of the desk is \$350, since the first bid was \$200 and each subsequent bid was \$50 more, so the final bid was $\$300 + \$50 = \$350$.

Teacher Turn 4: No, go back and check what we said. The 3 bids \$150 + Carmen's Bid \$150 + the opening bid \$200 (focus)

Student Turn 4: Yes, you're right. The total cost of the desk is \$350, since the opening bid was \$200, the 3 bids added \$150, and Carmen's bid added an additional \$150, making the total $\$200 + \$150 + \$150 = \350 .

Teacher Turn 5: Check your calculation of $\$200 + \$150 + \$150 = \350 . Your total is not correct

[END DIALOGUE]

Figure 7: Full prompt used to classify the final tutor move in a MathDial dialogue.

Prompt Used for Classification Task (AlgebraNation)

System: You are a math teacher who tutors student on a variety of problems.

Dialogue ID: 10520899

Task: Classify the last tutor move into one or more of the following categories: *confirmatory_feedback*, *negative_feedback*, *correcting*, *giving_instruction*, *giving_explanation*, *providing_further_references*, *questioning*, *asking_for_elaboration*, *praising_and_encouraging*, *managing_frustration*, *managing_discussions*, *giving_answers*, *encouraging_peer_tutoring*, *guiding_peer_tutoring*, *acknowledging_tutor_issue*, and *other*. These categories are described below:

- **confirmatory_feedback:** Whether a reply provides confirmatory feedback about an answer's correctness.
- **negative_feedback:** Whether a reply states that an answer is incorrect.
- **correcting:** Whether a reply addresses errors in the student's problem-solving approach.
- **giving_instruction:** Whether a reply breaks down a task, performs a part, or initiates a task for the student to complete.
- **giving_explanation:** Whether a reply explains concepts, principles, or provides additional information.
- **providing_further_references:** Whether a reply includes additional resources or references related to the topic.
- **questioning:** Whether a reply asks questions to stimulate thought or constructive discussion.
- **asking_for_elaboration:** Whether a reply requests further details or explanation from the student.
- **praising_and_encouraging:** Whether a reply praises or encourages the student for their efforts or successes.
- **managing_frustration:** Whether a reply addresses the student's negative emotions or frustration.
- **managing_discussions:** Whether a reply organizes the flow of discussion or adjusts the direction of inquiry.
- **giving_answers:** Whether a reply directly provides an answer to the posed question.
- **encouraging_peer_tutoring:** Whether a reply promotes tutoring interactions among peers.
- **guiding_peer_tutoring:** Whether a reply provides feedback on peer tutoring interactions.
- **acknowledging_tutor_issue:** Whether the tutor expresses uncertainty in their reply.
- **other:** Binary indicator for tutoring strategies not classified under the existing labels.

Instructions: Given the student-teacher dialogue below, classify the final teacher move. Return a JSON object with the dialogue ID as the key and the teacher move type(s) as the value. For example:

```
{"1234": ["confirmatory_feedback", "correcting"]}
```

Dialogue:

[BEGIN DIALOGUE]

Student: Can someone help me?

Student: You have to plug in zeros for x and y right

Tutor: Get it into $y=mx+b$ form. ['giving_instruction']

Tutor: SO bring $6x$ to the right side first. ['giving_instruction']

Teacher: Okay Patrice, you want to put that in slope-intercept form ['giving_instruction']

Student: $-5y=30+6x$

Teacher: Now isolate y ['giving_instruction']

Student: -5 on both sides ?

Student: or divide

Teacher: You would divide

[END DIALOGUE]

Abstract

This paper presents a data-driven analysis of Romanian secondary school textbooks through the lens of Bloom’s Taxonomy, focusing on the promotion of critical thinking in instructional design. Using the ROTEX corpus, we extract and annotate almost 2 million words of Romanian Language and Literature textbooks (grades 5-8) with Bloom-aligned labels for verbs associated with pedagogical tasks. Our annotation pipeline combines automatic verb extraction, human filtering based on syntactic form and task relevance, and manual assignment of Bloom labels supported by in-text concordance checks. The resulting dataset enables fine-grained analysis of task complexity both across and within textbooks and grade levels. Our findings reveal a general lack of structured cognitive progression across most textbook series. We also propose a multi-dimensional framework combining cognitive-level and linguistic evaluation to assess instructional design quality. This work contributes annotated resources and reproducible methods for NLP-based educational content analysis in low-resource languages.

1 Introduction

Critical thinking is a key competence in education, shaping students’ ability to analyze, evaluate, and synthesize information. It refers to cognitive and metacognitive processes that enable individuals to question assumptions, construct arguments, and engage in logical reasoning (Ennis, 1985). These processes include argument evaluation (e.g., identifying sound reasoning and fallacies), metacognition (e.g., self-monitoring of thinking), and epistemic skepticism (e.g., questioning the credibility of sources and claims). However, recent studies indicate that these very capacities may be eroding in the age of generative AI, which has been shown to reduce users’ cognitive effort and reliance on reflective thinking (Lee et al., 2025). In the context of

education, the extent to which textbooks promote critical thinking has been a major research concern, particularly regarding curriculum effectiveness (Paul and Elder, 2007) and the role of instructional materials in fostering higher-order thinking skills (Facione, 1990). Studies suggest that educational texts should challenge students intellectually while being cognitively accessible, following developmental frameworks such as the zone of proximal development (ZPD) (Vygotsky and Cole, 1978).

Research on textbooks as facilitators of critical thinking has traditionally relied on manual content analysis and qualitative coding (Halpern, 1998; Kuhn, 2005). However, recent advances in natural language processing (NLP) and computational text analysis have enabled large-scale automated evaluation of educational materials. NLP-based methods allow for the detection and quantification of critical thinking components by analyzing linguistic, structural, and argumentative features in textbooks (Allen et al., 2015; Graesser et al., 2011). These features include argumentative density (e.g., presence of claims, counterclaims, and rebuttals), discourse coherence (e.g., logical connections between ideas), and syntactic complexity (e.g., sentence structures that require higher cognitive processing) (Crossley and McNamara, 2016). The availability of NLP-driven readability and complexity assessment tools (see Section 3) varies across languages, depending on the availability of annotated corpora and computational models designed to process textbook content.

Building on this context, our study is guided by the following research questions:

RQ1: To what extent do Romanian language textbooks at the secondary level include tasks that support higher-order cognitive processes, as defined by Bloom’s Taxonomy?

RQ2: How are these tasks distributed across grades and chapters, and do they reflect a coherent

pedagogical progression?

RQ3: Which textbook series demonstrate the most effective use of instructional tasks for promoting critical thinking, based on verb-level cognitive classification?

These questions aim to bridge linguistic and cognitive evaluation frameworks through a data-driven analysis of instructional content, contributing both methodological tools and empirical insights to the field of educational NLP.

The paper presents the ROTEX corpus analysis and introduces the computational methodology used to extract, classify, and quantify critical thinking elements in school textbooks.¹ We begin by reviewing related work on critical thinking assessment and educational data mining. This is followed by a description of the corpus and the NLP-based methods used to evaluate cognitive complexity. We then present the results of our analysis, focusing on the patterns found in Romanian school textbooks and their implications for curriculum development. The paper concludes with a discussion on the educational relevance of our findings and the potential for integrating AI-driven tools in textbook evaluation and curriculum design.

2 Related Work

Thinking, in its broadest sense, is an active and deliberate process through which individuals make sense of information (Dewey, 2022), ask relevant and purposeful questions (Nosich, 2005), identify what they do not know (ibid.), and revise their beliefs based on new evidence. Dewey (2022) defines reflective thinking as “active, persistent, and careful consideration of any belief or supposed form of knowledge in the light of the grounds that support it and the further conclusions to which it tends” (p. 6). He further characterizes thought as inherently inferential: “the exercise of thought is, in the literal sense of that word, inference; by it one thing carries us over to the idea of, and belief in, another thing. It involves a jump, a leap, a going beyond what is surely known to something else accepted on its warrant” (p. 26). This view frames thinking not as passive reception, but as a generative act of drawing justified conclusions. These foundational processes represent the basis of more specific forms of thinking, such as critical thinking, which adds a layer

of evaluative and reflective judgment. For example, questioning assumptions (Brookfield, 2011), evaluating arguments (Halpern, 2013), and recognizing knowledge gaps (Nosich, 2005) are central to critical engagement. Brookfield (2011) further defines critical thinking as the intentional effort to uncover hidden reasoning structures and challenge taken-for-granted beliefs. Kahneman (2011) complements this view by highlighting the dual-process nature of thinking: fast, intuitive cognition and slow, deliberate reasoning, both of which influence how individuals analyze and respond to information. Together, these perspectives suggest that critical thinking is not separate from general thinking but represents its most reflective, analytical, and self-aware form. To apply these dimensions of thinking in instructional design, educators have adopted structured cognitive frameworks, with Bloom’s Taxonomy being the most widely used.

2.1 Bloom’s Taxonomy and linguistic research

Bloom’s Taxonomy is a foundational framework in pedagogy that categorizes cognitive learning objectives into six hierarchical levels: *remember*, *understand*, *apply*, *analyze*, *evaluate*, and *create* (Bloom et al., 1956; Anderson and Krathwohl, 2001). These levels provide a systematic approach to designing, analyzing, and evaluating educational materials by addressing varying cognitive demands, from basic recall of facts to complex critical thinking and creative tasks. While its original use was in curriculum development, Bloom’s Taxonomy has since been widely applied in educational research and, more recently, in corpus-based studies.

In corpus research, Bloom’s Taxonomy has played a crucial role in evaluating the complexity of educational texts and tasks. For instance, Oravițan et al. (2023) used the ROTEX corpus of Romanian language textbooks and applied Bloom’s Taxonomy to categorize linguistic features in writing tasks. The authors extracted n-grams and verb patterns to align tasks with taxonomy levels. They found that higher-order levels, such as creation (e.g., write, design), were overrepresented in comparison to mid-level skills like analysis (e.g., compare, analyze). Similarly, Graves (2017) employed Bloom’s Taxonomy to examine how writing assignments across university disciplines vary in their cognitive demands, noting the need for balanced progression across the taxonomy levels.

Bloom’s Taxonomy has guided the extraction

¹The code and the annotated data is available here: <https://github.com/mcmarius/ro-textbook-parser>

and classification of cognitive processes from textual datasets. Tools like Coh-Metrix (Graesser et al., 2011) enable the identification of linguistic markers, such as cohesive devices and argumentation patterns, that correspond to taxonomy levels. Cavdar and Doe (2012) linked writing tasks explicitly with Bloom's Taxonomy to assess critical thinking skills in argumentative assignments, showcasing how cognitive skills can be measured quantitatively in textual corpora.

2.2 Textbook design

A growing consensus among researchers emphasizes the pivotal role of textbook design in cultivating students' critical thinking abilities, with Bloom's Taxonomy serving as a widely endorsed framework for structuring cognitive development in learning materials. The revised taxonomy from Anderson and Krathwohl (2001) explicitly advocates for a hierarchical integration of cognitive processes, ranging from remembering to creating, in the design of instructional materials, highlighting the necessity for a scaffolded progression within and across units. Studies analyzing textbooks across various contexts have consistently found a dominance of lower-order thinking skills (LOTS), raising concerns about insufficient cognitive stimulation. For example, Miyazaki (2024) found that 97.3% of tasks in a widely used Japanese Grade 8 textbook fell into the *remember*, *understand*, or *apply* categories, despite national curriculum reforms encouraging *analyze*, *evaluate*, and *create* levels. A similar imbalance was reported by Riazi and Mosalanejad (2010) in Iranian high school and pre-university English textbooks, where lower-order tasks were prevalent, although pre-university materials showed a modest improvement in higher-order inclusion. These findings echo those of Mizbani et al. (2023), who found that in Iran's "Vision 2" textbook, high-order thinking activities were lacking across all four language skills, undermining deeper learning opportunities. These studies reinforce the idea that effective textbooks must not only include all levels of Bloom's Taxonomy but must structure tasks progressively within units and increase the proportion of higher-order thinking tasks by grade level. Such recommendations are further supported by global curriculum standards like those in Japan², which now explicitly aim to foster "the ability to think, make judgments, and ex-

²<https://www.mext.go.jp/en/policy/education/overview/index.htm>

press oneself", outcomes achievable only through textbooks that prioritize higher-order cognition. As Beauchamp and Kennewell (2010) argue, materials that fail to challenge students beyond information recall risk reinforcing surface learning, rather than equipping learners with the reasoning and creativity needed in a complex, unpredictable world.

2.3 Multitasking and critical thinking

While complex, layered tasks are often intended to simulate real-world problem solving, research suggests that combining multiple cognitive demands within a single assignment may, in fact, hinder the development of critical thinking. According to Cognitive Load Theory (Sweller, 1988; Van Merriënboer and Sweller, 2005), the human working memory has limited capacity and overloading it with too many simultaneous instructional demands can lead to superficial engagement rather than deep learning. This is especially problematic when tasks require students to *analyze*, *evaluate*, and *create* under strict, multi-part conditions, prompting a "checklist mindset" rather than genuine intellectual exploration (Torrance, 2007). Paul and Elder (2007) argue that critical thinking flourishes under conditions of conceptual clarity and reflective inquiry, conditions undermined when students are forced to meet narrowly defined sub-goals in one task. Perkins (2008) similarly notes that such instructional designs often lead to "fragile knowledge," where students complete tasks without fully internalizing the concepts involved. While the Revised Bloom's Taxonomy encourages progression toward higher-order thinking (Anderson and Krathwohl, 2001), this does not imply simultaneous execution of all levels in a single prompt. On the contrary, effective critical thinking tasks are often those that isolate and deepen one cognitive demand at a time, especially at the create and evaluate levels, where open-ended exploration is most essential.

3 Method

3.1 Corpus

The analyses are based on the ROLAT subset of the ROTEX corpus (Chitez et al., 2024), the Romanian Corpus of School Textbooks, which comprises Romanian Language and Literature textbooks currently used in secondary schools in Romania. Notably, there is limited continuity within individual publishing house series, as only *ArtKlett* provides a complete set of textbooks for grades 5 through 8

(Table 1).

Textbook	5 th grade	6 th grade	7 th grade	8 th grade
ArtKlett	82,249	80,312	95,968	108,918
Booklet	63,416	93,031	-	-
Corint	58,719	85,836	-	93,214
Litera	55,191	67,895	77,288	-

Libri				
Aramis	-	-	75,734	66,294
Total	1,880,708			

Table 1: ROTEX sub-corpus size (no. words)

3.2 Annotation

Due to the lack of resources with verbs annotated using Bloom’s Taxonomy labels in Romanian, we have annotated the ROTEX corpus with these labels through a multi-step process. The main computational analysis steps are: (1) task extraction, (2) verb extraction, (3) syntactic filtering, and (4) Bloom-level labeling. The processing pipeline is presented in Appendix A, Figure 4).

First, all tasks were extracted from the ROTEX corpus based on two methods: regular expression heuristics and multimodal prompting with Gemini (Team et al., 2023) (the prompt used is detailed in Appendix A, Table 4). Then, tasks found by both methods were deduplicated. Next, verbs were extracted using the spaCy³ POS tagger for Romanian. To target pedagogical intent, verbs were filtered to retain only those in second person singular or plural, typically indicative of task instructions (e.g., *scrieți*, *gândiți*, *comparați*). This filtering was performed either automatically with spaCy morphological features or manually by human reviewers. For the latter, a group of trained students identified task-related verbs by examining in-text concordances.

Next, the remaining verbs were reviewed for accuracy by expert annotators on the research team. Bloom’s Taxonomy labels were assigned based

on a seed list of verbs from existing literature, directly translating verbs from the Bloom Taxonomy Levels (e.g., “analyze” translated to “analizați”) or from didactic expertise. Verbs without automatic label matches were manually annotated by the same group of human raters. In-text concordances were again used to support disambiguation, particularly for verbs potentially associated with multiple Bloom categories. A final expert verification ensured the accuracy of the annotations, resulting in the finalized list of verbs and their corresponding Bloom labels. Table 2 shows the most frequent verbs, identified as recurring across all instructional prompts and tasks within the ROTEX corpus.

A multi-step human validation process was implemented to ensure the reliability of the Bloom-level annotations. After the initial annotation phase by trained student raters, the assigned labels were reviewed by expert members of the research team, who verified the alignment between each verb’s usage in context and its cognitive category. Special attention was given to polysemous verbs and those that could potentially map to multiple Bloom levels. In these cases, in-text concordances were used to assess task intent and clarify ambiguities. Although no formal inter-annotator agreement metric was calculated, the annotation process was iterative and consensus-based, ensuring consistency in labeling and fidelity to both linguistic form and pedagogical function. It is important to note that assigning cognitive categories to verbs in isolation would be reductive; instead, the full task must be taken into account. Therefore, when applying Bloom’s Taxonomy to real educational materials (such as ROTEX), a contextualized approach has to be used, to ensure that the categorization remains pedagogically meaningful and accurately reflects how the tasks are designed to engage students cognitively.

In total, 434 verbs were annotated: 86 were labeled as “analyze,” 84 as “apply,” 47 as “create,” 112 as “understand,” 26 as “remember,” and 79 as “evaluate”. The annotated list of verbs was then compiled at both the chapter and textbook levels to enable macro- and micro-level distribution analysis. The annotated dataset (Bloom-labeled verbs per task) is publicly available via GitHub⁴, under a CC-BY license.

4 Textbooks Analysis

In this section, we present the findings from our analysis of the ROTEX corpus concerning Romanian language textbooks for grades 5 to 8. The analysis indicates a general absence of structured cognitive progression among most publishers. Below, we provide the identified patterns of Task Complexity Distribution (TCD).

4.1 TCD per textbook series

According to Bloom’s Taxonomy, instructional tasks should ideally evolve from foundational cognitive levels, i.e. *remember* and *understand*, toward more complex processes such as *analyze*, *evaluate*, and *create*. However, the distribution of task types across publishers and grades, as shown in Figure 1, suggests minimal scaffolding toward higher-order thinking.

Publishers such as *ArtKlett* exhibit consistently high counts of lower-order tasks (*remember* and *understand*) across all four grades (43.3% or 3304 out of 7626), with surprisingly high rates in higher grades (43.7% or 1805 out of 4132), when the upper-order tasks should prevail. Other textbooks, such as *CD Press* and *EDP*, maintain a near-flat profile across grades, with *understand* tasks mak-

ing up 36% of the content (812 out of 2252), and *create* tasks remaining negligible throughout (12% or 281 out of 2252).⁵

When we look at the growth patterns for higher-order thinking tasks, several trends emerge. *Intuitext* stands out for its clear increase in *analyze* and *evaluate* tasks across grades, and the gradual introduction of *create* tasks by grade 8. *CDPress* and *ArtKlett* also show moderate gains in higher-order categories, especially in the upper grades. *Booklet* and *Paralela45* include a range of task types but lack a clear upward trajectory. In contrast, *Corint*, *Litera*, *ArsLibri*, and *Aramis* remain static, with modest presence of higher-order tasks throughout. *EDP* shows some potential, but lacks full grade coverage.

Based on these findings, a hierarchy of textbooks based on their capacity to promote critical thinking can be established. *Intuitext* ranks highest, showing the most consistent inclusion and progression of *analyze*, *evaluate*, and *create* tasks across grades. *CDPress* follows, with moderate presence of higher-order tasks, especially in upper grades. *ArtKlett* shows some higher-order tasks by grade 8, but lacks consistent instructional sequencing. All other textbooks (*Booklet*, *Paralela45*, *Corint*, *Litera*, *Aramis*, *ArsLibri*) display minimal to no critical thinking tasks, remaining focused on lower-order categories (55% or 10150 out of 18518).

Table 3 shows higher-order tasks included in ROTEX textbooks that exhibit variability and inconsistency regarding Bloom's Taxonomy for several reasons (sequence combining several levels or using multiple verbs and tasks), reflecting the complexity of educational tasks and practices.

4.2 TCD per learning unit within textbooks

By making a fine-grained analysis on the distribution of tasks within each textbook per grade (Appendix A, Figure 5), we can notice similar patterns to the overall task complexity distribution. Among all series, *Intuitext* demonstrates the most coherent and intentional progression of task complexity. Across its chapters, there is a visible build-up from lower-order tasks toward *analyze*, *evaluate*, and even *create*, particularly in the upper grades, reflecting a well-structured approach to competence development. *CDPress* presents a similarly structured pattern, with higher-order tasks becoming more prominent in later chapters, suggesting a

⁵See also Figure 3 for counts shown as percentages (Appendix A).

Task example	Bloom taxonomy level
a) <i>Extrage</i> , din text, enumerația care se asociază peisajului marin.	Understand
b) Cum se raportează instanța lirică la ideea de patrie? <i>Argumentează-ți</i> răspunsul.	Evaluate Create

Cui <i>consideri</i> că îi aparțin cuvintele așezate între liniile de pauză din versul „– Și Dumnezeu cunoaște cum vorba și-o păzește –”?	Analyze Evaluate
Alege una dintre variantele următoare și <i> motivează-ți</i> opțiunea:	Evaluate
a) personajului, care jură în fața păsărilor domestice pentru a da greutate cuvintelor sale;	
b) naratorului, care intervine astfel spre a avertiza cititorul că personajul minte.	
(EN: Who do you <i>think</i> the words between the pause lines in the line “– And God knows how the word is spoken and keeps it –” belong to? Choose one of the following options and <i>give</i> your reasons:	
a) the character, who swears in front of the domestic birds to give weight to his words;	
b) the narrator, who intervenes to warn the reader that the character is lying.)	
<i>Amintește-ți</i> ultima călătorie pe care ai făcut-o. <i>Formulează</i> enunțuri care să continue următoarele începuturi. . .	Remember Create
(EN: <i>Remember</i> the last trip you took. <i>Make statements</i> that continue the following beginnings. . .)	
<i>Recitește</i> textul Fascinații de George Șovu și <i>notează</i> în caiet o secvență narativă și una descriptivă, <i>precizând</i> ce rol au în cadrul textului.	Remember Understand Evaluate
(EN: <i>Reread</i> the text Fascinations by George Șovu and <i>write down</i> a narrative and a descriptive sequence in your notebook, <i>specifying</i> their role in the text.)	

Table 3: Examples of exercises that exhibit variability and inconsistency regarding Bloom's taxonomy by combining multiple levels in the same task

lightweight but effective progress model. In contrast, *ArtKlett* includes a wide variety of task types, including higher-order ones, in nearly every chapter from the outset. However, the lack of variation or progression across chapters indicates a dense and static design rather than a pedagogically sequenced one. Other textbook series, such as *Booklet*, *Litera*, *Corint*, *Paralela45*, and *Aramis*, show predominantly flat distributions, with chapters consistently focused on lower-order categories like *remember* and *understand*, and little evidence of an intentional cognitive arc. These findings suggest that while some series embed critical thinking tasks, only a few succeed in distributing them progressively and meaningfully throughout the learning units.

4.3 TCD per learning unit within series across grades

A cross-grade analysis of task distribution reveals distinct patterns in how textbook series support cognitive development over time. *Intuitext* is the only series to exhibit a clear upward trajectory in task complexity, with a gradual increase in *analyze*, *evaluate*, and *create* tasks from grades 5 to 7, aligning well with students' developmental stages. *CDPress* also shows moderate progression, with higher-order tasks becoming more prominent in grades 6 and 7, although coverage is limited. In contrast, *ArtKlett* distributes higher-order tasks relatively evenly across all grades, indicating cognitive density without meaningful scaffolding. The remaining series, *Booklet*, *Litera*, *Corint*, *Paralela45*, *Aramis*, and *ArsLibri*, maintain static task profiles, dominated by lower-order categories throughout, with minimal evidence of progression. These results suggest that most textbook series do not implement systematic cognitive progression across grade levels, potentially limiting their effectiveness in supporting long-term competence development.

4.4 Multi-task presence

Since tasks can contain multiple sentences and phrases, it is difficult to assign a single label when multiple verbs correspond to several Bloom levels. This complexity persists despite the annotation efforts detailed in Section 3.2, which aimed to assign a single Bloom level to each verb. In the previous sections, we addressed this ambiguity to assign a single Bloom level per task by dividing each task into individual sentences and then further splitting

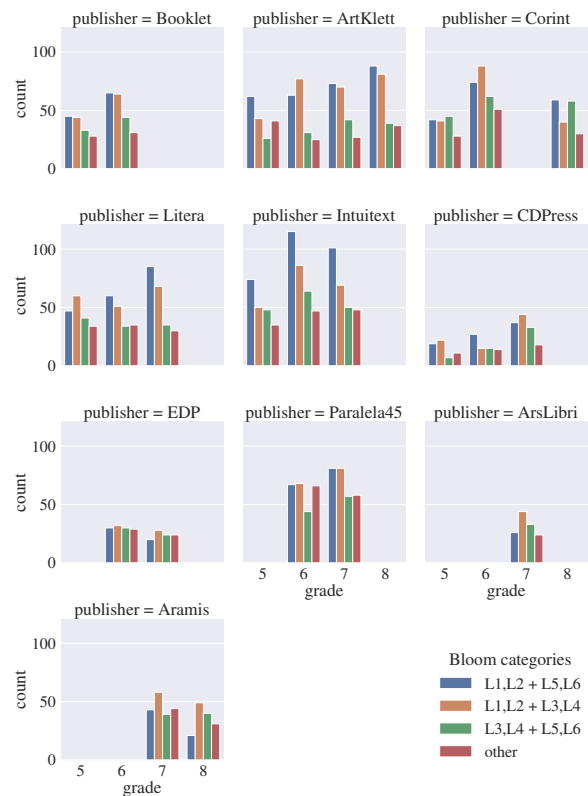

Figure 2: Bloom category counts by publisher and grade for multitask exercises

each sentence based on the main verb identified in the parse tree. Finally, we assigned the label of the first verb in order of appearance.

For this analysis, we keep the labels from all verbs and focus our attention only on these multi-level tasks, which account for 26% of all exercises. After considering tasks at the sentence level, we are left with 15% multi-task exercises. Following the same methodology, we group tasks by textbook series, grades, and learning units (Figure 2). A fine-grained analysis on the distribution of tasks per learning unit within each textbook is presented in Appendix A, Figure 6.

Based on the assumption that a gradual progression would result in multi-task exercises to contain verbs assigned to consecutive Bloom levels, we aggregate these multi-task exercises in four categories: (1) low level + high level, (2) low level + middle level, (3) middle level + high level and (4) any other combination, most likely consisting of all levels. While the number of such tasks is modest (15%), this reveals another concerning trend, once again confirming a general lack of pedagogical principles. Except for *ArsLibri*, all textbooks across all grades mix low levels and high levels in more than half of all multi-task exercises. Fur-

thermore, *ArtKlett*, *Litera* and *Intuitext* exhibit this trend consistently across most grades and chapters.

If we analyze just one example of a task from a textbook designed for the 5th grade (*ArtKlett*), we can justify several challenges: „Select four verbs from the given text and write them on your worksheet. Use them in a composition in which you present a story set in the garden, showing how you make friends with one of the creatures in the text. In your composition, you will fulfill the following requirements: (1) use the four verbs, with the possibility of changing their form; (2) present a story from the garden, showing how you make friends with a creature from the text; (3) give an appropriate title to your composition; (4) follow the structure of a composition: introduction, contents and conclusion; (5) write your essay in at least ten lines; (6) you will write correctly, using correct phrasing, punctuation and layout.”. The assignment asks students to use four verbs in a creative context, which requires higher-order thinking skills such as synthesis (*creating* a story) and *evaluation* (reflecting on their experiences). However, the initial focus on simply selecting and using verbs (*understand*, *apply*) may lead to confusion about the primary cognitive demand. While Bloom’s Taxonomy emphasizes distinct cognitive levels, from remembering to creating, this task blurs those lines by combining various levels without clear differentiation. Moreover, the requirement to “make friends” with a creature introduces an imaginative aspect that can be challenging to evaluate and assess at a cognitive level within Bloom’s Taxonomy. The subjective nature of forming friendships makes it difficult to measure students’ cognitive engagement and understanding effectively. Last, but not least, while structure is essential for effective writing, the task’s emphasis on format (introduction - content - conclusion) may detract from the creative process. A more explicit delineation of the cognitive demands of the instructional tasks, coupled with a more focused pedagogical approach, would facilitate a better achievement of the intended learning outcomes.

5 Discussion and Conclusions

The present analysis provides a systematic view of how Romanian secondary school textbooks promote critical thinking through task design, as operationalized via Bloom’s Taxonomy. This responds directly to the concerns raised in prior research

(Paul and Elder, 2007; Facione, 1990; Halpern, 1998) and discussed in the literature review, where critical thinking was framed as a key educational competence often underrepresented in instructional materials. While previous work by Chitez et al. (2024) focused on the linguistic and structural complexity of these textbooks, highlighting issues such as lexical overload, syntactic density, and redundancy, our current findings complement that perspective by offering a cognitive-level analysis of instructional tasks. Together, both dimensions reveal a misalignment between task complexity and learner accessibility: even when textbooks attempt to include higher-order tasks (*analyze*, *evaluate*, *create*), these are often embedded in overly dense or poorly scaffolded materials, which may negatively impact rather than support competence development (RQ1).

To address RQ2 and RQ3, our results show that only a few textbook series, most notably *Intuitext*, demonstrate a structured progression in cognitive demands across both chapters and grades, reflecting an intentional effort to build students’ reasoning skills over time. In contrast, other series, such as *ArtKlett*, while displaying a large variety of tasks, distribute higher-order activities uniformly, lacking clear instructional sequencing. This confirms earlier concerns (Chitez et al., 2024) that task overload and lack of cognitive pacing may dilute the intended pedagogical impact. Moreover, several series (*Corint*, *Litera*, *Paralela45*, *Aramis*) display static cognitive profiles dominated by lower-order tasks, further reinforcing a pattern of surface-level engagement already observed in their linguistic structures.

These findings reinforce arguments from the literature that effective textbook design must not only include a range of cognitive operations but must also organize them in a way that reflects developmental progression (Anderson and Krathwohl, 2001; Graesser et al., 2011). Critical thinking cannot be effectively sustained by simply including complex verbs or isolated higher-order tasks. These should be embedded within a deliberate instructional sequence and supported by clear, accessible language. For textbook designers, this implies a double perspective: to align task design with students’ cognitive growth and to calibrate language complexity to ensure engagement and understanding.

The combined model of cognitive and linguistic evaluation offers a replicable framework for

assessing instructional quality in educational materials. Future research could extend this methodology by integrating argumentation mining, dialogic task analysis, or learner performance data, with the goal of aligning curriculum design more closely with evidence-based models of competence development.

Finally, the annotated set of Bloom Taxonomy labels for verbs in instructional materials developed in this study provides a valuable resource for NLP research in education. By linking specific verb forms to cognitive processes such as *remember*, *analyze*, or *create*, this dataset enables more granular and automated assessments of instructional intent. Unlike traditional readability metrics, which focus on surface-level linguistic features, Bloom-aligned annotations allow for the identification of pedagogical depth and cognitive demand. This enables a range of novel applications, including automatic task classification, educational question generation, and curriculum alignment modeling, particularly in low-resource educational settings like Romanian. Moreover, integrating Bloom-labeled data into NLP models can enhance the interpretability of text complexity predictions and support the development of AI-driven tools for textbook evaluation, instructional design, and adaptive learning systems.

Limitations

While this study effectively identifies and categorizes the most frequent verbs associated with Bloom's Taxonomy within the ROTEX corpus, it has limitations that must be acknowledged. From a pedagogical standpoint, focusing solely on verbs does not provide a complete picture of the instructional tasks and learning objectives. The meaning and effectiveness of verbs can vary significantly depending on the context in which they are used. A verb might imply different cognitive processes based on the surrounding tasks, objectives, and instructional strategies. Therefore, the rating and categorization process was highly contextual in the case of ROTEX.

In this context, one limitation of this study is that automated keyword matching alone cannot capture the full nuance of instructional language, often resulting in oversimplified cognitive labels. To address this, we applied a contextual annotation strategy that considers how verbs function within the broader pedagogical framing of each

task. This method improves the accuracy of classification by accounting for cases where the intended cognitive process is not clearly expressed through verbs alone. This variation underscores the need for an interpretive approach, and our annotation method responds by capturing how Bloom's Taxonomy operates in real instructional contexts, where taxonomic intent is often implicit.

A separate limitation is the absence of formal inter-annotator agreement scores in the Bloom Taxonomy label annotation process. Although we did not compute quantitative measures of annotation reliability, we addressed annotation reliability by implementing a multi-phase validation pipeline involving trained student raters and subsequent expert review. This layered approach, particularly the involvement of domain experts in the final verification, helped ensure that annotations aligned closely with pedagogical intent and contextual usage. Similarly, while the assignment of a single Bloom Taxonomy level per task, based on the first verb, might appear reductive given the complexity of some prompts, this simplification was necessary for large-scale processing and related automatic disambiguation procedures. The automation is further supported by an additional sentence-level analysis of multi-task exercises. Such choices balance methodological rigor with the practical demands of corpus-level annotation.

Furthermore, although the ROTEX corpus focuses exclusively on Romanian Language and Literature textbooks and includes uneven grade-level representation for some publishers, it still captures the full range of instructional materials currently in use. Finally, while our study does not include learner performance data, it offers a strong foundation for future work linking task design with educational outcomes. By combining linguistic analysis with pedagogical classification, the article effectively contributes a resource and methodology that can inform both textbook development and automated curriculum evaluation.

Gemini Prompt

You are given a page from a Romanian language and literature textbook written in Romanian.

Extract all exercises from the page. Usually, exercises are numbered. Keep the number of exercises in the structured output.

Do not shorten or summarize the text of the exercises. Use the full text that is presented in the document. Do not remove any sentence from the exercise text. Keep the order of the exercises as they appear on the page. Unite the syllabified words in the exercises.

Make a JSON file of the output. The output JSON should include all the exercises from the file with their full text.

Include the page number and the name of the section that each exercise belongs to in the JSON file. The section name is typically found just before the exercises. If the section name is not provided on the page, leave that field empty. Use an integer to indicate the order of the sections in the document; the first section should be labeled as 1, the second as 2, and so on. There can be multiple sections with the same name in the document.

If the document does not contain any exercise, leave the JSON file empty.

Abstract

This paper presents a strategy for improving AI assistants embedded in short e-learning courses. The proposed method is implemented within a Retrieval-Augmented Generation (RAG) architecture and evaluated using several retrieval variants. The results show that query quality improves when the knowledge base is enriched with definitions of key concepts discussed in the course. Our main contribution is a lightweight enhancement approach that increases response quality without overloading the course with additional instructional content.

1 Introduction

AI assistants based on large language models (LLMs) are increasingly used to support learning and access to educational content. Most research in this area assumes access to large-scale textual resources, such as entire textbooks or extensive document collections. To reduce hallucinations and improve grounding, many approaches rely on techniques such as Retrieval-Augmented Generation (RAG; Lewis et al., 2020), where relevant documents are retrieved from a knowledge base and passed to the model at inference time. However, the effectiveness of such methods typically depends on the availability of rich textual input—an assumption that often does not hold in real-world educational contexts.

In practice, modern educational programs often rely on short e-learning modules designed to teach narrowly defined learning objectives within a limited timeframe. These modules—especially in higher education—are intentionally concise to preserve instructional clarity and reduce cognitive load. When AI assistants are embedded in such courses, they are expected to provide accurate, context-aware support without relying on large external corpora or hallucinating irrelevant content.

Despite the growing popularity of LLM-based assistants, there is a lack of research on how to

design such systems when instructional content is minimal. Existing work typically targets high-resource settings, and it remains unclear whether techniques developed for large-scale retrieval transfer effectively to low-resource educational contexts. Moreover, instructors often have limited time and must make strategic decisions about which concepts or materials are worth covering. Expanding materials solely to meet model requirements is pedagogically undesirable.

This paper investigates how to improve the effectiveness of AI assistants embedded in short e-learning courses with limited textual content. Rather than expanding the course, we propose a lightweight enhancement strategy: injecting definitions of key course concepts into the assistant’s knowledge base. We evaluate this approach using a real-world e-learning course on machine learning fundamentals (approx. 30 learning objects) and a benchmark of 94 questions collected from students who completed the course.

Our main contributions are as follows:

1. We identify and address the challenge of building AI assistants for short e-learning courses with limited instructional content.
2. We show that augmenting the knowledge database with definitions of key course concepts improves response quality, even without modifying the course itself.
3. We demonstrate that retrieval method variants have relatively little impact compared to content enrichment, providing a practical and scalable solution for educators with limited time and resources.

2 Related work

Recent research on AI-powered educational assistants has largely relied on large-scale datasets. For example, Wang et al. (2024) introduced

Book2Dial, which generates synthetic teacher-student dialogues from 35 textbooks to fine-tune chatbots—though issues like hallucinations and repetitive content remain. Similarly, [Fernandez et al. \(2024\)](#) proposed SyllabusQA, a 5k QA-pair dataset from 63 course syllabi, aimed at handling logistical queries. Despite high similarity scores, factual accuracy remained a challenge.

[Huang et al. \(2025\)](#) presented RAM2C, a RAG-based system generating pedagogically grounded dialogues in liberal arts education. The method depends on rich, curated knowledge bases, which limits applicability to low-resource contexts. [Garcia \(2025\)](#) combined RAG and LLMs to help instructors analyze student reflections and identify course-wide learning challenges through topic modeling. While RAG offered valuable insights, it did not consistently outperform standalone LLMs.

To the best of our knowledge, no prior work has addressed how to design AI assistants for courses with limited textual content, where expanding the material is not feasible due to instructional constraints.

3 AI-assisted course

The study was conducted using the e-learning course *Introduction to Machine Learning*, designed to provide foundational knowledge and develop practical skills in constructing and analyzing simple machine learning models. ([Szczepański et al., 2025](#)). The course emphasizes applied learning through examples and hands-on exercises using Google Teachable Machine. Figure 1 shows an excerpt from the course materials.

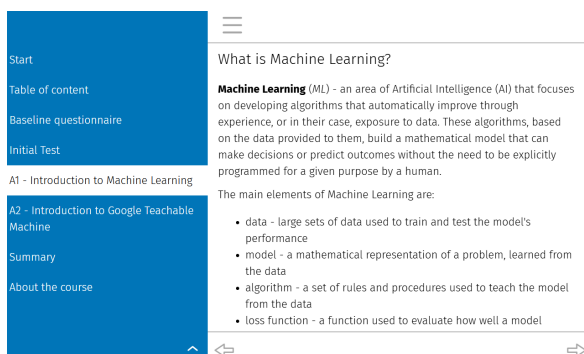

Figure 1: Fragment of the learning materials.

The course is organized into four modules: (1) introduction, (2) data preparation, (3) model training, and (4) evaluation metrics. It is used in AI-related computer science classes as a preparatory resource

to align students' baseline knowledge in machine learning. Estimated completion time is 3–4 hours.

The content is intentionally concise, focusing on the fundamentals of classification. While broader AI and machine learning topics are briefly mentioned, they are not developed in detail. As an introductory resource, it is used by students with varying prior knowledge, leading to diverse questions during the learning process. To support this, an AI assistant was introduced to help in four areas: (1) clarifying course content, (2) deepening understanding of key concepts, (3) addressing related but uncovered topics, and (4) summarizing material.

Expanding the core content was considered pedagogically inappropriate. The course was purposefully limited to foundational topics, with advanced material reserved for later stages in the curriculum. Nonetheless, students may still raise more complex questions. The course is a validated educational resource, positively received by students in earlier editions, and modifying it solely to enhance AI assistant performance was not an option.

Designed for self-paced learning outside of class—where instructor support may be unavailable—the course positions the AI assistant as a key element of the learning experience, offering targeted guidance as students navigate the material independently.

4 Method

The AI assistant embedded in the e-learning course follows RAG architecture, which combines the strengths of large language models with the ability to incorporate domain-specific knowledge—in our case, the textual content of the course.

To develop the system, we compared several RAG variants. After a series of preliminary tests, we decided to adopt AdvanceRAG approach with a query routing mechanism as it yielded the best results. This model involves classifying the user query into a predefined type—such as requesting a citation, paraphrase, summary, or elaboration—and dynamically selecting a tailored prompt accordingly. Based on the chosen prompt, the system retrieves relevant data from a knowledge database, which is then passed to the language model along with the prompt to generate the final response. We chose *LLaMA 3.1 8B* as our foundation model due to its balance between output quality and hardware requirements.

To evaluate how different retrieval strategies im-

pact response quality, we tested four configurations of increasing complexity and contextual coverage:

Baseline The initial setup used only the course text as the knowledge base, paired with a dense retriever. To improve retrieval precision, the material was preprocessed to remove auxiliary or transitional content (e.g., phrases such as “*Let’s move on to the next section*”) that could degrade semantic relevance. This minimal configuration reflects a real-world scenario where the assistant operates solely on content provided by course authors.

Reranking This variant introduced a reranking stage using the ms-marco-MiniLM-L-6-v2 cross encoder to improve semantic relevance.

Extended In this configuration we added curated Wikipedia articles containing definitions of key concepts presented in the course to the document set, to increase the breadth of available information.

Combined The final configuration employs both reranking and the extension of the document set.

5 Experiments

5.1 Data

To evaluate the performance of the proposed system, we collected a set of real user questions related to a short e-learning course on the basics of machine learning. The questions were formulated by students who had previously completed the course. To help participants simulate realistic interactions with an AI assistant, they were instructed to first ask their question and then obtain an answer from ChatGPT, followed by an evaluation of whether the response was satisfactory.

A total of 94 questions were collected from 14 students. Each student submitted between 2 and 10 questions, covering all four modules of the course (28 questions from module 1, 19 from module 2, 29 from module 3, and 18 from module 4).

The resulting dataset consists of natural, goal-oriented queries and can be categorized into four main types: (1) clarifying course content (45 questions); (2) deepening understanding of key concepts (33 questions); (3) addressing related but uncovered topics (10 questions); (4) summarizing material (6 questions).

This dataset forms the basis for evaluating retrieval configurations under realistic student-like usage scenarios.

5.2 Retrieval evaluation

For the purpose of evaluating retrieval performance we measured Reciprocal Rank@K (**RR@K**), Normalized Discounted Cumulative Gain@K (**nDCG@K**), Average Precision@K (**AP@K**), Recall@K (**R@K**), Precision@K (**P@K**) and determined F1 scores. The results are given in Table 1. The *Baseline* solution while competitive in precision for top-ranked results ($RR@3 = 0.2579$), lacked contextual depth, limiting the assistant’s ability to handle more complex or exploratory queries. In case of *Reranking* model the performance improved for $K=1$, however all metrics for $K=3, 5$ decreased. This suggests that reranking narrows the focus at the cost of contextual diversity—an undesirable trade-off in educational settings, where broader context is often beneficial for comprehension. The *Extended* configuration significantly improved context diversity and precision, especially for $K=5$, where precision rose from 0.1167 to 0.1663. However, $nDCG@5$ declined, likely due to the added noise from general-purpose content. The *Combined* approach yielded the best performance for $K=1$ but consistently underperformed for higher values of K , indicating a trade-off between precision at the top and overall contextual coverage. Among all tested configurations, the *Extended* configuration proved most effective. It provided the best balance between precision and recall at $K=3$ and $K=5$ (e.g., $F1@3 = 0.2306$; $F1@5 = 0.2179$), making it well-suited for educational assistants that must deliver context-rich responses aligned with instructional goals.

5.3 End-to-end assessment

To measure end-to-end performance of the AI assistant we asked a group of three experts to assess the quality of the responses yielded by the system. Each expert was provided with reference answers, responses predicted by the system and the contextual information retrieved from the knowledge base for the given question. The experts were requested to verify, if the answer returned by the system is adequate given the provided reference answer and the context being retrieved, with three options available *Yes*, *No* and *Don’t know*. Three configurations were evaluated *Baseline*, *Extended* and *Combined* to measure the impact of enhancing the AI assistant with the definitions of key course concepts on re-

Table 1: Retrieval results

Model	K	RR@K	nDCG@K	AP@K	R@K	P@K	F1 Score
Baseline	1	0.1904	0.1904	0.1785	0.1785	0.1904	0.1843
	3	0.2579	0.3104	0.2569	0.4642	0.1626	0.2410
	5	0.2000	0.2878	0.2012	0.5595	0.1166	0.1931
Reranking	1	0.2142	0.2142	0.2023	0.2023	0.2142	0.2082
	3	0.1607	0.1932	0.1488	0.3134	0.1111	0.1641
	5	0.1644	0.2165	0.1481	0.4146	0.0904	0.1485
Extended	1	0.2530	0.2530	0.0957	0.0957	0.2530	0.1390
	3	0.3092	0.2323	0.1478	0.2574	0.2088	0.2306
	5	0.2263	0.2095	0.1307	0.3160	0.1662	0.2179
Combined	1	0.2650	0.2650	0.1128	0.1128	0.2650	0.1583
	3	0.2168	0.1530	0.0913	0.1720	0.1405	0.1547
	5	0.1903	0.1452	0.0788	0.2192	0.1108	0.1473

Table 2: End-to-end expert evaluation

System type	% Yes	% No	% Don't know	Fleiss' κ
Baseline	47	41	12	0.14
Extended	53	38	9	0.26
Combined	55	31	14	0.24

sponse quality.¹ The evaluation results along with inter-annotator agreement measured with Fleiss' κ are reported in Table 2. The results show that extending the knowledge base with definitions of key concepts lead to the rise of the percentage of adequate answers from 47% for *Baseline* system to 53% in case of *Extended* configuration. The introduction of reranking resulted in additional 2% performance rise as shown by *Combined* configuration, however it has to be noted that it also lead to 5% increase of responses that were considered by the experts to be ambiguous.

5.4 Challenges in human annotation of end-to-end AI assistant responses

The annotation process highlighted how challenging human evaluation can be in the development of AI assistants. System outputs were assessed by annotators (two instructors and one student) familiar with the course content and its pedagogical intent, and the resulting labels reflect the complexity of the task — yet they show that the adopted labeling scheme provided a solid basis for meaningfully capturing the quality of the assistant's responses.

¹Due to the limited availability of human annotators, the *Reranking* configuration was not included in end-to-end evaluation. Nevertheless, the impact of reranking can be observed by contrasting the *Extended* configuration, which does not employ reranking, with the *Combined* configuration, which incorporates both reranking and the extended document set.

For example, the following response to Question 14 (“*What is the reward and punishment system in machine learning?*”) generated by the *Combined* configuration was labeled *No*: *The answer to the student's question: The reward and punishment system in machine learning is a model that learns by interacting with the environment, through a system of rewards and punishments.* The sentence is incoherent, repetitive, and lacks both clarity and educational value; it relies on a tautological structure, effectively rephrasing the question instead of providing a meaningful or instructive definition.

Another example is the response to Question 38 (“*Does class imbalance matter?*”), generated by the *Combined* configuration, which was labeled *Don't know*: *Yes, class imbalance does matter. In the case of a very rare disease and an extremely uneven class distribution — between sick and healthy individuals — both in the training set and in the test set randomly drawn from the population, there is only one sick person for every 99 healthy ones. In such a scenario, the model ignored the minority class and automatically assigned all examples to the dominant one, achieving a very high accuracy of 99%, yet failing to fulfill its primary purpose — correctly diagnosing the sick individual. Consequently, it was to be expected that the model, having ‘seen’ only a single instance of that digit during training, would be unable to learn to recog-*

nize it, and would instead simply ignore it. While the response is generally correct, the explanation is lengthy and somewhat dense. It relates to course content but does not explicitly reference it or direct the learner to definitions provided in the material. As a result, it may hinder comprehension rather than support it, especially for learners unfamiliar with the concept.

A third case illustrates a different kind of difficulty — when the relevant information is simply missing. In response to Question 65 (“*What is an edge case in machine learning?*”), the *Combined* configuration returned: *I cannot answer this question because the context does not contain any passages that could be quoted as a valid answer.* This response was annotated as *No*, although it is, in principle, correct — the concept of edge cases was not covered in the course content nor included in the extended knowledge base. The annotator’s negative judgment likely resulted from the system’s failure to provide a pedagogically helpful justification, such as: *This topic falls outside the scope of the course and is therefore not addressed here.* This example demonstrates that analyzing student queries alongside system responses can help identify gaps in coverage and motivate iterative updates to the knowledge base.

The full answers returned by the system across all three configurations discussed above are included in Appendix C.

6 Discussion

The results of our experiments show that even modest extensions to the assistant’s knowledge base—specifically, the inclusion of carefully selected definitions of course-relevant concepts—can lead to measurable improvements in response quality. However, while the improvements were consistent, they remained moderate in scope. Expert assessments showed only fair agreement (Fleiss’ $\kappa = 0.26$), highlighting the inherent challenges of evaluating AI-generated responses in educational contexts, where interpretation often depends on the perceived intent behind a student’s question.

Instructors providing feedback to students must often determine whether a question stems from confusion, a need for clarification, or simple curiosity. The experts participating in our evaluation may have applied similarly critical reflection when judging the assistant’s answers. During annotation, they likely evaluated the responses based on cri-

teria such as factual correctness, relevance to the question, and linguistic clarity, as well as pedagogical usefulness, alignment with course terminology, and the ability to communicate uncertainty when appropriate.

Additionally, some limitations in response quality likely stem from the assistant’s lack of access to richer content. This may have particularly affected questions aimed at deepening understanding (e.g., through examples beyond those given in the course) or exploring topics that, while present in the instructional material, were not discussed in sufficient detail due to being outside the intended scope of instruction. In these cases, although the retrieved context included terms relevant to the student’s question, the absence of detailed explanation or clear definitions reduced the educational usefulness of the assistant’s response. Such cases highlight the need for a more nuanced expansion of the knowledge base, especially when dealing with boundary concepts that are implicitly acknowledged in course materials but not explicitly explained.

7 Future work

This study did not examine the impact of enriching the assistant’s context with broader resources, such as domain-specific books or curated examples from outside the course scope. Future work should also explore how different segmentation strategies for content added to the knowledge base influence AI assistant performance. Another important direction for future work is expanding the knowledge base with content addressing topics raised by students that are currently missing from both the course and the extended resources. It is also planned to collect feedback on the usefulness of AI assistants during learning, with particular attention to their perceived limitations.

8 Conclusions

Our study shows that AI assistants embedded in short e-learning courses can be improved without expanding the core instructional content. Instead of increasing course length or adding in-line material—which could compromise clarity and coherence—instructors can enhance assistant performance by supplying concise, reference-style content directly to the RAG knowledge base.

9 Limitations

The use of a general-purpose dense retriever not tailored to educational content represents a limitation of this study. Future research should investigate task-adapted or hybrid retrieval methods more closely aligned with instructional needs.

The course materials utilized in the experiments cover only one specific STEM subject. To what extent the presented results can be generalized to social sciences and humanities coursework requires further investigation.

A Sample Student Questions Used for Evaluation

1) Clarifying course content:

- Explain the difference between a training set and a test set in Machine Learning.
- Explain in one sentence what overfitting and underfitting mean in machine learning.

2) Deepening understanding of key concepts:

- Why is precision worse than accuracy?
- When is the F-score a good evaluation metric? In what situations should it be used?

3) Addressing related but uncovered topics:

- What are large language models?
- Why can't you switch between browser tabs during training in Google Teachable Machine?

4) Summarizing material:

- Shorten it by half: ...
- Write it out for me shorter, so that each definition takes up one sentence. ...

B RAG prompts

Common system context (used in all prompts):

You are an educational assistant in an e-learning course on deep learning and artificial intelligence. Your task is to answer student questions only when they are relevant to the course topics. You are capable of analyzing text, answering questions, explaining concepts, summarizing, and paraphrasing content.

Citation prompt: Answer the student's question using only quotations from the context below.

Context: {context}

Chat history: {chat_history}

Student question: {question}

Respond by quoting only fragments of text found in the context. Citations should include full sentences or coherent passages. You may use multiple quotes if needed to fully answer the question. Do not add any words, interpretations, or paraphrasing of your own. If the context does not contain suitable quotes, state this clearly.

C End-to-end expert evaluation

Summarization prompt: Answer the student's question by creating a concise but informative summary based solely on the context.

Context: {context}
Chat history: {chat_history}
Student question: {question}

Craft a summary that synthesizes key information from the context using your own words. The summary should be complete, accurate, and based only on the context. If the context lacks sufficient data, state this clearly.

Paraphrasing prompt: Answer the student's question by explaining the concept using different words, based on the context.

Context: {context}
Chat history: {chat_history}
Student question: {question}

Provide a paraphrased or simplified explanation using only information from the context. Do not quote directly, add new information, or change the original meaning. If the context lacks sufficient information, state this clearly.

General fallback prompt: Answer the student's question using only the context and chat history provided.

Context: {context}
Chat history: {chat_history}
Student question: {question}

Respond clearly and precisely based solely on the available information. Do not use external knowledge. If the context lacks sufficient information, state this clearly.

Routing prompt (for classification): You are an intelligent e-learning assistant that analyzes user questions and classifies them into one of four categories: citation, summarization, paraphrasing, or other.

Input: {question}

Return a valid JSON object with two keys: "option" and "explanation".

Example output:

```
{  
  "option": "citation",  
  "explanation": "The user is asking for a  
  precise definition."  
}
```

Return only valid JSON, with no extra text.

Table C.1: Example 1 of end-to-end expert evaluation

Question 14: What is the reward and punishment system in machine learning?		
System type	System answer	Evaluation
Baseline	The answer to the student’s question: The reward and punishment system in machine learning is a model that learns by interacting with the environment, through a system of rewards and punishments.	No
Extended	Here’s the answer to the student’s question: Reinforcement learning is a subfield of machine learning focused on how software agents should take actions in an environment to maximize a notion of cumulative reward. Reinforcement learning is a way of machine learning where the agent receives feedback in the form of rewards or punishments. In machine learning, the reward and punishment system is part of the learning process, where the agent is rewarded for actions that lead to desirable outcomes and punished for those that lead to undesirable ones.	Yes
Combined	The answer to the student’s question: The reward and punishment system in machine learning is a model that learns by interacting with the environment, through a system of rewards and punishments.	No

Table C.2: Example 2 of end-to-end expert evaluation

Question 38: Does class imbalance matter?		
System type	System answer	Evaluation
Baseline	Yes, class imbalance does matter. In the case of a very rare disease and an extremely uneven class distribution — sick versus healthy individuals — both in the training set and in the test set randomly sampled from the population, there may be only one sick person for every 99 healthy ones. In such a scenario, the model simply ignored the minority class and automatically assigned all examples to the dominant one, achieving a seemingly high accuracy of 99%, while entirely failing at its main task: correctly diagnosing the sick individual. It was therefore to be expected that a model exposed to only a single instance of that digit during training would be unable to learn to recognize it — and would instead simply ignore it. This example clearly shows how important it is to ensure that all classes in the training set are represented in roughly equal numbers.	Don't know
Extended	Yes, class imbalance does matter. For instance, in the case of a very rare disease and an extremely uneven distribution between the sick and the healthy, the model may ignore the minority class and automatically assign all examples to the dominant one — achieving very high accuracy, yet failing to accomplish its primary objective. In such a case, the model will not be able to correctly diagnose the sick individual.	Yes
Combined	Yes, class imbalance does matter. In the case of a very rare disease and an extremely uneven class distribution — between sick and healthy individuals — both in the training set and in the test set randomly drawn from the population, there is only one sick person for every 99 healthy ones. In such a scenario, the model ignored the minority class and automatically assigned all examples to the dominant one, achieving a very high accuracy of 99%, yet failing to fulfill its primary purpose — correctly diagnosing the sick individual. Consequently, it was to be expected that the model, having "seen" only a single instance of that digit during training, would be unable to learn to recognize it, and would instead simply ignore it.	Don't know

Question 40: What is an edge case in machine learning?		
System type	System answer	Evaluation
Baseline	There is no answer to this question in the given context.	No
Extended	There is no answer to this question in the context.	No
Combined	I cannot answer this question because the context does not contain any passages that could be quoted as a valid answer.	No

Table C.4: Original Polish version of Example 1

Question 14 in Polish: Co to jest system kar i nagród w uczeniu maszynowym?	
System type	System answer in Polish
Baseline	Odpowiedź na pytanie kursanta: System kar i nagród w uczeniu maszynowym to model, który uczy się wchodząc w interakcje ze środowiskiem, poprzez system kar i nagród.
Extended	Oto odpowiedź na pytanie kursanta: Reinforcement learning jest obszarem uczenia maszynowego, który koncentruje się na tym, jak agenty software powinni podejmować działania w środowisku, aby maksymalizować pewną koncepcję nagród kumulatywnych. Reinforcement learning to sposób uczenia maszynowego, w którym agent otrzymuje feedback w postaci nagród lub kar za podejmowane działania. W uczeniu maszynowym system kar i nagród jest częścią procesu uczenia się, w którym agent otrzymuje nagrody za podejmowane działania, które prowadzą do pożądaných wyników, a kary za działania, które prowadzą do niepożądanych wyników.
Combined	Odpowiedź na pytanie kursanta: System kar i nagród w uczeniu maszynowym to model, który uczy się wchodząc w interakcje ze środowiskiem, poprzez system kar i nagród.

Table C.5: Original Polish version of Example 2

Question 38 in Polish: Czy ma znaczenie liczebność klas	
System type	System answer in Polish
Baseline	Tak, znaczenie ma liczebność klas. W przypadku bardzo rzadkiej choroby i skrajnie nierównej liczebności klas: chorych i zdrowych - zarówno w zbiorze uczącym, jak i w zbiorze testowym, losowo wybranym z populacji, mamy tylko jednego chorego na 99 zdrowych. Model w takim przypadku zignorował klasę mniej liczną i automatycznie przypisał wszystkie przykłady do klasy dominującej, osiągając przy tym bardzo wysoką dokładność (accuracy) na poziomie 99%, nie spełniając swojego głównego zadania, czyli prawidłowego zdiagnozowania osoby chorej. W związku z tym, należało spodziewać się, że model, "widząc" w procesie treningu tylko pojedyncze wystąpienie tej cyfry, nie będzie w stanie nauczyć się go rozpoznawać, a zamiast tego po prostu będzie je ignorował. Na tym przykładzie widać, jak ważne jest to, by wszystkie klasy w zbiorze uczącym miały podobną liczbę reprezentantów.
Extended	Tak, znaczenie ma liczebność klas. Na przykład, w przypadku bardzo rzadkiej choroby i skrajnie nierównej liczebności klas: chorych i zdrowych, model może zignorować klasę mniej liczną i automatycznie przypisać wszystkie przykłady do klasy dominującej, osiągając przy tym bardzo wysoką dokładność, ale nie spełniając swojego głównego zadania. W takim przypadku model nie będzie w stanie prawidłowo zdiagnozować osoby chorej.
Combined	Tak, znaczenie ma liczebność klas. Abstract

This paper presents an LLM-powered approach for generating concept maps to enhance digital reading comprehension in higher education. While particularly focused on supporting neurodivergent students with their distinct information processing patterns, this approach benefits all learners facing the cognitive challenges of digital text. We use GPT-4o-mini to extract concepts and relationships from educational texts across ten diverse disciplines using open-domain prompts without predefined categories or relation types, enabling discipline-agnostic extraction. Section-level processing achieved higher precision (83.62%) or concept extraction while paragraph-level processing demonstrated superior recall (74.51%) in identifying educationally relevant concepts. We implemented an interactive web-based visualization tool <https://simplified-cognitext.streamlit.app> that transforms extracted concepts into navigable concept maps. User evaluation (n=14) showed that participants experienced a 31.5% reduction in perceived cognitive load when using concept maps, despite spending more time with the visualization (22.6% increase). They also completed comprehension assessments more efficiently (14.1% faster) with comparable accuracy. This work demonstrates that LLM-based concept mapping can significantly reduce cognitive demands while supporting non-linear exploration.

1 Introduction

Complex academic texts in higher education present cognitive challenges for students who must process and retain extensive information across diverse disciplines. These challenges are particularly pronounced for neurodivergent students, including those with ADHD (Attention Deficit Hyperactivity Disorder), who process information differently and often struggle to identify and retrieve central ideas from traditional linear texts despite recognizing

their importance (Ben-Yehudah and Brann, 2019; Yeari et al., 2018).

These challenges are further amplified in digital reading environments. Rather than attempting to improve traditional digital reading directly, we propose concept maps as an alternative digital interface that transforms linear text into interactive visual knowledge structures, bypassing linear reading challenges entirely while maintaining comprehensive coverage of educational content. These visual representations externalize knowledge structures, potentially reducing cognitive load while supporting the visual-spatial processing strengths often seen in students with attention-related learning differences (Sperotto, 2016; Sweller, 1988). Rather than attempting to improve traditional reading directly, concept maps provide an alternative knowledge access method that bypasses linear reading challenges entirely while maintaining comprehensive coverage of educational content.

Despite advances in automated concept mapping, significant gaps remain in current tools. Existing automated approaches typically rely on rule-based systems or predefined ontologies that lack flexibility across different domains and disciplines, often struggling with domain-specific terminology and conceptual relationships. Furthermore, existing approaches frequently extract concepts without adequately capturing the nuanced relationships between them, resulting in concept maps that lack the semantic depth necessary for comprehensive understanding.¹

This paper investigates how large language models (LLMs) can generate comprehensive concept maps from educational texts across diverse academic disciplines. Rather than enhancing traditional digital reading, we propose concept maps as an alternative educational interface that trans-

¹All our resources including source codes and concept map data are publicly accessible through our open source project: <https://github.com/emorynlp/cognitext>

forms linear text into interactive visual knowledge structures, enabling students to access the same information through non-linear exploration. We examine three research questions:

1. How effectively can LLMs identify key concepts across diverse academic disciplines without domain-specific training or ontologies?
2. What differences exist in the extraction and representation of knowledge relationships across different academic disciplines?
3. To what extent do automatically generated concept maps reduce cognitive load and improve reading comprehension compared to traditional linear reading?

Our approach implements concept extraction to identify key terms and ideas, relation identification to determine semantic connections between concepts, and concept map generation to organize these elements into visual knowledge structures. We evaluate system performance across ten academic disciplines and assess the impact of resulting concept maps on reading comprehension and cognitive load.

This work makes several key contributions: (1) we establish a methodological framework for LLM-based concept extraction across different types of academic content; (2) we provide empirical evidence for domain-specific knowledge structures that inform adaptive concept mapping; (3) we demonstrate the practical application of language models for educational concept map generation; and (4) we present evidence that concept map visualization as a reading alternative significantly reduces cognitive load while maintaining or improving comprehension outcomes.

While each system component (preprocessing granularity, LLM-based extraction, and user evaluation) merits individual investigation, this work demonstrates their integration for practical educational applications. We focus on the educational impact as our primary contribution, with detailed component analysis providing supporting evidence for system design decisions.

2 Related Work

2.1 Cognitive Load in Educational Contexts

Cognitive Load Theory, developed by (Sweller, 1988), distinguishes between three types of mental

processing: intrinsic load (inherent task complexity), extraneous load (poor instructional design), and germane load (meaningful learning processes). Educational interventions that reduce extraneous load while maintaining or enhancing germane load can greatly improve learning outcomes, particularly for students with diverse cognitive processing patterns.

Complex academic texts impose substantial cognitive demands through dense information presentation, abstract concept relationships, and linear narrative structures that may not align with individual learning preferences. For neurodivergent students, these challenges are particularly pronounced. Le Cunff et al. (2024) demonstrated that neurodivergent students, particularly those with ADHD, reported significantly higher extraneous cognitive load compared to neurotypical peers, while showing no differences in intrinsic or germane cognitive load. This pattern suggests that the presentation format of educational materials, rather than their inherent complexity, creates disproportionate challenges.

While digital reading environments present additional complications—with neurobiological research by Zivan et al. (2023) revealing higher cognitive load patterns in screen-based reading—the fundamental challenge extends beyond medium to the linear, text-heavy presentation of complex information. Bahari et al. (2023) identified several approaches that successfully manage cognitive load in educational environments, including visualization-based approaches and argument mapping, with most strategies aimed at reducing extraneous cognitive load while fostering germane load through generative learning practices.

Concept maps specifically address cognitive load by transforming extraneous processing demands into germane learning opportunities. By externalizing knowledge structures and providing visual-spatial representations, concept maps can reduce the working memory burden of maintaining conceptual relationships while reading, allowing students to focus cognitive resources on understanding and connecting ideas rather than tracking linear narrative flow.

2.2 Automated Concept and Relation Extraction for Education

Automated concept extraction and concept map generation has evolved from rule-based approaches to sophisticated machine learning methods. Early

computational approaches established foundations for extracting concept maps from educational texts, with [Aguiar et al. \(2018\)](#) providing comprehensive approaches for concept maps mining from text.

Recent work has applied large language models to concept map generation. [Perin et al. \(2023\)](#) demonstrated automated concept map generation using fine-tuned large language models, while other work has shown that LLMs can identify conceptually complex regions of text ([Garbacea et al., 2021](#)) and extract concepts from academic materials while preserving semantic relationships ([Zhang et al., 2023](#)).

Educational relation extraction differs from general-purpose approaches in its emphasis on pedagogically meaningful connections that support learning progression ([Dessi et al., 2020](#)). Recent advances in prompt-based approaches have shown particular promise for educational contexts. [Chen et al. \(2022\)](#) introduced KnowPrompt, incorporating knowledge from relation labels into prompt construction. Advancing this, [Chen et al. \(2024\)](#) developed a Generative context-Aware Prompt-tuning method (GAP) that eliminates the need for domain experts to design prompts. Large language models can extract relational knowledge when prompted appropriately ([Jiang et al., 2020](#)), with models like GPT-3.5 and GPT-4 demonstrating competitive performance in processing domain-specific educational content with minimal training requirements ([Hu et al., 2024](#)).

The key challenge lies in distinguishing concepts and relations of varying pedagogical importance while capturing both local conceptual connections and broader structural relationships that reflect disciplinary knowledge organization. Our work builds on these foundations by implementing hierarchical concept classification and multi-level relation identification for cross-disciplinary educational applications.

2.3 Visualization Techniques for Knowledge Representation

Concept maps, originally developed by Novak ([Novak, 1998](#)) and refined by Novak and Cañas ([Novak and Cañas, 2008](#)), organize knowledge through explicit propositions with labeled relationships (e.g., "Photosynthesis → produces → Oxygen"). Unlike mind maps ([Buzan, 1993](#)), which support ideational writing through brainstorming via radial structures, concept maps employ hierarchical representations optimized for reading comprehension

and systematic knowledge acquisition.

Meta-analyses demonstrate educational effectiveness: [Anastasiou et al. \(2024\)](#) found a moderate positive effect of concept maps on science achievement ($g = 0.776$) across 55 studies, while [Schroeder et al. \(2018\)](#) reported similar benefits of learning with concept maps on educational outcomes ($g = 0.58$) across 142 studies. Recent neurological research by [Shealy et al. \(2022\)](#) demonstrated that concept mapping alters cognitive activation patterns, increasing activity in brain regions associated with divergent thinking. [Yang et al. \(2025\)](#) addressed cognitive load concerns by introducing progressive concept maps that integrate information incrementally, improving learning outcomes compared to conventional approaches.

Our approach builds on Novakian concept mapping theory specifically for reading support rather than writing facilitation. Alternative text representation frameworks include Schema Theory ([Bartlett, 1932](#); [Rumelhart, 1977](#)), van Dijk and Kintsch's macrostructures ([van Dijk and Kintsch, 1983](#)), and Rhetorical Structure Theory ([Mann and Thompson, 1988](#)). Our work combines LLM contextual understanding with comprehensive knowledge representation across diverse disciplines, implementing progressive disclosure to manage cognitive load in educational concept maps.

3 Methodology

We developed a systematic approach for extracting concepts and relationships from educational texts and transforming them into interactive concept maps. Figure 1 illustrates the key components of our methodology.

3.1 Dataset Selection and Preparation

We selected ten Wikipedia articles representing diverse academic disciplines: biology, mathematics/statistics, computer science, linguistics, art, history, philosophy, political science, health/medicine, and one general non-academic field. Articles were chosen based on specific criteria to represent content that undergraduate students would likely encounter during their academic studies but would not be familiar with from prior education.

Each selected article maintained sufficient conceptual depth, a neutral academic tone, and introduced new concepts rather than common basics. The articles ranged from 1,383 to 11,337 words (mean: 4,839). Preprocessing steps included

Figure 1: Overview of the methodology for concept & relation extraction, and concept map visualization.

HTML removal, section identification, reference removal, and tokenization using spaCy.

3.2 Text Processing Modes

We implemented three distinct text processing modes to evaluate how different granularities of input text affect extraction quality:

1. **Section-level processing** utilizes complete sections from articles as input units, enabling the system to process larger chunks of coherent text and potentially capture broader thematic relationships. Each complete section was provided as single input to GPT-4o-mini for concept and relation extraction.

2. **Paragraph-level processing** operates on individual paragraphs, allowing the system to focus on local concepts and relationships within more concentrated contexts. Individual paragraphs were processed separately as independent input units, with results from all paragraphs subsequently aggregated to form the complete concept map for each article.

3. **Paragraph-pruned processing** applies post-processing filters to the results obtained from paragraph-level processing to address noise and irrelevant concepts. After completing the standard paragraph-level extraction described above, we applied two filtering mechanisms: first, elimination of concepts appearing exclusively in single paragraphs to reduce noise from isolated mentions; second, semantic filtering using the allMiniLM-L6-v2 transformer model by Reimers and Gurevych (2019) to calculate similarity scores between concepts and their section contents, preserving only

concepts with similarity scores above 0.6.

3.3 Extraction Framework

3.3.1 Concept Extraction

The concept extraction process utilizes GPT-4o-mini with precise prompting strategies to identify educationally relevant concepts within academic texts. A concept is defined as "a significant term or phrase that represents a fundamental idea, entity, or phenomenon within a discipline."

The extraction methodology implements a hierarchical schema that categorizes concepts into three distinct layers based on educational significance:

1. **Priority Layer (Core Concepts):** Fundamental principles, key terminology, major themes, and critical processes (15-20%)
2. **Secondary Layer (Supporting Concepts):** Sub-processes, related theories, and component parts (40-50%)
3. **Tertiary Layer (Contextual Elements):** Author contributions, specific examples, and historical developments (30-40%)

We developed a specialized prompt structure that explicitly targets concepts answering fundamental knowledge questions ("what," "how," "why," and "when"), ensuring comprehensive coverage across knowledge dimensions.

3.3.2 Relation Extraction

The relation extraction framework defines semantic connections between previously extracted concepts as structured triplets consisting of a source concept, a target concept, and a descriptive relation type. The extraction employs a multi-tiered approach:

1. **Local Relations:** Connections between concepts within the same textual segment (section or paragraph)
2. **Global Relations:** Higher-order connections between concepts across different sections

This dual-layer approach addresses the challenge of aligning relation extraction with learning objectives by prioritizing pedagogically meaningful connections. Local relations establish foundational concept understanding within focused contexts, while global relations reveal broader conceptual frameworks essential for comprehensive domain knowledge. Combined with our hierarchical schema (Priority, Secondary, Tertiary layers) from concept extraction (Section 3.3.1), this ensures that extracted

relations support progressive learning objectives, with core concepts and their relationships receiving priority in visualization to align with pedagogical goals of foundational understanding before detailed exploration. Each identified relationship includes supporting evidence from the source text that validates its authenticity and enhances educational value, ensuring extracted relations support structured learning goals rather than arbitrary semantic associations.

3.4 Evaluation Framework

To establish a gold standard dataset, two undergraduate annotators independently performed complete manual concept and relation extraction from each article. The first annotator had greater familiarity with STEM disciplines, while the second had stronger background in liberal arts and humanities. Each annotator identified all educationally relevant concepts and their relationships within each text, creating comprehensive manual annotations that served as ground truth for evaluating our automated extraction performance.

Concepts were rated on a 4-point scale (0-3) assessing educational significance from irrelevant (0) to core concepts (3). Relations were evaluated on a 3-point scale (0-2) based on pedagogical utility. Inter-annotator agreement was assessed using Cohen's Kappa coefficient, with values of $\kappa = 0.76$ for concepts and $\kappa = 0.71$ for relations, indicating substantial agreement between annotators despite their different disciplinary backgrounds.

The evaluation employed precision, recall, and F1 scores, comparing our automated extractions against the manually created gold standard annotations. Fuzzy matching was applied to accommodate linguistic variability between automated and manual annotations. The matching algorithm applied a hierarchical process beginning with exact string comparisons and progressively applying more flexible techniques based on edit distance and word-level similarity to identify semantically equivalent concepts and relations across the two annotation sets.

We acknowledge that using undergraduate annotators rather than domain experts across all ten disciplines represents a limitation in our evaluation methodology, as disciplinary expertise could affect the identification of field-specific concepts and relationships.

3.5 Concept Map Visualization

We implemented an interactive concept map visualization system called Cognitext using D3.js force-directed layouts. The interface, shown in Figure 2, incorporates several features designed to support effective navigation:

1. **Hierarchical information architecture:** Priority concepts are displayed with the darkest node coloring to indicate their fundamental importance, while secondary and tertiary concepts remain initially hidden to prevent cognitive overload
2. **Self-directed exploration:** When priority concepts have connections to hidden lower-level concepts, they display a pulsing orange indicator circle that signals available deeper exploration and encourages user interaction
3. **Visual focus management:** Selecting concepts brings related nodes to the foreground while fading others
4. **Relationship transparency:** Hovering over connections reveals relationship types and supporting textual evidence
5. **Intelligent content enhancement:** An integrated concept chatbot provides contextual explanations and answers questions based on the extracted knowledge

Users interact with the system through multiple methods: exploring from central nodes outward, clicking for concept explanations, and rearranging nodes to customize their view. The implementation uses Python for backend processing and Streamlit Cloud for web deployment: <https://simplified-cognitext.streamlit.app>.

3.6 User Evaluation

To assess the efficacy of concept maps for reading comprehension, we conducted a controlled study with 14 undergraduate participants (8 female, 6 male; ages 19-24; 4 self-identified as ADHD). While the sample size is modest, it provides initial insights into concept map effectiveness.

Concept Map Generation. For the user study, concept maps were generated using section-level processing results, which achieved the highest average F1 score in our evaluation. To ensure valid

4 Results

4.1 Extraction Performance

Table 1 presents the performance metrics for concept extraction across various academic disciplines using fuzzy matching. We compared three distinct text processing approaches.

Section-level processing demonstrated superior precision across all disciplines, achieving an average precision of 83.62%, with biology (89.86%) and general domain (87.35%) articles showing highest performance. However, this approach showed comparatively lower recall (62.18% average), indicating that while it extracted highly relevant concepts, it missed some concepts present in the gold standard dataset.

Paragraph-level processing yielded considerably higher recall metrics (74.51% average), with political science (81.63%) and history (81.35%) articles showing highest recall. This improvement came at the cost of precision, which dropped to 57.49% average. The paragraph-level pruned approach achieved intermediate performance in both precision (66.87%) and recall (70.92%).

When comparing F1 scores, section-level processing performed best overall (71.20% average), followed by paragraph-level pruned (68.82%) and standard paragraph-level (64.89%) approaches.

Relation extraction performance followed similar patterns across processing approaches and disciplines (detailed results in Appendix A Table 3). Section-level processing achieved highest overall precision (78.61%), with biology and general articles showing particularly strong performance (82.09% and 83.51% respectively) and moderate recall (59.76%). Paragraph-level processing exhibited substantially lower precision (51.95%) but higher recall (69.08%), while the pruned approach demonstrated intermediate performance with 62.01% precision and 67.29% recall. Overall, section-level processing performed best with an average F1 score of 67.71%, followed by paragraph-level pruned (64.52%) and standard paragraph-level (59.28%) approaches.

4.2 Concept/Relation Distribution Patterns

Figure 3 presents a heatmap visualization of the normalized concept distribution across academic disciplines. When normalized for text length, the philosophy article showed the highest concept density (31.09 concepts per 1,000 words), followed by health/medicine (30.93) and political science

(27.66). In contrast, the history (9.61) and art (10.86) articles exhibited the lowest density.

Normalization revealed discipline-specific patterns in concept distribution. The computer science article emphasized problems & solutions and mathematical foundations (both 3.14 concepts per 1,000 words). The health/medicine article showed a pronounced focus on medical & safety concepts (7.73) and processes & mechanisms (6.87). The philosophy article demonstrated a great emphasis on core concepts (6.51) and socio-cultural contexts (4.34).

For relation distribution, Table 5 in Appendix A shows that structural relations emerged as the most frequent relation type across all disciplines, with the health/medicine (12.89), philosophy (11.57), and political science (10.19) articles showing the highest normalized frequencies. The overall relation density varied substantially across disciplines, with health/medicine exhibiting the highest density (54.22 relations per 1,000 words), followed by philosophy (45.55) and political science (41.48).

Figure 3: Concept distribution heatmap across academic disciplines, normalized per 1,000 words. Color intensity represents frequency, darker blue = higher density.

4.3 User Study Results

To evaluate concept map effectiveness on reading comprehension, we compared traditional linear reading with concept map-assisted reading (Table 2). Participants spent more time with the concept mapping tool (32.5 vs. 26.5 minutes, 22.6% increase) but completed comprehension assessments more quickly (18.3 vs. 21.3 minutes, 14.1% decrease).

Most significantly, participants reported substantially reduced perceived mental effort when using concept maps (5.0 vs. 7.3 on NASA TLX scale), representing a 31.5% decrease in cognitive

load that was statistically significant ($p = 0.00092$). Comprehension accuracy showed slight improvement (98% vs. 97%), though not statistically significant.

We acknowledge that our assessment instrument focused on propositional knowledge, which concept maps represent effectively, and this should be considered when interpreting the comparable accuracy results.

User feedback was generally positive (mean rating 4.21/5), with participants highlighting the tool's ability to "visually analyze basic concepts" and "show hierarchical relationships between different concepts."

Metric	Without Tool	With Tool
Reading Time	26.5 min	32.5 min
Assessment Time	21.3 min	18.3 min
Mental Effort	7.3	5.0
Correctness	97%	98%

Table 2: Comparison of reading performance with and without concept mapping tool. Reading time refers to text reading (linear condition) vs. concept map exploration (concept map condition)

5 Analysis and Discussion

5.1 Extraction Performance and Disciplinary Patterns

The consistent precision-recall trade-off across processing approaches demonstrates a fundamental tension in concept extraction methodology. Section-level processing achieved higher precision through comprehensive contextual understanding, while paragraph-level processing captured more concepts through granular analysis. The substantial precision advantage for relations (78.61% vs. 51.95%) suggests that relational semantics often depend on broader contextual understanding than can be captured within paragraph boundaries, aligning with discourse coherence theory that semantic relationships emerge from macro-level textual structures.

The paragraph-level pruned approach effectively mitigated many limitations of standard paragraph-level processing while preserving much of its recall advantage. This suggests that incorporating multi-stage validation processes into extraction pipelines can substantially improve performance without requiring contextual windows as large as section-level processing.

Cross-disciplinary analysis revealed systematic knowledge organization patterns reflecting epistemological differences between fields. Scientific text (biology) showed superior extraction metrics across all approaches, suggesting more explicit externalization of conceptual relationships through standardized linguistic patterns. Historical text performed better with paragraph-level processing, indicating conceptual relationships are established within localized narrative units rather than extended theoretical frameworks. The linguistics article's extraction challenges highlight complexities in meta-disciplinary discourse where language is both medium and subject of analysis.

The distinctive patterns in concept and relation distribution reflect disciplinary epistemologies. Philosophy's high density of causal relations but absence of functional relations suggests emphasis on conceptual reasoning, while health/medicine's high functional relation density points to procedural knowledge focus. These findings suggest that universal knowledge representation approaches may not be optimal, and concept maps might benefit from tailoring to specific relation structures observed in different academic content types.

5.2 Concept Map Effectiveness for Cognitive Load Reduction

The comparison of concept mapping visualization to traditional linear reading reveals a complex relationship between time investment, cognitive load, and comprehension outcomes. The observed increase in reading time (22.6%) paired with a decrease in assessment time (14.1%) when using the concept mapping tool suggests a shift in cognitive resource allocation. While users invested more time in initial exploration, they subsequently completed assessment tasks more efficiently.

The substantial reduction in perceived mental effort (31.5%) despite longer engagement time represents one of our most significant findings. This relationship suggests the visualization transformed extraneous cognitive load into germane cognitive load, enabling more productive mental processing rather than simply reducing overall demands. This transformation is particularly valuable for educational applications where sustained engagement with complex material is desirable.

While the marginal improvement in comprehension accuracy (1%) appears modest, this should be interpreted within the context of the already high baseline performance (97%), suggesting a po-

tential ceiling effect. The combination of comparable comprehension outcomes with significantly reduced cognitive effort indicates an improved efficiency ratio—participants achieved similar results with less mental strain.

The generally positive user feedback (4.21/5) confirms participants recognized value in the visualization approach. The implementation of hierarchical information architecture with progressive disclosure aligns with cognitive load theories by preventing information overload while maintaining access to comprehensive content, enabling incremental mental model construction while preserving underlying concept connections.

5.3 Implications for Educational Technology

These findings suggest that domain-agnostic extraction systems face inherent limitations, and maximizing extraction performance might benefit from adaptive approaches tailored to different discourse types. The cognitive load reduction without compromising comprehension indicates concept mapping tools could be particularly valuable for students experiencing cognitive fatigue during traditional reading, including those with attention-related difficulties.

Moreover, the implementation of hierarchical information architecture with progressive disclosure aligns with cognitive load theories by preventing information overload while maintaining access to comprehensive content. The observed self-directed exploration through concept maps aligns with constructivist learning principles, suggesting these tools can support diverse learning approaches and accommodate individual differences in background knowledge and processing styles while transforming extraneous cognitive load into germane cognitive load.

6 Conclusion and Future Work

This work demonstrates that LLM-based concept mapping can significantly reduce cognitive demands while supporting non-linear exploration of educational content. Our findings suggest concept mapping tools particularly benefit students experiencing cognitive fatigue, transforming linear text into interactive visualizations that support self-directed exploration.

Future work should prioritize three key directions based on our empirical findings:

Adaptive Extraction Methodologies. Our anal-

ysis revealed systematic variation across disciplines, with philosophy articles showing highest concept density (31.09 per 1,000 words) while history articles exhibited lowest (9.61). Future research should develop adaptive methodologies that automatically adjust to disciplinary discourse patterns by: (1) implementing discourse pattern recognition to select optimal processing granularity, (2) developing domain-specific relation taxonomies based on our finding that structural relations dominate in health/medicine (12.89 per 1,000 words) while causal relations are prominent in philosophy (10.85 per 1,000 words), (3) creating hierarchical processing pipelines that combine section-level precision (83.62%) with paragraph-level recall (74.51%), and (4) developing automated quality assurance methodologies that can refine extracted concepts and relations without manual intervention.

Longitudinal Impact Studies. While our study (n=14) demonstrated 31.5% cognitive load reduction, critical questions remain about long-term educational impact. Future studies should examine knowledge retention and transfer beyond immediate comprehension, conduct targeted research with larger samples of neurodivergent students (our study included only four self-identified participants), and investigate whether concept maps sustainably reduce cognitive load across time and contexts.

LMS Integration. Current implementation barriers limit practical deployment. Priority efforts should focus on developing plugins for major learning management systems (Canvas, Blackboard, Moodle), implementing collaborative features for shared editing and instructor annotations, and addressing processing latency through scalable architectures for institutional deployment.

These directions address our core finding that concept mapping transforms extraneous cognitive load into germane cognitive load while maintaining comprehension outcomes.

Limitations

Despite the promising results of this research, several limitations should be acknowledged when interpreting our findings.

Corpus limitations. Our analysis was restricted to examining only one article per academic discipline, which limits generalizability. The findings should be interpreted as article-specific observa-

tions that suggest potential disciplinary patterns rather than definitive characterizations of entire domains. Future work should expand the corpus to include multiple texts from each discipline to establish more generalizable patterns.

Ecological validity limitations. Our use of Wikipedia articles, while providing standardized, neutral content across disciplines, may not fully represent typical educational materials such as textbooks, journal articles, or course-specific readings. Wikipedia's encyclopedic structure and hyperlinked format may facilitate concept extraction differently than traditional academic texts. Future work should evaluate performance on authentic course materials to establish broader applicability.

Evaluation methodology limitations. Our evaluation relied on undergraduate annotators rather than domain experts, and comprehension questions were developed by the lead researcher rather than assessment professionals. While inter-annotator agreement was substantial and questions assessed multiple understanding levels, expert involvement would strengthen future evaluations.

Generalizability across learning differences. While we hypothesized particular benefits for students with attention-related learning differences, our sample included only a small number of self-identified neurodivergent participants (n=4). More targeted research with larger samples of neurodivergent students would be necessary to substantiate claims about differential benefits across students.

Assessment methodology limitations. The node-and-edge structure of concept maps excels at representing straightforward propositions (e.g., "Photosynthesis produces Oxygen") but struggles with conditional relationships (e.g., "A causes B only under specific conditions"), complex temporal sequences, or counterfactual reasoning. Consequently, our question development may have inadvertently excluded assessment items requiring these more complex cognitive operations, potentially favoring the concept map condition. While this limitation does not invalidate our findings within the scope of propositional knowledge comprehension, it restricts generalizability to the full spectrum of reading comprehension skills typically assessed in educational contexts.

Technical constraints. The use of GPT-4o-mini, while cost-efficient, introduced model-specific constraints including knowledge cutoff limitations, reduced parameter capacity compared to larger models, and context window restrictions that particu-

larly affected global relation extraction. These limitations may have impacted extraction performance, especially for longer documents. The system also demonstrated significant processing latency with longer articles, which could limit practical deployment in time-sensitive educational contexts.

Implementation challenges. The current implementation faces practical deployment barriers including limited integration with existing learning management systems, basic visualization capabilities without advanced features like collaborative editing, and minimal customization options for educators. These constraints, while providing clear directions for future development, limit immediate broad adoption in educational settings.

Acknowledgments

We thank the anonymous reviewers for their constructive feedback that significantly improved this work. We are grateful to our user study participants for their time and valuable insights. Special thanks to the Computer Science Department of Emory University and the Emory NLP Lab for providing computational resources and technical support. We are grateful to everyone who contributed to the creation of Cognitext and supported our efforts to improve educational comprehension for all learners.

A.3.1 Concept Extraction Prompt (Abbreviated)

A concept is defined as a significant term or phrase that represents a fundamental idea, entity, or phenomenon within a discipline. Extract key concepts from the provided text using the following guidelines.

Concept Layers: 1. **Core Concepts (Priority Layer):** - Primary theoretical concepts and fundamental principles - Key terminology and definitions essential to the topic - Major themes and overarching frameworks

2. **Supporting Concepts (Secondary Layer):** - Sub-processes and variations of core concepts - Related theories and complementary ideas - Component parts and organizational structures

3. **Contextual Elements (Tertiary Layer):** - Author names and their key contributions - Specific examples and case studies - Historical context and developments

Output Format: [List of JSON objects with entity, context, evidence, and layer fields]

A.3.2 Relation Extraction Prompt (Abbreviated)

Extract key relationships between these available concepts using the following guidelines. The extracted relations will be used for visualizations to aid educational comprehension.

Guidelines: - Ensure that the relations are clearly defined and relevant to the text’s main ideas. - Focus on capturing a variety of relationship types without restricting to specific categories. - Avoid speculative relationships; only include those with explicit or strong implicit textual support.

Output Format: [List of JSON objects with source, relation_type, target, and evidence fields]

Verb Placement Error Detection Datasets for Learners of Germanic Languages

Abstract

Correct verb placement is difficult to acquire for second-language (L2) learners of Germanic languages. However, word order errors and, consequently, verb placement errors, are heavily underrepresented in benchmark datasets of NLP tasks such as grammatical error detection (GED)/correction (GEC) and linguistic acceptability assessment (LA). If they are present, they are most often naively introduced, or classification occurs at the sentence level, preventing the precise identification of individual errors and the provision of appropriate feedback to learners. To remedy this, we present **GermDetect**: Universal Dependencies-based (UD), linguistically informed verb placement error detection datasets for learners of Germanic languages, designed as a token classification task. As our datasets are UD-based, we are able to provide them in most major Germanic languages: Afrikaans, German, Dutch, Faroese, Icelandic, Danish, Norwegian (Bokmål and Nynorsk), and Swedish. We train multilingual BERT (mBERT) models on GermDetect and show that linguistically informed, UD-based error induction results in more effective models for verb placement error detection than models trained on naively introduced errors. Finally, we conduct ablation studies on multilingual training and find that lower-resource languages benefit from the inclusion of structurally related languages in training.

1 Introduction

Correct verb placement is difficult to acquire for L2 learners of Germanic languages. This is due to the placement depending on different factors such as finiteness and the clause type in which the verbs occur. Example (1) illustrates a Dutch sentence consisting of a single main clause.

(1) *Hij heeft een hond gekocht.*

he has a dog bought
S V2 O O V

‘He has bought a dog.’

Two characteristics can be observed here: The finite verb *heeft* is placed in the second position (V2) and the non-finite, participle verb *gekocht* is placed clause-finally. Example (2), consisting of a main and a subordinate clause, illustrates how the verb placement changes: Here, the finite *weet* occupies the V2 position in the main clause, but both the finite *heeft* and non-finite *gekocht* are placed clause-finally in the subordinate clause, following subject-object-verb (SOV) word order.

(2) *Ik weet dat hij een hond heeft gekocht.*

I know that he a dog has bought
S V2 _ S O O V V

‘I know that he has bought a dog.’

These and other context-dependent changes in verb placement in Germanic languages are not trivial for L2 learners. Therefore, being able to provide accurate feedback to learners about their verb placement is crucial.

However, word order errors are heavily underrepresented in both GED/GEC shared task datasets and LA datasets. If they are present, they are often introduced naively, which means they do not represent the kinds of errors L2 learners are likely to make. This leaves the capability of GED systems to detect naturalistic word order errors underexplored. Verb placement errors, as a subset of word order errors, are even more poorly represented, which, in the context of Germanic languages, is particularly critical. Additionally, LA datasets are often formulated as sentence-level binary classification or pair-wise ranking tasks. This does not allow for locating errors within a sentence and therefore offers

Figure 1: Number of sentences per language in GermDetect (log scale); language codes follow ISO 639-1.

little usability for providing feedback to learners.

To address this gap, we present GermDetect: UD-based, linguistically informed verb placement error detection datasets for learners of Germanic languages that can serve as a new benchmark to test GED systems’ capabilities in detecting naturalistic verb placement errors. The token-level classification design allows individual errors in verb placement to be located, and the datasets are available in most major Germanic languages:¹ Afrikaans, German, Dutch, Faroese, Icelandic, Danish, Norwegian (Bokmål and Nynorsk), and Swedish. Figure 1 presents a brief overview of the magnitude of our dataset, with a more detailed breakdown in Appendix A. We make the datasets and the code available at <https://github.com/noahmanu/gerlangmod>.

In the following sections, we provide a brief introduction to related work, followed by a description of our dataset creation algorithm. We then present the results of different mBERT configurations on our new benchmark.

2 Related Work

In this section, we introduce verb placement rules in Germanic languages, briefly talk about the frequency of verb placement errors in learner corpora, present relevant GED/GEC/LA datasets and their shortcomings with regard to the evaluation of word order errors, and survey popular GED/GEC tools’ capabilities in detecting verb placement errors.

¹Excluding English as English is the only modern Germanic language that does not follow V2.

2.1 Verb Placement Rules in Germanic Languages

Correct verb placement is challenging to acquire for L2 learners of Germanic languages (Orgassa, 2009; Schimke and Dimroth, 2018; Westergaard and Lohndal, 2019; Angantýsson, 2021). This is due to the placement depending on different factors such as finiteness and the clause type in which the verbs occur.

All Germanic languages covered in GermDetect follow V2 in main clauses, which means that the finite verb always occupies the second position. Example (1) illustrates how in West Germanic languages, SOV is the default syntax pattern for all other verbs, i.e., non-finite verbs are placed clause-finally in main clauses. In subordinate clauses, where V2 does not hold, all verbs follow SOV and are therefore found at the end of the phrase. Example (3) demonstrates by means of a Swedish sentence that, in North Germanic languages, all verbs follow SVO in main clauses.

- (3) *Han har köpt en hund.*
 he has bought a dog
 S V2 V O O

This masks the V2 constraint, as the surface word order in main clauses often resembles that of canonical SVO languages. Example (4) briefly presents how, when an element other than the subject takes the clause-initial position, V2 holds while the rest of the main clause follows SVO.

- (4) *Kanske har han köpt en hund.*
 maybe has he bought a dog
 – V2 S V O O
 ‘Maybe he has bought a dog.’

Additionally, all GermDetect languages form polar questions by inversion, placing the finite verb in the clause-initial position.² Examples (5) and (6) illustrate this structure for both German and Faroese. Non-finite verbs follow the respective default syntax patterns.

- (5) *Hat er einen Hund gekauft?*
 has he a dog bought
 V1 S O O V
 ‘Has he bought a dog?’

²In analogy to V2, we call this position V1.

Languages	Main–Finite	Main–Non-Finite	Subordinate	PolarQ–Finite	PolarQ–Non-Finite
af, de, nl	V2	SOV	SOV	V1	SOV
fo, is, da, nb, nn, sv	V2	SVO	SVO	V1	SVO

Table 1: Overview of the most unmarked syntax patterns in the languages covered by GermDetect; distinction between finite and non-finite verbs in main clauses and polar questions (PolarQ), and subordinate clauses.

Dataset	Task	% WOE	Languages

Warstadt et al. (2020)	LA	19.4	en
Nielsen (2023)	LA	50.0	<u>da</u> , <u>fo</u> , <u>is</u> , <u>nb</u> , <u>nn</u> , <u>sv</u>
Volodina et al. (2023)	GED	N/A	cs, <u>de</u> , en, it, <u>sv</u>
Masciolini et al. (2025)	GEC	N/A	cs, <u>de</u> , el, en, et, <u>is</u> , it, lv, ru, sl, <u>sv</u> , uk

Table 2: Percentage of word order errors (WOE) in different benchmark datasets; languages covered by GermDetect underlined.

(6) *Hevur hann keypt ein hund?*
has he bought a dog
V1 S V O O

Table 1 summarizes the most unmarked syntax pattern for both language groups, i.e., West Germanic and North Germanic. With verb placement being this complex in Germanic languages, learners are prone to make errors when trying to acquire the correct syntax patterns. However, learners typically do not make random errors in verb placement. Instead, the errors they make are often influenced by their previous language background. Therefore, certain error types are less likely to occur than others. Example (7) shows an unlikely example of an error where the learner splits the noun phrase *een hond* by misplacing a verb between the elements of this constituent. This is unlikely because nominal constituents are generally joint units, so this would most likely be considered an error in any of the languages the learner knows.

(7) **Ik weet dat hij een heeft hond.*
I know that he a has dog

Example (8), in contrast, illustrates a more likely error that could be produced by a first-language English speaker.

(8) **Ik weet dat hij heeft een hond.*
I know that he has a dog

It is evident that verb placement presents itself as a very complex system of rules for L2 learners of Germanic languages to acquire. Next, we briefly show how this is reflected in real learner corpora.

2.2 Verb Placement Errors in Germanic Learner Corpora

In the German part of the MERLIN corpus (Boyd et al., 2014),³ which comprises texts from all CEFR levels but is especially rich in texts from levels A2–C1,⁴ 34% of errors are annotated as “movement errors”, i.e., errors corrected by placing a token in a different position within the same sentence.⁵ Out of these, 12.1% involve the misplacement of a verb.⁶ The vast majority of verb placement errors in MERLIN are concentrated among the levels A2–B2 (94.9%).

In the FalkoEssayL2 v2.4 corpus (Lüdeling et al., 2008),⁷ which only comprises German L2 texts at the levels B2–C2, movement errors make up 29.6% of total errors. Out of these, 12.5% involve the misplacement of a verb. This suggests that even at advanced levels, learners continue to produce verb placement errors at rates comparable to those at

³ Accessible at: <https://commul.eurac.edu/annis/merlin/>, last accessed: 2025/06/03.

⁴ CEFR: Common European Framework of Reference for Languages.

⁵ We only count grammatical errors towards the total, i.e., spelling errors are excluded.

⁶ Appendix B contains the queries with which we determined the number of total grammatical error occurrences in MERLIN and Falko, the number of movement errors, and the number of movement errors involving the misplacement of a verb.

⁷ Accessible at: <https://korpling.german.hu-berlin.de/falko-suche/>, last accessed: 2025/06/03.

earlier stages, highlighting the pedagogical value of providing targeted feedback on such errors.

In the Icelandic Child Language Error Corpus and the Icelandic L2 Error Corpus (Ingason et al., 2021; Glisic and Ingason, 2022), there are two designated error categories for verb placement errors related to V2 violations.⁸ This indicates that verb placement is not trivial not only in L2 learning but also in first-language acquisition.

However, verb placement errors as a subset of word order errors are heavily underrepresented in all relevant benchmark datasets as we will point out in the following section.

2.3 Word Order Errors in GED/GEC/LA Benchmark Datasets

In recent years, several shared tasks have been organized in the field of GED/GEC. Additionally, LA tasks have been developed to test language models’ linguistic capabilities. Table 2 presents the most prominent benchmark datasets from all three domains covering Germanic languages and the percentage of word order errors they contain.

All of the datasets have in common that word order errors typically only make up a very small fraction of the errors present within them, or no information about the distribution of word order errors is provided at all. Germanic languages other than English have only recently seen their representation increase. However, with the exception of the ScaLA dataset (Nielsen, 2023), no information is available about the presence and distribution of word order errors in the datasets containing subsets of the languages covered by GermDetect. This leaves the capabilities of language models in detecting erroneous word order underexplored.

This situation is especially critical in the context

⁸Both corpora are accessible at: <https://github.com/icelandic-lt/iceErrorCorpusSpecialized/>, last accessed: 2025/06/03. Verb placement errors are annotated with the error code *v3*.

of Germanic languages, whose successful acquisition depends on mastering their complex verb placement rules. Verb placement errors, as a subset of word order errors, are consequently even more poorly represented in the datasets, thus limiting the development of GED systems capable of reliably detecting and providing feedback on such errors. Moreover, in the only Germanic dataset where information about the presence of word order errors is available – the ScaLA dataset – such errors were introduced using a naive corruption strategy that swaps adjacent tokens.⁹ As a result, the dataset neither specifically targets verb placement errors nor reflects the kind of word order errors that naturally occur in learner language. Thus, it provides little insight into whether language models can detect naturalistic word order errors that could be produced by L2 learners.

2.4 Survey GED/GEC Tools

While numerous writing assistants claim to provide feedback on grammatical errors, few are suitable for detecting verb placement errors in Germanic languages other than English. Among those capable of handling word order errors to some extent, many lack API access, which complicates large-scale evaluation.

Table 3 presents an overview of the most popular tools, the languages they support, and whether word order errors, particularly those involving verb placement, are among the phenomena they claim to be able to identify and provide feedback on. As the table shows, two of the most popular tools – Grammarly and ProWritingAid – do not support any of the relevant languages covered by GermDetect. While Quillbot claims to handle syntax errors in German and Dutch, and LanguageTool does so

⁹To ensure the corrupted sentences are indeed ungrammatical, Nielsen (2023) enforces a variety of part-of-speech restrictions prohibiting certain token swaps.

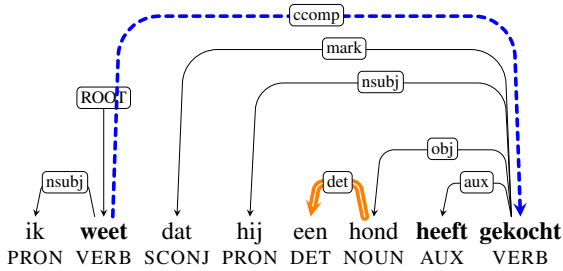

Figure 2: Dependency tree for the Dutch sequence “ik weet dat hij een hond heeft gekocht”; blue arc indicates where our algorithm splits verb phrases; orange arc indicates where our algorithm aggregates noun phrases into impermeable units.

Figure 3: Dependency tree for the Dutch sequence “ik weet dat hij een hond heeft gekocht”; verb-headed phrases are aggregated as verbal heads plus their dependencies; noun-headed phrases are impermeable units.

for German, our manual evaluation on 100 GermDetect test sentences for each of the two languages found that their feedback on verb placement errors was largely unreliable, inaccurate, or incomplete.¹⁰ This highlights that effective tools for providing feedback on verb placement in Germanic languages are unavailable as of today. To remedy this, in the following section, we present our linguistically informed corruption algorithm that can introduce verb placement errors into any UD-annotated Germanic language subject to V2 verb placement.

¹⁰A locally hosted server of LanguageTool’s Python wrapper (Version 6.5; available at <https://pypi.org/project/language-tool-python/>, last accessed: 2025/06/03) flagged none of the 132 verb placement errors present in the German test sentences as word order errors; via their respective GUIs, LanguageTool was able to identify 41 and Quillbot was able to identify 38 out of 132 verb placement errors. For Dutch, Quillbot was able to identify 37 out of 130 verb placement errors. We counted errors as correctly identified even when they were not explicitly flagged as syntax errors, as long as the tool highlighted the relevant part of the sentence – whether as a missing or superfluous word or verb, or with a vague message such as “something is wrong” in combination with the appropriate error correction suggestion, among other generic error types.

3 Dataset Creation

Here, we briefly present the UD datasets as a basis for GermDetect, we present our preprocessing steps, and we describe our data corruption algorithm in detail.

3.1 Universal Dependencies

As the basis for our datasets, we use the UD Treebanks (Version 2.15; Zeman et al., 2024), including all available datasets for each of the GermDetect languages. Appendix A summarizes the datasets and their sizes after removing sentences without verbs.

Figure 2 illustrates how sentences are annotated for dependency relations in UD. Our algorithm currently operates both on the part-of-speech (POS)-tag level and the dependency arc level, but tokens are typically annotated with more linguistic information. We remove common punctuation tokens and lowercase all characters to ensure that models trained on GermDetect data cannot fall back on any orthographic information when determining the (in)correctness of verb placement and have to rely on their syntactic understanding only. This is especially relevant for sentences that begin with verbs, as the initial capitalization can reveal their original position. If such verbs are moved to another part of the sentence, the capitalization may serve as an unintended signal of misplacement.

3.2 Corruption Algorithm

Given a dependency parse tree T for a sentence $S = \{w_1, w_2, \dots, w_n\}$, we define an aggregation procedure to extract syntactic substructures centered around **full verbs** and **nouns**. The algorithm proceeds as follows:

Step 1 - Aggregation of Verb-Headed Phrases. Identify all tokens $v \in S$ such that $\text{POS}(v) = \text{VERB}$. These serve as the roots of *verb-headed phrases*.¹¹

For each full verb v , construct a *verb-headed phrase* $V_v \subseteq S$ defined as:

- V_v includes the full verb v itself,
- Plus all tokens in S that are **recursively governed by v** – i.e., all descendants of v in the subtree rooted at v ,

¹¹Due to inconsistent annotations, some UD treebanks use the VERB POS-tag for adjectives derived from verbs. We implemented a number of additional checks to prevent these tokens from heading their own verb-headed phrases.

- With the constraint that no token is included if the dependency path from it to v passes through another full verb (cf. verb phrase splitting in Figure 2).

This ensures that each verb-headed phrase captures the local syntactic scope of a full verb, while nested verbs and their subtrees are aggregated independently.

Step 2 - Aggregation of Noun-Headed Phrases within Verb-Headed Phrases. Identify all tokens $n \in V_v$ such that $\text{POS}(n) = \text{NOUN}$. These serve as the roots of *noun-headed phrases* within verb-headed phrases.

For each noun n , construct a *noun-headed phrase* $N_n \subseteq V_v$ defined as:

- N_n includes the noun n itself,
- Plus all tokens in V_v that are **recursively governed** by n – i.e., all descendants of n in the subtree rooted at n ,
- With the constraint that no token is included if the dependency path from it to n passes through another noun.

Each noun phrase N_n is treated as an **impermeable unit**: During any subsequent processing, i.e., the data corruption, the tokens in N_n must remain contiguous and in their original order. No external tokens may be inserted into the span of a noun-headed phrase.

Step 3 - Output. The final output is a collection of verb-headed phrases $\{V_{v_1}, V_{v_2}, \dots, V_{v_i}\}$, each rooted at a full verb. Within each V_v , zero or more noun phrases $\{N_{n_1}, N_{n_2}, \dots, N_{n_j}\} \subseteq V_v$ are identified as impermeable subunits. This structure supports the linguistically-informed manipulation of the sentence while preserving core syntactic boundaries. Figure 3 illustrates how, with the help of UD’s dependency structure, we are able to isolate syntactic structures that often correspond to main and subordinate clauses. This allows us to inject the data with more targeted corruptions, which aim to reproduce learner errors more closely.

Step 4 - Corruption of Verb-Headed Phrases. Each extracted verb-headed phrase V_v is corrupted by permuting the positions of a randomly selected subset of its verb tokens. Specifically:

- Identify all verb tokens $\tau \in V_v$ such that $\text{POS}(\tau) \in \{\text{VERB}, \text{AUX}\}$. Each such token is

selected for permutation with a probability of roughly $p = 0.5$, resulting in the dataset containing approximately as many correctly placed as incorrectly placed verbs.

- The selected verb tokens may be relocated to any position within V_v , either before or after any other token, **provided that the relative order of all non-verb tokens is preserved.**
- Noun-headed phrases $N_n \subseteq V_v$ remain contiguous and untouched; verb tokens may move around them but not split them.
- If $V_v = V_{v_1}$, i.e., it is the first verb-headed phrase in the sentence, no verb token may occupy the first position in V_v , unless a verb originally located in this position remains in it. This constraint is imposed to avoid the accidental generation of valid polar question syntax, which would undermine the goal of synthetically generating syntactically perturbed structures.
- All verb tokens that are moved from their original positions are automatically labeled as syntactically incorrect (F), enabling the generation of training data for GED models. This labeling strategy is justified by the relatively rigid verb placement rules found in Germanic languages, as explained earlier. Verbs that remain in their original position are labeled as correct (C), all non-verb tokens are labeled as other (O).

Example (9) illustrates how misplacing a verb in the first position is not permitted by our algorithm. This is to avoid generating well-formed polar questions that would be incorrectly labeled as ungrammatical (cf. Table 1).¹²

- (9) ik **weet** | dat hij een_hond heeft gekocht
weet ik* | dat hij een_hond heeft gekocht

Example (10) showcases all possible corruptions when we reduce the number of verbs in the subordinate clause of our running example to one, resulting in *ik weet dat hij een hond heeft* “I know that he has a dog”. There are 5 positions that *heeft* can theoretically take. One of them corresponds to the correct placement, while the last corruption in

¹²In addition to the standard *left asterisk indicating linguistically unacceptable examples, we use the asterisk on the right* side to indicate examples not permitted by our algorithm.

the example is not permitted due to the impermeable noun-headed phrase constraint. If a verb in the phrase is selected to be permuted, a permitted position is randomly chosen.

- (10) ik weet | dat hij een_hond **heeft**
 ik weet | ***heeft** dat hij een_hond
 ik weet | *dat **heeft** hij een_hond
 ik weet | *dat hij **heeft** een_hond
 ik weet | *dat hij een **heeft** hond*

Finally, example (11) illustrates what a labeled corrupted sentence could look like if we reintroduced the second verb. Note that the relative order of non-verb tokens always remains the same but the relative order of verb tokens to one another can change.

- (11) *ik weet* | **dat gekocht* *hij heeft een*
 O C | O F O F O
hond
 O

The GermDetect algorithm makes it possible to insert errors that specifically target verb placement while making sure to exclude misplacements that are unlikely, such as breaking up noun phrases, or that would result in a well-formed sentence despite the change of verb placement, such as in polar questions. The full extent of our dataset is summarized in Appendix A.

4 Benchmark Results

In this section, we present our experimental setup and analyze the results of evaluating various mBERT configurations trained on GermDetect.

4.1 Experimental Setup

Following the creation of the GermDetect dataset, we train and evaluate multiple mBERT models using various training dataset configurations and their combinations (Devlin et al., 2019). We use mBERT as our base model primarily due to computational constraints and methodological considerations. All experiments are conducted locally on a MacBook Pro with an Apple M4 Pro chip and 24 GB of RAM (macOS 15.4.1), which makes training larger models such as XLM-R impractical (Conneau et al., 2020). In addition to its lighter memory footprint, mBERT’s relatively lower performance ceiling provides a clearer basis for analyzing the impact of

training data composition. Specifically, we compare training on the target language alone with training on the target language and related Germanic languages, as explained in Section 4.3. Since stronger models like XLM-R often achieve robust performance regardless of training data composition, they may obscure more subtle transfer effects that are easier to detect with a smaller model. This choice also supports the growing emphasis on environmentally responsible NLP, as smaller models require significantly less energy to train and deploy.

To implement our approach, we add a BertForTokenClassification head to mBERT and fine-tune the sequence tagger using Hugging Face’s Trainer API. Appendix C summarizes the parameters we use to train our models. For each input sentence, the model generates one of three labels for each token: O for tokens that are not verbs, and C (correct) or F (false) for verb tokens, depending on whether their placement in the sentence is correct or incorrect.

We retain the original dataset splits provided by UD for training, development, and testing, and we do not make any further modifications beyond removing sentences without any verb tokens, as explained in Section 3.1. During training, the models are evaluated based on their loss on the development set. At inference time, in line with earlier works in GED (Bell et al., 2019; Yuan et al., 2021; Volodina et al., 2023), the models are evaluated using the macro-averaged $F_{0.5}$ score, which we compute exclusively over the C and F categories. This metric places greater emphasis on precision than recall, which aligns with standard practice in intelligent computer-assisted language learning applications where false positives, i.e., flagging correct structures as incorrect, are especially undesirable as they risk demotivating learners.

4.2 Monolingual Baseline Configurations

Table 4 presents the $F_{0.5}$ performance results for different configurations of the mBERT model on the GermDetect test data.

We evaluate three baseline configurations: target, random, and adjacent. The target configuration trains models exclusively on GermDetect data from the target language. The random configuration trains models on data in which half of the verbs assume any position within a sentence other than their original position, while the other half remain in their original positions. This corruption strategy represents generic verb placement errors,

mBERT Configuration	F _{0.5} Score by Language								
	af	de	nl	fo	is	da	nb	nn	sv
random	0.74	0.80	0.72	0.63	0.74	0.76	0.80	0.79	0.79
adjacent	0.71	0.67	0.69	0.68	0.64	0.72	0.74	0.75	0.75
target	0.82	0.94	0.88	0.72	0.82	0.85	0.90	0.89	0.86
all	0.88	0.94	0.89	0.85	0.84	0.90	0.93	0.92	0.91
all-balanced	0.86	0.94	0.89	0.79	0.83	0.88	0.92	0.91	0.90
west	0.87	0.93	0.88	–	–	–	–	–	–
west-balanced	0.84	0.94	0.88	–	–	–	–	–	–
north	–	–	–	0.84	0.83	0.89	0.92	0.91	0.90
north-balanced	–	–	–	0.78	0.83	0.86	0.92	0.91	0.89
island	–	–	–	0.82	0.83	–	–	–	–
island-balanced	–	–	–	0.75	0.83	–	–	–	–
mainland	–	–	–	–	–	0.88	0.91	0.90	0.89
mainland-balanced	–	–	–	–	–	0.87	0.92	0.90	0.89

Table 4: Macro-averaged F_{0.5} performance scores (computed over the C and F categories only) of different configurations of the mBERT model across the Germanic languages covered by GermDetect; models ablate the influence of training classifiers based on different data corruption strategies and by combining the training data of structurally related groups of languages; balanced indicates that the target language sets the upper limit for how many sentences of each language are used to train the classifier.

i.e., linguistically uninformed verb placement errors. For the adjacent configuration, half of the verbs switch positions with one of their adjacent tokens (both left and right swaps are equally frequent), approximating the word-order error induction mechanism described in Nielsen (2023), but applied to verbs only.

As shown in the results, the target configuration significantly improves performance across all languages compared to both the random and adjacent configurations, indicating that training directly on GermDetect data effectively enhances the detection of naturalistic verb placement errors.

4.3 Ablation of Multilingual Configurations

Next, we assess the effects of training models on configurations that include structurally related languages.

For the all configuration, one model is trained on all available data. Similarly, the west, north, island, and mainland configurations each include all data from the languages within their respective groups.¹³ In the balanced configurations, the number of sentences from each language is capped at the level of the target language, ensuring that the target language contributes at least as many sen-

tences as any other included language. This means that, e.g., in the north-balanced configuration with Faroese as the target language, if the Faroese dataset contains X sentences, then each of the other North Germanic languages can contribute at most X sentences to the training set, ensuring that Faroese is not underrepresented in the training data.

The results demonstrate that training on all available data yields the best-performing models, consistent with the expectation that more data generally improves performance. However, training solely on West Germanic data yields performance scores nearly equivalent to those obtained by using all data when tested on West Germanic languages, a trend also observed among North Germanic languages. Furthermore, training exclusively on mainland Scandinavian languages results in only a minor performance reduction in these languages, compared to training on all North Germanic languages. These observations suggest that, while incorporating more diverse data is generally beneficial, the models effectively exploit structural similarities among related languages, achieving performance scores close to the best-performing configurations. Balancing the representation of languages within the training sets does not provide additional benefits; thus, it is preferable to utilize all available data.

¹³West Germanic: af, de, nl. North Germanic: fo, is, da, nb, nn, sv. Island Scandinavian: fo, is. Mainland Scandinavian: da, nb, nn, sv.

It is equally unsurprising that German benefits the least from the inclusion of related languages in training, as it is by far the most well-represented language in GermDetect. Similarly, Icelandic and Dutch also exhibit only minor performance improvements. In contrast, Afrikaans and Faroese – being the languages with the least available data – benefit the most from the inclusion of data from related languages in training.

5 Conclusion

We have introduced **GermDetect**: UD-based, linguistically informed verb placement error **detection** datasets for learners of **Germanic** languages, designed as a token classification task. As our datasets are UD-based, we can provide them in most major Germanic languages: Afrikaans, German, Dutch, Faroese, Icelandic, Danish, Norwegian (Bokmål and Nynorsk), and Swedish. Unlike existing resources, GermDetect targets a specific and pedagogically relevant error type that is under-represented in current benchmark datasets and goes undetected by most existing GED/GEC tools. Our results show that multilingual models trained on data corrupted by the GermDetect algorithm outperform models trained on naively corrupted data. Furthermore, while training on all data consistently yields the highest performance, models trained on structurally related languages perform nearly as well – demonstrating the benefits of typological similarity. Crucially, the amount of available training data strongly influences the degree to which models benefit from multilingual training: high-resource languages such as German, Icelandic, and Dutch see marginal improvements, whereas low-resource languages such as Afrikaans and Faroese benefit substantially. These findings highlight the importance of both linguistic structure and data quantity in training robust GED/GEC models and suggest that targeted, linguistically informed error induction can support the development of systems capable of providing fine-grained feedback on complex syntactic phenomena such as verb placement in Germanic languages.

Limitations

In its current implementation, the verb placement error generation algorithm is subject to several limitations. It assumes UD sentences to be grammatically well-formed and their annotations to be accurate. However, this is not always the case, as data

quality can vary and annotation practices can differ across datasets. To address this, future iterations of the algorithm should include more robust checks to ensure that all tokens are treated correctly, even in the presence of inconsistent or imperfect annotations. Another limitation lies in the assumption that every corruption introduced by the algorithm results in an incorrect sentence. In theory, however, some corruptions can still yield well-formed or acceptable constructions. Although restrictions are currently in place to prevent the generation of polar question syntax, and the relatively rigid word order of Germanic languages minimizes the number of such cases, they are not entirely eliminated. A manual inspection of 100 German sentences revealed an error rate of 2.9% in which verbs were incorrectly labeled. For Dutch, this error rate was 2.1%. Future developments should aim to reduce these accidentally grammatically sound relocations of verbs even further. In the Dutch sentences we manually checked, we also noticed that, for very long sentences, the algorithm sometimes did not restore the correct order of the extracted verb-headed phrases. This affected the soundness of the respective sentence in 4% of the sentences we checked. In a future iteration, it should be examined whether this was caused by an algorithmic shortcoming or by insufficient data and annotation quality.

Additionally, while keeping noun phrases intact represents a step toward introducing linguistically informed errors, further restrictions could be added – for instance, preserving additional syntactic structures or avoiding verb placements that would misrepresent subordinate clause boundaries, such as placing verbs in front of subordinations. Future versions of the algorithm could also take further advantage of the rich linguistic information already present in UD annotations to better approximate a wider range of learner phenomena. Another issue arises when the root of a sentence is not a verb but a noun, which can occur in some UD treebanks when the main clause contains a copula verb. In such cases, the corresponding noun phrase is currently not impermeable. Moreover, although the current implementation provides feedback on the position of verb placement errors, it does not yet explain why a given verb placement is correct or incorrect. Providing this type of explanatory feedback in the form of a feedback message would offer more meaningful support to learners. Lastly, it goes without saying that it would be desirable to evaluate our models on actual learner data once

natural learner data annotated for verb placement errors become available.

Ethics Statement

We do not see any major ethical concerns in the context of this work. As always, to promote diversity, it would be desirable to extend the coverage of our datasets to more Germanic languages, in particular, lower-resourced ones, minority languages, and regional language varieties such as Luxembourgish, Frisian, Yiddish, Low German, Swiss German, etc. As our algorithm operates on UD data, this would be implementable as soon as sufficient UD-annotated data for these languages become available. Of course, implementing an API demonstration of our trained verb placement error detection tools is a natural next step to ensure that language learners can directly benefit from the models we developed.

Abstract

This study examines vulnerabilities in transformer-based automated short-answer grading systems used in medical education, with a focus on how these systems can be manipulated through adversarial gaming strategies. Our research identifies three main types of gaming strategies that exploit the system’s weaknesses, potentially leading to false positives. To counteract these vulnerabilities, we implement several adversarial training methods designed to enhance the system’s robustness. Our results indicate that these methods significantly reduce the susceptibility of grading systems to such manipulations, especially when combined with ensemble techniques like majority voting and Ridge regression, which further improve the system’s defense against sophisticated adversarial inputs. Additionally, employing large language models such as GPT-4 with varied prompting techniques has shown promise in recognizing and scoring gaming strategies effectively. The findings underscore the importance of continuous improvements in AI-driven educational tools to ensure their reliability and fairness in high-stakes settings.

1 Introduction

As technology advances, automated scoring of free-text responses is transforming how we evaluate written answers, making the process faster and more consistent (Yannakoudakis et al., 2011). Early research in this area has focused on instance-based methods, treating the task as a supervised text classification problem (Burrows et al., 2015), (Bai and Stede, 2023). In this approach, models are trained using labeled data to predict labels for unseen data, such as predicting whether a short answer submitted to an Automated Short Answer Grading (ASAG) system is correct or incorrect (Bonthu et al., 2021). More recently, some ASAG systems have taken a similarity-based approach, where each

new response is assigned the label of the response it most closely matches from a sample of previously annotated responses. Neural similarity-based models have further advanced this field by learning rich response (or question-response) embeddings and matching them using cosine similarity, demonstrating superior performance in capturing meaning beyond surface-level text (Schneider et al., 2022).

Despite the significant potential demonstrated by similarity-based ASAG models, these models are especially vulnerable to scoring errors when presented with certain kinds of responses (Section 2). This creates an opportunity for examinees to exploit these vulnerabilities to earn undeserved credit, which can erode trust in automated grading and raise concerns over the responsible use of AI in educational assessments. Deliberate attempts by examinees to exploit ASAG systems in this way are known as “gaming strategies.”

The objective of this study is to identify and analyze potential gaming strategies that students may use to manipulate or deceive automated short-answer grading (ASAG) systems, particularly within medical education. To counteract these vulnerabilities, we propose a dual approach combining: (1) adversarial training and ensemble techniques—such as majority voting and Ridge regression—applied to a transformer-based ASAG system (ACTA), and (2) prompt engineering techniques applied to a large language model (GPT-4) to evaluate its ability to detect and mitigate gaming attempts. This dual framework allows us to examine the effectiveness of both system-level defenses and LLM-based scoring interventions in improving accuracy and reducing false positive rates (FPR) when presented with adversarial inputs. We evaluate the robustness of these methods before and after the proposed defenses are applied. This investigation is guided by three research questions:

1. How vulnerable are transformer-based grad-

Component	Description
Stem	A previously healthy 26-year-old man is brought to the emergency department because of a tingling sensation in his fingers and toes for 3 days and progressive weakness of his legs. He had an upper respiratory tract infection 2 weeks ago. He has not traveled recently. He was unable to get up from bed this morning and called the ambulance. Temperature is 37.3°C (99.1°F), pulse is 110/min, respirations are 22/min, and blood pressure is 128/82 mm Hg. Pulse oximetry on room air shows an oxygen saturation of 99%. Physical examination shows weakness of all four extremities in flexion and extension; this weakness is increased in the distal compared with the proximal muscle groups. Deep tendon reflexes are absent throughout. The sensation is mildly decreased over both feet.

- ing systems to adversarial gaming strategies used by test takers?
2. What effect do adversarial training and ensemble methods have on system robustness?
 3. How effective are different prompt engineering strategies in identifying and mitigating adversarial inputs?

This study advances the ASAG field by addressing the critical issue of vulnerability to adversarial gaming strategies. By identifying such strategies and developing effective countermeasures, the robustness, integrity, and reliability of transformer-based short-answer grading systems can be improved. The reported findings have broad practical benefits including improving the trustworthiness of automated grading tools in educational settings and contributing to the security of AI-driven systems against adversarial attacks. The technical advancements that are reported are also complemented by theoretical insights into the challenge posed by gaming in the context of ASAG specifically as well as into the responsible use of AI in education more generally.

2 Related Work

With the advent of transformer models, neural similarity-based ASAG techniques have demonstrated improved accuracy and reduced data annotation requirements compared to instance-based methods (Bexte et al., 2023). However, these advancements have also introduced new challenges, particularly the susceptibility of similarity-based systems to adversarial attacks (Filighera et al., 2020). Such attacks can range from submitting random strings of letters (Ding et al., 2020) to adding irrelevant yet carefully chosen words to otherwise valid responses (Filighera et al., 2023), with the

goal of deceiving the model into misclassification. For example, Ding et al. (2020) found that a non-sensical string like "nswvtnvakgxpnm" could be classified as a correct response by an ASAG system.

Within the medical domain, Baldwin et al. (2025) have shown that several gaming strategies were successful in "deceiving" a similarity-based system. These strategies consisted of entering the following as responses to the short-answer questions: (1) random number of words selected at random from the stem¹, (2) random number of consecutive words selected at random from the stem, (3) random number of medical terms selected at random from the stem, (4) keywords selected from the stem by a content expert, and (5) a summary of the stem produced by GPT 3.5, as well as (6) listing multiple responses only one of which is correct. The results showed that the first five strategies lead to a success rate between 6% to 16%, while the last strategy led to a success rate of 57%, underscoring the need for addressing these vulnerabilities.

While prior work defined the problem of gaming strategies and quantified their effects on transformer-based scoring systems, this study focuses on systematically evaluating multiple adversarial training techniques and ensemble strategies to enhance system resilience within the clinical ASAG domain. Additionally, we explore the role of LLMs, such as GPT-4, in detecting and mitigating adversarial manipulation.

3 Methodology

This study investigates two approaches for defending against gaming strategies in automated short-answer grading (ASAG) systems. The first ap-

¹An item stem is the part of a test question that presents the problem or scenario to be answered or responded to, as shown in Table 1.

proach centers on the ACTA system, a transformer-based model that classifies short medical responses as correct or incorrect by leveraging sentence-BERT embeddings and a similarity-based matching mechanism. This approach is trying to enhance the robustness of the ACTA system through adversarial training and ensemble methods. The second approach involves a large language model (LLM)-based method, where GPT-4 is used with various prompt engineering techniques to independently score student responses and detect gaming strategies. This allows us to examine the effectiveness of both system-level defenses and LLM-based scoring interventions.

3.1 ACTA System Overview

Experiments were undertaken using the ACTA system (Analysis of Clinical Text for Assessment; Suen et al. (2023)), a transformer-based ASAG system designed to classify short responses to medical questions as correct or incorrect. To achieve this, ACTA utilizes sentence BERT (Reimers and Gurevych, 2019) and contrastive learning. When presented with a new response, ACTA matches it to the most similar response within a training set of human-scored responses and assigns it the matched response's label (correct or incorrect), provided their similarity exceeds a given operational threshold (for a detailed description of ACTA, see Suen et al. (2023)). While ACTA achieves near human-level performance with a binary F1 score of .98, previously reported weaknesses of transformer-based grading systems require an investigation of ACTA's susceptibility to gaming.

We evaluate the effectiveness of adversarial training by assessing the ACTA system's performance on gaming data both before and after the training is applied.

3.2 Prompt Engineering with GPT-4

Using large language models to score the real dataset has already shown promising results. This motivated the use of these models with different prompting techniques to evaluate whether large language models can accurately recognize and score gaming responses. Due to the consistently strong performance demonstrated by ChatGPT4 (Achiam et al., 2023) across various experimental settings, this model was selected as the primary tool for conducting this series of experiments.

To evaluate system robustness, we simulate gaming strategies that students might use to deceive

ASAG systems—detailed in Section 4. These adversarial examples are used both to adversarially train the ACTA model and to test the effectiveness of prompt engineering with GPT-4.

4 Experiment Design

4.1 Dataset

The dataset comprises 71 short-answer questions (SAQs) with 36,735 responses from 24,235 examinees. An example of an SAQ is shown in Table 1. Responses were collected during the administration of a Medicine Clinical Science subject exam distributed to a large number of medical schools in the US and Canada for use as a summative, end-of-semester exam.

4.2 Gaming Strategies Simulation

Following Baldwin et al. (2025), we simulate three gaming strategies meant to resemble how students *without* the requisite knowledge of a correct answer might nevertheless respond to an item. Data were generated as follows:

1. Simulate responses by randomly sampling words (excluding stop words) from a given item's clinical vignette. Variations of this strategy include consecutive words, non-consecutive words, and samples of words that appear in both the item description *and* a generic list of medical terms.
2. Utilize a summary of the clinical scenario as a response. Summaries were obtained using ChatGPT.
3. Utilize "mixed" responses that combine both correct and plausible incorrect answers into a single response, which, following operational guidelines, should be scored as incorrect.

For our data, the strategies generated an impractically large number of responses. To create a set of responses that could feasibly be used as part of an operational process, we randomly sample 5% from each strategy, resulting in 14,657, 573, and 584 simulated responses for strategies 1, 2, and 3, respectively. While simulated responses were largely nonce phrases or unequivocally incorrect, 3 simulated responses exactly matched (real) correct responses from the training data. Three misclassifications were deemed tolerable for our purpose, and all artificial responses were designated as incorrect.

Following a principal component analysis (PCA), Figures 2 and 3 plot the responses for two

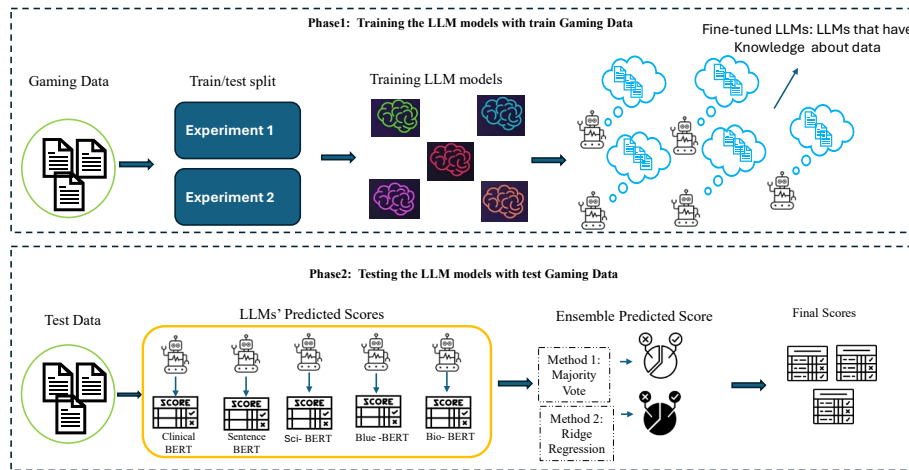

Figure 1: Adversarial Defense Workflow. Gaming data is combined with real data for training and testing purposes.

Figure 2: PCA of Response Embedding for Item 1

Figure 3: PCA of Response Embedding for Item 2

SAQs in the space defined by principal components 1 and 2. Differences in the identification of adversarial examples across items can be observed. For SAQ 1 (Figure 2), the distribution of gaming responses shares considerable overlap with the distribution of correct responses, suggesting that gaming responses may have a relatively high probability of being misclassified. In contrast, for SAQ 2 (Figure 3), gaming responses are comparatively isolated, suggesting that these responses may be more readily identified by an ASAG system.

4.3 Adversarial Training Setup for ACTA

To enhance the resilience of the ACTA system against gaming responses, two adversarial training experiments were undertaken to investigate (i) whether adversarial training based on all three types of gaming responses improves system robustness to these types of responses and (ii) whether adversarial training based on two types of gaming responses

improves robustness to a third type of responses. The general workflow is demonstrated in Figure 1. The first experiment entailed the inclusion of 70% of the simulated responses from each strategy into the training dataset (together with the authentic responses), with the remaining 30% of both artificial and authentic responses allocated to the test set. The objective of the second experiment was to assess the capacity of data derived from specific strategies to bolster the model's defenses against gaming strategies that were not identified during the training phase. This was achieved through the implementation of a 3-fold cross-validation method, where the model was trained on data from two gaming strategies and tested on the third. This approach enabled the evaluation of the model's enhanced ability to recognize unknown examples through exposure to known gaming adversarial examples.

To enhance the results and evaluate the efficacy

of various models, we employed five different models for response embeddings to predict whether a response was related to gaming: Clinical-BERT (Huang et al., 2019), Bio-BERT (Lee et al., 2020), Sci-BERT (Beltagy et al., 2019), and Blue-BERT (Peng et al., 2019). These models are pretrained on medical domain datasets, leveraging their specialized knowledge to aid in training the system. They were fine-tuned with the adversarial data in a 70/30 split (for experiment 1) and fine-tuned with two gaming strategies, and tested on the third one for experiment 2, as detailed above. These fine-tuned models are then used to classify responses as correct or incorrect. The embeddings generated by these models were then combined with the ACTA model using a majority vote method and ridge regression to determine if there was an improvement.

4.4 Prompt Engineering Setup for GPT-4

Three prompting techniques were employed in this experiment:

1. The model was provided with the item questions and the examinee’s response to the question. The model was then asked to score the response, given the question.
2. The model was given the questions along with examples of correct answers for each question. The model was then asked to score the examinee’s response.
3. The model was provided with examples of correct answers only, and then asked to score the examinee’s response.

Using ChatGPT-4, scores using each of these strategies were obtained. Due to resource limitations, 100 samples of each gaming data and real data were used for these experiments.

5 Results

5.1 ACTA Pre-Adversarial Training Results

We began by evaluating ACTA’s scoring of gaming responses prior to any adversarial training. The model was trained on 70% (26,095) of the real responses and evaluated on the remaining 30% (10, 890) combined with all artificial responses. Since the number of simulated gaming responses varies across strategies and experiments, we report two separate measures: F1 for real responses and false positive rate (FPR) for artificial responses. ACTA performed well when scoring real data (F1 = .9845); however, the gaming strategies deceived

ACTA into misclassifying many of the artificial responses as “correct.” FPRs for strategies 1, 2, and 3 were .061, .189, and .435, respectively, demonstrating the vulnerability of this system to examinee gaming (Table 2). Responses from strategy 3 were especially challenging to classify correctly, illustrating the potential for examinees with partial knowledge to game systems that have not been adversarial trained by simply listing as many plausible answers as possible.

5.2 ACTA Post Adversarial Training Results

The results from the experiments described above are shown in Figures 5 and 6 and Tables 3 and 4. In the first experiment, the model maintained a high F1 score, with substantial reductions in FPRs across various gaming strategies and embedding models. This demonstrates the efficiency of adversarial training in enhancing model accuracy. The FPR results for the gaming strategy “Information from the Stem” were consistently the lowest across models, indicating that even without adversarial training, this model recognized these responses better than the other two gaming strategies. The post-adversarial training gains for the “Mixed Responses” strategy are particularly encouraging, suggesting that training on simulated gaming responses is an effective countermeasure against the most successful gaming strategy. This highlights the significant benefits of adversarial training for defending against complex adversarial attacks.

The second experiment also maintained a high F1 score of 0.98 for real responses, while still providing some improvements with gaming detection. These results suggest that familiarity with known gaming strategies helps the model recognize responses based on unknown gaming strategies, enhancing overall robustness. The model’s resilience is significantly bolstered by training with ‘strong’ gaming examples (high FPR) instead of ‘weak’ ones. The model’s performance was least effective under strategy 3; however, incorporating this strategy into adversarial training markedly improved model efficiency against strategies 1 and 2. In contrast, training with the relatively weaker strategies 1 and 2 yielded lesser improvements in detecting strategy 3, reducing the FPR from 0.435 to 0.067, which is the smallest FPR for the ACTA model in the second experiment among all the models. This observation highlights the intricate relationship between the effectiveness of gaming strategies and the robustness of model training, suggest-

ing a positive correlation where more sophisticated adversarial training leads to improved robustness. Table 4 shows the FPR results after applying the embedding models’ results to Majority Vote and Ridge Regression (“AdvT2”). Ridge regression outperformed the majority vote with the FPRs for both experiments 1 and 2 (Figure 6). These findings suggest the effectiveness of these two models compared to considering an individual embedding model. Similar to the embedding model FPR results, gaming strategy 3 is more challenging to recognize and has a higher FPR than gaming strategies 1 and 2. However, FPR results for all gaming strategies are improved compared to each embedding model’s results.

5.3 Prompt Engineering Results

Summary results from the prompt engineering experiments are shown in Table 5. Because it performed best overall, only results from the first

prompting strategy, submitting a question and a response and requesting a score, are reported.

For the experiment with real data, the model maintained high performance, with an accuracy of 0.93, a precision of 0.97, and False Positive Rate (FPR) of 0.06. For the gaming data, the highest accuracy was achieved for the third gaming strategy, “submit multiple answers”, with an accuracy of 0.99, a TNR of 0.99, and the lowest FPR of 0.01. This suggests that in this experiment, ChatGPT-4 was more successful in recognizing and scoring responses generated using the third strategy compared to the adversarial training approaches reported above. The second gaming strategy, “summarize item vignette”, also performed strongly with an accuracy of 0.97 and an FPR of 0.028. The first strategy, “copy words from the item vignette”, had the lowest performance among the gaming strategies, with an accuracy of 0.89 and an FPR of 0.11. These results underscore the model’s effectiveness in handling various gaming strategies, with notable success in the third strategy, and relative ineffectiveness with responses from the first strategy.

6 Error Analysis

6.1 Error Analysis For Adversarial Training

The model’s performance was notably better for gaming strategies it was trained on compared to those it had not encountered during training. This points to a potential overfitting issue, where the model becomes too specialized in detecting known adversarial patterns but may struggle with novel or unseen strategies. Despite the reductions in FPRs, some gaming strategies, particularly Strategy 3 (“Mixed Responses”), remained challenging for the model to detect. This suggests that while adversarial training improves the model’s defenses, it may not fully mitigate all vulnerabilities, especially for more sophisticated or nuanced gaming strategies. The quality and representativeness of the adversarial examples used in training had a sig-

nificant impact on the model’s performance. Training with “strong“ adversarial examples (those with high FPRs) led to more substantial improvements in robustness, whereas training with “weaker“ examples provided less benefit. This underscores the importance of carefully selecting adversarial examples that accurately reflect the types of gaming strategies the model might encounter in real-world applications. The cross-validation experiments demonstrated that while training on multiple gaming strategies can enhance the model’s generalization capabilities, the process is complex and computationally expensive.

6.2 Error Analysis For Prompt Engineering

Upon reviewing the rationales across various datasets, several common patterns emerged that explain why certain responses were predicted wrong.

Summary of the clinical scenario: Many rationales indicate that a response “aligns with the intended correct pattern“ or “matches the expected correct response.“ This suggests that the system recognizes patterns it anticipates, regardless of the response’s accuracy. For instance, if a response correctly lists all the symptoms of a disease, the model may consider it correct simply because it aligns with the expected diagnosis related to those symptoms. Some rationales reveal that the presence of specific keywords in the responses triggers the system to mark it as correct, e.g., phrases like “man, 36, suffers sleepiness, ED, weight gain, hypertension“ match key descriptors associated with the correct answers, such as “sleep study.“

If a response mentions symptoms that suggest a disease, the model may consider it correct, even if the actual cause of the disease differs. An example would be a response stating, “Man on anti-malaria drugs shows signs of hemolysis,“ where the correct answer is “Hemolysis due to G6PD deficiency“. In this case, because the hemolysis disease was mentioned in the response, the model scored this response as correct.

Utilize mixed responses: Here, the rationales often point to specific phrases within the response, indicating that the model matches exact or nearly exact phrases it expects, regardless of whether the combination is logically sound. If a response includes correct elements alongside irrelevant parts that do not negate the correct diagnosis, the model may still consider it correct. For instance, “Rheumatic fever“ might be irrelevant, but it does not invalidate the correct diagnosis of

“systemic sclerosis (scleroderma).“ Sometimes, the model assesses the overall picture of the response; if a disease shares similarities with another mentioned in the response, it may still be considered correct. For example, the response “chronic obstructive pulmonary disease bronchiectasis“ might be deemed correct because “bronchiectasis“ was the intended correct answer, and it shares similarities with “chronic obstructive pulmonary disease bronchiectasis“.

Randomly sampling words: This strategy involves the use of random words; in cases where the model erroneously produces a correct score, the sample words are general and provide no specific clues about the disease. In such cases, the model relies on the question and uses the information provided to predict the disease, ultimately considering the response correct, although there was not any correct information in the response.

Real Dataset: If a response contains minor misspellings, the model may consider it incorrect, even if it matches the correct response. Conversely, the model may consider a vague term correct if it encompasses the specific diagnoses listed. For example, the response “heart disease“ might be accepted as correct, even if the correct answer is a specific type of heart failure or disease. The rationales sometimes rely on broad medical logic. The model might still consider it correct when a response refers to a general disease category without specifying details or subcategories. This suggests that the model applies standard medical reasoning but may lack the subtlety needed to distinguish between similar conditions. In some cases where the general concept is correct but details are slightly different, the model may still mark the response as wrong despite its correctness. These patterns indicate that the model prioritizes exact matches and penalizes variations, even when the overall concept is correct, highlighting its limitations in understanding nuanced or slightly varied responses.

7 Discussion

These results add new evidence related to exploitable vulnerabilities in transformer-based grading systems. Despite being artificially generated approximations of potential gaming behaviors, all three gaming strategies were successful in deceiving the non-adversarial trained system. This aligns with findings from previous research, which also reported that adversarial approaches could compro-

mise the integrity of automated systems, particularly when the system is not specifically trained to recognize such attacks (Baldwin et al., 2025). The first group of adversarial training experiments showed that data augmentation is a promising way to fortify ASAG systems against such attacks. The cross-validation experiments also showed that it is beneficial to train on examples across gaming strategies, suggesting a transfer of learning between strategies, which holds the potential to protect against unforeseen gaming tactics that may arise in practice.

The results show that incorporating embedding models into Majority Vote and Ridge Regression significantly reduced the false positive rates (FPR) in experiments, which is in line with findings from research on ensemble learning methods that demonstrate their superiority in reducing error rates (Naderalvojud and Hernandez-Boussard, 2023). Among the gaming strategies evaluated, strategy 3 proved to be the most challenging to recognize, yielding higher FPRs than strategies 1 and 2. Despite this, the FPR results across all gaming strategies showed improvement when compared to the results of each individual embedding model. This mirrors findings in previous studies, where certain adversarial strategies consistently posed greater challenges to detection systems.

The experiments demonstrated the first prompting strategy was effective, where the model was given questions and responses to score. With real data, the model showed high accuracy and precision and a low FPR, indicating robust performance in evaluating genuine responses. For gaming data, the best results were seen in the “submit multiple answers” strategy (consistent with Baldwin et al. (2025)). The “summarize item vignette” strategy also performed well; however, the “copy words from the item vignette” strategy performed relatively poorly.

In summary, while the non-adversarially trained system was susceptible to gaming, the defense mechanisms explored in this paper showed significant reduction in FPR both when training within strategy and across strategies. As the understanding of possible gaming strategies in the context of medical education matures, future work will include the simulation of new adversarial attacks for ASAG systems that are more closely aligned with human behaviors as well as further experimentation with adversarial training. Employing regularization techniques such as dropout, weight decay, and early

stopping can limit overfitting, which may improve a model’s generalizability. Furthermore, employing various prompt engineering techniques with LLMs also has the potential to enhance performance.

8 Limitations and Ethical Considerations

While this study provides promising directions for improving robustness in ASAG systems, several limitations must be acknowledged. First, the adversarial examples used in our experiments are simulated approximations of gaming strategies, rather than authentic, organically derived examples from real-world test-takers. As such, while the strategies are plausible and their effectiveness in gaming the scoring system was proven, they may not fully reflect the diversity and nuance of actual test-taker behaviors, particularly in high-stakes environments. Furthermore, the experiments were conducted within a single domain and dataset, and the generalizability of the findings to other domains—such as legal education, K-12, or general writing assessment—remains uncertain. Different domains may involve distinct response styles, expectations, learner populations, and gaming behaviors, which could impact the effectiveness of adversarial training strategies. Last but not least, this study explored the effects of these gaming strategies on the ACTA scoring system and on using GPT-4 to score responses via prompt engineering. The extent to which these results generalize to other transformer-based or few-shot scoring systems is an open question.

From an ethical standpoint, adversarial training raises important questions related to fairness, transparency, and trust in AI-based scoring. While improving robustness is a core goal, it is also critical to ensure that ASAG systems do not unfairly penalize legitimate test-taking strategies or linguistic variability, especially among non-native speakers or individuals from underrepresented groups.

It should also be recognized that research into gaming strategies inherently raises concerns about dual-use. While our intention is to strengthen the integrity of ASAG systems, the publication of methods for generating adversarial responses could inadvertently aid malicious actors. To mitigate this risk, we have intentionally abstracted implementation details and focused on generalizable insights rather than system-specific exploits.

On the positive side, adversarial examples can serve an additional purpose in enhancing explain-

ability. When used in conjunction with feature attribution methods, adversarial perturbations can help identify which aspects of a response most influence model predictions. For example, if minor lexical changes significantly affect scoring, it may indicate an over-reliance on specific keywords or surface features rather than deeper semantic understanding. For example, the error analyses of the prompt engineering approach revealed that the models tend to recognize anticipated patterns as a proxy to accuracy, which is what makes them particularly susceptible to gaming responses that follow the expected pattern of correct answers. These insights are critical for diagnosing model weaknesses, refining scoring rubrics, and improving transparency. In high-stakes assessment, the ability to explain and justify model decisions is essential for fostering user trust and ensuring accountability in automated assessment.

Overall, while adversarial training is a valuable tool for increasing the reliability of ASAG systems, its application must be guided by ethical principles that prioritize fairness, interpretability, and alignment with educational values.

EyeLLM: Using Lookback Fixations to Enhance Human-LLM Alignment for Text Completion

Astha Singh¹, Mark Torrance², Evgeny Chukharev¹

¹Iowa State University, ²Nottingham Trent University
asthas@iastate.edu, mark.torrance@ntu.ac.uk, evgeny@iastate.edu

Abstract

Recent advances in LLMs offer new opportunities for supporting student writing, particularly through real-time, composition-level feedback. However, for such support to be effective, LLMs need to generate text completions that align with the writer’s internal representation of their developing message, a representation that is often implicit and difficult to observe. This paper investigates the use of eye-tracking data, specifically lookback fixations during pauses in text production, as a cue to this internal representation. Using eye movement data from students composing texts, we compare human-generated completions with LLM-generated completions based on prompts that either include or exclude words and sentences fixated during pauses. We find that incorporating lookback fixations enhances human-LLM alignment in generating text completions. These results provide empirical support for generating fixation-aware LLM feedback and lay the foundation for future educational tools that deliver real-time, composition-level feedback grounded in writers’ attention and cognitive processes.¹

1 Introduction

Natural language processing (NLP) solutions exist for scaffolding students who are learning to produce effective text. These support both surface-level accuracy (grammar and spelling), and also compositional-level effectiveness, i.e. helping students produce text that communicates a coherent message (e.g., Franzke et al., 2005; Roscoe and McNamara, 2013). Recent advances in large lan-

guage models (LLMs) enable promising innovative applications for intelligent support of writing tasks. Specifically, there are potential advantages to providing composition-level feedback in real time, while the writer is still forming their message, rather than retrospectively, once their text is complete.

Achieving this is challenging, but is brought within reach by LLMs. These can generate plausible completions to text that a student is in the process of composing. However, providing feedback based on these plausible completions has limited learning benefit unless the LLM-generated completions are aligned with those that the student intended to produce. Human-LLM alignment will increase if the LLM captures important features of the writer’s current internal representation of their developing message. However, these mental representations are not directly observable. They are also likely to be implicit, at least in part: The writer might not have explicitly articulated their developing message even in their own internal representation (Torrance, 2016).

One possible clue to this implicit internal representation is provided by writers’ eye movement. During text production writers frequently hesitate, often very briefly, and look back within their own text. These lookback eye movements typically involve “hopping around” between isolated words and phrases rather than sustained reading (Chukharev-Hudilainen et al., 2019; Torrance et al., 2016). This eye movement is, however, targeted: Words are not fixated at random, but tend to be informationally rich. Previous work in cognitive psychology has suggested that lookbacks may be driven by the writer’s internal representation of the emerging message (Torrance, 2016; Torrance et al., 2016), but this hypothesis has not been systematically evaluated.

In this paper, we propose the use of eye-tracking cues to enhance LLM performance in predicting

¹Following the initial submission, we discovered an error in one of the analysis scripts that inadvertently introduced data contamination. To ensure the validity of the findings, all models were rerun using corrected code. This version reports the updated results. While specific numerical values have changed, the main conclusions of the study remain unaffected. Our code is available publicly at <https://go.chukharev.com/bea-2025>.

text completion. If eye fixations cue content for what the writer produces next, then lookback data can help provide completion suggestions that align more closely with the writer’s current thinking. To test this hypothesis, we use keystroke and eye movement data from human writers composing argumentative texts. We extract hesitation events: pauses when writers stopped and looked back into their text and then, without editing, continued writing (e.g., finishing the sentence that they were writing before the pause). We compare writers’ own completions with LLM completions generated on the basis of prompts that did and did not include the words and sentences that the writers fixated on during lookback. Increased overlap between LLM and writer completions when prompts incorporate information from lookbacks would be evidence for the potential value of eye-movement-informed message-level scaffolding of written composition.

The purpose of this paper is two-fold: First, we evaluate whether the information on the writer’s lookback fixations can enhance the alignment between the human and the LLM in the text completion task. Second, we investigate whether LLM text completions with and without eye movement data can provide evidence for the (cognitive) hypothesis about the role of lookbacks in human text production. This lays the necessary groundwork for designing novel educational applications wherein useful composition-level feedback can be provided to students in real time, before the text is completed by the student.

2 Related Work

Functions of reading during writing in humans.

Research in cognitive psychology suggests that writers often look back at their own text during pauses in production, particularly near sentence boundaries. These fixations frequently involve lexical processing rather than simple error-checking. Most are not part of sustained reading sequences but instead consist of gaze shifts among isolated words via forward and backward saccades. These lookbacks are thought to support the planning of upcoming text rather than merely identifying mistakes in previously written content (Chukharev-Hudilainen et al., 2019; Torrance et al., 2016).

Human–LLM Alignment. Recent efforts to enhance alignment between humans and large language models (LLMs) in writing support systems have focused on modeling writers’ intentions and

cognitive states (Zhang et al., 2024; Gero et al., 2022). However, these internal intentions are often difficult to directly observe. Looking back into existing text, in addition to supporting error monitoring, is likely to support ongoing text production, cuing both message and linguistic (lexical, syntactic) form for what the writer will say next (Chukharev-Hudilainen et al., 2019; Torrance et al., 2016). Knowledge of what words and sentences a writer fixates during these lookbacks, therefore, may provides insight into the writer’s evolving mental representation of their developing composition.

While some recent approaches have explored aligning LLM-generated suggestions with user intentions (Reza et al., 2025), most have not incorporated real-time behavioral signals. Our work builds on this line of inquiry by explicitly integrating gaze-based cues into prompting strategies, aiming to improve alignment between LLM completions and the writer’s unfolding mental model.

Eye-Tracking in NLP. Eye-tracking data has also been leveraged to improve NLP models across a variety of tasks. Prior studies show that incorporating gaze signals can enhance performance in named entity recognition (Hollenstein and Zhang, 2019), text comprehension (Reich et al., 2022), and question answering (Wang et al., 2024). More recently, (López-Cardona et al., 2025) introduced a reward model that uses eye-tracking data to optimize Human–AI alignment. Advances in LLMs have further spurred research into using neural and behavioral signals for better alignment. For instance, (Aw et al., 2023) demonstrate how instruction-tuning can align LLMs with human brain signals. In a similar vein, our study investigates whether reading fixations can serve as meaningful input for improving alignment between LLM text completion responses and writers’ cognitive processes.

3 Methodology

3.1 Data

Thirty undergraduate college students (22 women, 8 men, age range 18–22, mean age 19.7 years) composed two texts each using the CyWrite text editor (Chukharev-Hudilainen et al., 2019)², while their eye movements were recorded with an SR Research EyeLink 1000 Plus system in a monocular remote setup, calibrated using a 9-point procedure. CyWrite maps on-screen eye fixation coordinates to

²<https://github.com/chukharev/cywrite>

corresponding in-text locations – i.e., the specific words being fixated – accounting for scrolling, line wrapping, and text edits. The writing task appeared as the top paragraph in the editor, with participants composing their responses below it. There was no time limit for the writing tasks, the order of tasks was counterbalanced across participants, and a short break was provided between the two tasks for each participant. Participants were not allowed to consult any external sources. All texts were composed in English, and all participants reported that English was their first language.

CyWrite generates a time-aligned log file that records the timestamp for every key press, key release, and eye fixation. Fixations are classified into sustained reading (operationalized as sequences of at least three consecutive eye fixations on words within the same line of text progressing from left to right) and fixating isolated words (defined as fixations on text that are not part of sustained reading sequences). For this study, we define *hesitations* as pauses between successive keypresses during which the participant engages in sustained reading.

3.2 Language Models

We generate responses for four LLMs, namely, GPT-3.5, GPT-4, LLaMa3-8B and Mistral7B. We use gpt-3.5-turbo (OpenAI, 2023) and gpt-4.1 (Achiam et al., 2023) via the OpenAI API. The exact number of parameters for the GPT models have not been officially disclosed but gpt-3.5-turbo is expected to have approximately 20 billion parameters (Singh et al., 2023). The responses are generated at a temperature setting of 0.7. We use Llama3-8B and Mistral-7B through ollama (Ollama, 2023). LLaMa3-8B and Mistral-7B have 8 billion and 7 billion parameters, respectively. For all the models, the number of tokens to be generated is dynamically defined to be approximately equal to the number of tokens in the corresponding *completion*.

3.3 Prompt Design

We first create a baseline prompt that consists of the *pretext*, an instructional prompt, and the task description provided to the student. The two task descriptions are:

- Some people have said that finding and implementing green technologies, such as wind or solar power, should be the focus of our efforts to avert climate crisis. To what extent do you

agree or disagree with this statement? Try to support your arguments with appropriate evidence from, for example, your knowledge of scientific evidence, your own experience, or your observations and reading.

- Some people have argued that animals should be given similar rights to humans. To what extent do you agree or disagree with this statement? Try to support your arguments with appropriate evidence from, for example, your knowledge of scientific evidence, your own experience, or your observations and reading.

To contrast the LLM responses with fixations against those without fixations, we generate responses for a control condition where along with the baseline prompt we provide the LLM with a matched number of non-fixated non-stop words from the *pretext* (if there are fewer non-fixated words in the *pretext* than fixated words, we include all non-fixated words). Thus, we generate LLM responses in four conditions:

1. **Baseline.** Baseline Prompt only
2. **Words.** Baseline + fixated non-stop words
3. **Sentences.** Baseline + filtered fixated sentences
4. **Control.** Baseline + a matched number of non-fixated words

The prompts for each of the conditions are presented in Table 1.

3.4 Evaluation Metrics

To evaluate the performance of LLMs with and without fixations, we establish similarity between human and LLM-generated completions in each of the four conditions on both semantic and token-based (surface linguistic form) measures.

3.4.1 Semantic Similarity

We quantify the semantic similarity between human and LLM responses by computing the cosine similarity between embedding vectors generated from the completions using the text-embedding-ada-002 model via OpenAI API (OpenAI, 2024). This approach captures global semantic alignment between the different completions.

3.4.2 Token-based Similarity

We calculate two token-based similarity metrics: F1 Score and Jaccard Index.

Condition	Prompt
Baseline	This was the task description provided to a student: <task_description >. Please write a continuation of: <pretext >.
Words	This was the task description provided to a student: <task_description >. We have identified the following key words as particularly important: <fixated words >. Please write a continuation of: <pretext >.
Sentences	This was the task description provided to a student: <task_description >. We have identified the following sentences as particularly important: <fixated sentences >. Please write a continuation of: <pretext >.
Control	This was the task description provided to a student: <task_description >. We have identified the following key words as particularly important: <non-fixated words >. Please write a continuation of: <pretext >.

Table 1: Prompt for each condition

F1 Score: F1 score accounts for both precision and recall, making it useful for evaluating word overlap between the two texts. Precision measures the proportion of shared words in the second text (W_2), while recall measures the proportion of shared words in the first text (W_1).

$$\text{Precision} = \frac{|W_1 \cap W_2|}{|W_2|}$$

$$\text{Recall} = \frac{|W_1 \cap W_2|}{|W_1|}$$

The **F1 Score**, which balances precision and recall, is calculated as:

$$\text{F1 Score} = 2 \times \frac{\text{Precision} \times \text{Recall}}{\text{Precision} + \text{Recall}}$$

Jaccard Index: Jaccard Index is a set-based measure that quantifies the overlap between two texts by comparing the size of their intersection with their union. This metric focuses on shared words without considering their relative frequency. It is defined as:

$$\text{Jaccard Similarity} = \frac{|W_1 \cap W_2|}{|W_1 \cup W_2|}$$

4 Approach

In this section, we present our approach to data extraction and LLM response generation. The approach is outlined in Figure 1.

4.1 Extract Hesitation Events

The first step in our approach is to obtain valid hesitation events from human text production data. We defined *hesitations* as inter-keypress intervals where writing is interrupted by a pause, during

which the writer engages in sustained reading. At the time of hesitation, we extract the span of text between the start of the current paragraph and the cursor location. We call this the *pretext*. In Figure 2, | represents the cursor location at the time of hesitation. We discard all hesitations where the pretext is empty.

Once we have a valid hesitation, we traverse the log file to extract the human *completion* of the pretext. To this end, we consider all keystrokes following the hesitation until the writer types a sentence-final punctuation symbol (./?/!). The completion is valid so long as the writer does not edit or delete any portion of the pretext at any point during the completion process. Valid human completions serve as the gold standard for comparison against the LLM-generated completions. However, we discard all invalid completions. We define a *hesitation event* as a valid hesitation followed by a valid completion. The process of extracting hesitation events is outlined in Algorithm 1.

Algorithm 1 Extract Hesitation Events

```

1: function GETHESITATIONS(data)
2:   for i in data do
3:     if len(data[i].pretext) > 0 then
4:       if sustained reading in data[i] then
5:         for j from i+1 to len(data) do
6:           if data[j] starts data[i] then
7:             if data ends in {.,?;!} then
8:               Extract  $e_n$ 

```

4.2 Extract Fixations

Once we have a set of valid hesitation events e_n (pretext, completion), we extract, from the available eye-tracking data, all eye fixations on the text that occurred during each hesitation event. We include both sustained reading fixations, and fixations on isolated words. We apply the following

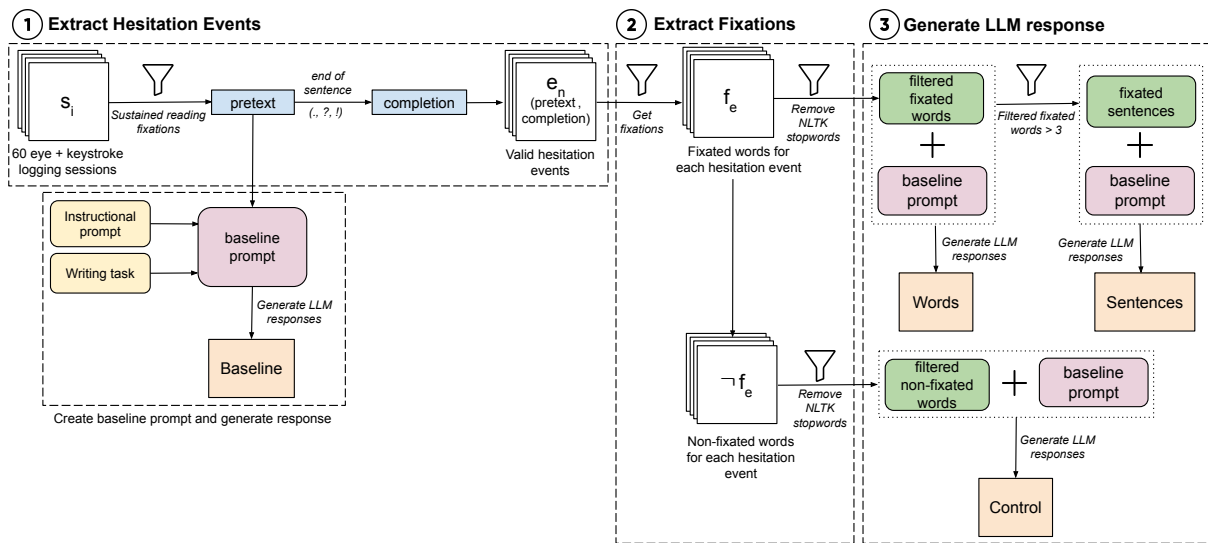

Figure 1: Overview of EyeLLM Approach

Figure 2: Example showing the extraction of pretext, fixations, and completion. (a) The writer pauses (hesitates) during text production. | indicates their cursor location at the point of hesitation. Everything between the start of the current paragraph and | is the *pretext*. (b) The writer fixates on the highlighted points as shown in the scanpath. Words containing eye fixations are *fixated words*. (c) The writer continues to produce text (highlighted in green). This is the *completion*.

Model	Similarity Scores											
	Semantic				F1				Jaccard			
	Control	Baseline	Words	Sentences	Control	Baseline	Words	Sentences	Control	Baseline	Words	Sentences
GPT-3.5	.8075	.8066	.8086*	.8090*	.1483	.1484	.1511*	.1480	.0823	.0824	.0841*	.0821
GPT-4	.8078	.8056*	.8089	.8101*	.1332	.1336	.1347	.1347	.0732	.0735	.0742	.0744
LLaMa3	.7945	.7958*	.7958	.7959	.1356	.1360	.1364	.1360	.0749	.0752	.0754	.0753
Mistral7B	.7935	.7919*	.7950*	.7945	.1228	.1244	.1262*	.1236	.0673	.0682	.0693*	.0678

Table 2: Average similarity scores across all LLMs. The highest score for each LLM is highlighted in **bold**. * marks scores that are significantly different from Control, $p < 0.01$.

filtering criteria:

1. We only include lookback fixations, i.e. fixations on the text before the cursor at the time of the hesitation.
2. We exclude fixations on words from the NLTK list of stop words, to ensure that only fixations on semantically important words are included.
3. For the Sentences condition, we identify *fixated sentences* as sentences that contain valid fixations on at least three words.

The process of extracting fixations is outlined in Algorithm 2. We only consider *hesitation events* that have at least 1 fixated word and at least 1 fixated sentence. After this filtering process, we get 822 valid hesitation events. The mean number of fixated words across all valid hesitation events is 11.11 (median 8), and the mean number of fixated sentences is 1.90 (median 1).

Algorithm 2 Extracting Fixations

```
1: function GETFIXATIONS(data, hesitation_events, n)
2:   for hesitation in hesitation_events do
3:     Extract fixations for current hesitation
4:     Remove fixations on stop words
5:     Store sentences with  $\geq n$  fixated words
6:     if valid fixations found then
7:       Append to results
8:     end if
9:   end for
10:  return results
```

4.3 Response Generation

After extracting fixation data for all hesitation events, we prompt several LLMs to generate completions. The full experimental setup is already described in Section 3.

5 Results

We run each model for 10 iterations. The results for all the models averaged over all iterations are presented in Table 2. We answer the following two research questions:

- **RQ1:** Does incorporating information about a writer’s lookback fixations improve the alignment between human and LLM-generated text completions?
- **RQ2:** How do different LLMs compare across conditions with and without lookback fixations?

5.1 RQ1: Impact of Lookback Fixations on the Similarity Scores

We perform inferential hypothesis testing to assess whether prompting condition had a statistically significant effect on similarity scores. In our analysis, we treat each similarity measure as a dependent variable. We fit linear mixed effects models (LMERs) with prompting condition (Control, Baseline, Words, Sentences) as the fixed factor. As detailed above, we generate completions 10 times for each *hesitation event*. LMERs therefore include random by-event intercepts and slopes for prompting condition.

First, we perform the analysis separately for each LLM. We fit LMERs for each measure (semantic similarity, F1, Jaccard), resulting in a total of 12 series of nested LMERs. In each series, we first fit an intercept-only model (M_0), and then add the prompting condition fixed effect (M_1). We compare model fit using the likelihood ratio test. We adopt a conservative significance threshold $p < .01$ to guard against Type I errors. When M_1 significantly improves model fit over M_0 , we evaluate the fixed-effect coefficients in M_1 to determine which prompting conditions show significant differences from the Control.

The results are shown in Table 2 and Figure 3. As expected, the Control condition does not outperform Baseline for F1 and Jaccard scores. For semantic similarity, however, Control provides significant performance gains over Baseline for GPT-4 and Mistral7B. This suggests that providing additional input to the LLM (even if it is unrelated to the eye-tracking signal) can improve human-LLM alignment in text completion.

Crucially, introducing eye-tracking signals (via Words and Sentences conditions) yields modest but statistically significant improvements over Control in all LLMs except LLaMa3. In terms of semantic similarity, Sentences generally outperform Words, except in Mistral7B. For token-based metrics (F1 and Jaccard), Words tend to perform better than Sentences, with GPT-4 being the exception.

To assess the overall effect of prompting condition across LLMs, we examine differences of average similarity scores between Control and other conditions (Table 3). To test for significance of these differences, we fit one LMER per similarity metric using data from all LLMs, treating LLM as a fixed effect, and including its interaction with prompting condition. Due to LMER convergence

issues, we simplify the random effects structure by removing the random by-event slopes. We then perform Tukey-adjusted pairwise comparisons of estimated marginal means across prompting conditions. We find that, for semantic similarity, all pairwise differences across conditions are statistically significant ($p < .0001$) except between Sentences and Words ($p = .426$). For F1 and Jaccard, Words significantly outperform all other conditions ($p < .01$), while differences among the remaining conditions are not significant ($p > .15$).

These findings support our hypothesis that including fixation-based information in prompts improves human–LLM alignment. Although LLM responses vary in sensitivity to the eye-tracking signal, overall we find that providing LLMs with fixated sentences enhances semantic alignment, while providing fixated words enhances both semantic and token-level alignment with human text completions.

Metric	Change relative to Control			
	Control	Baseline	Words	Sentences
Semantic	.8008	-.0008*	+.0013*	+.0016*
F1 Score	.1350	+.0006	+.0021*	+.0006
Jaccard	.0744	+.0004	+.0013*	+.0005

Table 3: Performance changes across prompting conditions, relative to the Control. Bold values indicate improvements. * indicates significant change ($p < .01$). Averages computed across all models.

5.2 RQ2: Differences among LLMs in Performance Across Prompting Conditions

To assess whether differences between LLMs are statistically significant, we extend the inferential tests from Section 5.1 by fitting a series of nested linear mixed-effects models (LMERs) for each similarity measure, using data from all four LLMs. We begin with a baseline intercept-only model (M_0), then sequentially add the fixed effect for prompting condition (M_1), the fixed effect for LLM (M_2), and finally the interaction between condition and LLM (M_3). Due to convergence issues, we remove by-event slopes from the random effects structure.

Model comparisons are conducted using likelihood ratio tests. For semantic similarity, successive models significantly improve the fit ($M_3 > M_2 > M_1 > M_0$, all $p < .0001$). The significant interaction term in M_3 for semantic similarity

indicates that the effect of prompting condition varies by LLM—that is, not only do the LLMs differ overall, but the way they respond to different prompting conditions also differs significantly, but only with respect to the semantic metric. On the other hand, for Jaccard and F1, M_3 does not provide further improvement of model fit over M_2 ($p = .018$; $p = .044$, respectively). This suggests no evidence for the condition-LLM interaction for the token-based metrics.

Pairwise comparisons between LLMs reveal significant differences throughout (all $p < .0001$ with Tukey adjustment), with the exception of the difference between GPT-3.5 and GPT-4 for semantic similarity ($p = .157$).

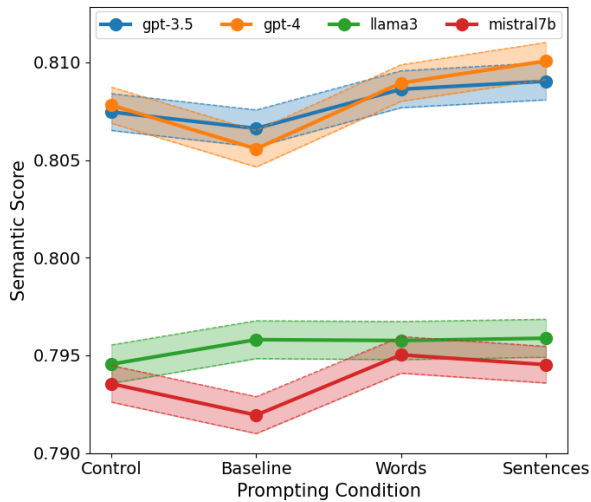

We present an overview of descriptive statistics for different similarity measures below.

Semantic Similarity: As shown in Figure 3a, GPT models consistently outperform LLaMa and Mistral in the semantic alignment across all conditions. With eye-tracking cues, all models show small relative improvements compared to the Control condition (between +.13% and +.29%), but only some of these improvements are statistically significant.

F1 Score: Figure 3b presents model comparisons based on the F1 score. Interestingly, GPT-3.5 outperforms all other models across all prompting conditions, showing the strongest token-level alignment with human completions. GPT-4 and LLaMa3 are closely comparable, while Mistral7B consistently underperforms relative to other models. Across prompting conditions, F1 score changes show greater variability. From Control to Words, only Mistral7B and GPT-3.5 show significant improvement (by +2.77% and +1.89%, respectively). GPT-4 and LLaMa3 show smaller improvements that do not reach significance threshold. All changes from Control to Sentences (ranging from +1.13% to -0.98%) are not statistically significant.

Jaccard Index: As shown in Figure 3c, Jaccard scores generally follow trends seen in F1 scores. From Control to Words, all models improve (between +0.67% and +2.97%), but only GPT-3.5 and Mistral7B show significant improvements. The shift to Sentences shows mixed changes (between +1.64% and -0.74%), none of which reach significance.

Overall, both GPT models show greatest semantic alignment with student text completions, while

(a) Semantic Score

(b) F1 Score

(c) Jaccard Index

Figure 3: Scores of different models across prompting conditions with 95% confidence intervals.

GPT-3.5 clearly leads on token-based similarity metrics. Eye-tracking cues are not sufficient to significantly change the relative performance of any two LLMs on any of the measures investigated.

6 Summary and Conclusion

To our knowledge, this paper is the first to investigate the impact of word- and sentence-level lookback fixation signal captured during writing pauses on LLM-generated text completions.

We first asked whether the eye-tracking cues improve the human-LLM alignment in the text completion task. By comparing different prompting conditions, we demonstrated that the addition of both the words and the sentences that a writer fixates resulted in small, but statistically significant improvement in the semantic alignment between LLM-generated text completions and what the writer themselves actually wrote. Adding fixated words (but not sentences) improves performance on token-based similarity metrics. This provides tentative (but, to date, best-available) evidence of the role of lookback in text planning and, again tentatively, suggests value in incorporating lookback data in intelligent, real-time tools for supporting and training written composition skills.

We then asked how different LLMs compare across prompting conditions. We found that GPT models outperform smaller open-source models on semantic metrics, while GPT-3.5 offers substantial advantages in token-based similarity. For semantic (but not token-based) metrics, significant statistical interaction between LLM and prompting condition suggests that different LLMs react differently to the eye-tracking signal.

Relative performance gains, while statistically significant, were small (in single-digit percent) across LLMs and similarity metrics. It remains to be seen whether improvements on this scale have practical value for developing educational technologies that support written composition. At the very least, they highlight the need for further research into how lookback information can be used to refine prompts.

Limitations

One limitation of our study lies in the scope of the data collected, which includes responses from 30 students. Nonetheless, we extracted 822 valid hesitation events across 60 composition sessions, reinforcing the robustness of our findings. Secondly,

while the variation in scores across conditions is statistically significant, it is relatively small and its practical significance will depend on the use case. Lastly, we do not present a complete end-to-end tool for providing LLM-generated writing assistance. However, this work establishes a strong foundation for future development in that direction.

Span Labeling with Large Language Models: Shell vs. Meat

Abstract

We present a method for labeling spans of text with large language models (LLMs) and apply it to the task of identifying *shell language*, language which plays a structural or connective role without constituting the main content of a text. We compare several recent LLMs by evaluating their "annotations" against a small human-curated test set, and train a smaller supervised model on thousands of LLM-annotated examples. The described method enables workflows that can learn complex or nuanced linguistic phenomena without tedious, large-scale hand-annotations of training data or specialized feature engineering.

1 Introduction

Madnani et al. (2012) show that writers or speakers engaging in argumentative discourse do not simply enumerate their claims and evidence, but rather structure them in some manner for their argument to be convincing. Such discourse, therefore, might contain not only language expressing the core claims and evidence (the “meat” of the argument), but also language used to organize or support them (the “shell”). The authors also propose approaches to automatically detect shell language in real-world examples of argumentative discourse, such as test-taker responses and political debates.

To illustrate the difference between “meat” and “shell”, we provide a hypothetical test-taker response below discussing whether people learn better by being told what to do or shown what to do. Spans representing shell language are shown in bold while the core content of the argument is shown as plain text.

This is a very interesting topic for a debate. I would advocate the argument that being shown what to do is the better option because people are visual

learners. They learn better by watching than by just being listening to what someone else tells them. **While this may not apply to everyone, I think that** it certainly applies to the average joe. **For this reason, it is therefore clear that** being shown what to do is better.

In this paper, we build on the work of Madnani et al. (2012) by focusing more deeply on how shell language is used in responses written by test-takers for the Duolingo English Test (DET), a high-stakes English language proficiency test. Our goal is to build a finer-grained, accurate, and scalable shell detection pipeline for this use case, leveraging modern transformer-based approaches to power each stage.

We first detail our motivations for applying shell detection to test-taker responses (§2). Next, we discuss our annotation rubric for identifying shell language (§3) and our small-scale use of human annotation to validate and refine this rubric. We experiment with automatic annotation of test-taker responses using both non-reasoning & reasoning foundation models (§4), resulting in strong machine-human agreement rates. Then, we attempt to distill our annotations into a BERT model that would be cheaper & faster to deploy for operational use (§5), and provide additional discussion of our approach and error analysis (§6). Finally, we conclude with a comparison to related work (§7) and possible directions for future work (§8).

2 Motivation

English language assessments typically contain prompts asking test-takers to write open-ended responses as a demonstration of their writing proficiency. These prompts generally require arguing for/against a position with appropriate supporting

evidence, or relating a past event matching a high level-description (e.g. “talk about a time when...”). Given the nature of the writing tasks, these responses are likely to contain some amount of shell language, as illustrated by the sample response in the previous section.

A certain amount of shell is useful – necessary, in fact – to scaffold one’s arguments and produce a comprehensible and convincing argument. However, we have observed that many test-takers overuse such language to artificially inflate response length and vocabulary sophistication – both of which can impact the accuracy of automated essay scoring systems.

In this paper, we want to reliably identify (and categorize) spans of shell language in test-taker responses, independently of whether it is used appropriately to connect and organize the text or misused to pad it out with formulaic phrases. Some possible applications of reliable shell detection would include:

- Detecting the use of memorized response templates and other bad-faith patterns that rely on shell language overuse,
- Developing an independent measure of content development (the “meat”), and
- Gaining insights into stylistic variance that may arise even in the absence of shell overuse

Achieving these goals would allow us not only to improve the robustness of automated assessment to a common strategy employed by test-takers to fool automated scoring systems but also to improve measurement of content and coherence.

3 Annotation Rubric

The starting point of our pipeline, and the foundation of our approach, is an annotation rubric which defines & categorizes shell text. We use this rubric for manual annotation as well as to bootstrap automatic annotations using large language models. Since [Madnani et al. \(2012\)](#) do not share any annotation guidelines, we construct our own rubric for identifying shell language in test-taker responses.

We relied on multiple rounds of human annotation to start with an initial draft of our shell annotation rubric¹ and refine it into its final form.

¹To create the initial draft rubric, we employed few-shot prompting, supplying ChatGPT with a general description of shell language from ([Madnani et al., 2012](#)) along with 100 actual test-taker responses containing a range of shell language spans.

Specifically, the authors first collaboratively annotated 11 test-taker responses using the draft rubric and made major revisions based on the ensuing discussions. Next, the authors independently annotated 50 additional responses based on the revised rubric to determine any remaining discrepancies which were then resolved in a curation session. No changes were made to the rubric after this point. Annotation, review and curation were performed using INCEPTION ([Klie et al., 2018](#)).

Given that our goal is to enable finer-grained analyses of shell language, our final rubric defines multiple shell categories, as described in the subsections below.

3.1 Category A: Discourse Markers/Linking Expressions

The shell language spans in this category are defined to be words and phrases that are either serving an organizational or discursive purpose. For example, ones that link sentences or paragraphs with the goal of progressing between ideas. However, single-word coordinating conjunctions like “because”, “but”, “and”, etc. within sentences are not annotated as shell language. Examples of category A spans observed in test-taker responses include but are not limited to:

- To begin with ...
- In conclusion ...
- Firstly ...
- Secondly ...
- In addition ...
- There are three examples of ...
- For example, ...
- That is because ...
- Expanding on the previous discussion ...
- This is another reason
- ... in addition to the previous discussion

As the examples show, this category is mainly defined by short phrases and expressions, not entire sentences. A complete sentence of shell-like material is more likely to be category B, which we describe next.

3.2 Category B: General/Vague Statements

This category consists of phrases or statements that are formal and/or impersonal in nature and add emphasis, reflection, or consideration of the prompt or topic under consideration but *without* any real

content. Spans of this extremely productive category are often employed as padding in bad-faith responses. A very small subset of observed examples is shown below.

- It is imperative to recognize that ...
- ... would be very significant for us
- In today's age ...
- Today in society, there is a heated on-going discussion on the topic of ...
- If you ask me I would say that the statement has both pros and cons.
- In this burgeoning epoch of science and technology, we are dwelling in the 21st century.
- There is a widespread worry that this will lead to a myriad of concern in the world.

3.3 Category C: Prompt/Topic Restatement

This category contains sentences or chunks that simply restate the prompt or initial argument without any further development. We have observed that when a large part of the prompt is restated, the surrounding phrases are often from categories A or B. A few real-world examples are shown below with the corresponding prompt in parentheses. Note that only the category C spans are shown in bold; spans of any other categories are not shown.

- Today in the society, there is a heated on-going on discussion on the topic that **due to the invention of cell phones, people can communicate via text messages.**
(*Due to the invention of cell phones, people can communicate via text messages. Describe the ways texting has changed how we communicate.*)
- One of the most important trends in today's world is the sudden upsurge in the statement that **Acquiring new knowledge and skills doesn't always happen quickly.**
(*Acquiring new knowledge and skills doesn't always happen quickly. Do you think that patience is key when it comes to learning, or do you think it is possible to learn things quickly if you are motivated? Support your opinion with your personal experience and observation.*)

It must also be noted that not *all* mentions of the prompt should automatically be marked as shell. Specifically, we do not mark such a mention as shell if the response:

1. sufficiently restructures or paraphrases it (especially to use it as a topic claim) instead of just quoting or restating it, or
2. simply refers to entities or noun phrases from the prompt in context.

As an example consider the span ... being focused on a single thing is more likely to lead to higher productivity in a response to the prompt *Are you more productive when you are doing a few things at the same time, or are you more productive when you have only a single thing to focus on? What do you think helps you to be more productive?* We would not mark this as a category C shell span because the prompt topic has been paraphrased sufficiently to serve as a topic claim/thesis statement. This distinction is somewhat subjective, and while we achieved good inter-annotator agreement on this category, this point was likely a source of ambiguity for models.

3.4 Category D: Appeal to Authority

This category includes mentions of reports or studies that imply external validation or evidence. Examples include:

- A report from University of Maryland shows that ...
- Oxford University conducted a study that confirmed ...
- For example, a report published by The New York Times reveals that ...

3.5 Category E: Stance-taking

This category contains phrases or statements used to convey the writer's stance or position, whether in the first-person or third. Observed examples include:

- I feel/believe/think (that) ...
- From my point of view ...
- In my opinion ...
- Yes, I agree with the statement that ...

The exception for this category are phrases that are used to convey the writer's personal preference and do not serve a stance-taking role. For example,

consider the sentence I like good environment for touring because i loved with nature. Here, the phrase I like is used to convey the writer’s personal preference for a specific type of environment rather than their argumentative stance.

3.6 Rubric usage

Although our final rubric delineates five different categories of shell text, many shell language spans usually serve multiple purposes (e.g., the phrase More and more people believe that ... can be said to convey both general emphasis (category B) and the writer’s position (category E). In such cases, our practice is to consistently choose the category that seems more relevant in the context of the full response. For purposes of evaluation and error analysis, we also sometimes refer to a sixth category “O” consisting of all spans *not* labeled as shell (the “meat” of the response). We do not separately label this category manually or ask models to directly annotate O spans; it’s defined by the absence of annotations for other classes.

Once the final rubric was created, the authors independently annotated 92 additional responses followed by curation, for a final dataset of 142 responses with individual and curated shell annotations. Note that the first 11 annotated responses (used to make major revisions to the initial rubric) are *not* part of this final set, as their annotations do not reflect the final rubric. We then split this dataset into a "training set" of 40 responses, from which few-shot examples are drawn (see §4), and a test set of 102 responses.

4 Scaling Annotation with LLMs

Shell annotation is a complex task and traditional supervised approaches would require a much larger number of annotated examples to train, but human span annotation is time-intensive and tedious. In this section we evaluate the accuracy of annotations elicited with few-shot learning.

4.1 Method

For LLM-based annotation, we compare five models: DeepSeek-V3 (Chandra et al., 1981) GPT-4o (Hurst et al., 2024), DeepSeek-R1 (Liu et al., 2024), o1 (Jaech et al., 2024), and o3-mini (OpenAI, 2025). Note that the first two are non-reasoning models, while the latter three use self-prompting or reasoning techniques recently popularized by o1 and DeepSeek-R1.

```
<shell category="B"> In this modern world </shell>, artificial intelligence <shell category="B"> is so well known in the world </shell>, which is a kind of intelligence. <shell category="A"> Futhermore </shell>, <shell category="E"> I firmly agree with this given notion that </shell> intelligence has distinct types.
```

Figure 1: Markup format for LLM annotations.

Model	Success rate	Format errs	Generation errs
DeepSeek-R1	0.75	3	22
DeepSeek-V3	0.95	4	1
gpt-4o	0.93	7	0
o1	0.98	0	2
o3-mini	0.99	0	1

Table 1: Success rate of generating a valid annotation on the first try, by model (using 5 examples). Error counts are out of 102 responses. Note that DeepSeek-R1 had high rates of prematurely truncated responses seemingly unrelated to the task.

For each model, we use the same prompt containing the entire rubric, along with either 5 or 10 example responses annotated in an XML-like format with the shell category as an attribute (see Figure 1). We use this prompt to elicit span annotations on our eval set of 102 instances; the model is provided with the writing prompt and unannotated test-taker response, and responds with the annotated text in the same format as the examples. We chose this format based on its expressivity and convenience and did not experiment with any additional formats for now (see §7 for more discussion).

We validate the annotations by trying to automatically parse the XML, checking that there are no nested tags or task-unrelated tags, and that the text is unaltered from the original. The rate of validation failure varies by model. Furthermore, this failure rate is not necessarily constant for a given model; responses where annotation failed on the first round were more likely to also fail on a second try, suggesting that some examples are inherently hard to produce valid annotations for. The most common causes of error were incorrectly formatted XML (unclosed tags, nested tags or non-task-related tags) and missing sentences or phrases. Notably, we found almost no cases where the generated annotated text included unwanted “corrections” of grammatical or typographical er-

(a) Multiclass shell labeling.

(b) Binary shell labeling.

(c) Multiclass shell labeling (B and C categories excluded).

Figure 2: Token-level F_1 for three shell annotation tasks. Reasoning models outperform non-reasoning models, and the ensembles improve slightly over the best individual models. Exclusion of B and C categories improves micro-averaged F_1 for all models.

rors in the original test-taker response, with the exception of whitespace errors such as replacing multiple spaces with a single space or inserting a missing space after sentence-final punctuation. For purposes of evaluation, we automatically resolved these whitespace errors by editing all annotated versions of a text to match the original (to ensure

Figure 3: Confusion matrix for all-ensemble.

tokenization was compatible) before comparing annotations. For our provider of DeepSeek-R1, a significant fraction of long responses were cut off prematurely, increasing the error rate beyond what was attributable to formatting errors. Table 1 compares the LLMs by the fraction of responses that passed validation with a single request.

4.2 Results

Next, we compute token-level metrics for the LLM annotations using the curated human labels as the gold standard, and compare to the inter-annotator agreement for the human annotators. Figure 2 shows results for binary (shell vs non-shell) and multiclass evaluation.

We present the confusion matrix for the all-model ensemble in Figure 3 as a relatively representative example of the errors made by all models. The counts represent individual token counts. The confusion matrix provides insight into specific pairs of categories often confused; for example, we see that categories D and E have few false positives, i.e. they are rarely predicted when the true label is another category. We also observe that B and C are the categories with the most errors (both because they have high true token counts and because they require the most subjective decisions). For this reason, we also include F_1 results considering only a subset of shell category labels (all except B and C) in Figure 2.

Model	Prompt tokens	Completion Tokens	Total cost
DeepSeek-R1	431,316	127,414	\$2.19
DeepSeek-V3	431,737	15,566	\$0.56
GPT-4o	430,290	15,859	\$1.06
o1	425,061	257,592	\$20.28
o3-mini	431,234	492,148	\$2.54

Table 2: Comparing prompt tokens, completion tokens, and total cost when annotating our curated evaluation set of 102 responses using various LLMs.

4.3 Costs

Our method of shell annotation with large language models requires a lengthy rubric and several example texts to be provided in the prompt for every instance. This is a relatively costly approach. In addition, our use of reasoning models leads to high completion token counts.

In order to provide a useful comparison of model costs, Table 2 shows prompt/completion token counts and costs when annotating our curated evaluation set of 102 responses using the same set of LLMs we used in §4. Note that we do not retry any incorrectly formatted annotations for this specific set, so the error rates reported in Table 1 should also be considered when comparing these costs.

In addition, one would expect to incur significant upfront costs iterating and validating the annotation scheme and rubrics. In our case, we spent a total of \$3,665.45 across all experiments.

5 Supervised Learning to Detect Shell

In this section, we attempt to distill a large number of LLM-based annotations into a BERT variant, ModernBERT (Warner et al., 2024). There are several advantages to this approach: BERT models are cheaper, can be run locally (avoiding dependence on external APIs) and can directly produce per-token labels rather than generating the annotated text, removing a potential source of errors.

Based on the results in §4, we choose OpenAI’s o1 model as the best single model for the task. Using the same approach as previously described, we prompt o1 to annotate 7100 additional test-taker responses, and split the resulting dataset into a training set (6500 responses) and a validation set (600 responses). We then convert the annotations into BIO format (Ramshaw and Marcus, 1999) and finetune ModernBERT on three training samples with different sizes: 500, 1000, and the full 6500. For all finetuning runs, we set the batch size to 12 and learning rate to $7e^{-05}$ and train for 10 epochs with early stopping based on the performance on the

Figure 4: ModernBERT F_1 for each task on the human-labeled test set (102 examples). Notably, multiclass labeling performance is actually higher than binary labeling performance on equal data sizes.

Figure 5: ModernBERT F_1 for each task on the o1-labeled dev set (600 examples). Performance is significantly higher than on the human-labeled test set, suggesting that the BERT model has learned o1-generated patterns that are misaligned to human raters.

validation set.²

We finetune and evaluate ModernBERT on three tasks: binary shell labeling, binary shell labeling with B and C categories excluded, and multiclass labeling (see Figure 4). ModernBERT substantially under-performs the LLM used to train it (o1 with 5 examples) on the human-labeled test set, never surpassing 0.6 F_1 even for the easiest task. However, on the o1-labeled validation set, ModernBERT trained on 6500 examples surpasses 0.75 F_1 for multiclass labeling (Figure 5).

²Learning rate was chosen based on a search over the validation set when training on 500 responses.

6 Discussion

6.1 o1 error analysis

Shell labeling is a difficult and to some extent subjective task. In this section, we present a qualitative analysis of the differences between the best-performing single LLM (o1) and curated human annotations, along with examples. To improve readability, we use `<X>...</X>` as a shorthand for `<shell category="X">...</shell>`.

The most common error categories in the confusion matrix in Figure 3 are missing tokens of categories B (general statements) and C (topic restatement), and various non-B tokens labeled as B. We observe a similar pattern when looking at whole-span errors³. The most common cases of whole-span errors are B-spans applied to O and A text. O spans applied to C text (i.e. missed C labels) are also common. This is perhaps to be expected given the rubric; B and C are the most contextual and nuanced categories, requiring consideration of what is specific to the prompt vs generic and what is restatement vs original.

In the following example, the model identified most of the sentence as B, possibly due to the positive emphasis ("outstanding", "wide knowledge") which is often seen in B spans.

Curated O vs. LLM B

```
<A>First of all</A> <E>it is true that</E> college and university can serve as an outstanding place to gaing wide knowledge and contact as you can meet with like minded individuals <A>First of all</A> <E>it is true that</E> <B>college and university can serve as an outstanding place to gaing wide knowledge and contact as you can meet with like minded individuals</B>
```

In another case, a partial reference to the prompt ("the second part of the statement") was mistakenly treated as a restatement of the prompt, as shown below. This may be a case where o1 talked itself into an otherwise unlikely error.

³Whole-span errors occur when a predicted span has no overlap with a human-annotated span of the same category. Boundary errors, by contrast, involve partial overlap but incorrect span length.

Curated O vs. LLM C

```
<E>I storngly prefer</E> the second part of the statement <A>for many reasons</A>. <E>I storngly prefer</E> <C>the second part of the statement</C> <A>for many reasons</A>.
```

Below we considered this declaration of "heated debate" to be an instance of B, but o1 did not:

Curated B vs. LLM O

```
<C>intercultural communication can be a valuable learning experience</C> <B>has sparked a heated debate.</B> <C>intercultural communication can be a valuable learning experience</C> has sparked a heated debate.
```

A common boundary error involved commas. During manual annotation, we settled on a convention of excluding trailing commas from shell spans but did not explicitly specify this in the rubric. O1 frequently took the opposite approach as shown below, causing a 1-token error.

Curated vs. LLM

```
<A>To sum up</A>, ... <A>To sum up,</A> ... <A>For my experience</A>, ... <A>For my experience,</A> ...
```

Finally, we excluded mentions of topics or entities from the prompt from annotations in sentences that were otherwise B. This was attested in a few examples, but not made explicit in the rubric, and o1 tended to include them, leading to boundary errors, as the example shows.

Curated vs. LLM

```
<B>A serious amount of worldwide attention has been drawn to</B> the intercultural communication. <B>Beacuse of the existence of evidencen in favour of as well as against the approval of</B> intercultural communication. <B>A serious amount of worldwide attention has been drawn to the intercultural communication.</B> <B>Beacuse of the existence of evidencen in favour of as well as against the approval of intercultural communication.</B>
```

6.2 Interpretation

Many error types above are consistent and systematic, which is a promising sign for improving the accuracy of automatic shell annotation. In a few cases, o1’s annotations were arguably more consistent with the intent of the rubric than the curated human annotations. For example, some spans of A and E were missed by human annotators, categories which were fairly reliably marked by o1. In other cases, o1 marked statements that broadly paraphrased statements from the prompt as C when human annotators judged the paraphrase as original in form, though not content.

As expected, the two step training procedure in §5 results in a model that suffers from two sources of errors: errors between o1 and human annotators, and errors between ModernBERT and o1. In fact, it seems that ModernBERT does not learn to correct any significant portion of o1’s errors, as the total error rate is not much better than if the two sources of error were entirely independent: we observe $0.559F_1$ for the largest ModernBERT model for multiclass labeling, vs. 0.531 expected ($0.7 \text{ o1 } F_1 \times 0.752 \text{ ModernBERT } F_1 \text{ on o1’s labels}$). This is consistent with LLMs consistently diverging from human annotations; ModernBERT is learning to imitate systematic error, rather than guessing in response to random noise.

7 Related work

The work most closely related to ours and the one we build upon is that of [Madnani et al. \(2012\)](#). However, there are also salient differences between our work and theirs. They rely on a small set of human annotations to train a binary, feature-based, discriminative classifier for shell language whereas we use a small, curated set of human annotations to bootstrap LLM-generated annotations at scale, and then distill them into an end-to-end transformer model used for finer-grained, multi-class, shell span classification. Additionally, while they do not share any information about their annotation process, we share a detailed rubric along with examples for each shell category. [Bejar et al. \(2013\)](#) apply the shell model developed by [Madnani et al. \(2012\)](#) to GRE essays to evaluate whether it agrees with expert raters’ judgments and whether the presence of shell language has an effect on the essay scores. [Du et al. \(2014\)](#) devise an unsupervised

HMM-LDA topic model for shell language and apply it to posts from online debate forums. Similarly, [Ó Séaghdha and Teufel \(2014\)](#) use a topic model to capture words & constructs used to express rhetorical function in scientific papers.

LLMs have been extensively used for a wide range of linguistic analysis tasks. Some of these tasks are fairly straightforward. For example, [Hao et al. \(2024\)](#) use ChatGPT to annotate conversation chat turns in a collaborative problem solving setting with a pre-defined set of labels. However, the decoder-only framework for text generation makes it difficult to represent more complex linguistic structures such as spans or dependency relations and their relationships to the annotated text, and, to our knowledge, there has been no consensus on the format to use for span annotation with LLMs (regardless of the particular application). [Blevins et al. \(2022\)](#) experimented with LLMs for sequence tagging tasks, including multi-token spans for chunking and NER. They framed the task as BIO tagging at the word level, regenerating the text with labels following each word. Since our spans are frequently even longer than syntactic chunks, and rarely as short as single words, we opt for a format that abstracts away from individual word labels.

More recently, [Kasner et al. \(2025\)](#) experimented with span annotation for evaluation of generated text by using structured decoding to get a list of spans with category labels in JSON format. This has the advantage of not requiring re-generation of the full input text. However, our application does not require full category names for individual annotations (only a single-character label) and we expect to label relatively densely (such that a significant fraction of the text would have to be copied in the output anyway). Future work should directly compare these output formats on a single task (or multiple tasks) and investigate the effects of output format on overall performance and error types.

8 Conclusions and Next Steps

We have shown that LLMs can be used for scalable span annotation and that reasoning models have a distinct advantage at the task of labeling shell text. However, both the original LLM annotation process and training a smaller model to imitate an LLM’s annotations remain error-prone. Based on the consistency of certain error types (§6), we believe that refinements to the annotation rubric could significantly improve the accuracy of LLM

annotation. For example, the distinction between a clear restatement of the prompt and its paraphrase is a bit subtle and can be made clearer to ensure a more consistent interpretation. Other directions for future work include:

- a more thorough hyperparameter search to improve supervised learning,
- finetuning a reasoning LLM either directly on the curated human data or a combination of human and LLM-annotated data (given the small size of the human data), and
- experimenting with other output formats from related work such as structured decoding for greater consistency.

While our supervised shell detection results certainly leave room for improvement, we hope that the work done in this paper can still serve as a source of useful information to other researchers working on shell language detection and, more broadly, LLM-based span annotation. We believe that the workflow proposed in this paper can be applied to other types of non-overlapping span-labeling tasks, assuming a rubric with clearly defined categories and reliable human-human agreement.

9 Acknowledgements

We thank the anonymous reviewers, as well as Kevin Yancey and Alina von Davier, for their valuable feedback.

Limitations

There are several limitations of this work. Most significantly, while the two-step annotation procedure we describe yields promising results, the resulting error rate of the final ModernBERT model may limit its application without additional refinements to the rubric and/or the training procedure (including improved hyperparameter tuning). For our LLM experiments, we compared several different models in §4 and found that an ensemble of multiple models performed best. However, our budget and time constraints limited the number of compared models, and, in the end, we had to pick the best single model (o1) to produce training data for ModernBERT instead of the ensemble. Due to limited space, our error analysis only covers errors made by o1, and does not show the extent to which the same patterns may be shared by other LLMs or

ModernBERT. Finally, our results are limited to the specific choice of span annotation format that we chose. As mentioned in §7, other formats may have different tradeoffs, which we hope future work will explore.

Intent Matters: Enhancing AI Tutoring with Fine-Grained Pedagogical Intent Annotation

Kseniia Petukhova, Ekaterina Kochmar

Mohamed bin Zayed University of Artificial Intelligence
{kseniia.petukhova, ekaterina.kochmar}@mbzuai.ac.ae

Abstract

Large language models (LLMs) hold great promise for educational applications, particularly in intelligent tutoring systems. However, effective tutoring requires alignment with pedagogical strategies – something current LLMs lack without task-specific adaptation. In this work, we explore whether fine-grained annotation of teacher intents can improve the quality of LLM-generated tutoring responses. We focus on MathDial, a dialog dataset for math instruction, and apply an automated annotation framework to re-annotate a portion of the dataset using a detailed taxonomy of eleven pedagogical intents. We then fine-tune an LLM using these new annotations and compare its performance to models trained on the original four-category taxonomy. Both automatic and qualitative evaluations show that the fine-grained model produces more pedagogically aligned and effective responses. Our findings highlight the value of intent specificity for controlled text generation in educational settings, and we release our annotated data and code to facilitate further research: <https://github.com/Kpetyxova/autoTree/tree/main/mathdial>

1 Introduction

Human tutoring is a cornerstone of educational development, playing a vital role in empowering learners and fostering societal progress. One-on-one tutoring has long been recognized as highly effective (Bloom, 1984); however, its widespread implementation is constrained by the limited availability of qualified tutors. Recent advancements in LLMs have shown great promise in educational contexts (Wang et al., 2024; Gan et al., 2023), leading to the emergence of LLM-powered intelligent tutoring systems (ITS) (Pal Chowdhury et al., 2024; Liu et al., 2024) and the use of LLMs as tutors via advanced prompting strategies (Denny et al., 2024; Mollick and Mollick, 2024). These AI tutors serve

a range of educational objectives (Wollny et al., 2021), with one of the most prominent being the remediation of student mistakes and confusion – an area that continues to drive the development of AI tutoring systems (Macina et al., 2023; Wang et al., 2023).

While LLMs do well both at generating human-like conversations and at addressing various reasoning tasks, such as commonsense reasoning and basic mathematical reasoning (Achiam et al., 2023; Kojima et al., 2022; Laskar et al., 2023; Yang et al., 2024), they cannot be directly deployed in educational systems without significant adaptation. Effective tutoring requires more than fluent conversation – it involves guiding learners to discover answers on their own. Rather than simply providing solutions, a good tutor employs strategies such as giving hints, asking questions in a Socratic dialog (Carey and Mullan, 2004), and encouraging active problem-solving. As such, LLM-based tutors should ideally align with human tutoring strategies (Nye et al., 2014) and active learning practices shown to enhance student outcomes (Freeman et al., 2014).

In order to have such models, we need dialog tutoring datasets. MathDial (Macina et al., 2023) is one such dataset, comprising tutor-student dialogs centered around math reasoning tasks. Each teacher utterance is labeled with one of four pedagogical move types from Macina et al. (2023): *Focus* (guiding task progress), *Probing* (encouraging conceptual exploration), *Telling* (providing help when students are stuck), or *Generic* (non-pedagogical conversational turns). These annotations were provided by teachers during data collection to better scaffold student learning. While this four-category taxonomy offers a helpful high-level structure, it lacks the fine-grained detail needed for advanced applications such as controlled response generation, pedagogical analysis, and behavior modeling in AI tutors. At the same time,

finer-grained annotations may enable better interpretability, improved pedagogical alignment, and greater flexibility in guiding student learning experiences.

Although MathDial’s original taxonomy includes only four broad categories, the authors also provide an expanded set of eleven fine-grained intents, which could offer greater control and variety in AI-generated tutoring responses. Building on this, in this work, we apply a fully automated framework for conversational discourse annotation (Petukhova and Kochmar, 2025) to **re-annotate a portion of the MathDial dataset using the finer-grained eleven-intent taxonomy**. This annotation framework uses LLMs to automatically construct a decision tree from the taxonomy and use it to label utterances, providing a scalable alternative to manual annotation. This approach has demonstrated superior performance compared to crowdworkers in annotating dialog with speech functions taxonomy (Eggins and Slade, 2004).

Our goal in this work is to assess whether such more detailed annotations can improve the quality of LLM-based tutoring through fine-tuning models on both the original and re-annotated data. Specifically, we fine-tune Mistral-7B-Instruct on the original coarse-grained as well as the new fine-grained annotation, and compare the generated tutor responses using automatic metrics and human evaluation. Our results demonstrate that **the fine-grained model produces more pedagogically aligned and effective responses**. To facilitate further research and development, we release a public repository containing both the code and the re-annotated dataset.¹

2 Background & Related work

2.1 The MathDial Dataset

We build on the foundational work of Macina et al. (2023), whose dataset provide an invaluable basis for advancing pedagogically aligned dialog systems. MathDial is a large-scale, high-quality dialog tutoring dataset focused on multi-step math reasoning problems. Unlike previous datasets that suffer from low pedagogical quality, small size, or lack of grounding, MathDial provides rich annotations grounded in realistic student confusions and pedagogical strategies. The authors introduce a novel semi-synthetic data collection framework

¹Available at <https://github.com/Kpetyxova/autoTree/tree/main/mathdial>.

that pairs expert human teachers with LLMs simulating students and their errors, enabling scalable and controlled creation of educational dialogs that closely mimic authentic tutoring scenarios. This approach effectively addresses privacy concerns and quality issues associated with crowdsourcing or classroom recordings.

The authors’ methodology consists of a Wizard-of-Oz-inspired framework (Kelley, 1984), where expert teachers engage in one-on-one tutoring dialogs with LLMs acting as students. These student models are carefully prompted with student profiles and frequently occurring conceptual errors generated using temperature sampling over diverse reasoning paths produced by LLMs. The math word problems (MWP) used are sourced from GSM8K (Cobbe et al., 2021). Teachers are instructed to scaffold student understanding using a taxonomy of four pedagogical moves: *Focus*, *Probing*, *Telling*, and *Generic*, with additional fine-grained intents (see Table 1).

Crucially, before writing a response, teachers must annotate the pedagogical move being employed, encouraging more intentional strategy use. The dialogs are also grounded in metadata, including the specific confusion, full problem, step-by-step solutions, and whether the confusion was resolved, thus offering rich signals for training AI tutors.

Empirical evaluation demonstrates that models fine-tuned on MathDial significantly outperform both zero-shot and instruction-tuned larger LLMs like ChatGPT in terms of correctness and equitable tutoring (Macina et al., 2023). Notably, fine-tuned open-source models achieved similar rates of student problem-solving success while reducing the incidence of “telling” – prematurely giving away solutions. Human evaluations confirmed that these fine-tuned models were more coherent, correct, and pedagogically effective than large prompted models.

2.2 Annotation Framework

While manual discourse annotation is costly and time-consuming, advances in LLM-based annotation present a promising alternative with demonstrated improvements in speed, consistency, and cost-effectiveness (Gilardi et al., 2023; Hao et al., 2024). Petukhova and Kochmar (2025) have recently proposed an open-source pipeline for fully automated discourse annotation using LLMs. Specifically, this pipeline automates the construc-

Category	Intent	Example
Focus	Seek Strategy	<i>So what should you do next?</i>
	Guiding Student Focus	<i>Can you calculate ... ?</i>
	Recall Relevant Information	<i>Can you reread the question and tell me what is ... ?</i>
Probing	Asking for Explanation	<i>Why do you think you need to add these numbers?</i>
	Seeking Self Correction	<i>Are you sure you need to add here?</i>
	Perturbing the Question	<i>How would things change if they had ... items instead?</i>
	Seeking World Knowledge	<i>How do you calculate the perimeter of a square?</i>
Telling	Revealing Strategy	<i>You need to add ... to ... to get your answer.</i>
	Revealing Answer	<i>No, he had ... items.</i>
Generic	Greeting/Farewell	<i>Hi ... , how are you doing with the word problem? Good Job! Is there anything else I can help with?</i>
	General Inquiry	<i>Can you go walk me through your solution?</i>

Table 1: Teacher moves with examples of utterances and their intents from MathDial (Macina et al., 2023).

tion of hierarchical tree annotation schemes and the annotation of utterances within dialogs, making it a promising and scalable approach for enriching the MathDial dataset with more detailed teacher intent annotations.

Petukhova and Kochmar (2025) explore multiple configurations for tree construction and annotation, including binary and non-binary structures, frequency-based grouping, and optimal split strategies, and report that the frequency-guided optimal split selection using GPT-4o outperforms crowdworkers on dialog annotation tasks based on the taxonomy of speech functions (Eggin and Slade, 2004), while reducing total annotation time from over 30 hours to under 1.5 hours. Therefore, in our work, we adopt this configuration using the publicly available implementation.²

2.3 Controlled Generation

Controlled text generation (CTG) aims to direct language models to produce outputs that adhere to specific attributes or constraints, such as sentiment, style, or intent. A prevalent method in CTG involves fine-tuning models with prompts that include explicit intent labels, enabling the generation of text aligned with desired behaviors (Liang et al., 2024).

Instruction fine-tuning has emerged as an effective strategy for this purpose. By training models on datasets where prompts are augmented with natural language instructions or intent labels, models learn to condition their outputs accordingly. For instance, the InstructCTG framework demonstrates how conditioning on natural language descriptions and demonstrations of constraints allows models to generate text that satisfies various requirements without altering the decoding process (Zhou et al., 2023).

²<https://github.com/Kpetyxova/autoTree>

This approach is particularly beneficial in educational contexts, where aligning generated content with pedagogical strategies is crucial. By fine-tuning models with prompts that specify instructional intents, AI tutors can provide more effective and tailored support to learners (Jia et al., 2025).

3 Re-annotating the MathDial Dataset

3.1 Tree Creation

To construct a tree for the extended taxonomy proposed in MathDial, we used the best framework configuration from Petukhova and Kochmar (2025) – frequency-guided optimal split selection and backtracking. This method iteratively selects among the candidate splits by scoring them and choosing the highest-ranked one, with backtracking employed if a viable partition cannot be formed. Additionally, the approach biases the tree construction toward more frequent classes, making them quicker to reach and producing trees that better reflect real-world class distributions. The tree was generated based on eleven intent names and their corresponding examples (see Table 1). The resulting tree, presented in textual form in Figure 1, has a depth of two with five branches emerging from the root node.

Interestingly, most intents are grouped according to high-level categories defined in Macina et al. (2023), except for the *Probing* intents, which are split into two separate groups: (1) *Asking for Explanation* and *Seeking Self-Correction*, and (2) *Perturbing the Question* and *Seeking World Knowledge*. While this split was not predefined, it is interpretable: the first group centers on prompting students to reflect on and assess their reasoning, whereas the second group encourages them to explore broader or external concepts beyond the immediate problem.

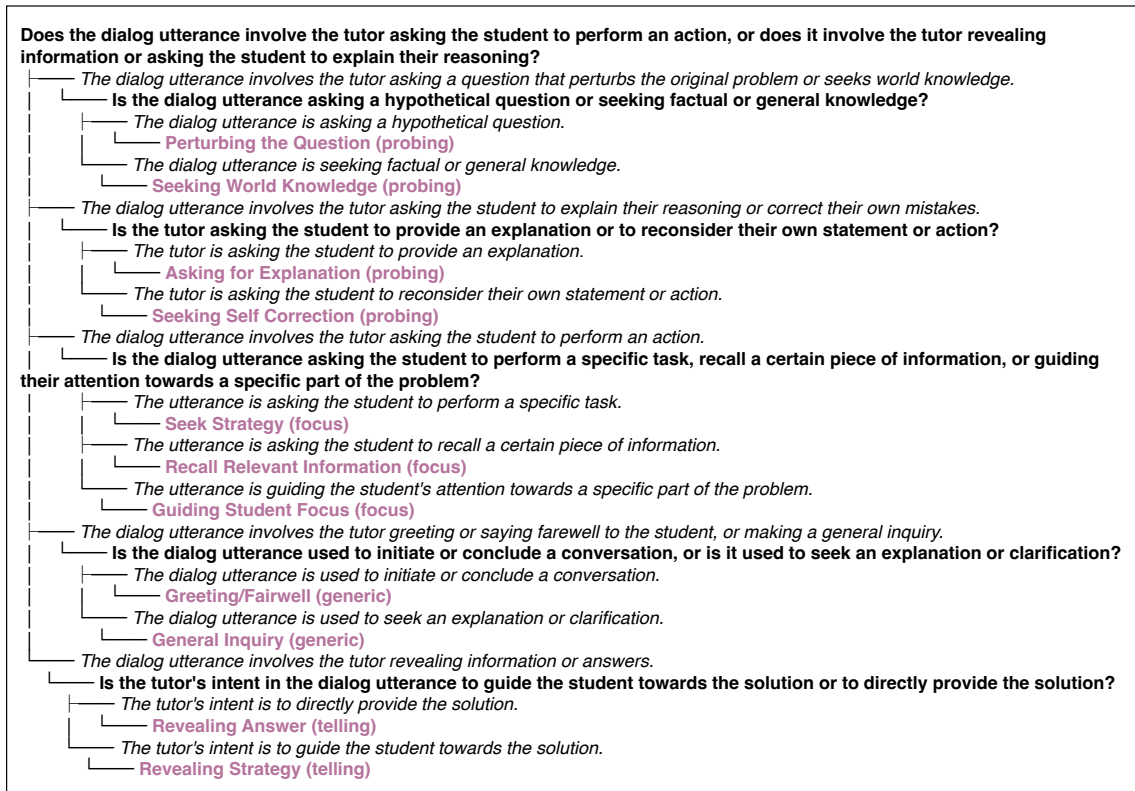

Figure 1: Tree created for the extended taxonomy of the MathDial dataset using the framework from [Petukhova and Kochmar \(2025\)](#). Questions corresponding to tree nodes are in **bold**, possible answers that represent branches are in *italics*, and leaf nodes, representing the eleven intents, are in **purple bold**.

3.2 Annotation

Data Preprocessing Out of 2,861 dialogs, we randomly selected 500 dialogs for training, 100 for validation, and 100 for testing.

An example of the original tutor intent annotation in MathDial is shown in Figure 2. A single label is applied to each teacher utterance in the original annotation, which, while effective for high-level analysis, may limit flexibility in downstream applications requiring finer-grained control. For instance, an utterance [I see.]₁ [But we’re dealing with individual pies here, rather than slices.]₂ [If you had a birthday cake, and lots of guests at your party, you couldn’t just keep producing slices of cake.]₃ [Can you think of another way to figure out how everyone gets a piece?]₄ in MathDial is annotated as *Probing*. However, this utterance comprises several discourse units with distinct functions: segment [1] appears to be *Generic*, segment [2] aligns with *Focus* (specifically, *Guiding Student Focus*) as it redirects the student’s attention, segment [3] fits the *Probing* category, and segment [4] corresponds to *Focus* (*Seek Strategy*) because

it prompts the student to think of an alternative solution.

In contrast, in other cases, the assigned label appears to follow the final part of the utterance. For example, the utterance [But there are always 4 slices in a shepherd’s pie, so using the total number of slices might not be helpful.]₁ [Are there any other quantities you could use to divide by the slices in the pie?]₂ is labeled as *Focus*. Here, while *Focus* applies to the second sentence [2], it would be more appropriate to label the first sentence [1] as *Telling*. This inconsistency – where labels are sometimes based on the first segment and other times on the last – underscores the potential benefits of a more fine-grained and consistent annotation approach for certain downstream tasks.

Ideally, annotation should be performed at the elementary discourse units (EDUs) level rather than entire utterances. EDUs are segments of text that typically correspond to clauses ([Jurafsky and Martin](#)). Therefore, in this work, we preprocess the data by first splitting teacher utterances into EDUs.

Since no state-of-the-art method currently ex-

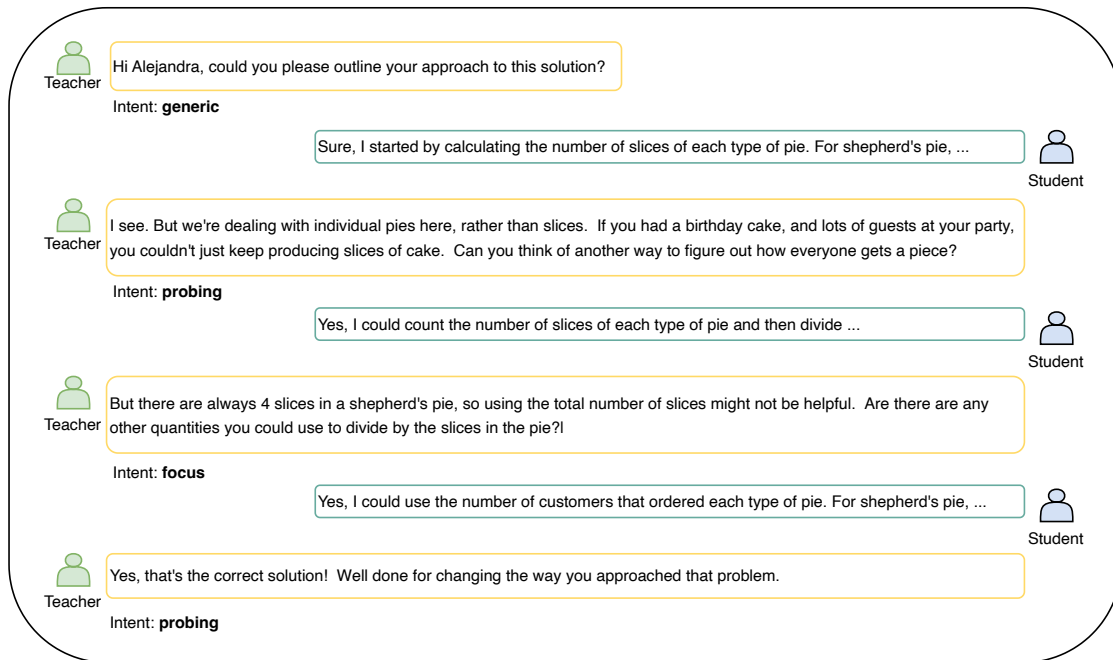

Figure 2: An example of teacher utterances and their annotated intents from MathDial.

ists for automatically dividing the text into EDUs, we use the following strategy: (1) Punctuation Removal: first, we remove all punctuation from the utterances; (2) Punctuation Restoration: next, we restore the punctuation using a model trained for this task;³ (3) Comparison and Segmentation: finally, we compare the original utterance with the punctuation-restored version. If the restored punctuation replaces a comma in the original text with a period, question mark, or exclamation mark, we split the utterance at that comma, thereby creating separate EDUs. By default, we also split different sentences into separate EDUs. Each EDU that resulted from the original utterance through this process inherits the original label assigned to the full utterance in MathDial (i.e., one of the four high-level categories).

After the data is split into EDUs, the number of resulting teacher utterances in the **train** split is **5,174**. The **validation** and **test** sets are similarly segmented into EDUs and limited to **100** teacher utterances each.

Annotation Using the generated tree, a GPT-4o-based annotation pipeline from [Petukhova and Kochmar \(2025\)](#) is applied. Since the tree’s structure aligns with the hierarchical intent relationships

³<https://huggingface.co/oliverguhr/fullstop-punctuation-multilang-large>

proposed by the authors of MathDial, we can reasonably expect that annotation based on this tree will reflect those relationships. For instance, if the annotation using the tree assigns the label *Perturbing the Question*, the original annotation should correspondingly contain *Probing*, and so on. Based on this alignment, we can evaluate the annotation quality, at least in terms of consistency with the original higher-level annotations.

Table 2 presents weighted precision (P_w), recall (R_w), and F1 ($F1_w$) as well as macro F1 (F1) scores when comparing lower-level intent annotations on the training set to the original high-level teacher move categories. The low scores are expected, given that the original teacher utterances were split into EDUs while retaining the same label. As discussed earlier, different EDUs within the same utterance would often be of distinct types, which was not accounted for in the original annotation in MathDial.

P_w	R_w	$F1_w$	F1
0.40	0.38	0.36	0.27

Table 2: Evaluation of 11-label annotation on the training set, comparing the new alignment with the original 4-label annotation from MathDial, using the annotation framework from [Petukhova and Kochmar \(2025\)](#).

Among the 5,174 teacher utterances, 1,319 remained unchanged from the original dataset, as

they originally consisted of a single EDU. Annotation results for these utterances are presented in Table 3. While these metrics are higher than those in Table 2, they still indicate relatively poor performance.

P_w	R_w	$F1_w$	$F1$
0.48	0.45	0.43	0.31

Table 3: Evaluation of 11-label annotation on the training set utterances that remained unchanged (i.e., originally consisted of a single EDU), comparing the new alignment with the original 4-label annotation from MathDial, using the annotation framework from Petukhova and Kochmar (2025).

However, a manual analysis revealed significant inconsistencies in the original annotation. Consider the following illustrative examples:

- A student initially identifies 14 as the correct final answer to the task. However, during the discussion, the student incorrectly restates the final solution as $10 + 10 + 4 = 24$. The teacher responds, *Is that 14?* — referring back to the earlier moment when 14 was correctly identified as the expected answer (see the full dialog in Appendix A). The tree-based annotation classifies this teacher utterance as *Seeking Self-Correction*, corresponding to *Probing*. However, in the original dataset, it is labeled as *Telling*, which we believe is not accurate.
- The tutor says, *You need to add brackets to (8-2) and remember the order of operations.* The student responds, *Yes, I understand now. The correct equation should be $6 + (8 + 8) - 2 = 22$ new books.* The teacher replies, *No, I said it's 8-2, not 8+8.* Although the tree-based annotation assigns this utterance to *Revealing Answer (Telling)*, the original annotation labels it as *Generic*, possibly reflecting a different interpretation or contextual judgment.
- A student states, $6 + 8 + (8 - 2) = 22$. The teacher responds, *Please explain how you got 22.* The tree-based annotation categorizes this utterance as *Asking for Explanation*, which corresponds to *Probing*. However, in the original dataset, it is labeled as *Generic*, which does not align well with the intent of the utterance.

Given the prevalence of such unclear or ambiguous cases in the original annotation of the dataset,

we cannot conclude that the tree-based annotation is inaccurate. Instead, these inconsistencies in the original annotation suggest that the discrepancies in the evaluation metrics may be due, at least in part, to ambiguities in the original dataset.

The distribution of the eleven predicted intents across all dataset splits (train, validation, and test) is shown in Figure 3.

4 Controlled Generation

To demonstrate the benefits of an extended taxonomy with annotations collected using the framework from Petukhova and Kochmar (2025), we fine-tune an LLM to predict the next teacher utterance. The model is trained using the math task description, its gold solution, the student’s solution, the dialog history, and the teacher’s next utterance intent as predicted by the annotation framework.

Additionally, we fine-tune a second version of the same model using the original four-intent annotation. We then compare the performance of these two fine-tuned models with each other, as well as with the same LLM in its zero-shot setting.

Model We use Mistral-7B-Instruct as the base model for fine-tuning, specifically its 4-bit quantized version from Hugging Face.⁴ The maximum sequence length is set to 1,600. We fine-tune the model using QLoRA (Quantized Low-Rank Adaptation) (Hu et al., 2022), a parameter-efficient method that applies low-rank adapters with quantization to reduce memory and compute costs. We use a rank of $r = 32$ and scaling factor $\alpha = 32$. Fine-tuning is conducted for one epoch with a learning rate of $2e^{-5}$, batch size 8, and gradient accumulation of 4. We employ the AdamW optimizer (Loshchilov and Hutter, 2019), linear scheduling with a warmup (0.1), weight decay of 0.1, and evaluate every 50 steps using SACREBLEU (Post, 2018).

Data Preprocessing We convert the annotated samples into pairs of prompts and gold outputs, where each prompt consists of an instruction, the math task, the gold solution for the task, the student’s solution, the dialog history, and the intent of the following teacher utterance (which is available from the annotated data). While the intent is available as an annotation during both training and evaluation – since we have access to the gold next

⁴<https://huggingface.co/unsloth/mistral-7b-instruct-v0.3-bnb-4bit>

Figure 3: Overall distribution of the eleven predicted intents in the re-annotated dataset.

teacher utterance and can classify its intent – for real-world applications this intent would need to be predicted by a separate model as part of a controlled generation pipeline. The prompt template is shown in Appendix B.

Evaluation We conduct an automatic evaluation of generated outputs using reference-based metrics, including CHRF++ (character n-gram F -score) (Popović, 2017), SACREBLEU (a weighted geometric mean of n -gram precision scores), and ROUGE-1, ROUGE-2, and ROUGE-L (recall-oriented measures of n -gram overlap) (Lin, 2004). In addition, we conduct a small-scale human evaluation.

Results Table 4 presents the generation results for both zero-shot and fine-tuning settings, comparing two annotation schemes: the original four teacher intents provided in the MathDial dataset and the extended set of eleven intents. As expected, the fine-tuned LLM outperforms the zero-shot baseline, and the model trained on the more fine-grained, eleven-intent annotation consistently achieves higher scores across all metrics.

In addition to automated metrics, we conducted a human evaluation with four annotators, each holding at least a Master’s degree in Natural Language Processing. We randomly selected seven dialogs from the test set, resulting in 30 response pairs – one from the model fine-tuned on four intents and one from the model fine-tuned on eleven intents. Each annotator was shown these pairs and asked to decide which response was better or whether

both were equally good or poor (see Figure 4). Based on majority voting, responses from the FT-11 model were preferred in 56.7% of cases.⁵ The inter-annotator agreement, measured using Fleiss’ Kappa, is $\kappa = 0.33$, indicating fair agreement.

Figure 4: Results of human evaluation. Four annotators were asked to choose the better response or indicate if both were equally good or bad. Final decisions were determined via a majority vote.

Manual analysis (see Figure 5) indicates that the responses generated by the model fine-tuned on eleven intents (FT-11) are superior to those from the model fine-tuned on four intents (FT-4), based on the following observations:

- FT-11 consistently demonstrates a deeper understanding of conversational strategies, such

⁵There were no ties in the majority votes – each example received a clear decision.

Configuration	CHRF++	SACREBLEU	ROUGE-1	ROUGE-2	ROUGE-L
Zero-Shot, 4 intents	16.50	0.93	8.93	2.19	7.10
Zero-Shot, 11 intents	17.11	0.73	8.72	1.95	6.87
Fine-Tuning, 4 intents	16.82	2.67	17.13	5.61	15.95
Fine-Tuning, 11 intents	18.06	4.59	20.73	7.39	19.28

Table 4: Evaluation of controlled generation on the test set from MathDial in a zero-shot setting and with fine-tuned Mistral, comparing using the original four intents from MathDial with eleven intents annotated using the framework from [Petukhova and Kochmar \(2025\)](#).

as using more effective questioning techniques. For instance, when addressing the incorrect prom couples calculation (see the first example in Figure 5), FT-11 explicitly prompts the student to reconsider the original conditions (*So, if we know that there were 123 students at the prom, how many couples were there?*). In contrast, FT-4 merely restates the incorrect scenario (*So, if we have 120 couples, how many students attended the prom?*), which is less effective in guiding the student to realize their mistake.

- FT-11 more directly addresses student misconceptions. In the second example in Figure 5, FT-11 directly questions the student’s arbitrary assumption (*How did you get 100 cows?*), aligning closely with the teacher’s gold standard (*Claire, why did you assume that the farmer had 100 cows?*). FT-4 is less focused, requesting the student to explain calculations instead of addressing the root cause of misunderstanding.
- FT-11 responses tend to be concise yet relevant, prompting students to reflect critically on their reasoning rather than reiterating previous statements. For example, in the third scenario in Figure 5, FT-11 succinctly acknowledges correctness (*Correct.*), aligning well with the actual teacher response (*That’s right.*), while FT-4 unnecessarily repeats previous questions, demonstrating less effective dialog management.

5 Conclusions

In this work, we examined the impact of fine-grained annotation on controlled response generation in the MathDial dataset. By expanding the original taxonomy of teacher moves from four broad categories to eleven more specific intents and using the framework for automated tree creation and annotation from [Petukhova and Kochmar](#)

(2025), we demonstrated that this approach enhances the performance of a fine-tuned LLM in generating meaningful responses.

The results confirm that fine-tuning on a dataset with high-granularity labels leads to better alignment with expected teacher responses, outperforming both the zero-shot setting and fine-tuning on the original four-category annotation. This suggests that the specificity of intent labels is crucial for enhancing the model’s ability to generate targeted and effective tutoring responses.

Furthermore, the manual analysis of the annotation process revealed inconsistencies in the original dataset, highlighting the importance of high-quality, well-structured intent annotation. The tree-based annotation framework proposed in [Petukhova and Kochmar \(2025\)](#) provides a systematic way to refine such datasets, making them more suitable for training controllable generation models.

Limitations

Due to resource constraints, we re-annotate only a subset of the MathDial dataset and utilize a small language model for fine-tuning.

These limitations suggest several directions for future work: (1) re-annotating the entire dataset to enable training of higher-quality models, and (2) exploring larger open-source models for improved fine-tuning performance.

In addition, we acknowledge that our conclusions are based on the use of automated metrics and small-scale human evaluation. In order to demonstrate the real-world impact of these findings and assess the pedagogical value of the generated tutor interventions, future work should consider verifying these conclusions with actual teachers and students.

Ethical Considerations

As this work is exploratory and the outputs of the models used in this research have not been tested with real students, we do not anticipate any significant risks associated with this work or the use

Task	Student's Incorrect Solution	Dialog
Chalktown High School had their prom last weekend. There were 123 students who attended. If 3 students attended on their own, how many couples came to the prom?	Let's call the number of couples that attended the prom "c". We know that there were 123 students total, and that 3 of them attended on their own. This means that the rest of the students attended as couples. So we can set up the equation: couples + 3 = 123 Subtracting 3 from both sides: couples = 120 So there were 120 couples that attended the prom. 120	<p>Teacher: Hey Heidi, do you know what a couple is?</p> <p>Student: Yes, a couple is two people who are together, usually a romantic couple.</p> <p>Teacher: So if we had 120 couples attending the prom, how many students would that be in total?</p> <p>Student: 120 couples would be 240 students in total, since each couple is made up of two people.</p> <p>Teacher: Great.</p> <p>Teacher: would you like to check your solution again, bearing in mind what youve just told me, please?</p> <p>Student: Sure. So if we have 120 couples, that would mean there are 240 students in total. We know that 3 students attended on their own, so if we subtract 3 from 240, we get 237. So there were 120 couples and 237 students in total at the prom.</p> <p>Teacher: We need to read the question again.</p> <p>Teacher: the question tells us how many people were at the prom.</p> <p>Next Teacher Utterance: Gold: lets start over from the beginning and ill help you if needed. FT-4 (focus): So, if we have 120 couples, how many students attended the prom? FT-11 (Seek Strategy): So, if we know that there were 123 students at the prom, how many couples were there?</p>
40% of a farmer's cattle are males. The rest are females. If a female cow produces 2 gallons of milk a day, how much milk will the farmer get a day if he has 50 male cows?	If 40% of the cattle are males, then 100% - 40% = 60% are females. Let's say the farmer has a total of 100 cows, then 40% of 100 = 40 cows are males. So 60 cows are females. If each female cow produces 2 gallons of milk a day, then 60 x 2 = 120 gallons of milk will be produced a day. Since the farmer has 50 male cows, they don't produce milk, so the total milk produced a day is 120 gallons.	<p>Teacher: Hi, could you please walk me through your solution?</p> <p>Student: Sure. I started by figuring out that 40% of the cattle were males, so 100% - 40% = 60% were females. Then I assumed that the farmer had a total of 100 cows, so 40% of 100 = 40 cows were males and 60 cows were females. I then multiplied the number of female cows (60) by 2 gallons of milk a day to get 120 gallons of milk produced a day. Since the farmer only has 50 male cows, they don't produce any milk, so the total milk produced a day is 120 gallons.</p> <p>Next Teacher Utterance: Gold: Claire, why did you assume that the farmer had 100 cows? FT-4 (generic): Hi, could you please explain how you got 120 gallons of milk from 60 cows? FT-11 (Seek Strategy): How did you get 100 cows?</p>
It takes 3 men an hour to complete a job. If they are hired to work on 5 such similar jobs by a company that pays each of them \$10 per hour, calculate the total amount of money the three will earn when they complete the jobs?	It takes 3 men an hour to complete a job, so it will take them 3 x 5 = 15 hours to complete the 5 jobs. If they are paid \$10 per hour, the total amount of money each of them will earn when they complete the jobs is \$10 x 15 = \$150. Therefore, the total amount of money the three will earn when they complete the jobs is \$150 x 3 = \$450.	<p>Teacher: Hi Brenda.</p> <p>Teacher: lets take this step by step.</p> <p>Teacher: How much would one man earn for one job?</p> <p>Student: Hi, one man would earn \$10 for one job.</p> <p>Teacher: How many jobs are there?</p> <p>Student: There are 5 jobs.</p> <p>Teacher: How much would one man doing the 5 jobs earn?</p> <p>Student: One man doing the 5 jobs would earn \$10 x 5 = \$50.</p> <p>Teacher: Great, How many men are there?</p> <p>Student: There are 3 men.</p> <p>Teacher: So each man is paid 50 total for the 5 jobs and there are 3 men.</p> <p>Teacher: so how much is the total for the 3 men?</p> <p>Student: The total for the 3 men is \$50 x 3 = \$150.</p> <p>Next Teacher Utterance: Gold: Thats right. FT-4 (generic): So how much is the total for the 3 men? FT-11 (Revealing Answer): Correct.</p>

Figure 5: Examples of responses generated by a model fine-tuned on the original four-intent annotation set (FT-4) and by a model fine-tuned on data annotated with eleven intents using the framework from [Petukhova and Kochmar \(2025\)](#) (FT-11), alongside actual responses from teachers (Gold).

of the re-annotated dataset. At the same time, we acknowledge that this work uses LLMs, and such models may present risks when applied in real-life educational scenarios, as they may generate outputs that, despite being plausible, are factually inaccurate or nonsensical, which in turn may lead to misguided decision making and propagation of biases. While we do not foresee any immediate risks associated with the research presented in our paper, if future work based on this research ap-

plies presented approaches to real-life scenarios, appropriate safeguards should be applied.

A Output of the Tree Creation Step

Task: Harry decided to buy some balloons for his friend's birthday party. One balloon costs \$0.5, and a pack of 10 balloons is cheaper and costs only \$3. Finally, Harry wants to bring to the party exactly 14 balloons. How much did he need to pay for them?

Correct Solution: To buy 14 balloons, Harry should buy one pack of 10, and $14 - 10 = 4$ separate balloons.

The price of 4 balloons is $4 \times 0.5 = \$2$.

In total, the pack and separate balloons would cost Harry in total $3 + 2 = \$5$.

5

Student's incorrect answer: Harry needs to buy 2 packs of 10 balloons, which will give him 20 balloons in total. He will then need to buy 4 more individual balloons to get to 14.

2 packs of 10 balloons cost $2 \times \$3 = \6 .

4 individual balloons cost $4 \times \$0.5 = \2 .

Therefore, Harry needed to pay $\$6 + \$2 = \$8$ for 14 balloons.

8

Dialog:

Teacher: (generic)Hi Michael, could you please walk me through your solution?

Student: Sure. I calculated that Harry needed to buy 2 packs of 10 balloons, which cost $2 \times \$3 = \6 . Then, he needed to buy 4 individual balloons, which cost $4 \times \$0.5 = \2 . So, the total cost was $\$6 + \$2 = \$8$.

Teacher: (focus)So can you please tell me why he needs two packs of 10 (which is 20) and another 4 on top? What's $20 + 4$?

Student: Harry needs two packs of 10 balloons because each pack costs \$3 and buying two packs is cheaper than buying 20 individual balloons. Then, he needs to buy 4 more individual balloons to get to 14 balloons in total. $20 + 4 = 24$, so Harry has enough balloons for the party.

Teacher: (focus)Please could you tell me how many balloons Harry requires in the math problem.

Student: Harry needs 14 balloons for the party.

Teacher: (focus)So is that 24?EOM!Student: No, 14. He needs two packs of 10 balloons and 4 individual balloons, which gives him a total of 24 balloons, but he only needs 14.

Teacher: (focus)So how many packs of 10, plus single balloons does he really need to equal 14?

Student: Harry needs two packs of 10 balloons and 4 individual balloons to equal 14.

Teacher: (probing)so what's $10+10+4$?

Student: $10+10+4 = 24$.

Teacher: (telling)Is that 14?

Student: No, 24 is not 14. Harry needs two packs of 10 balloons and 4 individual balloons, which gives him a total of 24 balloons, but he only needs 14.

Teacher: (telling)So Harry needs one pack of 10, which equals \$3. Plus he needs four separate balloons at \$0.5 each, can you tell me how much he needs to spend?

Student: Harry needs to spend \$3 for one pack of 10 balloons and \$2 for four individual balloons, so the total cost is $\$3 + \$2 = \$5$.

Teacher: (generic)Brilliant, can you see where you were duplicating the packs of 10

Student: Yes, I was calculating that Harry needed to buy two packs of 10 balloons, which cost $2 \times \$3 = \6 . Then, I was calculating that he needed to buy 4 individual balloons, which cost $4 \times \$0.5 = \2 . So, the total cost was $\$6 + \$2 = \$8$, which was incorrect because I was duplicating the packs of 10.

Abstract

Large Language Models (LLMs) offer exciting potential as educational tutors, and much research explores this potential. Unfortunately, there's little research in understanding the baseline behavioral pattern differences that LLM tutors exhibit, in contrast to human tutors. We conduct a preliminary study of these differences with the CIMA dataset and three state-of-the-art LLMs (GPT-4o, Gemini Pro 1.5, and LLaMA 3.1 450B). Our results reveal systematic deviations in these baseline patterns, particularly in the tutoring actions selected, complexity of responses, and even within different LLMs.

This research brings forward some early results in understanding how LLMs when deployed as tutors exhibit systematic differences, which has implications for educational technology design and deployment. We note that while LLMs enable more powerful and fluid interaction than previous systems, they simultaneously develop characteristic patterns distinct from human teaching. Understanding these differences can inform better integration of AI in educational settings.

1 Introduction

Large Language Models (LLMs) offer unprecedented capabilities for creating educational technologies that can interact with students. Unlike traditional intelligent tutoring systems (ITS), which were often limited by constrained interfaces and rigid interaction patterns (Alkhatlan and Kalita, 2019; Mousavinasab et al., 2021), LLMs provide natural-language interactions that draw on extensive linguistic and contextual training (Brown et al., 2020; Bommasani et al., 2022). This allows LLMs to respond to learner inputs in ways that more closely resemble human tutors, presenting new possibilities for personalized learning experiences.

Despite their potential, important questions remain about how closely LLM tutoring interactions

align with human tutoring practices. Existing literature on human tutoring and ITSs emphasize strategies such as scaffolding, immediate feedback, and adaptive questioning to meet the learners' needs (Chi et al., 2001; VanLehn, 2011). However, the conversational and pedagogical behaviors of LLMs in tutoring scenarios remain underexplored.

The current work addresses this research gap. Utilizing the CIMA dataset of language teaching dialogues (Stasaski et al., 2020), which contains multiple responses of human tutors to the same students in an Italian language learning context, we systematically examine and compare the structural pedagogical patterns of human tutors and several state-of-the-art language models, GPT-4o (OpenAI et al., 2024), Gemini Pro 1.5 (Team et al., 2024), and LLaMA 3.1 405B (Grattafiori et al., 2024). We identify and characterize behavioral patterns of LLM tutors and human tutors, focusing on action preferences and response complexity.

Our analysis reveals several key findings:

1. Both human and AI tutors show similar high-level preferences in action selection, with hints comprising approximately 45% of all tutoring actions.
2. Human tutors strongly prefer single-action responses (approximately 72% of interactions), while LLM tutors consistently combine multiple pedagogical actions in their responses.
3. Each LLM exhibits its own characteristic pattern, highlighting the need for LLM-specific tailoring.

As these systems continue to evolve and be deployed in diverse learning contexts, recognizing their distinctive behavioral patterns becomes increasingly important—not to eliminate differences, but to use them more effectively in creating educational experiences that complement human instruction.

2 Related Work

2.1 Evolution of Intelligent Tutoring Systems

Intelligent Tutoring Systems (ITS) have evolved significantly over decades, from rule-based systems with limited interaction capabilities to increasingly sophisticated architectures. Traditional ITS platforms like Cognitive Tutors (Anderson et al., 1995) and knowledge-based tutors (Akkila et al., 2019) demonstrated effectiveness in specific domains but were constrained by rigid interaction patterns and limited adaptability. These systems typically operated within carefully engineered knowledge frameworks, making them powerful but inflexible (VanLehn, 2011; Ma et al., 2014).

The field has progressively sought more natural and adaptive educational technologies. Dialog-based tutoring systems (Graesser et al., 1999; Rus et al., 2013) attempted to incorporate conversational elements but remained limited by predefined pathways. Recent advances in NLP have enabled more sophisticated systems capable of processing and generating natural language interactions (Rus et al., 2013; Nye et al., 2014), setting the stage for the current generation of LLM-based educational tools.

2.2 Language Models in Educational Applications

Large Language Models represent a fundamental shift in educational technology, offering unprecedented fluidity in natural language interaction coupled with broad knowledge coverage. Recent research has explored various applications of LLMs in education, including personalized learning (Park et al., 2024), assessment (Wang et al., 2024), and tutoring (Kumar et al., 2024).

Studies have demonstrated LLMs' potential to support complex learning processes through adaptive dialogue (Schmucker et al., 2023) and to generate contextually relevant explanations (Naik et al., 2024). LLMs' performance as educational tools has primarily been studied through various metrics such as learning gain (Pardos and Bhandari, 2023) or through assessing the quality or correctness of LLM responses (Kumar et al., 2024).

However, while these systems enable more natural interaction, they simultaneously operate according to statistical patterns learned during training rather than pedagogical principles explicitly encoded by designers (Brown et al., 2020; Bommasani et al., 2022). This tension between fluid

interfaces and underlying fixed statistical patterns remains underexplored in educational applications of LLMs.

2.3 Tutoring Patterns and Behaviors

Research on human tutoring has extensively documented the patterns that characterize effective teaching interactions. Chi et al. (2001) identified interactive patterns like scaffolding and feedback loops that support student learning. VanLehn (2011) further explored the balance between different pedagogical moves, noting that expert tutors dynamically adjust their approach based on student needs. Feedback, specifically, has been widely studied, with Hattie and Timperley (2007) emphasizing its critical role in facilitating student learning through targeted interventions.

In comparing AI and human tutoring behaviors, early work by Graesser et al. (1999) examined differences between human tutors and AutoTutor, finding systematic differences in questioning strategies and elaboration patterns. More recent work by Stasaski et al. (2020) with the CIMA dataset highlighted the diversity of valid teaching approaches human tutors employ, noting the low agreement rate (18.1%) between different tutors responding to the same student input. This underscores the complexity of establishing normative patterns for tutoring behavior.

2.4 Interaction Patterns in Language Models

Research on conversational behavior and dialogue generation in LLMs has identified patterns related to turn-taking, conversational coherence, and response complexity (Sandler et al., 2024; Shaikh et al., 2023). These studies highlight that while LLMs produce coherent interactions, the underlying statistical nature can lead to repetitive patterns and superficial dialogues – this behavior has, in part, also led to LLMs being labeled as “stochastic parrots” (Bender et al., 2021).

The few studies that have examined instructional patterns in AI systems have typically focused on direct comparisons of specific responses rather than population-level analysis of behavioral distributions (Puech et al., 2024). These findings emphasize the need to systematically analyze LLM interaction patterns to better understand their educational utility and identify areas for improvement.

2.5 Research Gap

Our research addresses the need to systematically analyze LLM interaction patterns by conducting a detailed comparison of human and LLM tutoring patterns across multiple dimensions of analysis, focusing on action distributions, response complexity, and teaching dynamics. This population-level approach provides a new perspective on how LLMs function in educational contexts compared to human tutors, with implications for both educational technology design and pedagogical theory.

3 Methodology

3.1 Research Questions

This study investigates differences between how language models and humans approach the tutoring task. We examine the underlying patterns in how these systems engage with learners compared to human tutors. This focus can be broken down into specific questions in light of ITS and AI:

1. How do artificial tutoring systems function when given the same context as human tutors?
2. What systematic differences emerge in how AI and human tutors structure their teaching interactions?

These questions address core theoretical interests about the nature of LLMs as ITS while avoiding assumptions about what constitutes “correct” or “effective” tutoring. By focusing on behavioral patterns rather than performance metrics, we aim to understand fundamental differences in how artificial and human tutors approach the teaching task.

3.2 Design Principles

Our methodology is shaped by several key principles:

Population-Level Analysis: Rather than attempting direct turn-by-turn comparisons between human and LLM responses, we focus on analyzing aggregate behavioral patterns across the entire dataset. This approach is particularly important given the low agreement rate (18.1%) observed between human tutors in the CIMA dataset.

Reference Distribution Approach: We aggregate human tutor responses to create reference distributions that capture the characteristic patterns of human tutoring behavior. These distributions serve as a baseline for comparative analysis.

Model Comparison: We maintain separate distributions for different LLM configurations, enabling us to distinguish between model-specific behaviors and general LLM characteristics.

This approach reorients our research question from “Does this LLM respond like a human tutor would?” to “Does this LLM’s pattern of action choices align with the patterns we observe in human tutors?”.

3.3 Dataset

Our analysis utilizes the CIMA (Conversational Instruction with Multi-responses and Actions) dataset (Stasaski et al., 2020), which provides tutoring dialogues focused on teaching Italian prepositional phrases to English speakers. The dataset is particularly valuable for our study as it captures multiple valid tutoring responses for each student interaction, reflecting the reality that there is rarely one “correct” way to respond in a tutoring context.

Key features of the dataset include:

- **Multiple Valid Approaches:** For each student utterance, three different tutors provide responses, showing distinct but equally valid tutoring strategies.
- **Action Labeling:** Each response is annotated with pedagogical actions (Hint, Question, Correction, Confirmation, Other).
- **Progressive Learning:** The dataset captures how concepts build across exercises.

The dataset contains 391 completed exercises across 77 students, with each exercise grounded in both visual and conceptual representations. The mean response lengths (6.82 words for students, 9.99 words for tutors) indicate substantive interactions. This richness, combined with explicit action labeling, provides a strong foundation for analyzing how different tutors structure their teaching interventions.

3.4 Dataset Enhancement with AI Tutors

To enable direct comparison between human and artificial tutoring patterns, we enhanced the CIMA dataset by generating parallel responses from state-of-the-art language models. We selected three advanced instruction-tuned models:

- GPT-4o 2024-08-06 (OpenAI) (OpenAI et al., 2024)

- Gemini Pro 1.5 (Google) (Team et al., 2024).
- LLaMA 3.1 405B instruct nitro (Meta) (Grattafiori et al., 2024)

This selection from different providers, each with distinct architectural choices and training approaches, allows us to distinguish between behaviors fundamental to language models in general versus those specific to particular implementations.

For response generation, we developed a structured prompting system that provides each model with equivalent context to what human tutors received in the original dataset. Each interaction uses a prompt template that specifies:

You are a language tutor teaching Italian. Available actions:

- Question: Ask student for clarification or to elaborate
- Hint: Provide indirect guidance
- Correction: Point out and fix errors
- Confirmation: Acknowledge correct responses
- Other: Any other type of response

Context:

- Target phrase (IT): {target_phrase['it']}
- Target phrase (EN): {target_phrase['en']}
- Grammar rules: {grammar_rules}
- Conversation history: {conversation_history}

Please provide a response as a tutor to the student's last message. Respond in JSON format with: { "response": "your response text", "actions": ["your action types"] }

This approach ensures consistent action categorization and response formats across all interactions.

3.5 Analysis Framework

Our analysis examines two key dimensions of tutoring behavior:

- **Action Distribution Analysis:** We examine the relative frequency of fundamental tutoring actions across different populations. This analysis compares the baseline distribution derived from human tutors against Language Model behavior, identifying systematic preferences or avoidances in action selection.

- **Action Combination Analysis:** We investigate patterns in how actions are combined within individual responses, including the typical number of actions per response and the balance between single-action and multi-action responses.

3.6 Methodological Limitations

Our analysis framework operates within several important constraints:

- **Dataset Characteristics:** The study utilizes a dataset limited to Italian preposition instruction with crowdsourced rather than professional tutors.
- **Structural Constraints:** The prescribed JSON response format may influence natural interaction patterns, and the restricted action vocabulary limits expressive range.
- **Model Implementation:** Analysis is limited to three model variants with a single prompt template approach and no model fine-tuning.
- **Scope of Conclusions:** While we can identify alignment or deviation from human behavioral patterns, we cannot evaluate the optimality of tutoring choices or assess the quality of specific responses.

Our focus on action distributions represents a deliberate methodological choice, prioritizing the analysis of strategic-level behavioral alignment over response-level quality assessment.

4 Analysis

Our analysis revealed systematic differences in how language models and human tutors approach the educational task, with patterns emerging across multiple dimensions of analysis.

4.1 Action Distributions

Both human and AI tutors demonstrate a strong preference for hints as their primary teaching action, with hints comprising approximately 45% of all actions across both human and LLM sessions (Figure 1). This suggests fundamental alignment in basic tutoring strategy, possibly reflecting the effectiveness of scaffolded guidance over direct instruction.

However, examining the broader action distributions reveals key differences in pedagogical approaches. Human tutors show a more balanced

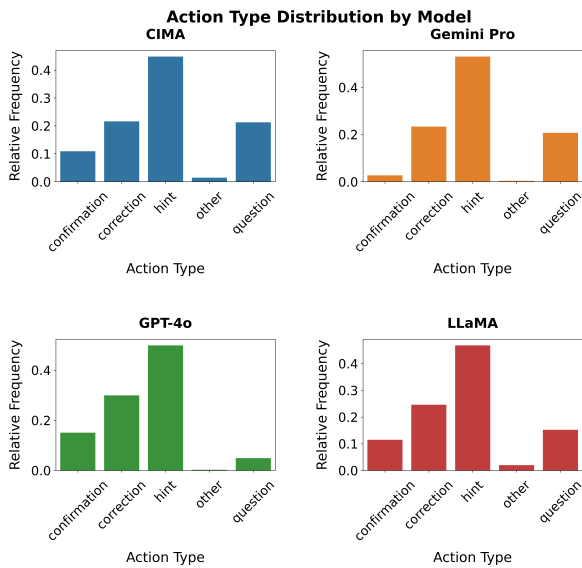

Figure 1: Distribution of actions by different tutors, showing the relative frequency of different pedagogical strategies.

distribution between corrections (20.3%) and questions (21.5%), suggesting a diverse approach. In contrast, AI systems exhibit model-specific patterns - while all maintain the primacy of hints, they differ in secondary strategies. GPT-4o and Gemini Pro 1.5 demonstrate a stronger tendency toward corrections (28.7% and 29.4% respectively) compared to questions (7.3% and 6.8%), while LLaMA 3.1 maintains a more balanced profile closer to human tutors.

Statistical analysis confirmed that the observed differences in action distributions between human and AI tutors were significant ($\chi^2 = 495.17$, $p < .001$, Cramer's $V = 0.124$), indicating a weak to moderate effect size. This suggests an interesting pattern: while there is fundamental alignment in primary teaching strategies (the preference for hints), significant differences emerge in how secondary strategies are deployed. This nuanced finding reveals that LLMs have captured core aspects of tutoring behavior while diverging in other dimensions.

4.2 Response Complexity

The most striking difference between human and AI tutors emerges in response complexity (Figure 2). Human tutors demonstrate a strong and consistent pattern for single-action responses, with approximately 71.8% of responses containing just one action, 24.6% containing two actions, and only 3.6% containing three or more. This pattern sug-

gests a teaching strategy focused on clear, targeted interventions.

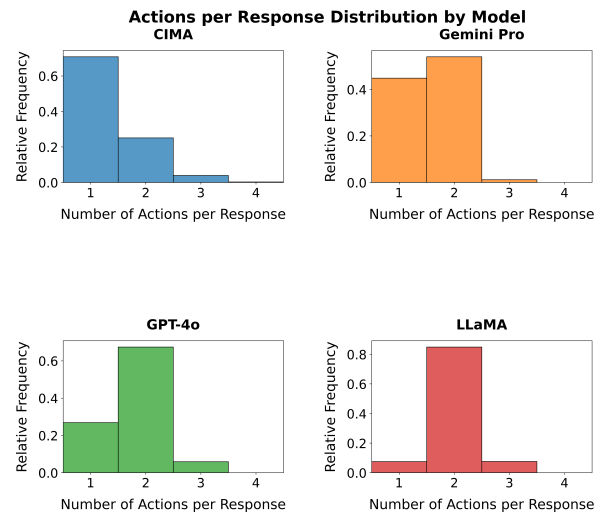

Figure 2: Distribution of the number of pedagogical actions per response in tutoring sessions.

In contrast, AI tutors consistently combine multiple actions in their responses, though with interesting variations between systems. LLaMA shows the strongest preference for dual-action responses (82.3%), while GPT-4o and Gemini Pro display a more balanced distribution. GPT-4o uses single actions in about 31.5% of responses and dual actions in 64.7%, while Gemini Pro shows a more even split between single (42.8%) and dual actions (54.9%).

A Kruskal-Wallis test revealed significant differences in the number of actions per response across the four tutor types (human and three LLMs) ($H = 1507.37$, $p < .001$). Post-hoc pairwise comparisons with Bonferroni correction showed significant differences between humans and each LLM ($p < .001$ for all comparisons), as well as between all pairs of LLMs ($p < .001$). This confirms that not only do AI tutors differ from human tutors in response complexity, but each AI model exhibits its own statistically distinct pattern in how it structures responses.

5 Discussion

5.1 Summary of Research Findings

Our study provides a comparative population-level view of how LLM tutors and human tutors approach the teaching task.

Our first finding is that both human tutors and LLM tutors share a high-level strategy, where hints are the main tutoring action (approximately 45%

of all actions each). This suggests that LLMs have learned to prioritize guidance much like human experts. The secondary actions show some differences. Human tutors use a somewhat balanced mix of questions and corrections in the interactions (roughly 20% each), indicating an approach that alternates between direct feedback and prompting student thinking. For the secondary actions, LLM tutors show skewed distributions; for example, GPT-4o and Gemini 1.5 rely more heavily on corrections, whereas LLaMa 3.1 maintained a more human-like balance.

These differences in action preference suggest that while LLMs have captured the primary tactic of hinting, they diverge in how they follow up, either by explaining or correcting or by probing the learner.

The second finding is the strong contrast in response complexity between human tutors and LLMs. Human tutors strongly prefer a concise, single-action response (roughly 70% of human tutor responses in the dataset had only one pedagogical action). In comparison, LLM tutors frequently combine multiple actions in a single response; the difference was the strongest for LLaMa 3.1, where over 80% of the responses had two actions). Statistical tests confirmed that these differences in response complexity are significant.

The third finding is that LLMs have unique behavioral signatures. Although the three evaluated LLMs have been trained with large masses of data, each had their distinct tutoring style. This highlights that the way how an LLM interacts reflects the model’s design choices or fine-tuning. These results extend the prior observations by Graesser et al. (1999), who noted systematic differences in tutoring style between a classical ITS (AutoTutor) and human tutors. We find that LLM-based tutors likewise deviate from human tutors.

5.2 Pedagogical and Practical Implications

The differences identified in our analysis have implications for educational practice and the design of AI tutoring systems. First, the alignment of primary strategy in terms of heavy use of hints highlights that LLMs have converged on a generally effective tutoring practice. This is encouraging from a pedagogical point of view, as hints are known to facilitate learning by prompting student thinking (Chi et al., 2001).

However, the way how LLM tutors use secondary strategies could affect learning in subtle

ways. For example, the LLMs were more likely to provide corrections, and asked prompting questions less frequently than human tutors. Asking questions is often used to encourage active learning – if an LLM tutor predominantly gives corrections, the student might become more passive in the learning process.

On the other hand, providing rapid corrections can be also be beneficial, depending on the scenario. The pedagogical implication is that LLM tutors should be tailored to the contexts and objectives: if the objective is to foster student reasoning, LLMs should be tweaked to ask more open-ended questions rather than providing quick fixes. Furthermore, compound responses might overwhelm the learner, and to avoid this, LLMs should be adapted to match the user competences. That is, there is room for improvement in the pedagogical quality and ability of LLM-driven tutors.

Broadly speaking, our results emphasize that LLM tutors, despite the fluent dialogue, have embedded biases in how they tutor. This resonates with the tension noted by Horvitz between fluid and natural interfaces and the rigid patterns of automated systems (Horvitz, 1999).

5.3 Limitations

Our work comes with a set of limitations, which we acknowledge. Firstly, our study focuses on a single dataset and domain, i.e. the CIMA dataset of Italian language learning dialogues (Stasaski et al., 2020). The tutoring patterns that we focused on (for both humans and LLMs) may be specific to language teaching or even to particular prompts and tasks in CIMA, and it is possible that the balance of actions and complexity would be different to other datasets. This means that the generalizability of the results should be assessed with additional contexts and datasets.

Secondly, our analysis focused on population-level comparisons, but it does not capture how a tutor might adapt over a tutoring session. Human tutors often dynamically adjust their strategy based on students’ progress, but we do not know to what extent this holds for LLM tutors, and our current analysis misses these dynamics.

Thirdly, our annotation strategy was automatic, and relied on the existing categories in the CIMA dataset. It is possible that LLM (or human) actions do not always neatly fall into specific categories. We sought to mitigate this by using clear definitions, but acknowledge the presence of noise. Ad-

ditionally, we relied on LLMs' self-reported action classifications without manual validation. While our population-level patterns are robust to some classification noise, future work should validate the accuracy of these self-classifications. Furthermore, our analysis does not capture subtler nuances in responses; as an example, a human tutor might provide a more encouraging response than an LLM, even if both responses are categorized as hints.

Additionally, as the CIMA dataset was released in 2020 and our tested LLMs were trained on data through 2023-2024, it is possible that the dataset appeared in their training corpora. While this does not invalidate our behavioral analysis—the patterns we observe reflect how these models approach tutoring tasks regardless of prior exposure—it should be considered when interpreting the alignment between LLM and human tutoring strategies.

Finally, we cannot deduce the efficiency of the tutoring. This is a limitation of the practical significance of the work. Despite these issues, our work fills a gap by systematically comparing the baseline behaviors of human and LLM tutors.

6 Conclusion

In this paper, we studied LLM-based tutors differ from human tutors in their interaction patterns, conducting a population-level analysis using the CIMA tutoring dataset. Our focus was on the behavioral structure of the tutoring, composed of what actions the tutors take and how they deliver them.

By generating parallel tutoring responses using three state-of-the-art LLMs and comparing them against human tutor responses, we observe the following: (1) LLM tutors and human tutors have similar high-level tactics with a shared emphasis on giving hints, which indicates that current LLMs have learned or been tuned to adopt some of the existing practices of humans; (2) When going beyond the high-level tactics, there are significant differences in how LLM tutors balance their actions and in how complex the responses are; (3) The differences are not uniform across the LLM tutors, which highlights that each LLM has its own “personal” style of tutoring. These findings were made possible by analyzing the aggregate patterns over many tutoring responses, moving beyond anecdotal or one-to-one comparisons.

Recognizing and understanding these patterns is important when seeking to make informed decisions on how to effectively integrate LLMs into

learning environments. The differences that we highlight suggest areas where LLM tutors might benefit from additional tailoring (e.g. tailoring LLMs to the context and objectives, and to match the user competences).

In conclusion, we present a foundation for treating behavioral patterns of LLM tutors as a subject of study by its own right, parallel to how one might study different teaching styles among human tutors. We have also shown how to quantitatively characterize how an LLM “teaches”. Such a characterization can help in aligning LLM tutor behavior towards educational best practices, while also benefiting from the existing capacities such as consistency and breadth.

Abstract

Large Language Models (LLMs) have shown impressive performance in mathematical reasoning tasks when guided by Chain-of-Thought (CoT) prompting. However, they tend to produce highly confident yet incorrect outputs, which poses significant risks in domains like education, where users may lack the expertise to assess reasoning steps. To address this, we propose a structured framework that models stepwise confidence as a temporal signal and evaluates it using Signal Temporal Logic (STL). In particular, we define formal STL-based constraints to capture desirable temporal properties and compute robustness scores that serve as structured, interpretable confidence estimates. Our approach also introduces a set of uncertainty reshaping strategies to enforce smoothness, monotonicity, and causal consistency across the reasoning trajectory. Experiments show that our approach consistently improves calibration metrics and provides more reliable uncertainty estimates than conventional confidence aggregation and post-hoc calibration.

1 Introduction

Large language models (LLMs) are increasingly applied in educational contexts such as concept explanation, question answering, and personalized tutoring, especially in STEM domains like mathematics (Kasneji et al., 2023). These models exhibit strong capabilities in solving complex problems; however, they also tend to produce answers that are fluent and seemingly confident, yet factually incorrect. In educational settings, such outputs can be particularly problematic, as students may lack the expertise to distinguish between correct and incorrect reasoning (Polyxeni Paulina Kastania, 2024), and may be misled by responses that appear trustworthy. This mismatch between confidence and correctness raises critical concerns about the reliability of LLM-generated answers and highlights

the importance of integrating uncertainty estimation into educational AI systems.

Although prior work has explored various uncertainty estimation techniques, such as predictive entropy, sampling-based variance, and confidence calibration, most studies focus on general NLP tasks rather than educational scenarios (Zhao et al., 2021; Jiang et al., 2021). In educational contexts like mathematics learning, well-calibrated uncertainty can be especially useful for guiding student attention, supporting teacher oversight, and improving feedback systems. However, existing uncertainty metrics often show poor alignment with actual correctness (Zhu et al., 2025).

In this work, we address this challenge by proposing a novel approach to *estimate uncertainty in LLM-based chain-of-thought (CoT) reasoning* for high school mathematics problems. Our method models the sequence of reasoning steps as a temporal confidence signal and evaluates its structural properties using Signal Temporal Logic (STL) (Fainekos and Pappas, 2006). Instead of modifying the LLM or directly penalizing its outputs, we quantify undesirable confidence behaviors, such as abrupt increases following uncertain steps, by computing robustness scores against formal STL constraints. This yields a constraint-aware aggregation scheme that captures how confidence is expected to evolve over time, offering a structured and interpretable view of the reasoning process while improving calibration. We evaluate our method on a curated dataset of Chinese Gaokao mathematics multiple-choice questions (Zhang et al., 2023). Experimental results show that our method significantly improves calibration, reducing Expected Calibration Error (ECE) compared to baseline uncertainty aggregation methods.

This paper’s contributions are: (1) a novel perspective that treats stepwise confidence in chain-of-thought reasoning as a temporal signal amenable to formal analysis, (2) a constraint-aware modeling

approach that reshapes confidence trajectories and quantifies their structural quality using STL robustness and (3) empirical validation of our method’s effectiveness on Chinese Gaokao mathematics. Fig 1 provides an overview of our pipeline: starting from stepwise CoT confidence, we apply uncertainty reshaping followed by STL-based temporal logic evaluation. This transformation results in interpretable, structure-aware confidence scores.

2 Related Work

Applications of LLMs in Education: LLMs have been widely adopted in educational settings for tasks such as grammar correction, content generation, problem explanation, and intelligent tutoring. Prior studies highlight their potential to support learners across domains like language writing (Kasneji et al., 2023), mathematics (Gan et al., 2023), and personalized feedback (Zhou et al., 2025; Wang et al., 2024). For instance, LLMs like MathGPT and Khanmigo have been used to generate step-by-step math explanations aligned with curriculum standards (Shah et al., 2024), while ChatGPT has shown promise in automated feedback for student essays and short answers (Kasneji et al., 2023). Despite these advances, concerns remain around academic integrity, hallucinated outputs, and students over-relying on unverified responses (Benítez et al., 2024). Moreover, few works explicitly quantify how reliable these educational outputs are, or how uncertainty signals can be used to guide learners or inform teachers. As LLMs become integral to education technology, recent surveys have called for deeper investigations into trust, transparency, and uncertainty in educational applications (Idris et al., 2024).

Uncertainty in LLMs: LLMs exhibit remarkable fluency across diverse NLP tasks, yet their outputs often suffer from overconfidence and miscalibration (Kadavath et al., 2022), especially in impact-sensitive domains such as education. Existing work has explored various uncertainty estimation techniques, including entropy-based methods like predictive entropy and confidence gaps (Zhu et al., 2025), as well as sampling consistency across outputs (Lyu et al., 2025). Confidence calibration is another active area, revealing that LLMs tend to be overconfident, particularly in zero-shot or out-of-domain tasks (Desai and Durrett, 2020; Zhao et al., 2021). Recent studies also propose using uncertainty signals to guide reasoning, such as

Uncertainty-Guided CoT prompting (Zhu et al., 2025), active prompting for data selection, and consistency-based calibration (Diao et al., 2023; Lyu et al., 2025). However, most of these methods have been evaluated on general NLP or code generation tasks, with limited attention to structured educational settings like math problem solving, where reliable uncertainty estimates can help students assess model-generated reasoning and assist teachers in diagnosing student understanding..

CoT and STL: Recent advances in CoT prompting have significantly improved the multi-step reasoning ability of LLMs, yet they also introduce new layers of uncertainty, such as error propagation across intermediate steps and unfaithful explanations (Zhang et al., 2022; Wang et al., 2022; Tanneru et al., 2024). In this work, we propose a novel perspective that treats CoT steps as discrete temporal signals, enabling the use of STL to formally specify and evaluate reasoning quality over time (Rescher and Urquhart, 2012). STL allows for expressive specifications like *eventually correct* or *always consistent*, and provides quantitative robustness scores that capture the degree of satisfaction or violation (Fainekos and Pappas, 2006). This formalism has been successfully applied in domains such as motion planning (van Huijgevoort et al., 2024), reinforcement learning (Li et al., 2017), and control synthesis, and offers a promising path toward interpretable and rigorous evaluation of LLM-generated reasoning trajectories. Applying STL to CoT would not only enable structured detection of flawed reasoning patterns but also facilitate the development of confidence-aware feedback and scoring systems in education and other applications.

3 STL-Guided Confidence Estimation

Our approach consists of three stages: (1) generating a stepwise confidence signal via CoT prompting, (2) applying uncertainty reshaping strategies to promote temporal consistency, and (3) evaluating the reshaped sequence using STL. This pipeline is illustrated in Fig 1(b), showing how each reshaping strategy transforms a sample confidence trajectory. Compared to the original signal, our smoothing strategies effectively suppress abrupt spikes and produce a more temporally coherent confidence trajectory, while preserving the overall trend of reasoning. This behavior is crucial for downstream STL-based evaluation, which benefits

Figure 1: (a) Conventional methods output global confidence via logit, self-evaluation, or internal analysis. (b) Our method models step-wise CoT confidence as a temporal signal, applies signal reshaping, and evaluates robustness using STL to obtain a temporally consistent confidence score.

from smoother and more causally consistent input signals.

3.1 Problem Setup

We model LLMs as autonomous agents tasked with solving high school mathematics problems. Given an input question $q \in \mathcal{Q}$, the agent generates a final answer $a \in \mathcal{A}$ along with a scalar uncertainty score $u \in [0, 1]$, representing its confidence in the answer. Ideally, high confidence should correspond to high correctness probability, and vice versa (Guo et al., 2017).

To evaluate calibration, we employ the *Expected Calibration Error (ECE)* (Naeni et al., 2015; De-sai and Durrett, 2020), a widely-used metric that quantifies the mismatch between confidence and accuracy. Formally, we partition predictions into M bins based on their confidence values and compute:

$$\text{ECE} = \sum_{m=1}^M \frac{|B_m|}{n} |\text{acc}(B_m) - \text{conf}(B_m)|, \quad (1)$$

where B_m denotes the set of predictions falling into the m -th confidence bin, $\text{acc}(B_m)$ is the empirical accuracy defined as

$$\text{acc}(B_m) = \frac{1}{|B_m|} \sum_{i \in B_m} \mathbf{1}[\hat{a}_i = a_i], \quad (2)$$

and $\text{conf}(B_m)$ is the average predicted confidence. Here, n is the total number of examples, and $\mathbf{1}[\cdot]$ is the indicator function that returns 1 if the prediction is correct, and 0 otherwise. Since the task is formulated as multiple-choice classification, both model predictions and ground-truth answers are represented as one of a finite set of discrete options (e.g., A, B, C, D). This allows correctness to be determined via exact match of the selected option label, avoiding ambiguities arising from natural language variation. rect , and 0 otherwise.

In addition to ECE, we also report the *Brier Score (BS)* as a complementary calibration metric. The Brier Score measures the mean squared error between predicted confidence and ground-truth correctness, defined as:

$$\text{BS} = \frac{1}{n} \sum_{i=1}^n (c_i - y_i)^2, \quad (3)$$

where $c_i \in [0, 1]$ is the model’s predicted confidence for example i , and $y_i \in \{0, 1\}$ is the binary correctness label. Lower Brier Scores indicate better calibrated and more reliable confidence estimates.

Unlike conventional classification tasks, reasoning in LLMs often unfolds over multiple steps (Wei et al., 2022). This raises an additional challenge: confidence should not only be calibrated across

Question	Logit	Self-Eval	Internal
Given vectors $\mathbf{a} = (2, 3)$ and $\mathbf{b} = (x, 6)$. Determine whether the condition “ $x > -9$ ” is a sufficient and/or necessary condition for “the angle between \mathbf{a} and \mathbf{b} is acute.” Options: A. Sufficient but not necessary B. Necessary but not sufficient C. Sufficient and necessary D. Neither sufficient nor necessary <i>Model answer: C (incorrect), True answer: B</i>	0.99	0.98	0.99
Set parabola $C : y^2 = 4x$. The focus is F . A line passes through $(-2, 0)$ with slope $\frac{2}{3}$, intersecting C at points M and N . Compute $F\vec{M} \cdot F\vec{N}$. Options: A. 5 B. 6 C. 7 D. 8 (correct) <i>Model answer: D (correct)</i>	0.98	0.95	0.97

Table 1: Examples of high school mathematics questions and confidence scores from three estimation strategies: Logit-based, Self-evaluation, and Internal consistency. While the model is highly confident in all three views, the first question is incorrectly answered, leading to significant miscalibration. The **Expected Calibration Error (ECE)** for Logit, Self-Eval, and Internal confidences are **0.485**, **0.465**, and **0.480**, respectively.

examples, but also evolve smoothly and consistently over the reasoning trajectory (Zhu et al., 2025). Hence, the problem extends to generating temporally coherent uncertainty sequences that reflect both local confidence (per step) and global correctness (final answer). Our objective is thus to design a framework where uncertainty estimates are not only well-calibrated across examples, but also evolve in a temporally consistent manner—exhibiting properties such as smooth progression, causal coherence, and alignment with the underlying reasoning process.

3.2 Uncertainty Reshaping Strategies

To model reasoning-time uncertainty, we use CoT prompting to elicit a sequence of intermediate reasoning steps $\{s_1, \dots, s_T\}$, each associated with a confidence score $c_t \in [0, 1]$. We treat the resulting confidence sequence $\mathbf{c} = \{c_1, \dots, c_T\}$ as a temporal signal (Rescher and Urquhart, 2012). However, due to the inherent causal nature of reasoning, abrupt increases in confidence, especially after initially low-confidence steps, can be misleading (Zhu et al., 2025). To take advantage of this insight, we propose several signal reshaping functions that induce smoother and causally consistent confidence evolution. While some of these strategies are conceptually related to smoothing methods in time-series analysis, they are, to the best of our knowledge, novel in the context of modeling stepwise confidence in LLM-based reasoning.

- **Causal Minimum Smoothing (CMS):** Limits future confidence based on past minimum values plus a small fixed margin δ :

$$\tilde{c}_t = \min \left(c_t, \min_{i < t} c_i + \delta \right)$$

- **Exponential Decay Smoothing (EDS):** Applies exponential smoothing by blending the current value with the average of past values:

$$\tilde{c}_t = \alpha \cdot c_t + (1 - \alpha) \cdot \frac{1}{t} \sum_{i=1}^{t-1} c_i$$

- **Monotonic Penalty Smoothing (MPS):** Dampens confidence spikes if the previous step is below a fixed threshold τ . This focuses on upward spikes, which are more likely to mislead following uncertain steps:

$$\tilde{c}_t = \begin{cases} \frac{c_{t-1} + c_t}{2} & \text{if } c_{t-1} < \tau \text{ and } c_t > c_{t-1} \\ c_t & \text{otherwise} \end{cases}$$

- **Guarded Smoothing (GS):** Caps sudden jumps beyond threshold τ plus tolerance ϵ :

$$\tilde{c}_t = \begin{cases} \tau + \epsilon, & \text{if } c_{t-1} < \tau \text{ and } c_t > \tau + \epsilon \\ c_t, & \text{otherwise} \end{cases}$$

The reshaped sequence $\tilde{\mathbf{c}} = \{\tilde{c}_1, \dots, \tilde{c}_T\}$ is passed to a formal temporal logic evaluation module described next as shown in Fig. 1(b).

3.3 STL-Based Temporal Evaluation

Rather than relying solely on the final-step confidence c_T or averaging all stepwise confidences, we propose a STL-based framework to evaluate the temporal structure of the confidence trajectory $\tilde{\mathbf{c}} = \{\tilde{c}_1, \dots, \tilde{c}_T\}$ (Fainekos and Pappas, 2006). STL enables formal specification of desired temporal properties of confidence during reasoning, such as smooth progression or eventual certainty.

Each STL formula encodes a specific temporal pattern, and its associated robustness score

Figure 2: Visualization examples of stepwise confidence signals before and after applying different uncertainty reshaping strategies. Each subplot compares the original confidence trajectory (yellow) against a smoothed version (orange) using one of the following methods: (left to right) Causal Minimum Smoothing (CMS), Exponential Decay Smoothing (EDS), Monotonic Penalty Smoothing (MPS), and Guarded Smoothing (GS). These transformations produce smoother and more temporally consistent confidence profiles while preserving the overall trend.

$\rho_i = \rho(\tilde{c}, \text{STL}) \in \mathbf{R}$ quantifies how well the reshaped signal satisfies that property (Donzé and Maler, 2010). A positive score indicates the satisfaction margin, while a negative score represents the magnitude of a violation.

We define three STL specifications, each yielding a separate confidence score:

- **Eventually Confident:** Confidence should eventually rise above a threshold τ :

$$\text{STL1} = \diamond_{[t_1, t_2]}(\tilde{c}(t) > \tau)$$

- **Always Stable or Increasing:** Confidence should not drop abruptly:

$$\begin{aligned} \Delta\tilde{c}(t) &= \tilde{c}(t) - \tilde{c}(t-1) \\ \text{STL2} &= \square_{[t_1, t_2]}(\Delta\tilde{c}(t) \geq -\epsilon) \end{aligned}$$

- **Local Smoothness:** Confidence should not change too much between steps:

$$\text{STL3} = \square_{[t_1, t_2]}(|\Delta\tilde{c}(t)| \leq \delta)$$

Each resulting score $\hat{c} = \text{ReLU}(\rho(\tilde{c}, \text{STL})) \in [0, 1]$ represents an interpretable, temporally-informed confidence score derived from logic-based robustness. These scores can be used independently for analysis or combined in multi-dimensional calibration evaluation.

While our STL-based scoring framework does not require labeled data during reasoning, it does rely on threshold hyperparameters (e.g., τ, ϵ, δ) that influence robustness computation. To set them, we perform a grid search on a held-out validation set. This makes our approach partially *post-hoc* in nature: only the STL evaluation stage requires data-driven tuning, whereas the preceding confidence reshaping is fully unsupervised and model-agnostic.

4 Experiments

In Section 4, we present an ablation study and a comparison against established post-hoc calibration techniques that investigates the impact of STL parameterization and compares our method against established post-hoc calibration techniques such as *Temperature Scaling* (Guo et al., 2017) and *Histogram Binning* (Zadrozny and Elkan, 2001). Our results show that STL-based evaluation provides not only competitive calibration performance but also interpretable, temporally grounded diagnostics of reasoning quality.

Experimental Setup: We conduct our experiments using the Qwen-7B language model,¹ a high-performing open-source LLM optimized for Chinese and mathematical reasoning tasks. Our evaluation is conducted on all multiple-choice questions from Chinese national college entrance exams (Gaokao) spanning 2010 to 2022, totaling 12 years of official high school mathematics problems. These questions are drawn from GAOKAO-Bench (Zhang et al., 2023), to assess LLMs’ language understanding and symbolic reasoning capabilities using real-world exam data. Table 1 illustrates representative examples.

To prevent the model from relying on surface-level pattern matching or memorized templates, we augment the dataset following strategies inspired by GSM-Symbolic (Mirzadeh et al., 2024), which shows that LLMs often fail when symbols, numbers, or phrasing are changed. We use a more advanced reasoning model – OpenAI’s o1 API to perform all paraphrasing operations in a controlled and semantically faithful manner. Specifically, each original problem is rewritten to preserve logical structure and correct answer while varying lexical expressions (e.g., transforming “find

¹<https://huggingface.co/Qwen/Qwen-7B>

Figure 3: ECE comparison of four confidence estimation methods. (1) Final-step confidence; (2) average confidence over CoT steps; (3) CoT confidence after applying Uncertainty Reshaping Strategies; and (4) STL-based CoT confidence, which combines Uncertainty Reshaping Strategies with the **STL1** formula (*Eventually Confident*: confidence should eventually exceed a threshold τ). The STL1-enhanced method achieves the best calibration (ECE = 5.5).

the intersection of sets A and B” into “determine the elements shared by both A and B”). We further introduce linguistic variation through backtranslation, translating problems into a pivot language (such as French) and then back to English, thereby injecting natural noise without changing semantics. Additionally, symbolic formulations are diversified using template-based transformations—for example, the set expression “ $A \cap B$ ” may be rephrased as “ $x \in Z, \sqrt{x} \leq 4$ ” or “ $B = \{x \in Z \mid x^2 \leq 16\}$ ”. These augmentations collectively evaluate the model’s robustness to paraphrasing, symbol rewriting, and structural variation, ensuring assessment focuses on genuine reasoning rather than memorized syntax. The correct answer for each augmented sample is inherited from the corresponding original Gaokao-Bench problem, since paraphrasing and symbolic transformations preserve semantic and logical equivalence. In total, the original 432 questions are each rewritten twice, resulting in a final dataset of 1,296 problem instances for evaluation.

Quantitative Results and Analysis: To illustrate how different estimation methods affect calibration behavior, Figure 3 shows an example confidence histogram under four representative strategies. While it only reflects a single problem instance and one STL constraint (STL1), the figure demonstrates how reshaping and temporal logic evaluation yield more aligned and interpretable confidence estimates. We now turn to aggregate results across the full test set. All scores are averaged over three runs, and \pm denotes standard deviation caused by the randomness introduced through

temperature-controlled decoding, which affects the variability and creativity of LLM outputs. Table 2 presents the Expected Calibration Error (ECE) for various estimation strategies across three types of uncertainty sources: logits-based, self-evaluation-based, and internal-based. Table 3 complements this with Brier Scores, which jointly capture calibration and sharpness of probabilistic estimates.

From the ECE results, we observe that traditional post-hoc calibration methods such as Temperature Scaling (Guo et al., 2017) and Histogram Binning (Zadrozny and Elkan, 2001) reduce miscalibration compared to raw one-step uncertainty. For example, Histogram Binning achieves an ECE of 0.139 on logits-based predictions, improving substantially over the one-step baseline (0.324). However, these methods operate globally and do not account for the multi-step nature of reasoning in LLMs.

In contrast, CoT-based methods yield stronger performance, especially when combined with our proposed Uncertainty Reshaping Strategies. Simply averaging confidence across CoT steps reduces ECE across all sources, and applying smoothing techniques such as Causal Minimum Smoothing (CMS) or Exponential Decay Smoothing (EDS) brings further gains. For instance, CMS reduces logits-based ECE to 0.107, the lowest among all non-STL methods.

STL-based temporal evaluation further improves calibration. By enforcing high-level temporal constraints like *Eventually Confident* (STL1), *Always Stable* (STL2), and *Locally Smooth* (STL3), the model’s confidence trajectory becomes more inter-

Method	Reshaping Strategy	Logits-based ↓	Self-evaluation-based ↓	Internal-based ↓
1-step Uncertainty	-	0.324 ± 0.045	0.692 ± 0.035	0.694 ± 0.033

	MPS	0.211 ± 0.019	0.080 ± 0.017	0.100 ± 0.046
	GS	0.212 ± 0.026	0.077 ± 0.018	0.096 ± 0.035
STL2 (Always Stable)	-	0.170 ± 0.071	0.113 ± 0.011	0.075 ± 0.040
	CMS	0.153 ± 0.021	0.126 ± 0.013	0.074 ± 0.030
	EDS	0.114 ± 0.063	0.114 ± 0.015	0.056 ± 0.028
	MPS	0.188 ± 0.009	0.118 ± 0.015	0.063 ± 0.013
	GS	0.164 ± 0.074	0.111 ± 0.013	0.070 ± 0.039
STL3 (Locally Smooth)	-	0.184 ± 0.021	0.154 ± 0.015	0.099 ± 0.031
	CMS	0.122 ± 0.018	0.081 ± 0.037	0.084 ± 0.030
	EDS	0.149 ± 0.008	0.076 ± 0.040	0.083 ± 0.034
	MPS	0.171 ± 0.025	0.151 ± 0.030	0.083 ± 0.046
	GS	0.180 ± 0.017	0.118 ± 0.006	0.091 ± 0.043

Table 2: Expected Calibration Error (ECE) comparison across confidence sources and estimation strategies. STL-based methods, particularly STL1–STL3 combined with Uncertainty Reshaping (CMS, EDS), consistently yield better calibration than traditional techniques.

pretable and aligned with reasoning quality. STL1 combined with GS achieves an ECE of 0.077 on self-evaluation-based confidence and 0.096 on internal-based, outperforming all other approaches. Notably, STL2 with EDS reaches an ECE of 0.056 on internal-based confidence—the best result across all settings.

The Brier Score analysis mirrors this trend. STL methods consistently produce lower scores than CoT average or standard post-hoc techniques. STL1 with CMS achieves the best self-evaluation-based Brier Score (0.234), while STL2 with EDS offers the best internal-based score (0.056). These results confirm that applying STL logic not only improves calibration error but also leads to sharper, more reliable probability estimates.

Overall, STL-based confidence estimation outperforms traditional calibration and CoT-only baselines, particularly when paired with CMS or EDS. These findings highlight the value of structured temporal logic as a calibration framework for LLM-based reasoning, offering both theoretical guarantees and empirical gains.

5 Conclusion

This paper presents a structured approach to confidence estimation for LLM-based mathematical reasoning. By modeling stepwise confidence as a tem-

poral signal and evaluating its quality using STL, our method addresses limitations in traditional calibration and step-level aggregation techniques. We introduce a suite of uncertainty reshaping strategies and STL-based robustness constraints that enforce desirable properties such as eventual certainty, monotonic progression, and local smoothness.

Experimental results on GAOKAO-Bench demonstrate that our STL-based evaluation, particularly when paired with smoothing strategies like CMS and EDS, consistently achieves lower ECE and Brier Scores compared to standard baselines. Beyond quantitative improvements, the framework provides a principled, interpretable method for diagnosing and enhancing reasoning quality in educational LLM applications.

6 Limitations

While our method improves calibration and interpretability, it is currently limited to high school-level multiple-choice math problems. Extending the framework to open-ended questions, formal proofs, or multi-modal reasoning is a promising direction. Since all experiments are conducted on Qwen-7B, generalization to other models remains uncertain. Testing on models like Gemma 3, Llama 3.2, or DeepSeek would help assess robustness across architectures.

Method	Reshaping Strategy	Logits-based ↓	Self-evaluation-based ↓	Internal-based ↓

	EDS	0.239 ± 0.006	0.242 ± 0.001	0.244 ± 0.000
	MPS	0.236 ± 0.010	0.236 ± 0.003	0.238 ± 0.002
	GS	0.233 ± 0.011	0.235 ± 0.001	0.249 ± 0.002

Table 3: Brier Score comparison across methods. Lower scores indicate better-calibrated and sharper probabilistic predictions. STL-based temporal constraints further improve performance beyond CoT averaging and post-hoc calibration.

Both the reshaping strategies and STL specifications are manually defined. Future work could explore learning them dynamically via reinforcement learning or differentiable logic, enabling more adaptive and data-driven calibration beyond manual tuning.

This paper focuses on linear chain-of-thought reasoning. More complex prompting paradigms, such as tree-of-thought (Yao et al., 2023), introduce branching and cyclic structures that pose new challenges for temporal modeling. Extending our evaluation to computation tree logic (CTL) to accommodate such structures would broaden its applicability to richer and more realistic cognitive processes.

Finally, our method is post-hoc and does not influence model inference. Integrating uncertainty feedback into real-time tutoring systems could enable dynamic intervention, hinting, and early error detection.

Abstract

This paper presents an automated scoring approach for a formative assessment tool aimed at helping learner physicians enhance their communication skills through simulated patient interactions. The system evaluates transcribed learner responses by detecting key communicative behaviors, such as acknowledgment, empathy, and clarity. Built on an adapted version of the ACTA scoring framework, the model achieves a mean binary F1 score of 0.94 across 8 clinical scenarios. A central contribution of this work is the investigation of how to balance scoring accuracy with scalability. We demonstrate that synthetic training data offers a promising path toward reducing reliance on large, annotated datasets—making automated scoring more accurate and scalable.

1 Introduction

The ability to automatically evaluate free-text responses has become one of the most impactful applications of natural language processing (NLP) in education. Traditionally, research in this area has focused on automated short-answer grading (ASAG) (Haller et al., 2022; Suen et al., 2023; Clauser et al., 2024) and essay scoring (Klebanov and Madnani, 2022). Recently, the scope has expanded to scoring clinical patient notes written by medical students, which involves determining whether critical medical concepts outlined in a scoring rubric are accurately addressed (Sarker et al., 2019; Harik et al., 2023; Yaneva et al., 2024). While traditional ASAG approaches focus on evaluating factual correctness or content coverage in student responses, our work extends this paradigm to assess the quality of interpersonal communication skills—a domain where responses are more nuanced and context-dependent than typical short-answer assessments.

In this paper, we further extend NLP-based scoring in medical education by introducing a new task:

automated scoring of communication skills in a learning tool for physician-patient interactions. Our work is part of the Communication Learning Assessment (CLA) framework (White et al., 2024), a structured educational program that helps medical learners practice communication skills through realistic patient interactions. In a typical CLA scenario, learners watch a brief video of a patient expressing concerns, seeking clarification about their diagnosis, or struggling with treatment adherence, among other examples. They then respond verbally to that scenario (their response can be up to one minute long), aiming to demonstrate key communication behaviors pertinent to the situation. In CLA, these expected behaviors are called learning points (LPs). For example, the LP "Praise patient's weight loss efforts" might be demonstrated by a learner saying, "I'm really proud of you for sticking with it." Evaluating these responses involves identifying specific spans of speech from the learner response that align with LPs from the scoring rubric of the scenario.

The primary contribution of this work is three-fold: (1) we investigate the application of automated approaches for scoring communication skills; (2) we evaluate various techniques aimed at improving model performance; and (3) we consider the scalability of these techniques in practical deployment scenarios. While strategies such as increasing the volume of human-annotated data can enhance performance, they are inherently limited by resource constraints and thus do not support scalable solutions. To address this, we focus on approaches such as data augmentation, few-shot learning, and automated generation of training data—methods that hold promise for improving model performance while maintaining scalability.

2 Dataset and Annotation

The dataset used in this study consists of transcribed learner responses collected from simu-

Case ID	Total	#Positive	#Negative	#LPs
174	162	91	71	3
175	120	71	49	2
176	162	80	82	3
177	236	164	72	4
178	138	55	82	3
180	165	99	66	3
182	232	171	61	4
192	236	134	102	4

Table 1: Summary statistics per case. *#Positive* refers to the number of responses that reflect a learning point (LP). *#Negative* refers to the number of responses constructed without any such reflection (i.e., the learner did not address the LP). *#LPs* denotes the number of distinct LPs associated with each case.

lated physician-patient interactions across 8 clinical cases (see Table 1). Each case contains between 120 and 236 learner responses. The learners were 3rd and 4th year US medical students who passed the USMLE[®] Step 1 exam¹. Recruitment was carried out by NBME.

Annotations were guided by a detailed rubric capturing key communication behaviors essential for effective physician-patient interactions, such as acknowledgment of patient concerns, provision of clear explanations, demonstration of empathy, and reinforcement of positive behaviors. This rubric included 26 unique Learning Points (LPs), each associated exclusively with one of the 8 clinical cases, with each case containing between 2 and 4 distinct LPs. Annotators were instructed to precisely identify reflective text spans corresponding to each LP by providing exact character-level indices within learner responses. Negative samples for each LP were systematically derived by listing all learner responses from the same clinical case that were not annotated as reflecting that specific LP, ensuring comprehensive negative examples.

Annotations were performed by NBME staff members who were trained domain experts in clinical communication. For each case, 60 responses were randomly selected for annotation development. Initially, five responses per case were independently annotated by three senior and two junior annotators, producing a total of 25 annotations. Annotators then discussed these annotations to resolve disagreements and establish consensus. Following this consensus-building step, annotators independently annotated seven additional responses each,

¹A high-stakes US medical licensure exam, <https://www.usmle.org/>

resulting in 35 annotated responses per case. Finally, a senior annotator reviewed and finalized annotations for all 60 responses per case to ensure consistency and annotation quality. On average, each LP received approximately 45 annotations, with the exact count ranging from 20 to 80 per LP. Overall, approximately 60% of annotations explicitly reflected the targeted LPs. Table 1 summarizes detailed annotation statistics by clinical case.

3 Model Adaptation and Training

We base our automated scoring on ACTA (Yaneva et al., 2024), which uses a DeBERTa-large architecture as a sequence-level classifier for identifying exact spans that reflect targeted Learning Points (LPs) in learner responses. Instead of predicting per-token labels, ACTA is trained to output the character-level start and end of the span corresponding to the LP, given the response and LP description as inputs. Training uses cross-entropy loss over all possible spans.

The original LP descriptions in our rubric were intentionally concise for human annotators (e.g., "Risks of MRI"), but this brevity posed challenges for ACTA's sequence classification architecture, which relies on semantic relationships between LP descriptions and response text. Terse descriptions lack the contextual cues necessary for distinguishing between superficially similar content and actual demonstrations of the targeted behavior. To address this limitation, we expanded LP descriptions to include specific behavioral indicators. For example, "Risks of MRI" became "Risks of MRI: Avoid unnecessary, costly, and risky tests," providing explicit guidance about the communication goal and enabling DeBERTa's attention mechanism to better identify relevant response segments.

We explored two approaches for generating these expanded LP descriptions:

- **ACTA-M (Manual Summaries):** Domain experts manually created enhanced descriptions for LPs with fewer than 20 positive annotations, incorporating clinical expertise to capture nuanced communication behaviors.
- **ACTA-A (Automated Summaries):** We used Qwen2.5-32B-instruct (4-bit) (Bai et al., 2024) to automatically generate augmented LP descriptions by synthesizing patterns from aggregated positive annotations, providing a scalable alternative to manual expansion.

Case ID	One model per case			One model for all cases			LLM scoring

Table 2: Comparison of binary F1 scores for ACTA with original and augmented learning point descriptions (ACTA-A and ACTA-M), and LLM-based scoring (i.e., a few-shot approach).

For evaluation, we employed 5-fold cross-validation at the case level, distributing the 8 clinical cases such that each fold used 6-7 cases for training and 1-2 cases for testing. This ensures the model is evaluated on entirely unseen clinical scenarios. We fine-tuned² DeBERTa-large on each fold’s training data. For automated summaries (ACTA-A), descriptions were generated separately for each fold using only that fold’s training annotations to prevent information leakage.

In addition to these two augmented versions of ACTA, we evaluated two other methods:

- **LLM scoring:** a few-shot scoring approach using large language models (LLMs) to detect learning points directly from learner responses. To evaluate whether few-shot classification could serve as an effective alternative or complement to ACTA without fine-tuning, we experimented with two large language models: Qwen2.5-32B-instruct (4-bit) and GPT-4o (OpenAI, 2024). Qwen was selected due to its instruction-tuning and demonstrated effectiveness in similar instructional tasks. GPT-4o was chosen based on its advanced reasoning capabilities and broad applicability to instructional scenarios (Brown et al., 2020; Wei et al., 2022). These choices align with established best practices in leveraging instruction-tuned language models for few-shot classification tasks. For each Learning Point (LP), the models were prompted with detailed task instructions alongside five positive and five negative examples, following a structured few-shot format designed to encourage consistent performance.

²epochs=10, batch_size=8, learning_rate=2e-5, max_length=256

- **Synthetic responses:** To investigate whether synthetic data can effectively address lower scoring accuracy for Learning Points (LPs) with limited annotations, we supplemented our dataset using synthetic learner responses generated by the Qwen2.5-32B-instruct model. For each LP with sparse annotations, we prompted the LLM with task-specific instructions, definitions of the target LP, and selected positive examples from real learner data. The model then generated realistic synthetic responses explicitly demonstrating the targeted LP. This synthetic dataset augmentation enabled us to expand training data without the cost and time constraints of additional student data collection or manual annotation.

Model evaluation was performed using binary F1 score, measuring accuracy in detecting the presence or absence of communication behaviors.

4 Results

Table 2 summarizes the performance of ACTA using the original learning points compared with augmented descriptions (ACTA-A and ACTA-M) using five-fold cross-validation, as well as results from the few-shot approach using LLM scoring and the use of synthetic responses. Manual summaries (ACTA-M) achieved the highest average binary F1 scores (0.933 for the one-model-per-case setting and 0.939 for the one-model-for-all-cases setting), highlighting the moderate effectiveness of human-crafted augmentation. The automated augmentation approach (ACTA-A) also yielded moderate improvements, indicating its potential as a scalable alternative. LLM-based scoring alone did not improve performance, but it produced results

that were nearly comparable to ACTA (e.g., 0.90 vs. 0.933). We note that this was achieved without the need for extensive data collection or human annotation, aside from the need for annotated data for evaluation purposes.

Finally, the use of synthetic responses led to substantial improvements in scalability. Table 3 shows that training ACTA solely on synthetic data (50 generated examples per case-LP pair) provided only moderate performance gains compared to a simple baseline (0.757 vs. 0.723 average binary F1). However, combining a small amount of real annotated data (15 encounters per case) with synthetic responses significantly improved results (0.878 average binary F1), clearly outperforming models trained only on limited real data (0.793 average binary F1). These results indicate that synthetic responses can effectively reduce the need for human annotation without sacrificing performance.

Performance varied across clinical cases, suggesting the benefit of tailoring augmentation strategies to specific learning point characteristics. We also note the comparability of results from using one model for all cases compared to using one model per case.

5 Error Analysis

We conducted an error analysis to understand the limitations and inform future scoring improvements. The analysis focuses on three perspectives: (1) the relationship between annotation quantity and model performance, (2) specific learning points with low model performance, and (3) cases that showed consistently low performance.

First, we observe a clear relationship between the number of positive annotations per LP and binary F1 scores (see Figure 1). LPs with more than 30 annotations generally achieve binary F1 scores above 0.87, indicating that sufficient annotation quantity is critical for model performance. This threshold is empirically derived by examining the distribution in Figure 1, where performance plateaus become apparent.

Second, to understand LPs with low binary F1 scores (< 0.85), we perform both quantitative and qualitative analyses. A systematic human review is conducted where three annotators independently examine 37 false negatives (instances where ACTA failed to identify an originally annotated LP) and 81 false positives. Among the 35 false negatives with complete reviews, only 51.4% were confirmed

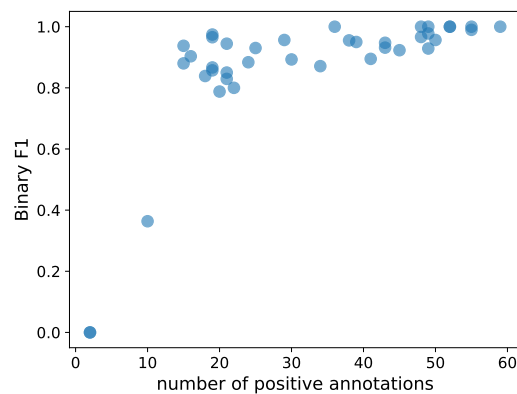

Figure 1: Relationship between the number of positive annotations per learning point and binary F1 score. LPs with more annotations generally achieve higher binary F1 scores. This indicates that sufficient annotations are important for accurate automated scoring.

as true model errors by majority vote, while 48.6% were retrospectively deemed correct predictions by ACTA. This finding reveals that nearly half of apparent model “errors” may actually reflect annotation inconsistencies rather than model failures. The analysis identified three primary factors contributing to lower performance: (1) insufficient positive training examples limiting the model’s exposure to representative spans, (2) inherently ambiguous LP definitions leading to inconsistent interpretations, and (3) the intrinsic subjectivity in identifying nuanced communication behaviors despite our rigorous annotation process.

Third, cases 174 and 176 demonstrated consistently lower performance across multiple LPs. This pattern suggests these cases contain inherently more challenging communication scenarios or LPs that are particularly difficult to identify consistently. This finding emphasizes the need for targeted annotation efforts and potentially refined LP definitions for such challenging cases.

Overall, the error analysis reveals that identifying physician communication behaviors (PCBs) is highly subjective and complex. While our annotation process included consensus-building and final adjudication by senior annotators, the nuanced nature of communication skills—such as distinguishing between implicit and explicit empathy—introduces unavoidable interpretive variation. These findings underscore the importance of sufficient annotation volume and suggest that enhanced annotation guidelines with stricter quality control would be valuable for future iterations.

Case ID	Baseline	50 Synthetic	5 Real + 50 Synthetic	15 Real	15 Real + 50 Synthetic
174	0.712	0.754	0.770	0.763	0.828
175	0.734	0.817	0.855	0.852	0.905
176	0.649	0.684	0.810	0.638	0.861
177	0.813	0.826	0.830	0.900	0.894
178	0.577	0.580	0.732	0.843	0.842
180	0.739	0.812	0.848	0.900	0.909
182	0.841	0.812	0.893	0.743	0.926
192	0.718	0.773	0.823	0.704	0.858
Average	0.723	0.757	0.820	0.793	0.878

Table 3: Binary F1 scores across different training scenarios. **Baseline** assumes every learning point is present (i.e., full recall). **5/15 Real** uses 5 or 15 real annotated encounters per case. **Synthetic** refers to LLM-generated responses (50 per case-LP pair) created using Qwen32B-4bit. Performance is evaluated on real learner responses.

6 Discussion

This study contributes to the ongoing conversation on improving NLP-driven assessment by examining whether data augmentation, few-shot learning, and synthetic data can mitigate the scalability challenges of manual annotation.

Our experiments yielded mixed results. Neither manual (ACTA-M) nor automated (ACTA-A) data augmentation methods showed substantial improvements over the baseline model. Similarly, the few-shot learning models did not outperform the ACTA model. However, the few-shot approach performed almost comparably to the baseline model without the need for extensive data collection or human annotation, which is a significant advantage in scenarios where resources for annotation are limited. A potential explanation for these findings is the relatively small sample size of cases and annotations used, which may have limited the diversity and complexity of the learning points. Moreover, our baseline model—a DeBERTa-based classifier trained with the available annotated data—had already achieved strong F1 scores, reducing the room for significant improvement via augmentation or alternative training strategies.

A key contribution for improving scalability were the synthetic data experiments. Training ACTA exclusively on synthetic responses (generated using Qwen32B-4bit) provided moderate improvements over a naive baseline, indicating synthetic responses alone may be a viable initial training strategy in low-resource settings. However, combining a relatively small set of human-annotated responses with synthetic data significantly increased model performance (average binary F1 from 0.793 to 0.878), clearly demonstrating that synthetic responses can meaningfully reduce the need for extensive manual annotation.

These results suggest that synthetic data is a practical and scalable approach to addressing annotation bottlenecks without sacrificing model accuracy.

Analysis of annotation density (Figure 1) further reaffirmed that performance improves with an increasing number of positive annotations per LP, highlighting the importance of targeted annotation efforts. Additionally, the comparable results from case-specific models and general models suggest that unified modeling strategies may be viable.

7 Limitations

Some limitations of this research stem from the small sample size of annotated responses, and the small number of vignettes. Additionally, resource constraints prevented all responses from being double-rated. While the scoring method remains interpretable by linking LPs to specific phrases in the responses, the neural models used to define phrase boundaries operate as black boxes and require careful evaluation for potential bias.

Although the few-shot LLM-based scoring approach demonstrates promising generalization without explicit fine-tuning, it shows limitations compared to ACTA models. Specifically, few-shot methods heavily depend on prompt quality and the selection of examples provided, making their performance less consistent and potentially sensitive to minor changes in prompt design. Furthermore, few-shot predictions inherently offer lower interpretability than token-level classifiers like ACTA, as LLM decisions emerge directly from prompt conditioning without explicit textual evidence or intermediate classification steps. This reduced transparency can limit their practical usefulness, especially in educational contexts where detailed feedback and justification of model predictions are often necessary. Further research is needed to investigate the

varying levels of risk that the lower explainability of few-shot learning models presents across different assessment domains. These risks can be better understood and mitigated through additional evaluation studies that provide more evidence on how to address potential concerns.

Likewise, the addition of synthetic data for training purposes needs to be carefully evaluated using a high-quality dataset of carefully annotated real learner responses. We note that while synthetic data can meaningfully reduce the need for data collection and human annotation, it cannot fully replace that need as such data will always be needed for a robust evaluation of any scoring system.

8 Ethical Considerations

Like many other products, automated scoring tools function as socio-technical systems, where their impact depends not only on their technical capabilities but also on how they are used and how their outputs are interpreted. Below, we outline specific aspects of the use of this system in different contexts that merit discussion of ethical implications.

In a summative assessment context, the models outlined here are designed as hybrid systems, ensuring that responses from examinees who are borderline or below the passing threshold are always reviewed by human raters. In a formative setting, it is essential to closely analyze how the system's implementation affects learning outcomes, offering critical validity evidence. This includes determining whether automated feedback aids or obstructs skill development, how examinees engage with the feedback, and whether the reliance on automated scoring impacts learning strategies over time. In the case of formative assessment, which is the primary purpose of the CLA tool, a possible negative consequence could also be "washback"—a focus on developing only the skills directly addressed by the tool. It is also crucial to evaluate whether specific learner groups benefit more than others and to identify any unintended effects, such as overdependence on the system or reinforcement of existing biases. A comprehensive exploration of these factors will help ensure that automated scoring systems function as valuable educational tools, rather than mechanical evaluation devices.

The scores provided by the automated scoring engine are currently in their raw form and have not yet been converted into feedback for students or faculty. This transformation into actionable feed-

back is a crucial step because raw scores alone do not provide the necessary context or guidance for improving performance. For students, feedback is essential to understand their strengths and weaknesses, guiding them on how to improve and which areas to focus on. Without clear, specific feedback, students may struggle to make meaningful improvements, as they may not fully understand the implications of their scores or how to address their performance gaps. For faculty, the feedback generated from the automated scores can provide valuable insights into student progress, helping instructors identify areas where students may be struggling, and informing instructional adjustments. This step also allows faculty to engage with the results in a more meaningful way, facilitating a deeper understanding of the learning process and ensuring that the assessment tools align with educational goals. Therefore, transforming raw scores into detailed, constructive feedback is vital to ensure that the automated scoring system contributes effectively to the learning process and supports both student development and instructional improvements.

Decoding Actionability: A Computational Analysis of Teacher Observation Feedback

Mayank Sharma

Abstract

This study presents a computational analysis to classify actionability in teacher feedback. We fine-tuned a RoBERTa model on 662 manually annotated feedback examples from West African classrooms, achieving strong classification performance (accuracy = 0.94, precision = 0.90, recall = 0.96, f1 = 0.93). This enabled classification of over 12,000 feedback instances. A comparison of linguistic features indicated that actionable feedback was associated with lower word count but higher readability, greater lexical diversity, and more modifier usage. These findings suggest that concise, accessible language with precise descriptive terms may be more actionable for teachers. Our results support focusing on clarity in teacher observation protocols while demonstrating the potential of computational approaches in analyzing educational feedback at scale.

1 Introduction

Classroom observation plays a crucial role in evaluating and enhancing instructional quality (Adelman and Walker, 1975; Wragg, 2011). By offering a direct perspective on teaching in authentic settings, it provides insights into how educators engage with students and structure their instruction (Millman and Darling-Hammond, 1990; Putnam and Borko, 2000). It also serves as a vital link between teaching practices and student learning outcomes, thus creating the foundation for teacher professional development (Kane and Staiger, 2012).

Given this significance, the quality of feedback derived from classroom observations is essential (Lazarev and Newman, 2015). While various characteristics contribute to effective feedback, including constructive tone and clarity, research emphasizes that specificity and actionability are particularly crucial for enhancing teacher performance (Archer et al., 2016). Truly actionable feedback provides specific recommendations and clear di-

rection, establishing concrete performance expectations and supporting professional growth (Cannon and Witherspoon, 2005). By focusing on observable teaching behaviors rather than personal attributes, such feedback enables meaningful instructional improvements (Archer et al., 2016).

Although research on actionable feedback originated largely outside education, its principles have proven directly applicable to classroom contexts. In organizational psychology, Cannon and Witherspoon (2005) identified key elements of actionable feedback: specificity, balanced positive and constructive components, and clear connections between observed behaviors and suggested improvements. This aligned with Kluger and DeNisi (1996)'s comprehensive meta-analysis of over 3,000 feedback interventions, which found that feedback effectiveness varies dramatically based on specificity and delivery characteristics. Within education-specific research, multiple studies have confirmed and extended these general principles. For example, Allen et al. (2011) demonstrated that structured feedback systems yield measurable improvements in teaching quality. Similarly, Thurlings et al. (2013) found that effective teacher feedback typically contains explicit behavioral descriptions, rationales for suggested changes, and concrete examples of alternative approaches. Quantitative evidence from Steinberg and Sartain (2015)'s analysis of over 12,000 teacher observation records showed that feedback incorporating concrete examples and precise language led to measurable gains in subsequent evaluations. In a similar way, Hill et al. (2012) established that feedback quality directly correlates with improvements in instructional practice, particularly when including specific action steps. In fact, Darling-Hammond et al. (2017)'s work on professional development systems reinforces the critical role of actionable feedback as a bridge between observation and implementation.

Despite the importance of actionable feedback, classroom observers often struggle to provide guidance that teachers can readily implement (Kraft et al., 2018). This implementation gap stems from inconsistent understanding of what constitutes actionable feedback and the absence of systematic approaches to analyze feedback quality at scale. Computational approaches offer promising avenues for analyzing observation feedback and identifying patterns in actionable feedback. However, applying these methods to classroom observation requires addressing how actionability can be computationally defined and recognized. Our research bridges educational theory and computational methods to develop methods that can meaningfully evaluate the actionability of teacher feedback.

2 Prior Work

While we were not able to identify any existing studies specifically focused on using NLP approaches to identify actionable teacher feedback, adjacent educational research provides relevant context for our work. In the domain of classroom observation, Demszky et al. (2021) analyzed linguistic features in teacher speech to evaluate instructional effectiveness. Similarly, Suresh et al. (2019) examined different dimensions of teacher feedback, though their work did not address actionability specifically. Beyond teacher-focused research, computational analyses of student-centered feedback have shown promising results. Leeman-Munk et al. (2014) developed methods to evaluate student writing and identify improvement areas, while Madnani et al. (2017) created models for standardized writing assessments that demonstrated reliability comparable to human raters.

The emergence of large language models (LLMs) has also sparked interest in their potential for educational annotation and classification tasks. However, Wang et al. (2023) found that models like GPT struggled to accurately classify nuanced educational distinctions. This aligns with Hardy (2025)’s assertion that classroom settings represent “out-of-distribution” data for LLMs, which are primarily trained on broad internet crawls. Additionally, concerns about data privacy, environmental impact, and the ethics of automated educational assessments complicate their use in education. In contrast, specialized transformer-based models offer more promising results for educational applications. Research indicates that models such as BERT (De-

vlin et al., 2019) and RoBERTa (Liu et al., 2019), when properly trained on educational data, can outperform larger LLMs in classifying teacher-student interactions (Wang et al., 2023). Zhang and Litman (2021) demonstrated that these models can be trained on modest amounts of annotated educational data while maintaining strong performance, making them more practical for applications where annotated data may be limited.

Our Study

Despite substantial research on the importance of actionable feedback, computational approaches for identifying actionability in teacher observation feedback remain largely unexplored. This gap appears to exist primarily because of: (1) the lack of clear, consensus definitions of “actionability” in educational contexts; and (2) the scarcity of annotated datasets, as creating these typically requires time-consuming and resource-intensive manual annotation by educational experts (Shah and Pabel, 2019; Shaik et al., 2022).

Our study addresses these gaps through a novel approach where we first established a training dataset by annotation of approximately 660 instances of classroom observation feedback as either actionable or vague. Using this annotated corpus, we fine-tuned RoBERTa to extend this classification to a much larger dataset of over 12,000 feedback instances. With this comprehensive dataset, we conducted an examination of the linguistic features associated with actionability. These findings hold potential to inform the training of classroom observers, guide the development of automated feedback assessment tools, and help improve teacher professional development.

3 Data

This study utilized a large-scale dataset collected from classrooms in Sierra Leone, Liberia, and Ghana by Rising Academies during 2023-2025. The dataset includes $N = 13,118$ classroom observation records, each documenting teacher feedback provided by trained observers. Descriptive statistics on the schools, grades and subjects from which these observations were sourced are presented in Table 1. As shown, the observations come from 273 schools (approx. 48 observations/school) and were recorded by 76 observers (approx. 173 observations/observer).

Each observation was recorded using a struc-

Table 1: Descriptive statistics on observations. *Note.* For the purposes of this study, data from Grades 1-6 and 4 subjects: Reading, Math, Faster Reading, and Faster Math, were selected. Faster Reading and Faster Math are accelerated learning programs designed to supplement regular school curricula ($N = 13118$)

tured two-column format that included: (1) *What Went Well* (WWW) statements, which highlighted teacher strengths or effective strategies, and (2) *Even Better If* (EBI) suggestions, aimed at guiding improvements in teaching practices. As shown in the distribution in Figure 1, the average feedback length was 16.95 words ($SD = 10.83$). While the feedback length was relatively short, there was significant variation in its detail and clarity, ranging from broad praise/criticism to more specific recommendations. Due to the short length, no textual preprocessing was applied.

4 Methods

We organized our study into five sequential phases (visualized in Figure 2):

Figure 1: Probability density distribution of feedback length (in words; $N = 13118$)

Phase 1: Annotation and rubric development

In this phase, we developed a training dataset for fine-tuning RoBERTa through a rigorous annotation process. A stratified subsample of 750 comments was selected across multiple dimensions (school categories, grade levels, and subject areas) to ensure representativeness. Two independent researchers annotated each observation feedback according to a standardized rubric derived from established literature (see Appendix A for details), classifying comments as either “actionable” or “vague.” This dual-annotation approach facilitated the calculation of inter-rater reliability using Cohen’s Kappa (κ), yielding a coefficient of 0.60, which indicated moderate agreement.

Discrepancies were methodically resolved through iterative analytical discussions, which simultaneously informed the refinement of our annotation protocol, culminating in the revised rubric presented in Appendix A. The operationalization of “actionable” feedback centered on the presence of concrete, specific suggestions with explicit guidance on both implementation targets and mechanisms. For instance, the comment “*The teacher did great grouping learners and made them pick one word on a flash card where the group later leads in learning the new word. It would be better if the teacher completed the lesson in one hour to allow time for other lessons*” exemplified actionable feedback due to its specific temporal recommendation and clear rationale. Conversely, feedback was classified as “vague” when it lacked implementation specificity, regardless of the presence of ostensibly directive phrases such as “*even better if*” or “*could have.*” The comment “*Giving more energy to make the class exciting was absolutely missing*” illustrates this classification, as it presents an evaluative

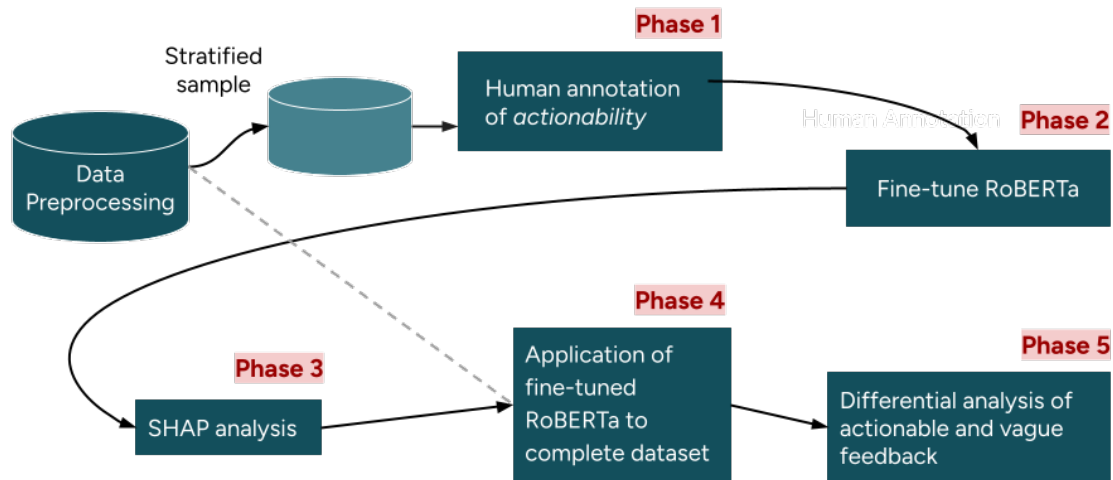

Figure 2: Flow chart for the study

statement without concrete behavioral specifications for improvement. We also excluded instances lacking sufficient evaluative clarity, resulting in a final annotated corpus of 662 comments (reduced from the initial 750). This dataset served as the training corpus for the next phase.

Phase 2: Fine-tuning RoBERTa on the annotated dataset

Model Specification

We fine-tuned RoBERTa (Liu et al., 2019) (using Hugging Face’s `roberta-base`¹) on our annotated dataset. An input token length of 512 was selected for the textual embeddings, with truncation and padding applied as needed. This vector was thresholded using `threshold=0.6` to produce the output vector. We chose this value to prioritize precision over recall, as our context requires high-confidence predictions of actionability rather than maximizing the identification of all potentially actionable feedback.

Training

The model was trained on a T4 GPU via Google Colab² using adam optimizer with `learning_rate=2e-5` with `linear_decay` of 0.01. For training, a `batch_size=16` was cho-

¹Available at <https://huggingface.co/FacebookAI/roberta-base>

²Available at <https://colab.research.google.com/>

sen, while `batch_size=32` was chosen for evaluation, keeping in mind compute bandwidths. We trained the model for 5 epochs and reported results from epoch 3 as the final epoch because model performance degraded afterward. The standard cross-entropy loss function was chosen (default for `roberta-base`).

Evaluation

To evaluate the model’s performance, we used a held-out test set comprising 20% of the total dataset. The assessment was based on standard classification metrics: accuracy, precision, recall, and f1-score.

Phase 3: SHAP analysis

To gain deeper insights into the textual features driving our model’s decisions, we employed SHapley Additive exPlanations (SHAP) analysis (Lundberg and Lee, 2017). This model-agnostic technique provides interpretability by attributing prediction outcomes to specific input features; in this study, words and phrases within the observation comments.

Recent work by Benslimane et al. (2024) validated SHAP’s effectiveness for analyzing short, informal texts, demonstrating its reliability in identifying semantic patterns including emotional tone, gender references, and political language. Building on this empirical evidence, we applied SHAP to analyze 500 teacher feedback instances (250 ac-

tionable, 250 vague) and quantified each token's influence on model classification decisions. To identify consistent patterns, we aggregated SHAP values by unique tokens, calculated mean importance scores across all samples, and ranked terms according to their average contribution to classification outcomes.

Phase 4: Application of fine-tuned RoBERTa to the complete dataset

We utilized our fine-tuned RoBERTa model to categorize the rest of the observations as “vague” or “actionable.” The model from the best-performing cross-validation fold was selected and used to make these predictions. A custom PyTorch Dataset class was implemented, which tokenized input text using the RoBERTa tokenizer with a maximum sequence length of 512. Tokenized inputs were converted into tensors with appropriate attention masks. To ensure computational efficiency, batch predictions (with `batch_size=32`) were performed using PyTorch's DataLoader. For each batch, input tensors were used to extract logits. From these logits, class predictions were obtained using the `argmax` function, and class probabilities using the `softmax` function. Instances with `softmax` probabilities less than 0.90 were classified as “low probability” instances and removed from the dataset.

Phase 5: Differential Analysis of Actionable and Vague Feedback

In this step, we extracted several linguistic features known to be associated with text clarity, specificity, and directiveness. These features were selected to potentially distinguish actionable observations from vague observations classified in the last step:

1. **Word Count:** We calculated the total number of words in each observation using NLTK's word tokenization. Previous research suggests that actionable feedback tends to be more detailed, which could potentially result in higher word counts that provide implementable information (Winstone et al., 2016).
2. **Reading Ease:** We calculated Flesch reading ease using `textstat`. In this metric, the readability of the observation was scored on a 100-point scale, with higher scores indicating easier reading (Flesch, 1948). More accessible language may correlate with feedback that can be readily understood and implemented. Previous work has demonstrated that Flesch

Reading Ease can be effectively used with short-form textual data such as tweets, and can enable robust analysis of readability even in brief, informal text (Davenport and DeLine, 2014).

3. **Lexical Diversity:** This was calculated using NLTK's word tokenization as the ratio of unique words to total words in the observation text. Higher lexical diversity may indicate more specific feedback, potentially offering clearer guidance for action. Conversely, excessive diversity might introduce complexity that reduces actionability.
4. **Modifier Count:** This was calculated by counting modifiers (adjectives and adverbs) in the observations using spaCy's POS tagger. Higher modifier counts might indicate more descriptive or qualifying language, which could potentially correlate with either actionability.

We ran a logistic regression model that included the linguistic features as predictors and feedback category as the outcome to examine the odds ratio for the categories.

The code used in the study is available on a publicly accessible [GitHub repository](#).

5 Results and Discussion

In this section, we present results from Phases 2-5, as Phase 1 has already been described completely in the Methods section.

Phase 2: Fine-tuning RoBERTa on the annotated dataset

Fine-tuned RoBERTa demonstrated strong and stable performance in distinguishing actionable from vague teacher feedback. Using stratified 5-fold cross-validation on 662 annotated examples, the model achieved a mean accuracy of 0.94, precision of 0.90, recall of 0.96, and f1 of 0.93 across folds, with an F1 standard deviation of 0.03. These metrics reflect performance on held-out validation sets and suggest the model generalizes well despite the modest dataset size. This aligns with findings by Zhang and Litman (2021) that well-curated educational data, even in small quantities, can yield high-performing models when paired with appropriate architectures.

Overfitting was monitored via 5-fold cross-validation and early stopping. The model showed

consistently high validation performance (mean F1 = 0.93, SD = 0.03), with no signs of overfitting.

Phase 3: SHAP analysis

Table 2 presents the top 20 most influential words for actionable and vague feedback based on SHAP analysis (positive values indicate features associated with “actionable” class, while negative values indicate association with “vague” class). The results provide mixed evidence without clear-cut patterns. While some action verbs and specific instructional behaviors (e.g., “struggled,” “checks,” “encourages,” “provide”) appear in the actionable feedback category, and certain comparative and conditional terms (“whether,” “enough,” “instead”) appear in the vague feedback category, the overall linguistic distinctions lack sufficient consistency to draw definitive conclusions. The absence of strong patterns suggests that actionability may be determined by relationship between words rather than individual word choices alone.

Actionable Feedback		Vague Feedback	
Word	SHAP Value	Word	SHAP Value
struggled	0.055	sa	-0.051
checks	0.052	equal	-0.025

Table 2: Top 20 most important words for feedback classification with their SHAP values.

Phase 4: Application of fine-tuned RoBERTa to the complete dataset

“Low probability” predictions constituted about 329 observations (2.5%) of the total data. After their removal, distribution in the complete dataset was as follows: 52.7% (or $n = 6741$) classified as “vague”, and 47.3% (or $n = 6048$) as “actionable.”

Phase 5: Differential Analysis of Actionable and Vague Feedback

Logistic regression analysis (Table 3 and Figure 3) revealed several significant associations between linguistic features and feedback actionability. Word count showed a strong negative relationship with actionability ($-16.637, p < .001$), indicating shorter feedback was more likely classified as actionable, contrary to our proposed hypothesis.

Flesch Reading Ease demonstrated a strong positive association with actionability ($11.751, p < .001$), suggesting more readable feedback was more likely to be actionable, aligning with our hypothesis about language complexity.

Lexical diversity showed a moderate positive association ($0.418, p < .001$, odds ratio = 1.52), with more varied vocabulary correlating with actionability. Similarly, modifier count had a significant positive relationship ($0.187, p < .001$, odds ratio = 1.21), suggesting adjectives and adverbs may help describe teaching behaviors with needed precision.

Overall, the model showed a pseudo R^2 of 0.159, accuracy of 0.68, precision of 0.70 (actionable), recall of 0.58, F1-score of 0.63, and an AUC-ROC of 0.76.

6 Conclusion

Our study provides empirical support for computational approaches to analyzing actionable teacher feedback. The high performance of our fine-tuned RoBERTa model (accuracy = 0.94, precision = 0.90, recall = 0.96, $f1 = 0.93$) demonstrates that RoBERTa can effectively distinguish between actionable and vague feedback, even with a relatively modest training dataset of 662 annotated examples.

The SHAP analysis revealed several interesting patterns in the linguistic features associated with actionable feedback. Action verbs (e.g., “struggled,” “checks,” “encourages”) and specific instructional behaviors appeared more frequently in actionable feedback, while comparative and conditional language (e.g., “whether,” “enough,” “instead”) was more characteristic of vague feedback. However, these patterns were not uniformly consistent, suggesting that actionability may be determined more by the relationships between words and phrases rather than by individual word choices alone.

An analysis of linguistic features suggested that contrary to our initial expectations, word count showed a significant negative relationship with actionability, indicating that shorter feedback was

Feature	Coefficient	Std Error	Odds Ratio
Word Count	-16.637***	1.510	5.95×10^{-8}
Flesch Reading Ease	11.751***	1.013	1.3×10^5
Lexical Diversity	0.418***	0.029	1.52
Modifier Count	0.187***	0.033	1.21

Table 3: Results of logistic regression predicting feedback actionability (*** $p < .001$)

Figure 3: Odds ratios for predictors of actionable feedback

more likely to be classified as actionable. This finding challenges the common assumption that more detailed feedback is necessarily more actionable. It suggests that concision may actually enhance clarity and implementability—verbose feedback might obscure key action points with extraneous information.

The positive association between Flesch Reading Ease and actionability aligns with our hypothesis that more readable feedback is more actionable. This finding indicates that accessible language is crucial for feedback that can be readily understood and implemented.

Our findings suggest three practical implications for teacher professional development. First, our study suggests that concise, readable feedback with precise descriptive language could enhance actionability of feedback given by observers. Second, training programs for classroom observers could benefit from incorporating linguistic guidelines that emphasize readability, appropriate lexical diversity, and effective use of modifiers to enhance feedback actionability. Third, computational approaches like our RoBERTa model could serve as supportive tools for observers to assess and potentially improve the actionability of their feedback before

sharing it with teachers, though such applications should complement rather than replace human judgment.

7 Limitations and Future Work

This study has several limitations that point to directions for future research. While our RoBERTa model performed strongly even with 662 annotated examples, the relatively small training set still poses challenges for generalizability. Its success reflects the effectiveness of fine-tuning on well-curated educational data, but broader representation across feedback styles, school contexts, and observer types would strengthen model robustness and reduce the risk of overfitting.

Second, the scope of this study was limited to early primary classrooms (Grades 1–6) and core subjects (English and Math) in a specific cultural setting. Findings may not fully generalize to other grade levels, subjects, or educational systems. Additionally, because the model was trained on English-language feedback, linguistic and cultural differences in how actionability is expressed remain underexplored.

Third, while SHAP analysis revealed some useful patterns, many influential words, especially

in vague feedback, were ambiguous or context-dependent, highlighting the challenge of capturing actionability through isolated word-level features.

Finally, our binary classification approach, while practical, likely oversimplifies the feedback quality spectrum. Actionability may be better understood as a continuum (from highly vague to highly specific). A multi-point ordinal scale (e.g., 5–7 categories) could offer more granular insights, especially for training observers or improving vague feedback. Moving to such a framework would require more complex annotation protocols, higher inter-rater alignment, and substantially larger datasets—but the added nuance may justify this investment by producing models that offer not just detection, but actionable guidance.

Future work should: (1) expand annotations across more diverse educational contexts, (2) test cross-cultural variation in feedback actionability, and (3) explore methods for refining or rewriting vague comments into actionable ones to support professional development more directly.

Acknowledgments

We are deeply grateful to Francisco Carballo Santiago from Rising Academies for providing us with this dataset and assisting in our initial exploration. We also extend our thanks to Sanne Smith and Michael Hardy for their invaluable insights into our research questions, figures, tables, and early drafts of the paper. Finally, we thank our peers for their participation in peer review sessions, which significantly contributed to strengthening our study.

Ethics Statement

Potential Misuse: Our model could be misused in high-stakes evaluations, leading to the automated assessment of observer performance without appropriate human oversight. We explicitly discourage such use and advocate for responsible deployment. **Privacy Considerations:** Implementing this technology would require strict privacy protocols to protect teacher identities. Observation data should be de-identified before being fed into the model to ensure confidentiality.

Feedback Type	Rubric
Actionable	<ul style="list-style-type: none">• Provides clear and specific suggestions for improvement (Archer et al., 2016; Cannon and Witherspoon, 2005)• Offers explicit guidance on:<ul style="list-style-type: none">– <i>What</i> the teacher should do next– <i>How</i> the suggested change can be implemented• Focuses on observable behaviors rather than personality traits (Archer et al., 2016)• Establishes clear connections between observed behaviors and suggested improvements (Cannon and Witherspoon, 2005)• Provides balanced positive and constructive components (Cannon and Witherspoon, 2005)• May or may not contain indicative phrases (e.g., “<i>even better if</i>,” “<i>could have</i>”); presence of such phrases is not required• Includes concrete examples of alternative approaches
Vague	<ul style="list-style-type: none">• Lacks concrete or specific suggestions for improvement (Archer et al., 2016)• Fails to provide clear guidance on implementation steps (Kraft et al., 2018)• May focus on general impressions rather than specific teaching behaviors (Archer et al., 2016)• Lacks explicit connection between observation and suggested change (Cannon and Witherspoon, 2005)• Provides limited or no concrete examples of alternative approaches• May use evaluative language without actionable direction (Allen et al., 2011)• May include general phrases (e.g., “<i>even better if</i>,” “<i>could have</i>”), but their presence does not ensure clarity; feedback is considered vague if the intended action or direction remains ambiguous or insufficiently specified

EduCSW: Building a Mandarin-English Code-Switched Generation Pipeline for Computer Science Learning

Ruishi Chen*
Stanford University
ruishich@stanford.edu

Yiling Zhao*
Stanford University
ylzhao@stanford.edu

Abstract

This paper presents *EduCSW*, a novel pipeline for generating Mandarin-English code-switched text to support AI-powered educational tools that adapt computer science instruction to learners’ language proficiency through mixed-language delivery. To address the scarcity of code-mixed datasets, we propose an encoder-decoder architecture that generates natural code-switched text using only minimal existing code-mixed examples and parallel corpora. Evaluated on a corpus curated for computer science education, human annotators rated 60–64% of our model’s outputs as natural, significantly outperforming both a baseline fine-tuned neural machine translation (NMT) model (22–24%) and the DeepSeek-R1 model (34–44%). The generated text achieves a Code-Mixing Index (CMI) of 25.28%, aligning with patterns observed in spontaneous Mandarin-English code-switching. Designed to be generalizable across language pairs and domains, this pipeline lays the groundwork for generating training data to support the development of educational tools with dynamic code-switching capabilities.

1 Introduction

Code-switching (CSW), the practice of alternating between two or more languages within an utterance or conversation, is prevalent across diverse settings and multilingual communities (Gardner-Chloros, 2009; Poplack, 2001). Prior research has shown that CSW enables language learners to express their perspectives, convey culturally specific ideas, and build social relationships (Bhatia and Ritchie, 2006). In educational contexts, CSW has been found to enhance student engagement and help teachers clarify complex concepts, making it a valuable pedagogical strategy in multilingual classrooms (Sakaria and Priyana, 2018).

Despite its demonstrated benefits, support for code-mixing in educational tools remains limited (Yong et al., 2023). This gap is particularly pronounced in computer science education, where much of the terminology originates in English (Foote, 2023). For English-as-a-second-language learners, especially Chinese students pursuing studies abroad, this creates a dual challenge: mastering both general English and domain-specific vocabulary needed to comprehend technical content and participate in academic discourse.

Recent advances in large language models (LLMs) and speech recognition have shown potential in addressing challenges in CSW research (Giattino et al., 2023). While efforts have been made in speech translation for code-switched recognition (Alastruey et al., 2023; Wang and Li, 2023) and decoding code-mixed text (Sterner and Teufel, 2023), progress remains hindered by several issues. Studies reveal that even advanced multilingual LLMs struggle to produce natural code-switched text, often defaulting to full translation instead of authentically mixing languages (Kaji and Shah, 2023). This limitation stems from training predominantly on monolingual datasets, rather than natural code-switched corpora (Zhang et al., 2023). Moreover, challenges such as limited availability of code-mixed textual data, grammatical complexity, and domain mismatch further restrict development (Hussein et al., 2023). In particular, the lack of publicly available Mandarin-English code-mixed datasets impedes the creation of LLM-powered educational tools that support CSW.

To address these challenges, our work makes two primary contributions to CSW research. First, we introduce a generalizable pipeline for code-mixed data generation that can be adapted to various language pairs and subject domains. Second, we demonstrate its effectiveness by curating a domain-specific dataset for computer science education, focused on Chinese students studying at English-

*Equal contribution.

medium universities. This implementation lays the foundation for developing AI-powered tutoring systems that dynamically incorporate code-switching to support learners' acquisition of English technical language.

2 Related Work

2.1 Code-switching Background

CSW research has a relatively long history, dating back to the early 1900s (Winata et al., 2023). As the field evolved, advancements in machine learning, particularly deep learning (Gupta et al., 2020), have enabled more effective methods for both curating CSW datasets and managing various CSW tasks (Yong et al., 2023). However, the field faces considerable challenges, notably the scarcity of publicly available CSW datasets (Pratapa et al., 2018; Winata et al., 2023). Additionally, formal records of CSW texts are limited, and a significant portion of existing data is private or restricted, making it difficult to evaluate models and expand CSW research into new languages and contexts. These limitations hinder the diversification of CSW tasks and slow progress in generating comprehensive multilingual datasets.

Studies have attempted to identify key linguistic features in CSW with the goal of generating synthetic CSW data to address various challenges. Prior research has highlighted the Equivalence Constraint theory, which suggests that CSW occurs when the grammatical rules of all involved languages are maintained in a given sentence (Winata et al., 2023; Deuchar, 2020). Other works have identified the Matrix Language Frame (MLF) model (Myers-Scotton, 2001), which posits the existence of a dominant "matrix" language providing the grammatical structure, while the "embedded" language contributes additional content. This model has been proven successful in preserving syntactic features and grammatical structures from the matrix language (Callahan, 2002; Deuchar, 2006; Rahimi and Dabaghi, 2013).

2.2 Code-switching in Education

Most of the research has focused on the use of CSW in bilingual-classroom settings, suggesting its potential in enhancing instruction across subjects and improving classroom engagement. Sakaria and Priyana have identified that the use of code-switched instructional language can increase the efficiency in delivering lesson objectives and pro-

vide a theoretical framework (Sakaria and Priyana, 2018). Meanwhile, Milroy et al. also proposed that the use of code-switching can help teachers shape classroom culture, fostering different teacher-student relationships in the classroom environment (Milroy and Muysken, 1995). For instance, when teachers use the students' first language in instruction, it creates a playful and less formal environment. When the teachers switch back to the language the students are learning in that session, they reassert their authority and thus redefine the situation to be more formal.

These studies reveal the multifaceted benefits of code-switching, providing greater motivation for us to empower education by addressing the data scarcity issues in this field.

2.3 Algorithmic Solutions to Generating Code-mixed Data

Prior studies have adopted various linguistic theories and advanced language models to address the challenges in generating code-mixed texts, each reflecting distinct emphases.

For instance, Pratapa et al. (Pratapa et al., 2018) employed equivalence constraint theory, focusing on syntactic compatibility at switch points where language structures coincide. They used projections of parallel monolingual sentences to generate grammatically valid code-mixed sentences. Gupta et al. (Gupta et al., 2020) applied the Matrix Language Frame (MLF) theory, emphasizing the role of a dominant language in structuring code-mixed sentences. Tarunesh et al. (Tarunesh et al., 2021) utilized the Embedded Matrix Theory (EMT), a variation of MLF, applying clause substitution methods to create code-mixed text that satisfies Hindi-English grammatical structures.

For code-mixed data evaluation, prior scholars have proved the efficiency in various methods when assessing the naturalness of code-mixed data. Pratapa et al. (Pratapa et al., 2018) primarily assessed perplexity reductions on real code-mixed test sets using their RNN language model, which was trained on various combinations of monolingual, synthetic, and real code-mixed data. In contrast, Gupta et al. (Gupta et al., 2020) employed more direct metrics such as BiLingual Evaluation Understudy (BLEU) (Papineni et al., 2001), ROUGE (Lin and Hovy, 2002), and METEOR (Lavie and Agarwal, 2007), along with human evaluation to assess the syntactic and semantic correctness, and natural-

ness of the generated code-mixed sentences. These diverse approaches guided our team in developing appropriate validation methods for our generated synthetic texts.

3 Method

This section outlines the data source utilized for this project and then presents the generalizable code-switched generation pipeline (see Appendix A.1 for more details). The repository is publicly available¹.

3.1 Data

A representative Mandarin-English code-mixed dataset for computer science education must possess two essential characteristics.

First, the dataset should accurately represent instructional language and encompass educational materials in computer science. This provides a domain-specific context that can shape the generated code-mixed corpus to offer effective and specific support for computer science instruction.

Second, the corpus should align with how bilingual users naturally develop and use code-mixed content in educational and daily contexts. This naturalness is critical as it ensures the code-mixed text authentically reflects the language patterns observed in real-world bilingual educational settings.

Accordingly, we utilize two datasets that satisfy the above criteria in our project: a Mandarin dataset capturing domain-specific computer science instructional content, and a second dataset reflecting spontaneous code-mixing patterns in Mandarin-English speakers’ daily communication.

3.1.1 Computer Science Instruction Dataset

This study incorporates the Hugging Face dataset `2imi9/llama2_7B_data_10G`, which contains ten gigabytes of bilingual text data sourced from Hugging Face and the Chinese Software Developer Network (CSDN), covering technical instructions in computer science. The dataset was carefully curated to support the development of AI-powered educational tools for personalized learning in Shenzhen University’s *University Computer* course. It includes a column of conceptual questions (“Instruction”) and serves as the primary input for generating code-mixed representations in this study. Due to computational constraints, we used a subset of this dataset containing 744 technical instructions for computer science (file name:

¹<https://github.com/RuishiCh-git/EduCSW/tree/main>

`data_alpaca_standardized_data`), which captures common questions and explanations of key computer science terminology.

Instruction

Table 1: Sample Data Entries (The parentheses contain translations, not part of the data.)

3.1.2 Spontaneous Mandarin-English Code-Mixed Dataset

To train our model on real CSW data, we incorporated the speech transcription dataset `CAiRE/ASCEND` (Lovenia et al., 2022)² into our pipeline. We filtered the original training dataset to retain only code-mixed text, resulting in 2,739 code-mixed utterances used in this study. This subset provides a Mandarin-English code-switching corpus that reflects authentic code-switched language patterns in bilingual speakers’ habits. Sample code-mixed transcriptions from this dataset are shown in Table 2.

Table 2: Sample Mandarin-English code-mixed data (The parentheses contain translations, not part of the data.)

3.2 Pipeline

Overall, the code-mixed text generation included three key stages: the *Preparation* stage, the *Code-mixed generation* stage, and the *Evaluation* stage.

²ASCEND (A Spontaneous Chinese-English Dataset) is a spontaneous multi-turn conversational dialogue recorded in Hong Kong.

3.2.1 Preparation Stage

The preparation stage includes three major steps: parallel corpus preparation, language alignment, and hard-coded code-mixed data generation.

Firstly, the machine translation model Helsinki-NLP/opus-mt-zh-en (Tiedemann and Thottingal, 2020)³ was used to obtain the corresponding English corpus for the Mandarin computer science instruction dataset.

Secondly, the word aligner awesome-align (Dou and Neubig, 2021) was employed to create an alignment matrix for the parallel corpus. The input consists of parallel sentences separated by “|||”, and the output is in the i-j Pharaoh format. A pair i-j indicates that the i-th word (zero-indexed) of the source sentence (Mandarin) is aligned to the j-th word of the target sentence (English). An example is shown in Appendix A.2.

Thirdly, a BERT-based Named Entity model and the *jieba* module were used to tokenize and extract linguistic features and tags from English and Mandarin corpus. The Matrix Language Frame (MLF)⁴ was followed to generate code-switched text (Myers-Scotton, 2002). In this study, Mandarin serves as the matrix language dominating the sentence, while English is the embedded language inserted into the sentence. Named entities (NE), noun phrases (NP), and adjectives (ADJ) in the English sentence were identified as candidate words/phrases for insertion into the Chinese sentence.

For each candidate word/phrase, the language switch-point was determined based on the POS tag and position in the sentence. Insertion probabilities were set to 20% - 30% to achieve an observed code-mixing index (CMI) consistent with natural code-mixed utterances, based on prior literature (Li et al., 2012). If a switch was decided, the English word/phrase was inserted into the corresponding position in the Mandarin sentence. The resulting dataset was used as the first round of “hard-coded” CSW data.

³This model was developed by the Language Technology Research Group at the University of Helsinki and is designed to translate from Chinese (source language) to English (target language).

⁴MLF, proposed by Myers-Scotton, introduced the “asymmetry principle,” where the language providing the morphosyntactic structure is the “matrix language,” while the “embedded language” contributes elements that switch into the matrix language (Myers-Scotton, 2002)

3.2.2 Code-Mixed Generation Model

We experimented with three approaches for code-mixed data generation. The first approach extends a neural machine translation (NMT) model, serving as a baseline for comparison. The second uses the DeepSeek-R1 model to establish a benchmark performance. The third, and our primary contribution, is a custom encoder-decoder architecture designed specifically for generating natural code-switched text.

Approach 1: Fine-tuning NMT For the Neural Machine Translation (NMT) fine-tuning approach, we used the Helsinki-NLP/opus-mt-zh-en model⁵, originally designed for Chinese-to-English translation. This model served as our baseline for generating code-switched text. It consists of approximately 77 million parameters and features an architecture with 6 encoder layers and 6 decoder layers, offering a robust foundation for capturing the complexities of both Chinese and English, as well as the nuances of code-switching patterns.

To adapt the model to our specific task, we used two primary sources of training data: the first round of “hard-coded” CSW data and code-mixed transcriptions from the ASCEND dataset (Lovenia et al., 2022). This combination was selected to balance domain-specific accuracy with the naturalness of authentic code-switching.

The model was fine-tuned over 3 epochs, using a learning rate of $2e-5$ and a batch size of 16 per device. These parameters were chosen to ensure adequate adaptation to the code-switching task while minimizing the risk of overfitting. The fine-tuning concluded with a final training loss of 0.709, indicating a solid trade-off between specialization and generalization. The resulting model is publicly available⁶.

Approach 2: DeepSeek-R1 Benchmark To benchmark our code-mixed text generation pipeline against a strong pre-trained baseline, we utilized Distilled DeepSeek-R1 7B, based on Qwen—a large language model trained on both Chinese and English corpora (DeepSeek-AI, 2025). DeepSeek has demonstrated remarkable performance across a range of Chinese natural language understanding and generation tasks, making it a valuable reference point for evaluating code-switching capabilities.

⁵<https://huggingface.co/Helsinki-NLP/opus-mt-zh-en>

⁶<https://huggingface.co/y131/code-mixed-cs-edu-model>

ties. Although DeepSeek is not explicitly trained for code-switching, it offers insight into how well general-purpose, state-of-the-art language models can handle code-mixing in the absence of domain-specific supervision. As such, this benchmark serves as a reasonable point of comparison for our customized generation pipeline.

We adopted a few-shot prompting strategy to guide DeepSeek toward producing Mandarin-English code-switched output. Each prompt included two illustrative examples demonstrating how to naturally integrate English computer science terminology into Mandarin instructional sentences. These examples showcased both noun phrase-level and verb-level switches—patterns commonly observed in bilingual academic discourse. The complete prompt is provided in Appendix A.5. This prompt was applied to all 744 Mandarin instructional sentences in our dataset. Model outputs were collected without any post-processing to preserve their authenticity for subsequent evaluation.

Approach 3: Encoder-Decoder Architecture

For the encoder-decoder architecture model, the rationale is to use the encoder to provide context while the decoder generates target sequences with a copy mechanism, improving model performance through a combination of translation and copying from input text.

We first leverage **transfer learning** to initiate our code-mixed generation model. This approach aims to reduce the required training data for code-mixed generation while ensuring high-quality bilingual representations essential for natural code-switching data generation. Specifically, we fine-tune the neural machine translation model [Helsinki-NLP/opus-mt-zh-en](#) on our curated parallel corpus of computer science educational content and dialogue. The fine-tuning process enables the model to capture language-specific features, including domain-specific terminology and language patterns unique to computer science education in both Mandarin and English, as well as cross-lingual mappings, such as semantic equivalences and contextual relationships between the language pairs.

The weights learned during this fine-tuning phase provide monolingual understanding and capture cross-lingual feature characteristics. The next step is to use an **encoder-decoder architecture** that builds on the fine-tuned weights to integrate additional components extracted from the prelimi-

nary code-mixed dataset to build the code-mixed text generation model.

The **encoder**, built on the transformer layers of the MarianMTModel, processes the sequences of tokens in Chinese texts to produce hidden states that capture sequential dependencies and generate contextual representations for the sentences. These representations are then received by the attention mechanism in the decoder, allowing the model to have more focused access to relevant source information. This enables the preservation of both language-specific features and cross-lingual relationships.

Subsequently, the **decoder** uses a processing mechanism to adopt a standard decoder path for translation logits and a dedicated gate mechanism for copy probability calculation. With the attention mechanism, the encoder’s representations are processed to produce hidden states, which inform both generation and copying decisions. When copying from the input texts is decided, the model computes copy probabilities for the input tokens. Subsequently, the model expands input tokens to align with the target sequence length and then maps the tokens into the known vocabulary space using scatter operations, locating the vocabulary tokens in the input text. Such a mechanism is important to preserve technical terminology for conversational corpus related to Computer Science, where many words tend to co-occur for domain-specific meanings. For example, with the term ‘neural network,’ the model can directly copy these tokens rather than regenerate words for “network” or “neural” to maintain precise technical accuracy.

With the encoder-decoder architecture built, we optimize our operation with a specialized loss function that combines loss with a mixing ratio penalty. In particular, we incorporate a Code-Mixing Loss function to calculate the ratio of Chinese to English tokens and penalize the outputs that deviate from a ratio of 0.5 (set for a minimal mixing ratio). This approach preserves semantic accuracy within the code-mixed dataset while encouraging the model to learn from the trained dataset and generate balanced code-mixing data.

During training, the model processes both the hard-coded CSW data and the transcriptions from the ASCEND dataset (Lovenia et al., 2022). The training setup uses parallel data: the original Mandarin text serves as input, while the corresponding code-mixed versions (both hard-coded and AS-

CEND transcripts) serve as the target outputs. The generation strategy employs beam search with a beam width of 5, meaning it maintains the top 5 most probable sequences at each decoding step. Then, the model uses a 2-gram prevention strategy to prevent two consecutive tokens from appearing more than once in the generated sequence. These parameters were chosen to maintain output diversity and technical accuracy while preventing common generation issues like repetitive text.

4 Results and Evaluation

4.1 Description of Generated CSW Data

The 744 Mandarin text entries from the [2imi9/llama2_7B_data_10G](#) dataset were used as input for all three of our code-mixed generation models: the fine-tuned NMT approach, DeepSeek-R1, and the encoder-decoder architecture. This parallel processing enabled the generation of three distinct sets of code-switched (CSW) data, facilitating a comparative analysis across methods.

The generated CSW text preserves the educational content and structure of the original Mandarin entries while incorporating English elements in a way that reflects natural code-switching patterns commonly observed in bilingual educational contexts.

4.2 Evaluation

4.2.1 Code-Mixing Index

The Code-Mixing Index (CMI) (Das and Gambäck, 2014) is a widely used metric for measuring the complexity of code-mixed text (Srivastava and Singh, 2021). It quantifies the fraction of tokens or words that differ from the matrix language⁷. In our study, we calculated the sentence-level CMI⁸ by dividing the number of English tokens by the total word count in each CSW sentence.

The overall CMI for each generated CSW dataset was computed as the average of all sentence-level CMIs within that dataset. As presented in Table 3, the CMI for the hard-coded first round of generated CSW data is 26.98%. The CMIs for the NMT fine-tuning, DeepSeek-R1, and encoder-decoder approaches are 23.05%, 9.95%, and 25.28%, respectively.

Notably, the CMIs for most of our generated CSW datasets fall within the 20% to 30% range,

⁷<https://tech.skit.ai/Code-Mixing-Metrics/>

⁸See Appendix A.4 for CMI formula.

Method	Matrix Lang.	CMI
Hard Code	/	26.89%
NMT Fine-tuning	Chinese	23.05%
Deepseek R1	Chinese	9.95%
Encoder/Decoder	Chinese	25.28%

Table 3: CMIs for Different Methods

which aligns with values observed in spontaneous Chinese-English code-switching utterances from prior studies (see Appendix A.3). This suggests that our generated CSW data—excluding the output from DeepSeek-R1—closely mirrors natural code-mixing patterns, reinforcing the credibility and authenticity of the synthetic text. The substantially lower CMI of DeepSeek-R1 (9.95%) indicates limited code-switching behavior, which may reduce its effectiveness for simulating natural bilingual communication.

4.2.2 Human Labeling

To comprehensively evaluate the quality of the generated data, we recruited two bilingual annotators to label the CSW outputs from the NMT model, DeepSeek-R1, and the encoder-decoder framework. Both annotators were proficient in Mandarin-English code-mixing and had familiarity with domain-specific computer science terminology. They were instructed to rate the naturalness of each sentence using a standardized 3-point Likert scale (Joshi et al., 2015): unnatural (1), acceptable (2), and natural (3). If a sentence contained nonsensical segments that severely disrupted its meaning, annotators could label it as “wrong,” in which case it was excluded from the naturalness evaluation.

Each annotator labeled 50 entries from each of the three models. These entries were derived from 50 randomly sampled Chinese input sentences. To assess annotation consistency, we calculated inter-rater reliability using Cohen’s kappa coefficient (Blackman and Koval, 2000). The resulting κ values were 0.6739 for the fine-tuned NMT model, 0.6793 for the encoder-decoder model, and 0.7622 for DeepSeek-R1—indicating moderate to strong agreement between annotators.

We then compared the performance of the three models in generating natural CSW outputs. Table 4 presents the percentage of outputs rated as natural. The encoder-decoder approach significantly outperformed both the fine-tuned NMT and DeepSeek-R1

models. Annotators consistently rated a higher proportion of encoder-decoder outputs as natural (64% and 60%) compared to those from the NMT model (22% and 24%) and DeepSeek-R1 (34% and 44%).

Labeler	Fine-tuned NMT	DeepSeek R1-Distill	Encoder Decoder
1	22%	44%	64%
2	24%	34%	60%

Table 4: Comparison of Natural Output Percentages by Annotators

Sentences annotated as natural typically demonstrated preservation of the grammatical rules of the matrix language (Mandarin) and exhibited switches at technical terms and language-sensitive words (words more commonly used in English). For instance, in the example shown in Table 5, the technical terms “自然语言处理” and “机器学习” in the input Mandarin sentence were switched to English expressions “language processing” and “machine learning” respectively, and the resulting sentence was labeled as natural.

Conversely, sentences labeled as unnatural often disobeyed Mandarin grammar and displayed issues such as incomplete semantic segments, mistranslations, or unbalanced proportions of Mandarin and English segments. Examples of such cases are also provided in Table 5.

4.2.3 Qualitative Evaluation

To further assess the quality of the generated code-switched text, we conducted a qualitative evaluation of outputs from the fine-tuned NMT approach, DeepSeek-R1, and the encoder-decoder framework. This analysis revealed clear differences in code-switching quality among the three methods.

The encoder-decoder framework demonstrated a superior ability to generate natural and coherent code-switched text. As shown in Appendix A.6, its outputs exhibit several favorable characteristics. The code-switched segments primarily consist of noun phrases and computer science-related terms in English, reflecting authentic bilingual speech patterns. Language switch points appear more natural and intuitive, and grammatical structures in both languages are better preserved, resulting in higher overall linguistic quality.

In contrast, the fine-tuned NMT model showed notable limitations. As illustrated in Appendix A.6, its outputs often exhibit grammatical inconsistencies when transitioning between English and Chi-

(In NLP, how can we use machine learning for analysis? Please clarify the meanings of “processing” and “application processing” in “depletion of”.)	<i>Unnatural</i>

Table 5: Comparison of Natural and Unnatural Labels (The parentheses contain translations, not part of the data.)

nese. Additionally, it occasionally produces nonsensical or incoherent English terms (e.g., “convergence,” “protology,” “diploration”), leading to awkward transitions and a lower degree of naturalness compared to the encoder-decoder output.

DeepSeek-R1, a large language model trained on Chinese text, also displayed weaknesses in generating natural code-switching. Many outputs defaulted to full English translations rather than producing genuine code-switched language, resulting in a low Code-Mixing Index (CMI) and limited alignment with real-world bilingual discourse. While DeepSeek-R1 occasionally produced natural-sounding examples, its performance was inconsistent, and it was outperformed overall by the encoder-decoder framework.

In summary, the qualitative evaluation shows that the encoder-decoder model consistently generates more natural, coherent, and contextually appropriate code-switched text than both the fine-tuned NMT and DeepSeek-R1 approaches. Its outputs closely mimic authentic bilingual communication, particularly in technical domains, and exhibit a balanced and grammatically sound integration of

English terminology.

5 Discussion & Conclusion

In this study, we developed a comprehensive, effective, and reusable pipeline for generating synthetic code-mixed data, with the goal of supporting the training of human-centered tutoring large language models (LLMs) and chatbots that communicate using a code-mixed approach. This work is motivated by the pedagogical value of code-mixed instruction for bilingual learners adapting to second-language environments. At the same time, existing publicly available LLMs show limited proficiency in handling code-switching, often focusing narrowly on topic-related nouns (Yong et al., 2023). In addition to proposing a general pipeline, we apply it to create a Mandarin-English code-mixed dataset specifically curated for computer science education.

We accomplished two key objectives:

First, we successfully developed a generalizable pipeline for generating code-mixed data across language pairs (with English as one of the languages). The pipeline consists of three main steps: (1) generating preliminary synthetic code-switched data using the Matrix Language Frame (MLF) theory and BERT-based Named Entity Recognition to prepare the non-English monolingual data; (2) passing the text through an encoder-decoder architecture initialized with weights from an NMT model fine-tuned on a parallel corpus, and training it using both the synthetically generated and real code-mixed data; and (3) iteratively annotating and retraining to enhance the naturalness of the generated outputs.

To adapt the pipeline for other language pairs, users only need to modify two components: (1) the Matrix Language Frame to match the grammatical structure of the target language, and (2) the code-switched speech transcription dataset, which is often more readily available than textual resources. With these changes, users can input their own monolingual data and generate suitable code-mixed datasets for downstream tasks.

Second, we successfully curated a domain-specific code-mixed dataset for computer science education that can support downstream training of LLMs or chatbots. This dataset was validated through three evaluation methods: the Code-Mixing Index (CMI), human ratings, and qualitative analysis. Across all measures, our encoder-decoder architecture outperformed both the state-

of-the-art DeepSeek LLM and a traditional fine-tuned neural machine translation model in generating natural code-switched text.

We offer two suggestions based on our findings. First, given the success of our pipeline in the computer science domain, we recommend applying this approach in other STEM fields where technical vocabulary creates challenges for bilingual learners (Bhatia and Ritchie, 2006). Second, we encourage the development of interactive tutoring systems and LLM-powered chatbots using our curated dataset and pipeline, with the capacity to dynamically adjust the degree of code-mixing based on learners' language proficiency. As supported by prior work (Milroy and Muysken, 1995), flexible language use in educational settings can greatly enhance learner engagement and comprehension.

5.1 Limitation and Future Work

We identify two limitations in this study.

First, although we use transcriptions from a code-mixed audio dataset to fine-tune the naturalness of our model's outputs, the ASCEND training dataset occasionally contains spelling errors, incomplete sentences, and casual conversational utterances. These issues may affect the quality of the generated code-mixed text. Future researchers may improve results by further cleaning and curating a high-quality subset of the transcription data or by sourcing data from more professional or domain-relevant contexts.

Second, due to the nature of the fine-tuned NMT model being primarily designed for translation tasks, it occasionally produces fully translated English output. This indicates that the model's control over the language mixing ratio is not yet optimal. Future work could explore increasing the number of training iterations and implementing a feedback loop to monitor and dynamically adjust the language balance during generation, thereby enhancing the consistency and naturalness of code-switching.

6 Ethical Consideration

Our primary data source, the Mandarin instructional dataset for computer science learning, is open-sourced on Hugging Face and explicitly designed to improve AI model performance in educational settings. Our use aligns with this stated purpose, and we have properly cited the source. Similarly, the ASCEND dataset, used for code-

mixing patterns, is open-sourced and appropriately cited. For annotation, we engaged voluntary participants, ensuring ethical practices in data labeling.

The primary application of our work is developing AI-powered tutoring chat bots for personalized computer science learning, bridging the gap for bilingual learners transitioning from Mandarin to English-language education. We acknowledge the need to preserve language integrity, respect cultural nuances, and avoid exacerbating educational disparities.

STAIR-AIG: Optimizing the Automated Item Generation Process through Human-AI Collaboration for Critical Thinking Assessment

Euigyum Kim¹, Seewoo Li², Salah Khalil³, and Hyo Jeong Shin^{1*}

¹Sogang University, Seoul, South Korea

²University of California, Los Angeles, USA

³MACAT International Ltd., United Kingdom

Abstract

The advent of artificial intelligence (AI) has marked a transformative era in educational measurement and evaluation, particularly in the development of assessment items. Large language models (LLMs) have emerged as promising tools for scalable automatic item generation (AIG), yet concerns remain about the validity of AI-generated items in various domains. To address this issue, we propose STAIR-AIG (*Systematic Tool for Assessment Item Review in Automatic Item Generation*), a human-in-the-loop framework that integrates expert judgment to optimize the quality of AIG items. To explore the functionality of the tool, AIG items were generated in the domain of critical thinking. Subsequently, the human expert and four OpenAI LLMs conducted a review of the AIG items. The results show that while the LLMs demonstrated high consistency in their rating of the AIG items, they exhibited a tendency towards leniency. In contrast, the human expert provided more variable and strict evaluations, identifying issues such as the irrelevance of the construct and cultural insensitivity. These findings highlight the viability of STAIR-AIG as a structured human-AI collaboration approach that facilitates rigorous item review, thus optimizing the quality of AIG items. Furthermore, STAIR-AIG enables iterative review processes and accumulates human feedback, facilitating the refinement of models and prompts. This, in turn, would establish a more reliable and comprehensive pipeline to improve AIG practices.

1 Introduction

Recent advances in natural language processing (NLP) and generative artificial intelligence (AI), particularly large language models (LLMs), have transformed educational measurement from relatively labor-intensive processes to more automated, scalable, and efficient approaches (Srinivasan, 2022; Wang et al., 2024).

Prominent examples include automated scoring (Latif and Zhai, 2024; Lee et al., 2024; Luchini et al., 2025) and automated feedback generation (Hahn et al., 2021; Chan et al., 2025), which substantially improve efficiency by reducing human labor while ensuring relatively valid and consistent outcomes.

Among these innovations, automatic item generation (AIG) has emerged as a particularly pertinent application of LLM for the rapid and effective development of assessment items (Gierl and Lai, 2013; Kurdi et al., 2020). Traditional AIG approaches generated new items by replacing different numbers or words in predefined models or templates, aiming to assess the same underlying construct. With the advent of LLMs, AIG has now entered a new phase, enabling educational researchers and practitioners to generate numerous items with minimal programming expertise. However, regardless of the AIG model used, the quality, appropriateness, and validity of AI-generated items still remain questionable. Consequently, the incorporation of quality assurance processes and human participation is deemed inevitable to ensure that AIG systems are generating content as intended (von Davier and Burstein, 2024).

In particular, it is important to ensure that the assessment items are aligned with target measurement constructs, as poorly defined constructs and superficially designed items can undermine the validity and reliability of the assessment (Liu et al., 2016). Consequently, a robust human-AI collaboration (HAIC) (Fragiadakis et al., 2025) is essential not only to leverage the scalability and efficiency of the AIG process, but also to ensure overall quality and safeguard the validity of AI-generated assessment items (Hao et al., 2024). Nevertheless, prior literature reveals a lack of empirical studies validating the appropriateness of AI-generated items for assessing cognitive skills within human-AI collaborative contexts.

*Corresponding author: hshinedu@sogang.ac.kr

To address this gap, the present study introduces **STAIR-AIG** (*Systematic Tool for Assessment Item Review in Automatic Item Generation*), an item review tool that supports systematic and efficient human review of AI-generated assessment items. We illustrate its potential as both a practical tool and a conceptual AIG framework by applying it to the domain of critical thinking (CT), a higher-order cognitive skill widely recognized as an essential 21st-century core competency (World Economic Forum, 2015). In complex cognitive domains, such as CT, the expert review by the human is particularly important in that defining the measurement structures and developing the assessment items are quite challenging (Shin et al., 2025).

By leveraging NLP techniques, our tool provides a comprehensive linguistic feature analysis of items. This empowers human reviewers to integrate their domain knowledge in a more effective way. Furthermore, the evaluations of AIG items by human experts are stored as data, so they continuously contribute to the improvement and refinement of the internal LLMs within the AIG pipeline. In contrast to conventional methods, which generally rely exclusively on human review as a final gatekeeping measure in a linear fashion, STAIR-AIG incorporates multiple structured touch-points for expert judgment at each stage. This facilitates continuous evaluation, targeted refinement of AI-generated elements, and ongoing enhancement of LLMs for AIG through structured human feedback and prompt optimization in a dynamic manner.

In the following, we illustrate the use of the STAIR-AIG tool as a human-in-the-loop AIG process. We review the relevant literature on AIG and the traditional item review process. Then, we present a case study that demonstrates the use of the STAIR-AIG tool in the CT domain. Subsequently, we compare the evaluations performed by a human expert with those generated by the LLM to identify discrepancies and examine the implications of their collaboration for enhancing the AIG process.

2 Related Works

2.1 Automatic Item Generation

With the growing interest in AIG to build reliable computer-based assessments by stably and efficiently feeding items into the item bank, the number of publications on AIG has recently increased (Kurdi et al., 2020). Before the advent of LLMs, the techniques of AIG studies were based on syntax

or templates that harness computational power to reduce human labor, such as employing grammar correction programs and developing templates to build software programs (Bejar, 1996, 2002; Singley and Bennett, 2002). In contrast, the recent rise of LLMs in the AI research field has enabled AIG researchers to generate items without extensive software engineering, while empowering item developers to effectively realize their nuanced intentions within the generation process (Attali et al., 2022; Bezirhan and von Davier, 2023).

In line with current research trends in AIG based on LLMs, this study utilizes CT items developed through a structured AIG procedure (Shin et al., 2025). This approach leverages prompt engineering techniques using LLM and is structured into three distinct modules—passage, question, and choices statements—to support systematic generation and monitoring. Within each module, detailed prompts are provided to the LLM to generate components of items intended to assess CT skills. The modules are executed sequentially to form a complete item, which is then finalized through expert review and revision. Psychometric analyses of the pilot-study data confirmed that the generated items were functioning as intended (Shin et al., 2025).

2.2 Assessment Item Review Procedure

Traditionally, the development and validation of assessment items have relied heavily on expert-driven review procedures to ensure validity, cognitive alignment, and fairness (Haladyna and Rodriguez, 2013). Guidelines from organizations such as the National Council on Measurement in Education (NCME) and the International Test Commission (ITC) emphasize the need for refinements guided by expert judgment to avoid common errors in the writing of items and to secure the validity of the construct (Haladyna and Rodriguez, 2013; Commission and of Test Publishers, 2022). However, this systematic review process, while essential, is highly time-consuming, especially in large-scale assessment contexts.

To overcome these challenges and efficiently support assessments at scale, hybrid frameworks integrating automation with human supervision are increasingly adopted. An innovative example is the *Item Factory* developed for the Duolingo English Test (DET), an item review system that incorporates human-in-the-loop processes, particularly for the development of high-stakes international DET items (von Davier et al., 2024). The *Item Factory*

Figure 1: Pipeline of STAIR-AIG workflow

facilitates asynchronous collaboration between subject matter experts, supports reviewer calibration, and provides a structured audit trail of editorial decisions (von Davier et al., 2024). This approach not only maintains rigorous educational standards and test fairness, but also exemplifies how scalable and automated processes complemented by human oversight can enhance the quality and efficiency of assessment item review.

Item review tools, including *Item Factory*, are likely to be designed according to the types of items that are closely related to measurement constructs. To our knowledge, no open-source tool yet facilitates AIG item review for higher-order thinking skills. In the following, we present the STAIR-AIG tool and workflow as a human-in-the-loop procedure to review and optimize AIG items for CT.

3 Development of STAIR-AIG

3.1 STAIR-AIG Workflow

STAIR-AIG is developed as an iterative HAIC framework that goes beyond the static and unidirectional AIG process by continuously incorporating human reviewers' feedback to refine LLM behavior. By providing supplementary NLP features to human reviewers, human experts are expected to integrate their domain knowledge more effectively. In addition, it envisions the advancement of an AIG pipeline by automatically converting human reviews into training data for LLMs. These evaluations and human expert insights are then used to iteratively improve both AIG models through reinforcement learning from human feedback (RLHF) (Christiano et al., 2017; Ziegler et al., 2020) and optimize their associated prompts (Lin et al., 2024),

ultimately reducing the human effort required to develop and review items that target complex cognitive constructs such as CT.

Figure 1 represents a comprehensive pipeline of the STAIR-AIG workflow. As seen in the figure, the STAIR-AIG workflow is organized as a multistage iterative loop. Preliminary items generated through prompt engineering by LLMs undergo initial evaluation and review via automated analytics, where LLMs function as auxiliary reviewers. Human reviewers then assess each item based on qualitative criteria, including content validity, appropriateness, and cognitive alignment using the STAIR-AIG tool. Importantly, reviewers provide both three-point scale ratings and open-ended feedback, and in many cases, they can directly edit the content of items. These structured data, comments, scores, and editorial changes are saved as review metadata and would be utilized to refine and enhance the performance of the AIG models.

What distinguishes STAIR-AIG is its integration of these human-generated review signals into both upstream and downstream optimization processes. On the one hand, reviewer feedback is used for prompt optimization (Lin et al., 2024), improving future item generation by refining how prompts are constructed. On the other hand, the accumulated data from reviews and edits serves as training data for RLHF (Christiano et al., 2017), fine-tuning the LLM to produce items that better align with expert judgment and the intended assessment objectives. As shown in Figure 2, this feedback loop system, inspired by the HAIC framework presented in Huang (2019), exemplifies a HAIC-based workflow designed to optimize the quality of AIG items.

Figure 2: HAIC workflow in AIG

3.2 STAIR-AIG Modules

The STAIR-AIG system comprises two central modules designed to systematically evaluate and continuously improve the AIG process.

3.2.1 Item Analysis Module

The item analysis module operates as the preliminary review stage. Items undergo automated analysis based on quantitative linguistic metrics. The metrics include traditional NLP features, including type-token ratio, sentence length, and readability indices such as Flesch-Kincaid grade level, ensuring that the items are written clearly for the target age groups (Collins-Thompson, 2014). These metrics are selected to capture linguistic features that influence item clarity, cognitive load, and appropriateness, and to support early-stage quality screening for human review.

- **Type-Token Ratio (TTR):** A common measure of lexical diversity, defined as

$$\text{TTR} = \frac{|V|}{|W|} \quad (1)$$

where $|V|$ is the number of unique types and $|W|$ is the total number of tokens.

- **Average Sentence Length (ASL):** A measure of syntactic complexity, defined as

$$\text{ASL} = \frac{N_w}{N_s} \quad (2)$$

where N_w is the total words count and N_s is the total number of sentences.

- **Average Syllables per Word (ASW):** A measure of word complexity, defined as

$$\text{ASW} = \frac{N_{syll}}{N_w} \quad (3)$$

where N_{syll} is the total number of syllables and N_w is the total number of words.

- **Flesch-Kincaid Grade Level:** A readability index that estimates the school grade level required to understand a given text (Kincaid et al., 1975), calculated as

$$\text{FKGL} = 0.39 \cdot \text{ASL} + 11.8 \cdot \text{ASW} - 15.59 \quad (4)$$

We compute linguistic features by applying an XLM-RoBERTa tokenizer as a text preprocessing step (Conneau et al., 2020). Leveraging these linguistic features, the module automatically evaluates text difficulty, grade-level appropriateness, and lexical diversity metrics, which significantly reduce the workload placed upon human reviewers, thereby enhancing review efficiency and providing human reviewer with detailed item specification information to facilitate effective and timely review.

3.2.2 Item Review Module

Central to the STAIR-AIG system is the item review module, a structured interface that enables human experts to systematically evaluate AI-generated items. Items approved by the initial automated analysis are presented through this module interface. This module segments each item into specific components, such as passages, questions, and answer choices, allowing reviewers to provide detailed evaluations of each component.

Expert reviewers evaluate each component using a three-point quality scale that serves as the basis for determining whether an item would be accepted, revised, or discarded. Reviewer feedback serves a dual purpose. Qualitative comments contribute to improving the item generation prompts, while direct revision suggestions help finalize the item for operational use and also support future model refinement. Through this human-in-the-loop iterative process, STAIR-AIG continuously improves the quality and validity of the items. Once finalized, high-quality items generated by AI and modified by human experts are stored in an item bank for operational deployment. Item review module as an interface of STAIR-AIG is shown in Figure 3.

4 Empirical Research

In this empirical study, only the first round review was performed within the STAIR-AIG workflow. This initial implementation served to examine the utility of the tool and to investigate the discrepancies of review results between the human reviewer and LLM judges at the early stage of the proposed STAIR-AIG workflow.

Figure 3: STAIR-AIG interface

4.1 Data

The items that were reviewed through STAIR-AIG in this study were developed by a MACAT, specializing in CT frameworks and evaluation solutions. They are based on a framework that measures and assesses CT competencies across six subdomains—Problem solving, Analysis, Creative thinking, Interpretation, Evaluation, and Reasoning (PACIER) (MACAT, 2025; Shin et al., 2025).

In this round, a total of 24 AI-generated items were reviewed, comprising multiple choice (MC) and fill-in-the-blank (FIB) types. Specifically, the assessment included 18 MC items (3 per PACIER domain) and 6 FIB items (1 per PACIER domain). Although actual CT assessment typically employs 4 choices for MC items and 3 choices for FIB items, the initial AIG items were deliberately prompted to generate 10 and 6 choices respectively, to promote a rigorous quality review without being forced to choose from all the bad choices. As for an example, an operating sample item for MACAT’s CT assessment is illustrated in Figure 4.

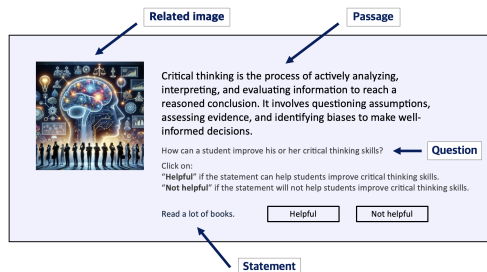

Figure 4: Sample item of CT assessment.

4.2 Item Review by Human Expert

The key review process for the 24 AIG items was conducted by a human expert who specialized in

CT domain. The human expert reviewed each item systematically following the instructions and steps using the STAIR-AIG tool, indicating the quality of the items and their components on three-point rating scales.

- **Dissatisfied:** Fundamentally flawed or inappropriate item for CT assessment, and thus should be discarded. (Score: 1)
- **Neutral:** Requires revisions to improve clarity and relevance or modification of difficulty level. (Score: 2)
- **Satisfied:** Suitable for immediate use or requires minimal edits. (Score: 3)

Specifically, the expert provided ratings and comments on each of the item components, including passages, questions, choices, and overall quality of the items, referencing the analytic information provided by the item analysis module. Revision suggestions were also written directly by the expert in the open text field when necessary. Items that were rated as *neutral* or *satisfied* received detailed revision suggestions to support iterative refinement. After the review, all data including evaluations, revisions, and edits were provisionally stored as a CSV file for future model fine-tuning.

4.3 Item Quality Review by LLMs

In parallel to the human review, four OpenAI LLMs (GPT-4o, GPT-4.5-preview, o1-mini, and o3-mini) performed independent quality assessments using the LLM-as-a-judge methodology (Zheng et al., 2023). Although prior work has shown that LLM-as-a-judge is closely aligned with human preferences on a variety of tasks (Zheng et al., 2023; Gu et al., 2025), there is a lack of prior research exploring its applicability in the context of complex cognitive skills, specifically in the evaluation of the quality of the AIG items. Therefore, we explored the possibility of using LLM-as-a-judge as an additional reviewer.

Each model evaluated the AIG items based on the same criteria and the same interface used by human reviewers. The prompts were carefully aligned and mirrored with the human evaluation guidelines to ensure methodological consistency. To maintain independence between human and LLM evaluations, we adopted zero-shot learning as an in-context learning approach in which models relied solely on their pre-trained knowledge without being

provided with any task-specific examples (Brown et al., 2020). This prevents potential contamination between evaluation sources while utilizing LLM’s generalized reasoning capabilities, distinct from human influence. The evaluations by LLMs were then compared with human review. Detailed prompts are provided in the Appendix A.

5 Results

5.1 Quantitative Results

5.1.1 Comparison of Human Reviews with LLM-generated Reviews

Analysis of 18 MC and 6 FIB items reveals differences in rating patterns between the human expert and LLM judges. The descriptive statistics for both item types are reported in Table 1, indicating that a human expert tends to assign lower scores overall and exhibits greater variability across all items.

In contrast, LLM judges consistently delivered higher scores across all evaluated dimensions with lower standard deviations. The o3-mini model, in particular, demonstrated extreme uniformity, assigning perfect or near-perfect scores with minimal variance. Specifically, even among LLMs, there is a subtle stratification that GPT-4.5-preview and GPT-4o exhibited slightly more variation and lower means than o3-mini. Also, in MC evaluations, the scores of the o1-mini model were closer to those of the human expert, especially in question quality.

Concretely, as illustrated in Figure 5 and Figure 6, LLMs tend to be consistently generous in their evaluations, while the human expert demonstrated a more critical and sensitive attitude marked by greater variability. A particularly notable pattern emerges in the ‘Question Rating’ category for FIB items, that the human expert consistently assigned the highest score to the 6 items. This uniformity is not coincidental. Since all FIB items had an identical question format, a consistent rating is justifiable and is an expected result, whereas some LLMs failed to reflect this.

5.1.2 Distribution of Ratings across Evaluators

Table 2 further illuminates the contrasting behaviors of human expert and LLM judges in evaluating the quality of AIG items. A notable pattern is the relatively frequent use of the lowest rating *Dissatisfied* (score of 1) by the human expert. Rather than indicating inconsistency, this tendency may reflect the human expert’s awareness of the qualitative

Figure 5: Rating patterns by evaluators for MC items

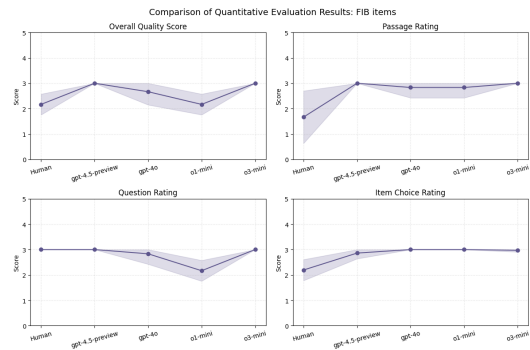

Figure 6: Rating patterns by evaluators for FIB item

aspects of the content of the item. This indicates that contextual appropriateness, coherence, and educational validity are often more readily detected through human expert, whereas automated systems may overlook such nuanced deficiencies.

In comparison, LLMs rarely gave the lowest rating of *Dissatisfied*. For example, o3-mini gave 100% *Satisfied* (score of 3) ratings in nearly every category. In the human rater effect study, this can be interpreted as a leniency or generosity (Wolfe, 2004). Even more conservative models such as o1-mini and GPT-4o showed minimal to zero use of the lowest category across MC and FIB items.

Furthermore, the human evaluator showed a more frequent use of the *Neutral* category (score of 2), which accounts for most of the responses. This middle-ground positioning can be interpreted as a nuanced case-by-case approach by the human evaluator, in contrast to the strong tendency of LLMs to assign the highest rating across most items.

5.2 Qualitative Feedback from Human Expert

To closely examine the reviews provided by the human expert, we performed a qualitative analysis of the reviewer’s written comments. Table 3 lists four themes that categorize and summarize the feedback. The human expert specialized in the as-

Table 1: Descriptive statistics for MC and FIB item reviews by evaluators

Item Type	Evaluator	Overall Quality Score				Passage Rating				Question Rating				Item Choices Rating			
		Mean	Std	Min	Max	Mean	Std	Min	Max	Mean	Std	Min	Max	Mean	Std	Min	Max

	GPT-4.5	0 (0%)	0 (0%)	6 (100%)	0 (0%)	0 (0%)	6 (100%)	0 (0%)	0 (0%)	6 (100%)	0 (0%)	5 (14%)	31 (86%)
	GPT-4o	0 (0%)	2 (33%)	4 (67%)	0 (0%)	1 (17%)	5 (83%)	0 (0%)	1 (17%)	5 (83%)	0 (0%)	0 (0%)	36 (100%)
	o1-mini	0 (0%)	5 (83%)	1 (17%)	0 (0%)	1 (17%)	5 (83%)	0 (0%)	5 (83%)	1 (17%)	0 (0%)	0 (0%)	36 (100%)
	o3-mini	0 (0%)	0 (0%)	6 (100%)	0 (0%)	0 (0%)	6 (100%)	0 (0%)	0 (0%)	6 (100%)	0 (0%)	1 (3%)	35 (97%)

assessment of CT skills provided detailed comments, such as concerns about vague terminology, overly obvious item structure, conceptual inconsistencies, and cultural bias, which were often overlooked by LLM judges. These qualitative insights are stored as data and will play an instrumental role in shaping the future STAIR-AIG protocol, particularly in optimizing the prompts used for AIG and in systematizing the rubrics for the LLM-based review.

It is also worth noting that the human expert raised the issue of the content validity of some AIG items. Specifically, some items were on the borderline of assessing CT or reading comprehension. In such cases, the human expert not only provided a detailed explanation of their reasoning but also directly revised the wording of the items to better align with the intended purpose of the assessment. Such feedback can also be saved as data and used to fine-tune the LLMs, ultimately supporting the development of more valid and reliable AIG-powered assessment content.

6 Conclusions & Implications

6.1 Conclusions

This study introduces STAIR-AIG, a structured, human-in-the-loop framework designed to improve the quality and validity of AI-generated assessment items. Using the STAIR-AIG tool, we collected and compared item reviews from a human expert

and four OpenAI LLMs. Our quantitative and qualitative analyses revealed that, while LLM’s evaluations demonstrated high consistency, their feedback was generally superficial and overly lenient. Often, LLMs neglected critical issues such as ambiguous terminology, cultural insensitivity, and insufficient cognitive depth. In contrast, the human expert provided more critical and nuanced feedback, effectively identifying subtle yet significant flaws.

The two core modules of STAIR-AIG significantly support human reviewers in conducting rigorous, systematic evaluations aligned with the test-taker’s background and the assessment goals, enhancing review efficiency. Notably, the discrepancies observed between human reviewers and LLM judges underscore the importance of a human-in-the-loop framework and an iterative review process. Ultimately, the data collected through these structured reviews is expected to improve the quality of AIG items and facilitate the development of more robust and refined assessment items.

6.2 Implications

As an example of a human-in-the-loop approach to AIG, this study sets the groundwork for extending STAIR-AIG into a comprehensive, full-cycle framework encompassing AIG, collaborative human-AI review, iterative refinement, pilot testing, psychometric validation, and model retrain-

Feedback Category	Review Comments
Terminology & Language Use Vague, overly technical, and structurally complex, which makes it misaligned with the assessment’s purpose.	<ul style="list-style-type: none"> - "Do not use so many different words for the same meaning." - "(...) is a difficult formulation for not-so-strong readers." - "(...) is unnecessarily vague scientific jargon." - "The term (...) might be too technical for many students and may lead to incorrect interpretations."
Item Construction & Clue Issues Wording or structure that makes answers too obvious or misleads test-takers.	<ul style="list-style-type: none"> - "When mentioning acronym, use full name, and in all further mentions, use acronym." - "Change order to avoid misinterpretation." - "Answer appears verbatim in the passage." - "Too simple and easy to see the answer." - "Why use the term (...) whereas in all statements you use the term (...)? Be consistent."
Conceptual Accuracy & Fit Inaccurate or inconsistent statements, which make it unsuitable for valid assessment.	<ul style="list-style-type: none"> - "I have read some publications about (...), but the definition that is used here does not really fit very well." - "Biased or misleading conclusion." - "(...) and (...) depends on interpretation."
Cultural Sensitivity Culturally biased, which offers a limited perspective and potentially disadvantaging test-takers from diverse backgrounds.	<ul style="list-style-type: none"> - "The concept of the (...) varies by culture and perspective." - "(...) might be ideal in some contexts, while (...) may carry a clearer negative connotation." - "(...) portrayed in a one-sided positive light." - "(...) is culturally or ethically biased."

Table 3: Categorization of reviewer feedback and representative comments

ing. The human-generated reviews collected in this study would serve as a valuable resource for the first round of LLM refinement. Drawing on this empirical data, future work would focus on optimizing LLM prompting strategies and applying RLHF to improve both the quality and validity of AI-generated items. This process will help establish a more data-driven and feedback-informed basis for optimizing AIG systems.

In addition, this research contributes to the emerging field of HAIC-based test design and administration, where prior work remains limited. By demonstrating the utility of structured human reviews in guiding both AIG prompting and model fine-tuning, the study highlights a scalable pathway for the application of AI to educational measurement. Similar to how the *Item Factory* is used for DET, the proposed STAIR-AIG tool is being implemented for MACAT’s CT assessment. The number of CT assessment items has rapidly doubled with the STAIR-AIG process, and the tool is being fully implemented to create an item bank of human-authored items alongside AIG for the CT assessment (Shin et al., 2024). This HAIC-driven approach showcases the increasing potential for the scholarly and sustainable use of AI in education.

6.3 Limitations

Despite its promise, this study has several limitations. First, the study was confined to an initial review by a human expert and four OpenAI LLMs,

followed by a comparative analysis of their ratings. The end-to-end STAIR-AIG workflow process, particularly the integration and refinement of the AIG model through iterative review, has yet to be realized. Future work will involve more comprehensive testing of the entire STAIR-AIG pipeline.

Second, although the STAIR-AIG framework is designed to support multiple rounds of review, the current study only included one round of review by one expert reviewer. Consequently, the results may not reflect the full potential of iterative refinement, thereby limiting the framework’s generalizability. Future research should explore the point at which discrepancies between LLMs and expert ratings converge. This will help us understand how LLMs behave when judging higher-order thinking skills, as well as inform the optimal stage for finalizing items for operational use and determining the maximum number of review cycles.

Third, while the item-review module was helpful to human reviewers, it could only analyze superficial metrics, such as TTR, ASL, and conventional readability indices. In the present study, grade-level suitability was judged solely based on these readability measures. Moving forward, the review module will integrate additional linguistic indicators that capture semantic dimensions in order to provide reviewers with more comprehensive support. Similarly, we did not directly measure whether the module substantially reduced the time reviewers

needed to complete their tasks. Therefore, future research would evaluate the practical effectiveness of STAIR-AIG by determining the degree to which it aids item review and the amount of time it saves compared to standard, tool-free review procedures.

Lastly, LLMs were given instructions that closely mirrored those provided to the human reviewer, yet their evaluations consistently exhibited leniency. To achieve a more harmonious integration of human and LLM ratings, future work should consider various prompt engineering techniques to calibrate LLM judgments more closely with the human evaluation standard in the CT domain. Furthermore, optimizing prompts accompanied by the psychometric results of the test data is expected to improve AIG models' ability to accurately generate and evaluate item difficulty and distractor plausibility. This would, in turn, strengthen the efficiency and validity of human-AI collaboration in test development.

Acknowledgments

This research was conducted in collaboration with the MACAT International Ltd., who provided support. We also sincerely appreciate the insightful comments and thoughtful suggestions on potential future directions for this research from the anonymous reviewers.

A Appendix

A.1 Prompt for Item Review by LLMs

The following is an excerpt of the prompt used to instruct the LLMs in reviewing the quality of CT items. The prompt defines the evaluation criteria, output structure, and PACIER framework to assess item quality.

Listing 1: System prompt

```
You are a Critical Thinking Assessment's Item Review Expert with extensive experience in educational evaluation and test design, specializing in critical thinking.

Your role is to systematically evaluate the quality of test items based on established frameworks, ensuring fairness, reliability, and alignment with learning objectives.
```

```
Item_1_Choice_1 Review, Item_1_Choice_1 Rating,
Item_1_Choice_1 Revision Suggestion, ... (repeat for
Choices 2 through 10)
```

```
## Additional Guidelines
```

- Ensure alignment with cognitive and linguistic proficiency standards.
- **Maintain consistency** across evaluations to avoid bias.
- Do not include markdown, bullet points, or additional explanations.
- Return only key-value pairs as output.

Listing 2: User prompt: Review Context

```
## Review Context
- The exam items are designed for Grade 7~8 learners.
- Each item consists of a Passage, a Question, and 6 Answer Choices (each with an Explanation).
- Your task is to rigorously evaluate the quality of each component and provide structured feedback.

## PACIER Framework (Cognitive Process Dimensions)
The PACIER framework categorizes cognitive processes into six distinct levels:
- Problem-Solving (P): (...)
- Creative Thinking (C): (...)
- Interpretation (I): (...)
- Evaluation (E): (...)
- Reasoning (R): (...)
Each test item should align with at least one PACIER category, ensuring it assesses critical thinking skills effectively.
```

Listing 3: User prompt: Review Methods

```
## Evaluation Methodology
1. Assessment Criteria
- Passage: Relevance, clarity, and cognitive demand.
- Question: Alignment with passage, clarity, and ability to assess critical thinking.
- Answer Choices: Plausibility of distractors, clarity, and correctness of explanations.

2. Comparative Judgment
- Evaluate each component relative to high-quality reference items to ensure consistency.

3. Rating Scale
- Dissatisfied: Fundamentally flawed or inappropriate for assessment and thus discarded without revision suggestions.
- Neutral: Requires revisions to improve clarity, relevance, or difficulty. You should provide detailed feedback and specific revision recommendations.
- Satisfied: Suitable for immediate use or required minimal edits. You could directly accept these items or suggest minor enhancements.

4. Actionable Feedback
- Provide concise but specific feedback justifying each rating.

5. Final Output Format (Plain Key-Value Pairs, CSV-Ready)
Output only concise final results in plain key-value pairs (one per line) using the following CSV column structure:

Item Number, Type, Topic, Subtopic, PACIER, Difficulty, Overall Quality Score, Overall Comment, Passage Comment, Passage Rating, Passage Revision, Question Comment, Question Rating, Question Revision,
```

UPSC2M: Benchmarking Adaptive Learning from Two Million MCQ Attempts

Kevin Shi, Karttikeya Mangalam

SigIQ.ai

Correspondence: kevin@sigiq.ai

Abstract

We present UPSC2M, a large-scale dataset comprising two million multiple-choice question attempts from over 46,000 students, spanning nearly 9,000 questions across seven subject areas. The questions are drawn from the Union Public Service Commission (UPSC) examination, one of India’s most competitive and high-stakes assessments. Each attempt includes both response correctness and time taken, enabling fine-grained analysis of learner behavior and question characteristics. Over this dataset, we define two core benchmark tasks: question difficulty estimation and student performance prediction. The first task involves predicting empirical correctness rates using only question text. The second task focuses on predicting the likelihood of a correct response based on prior interactions. We evaluate simple baseline models on both tasks to demonstrate feasibility and establish reference points. Together, the dataset and benchmarks offer a strong foundation for building scalable, personalized educational systems. We release the dataset and code to support further research at the intersection of content understanding, learner modeling, and adaptive assessment: github.com/kevins-hi/upsc2m.

1 Introduction

As digital learning platforms become increasingly central to education, there is growing demand for intelligent systems that can adapt to individual learners, curate relevant content, and deliver targeted assessments. At the heart of such systems lie two fundamental modeling tasks: estimating the difficulty of educational content and predicting student performance. These capabilities underpin a wide range of applications—from personalized question selection to real-time learner diagnostics. When combined, they serve as the foundation for fully automated adaptive learning systems that dynamically tailor instruction based on both content complexity and learner proficiency.

Figure 1: UPSC2M visualized as a list of students, each associated with a set of question attempts. Each attempt records the student ID, question ID, selected answer, whether it was correct, and the time taken to answer.

Statistic	Count
Unique Students	46,235
Unique Questions	8,973
Total Interactions	1,962,573

Table 1: Summary statistics for the UPSC2M dataset.

Much of the existing work in educational modeling has relied on small-scale classroom data or narrow subject domains, limiting the development of models for real-world settings. To bridge this gap, we introduce UPSC2M, a large-scale dataset of 1,962,573 question attempts from aspirants preparing for the Union Public Service Commission (UPSC) examination—one of India’s most competitive standardized tests. Spanning 8,973 questions across seven subjects, UPSC2M includes correctness and timing data from 46,235 students.

We propose two core tasks supported by this dataset. The first is *Question Difficulty Estimation*, where models predict empirical difficulty from question text alone. The second is *Student Performance Prediction*, where models forecast whether a student will answer a question correctly, given their prior interactions. These tasks reflect key challenges in real-world adaptivity and serve as modular building blocks for intelligent tutoring and assessment systems.

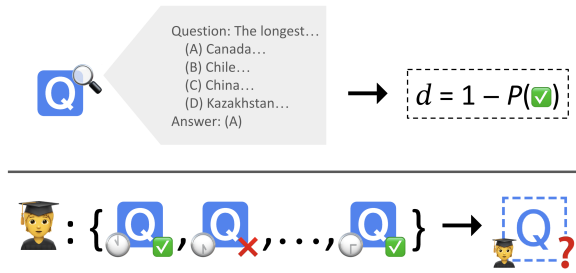

Figure 2: Illustration of the two benchmark tasks: question difficulty estimation (top) and student performance prediction (bottom). In the first task, the goal is to estimate the difficulty of a question—defined as one minus the empirical probability of a correct response—based solely on its text. In the second task, given a student’s prior question attempts, predict whether the student will correctly answer a new, unseen question.

Our contributions are threefold: (1) We release UPSC2M, a large-scale dataset capturing both question content and behavioral interaction data in a high-stakes, multi-subject testing context. (2) We define two core prediction tasks that capture key challenges in adaptive education. (3) We establish baselines and outline directions for future work. Together, UPSC2M and its benchmark tasks provide a robust foundation for research in scalable personalized education. By supporting more accurate models of question difficulty and student performance, this work lays the groundwork for educational platforms that adapt to individual needs at scale, expanding access to high-quality, personalized learning for students regardless of background.

2 Related Work

Large-scale Interaction Datasets A number of publicly available datasets have driven progress in student modeling and adaptive learning. The PSLC DataShop repository provides tens of thousands of student–problem interactions across diverse domains (Stamper et al., 2011), and the ASSISTments dataset offers fine-grained logs of middle-school mathematics practice. More recently, EdNet—a hierarchical dataset of over 130 million interactions from an online tutoring platform—has enabled deep sequence models at unprecedented scale (Choi et al., 2020). Our dataset, UPSC2M, complements these by focusing on a highly competitive, multi-subject exam context, capturing both correctness and response-time signals for UPSC aspirants.

Question Difficulty Estimation Classical item response theory (IRT) models difficulty as a latent

parameter estimated from response patterns (Lord, 1980), but they rely solely on interaction counts. Recent work has explored textual and semantic features to predict question difficulty directly from content (Blum and Corter, 2014). By pairing a large, annotated UPSC question bank with empirical accuracy rates, UPSC2M supports both purely content-based difficulty regression and hybrid approaches that integrate behavioral priors.

Student Performance Prediction Predicting learner outcomes has a long history in educational data mining. Bayesian Knowledge Tracing (BKT) (Corbett and Anderson, 1994) and Performance Factor Analysis (PFA) (Pavlik Jr et al., 2009) established early probabilistic frameworks for tracking mastery. The advent of neural methods—e.g. Deep Knowledge Tracing (DKT) (Piech et al., 2015) has further improved sequence-based prediction. The UPSC2M dataset, with its detailed question content, student attempt outcomes, and rich temporal metadata, offers a new testbed for benchmarking such models on high-stakes exam data.

Applications for Adaptive Testing Adaptive testing algorithms—such as computerized adaptive testing (CAT) (Weiss, 2011)—depend critically on calibrated item difficulties and real-time performance estimates. Datasets that combine content features with large-scale attempt logs enable more responsive and personalized CAT systems. We anticipate that UPSC2M will spur advances in adaptive exam design, question selection strategies, and real-time learner diagnostics.

3 Proposed Dataset

3.1 Motivation and Collection

The UPSC exam is among the most competitive and high-stakes assessments in India, attracting over one million aspirants annually. The exam begins with Paper 1, a 2-hour, 100-question multiple-choice test that spans a broad spectrum of subjects, including history, polity, economy, science, geography, environment, and current affairs. Questions are carefully crafted to assess not only factual recall, but also higher-order reasoning, elimination strategies, and nuanced interpretive understanding under strict time constraints.

This examination offers a rich environment for studying educational modeling tasks. In particular, Paper 1 presents a uniquely challenging setting: questions span multiple knowledge domains, often

Subject	Question Count	Students per Question			Questions per Student		
		Mean	Median	Max	Mean	Median	Max
Current Affairs	1793	127.79	112	3576	20.13	5	1502
Polity	1487	348.00	79	3284	19.31	5	1425
History	1449	259.72	77	2559	20.94	5	1227
Economy	1111	183.86	72	1728	20.17	5	1069
Science	1094	139.81	19	2869	11.48	5	1008
Environment	1022	181.63	104	2801	11.70	4	913
Geography	1017	291.82	145	3055	19.93	5	956
Overall	8973	218.72	91	3576	42.45	8	6553

Table 2: Per-subject statistics in the UPSC2M dataset, including the number of questions and summary statistics for student and question engagement—measured as students per question and questions per student.

require implicit reasoning, and are attempted by a large student body interacting with a shared question bank. These characteristics make it an ideal testbed for developing, benchmarking, and evaluating adaptive educational technologies at scale.

To support research on adaptive learning algorithms, we deployed a custom learning platform targeting UPSC aspirants. Students engaged with a curated bank of 8,973 multiple-choice questions. Over a 2-year period, we collected interaction data from 46,235 students, totaling 1,962,573 question attempts. The resulting dataset has been rigorously cleaned and anonymized to ensure student privacy while retaining the signals necessary for downstream modeling tasks.

3.2 Dataset Schema

UPSC2M is a large-scale dataset comprising two components: an *attempts dataset* and a *questions dataset*. Each row in the attempts dataset represents a single interaction between a student and a question, capturing key fields including `user_id`, `question_id`, `user_answer`, `user_correct`, and `time_taken`. The accompanying questions dataset provides metadata for each question, including its `id`, `subject`, `question stem`, `multiple-choice options`, and the `correct answer`. While no student metadata is included, the dataset enables rich behavioral analysis: the `user_answer` field supports investigations into distractor effectiveness and common misconceptions, while the `time_taken` field—measured in seconds—offers a proxy for question engagement and fluency under time pressure. Each question is constrained to a 60-second limit, mirroring the real-world pacing of the UPSC exam.

3.3 Dataset Statistics

UPSC2M exhibits substantial scale and diversity in learner behavior across content categories. As shown in Table 2, each question is attempted by an average of 219 students, with some questions receiving over 3,000 attempts. This breadth of coverage stems from both the temporal dynamics of question exposure—where older or more prominently featured questions accumulate more interactions—and varying levels of learner interest across subject areas. Such variation necessitates models capable of generalizing across both high-frequency and low-frequency questions.

The average student attempted 42 questions, with the most active student answering over 6,500. This long-tailed distribution, typical of open educational platforms, supports modeling across a wide range of engagement levels. However, the low median number of questions per student indicates that many students engage only briefly, emphasizing the need for models that are robust to cold-start scenarios and sparse interaction histories.

4 Question Difficulty Estimation

4.1 Problem Formulation

We propose a task to estimate the empirical difficulty of a multiple-choice question using only its textual content. Each question is represented as a tuple (`id`, `subject`, `stem`, `options`, `answer`), where `stem` denotes the question prompt, `options` is a list of four candidate choices, and `answer` specifies the index of the correct option.

The empirical difficulty of a question is defined as $1 - p_{\text{correct}}$, rounded to two decimal places, where p_{correct} denotes the proportion of students in UPSC2M who answered the question correctly among those who attempted it. This definition re-

Method	RMSE	MAE	R ²
Training Mean	0.2057	0.1699	-0.0001
Text Embedding	0.1910	0.1543	0.1375

Table 3: Test set performance of regression models for question difficulty estimation. The *Training Mean* baseline predicts the mean difficulty for all training samples.

flects the intuition that more difficult questions are associated with lower observed accuracy.

Setup To support reproducible evaluation, the questions dataset includes a predefined `split` field designating train, validation, and test partitions in a 70/15/15 split. Each question is also annotated with a precomputed difficulty score based on the formulation above.

4.2 Text Embedding Regression

As a baseline for question difficulty estimation, we adopt a simple regression approach. Specifically, we encode the question using a frozen pretrained text encoder and train a small MLP to predict the associated difficulty.

Each question is serialized as a single string combining the stem and options, which is then passed through OpenAI’s `text-embedding-3-large` model—a general-purpose text embedding model. The resulting fixed-dimensional embedding serves as input to an MLP trained to minimize mean squared error against ground-truth difficulty scores. This approach offers a lightweight text-to-score mapping that sets a lower bound for models leveraging richer representations.

4.3 Results and Discussion

Our baseline achieves modest gains over a dummy regressor, reducing RMSE by 7.1% and MAE by 9.2%. While this demonstrates that semantic features carry some signal, the limited improvement underscores the difficulty of estimating question difficulty from text alone. These results motivate the incorporation of richer features—such as behavioral priors and structural cues.

Beyond benchmarking, automatic estimation of question difficulty has broad value in educational applications, enabling adaptive learning systems to personalize content to learner proficiency and maintain engagement. It also aids large-scale content management by facilitating question bank auditing, difficulty calibration, and the efficient construction

of balanced assessments with minimal manual effort. In generative settings, difficulty estimation models can act as verifiers to ensure that newly created questions meet predefined pedagogical goals. As educational platforms scale across diverse curricula and learner populations, automated question difficulty estimation will become a cornerstone of personalized adaptive learning infrastructure.

5 Student Performance Prediction

5.1 Problem Formulation

We propose a task to predict whether a student will answer a given multiple-choice question correctly, based on their prior interaction history. Each row in the `attempts` dataset represents a single interaction and is formatted as a tuple (`user_id`, `question_id`, `user_answer`, `user_correct`, `time_taken`), where `user_correct` is a binary label indicating whether the response was correct.

For evaluation, the fields `user_answer`, `user_correct`, and `time_taken` are treated as target variables—models may access them during training but must not use them as input features at inference time. At test time, each example is defined solely by the pair (`user_id`, `question_id`), and the model must predict whether the student answers the question correctly.

Formally, this task involves estimating the conditional probability that a student answers a question correctly, given their historical behavior. This formulation mirrors real-world scenarios in adaptive learning systems, where predicting a learner’s performance is essential.

Setup To facilitate reproducible evaluation, the `attempts` dataset includes a predefined `split` field that assigns each interaction to the training, validation, or test set, following an 80/10/10 ratio. The split is randomized at the interaction level, with post-processing to ensure that all students and questions in the validation and test sets also appear in the training set. This constraint ensures that models are evaluated on their ability to generalize to new interactions, rather than on cold-start cases with unseen students or questions.

5.2 Baselines

To contextualize the performance of more sophisticated models, we evaluate several simple baselines for this task.

Random and Zero Predictors As naive reference points, we consider two trivial classifiers. The *Random* baseline predicts correctness by sampling from the empirical label distribution in the training set, which shows a slight class imbalance (59.81% incorrect). The *Zero Predictor* always predicts the majority class (0 for incorrect), thereby serving as a worst-case lower bound on accuracy and calibration. While uninformative, these baselines are useful for verifying that more complex models exploit meaningful structure in the data.

Difficulty-Based Heuristic As a simple yet informative baseline, we ignore the student’s interaction history and estimate the probability of a correct response based solely on the difficulty of the target question. Specifically, we compute the predicted probability as $1 - d$, where d denotes the difficulty score of the question, defined in Section 4.1. This formulation assumes that all students have an equal chance of answering a question correctly, modulated only by how empirically difficult the question is for the population.

Despite its simplicity, this baseline captures coarse priors over questions and highlights the influence of item difficulty on student performance. Comparing it to history-aware models underscores the value of incorporating personalized signals.

5.3 Collaborative Filtering

To assess the utility of standard recommender system techniques for modeling student performance, we evaluate several collaborative filtering (CF) (Su and Khoshgoftaar, 2009) methods that treat the task as a matrix completion problem. The student-question interaction matrix is constructed from observed correctness labels, and models are trained to predict whether a student will answer a given question correctly.

We include matrix factorization methods such as Singular Value Decomposition (SVD) and Non-negative Matrix Factorization (NMF), which learn low-dimensional embeddings for students and questions based on historical responses. We also evaluate a bias-only model that estimates correctness using additive student and item biases, as well as a K-nearest neighbors (KNN) approach that aggregates correctness labels from similar students. Together, these methods span a spectrum of personalization strategies, from global baselines to fine-grained models that exploit relational structure in the data.

Method	Accuracy	AUC	Brier
Random	0.5204	0.5000	0.2400
Zero Predictor	0.6002	0.5000	0.3998
Heuristic	0.6698	0.7118	0.2080
KNN CF	0.6429	0.6461	0.2330
SVD CF	0.6755	0.7133	0.2076
NMF CF	0.6757	0.7157	0.2100
Bias Only CF	0.6788	0.7210	0.2051

Table 4: Test set performance of baseline methods on the student performance prediction task. *CF* denotes collaborative filtering.

These models serve as a classical baseline for student performance prediction, illustrating how much signal can be captured from past interactions alone, without access to question content.

5.4 Results and Discussion

Table 4 reports the performance of all baseline models on the student performance prediction task. The *Heuristic* model substantially outperforms trivial baselines, demonstrating that question difficulty alone provides a strong prior for estimating student success. This suggests that well-estimated item-level difficulty can serve as a meaningful signal, even without any personalization.

Among collaborative filtering methods, *Bias Only* yields the highest overall performance, while more expressive models such as *SVD*, *NMF*, and *KNN* fail to produce significant gains in accuracy. The high sparsity of the student-question matrix (99.62%) likely inhibits the ability of these models to learn effective representations or student neighborhoods, constraining their ability to capture student-specific patterns beyond simple item and student-level tendencies.

Predicting student performance is vital to adaptive educational systems, enabling personalized question selection, targeted review, and adaptive pacing to support diverse learners. When paired with difficulty estimation, it lays the groundwork for fully automated instruction by combining item-level insights with behavioral modeling. As educational platforms scale, these predictive capabilities are key to delivering truly individualized learning—ensuring each student receives the right content at the right time. Together, these tasks form the backbone of scalable, data-driven education.

Limitations

Our question difficulty estimation labels are based solely on correctness rates and ignore temporal or student-specific variation; future work may redefine difficulty through joint modeling of student and item characteristics, potentially incorporating response times. Our collaborative filtering models are likely hindered by the high prevalence of low-activity learners—the median questions attempted per student is just 8—which may limit generalization and overall performance. None of our current models incorporate response time features, which could offer valuable signals related to fluency or hesitation. Finally, while UPSC2M is large and diverse, its focus on one high-stakes exam context may limit direct transferability to other educational domains. Despite these limitations, we view our dataset and task formulations as a strong foundation for building more expressive, interpretable, and personalized models of learner behavior.

Abstract

Despite recent advances in AI detection methods, their practical application, especially in education, remains limited. Educators need functional tools pointing to *AI indicators within texts*, rather than merely estimating *whether* AI was used. GPTZero’s new AI Vocabulary feature, which highlights parts of a text likely to be AI-generated based on frequent words and phrases from LLM-generated texts, offers a potential solution. However, its effectiveness has not yet been empirically validated.

In this study, we examine whether GPTZero’s AI Vocabulary can effectively distinguish between LLM-generated and student-written essays. We analyze the AI Vocabulary lists published from October 2024 to March 2025 and evaluate them on a subset of the Ghostbuster dataset, which includes student and LLM essays. We train multiple Bag-of-Words classifiers using GPTZero’s AI Vocabulary terms as features and examine their individual contributions to classification.

Our findings show that simply checking for the presence, not the frequency, of specific AI terms yields the best results, particularly with ChatGPT-generated essays. However, performance drops to near-random when applied to Claude-generated essays, indicating that GPTZero’s AI Vocabulary may not generalize well to texts generated by LLMs other than ChatGPT. Additionally, all classifiers based on GPTZero’s AI Vocabulary significantly underperform compared to Bag-of-Words classifiers trained directly on the full dataset vocabulary. These findings suggest that fixed vocabularies based solely on lexical features, despite their interpretability, have limited effectiveness across different LLMs and educational writing contexts.

1 Introduction

Recently, the introduction of user-friendly interfaces such as ChatGPT (OpenAI, 2023) has made

a significant impact on education. An increasing number of students are using large language models (LLMs) to write essays (among other things), and this creates new challenges for educators to assess various skills and ensure academic integrity (Cotton et al., 2024). Even experienced teachers and those familiar with LLMs often struggle to tell apart student-written essays from those created by LLMs, as studies have shown (Fleckenstein et al., 2024; Waltzer et al., 2024; Perkins et al., 2024).

To address these challenges, numerous AI detection methods and tools have been developed (see Wu et al. 2025 for a review). However, as highlighted by Weber-Wulff et al. (2023), most detection tools in the market lack robustness with student texts and interpretability for non-expert users such as teachers. GPTZero (Tian and Cui, 2025), a popular AI detection tool, aims to offer a more transparent and interpretable solution. It analyzes texts for patterns, vocabulary and styles that are more common in AI-generated writing than in human writing, aiming to assist educators in verifying the authenticity of student work.

In October 2024, GPTZero introduced a new **AI Vocabulary**¹ feature (Figure 1), which highlights text parts that are likely to be AI-generated. This feature includes a list of the 50 words and phrases most commonly used by LLMs (Constantino, 2024), which can be interpreted as AI indicators, and is updated monthly. Each term is assigned a weight, indicating its frequency in AI-generated texts relative to human-written ones, and is accompanied by a contextual example. Since December 2024, the list has been expanded to include the top 100 words and phrases commonly used by AI. A key question, however, is whether this feature can be used to effectively distinguish LLM-generated essays from student-written ones. In this paper, we address this question by conducting

¹<https://gptzero.me/ai-vocabulary>

OCTOBER

Top 50 AI Words and Phrases Updated October 2024

These words and phrases are ranked based on the frequency they appear in AI documents, compared to human documents in our research of 3.3 million texts.

Phrase	Frequency used by AI vs. Human	Example
1. objective study aimed	269x more frequent in AI	The objective of the study aimed to uncover new insights into climate change.
2. research needed to understand	235x more frequent in AI	Further research is needed to understand the long-term effects.
3. despite facing	209x more frequent in AI	Despite facing numerous obstacles, the team succeeded.
4. play significant role shaping	182x more frequent in AI	Education systems play a significant role in shaping future generations.
5. crucial role in shaping	155x more frequent in AI	Parents play a crucial role in shaping their children's values.

Figure 1: Screenshot of GPTZero’s AI Vocabulary Released on October 7, 2024.

the first systematic study that assesses GPTZero’s AI Vocabulary feature in detecting LLM-generated content from educational contexts. Specifically, we integrate the AI Vocabulary lists (from October 2024 to March 2025) within supervised Bag-of-Words (BoW) classification models, namely two Naive Bayes classifiers trained on a subset of the Ghostbuster detector dataset (Verma et al., 2024), containing student and LLM-generated essays from ChatGPT (OpenAI, 2023) and Claude (Anthropic, 2023). We selected these models for their interpretability, as they allow us to inspect the contribution of each feature, namely the AI Vocabulary terms, to classification decisions. We position our work as a step toward evaluating the real-world utility of interpretable detection tools in educational contexts, where the use of AI is becoming increasingly widespread and, therefore, both reliable and efficient solutions are needed.

2 Background

Being able to differentiate between human-written and LLM-generated texts has recently become a much-discussed research topic, especially in academic and educational contexts. However, current AI detection methods present two main issues: (i) they often rely on non-transparent features, abstract and difficult for the average person to interpret and (ii) they have limited applicability for texts written by students, who are underrepresented in the training data.

Several current AI detection methods and sys-

tems prioritize model-based statistical metrics over basic linguistic features, such as perplexity (Vasilatos et al., 2023) and burstiness (Tian and Cui, 2025), log-probability (Solaiman et al., 2021) and high-dimensional neural representations (Guo et al., 2024). While highly performative, these methods do not offer interpretable justifications for their predictions, making it difficult for educators to reliably use and understand their outcomes (Ji et al., 2024). The underrepresentation of student texts in the detectors’ training sets represents another significant challenge. Student writing can exhibit lower fluency, formulaic phrasing or genre-specific traits that differ from both typical human and LLM-generated outputs. This mismatch can lead to high false positive rates, as observed in recent evaluations (Weber-Wulff et al., 2023; Liang et al., 2023; Perkins et al., 2024), as well as numerous false negatives, particularly when texts undergo simple adversarial modifications to evade the detectors (Weber-Wulff et al., 2023; Perkins et al., 2024).

In response to these AI detectors’ transparency issues, interpretable alternatives focusing on word frequency, n-gram patterns and stylometric indicators (Opara, 2024; Ciccarelli et al., 2024; Muñoz-Ortiz et al., 2024) have emerged to offer more transparent and pedagogically useful solutions. However, these methods are often less robust when applied to domain shifts or with LLM-generated texts modified to become less detectable. A hybrid detection tool, GPTZero (Tian and Cui, 2025), combines statistical features, such as perplexity and bursti-

ness, with more interpretable metrics, including readability, text complexity and average sentence length. Although it does not fully disclose the rationale behind its classifications, GPTZero claims to be “the top AI detector for teachers” (Tian and Cui, 2025). As such, it has recently introduced AI Vocabulary lists that highlight in text terms disproportionately used by LLMs compared to human authors, as a way to enhance interpretability and better support educational use among teachers.

Beyond AI detection models, some studies have recently emerged that focus on quantifying and analyzing a significant increase in the use of certain words and phrases, especially in scientific writing, after the introduction of LLMs. Kobak et al. (2024) employed large-scale corpus analysis of medical abstracts to track excess word usage and revealed a sharp rise in usually less frequent terms such as “delve” and “intricacies”. Juzek and Ward (2025) used model testing methods and human evaluators to explore why LLMs overrepresent certain terms, focusing on 21 “focal words”. However, their results turned out to be inconclusive. Mingmeng and Roberto (2024) quantitatively compared academic texts before and after the spread of LLMs, documenting a general trend towards producing more complex and abstract texts. Liang et al. (2024) analyzed textual features and metadata from papers across different domains, linking higher rates of LLMs use with texts whose first authors published more preprints, shorter papers or in more popular research fields.

While these studies provide interesting insights into possible LLM-influenced term choices, they mostly remain focused on quantitative and comparative vocabulary studies that analyze the language of scientific publications and do not directly extend to student writing or educational contexts. Moreover, to the best of our knowledge, no existing works have systematically leveraged terms more frequently used by LLMs to build and evaluate AI detection models focused on the educational domain, where they would currently be highly needed. This highlights a critical research gap, in which to explore whether vocabulary-based AI detection methods could be applied to distinguish student-written texts from LLM-generated ones, supporting educators in a more interpretable and linguistically justified manner. To address this gap, in this paper we evaluate for the first time GPTZero’s AI Vocabulary lists as a promising way to detect LLM-generated essays among student-written ones. To

the best of our knowledge, these are the only publicly available, extensive AI-vocabulary lists derived from a significant number of documents that go beyond scientific publications and likely include student-written texts, given GPTZero’s commitment to teachers and educational contexts². Moreover, they also provide data concerning the different word and phrase frequencies found in human-authored and LLM-generated texts (see Figure 1), further increasing their relevance. Starting with this study we aim to work towards developing a more transparent AI detection methodology applicable in educational contexts, reliable and better aligned with educators’ needs.

3 Method

3.1 GPTZero’s AI Vocabulary Lists

We collected the AI Vocabulary lists published on the GPTZero website between October 2024 and March 2025.³ Each month, we gathered a list of words and phrases together with their frequency estimates (see Appendix A), which had been estimated on 3.3 million texts (Tian and Cui, 2025). The October 2024 list featured the 50 most frequent AI-related terms, including single words and multi-word expressions. In November 2024, the same list (“Updated October 2024”) remained online. In December 2024, a new list (“Updated November 2024”), now including 99 items, was published.⁴ However, this updated list contained some errors, such as missing words, duplicate entries, and phrase variations. Subsequently, a corrected list with 100 items was published later on in December, 2024. This one still contained duplicates, so we removed exact double entries for the purpose of our experiments. In January 2025, a new list (“Updated January 2025”) with 100 unique phrases was published. No new list was published in February 2025; instead, the January 2025 list remained online for that month. The March 2025 list was labeled as “updated”, but it was identical to the January and February lists. As a result, there were only three distinct AI Vocabulary lists that we could use in our experiments: (a) the October 2024 list, (b) the November/December 2024 list, and (c) the January/February/March 2025 list. In addition, we constructed a *combined* list (“All”)

²<https://gptzero.me/educators>

³The reader can retrieve these lists using <https://web.archive.org/>.

⁴<https://web.archive.org/web/20241208223132/https://gptzero.me/ai-vocabulary>

that merged all unique words and phrases from these three sources.

3.2 Data

To detect LLM-generated essays using GPTZero’s AI Vocabulary, we used a subset of the data initially employed to train the Ghostbuster detector (Verma et al., 2024). This dataset originally contained 21,000 documents, including articles, creative writing pieces and student essays. For our experiments, we focus on a subset of 1,000 university student essays sourced from IvyPanda (IvyPanda, 2025), a platform where users can submit essays from high school and university levels concerning various topics and subjects, and 2,000 LLM-generated essays. To obtain the latter, Verma et al. (2024) used ChatGPT to generate the prompts corresponding to the unique 1,000 assignments based on which the student texts were written. These prompts were then used to generate 1,000 essays with ChatGPT and 1,000 essays with Claude. The desired essay length was also specified in them to match the human-written texts. The resulting median word count was 661 for student essays, 536 for ChatGPT-generated essays and 456 for Claude-generated essays. For the rest of the paper, we will refer to this subset of essays as the *Ghostbuster corpus*.

3.3 Models

We experimented with three classification models, each trained to predict whether an essay is written by a student or by (a) an LLM, (b) Claude, or (c) ChatGPT. To this end, we performed binary classification (using only the binary labels “AI” and “human”) on different dataset partitions: 1,000 student essays with (a) all 2,000 LLM-generated essays, (b) 1,000 essays generated by Claude, or (c) 1,000 essays generated by ChatGPT. We used *scikit-learn* (Pedregosa et al., 2011) to implement and train these classification models.

For each of these three classifiers, we estimated separate models for each of the four AI Vocabulary lists (monthly or combined), computing different feature vectors for the words and phrases in the list. For each list, we counted the occurrences of its items in the corpus using a Bag-of-Words (BoW) approach. Each AI word or phrase was treated as a distinct feature. Since the vocabulary included multi-word units (i.e., AI phrases), we employed an n -gram vectorization strategy to capture these phrases, setting n to range from 1 token up to the maximum number of tokens found in the longest

phrase in the list.⁵

We integrated the BoW features in a binary Naive Bayes classifier

$$P(c|w_1, \dots, w_n) \propto P(c) \prod_{i=1}^n P(w_i|c) \quad (1)$$

to predict the class c , namely whether an essay is generated by an AI (positive class) or written by a student (negative class). The models assumed independence between each word/phrase w and always used a uniform prior, assuming an equal chance (50%) that an essay belonged to one of the two⁶ classes.

We experimented with two types of feature vectors: (a) a Multinomial feature vector indicating the counts of the words and phrases in the essay, and (b) a Bernoulli feature vector indicating the presence or absence of the words and phrases in the essay.

For comparison, we also trained binary Naive Bayes classifiers – using either Multinomial or Bernoulli feature vectors – based on an alternative Bag-of-Words approach. In this configuration, the vocabulary comprised all unigram word types found in the Ghostbuster dataset, which were used to construct the feature vectors. These models served as a baseline to assess the effect of using the curated vocabulary lists in contrast to the default vocabulary derived directly from the training data.

3.4 Experiments

We trained a total of 24 classification models (3 AI x 4 lists x 2 features) using GPTZero AI Vocabulary lists, along with 6 reference models (3 AI x 2 features) based on the vocabulary derived from the Ghostbuster training data. To ensure an exhaustive evaluation, all models were trained and tested using leave-one-out cross-validation.

3.5 Metrics

We evaluated the classifiers’ performance using accuracy, (binary) precision, (binary) recall, (binary) F1-score, MCC (Matthews correlation coefficient) and AUROC (Area Under the Receiver Operating Characteristic curve) computed with *scikit-learn*

⁵This was implemented using `CountVectorizer`, with the `ngram_range` parameter set to `(1, max_phrase_length)`.

⁶It is important to reiterate that we did not perform any multiclass classification between the different LLMs in the dataset. We always compared LLM-generated to student-written, or Claude-generated to student-written, or GPT-generated to student-written (cf., *supra*).

(Pedregosa et al., 2011). Precision, recall and F1 score were computed for the positive class only (LLM-generated essays).

4 Results

4.1 GPTZero’s AI Vocabulary terms’ distribution in Ghostbuster

Table 1 lists the terms from GPTZero’s AI Vocabulary found in the Ghostbusters dataset. Of the 245 distinct words and phrases published between October 2024 and March 2025, only 98 appeared in the entire dataset, 53 in the Claude subset and 91 in the ChatGPT subset. These low and different distributions suggest that many AI-specific vocabulary terms identified by GPTZero as salient AI indicators, such as “left an indelible mark” (ranked 8th in Table 7 but only found 9 times in our corpus), “a rich tapestry” (ranked 18th in Table 7 but only found 6 times in our corpus), “offers valuable insights” (ranked 9th in Table 7 but only found 7 times in our corpus), “despite facing ” (ranked 3rd in Table 5 but only found 6 times in our corpus) and “study aims to explore” (ranked 6th in Table 5 but only found twice in our corpus) may not be frequently used in educational LLM-generated essays, in particular by models other than ChatGPT for most of the cases.

To assess the alignment between GPTZero’s AI Vocabulary rankings and their usage in LLM-generated essays, we calculated Spearman rank correlations between each term’s rank in the AI Vocabulary lists and its rank based on frequency of usage in LLM-generated texts (Claude and/or GPT). Our results (see Table 9) indicate generally weak or negative correlations between AI Vocabulary rankings and their occurrence across LLM-generated texts. There was, however, a significant positive correlation between the terms’ ranks in the October lists and their usage in Claude-generated texts ($\rho = 0.501$, $p < .001$), as well as between the terms’ ranks in the January-March lists and their usage in Claude-generated texts ($\rho = 0.476$, $p < .001$). In contrast, correlations with ChatGPT-generated texts remained low or negative, except for a modest positive correlation ($\rho = 0.211$, $p = .053$) with the November/December AI Vocabulary list⁷. Based on these findings, it is still

⁷These different correlation values suggest that while higher-ranked AI Vocabulary words tend to be relatively more frequent in Claude-generated essays compared to lower-ranked terms, their overall presence in such texts remains sparse.

unclear whether the actual ranks of the AI Vocabulary words and phrases in the list are informative and could consequently be used for AI text detection in education.

4.2 Classification performance with GPTZero’s AI Vocabulary lists

In our experiments, we evaluated two types of Naive Bayes classifiers, one using a Bernoulli feature vector and one using a Multinomial feature vector, based on GPTZero’s AI Vocabulary lists (from October 2024 to March 2025). We tested the classifiers in detecting AI-generated essays both individually, with each monthly AI Vocabulary list, and with a combined list containing 245 AI Vocabulary terms from all months. We evaluated both the full Ghostbuster essays corpus and subsets specific to Claude- and ChatGPT-generated texts.

Overall, classification results were close to random, with accuracy ranging from 0.363 to 0.755 for Bernoulli models and 0.363 to 0.729 for Multinomial models (see Table 2) using the different AI Vocabulary lists. However, we found more promising results when focusing specifically on ChatGPT-generated texts using the combined GPTZero’s AI Vocabulary lists of all months. Here, the Bernoulli model achieved the highest accuracy (0.755), high precision (0.882), moderate recall (0.588) and an F1 score of 0.705, which indicates good performance in identifying LLM-generated texts, although it might have missed some positive cases. The high precision score signals that the model does not make numerous false predictions causing it to mislabel student texts as AI-generated (a significant risk in educational contexts as highlighted by Liang et al. 2023). However, the moderate recall also indicates that the model’s sensitivity should increase in order to avoid some LLM-generated texts to go undetected (also particularly relevant in educational contexts as stressed by Fleckenstein et al. 2024; Weber-Wulff et al. 2023; Perkins et al. 2024). An MCC score of 0.541 supports our interpretation and an AUROC of 0.595 suggests that the model, despite being better than random, may struggle in more ambiguous cases. The Multinomial model, using the same feature set, yielded higher precision (0.884) and AUROC (0.705), indicating higher sensitivity to ChatGPT-generated content and a more balanced classification ability. This may be due to an overrepresentation of ChatGPT-generated texts in the datasets used by GPTZero to compile the AI Vocabulary lists. However, this model also reached

Table 2: Performance of classifiers on leave-one-out cross-validation. The highest accuracy values are indicated in boldface.

lower accuracy (0.729) and F1 score (0.660), making it less reliable.

These results suggest that binary-feature BoW models like Bernoulli may be more effective at detecting ChatGPT-generated texts based solely on AI-related terms’ presence, while frequency-based models like Multinomial may be better at identifying subtler vocabulary usage patterns. Finally, both Naive Bayes classifiers were significantly outperformed by a baseline Multinomial BoW classifier trained on the full vocabulary of the Ghostbuster dataset. This model achieved a maximum accuracy of 0.964 and an AUROC score of 0.991 (see Table 2) with Claude texts - differing from the previous highest results for ChatGPT-generated essays using the AI Vocabulary lists, possibly more effective given the absence or scarcity of Claude’s generated data for the compilation of the AI Vo-

cabulary lists⁸. This highlights the limitations of relying on fixed AI Vocabulary lists for AI detection, which might not reflect the language found in educational essays written by different LLMs and students.

4.3 AI Vocabulary terms contribution to classification

To better understand which specific AI Vocabulary terms influenced classification, we analyzed their log probabilities under our best-performing Naive Bayes models, namely the Bernoulli and Multinomial variants that achieved the highest classification results. These models were trained using the subset of ChatGPT-generated texts from the Ghostbuster corpus and the full combined AI Vocabulary list (with 245 terms from October 2024 to March

Table 4: Top 25 phrases contributing to LLM-generated text detection, ordered by log-probability from the best Multinomial Naive Bayes classifier using all AI Vocabulary lists on ChatGPT-generated essays. The *Rank* and *Frequency* columns relate to the combined GPTZero’s AI Vocabulary lists (245 phrases from October 2024 to March 2025), *Count* refers to the frequency in ChatGPT-generated texts, *OR* refers to the odds ratio in LLM-generated vs. human-authored texts and *LP* represents log probability of the phrase contribution to classification.

cation were largely the same, although in slightly different order (see Table 3 and Table 4). Each table includes the terms’ original *Rank* and *Frequency* in the combined AI Vocabulary list, their *Count* in ChatGPT-generated texts, the *OR* (indicating their relative likelihood in LLM vs. human text based

on odds ratios) and the models' log probabilities, LP (reflecting the terms' contribution to the model decision; lower values imply weaker impact).

We noticed in the Bernoulli and Multinomial classifiers that several words and phrases found in numerous ChatGPT-generated texts, such as “fostering” (counted 236 times), “prioritize” (227), “advancements” (62), “aligns” (66) and “showcasing” (49), despite being found more frequently in Ghostbuster's texts than in GPTZero's ranking lists, were less effective in distinguishing AI-generated from student-authored essays given their low log probabilities. Similarly, when considering terms that were highly ranked and common in AI Vocabulary lists, such as “provides valuable” (4th), “provides valuable insights” (7th), “indelible mark” (11th) and “valuable insights” (19th), we observed also low log probabilities, apart from recurring phrases, meaning that they did not significantly contribute to classification.

We decided to maintain separate entries for morphological variants rather than indexing them together to investigate whether certain preferences exist in LLM-generated texts. In this way, we could check if verb tense, number, or grammatical person can also influence AI-generated text detection. By maintaining distinctions such as “provide” vs. “provides” (valuable insights) and “study shed” vs. “study sheds” we can evaluate whether specific variants display distributional biases in LLM-generated texts compared to student-authored essays. However, if these differences prove insignificant, as seems to be the case in our experiments, in future works we could consider lemmatization or stemming.

Our findings are in line with our previous observations, provided in Section 4.1, where term rankings and frequencies did not seem to notably support classification. They, nevertheless, confirm our classification results described in Section 4.2, highlighting the strengths of the BoW Bernoulli model over the Multinomial one, accounting for the terms' presence only, rather than for their frequency, to better distinguish LLM-generated texts from student-written ones.

5 Conclusion

In this study, we presented the first empirical evaluation of GPTZero's AI Vocabulary lists as a way to detect AI-generated texts in educational settings. Our findings show that these precompiled vocabu-

lary lists, despite being transparent and easily interpretable for educators, have limited effectiveness in detecting LLM-generated texts among educational essays, especially beyond ChatGPT. Even for ChatGPT-generated texts, the classification performance of our Naive Bayes models based on AI Vocabulary lists was modest and only improved when using a combined list of 245 terms. We achieved better results with BoW models that used the full Ghostbuster dataset vocabulary, suggesting that broader language patterns may be more effective for AI detection with different LLMs.

Future research should focus on a deeper, more domain-specific analysis and comparison between student and LLM-generated texts in educational domains, including more diverse student samples and LLM-generated texts. Vocabulary-based AI detectors could benefit from the inclusion of additional functional and structural features, considering each term and phrase as linguistic constructions that reflect users' language more in detail.

Overall, although our results might not come close to state-of-the-art detectors, with this work we addressed a key research gap. To the best of our knowledge, no prior study has evaluated precompiled AI Vocabulary lists, publicly available and derived from a diverse set of texts beyond scientific articles, for AI detection in education. Our findings offer practical and detailed insights into the utility and accuracy of *transparent* linguistic features, such as AI Vocabulary lists, that can support educators in distinguishing LLM-generated and student-written texts. By doing so, this work contributes to the ongoing efforts to improve AI detection systems and lays a foundation for further investigation and refinement in educational contexts.

Limitations

Although our work provides useful evidence in the analysis of GPTZero's AI Vocabulary lists for AI detection, there are several limitations that need to be accounted for. First, we only tested two Bag-of-Words classifiers (Bernoulli and Multinomial) using a Naive Bayes approach. These are relatively simple models. More advanced machine learning and neural approaches could help to expand the testing framework and potentially improve detection accuracy. Second, the dataset used in this study, the Ghostbuster essay subcorpus, represents outputs from older versions of ChatGPT

and Claude models. As new model versions are released, the vocabulary patterns of current AI systems may differ significantly. Moreover, due to the lack of metadata, we assume students to be native English speakers. Future studies should examine L2 students, who may rely more on LLMs and for whom current detectors might be less effective. Third, as LLMs continue to evolve, their outputs become closer to human language, making fixed vocabulary lists less effective over time. To remain useful, these AI Vocabulary lists would need to be updated more frequently and adapted across different writing domains, to reflect changes in language use.

Acknowledgments

The authors would like to thank Piet Desmet for for his insightful comments and feedback. The research presented in this paper was funded by the Research Foundation Flanders (FWO) through a doctoral fellowship awarded to Veronica Juliana Schmalz (1108723N).

A GPTZero’s AI Vocabulary Lists

This appendix contains lists of the top AI words and phrases from GPTZero, spanning from October 2024 to March 2025. Each monthly list includes frequently used AI-related terms, along with their frequency estimates. The November list was initially identical to the October list with 50 entries, but an update appeared in December with 99 entries. However, this updated version contained errors such as missing determiners and prepositions (e.g., *crucial role understanding* instead of *a crucial role in understanding*) and incongruencies, including duplicate entries (e.g., 4) *provide valuable insights* - 464 and 84) *provide valuable insights* - 86). This list also contains numerous variations of the same phrase (e.g., 13) *plays a crucial role in understanding* - 247 and 14) *play a crucial role in understanding*- 242) and longer phrases that are part of other shorter phrases, also appearing in the list (e.g., 24) *plays a crucial role in shaping* - 178 and 26) *crucial role in shaping* - 171). The January, February and March lists were identical, so we report them in the same table. The frequency estimates indicate how many times more frequently a term appears in AI-written texts compared to human-written texts. For example, a term with a frequency estimate of 10 means it is ten times more common in AI texts than in human texts, based on a collection of 3.3 million documents (Tian and Cui, 2025).

Abstract

We present a case study on building task-specific models for grammatical error correction and explanation generation tailored to learners of Estonian. Our approach handles whole paragraphs instead of sentences and leverages prompting proprietary large language models for generating synthetic training data, addressing the limited availability of error correction data and the complete absence of correction justification/explanation data in Estonian. We describe the chosen approach and pipeline and provide technical details for the experimental part. The final outcome is a set of open-weight models, which are released with a permissive license along with the generated synthetic error correction and explanation data.

1 Introduction

Language models with emergent abilities are increasingly showing capacity for performing natural language processing tasks via prompting (OpenAI et al., 2024; Grattafiori et al., 2024; DeepSeek-AI et al., 2025, etc.). However, it has been shown that targeted effort can result in surpassing the most advanced proprietary models with more task-oriented models, e.g., for grammatical error correction (Luhtaru et al., 2024a). Furthermore, hybrid combinations of large language model (LLM) prompting and tuning for synthetic data generation, as well as tuning for the final task, show even more promise (Luhtaru et al., 2024b).

Here we present a case study on the development of grammatical error correction (GEC) and grammatical error explanation (GEE) generation for learners of Estonian. The overall goal is to create task-specific models reliable enough to correct learners' grammar and justify the corrections. Most importantly, while we use proprietary LLMs in this work for data generation, the final result consists of independent open-weight models that can be used for both research and commercial purposes.

The central theme of all the presented work is dealing with data scarcity. The amount of training data for GEC has recently improved but still shows imbalance between English and other languages (Masciolini et al., 2025b) and Estonian is no exception. More specifically, there is a modest amount of Estonian GEC data but no data for GEE. We address both data deficiencies by utilising synthetic data, obtained by prompting OpenAI LLMs (detailed later in the paper) to either introduce grammatical errors into correct texts, in a manner characteristic for language learners (for GEC), or by generating and filtering explanations of gold-standard corrections (for GEE).

Below we describe the developed pipeline and details of generating the data and training the final models in Section 3. Then we present a comprehensive qualitative and quantitative evaluation of the results in Section 4. Finally, Section 5 describes the user feedback, collected from two groups of users: teachers and learners of Estonian as a second language (L2). Since the presented project is an ongoing effort, we finish with a brief description of lessons learned and future work in Conclusion 6.

2 Related Work

2.1 Grammatical Error Correction

The task of grammatical error correction (GEC) is to automatically detect and correct erroneous text. Bryant et al. (2023) argue that although the denomination of the task refers to grammatical errors, the scope of the task is not strictly limited to grammatical errors but other types of errors as well, such as spelling and fluency errors.

Recent approaches have moved from neural MT (Yuan and Briscoe, 2016) to LLM-based (Masciolini et al., 2025a). Even without downstream fine-tuning, LLMs have shown to generate grammatically correct text as an emergent ability (Cao et al., 2023; Coyne et al., 2023), but the edits tend to be

fluency edits as opposed to minimal edits (Fang et al., 2023; Davis et al., 2024).

Automatic error generation (AEG) is a widely applied approach in GEC, consisting of injecting automatically generated errors into correct sentences in order to generate synthetic GEC data. Approaches to AEG include rule-based (Sidorov et al., 2013; Ma et al., 2022), statistical methods (Felice and Yuan, 2014; Kasewa et al., 2018), and neural networks-based work (Grundkiewicz et al., 2019; Bout et al., 2023).

Korotkova et al. (2019) used neural MT for GEC for Estonian. Luhtaru et al. (2024b) used fine-tuned LLMs for both artificial error generation and correction. They used L2 essays for generating errors and evaluated the results on the Estonian learner language (EstGEC-L2) corpus¹. They concluded that using Llama-2-based fine-tuned models gave the most human-like distribution of generated errors. Another dataset, the EKI error-annotated L2 (EKI-L2) corpus², was released in 2024. The two corpora are included in the MultiGEC-2025 shared task (Masciolini et al., 2025b). The best results were achieved by the multilingual LLM based model of Staruch (2025), providing the whole essay at once for correction. Most GEC approaches and evaluation methods are sentence-based (Bryant et al., 2023), including previous work in Estonian GEC, which limits the system’s access to the broader context necessary for correctly detecting and correcting paragraph- or document-level errors.

2.2 Grammatical Error Explanation

Alongside GEC, the task of grammatical error explanation (GEE) has received increasing attention. Providing a reason for each correction helps language learners and other users to understand and learn from their errors.

Chen et al. (2017) extracted grammar patterns from a reference corpus to assist L2 learners of English in academic writing. E.g., the correction *chance for giving* → *chance to give* would be explained by the edit pattern *chance: N for -ing* → *N to v*. Lai and Chang (2019) also detected problem words co-occurring with grammar edits. They formulated feedback templates depending on the error type, classified by ERRANT (Bryant et al., 2017).

Another enhanced GEC system by Kaneko et al. (2022) presents related language examples based

on k -nearest-neighbour machine translation trained with incorrect-correct sentence pairs from English learner corpora. However, GEE-specific datasets allow to train models that give more detailed responses. Hanawa et al. (2021) experimented with neural retrieval and generation methods using L2 English essays manually annotated with feedback comments. Fei et al. (2023) introduced a dataset with error type and problem word annotations, using it for BERT-based token classification and error class prediction.

While it is costly to produce human-annotated or carefully engineered corpus-induced training data, the prompting of LLMs can offer a more accessible solution for GEE. Maity et al. (2024) prompted various LLMs in one-shot mode to correct erroneous Bengali sentences and obtain a brief explanation of each error. Song et al. (2024) achieved a better GEE performance with a two-step pipeline for explaining German and Chinese error corrections. First, they prompted and fine-tuned LLMs to extract atomic edits (insert, delete, replace, relocate). Then, explanations were generated by few-shot prompting GPT-4. This significantly improved the results compared to using only sentence pairs as input. Kaneko and Okazaki (2024) and Ye et al. (2025) similarly leveraged the in-context learning capabilities of the GPT models to synthesize English and Chinese error explanation data, respectively. Ye et al. (2025) used their dataset to fine-tune open-source LLMs both in a pipeline and multi-task setting, integrating GEC and GEE.

We adopt the LLM-based pipeline approach and include error types in addition to atomic edits. As a novel contribution, we provide each edit with two explanations of different detail levels: 1) a brief overview of the error cause and 2) a more comprehensive reasoning mainly aimed at advanced learners and teachers. We create synthetic data with both types of explanations by few-shot prompting GPT-4o and fine-tune a Llama-2-based LLM adapted for Estonian.

3 System Development

The system development consisted of data generation and fine-tuning for GEC and GEE. The resulting system pipeline consists of three steps: 1) grammatical error correction, 2) error tagging and 3) error explanation. The models, alongside the generated synthetic training datasets, are public and have a permissive license.

¹<https://github.com/tlu-dt-nlp/EstGEC-L2-Corpus/>

²<https://doi.org/10.15155/27bh-ny83>

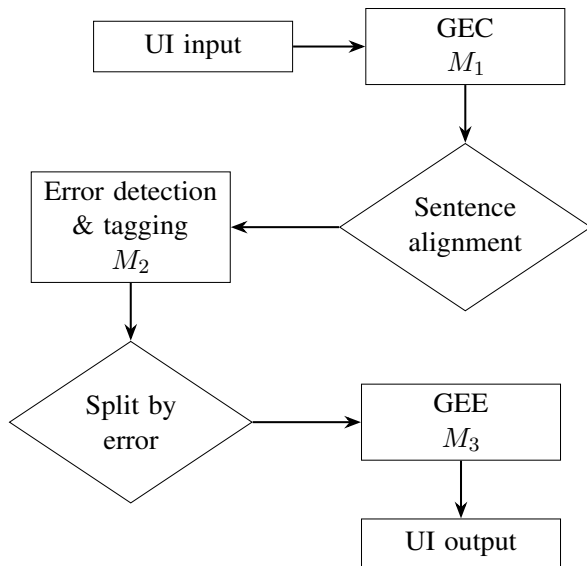

Figure 1: A high-level overview of the system. Each M denotes a model fine-tuned for the given task.

Figure 1 gives a high-level overview of the system (see a detailed example in Appendix A). The user’s input text, i.e., a paragraph, is passed to the first model M_1 as a whole, which then outputs the corrected text.³ The input and corrected text are split into sentences and aligned with the sentence aligner, resulting in input-output sentence pairs. If the input sentence is not equal to the output sentence, thus an error was corrected, the pair is passed to the second model M_2 , which outputs a list of tagged error corrections for each sentence pair.⁴ If input and output are equal, the following models are skipped. Otherwise, the sentence pair and the list of tagged errors are passed to the third model M_3 error by error, which explains the error correction.⁵

Next, we discuss these steps in detail. Fine-tuning is elaborated in Subsection 3.1. Subsections 3.2 and 3.3 delve into GEC and GEE model development, which involves experiments for data generation and finally generating the final datasets and fine-tuning the models. Although the GEC model works on paragraph level, GEE was performed on the sentence level due to context window limitations; to that extent, we performed sentence alignment, details of which are given in Subsection 3.4.

⁵<https://huggingface.co/tartuNLP/Llammas-base-p1-GPT-4o-human-error-explain-from-pseudo-m2>

3.1 Fine-tuning details

Base model For the base model we chose Llammas-base, which is a Llama 2 7B model that has been trained on Estonian texts in continued pre-training setting (Kuulmets et al., 2024) and has shown SOTA results by fine-tuning for Estonian sentence-level GEC (Luhtaru et al., 2024b).

Training parameters Apart from the maximum sequence length, which was 4096, 2048 and 4096 for M_1 , M_2 and M_3 , we used the same parameters as Luhtaru et al. (2024b) for all three models. For prompts, see Appendix B.

Hardware The models were trained on 2 AMD MI250X GPUs in the LUMI supercomputer,⁶ which totals 4 GPUS because AMD MI250X GPU is considered as two GPUs from both hardware and software perspectives in LUMI, each having access to 64 GB of memory.

3.2 Error correction and error type detection

For human-annotated training data, we used the EKI-L2 GEC corpus, which is part of MultiGEC-2025 (Masciolini et al., 2025b). It consists of 1,503 learner essays and 17,361 sentences, nearly 3/4 of which include at least one grammatical error. The dataset includes both minimal and fluency edits, we used the part with minimal corrections. Similarly to EstGEC-L2, its annotation follows the M^2 format and ERRANT error classification (Bryant et al., 2017) adapted for Estonian.

To increase the amount of pre-training data, we also generated synthetic data for Estonian. Moreover, as Luhtaru et al. (2024b) show that inserting errors into out-of-domain texts can actually hurt performance, we compare synthetic error addition to the original GEC data (corrected essays in EKI-L2), similar-domain human texts and synthetically generated texts. Human data from the similar domain consists of similar-sized excerpts of fiction, extracted from the Estonian National Corpus⁷.

We used OpenAI’s GPT-4o⁸ to generate essays based on EKI-L2. For each original corrected essay, we gave it as a 1-shot sample and prompted the model to generate a similar, correctly written essay given the original proficiency level. With temperature 1 the generated essays followed the argumentative structure of the sample with a new

⁶<https://www.lumi-supercomputer.eu/>

⁷<https://doi.org/10.15155/3-00-0000-0000-0000-08D17L>

⁸<https://platform.openai.com/docs/models/gpt-4o>

topic, at higher temperature levels the amount of noise rose sharply, so the essays were generated at 1.1. While we filtered out most of the noise, a few generated essays did include some grammatical errors.

GPT-4o few-shot prompting (at temperature 1.0) was then used to generate errors in these texts, sentence-by-sentence, given 5 randomly picked corrected-mistaken sentence pair samples from the original EKI-L2 corpus. Each of the four datasets was used as error correction training data to fine-tune a Llammas-base (Kuulmets et al., 2024) model for 3 epochs, which was then tested on 141 essays of the development set of EstGEC-L2 corpus (levels A2–C1).⁹ For training details, see Subsection 3.1. As some grammatical errors can only be detected when considering the context, the error correction models were given the whole essay as input, splitting only if the essay was too long to fit into the context window. The results can be seen in Table 1.

	P	R	F _{0.5}
Human errors			
EKI-L2	76.64	40.35	64.95
Synthetic errors			
EKI-L2	71.40	41.45	62.39
Fiction excerpts	70.55	46.55	63.96
Generated essays	69.70	49.19	64.33

Table 1: Error correction precision (P), recall (R) and F-score (F_{0.5}) after 3 epochs of training on different genres. Scores of the model trained on human errors versus models trained on synthetic errors generated into the listed datasets. EKI-L2 synthetic errors were generated into the target sentences, leaving with synthetic source sentences.

As automatically generated essays proved to yield good results compared to other training corpora, we 1) generated a 10 times larger set of essays, 2) introduced artificial errors to the generated essays and 3) employed a two-stage fine-tuning procedure for GEC. We first fine-tuned Llammas-base on a randomly shuffled 10:1 mixture of synthetic-human data. We then fine-tuned the best-performing checkpoint from the first stage on EKI-L2 human dataset. The checkpoint with the highest F_{0.5} score on the development set served as the base model for the second stage of the fine-tuning, which was fine-tuning the model again on the human dataset. The optimizer state was

⁹Originally 102 essays; longer essays were split.

reinitialized and the hyperparameters remained the same as in the first stage of fine-tuning. The third checkpoint of the final model served as the GEC model M_1 in the workflow.

For error detection and classification, we transformed EKI-L2 M^2 edits into simplified atomic edits with error type information, to be given as input for GEE. We fine-tuned a Llammas-base on the EKI-L2 set with atomic edits, resulting in the error tagging model M_2 in the workflow.

3.3 Error explanation

To generate training examples for GEE, we evaluated three approaches using OpenAI’s GPT models: 1) single-prompt parallel input, where the model was given original and corrected sentence pairs; 2) single-prompt error-tagged input, which provided correction edits and error-type information; and 3) prompt chaining with parallel input, which identified and explained corrections through separate prompts. These approaches were assessed using zero-shot and few-shot prompting.

The evaluation was based on 40 random sentence pairs from the EstGEC-L2 development set, including 10 pairs per proficiency level (A2–C1). In case of multiple error annotations, the first version was chosen. For each error, we requested either a single explanation or paired explanations: one brief and one more comprehensive. We rated their quality using colour codes based on traffic lights, so that green indicates good, yellow fair and red poor explanations. More precisely, green represents clear and sufficient information. Yellow denotes partial or nonfluent information that may still be helpful and does not mislead the user. Red explanations contain incorrect statements and terms, or simply describe the correction, but do not offer a justification. The explanation accuracy was defined as the percentage of good and fair explanations.

Annotators were three research group members with a linguistic background and previous experience in L2 error annotation. There was one annotator per each explanation. The annotation was reviewed by an L2 teaching expert participating in our project. The expert-guided evaluation principles were jointly discussed and specified throughout the evaluation process.

Initial experiments used Estonian and English zero-shot prompts and compared the performance of GPT-4o, GPT-4, and GPT-3.5 Turbo with Microsoft Azure’s default settings (temperature 0.7, top p 0.95) and reduced variability (lowering ei-

ther of the parameters). GPT-4o with default settings outperformed other models, producing fewer factual or logical errors, particularly in detecting Estonian case forms and sentence interpretation. Notably, Estonian prompts yielded more precise and fluent explanations. Requesting paired explanations provided higher-quality responses. In particular, comprehensive explanations could be considered more accurate and informative compared to single ones. Brief explanations were more problematic, often describing corrections (e.g., word x should be y) without any additional context.

The results generally improved by first generating the longer explanation instead of the shorter one. This way, the accuracy of long explanations increased from 29% to 64% with single-prompt parallel input and from 62.5% to 83% with error-tagged input. Brief explanation accuracy went from 0% to 18% with single-prompt parallel input and dropped from 54% to 48% with error-tagged input.

Adopting the paired explanation approach, we refined the best Estonian prompts to avoid redundant or insufficient information. For few-shot prompting, we constructed examples based on eight Estonian learner sentences, representing the 12 main error types and some combined errors (see (1) for an example of explanation input and output, translated into English). The single-prompt approach proved more effective with the few-shot method, whereas the prompt chaining did not yield better results. Its long explanation accuracy decreased from 58% to 36% and brief explanation accuracy from 56% to 44% compared to the zero-shot method. The main limitation was detecting atomic edits despite the few-shot examples. In a test where GPT-4o had to identify GEC edits three times per sentence pair and select the correct answer, it chose the right output for 28 out of 40 sentence pairs.

- (1) Source sentence: Head aega.
 Target sentence: Head aega! ('Goodbye!')
 Correction(s):
 1. incorrect punctuation: . -> !

 Explanation 1: . -> !
 Long: In Estonian, a greeting sentence ends with an exclamation mark, e.g., "Tere hommikust!" ('Good morning!'), "Head uut aastat!" ('Happy new year!').
 Brief: An exclamation mark is used after a greeting or wish.
 Error type: incorrect punctuation

Since the error-tagged input provided full alignment with actual edits and error types, we decided to use it for training data generation. In addition, this approach led to significantly higher accuracy in longer explanations (91% compared to 65% with parallel input). The accuracy of brief explanations was lower, equally 52%, mostly due to merely descriptive explanations. Therefore, we further improved the prompt to provide more meaningful clarifications. We synthesized error explanations based on the EKI L2 corpus from Subsection 3.2, using the 12,580 sentences that contain the atomic edits. We fine-tuned a Llammas-base model to generate explanations error-by-error on the synthesized dataset, resulting in model M_3 in the workflow.

3.4 Sentence alignment

As the error explanation model required input on sentence level, the essay from model M_1 error correction output had to be aligned with its input on sentence level. The same need came up when evaluating M_1 output. Complications rose when a sentence was split into several or several sentences joined as part of the correction, also when the M_1 model hallucinated new sentences, such as a greeting to start a letter. Sometimes a mismatch was caused by the sentence tokenizer mistaking the sentence boundaries in uncorrected text.

To solve this problem, we developed a simple many-to-many sentence aligner based on the Levenshtein distance. When aligning the gold standard and output essays during evaluation we considered the distance between corrected sentences of both essays, merging the gold M^2 representations as necessary. Testing on 400 essays of the training corpus, this rule-based aligner found correct alignments for 98% of the original sentences.

4 System Evaluation

4.1 Error correction performance

Error correction scores were automatically evaluated on the EstGEC-L2 development set using a modified version¹⁰ of the M^2 scorer (Dahlmeier and Ng, 2012). This yields error-level F-score comparing the output sentence with all given gold corrections, as well as a broad statistics of recall by error type. The modified version also takes into account that the word order error type ($R:WO$) used in train and test corpora can encompass other errors, as word order in Estonian tends to be rather

¹⁰<https://github.com/TartuNLP/estgec/>

free and the scope of that error type may include a large part of the sentence. The results on the development set of EstGEC-L2 corpus can be seen in Table 2, comparing the models trained on smaller or larger datasets of synthetic essays, and the latter model post-fine-tuned on human errors. While using a large number of generated essays did significantly raise recall, it is surprising that additional fine-tuning on human errors brought it down without much increase in precision. This may be partly due to the larger training set containing human errors already contributing to higher precision.

	P	R	F _{0.5}
GPT-4o	69.56	54.13	65.81
Synth _S	69.70	49.19	64.33
Synth _L -EKI-L2 Mix	75.61	45.68	66.85
+ EKI-L2 FT	76.45	42.45	65.90

Table 2: Scores of models trained on datasets with synthetic errors, based on the best F_{0.5} score across 3 epochs, compared to prompting GPT-4o at temperature 1 for GEC in a 1-shot setting (see Appendix B for details). Synth_S was trained on 1,503 generated essays with synthetic errors, while Synth_L-EKI-L2 Mix was trained on a dataset 10× larger, mixing synthetic and EKI-L2 errors. Synth_L-EKI-L2 Mix was also post-fine-tuned on EKI-L2.

While our F_{0.5} score is notably higher than the 49.44 reported by Staruch (2025), theirs was a multilingual system tested on a smaller subset of the EstGEC-L2 corpus. GPT-4o achieves a higher recall but a lower precision, resulting in a lower F_{0.5} score. We incorporated the EKI-L2 fine-tuned Synth_L-EKI-L2 Mix model trained for 3 epochs in our workflow as the final M₁ model, although its F_{0.5} score was better after epoch 1, recall was highest after 3 epochs.

The modified M² scorer shows recall by error type even if M₁ does not assign types. Considering the results (see Figure 2), the most difficult type by far is word order, mostly because the correction is considered accurate only if all possible encompassing errors are corrected as well. E.g., the phrase ‘*raamat loen ma*’ (‘*book-nom read I*’) should be corrected not only as ‘*ma loen raamat*’ (‘*I read book-nom*’), but also with the correct case ‘*ma loen raamatut*’ (‘*I read book-part*’). Note that the error correction model does not assign an error type, so even if it detects an error in the same scope as a nominal form error, it might try to replace or erase the whole word.

Leaving word order aside, the more difficult types to correct are word and punctuation choice (R:LEX, R:PUNCT), although missing punctuation marks (M:PUNCT) tend to be rather easy. This is somewhat expected as the choice of words for replacing an unsuitable one is rather large and not all suitable words are listed in human corrections. Inserting missing punctuation marks, correcting the capitalization (R:CASE) or whitespace, i.e., compounding errors (R:WS) as well as picking the right nominal or verb form (R:NOM:FORM, R:VERB:FORM) are all handled with slightly higher recall, as could be expected from a strong language model. As was seen from the evaluation scores, adding synthetic data helped raise recall. This seems to be mostly due to better detection of word order and compounding errors. The final model also detects capitalization errors noticeably better than the one trained on human errors, but if we consider corrections, then they are around the same level, as the model has trouble providing correct replacements. If we consider what may have contributed to the drop of precision in the final model, then most noticeable bottlenecks are detecting unnecessary words (U:LEX) and correcting complex errors where there are several mistakes in one word (e.g., wrong verb form with a spelling mistake – R:VERB:FORM:SPELL).

Figure 2: Recall by type for the 11 most frequent error types in the test corpus. Number of errors of each type present in test corpus is shown in columns for reference.

The test dataset has essays from proficiency levels A2–C1, whereas C1 was not present in the training corpus that contains K-12 student essays. When comparing error correction performance of the fine-tuned model across language proficiency levels (see Table 3), the results are quite uniform. The scores are a little better for A2, possibly because the sentences used are still rather simple. Recall is no-

	P	R	F _{0.5}
A2	74.12	48.99	67.22
B1	71.48	48.13	65.16
B2	74.00	43.32	64.82
C1	71.43	47.23	64.79
All	72.91	46.58	65.51

Table 3: GEC scores by language proficiency level.

ticeably lower for B2. The drop is most clear for two error types: word order and wrong punctuation mark. Out of 26 cases of wrongly chosen punctuation marks in B2 texts, none received the correct replacement, although a mistake was detected in more than third of these. B2 texts had more word order mistakes (196, compared to 127 in B1 texts and less than 100 on other levels), but even the recall of partial scope overlap was lower than for other levels: 32% compared to 47% or more. The distribution of more common error types and their detection rate can be seen in Figure 3. As for other proficiency levels, the model has relatively more difficulties detecting missing words in A2 texts, missing punctuation in B1 texts, and wrong capitalisation in C1 texts, although in the last case there were only 4 such mistakes present, which may be too few to draw conclusions.

4.2 Qualitative analysis of system output

For qualitative assessment of the three system components — corrector, error detector/classifier, and explainer — we randomly selected 40 sentences from the EstGEC-L2 test corpus, balanced for proficiency level (A2–C1). We compared two settings: a uniform 0.7 temperature and a varied higher temperature (1.0 for M_1 , 0.8 for M_2 , 0.9 for M_3) to encourage creativity.

In comparison with golden edits, we distinguished four correction types: necessary and suitable, necessary but incorrect, unnecessary but suitable, and unnecessary and incorrect. We calculated precision based on both types of suitable edits. The macro-averaged precision of error classification was assessed according to proposed changes, even if incorrect. Explanations were graded as good, fair, or poor, as described in section 3.2 (see translated examples in Appendix D). We separately evaluated explanations for necessary suitable corrections, since it is challenging or even futile to explain unnecessary or incorrect edits.

Lower temperature entailed higher correction

precision (89% vs. 76%) and fewer edits (63 vs. 71), while the number of suitable corrections was similar (56 vs. 54). The 0.7 setting also resulted in a greater overlap with reference edits (60% vs. 46%). However, the correction model then failed to detect word order errors. We suggest using an intermediate temperature for GEC. The average precision of error classification was comparable in the two conditions: 84% with higher and 87% with lower temperature.

The quality of explanations was generally better at the 0.7 temperature (see Table 4). Long explanations were more likely to be rated good or fair compared to the 0.9 temperature both in case of necessary corrections and all corrections, including optional and unjustified edits. Necessary brief explanations followed a different trend, being more accurate at the higher temperature. Nonetheless, when considering all system corrections, the proportion of good and fair explanations remained similar in the 0.7 setting, whereas radically dropping in the 0.9 setting. This refers to a better capability to justify optional edits at the lower temperature.

	Temp 0.7	Temp 0.9
Long explanations		
Necessary: good	51%	37%
Necessary: good/fair	66%	48%
All: good	51%	27%
All: good/fair	63.5%	37%
Brief explanations		
Necessary: good	45%	50%
Necessary: good/fair	70%	76%
All: good	46%	34%
All: good/fair	67%	51%

Table 4: GEE quality with two temperature settings.

In terms of GEE, our results can be compared with Maity et al. (2024) and Ye et al. (2025), who reported accuracy over 60%, and outperform Hanawa et al. (2021), who reached 40%–50% accuracy in explaining preposition errors and below 40% with various error types. One shortcoming was the inaccuracy of linguistic terms, such as using an existing term in a wrong context (e.g., false association of nominal case and word form) or forming a nonexistent term. This concerned 24% of long and 3% of brief explanations in the lower temperature setting. Furthermore, the prompt could be improved to explain context-dependent errors like grammatical form or word choice errors.

Figure 3: Error detection recall by language proficiency level for more common error types, considering at least partial overlap in scope.

5 User Feedback

5.1 Participants and questionnaire

The user test involved six learners and five teachers and/or testing experts of Estonian as L2. Volunteers were recruited using snowball sampling, considering their experience of learning and teaching at different proficiency levels. The teachers' expertise covered the whole range from pre-A1 to C1 level. Three teachers had taught adults and students from pre-A1- or A1- to C1-level. One had focused on adult learners with diverse backgrounds at levels A1 and A2. One had assessed exams at all tested levels but primarily at B2 and C1, prepared exam and screening test tasks, and briefly taught language courses. Three of the teachers were native Estonian speakers, one an Estonian-Russian bilingual and one a native Russian speaker who uses Estonian at home, at work and in daily life. The learners were Russian- and Ukrainian-speaking and bilingual (Ukrainian-Russian or Russian-Estonian). Three of them had lived in Estonia for many years or most of their lives and rated their language level as B2 and C1. The others reported their level to be A2 or B1, having spent 2.5–5.5 years in Estonia. Their exposure to Estonian ranged from rare use in lessons or grocery store to everyday use at work.

We used Google Forms to gather feedback through a semi-structured questionnaire. The respondents were given the option to answer the sur-

vey in English. We developed a demo application for testing (see Appendix C). First, we asked the users to assess the output for a sample B1-level text fragment. Repeated analysis of the same text may give varying results, so we presented a pre-given version of five corrections and explanations as screenshots to ensure response comparability. Subsequently, users interacted with the tool directly, correcting their own text or a student's writing, commenting on each correction and explanation and their general experience.

5.2 Results

Both teachers and learners found that the system makes most of the needed corrections and the majority of explanations could be useful in existing form or with some changes. 10 out of 11 test users considered the corrections somewhat useful or useful (corresponding to 4–5 on a 5-point Likert scale). Explanations were rated similarly by nine respondents. Three teachers and learners noted their plan to use the application in the future, one teacher and two learners would probably use it and one respondent from each group was not sure about it.

All corrections in the provided sample were considered appropriate, although two teachers noted that a lexical choice correction was not strictly necessary. Each explanation was rated on a three-point scale: useful – somewhat useful – not useful. Depending on the correction, long explanations

were found useful by 5–9 and brief explanations by 5–10 test users, averaging to 2/3 of the respondents. About 1/3 and 1/4 of the users, respectively, considered long and brief explanations somewhat useful. On average, one user did not think the shorter explanation was useful. The respondents agreed to defined error types, except for the case where word order and nominal form error occurred together but only the former was detected.

As expected, analysing user texts revealed more issues because these texts were generally longer than the sample and the system made more corrections in them. Teachers found an average of 82% and the learners 87% of corrections relevant. Both groups considered about 70% of long explanations at least somewhat useful, whereas brief explanations seemed useful to more than half of the learners and 3/4 of the teachers. Fixing and explaining structural errors in long complex sentences that contained numerous errors turned out to be challenging. The tool also had some trouble identifying and explaining combined errors. While our aim was to classify and explain all co-occurring error types, only one type may be detected and covered in the explanations (e.g., a spelling error is ignored alongside the choice of correct word form).

The explanations were said to give a comprehensive overview of the errors and help language learners notice errors they might be making systematically. Long explanations were rated higher in terms of content and wording, although there were also instances of complex language use or no added value compared to the shorter version. Users claimed that long explanations should complement short ones, while short explanations should still be informative. In some cases, two explanation layers may not be needed. Both teachers and learners recommended to put more emphasis on simple language comprehensible for A2- and B1-level learners, especially in brief explanations. Some suggestions were made to generalise or specify error classification and improve the user interface, however, the overall assessment was positive in both respects.

6 Conclusion

We trained a workflow of three fine-tuned models for GEC and GEE. Using synthesized L2 texts with introduced errors seems promising, but a larger training set might be necessary. Our first model corrects errors at the paragraph level and performs

well on L2 texts with a proficiency level not present in training data. The model yields higher precision with similar recall at lower temperatures but then struggles with word order errors, so we suggest using medium temperature.

We achieved better quality explanations in GEE by incorporating error types in addition to atomic edits in input and requesting two explanations (longer and shorter) for each error. This could be further improved as both LLM prompting and our fine-tuned model have low recall on detecting error types. It is also necessary to filter out low-quality explanations, such as including nonexistent nominal cases, by possibly using LLMs to evaluate the quality of a given explanation.

While our GEC model was paragraph-based, we used a sentence-based approach due to model limitations. In future work, we will apply a new methodology to preserve context and fit within hardware limits with the context window size. For each sentence in the essay, we will split essays into tuples of N consecutive sentences up to the given sentence. The new methodology could allow us to combine GEC and GEE into one model. In future work, we will also explore reversing the pipeline for fine-tuning for AEG.

Acknowledgments

The project “Autocorrect for Estonian as a 2nd language for learners and teachers” has been co-funded by Estonian Ministry of Education and Research and the European Union. We acknowledge University of Tartu, Estonia for awarding this project access to the LUMI supercomputer, owned by the EuroHPC Joint Undertaking, hosted by CSC (Finland) and the LUMI consortium through University of Tartu, Estonia.

Limitations

Although our GEC system is based on paragraphs, the GEE pipeline, including both error detection and explanation, is based on sentence level due to context window limitations, limiting the model’s capability to explain errors at the document level. Future work needs to classify and explain errors with context, as well as combine related errors for explanation.

The GEE pipeline relies on atomic edits with error-type information, which we found necessary for reasonable explanations. However, atomic edits are based on M^2 , thus making it costly to obtain

new data. Future work should explore the automatic generation of atomic edits.

Additionally, GEC scores rely highly on the sentence alignment method since the M^2 scorer works on the sentence level. Poor sentence alignment affects the scores negatively.

A System Overview

Figure 6 gives a detailed overview of the system with an example. The input paragraph translates to “I very much like classical music. We earlier bought the tickets. Sometimes already in January.” The explanations translate to “The correct spelling is “väga” (very)”, “Instead of the word “klassikat” (“classic” in the wrong case form), the word “klassikaline” should be used to show that the music is of classical type”, “In Estonian, the verb is generally before the adverb (adverb of time), for example, “ostsime piletid” (we bought the tickets) and “varem” (earlier). The original word order “varem ostsime piletid” is wrong.”

B Prompts

Tables 5, 6 and 7 display the prompts used for fine-tuning M_1 , M_2 and M_3 . The prompt format is from Luhtaru et al. (2024b), which in turn is loosely based on Alpaca (Taori et al., 2023) format. Table 8 shows the prompt used for GPT-4o for GEC.

C Demo application

For user testing, we developed a demo application¹¹ based on the Writing Evaluator proofreading tool of an Estonian language learning and analysis environment (Allkivi et al., 2024). The demo reuses existing interface components, such as approving or rejecting corrections and grouping errors by type.

After the user inserts their text, the back-end returns the corrected sentences along with error annotations, including error type and two accompanying

¹¹<https://elle.tlu.ee/corrector-test>

explanations. Users can interact with corrections in two ways: **inline view** — moving the cursor over a highlighted segment in the text triggers a popup displaying a short explanation and options to accept or reject the correction (See Figure 4); **sidebar view** — on the right side of the interface, corrections are grouped by type (see Figure 5). Clicking on a category reveals a list of related corrections with longer explanations.

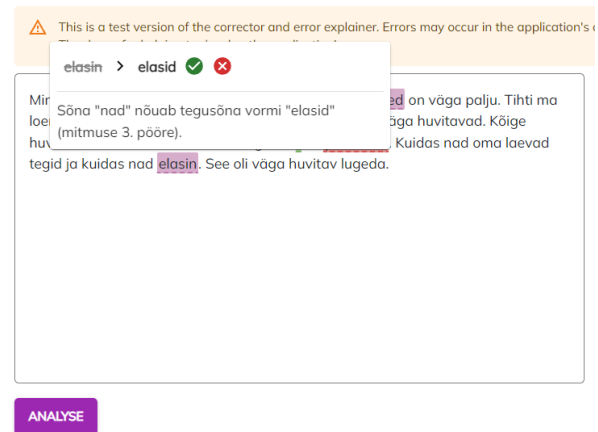

Figure 4: Popup view with a short explanation when hovering over a highlighted correction.

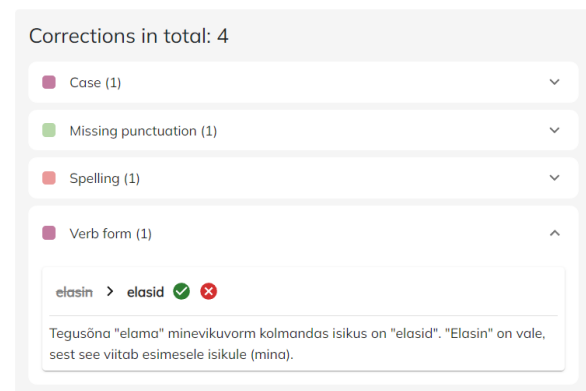

Figure 5: Sidebar displaying error categories and longer explanations under selected corrections.

D Example explanations

We rated the quality of system error explanations on the following scale: good — clearly presented and sufficient information; fair — partial or nonfluent but correct information; poor — use of incorrect statements and terms or edit description without additional context. Example (2) demonstrates a comprehensive and brief explanation annotated as good. Example (3) includes a brief explanation rated as fair and a longer explanation rated as poor.

```

### Instruction:
Reply with a corrected version of the input essay in Estonian with all grammatical and spelling errors fixed. If there
are no errors, reply with a copy of the original essay.

### Input:
{input}

### Response:
{correction}

```

Table 5: The GEC model M_1 fine-tuning prompt. The GEC instruction is a modification of the prompt by [Coyne et al. \(2023\)](#).

```

### Instruction:
Sa võrdled kahte eestikeelset lauset: keeleõppija kirjutatud algne lause ja parandatud lause. Genereeri vea kaupa
paranduste loend, kus on vealiik, algne tekst ja parandatud tekst.

### Input:
Algne lause: {original sentence}

Parandatud lause: {corrected sentence}

### Response:
Parandused: {list of atomic edits}

```

Table 6: The error detection and classification model M_2 fine-tuning prompt.

The correct word “terrassil” is in the adessive case form, not inessive, although both express location in Estonian. The brief explanation only considers the nominal form error, disregarding the spelling error (the base form is “terrass”, not “terrass”).

- (2) Source sentence: Pärast kontserdi me otsustasime juua kohvi restoranis ja koju minna jalgsi.
 Target sentence: Pärast kontserti me otsustasime juua kohvi restoranis ja koju minna jala.
 (‘After the concert, we decided to drink coffee in a restaurant and walk home.’)

Explanation: kontserdi -> kontserti
 Long: The word “päras” (‘after’) requires the partitive case, so the correct form is “kontserti”. The form “kontserdi” is in the genitive case and is not appropriate here.
 Brief: The word “päras” (‘after’) requires the partitive form “kontserti”.
 Error type: nominal form

- (3) Source sentence: Linnas ma istun terras ja joon siider.
 Target sentence: Linnas ma istun terrassil ja joon siidrit.
 (‘In the city, I sit on a terrace and drink

cider.’)

Explanation: terras -> terrassil
 Long: The inessive case form of the word “terrass” is “terrassil”. It expresses location (where?).
 Brief: The correct case form is “terrassil” (where?).
 Error type: nominal form

Instruction:
 Sa võrdled kahte eestikeelset lauset: keeleõppija kirjutatud algne lause ja parandatud lause. Sulle antakse paranduste loend, kus on vealiik, algne tekst ja parandatud tekst. Su ülesanne on selgitada ühte parandust. Selgita seda parandust, mis järgneb sõnale 'Selgitus'. Esiteks too välja põhjalikum selgitus, miks parandust vaja on. Teiseks anna lühike selgitus lihtsamas keeles. Pärast selgitust nimeta vealiik. Mitu vealiiki võivad kokku langeda. Omavahel seotud parandusi (näiteks sõnaühend, kus muutub mõlema sõna vorm) selgita koos. Sõnajärje parandusega kattuvaid muid parandusi selgita eraldi.

Input:
 {sentence pair, list of errors and input error to explain}

Response:
 {explanation for input error}

Table 7: The GEE model M_3 fine-tuning prompt.

Reply with a corrected version of the input text in Estonian with all grammatical and spelling errors fixed. If there are no errors, reply with a copy of the input text. There is one example of the task.

Input text: {example input paragraph}
 Corrected: {example corrected paragraph}

Input text: {input paragraph}
 Corrected:

Abstract

Automated item generation (AIG) is a key enabler for scaling language proficiency assessments. We present an end-to-end methodology for automated generation, annotation, and integration of adaptive writing items for the EF Standard English Test (EFSET), leveraging recent advances in large language models (LLMs). Our pipeline uses few-shot prompting with state-of-the-art LLMs to generate diverse, proficiency-aligned prompts, rigorously validated by expert reviewers. For robust scoring, we construct a synthetic response dataset via majority-vote LLM annotation and fine-tune a LLaMA 3.1 (8B) model. For each writing item, a range of proficiency-aligned synthetic responses, designed to emulate authentic student work, are produced for model training and evaluation. These results demonstrate substantial gains in scalability and validity, offering a replicable framework for next-generation adaptive language testing.

1 Introduction

The demand for scalable, authentic, and adaptive English proficiency assessments has grown rapidly in recent years, as language learning expands across global and digital platforms. This surge has compelled test developers to explore advanced Natural Language Processing (NLP) and Machine Learning (ML) solutions that can deliver reliable and fair measurement at scale. The EF Standard English Test (EFSET)¹ exemplifies recent innovation in this space, having introduced performance-based Writing and Speaking tasks that leverage state-of-the-art NLP and ML methods for both test delivery and automated scoring (Nebhi and Szaszák, 2023; Williams et al., 2022).

Despite these advances, item generation remains a major challenge for adaptive assessment. Creating high-quality prompts that are valid across a

range of topics, calibrated for all proficiency levels, and secure from test exposure is both resource-intensive and psychometrically complex (Zhang et al., 2022; Brown, 2023; Gierl and Haladyna, 2012). As the development and deployment of adaptive language tests like EFSET increases, scalable and robust methods for generating, validating, and securing writing assessment items are crucial for the advancement of fair and accurate proficiency measurement.

To address this issue, we present a novel pipeline for generating and incorporating new items into the EFSET writing assessment scoring process. Our method uses Large Language Models in Automatic Item Generation (AIG) and Synthetic Data Generation for Student Responses for scalable adaptive writing assessment. First, we generate new assessment items using a few-shot learning strategy applied to LLMs, systematically exploring multiple prompting combinations. Human evaluators then verify item quality, ensuring appropriate difficulty, clarity, and topic relevance.

In order to then integrate these validated, newly generated items into our existing automated assessment pipeline, we fine-tune a LLaMa-3.1 8B model via ORPO (Optimized Reward Preference Optimization) (Hong et al., 2024) to generate realistic student-like responses for these items across different proficiency levels. The fine-tuning relies on real test data combined with systematically generated synthetic annotations obtained via consensus annotation (majority vote) from three distinct LLM annotators. These item-response pairs then allow use to train our existing RoBERTa-based Transformer model for proficiency scoring on these new writing prompts. This synthetic annotation approach ensures scalable yet reliable response-label assignment without intensive human labor.

A summary of the main contributions of this paper is as follows: (1) we introduce an automated item generation (AIG) pipeline for adaptive writ-

¹<https://www.efset.org/en/>

ing assessment that leverages state-of-the-art large language models and few-shot prompting to create high-quality, proficiency-aligned prompts; (2) we propose and validate a synthetic data augmentation process based on fine-tuned LLMs and consensus annotation via majority voting, resulting in robust and reliable datasets for model training; and (3) we develop and empirically evaluate a fully automated scoring framework based on Transformer models (RoBERTa), demonstrating significant gains in accuracy and consistency through extensive testing on EFSET items and a carefully calibrated validation set.

In the following sections, we first review the state of the art in automated writing assessment and item generation. We then detail our methodology for prompt generation, dataset construction, and automated evaluation. Next, we present empirical results illustrating the validity and reliability of our approach on both the EFSET validation set and a dedicated calibration dataset. Finally, we discuss the implications and potential extensions of this framework for scalable, adaptive language proficiency assessment.

2 Related Work

This section synthesizes two key developments in recent research on automated language assessment. First, we review state-of-the-art approaches to item generation that leverage large language models (LLMs), prompt engineering, and few-shot learning to efficiently produce diverse and high-quality assessment prompts. Second, we examine emerging methods for synthetic data annotation, with a particular focus on the use of LLMs to simulate candidate responses and facilitate reliable labeling at scale for proficiency scoring tasks.

2.1 Automated Item Generation with LLMs and Prompting

The automated generation of test items, especially for language assessment, has evolved considerably in recent years. Early systems used template-based approaches, in which test developers designed fixed “item shells” and populated them with variable linguistic elements—such as word lists or grammatical forms—to produce items at scale (Bejar et al., 2003). For example, thousands of cloze items, exercises where words are removed from a passage for the student to fill in the gaps, could be created programmatically by instantiating such templates

with preselected vocabularies and distractors, providing structural consistency and psychometric control. However, content diversity and authenticity remained limited by the template bank, and extensive manual authoring was needed to cover new topics or scales. These constraints have since led to the exploration of more flexible, data-driven methods, most notably involving large language models (LLMs).

The advent of large pre-trained language models (LLMs) has fundamentally shifted automated item generation toward more data-driven, scalable, and flexible paradigms. Models such as GPT-3 and GPT-4 have been shown to generate diverse assessment items—including reading, writing, and cloze tasks—by leveraging few-shot prompting, where only a handful of examples guide the model’s output (Brown et al., 2020). Educational evaluation shows that LLM-generated items are closely aligned to human-authored items, with Zhang et al. (2022) reporting that over 80% of reading comprehension questions automatically generated by GPT-3 were rated as valid by expert reviewers, and prompt appropriateness and difficulty levels closely aligned to human-authored items. Similarly, Kurdi (2023) found that LLMs could create contextually relevant language assessment prompts, achieving human-likeness scores above 4/5 on standard rubrics. Research by Brown (2023) and Zhai et al. (2023) supports that such approaches not only accelerate item production and reduce costs, but also enable rapid adaptation to new topics and test formats, with acceptance rates for LLM-generated prompts ranging from 60–95% after light expert editing.

However, even high-performing LLM-generated items require careful evaluation and annotation before they can be reliably used in machine learning-based assessment pipelines to ensure that they are well-calibrated and capable of distinguishing student ability. Recent work has shown that using synthetic annotation, consensus labeling strategies (e.g., majority voting among multiple LLMs), or semi-automatic calibration processes significantly improves dataset consistency and psychometric validity (Liu, 2023; Mai, 2022; Clark, 2021; Yao et al., 2024).

2.2 Synthetic Data Annotation for Language Assessment

A persistent challenge in automated educational assessment is the limited availability of high-quality

annotated data required to train and validate modern NLP models for predicting student proficiency. Recent advances have addressed this by not only generating novel assessment prompts, but also leveraging LLMs to simulate candidate responses and assign linguistic proficiency or accuracy labels at scale (Yao et al., 2024; Wang et al., 2024; Brown, 2023).

For instance, Clark (2021) showed that the scarcity of labeled data for language tasks can be mitigated by generating synthetic examples, improving model robustness and generalization. Moreover, ensemble annotation methods—where multiple LLMs independently label each sample and a majority vote is used—have demonstrated increased labeling reliability, especially when compared to standard human annotation benchmarks (Liu, 2023). These synthetic annotation strategies make it possible to rapidly construct large, diverse, and reliable datasets matched to newly generated items.

Integrating both automated item generation and synthetic annotation creates a complete pipeline for adaptively expanding and enhancing machine learning-based scoring systems. Not only does this combination facilitate the inclusion of new item types without costly manual labeling, but it also supports the continual improvement of model accuracy, as shown by transformer-based scoring systems trained on such enriched datasets (Mayfield and Black, 2020; Mai, 2022). This integrated approach forms the basis for recent innovations in fully automated and scalable assessment frameworks.

3 Proposed Approach

This section presents our integrated pipeline for adaptive writing assessment, encompassing automated item generation, synthetic training data creation, LLM-based response simulation, and transformer-based scoring. Our approach is designed to efficiently generate, validate, and psychometrically calibrate novel test items, ensuring both robustness and scalability for deployment in real-world language proficiency testing environments.

3.1 Overview of the Integrated Pipeline Approach

Figure 3.1 presents the end-to-end pipeline developed for adaptive writing assessment. The process begins with the generation of new writing prompts,

using prompt engineering and few-shot learning with a single LLM (GPT-4o) to produce candidate items focused on specific topics and proficiency levels. All generated prompts undergo human expert review, where only validated items are retained for integration into the assessment bank.

We fine-tune a LLaMA 3.1 (8B) model—leveraging ORPO optimization—on a custom instruction dataset to generate synthetic student responses for each validated item reflecting varying proficiency levels. This instruction dataset is created by collecting real candidate answers, prompting several LLMs to annotate each response for accuracy using the few-shot paradigm, and applying a majority voting scheme to select the final label. Only samples with strong inter-model agreement are retained, ensuring high label reliability and calibration.

The resulting synthetic dataset, containing approximately 200 responses per new item, is then used to further train and fine-tune a RoBERTa-based transformer scoring model. This updated scoring engine is evaluated both on existing and new items to ensure seamless integration and consistency. Throughout the pipeline, quality is maintained through a combination of automated filtering and targeted human-in-the-loop validation, enabling scalable, reliable item generation and robust scoring for real-world proficiency assessment.

3.2 Phase 1: Automated Creation and Validation of Writing Items

The aim of this first phase is to automate the generation of writing prompts intended for students to write an essay about, each of which is targeted at a specific proficiency level and topic. We leveraged a large language model (LLM)—specifically, GPT-4o (OpenAI, 2024)—to achieve this. To ensure that the generated writing prompts were tailored to adaptive assessments, we provided the LLM with a set of representative triplets of writing prompt, proficiency level, and topic. We then guided the LLM to generate new writing items with the intended form, content scope, and level-appropriateness by few-shot prompting the LLM with examples of the target structure and the level of complexity required.

In order to guide the LLM, we first carefully curated a small set of ≈ 20 examples explicitly designed to match the communicative demands of English writing proficiency tests. Each writing example consisted of a proficiency level and a suc-

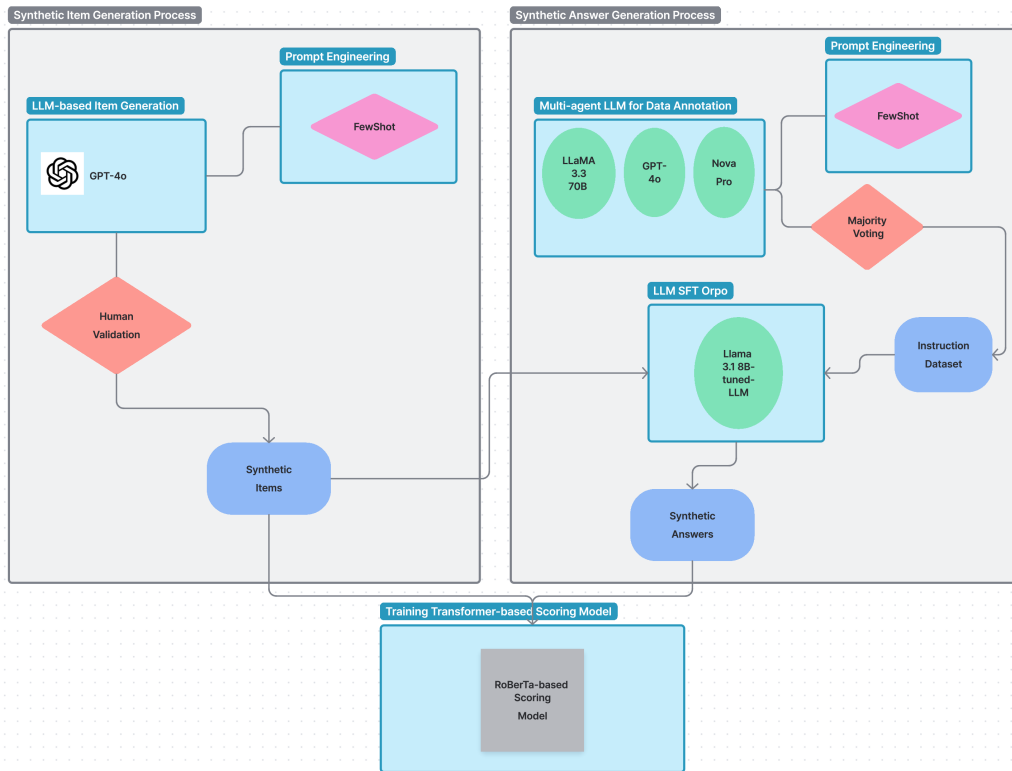

Figure 1: Pipeline for automated item and synthetic answer generation in the adaptive writing assessment

cinct writing prompt (no more than 25 words). To augment these examples with the topic as further context in the few-shot prompt, GPT-4o was applied to generate the topic for these hand-picked examples. The resulting triplets of example writing prompt, proficiency level and topic constituted our set of few-shot examples.

To generate a new writing item, we specified the desired topic(s) and proficiency level as part of the input for the LLM. A few semantically similar but diverse set of examples were chosen from our manually curated collection using LangChain’s Max-MarginalRelevanceExampleSelector (LangChain, 2025). These chosen examples were then passed into the LLM as a part of the input prompt to generate a new item based on the requested topic and proficiency level, as shown in Figure 2.

We ensured a wide coverage of content and linguistic complexity across all proficiency bands by systematically generating new items across multiple combinations of topic and proficiency level.

Five language assessment experts were asked to judge a sample of 100 prompts based on appropriateness for assessment regarding the following metrics: clarity, curriculum fit, and difficulty level. In addition, to further evaluate item quality, we com-

pared expert annotations on both difficulty level and topic with GPT-4o’s predictions, finding a correlation of nearly 0.9. This high level of agreement suggests that GPT-4o is able to closely approximate expert judgment in these qualitative aspects.

The use of LLMs and enabled rapid and scalable item generation, whilst retaining strict quality control through expert review, allowing the assessment to expand to new topics and levels efficiently and reliably, as recommended in recent work on few-shot prompting in language assessment contexts (insert citation).

3.3 Phase 2: Synthetic Generation of Training Data

In this phase, the aim was to generate a high-quality training set to generate responses for the new items produced in Phase 1. The use of ORPO in the next stage requires pairs of good and bad student responses for each item, and hence we require a way to assess the quality of generated responses to produce these pairs of examples. To do so, we first evaluated several available LLMs of different architectures and sizes for its ability to rate student responses. Each model was assessed for its consistency and reliability in assigning grammatical

```

Prompt:
Imagine you are a language teacher writing essay question prompts for an English
level written test. Given the level and topic, write a short prompt (max 25 words)
for the student. The prompt should be succinct and appropriate.

Examples:
Topic: Daily life
Level: 4
Prompt: Describe your daily routine.

Topic: Work, Company policies
Level: 6
Prompt: Your boss has asked for your help with the office dress code policy.
What rules do you suggest?
...

```

Figure 2: Illustration of a few-shot prompting template used for automated writing prompt generation.

accuracy scores to (item, response) pairs using a calibration set drawn from real test data. We measured agreement between each model and expert human annotations using Cohen’s Kappa statistic. Based on these preliminary experiments, we then selected the three LLMs that demonstrated the highest inter-annotator agreement with human raters as well as amongst themselves to perform a majority vote over the quality of the synthetic student response. This enabled us to then produce a larger dataset of pairs of student responses that can be used in the next phase of response generation.

For the annotation process, each selected LLM was first provided with a few-shot prompt comprising the grammatical accuracy scale (0–4) and multiple labeled examples. Each model independently assigned an accuracy score to every response, leveraging the internalized patterns from the few-shot instruction. Majority voting was then applied to the three scores produced for each sample, retaining the class most frequently assigned as the final label.

To ensure the highest possible data quality, we filtered the resulting dataset to retain only the samples where annotator agreement was strongest—either full consensus or clear majority among the three LLMs. This approach allowed us to construct a robust, reliable, and well-calibrated instruction dataset for producing realistic student responses via subsequent model fine-tuning and evaluation.

To evaluate the quality and reliability of the annotation process, we created an evaluation set (gold standard) consisting of approximately 200 (item, response) pairs. Each of these samples was independently annotated for grammatical accuracy, on a scale from 0 to 4, by five expert human raters. Only those samples with an inter-annotator agreement

above 70% were retained, ensuring a high level of reliability in the ground truth annotations.

This gold standard dataset was then used to benchmark each candidate LLM’s annotation performance. For the comparison, we calculated the Cohen’s Kappa score between the accuracy levels assigned by each LLM and the ground truth established by human annotations. The LLMs evaluated in this process included Llama 3.3 70B (Touvron et al., 2024), Nova Pro and Nova Small (AWS proprietary models²), Mistral Small and Mistral Large (Jiang et al., 2023), Claude Opus (Anthropic, 2024), and GPT-4o (OpenAI, 2024).

This systematic comparison enabled us to identify the models with the highest alignment to expert human judgments, guiding the selection of annotators for the synthetic data generation pipeline.

LLM Candidate	CK
LLaMA 33 70B	0.86
GPT-4o	0.87
Nova Pro	0.78
Mistral Small	0.18
Mistral Large	-0.01
Claude Opus	-0.08
Ensemble	0.89

Table 1: Cohen’s Kappa agreement between each LLM and gold standard human annotation

We selected the three best-performing LLMs, LLaMA 33 70B, GPT-4o, and Nova Pro as shown in Table 1, to form an ensemble for the majority voting procedure. Notably, this combination achieved a Cohen’s Kappa of 0.89 with the human-annotated gold standard, outperforming any individual model. This result demonstrates that major-

²Technical details available in the AWS Bedrock documentation: <https://docs.aws.amazon.com/bedrock/latest/userguide/model-parameters-nova.html>.

ity voting among top-performing models further increases annotation reliability and brings machine annotation closer to human-level agreement.

Finally, we generated our synthetic dataset of 20,000 pairs of responses, employing our ensemble of LLMs for the rating process to ensure that each pair consisted of one higher accuracy response and one lower accuracy response with the associated grammatical accuracy and proficiency level.

3.4 Phase 3: Fine-tuning of LLM-Based Response Generator

In this phase, we focused on enhancing the quality and proficiency alignment of synthetically generated responses by fine-tuning a large language model. We selected LLaMA 3.1 (8B parameters) as the base model for fine-tuning, utilizing the Optimized Reward Preference Optimization (ORPO) technique. The training data comprised approximately 20,000 synthetic samples generated during Phase 2, each annotated for grammatical accuracy and proficiency level.

Fine-tuning was conducted using a distributed training setup on the SageMaker infrastructure, employing the following configuration:

- **Instance type:** ml.g5.12xlarge
- **Environment:** PyTorch 2.5.1, GPU, CUDA 12.4, Ubuntu 22.04
- **Batch size:** 8 per device
- **Gradient accumulation steps:** 1
- **Learning rate:** 2×10^{-4}
- **Number of epochs:** 3
- **LoRA settings:** $r = 8$, $\alpha = 16$, dropout=0.1
- **Seed:** 42 (for reproducibility)

Model training was orchestrated with distributed computing support (Torchrun) to fully leverage available GPU resources, and checkpointing mechanisms were in place to ensure reliability.

Through this fine-tuning process, the LLaMA 3.1 model was adapted to generate candidate responses at specific proficiency levels, closely mimicking real student outputs in both accuracy and variety. The resulting model serves as a robust response generator for subsequent scoring model development and evaluation within the adaptive writing assessment pipeline.

3.5 Phase 4: Training Adaptive Transformer-Based Scoring Model

In the final phase, we aimed to robustly integrate the newly generated writing items into our automated scoring pipeline. To achieve this, we focused on the domain of education, and manually composed approximately thirty new writing prompts covering a broad range of proficiency levels, as generated during Phase 1.

For each prompt, the fine-tuned LLaMA 3.1 (8B) response generator was used to synthesize approximately 200 sample answers at varying proficiency levels. This resulted in a substantial and well-stratified dataset representing a wide spectrum of student abilities.

We then fine-tuned our RoBERTa-based transformer scoring model, training it on a combination of both initial (pre-existing) and newly generated items and responses. This approach was designed to ensure a smooth integration of new items into the scoring system while maintaining performance on established items.

The model was trained using the following hyperparameters with the TrainingArguments setup:

- **Evaluation and save strategy:** every 200 steps
- **Batch size:** 16 per device
- **Learning rate:** 2×10^{-5}
- **Warmup ratio:** 0.1
- **Epochs:** 6
- **Weight decay:** 0.01
- **Learning rate scheduler:** linear
- **Mixed precision training:** enabled (fp16)

This fine-tuning procedure enables the scoring model to generalize to new adaptive items and proficiency levels while ensuring reliable and consistent automated assessment performance.

4 Experiment

4.1 Psychometric Analysis

4.1.1 Dataset

We constructed a dataset containing 500 responses to approximately 50 different writing prompts, with

Level	Prompt	Synthetic Response	Label (proficiency)
2	What activities do you do at school?	I am studying english at university. I love english and talk with my friend, we share knowledge.	1
3	Describe your teaching style.	I like to teach students about english and use example and video for help them learn easy.	1
3	What do you think makes a good teacher?	A good teacher possesses patience, empathy, and effective communication skills. They foster a supportive environment, encourage critical thinking, and adapt teaching methods to cater to diverse learning styles, promoting academic growth and personal development in their students.	4
5	Explain the importance of extracurricular activities in a student's overall development.	Ggghhhhhhhhhhhhhhhhhhhhhhhhhhhhhhhhhhh	0
5	Describe a typical school day, including your classes, activities, and any special events you participate in.	My school day starts at 8am with class. I join clubs after and do volunteer work. Math is my favorite.	3

Table 2: Examples of synthetically generated items and responses on the topic of education, illustrating different levels of language proficiency.

an equal split between human-generated and automatically generated answers (250 each). Each response is scored on an ordinal scale from 0 to 4, providing a rich basis for psychometric analysis. This dual-sourced dataset enables us to directly compare human performance and large language model (LLM) behavior under similar assessment conditions.

4.1.2 Evaluation

To better understand the scoring dynamics and the comparability between synthetic and authentic responses, we conducted an Item Response Theory (IRT) analysis. Figure 4.1.2 presents average Item Characteristic Curves (ICCs) derived from the dataset, shown separately for human and LLM-generated responses. Each curve reflects the probability of achieving at least a given score threshold as a function of modeled proficiency, averaged across all items.

The ICCs for both human and synthetic responses reveal similar shapes and threshold spacing, indicating that LLM-generated answers closely emulate the probability distributions observed in real student performance. This suggests that synthetic responses can serve as effective proxies for actual learner data in calibrating and evaluating automated scoring models.

4.2 Pre-piloting Study

To validate the integration and quality of the newly generated items, a pre-piloting study was conducted with approximately 250 participants in Rwanda. The main objective of this phase was

to compare the performance and acceptability of the newly generated items. Participants completed a test composed of a balanced mix of traditional (previously validated) items and automatically generated new items. The distribution of items was designed to ensure diversity in both content and difficulty levels.

4.2.1 Comparative Analysis

To assess the effectiveness of the automatically generated items, we conducted a comparative analysis of success rates between old and newly generated items using statistical significance testing. For each item, we computed the difference in success rates and tested for significance using a z-test for proportions. To ensure a sufficient number of items per analysis group, we grouped the original 16 difficulty levels into 6 broader categories, thereby increasing the number of items per test group for more robust statistical analysis.

Table 3: Statistical Comparison: z-test and p-value for Each Item Level

Item-Level Group	z-score	p-value
1	4.35	0.001*
2	1.33	0.182
3	0.99	0.323
4	1.08	0.285
5	-1.96	0.056
6	-1.86	0.060

* Statistically significant at $p < 0.05$.

The results presented in Table 3 show that although most items did not show significant differences, the only statistically significant effects ($p < 0.05$) were observed between items in dif-

Figure 3: Average Item Characteristic Curves from IRT analysis of human and synthetic responses.

ficulty group 1 (the easiest items). For items belonging to difficulty group 5, p-values were close to the significance threshold, indicating borderline significance. These observations underscore the importance of careful quality control, particularly at both extremes of item difficulty, when integrating automatically generated items into assessments.

4.2.2 Item Characteristic Curve Analysis

To further assess the psychometric properties of both traditional and automatically generated items, we performed an Item Characteristic Curve (ICC) analysis using the Two-Parameter Logistic (2PL) model from Item Response Theory (IRT) (Baker and Kim, 2004). The 2PL model estimates two main parameters for each item: the difficulty parameter (indicating the level of ability required for a 50% probability of a correct response) and the discrimination parameter (reflecting how well the item differentiates between participants of differing ability levels).

For each item, we fitted the 2PL model using the participants' response data. T

Figure 4 displays the ICCs for three representative synthetic items extracted from the assessment. Each curve presents the probability of a correct response ($P(\theta)$) as a function of participant ability (θ), and the items were chosen to illustrate a range of difficulty and discrimination parameters.

- **Easy item:** This item is answered correctly by participants even at lower ability levels. The steep, less rounded shape of the ICC indicates a high discrimination parameter, meaning the item sharply differentiates between participants just below and just above its difficulty threshold.
- **Medium item:** This item requires a higher ability level for a 50% probability of a correct answer, suggesting moderate difficulty. It also

exhibits high discrimination, as seen in the sharp transition.

- **Difficult item:** This item is considerably harder and is only likely to be answered correctly by participants with the highest abilities. The more gradual slope of its ICC suggests a lower discrimination parameter compared to the other items.

These three examples demonstrate both the range of difficulty present in the test and the variation in item discrimination. Such diversity ensures that the assessment can reliably differentiate participants across a broad spectrum of ability levels.

Figure 4: Item Characteristic Curves for 3 synthetic items.

4.3 Scoring Model Evaluation

4.3.1 Dataset

To assess the impact of synthetic items on model training, we conducted controlled experiments using both authentic and synthetic data. The evaluation was performed on a fixed test set of 800 samples that included a balanced selection of prompts and responses, covering all proficiency levels and a wide range of topics.

4.3.2 Evaluation

We evaluated the proficiency classification task using three distinct transformer-based models, each fine-tuned on our training data. First, we included two widely used traditional encoders: **BERT-base-uncased** (Devlin et al., 2018) and **RoBERTa-base** (Liu et al., 2019). Both are pre-trained bidirectional transformers and have served as robust baselines for a range of NLP classification tasks. Second, we fine-tuned **Flan-T5 Base** (Longpre et al., 2023), an instruction-tuned sequence-to-sequence model with strong generalization abilities for text-to-text tasks, adapting it specifically for multi-class classification by framing the label prediction as sequence generation.

Table 4 summarizes the precision, recall, and F1-scores obtained by each model, macro-averaged across proficiency levels. RoBERTa shows the strongest overall performance (macro F1-score of 0.82), illustrating the benefits of its more advanced pre-training. BERT achieves good results but slightly lower than RoBERTa, consistent with prior findings in classification tasks. Notably, Flan-T5 Base also provides competitive performance (macro F1-score of 0.80), demonstrating the viability of adapting generative models to classification through prompt engineering and sequence-based fine-tuning.

Model	Precision	Recall	F1-score
BERT-base-uncased	0.80	0.77	0.78
Flan-T5 Base	0.81	0.80	0.80
RoBERTa-base	0.83	0.81	0.82

Table 4: Macro-averaged precision, recall, and F1-score for each fine-tuned model on proficiency classification.

5 Conclusion

In this work, we introduced an end-to-end automated pipeline for adaptive English writing assessment, leveraging recent advancements in large language models for both item generation and synthetic data annotation. Our methodology utilizes few-shot prompting, robust majority-vote labeling, and transformer-based scoring to efficiently generate, calibrate, and evaluate new writing tasks within a psychometrically-sound framework. Extensive experiments demonstrate that the proposed system achieves high agreement with expert evaluations, ensuring both the validity and scalability required for operational proficiency testing. We anticipate that this approach will provide a solid foundation

for future research on data-driven adaptive assessment and the broader application of LLMs in language testing.

Limitations

Automated scoring models risk perpetuating biases, particularly across demographic groups, language proficiencies, or socio-cultural contexts. The use of synthetic data and automated generation may also introduce or reinforce unintended patterns, potentially affecting educational fairness. To mitigate these risks, it is vital to incorporate diverse training data, implement human-in-the-loop evaluations, and regularly audit system performance. We regularly monitor test quality through ongoing psychometric analyses and expert human evaluation. This process ensures that both automated item generation and scoring maintain high standards of validity and reliability over time.

Furthermore, the introduction of a substantial number of new items into the assessment pool needs large-scale psychometric analysis to fully evaluate their functioning and impact. We acknowledge this as an essential next step, and plan to conduct comprehensive studies to further validate the psychometric properties of these newly introduced items across diverse populations and contexts.

Abstract

Communicative practice is critical for second language development, yet learners often lack targeted, engaging opportunities to use new grammar structures. While large language models (LLMs) can offer coherent interactions, they are not inherently aligned with pedagogical goals or proficiency levels. In this paper, we explore how LLMs can be integrated into a structured framework for enabling goal-oriented, grammar-focused interaction, building on an existing dialogue system. Through controlled simulations, we evaluate five LLMs across 75 A2-level tasks under two conditions: (i) grammar-targeted, task-anchored prompting and (ii) the addition of a lightweight post-generation validation pipeline using a grammar annotator. Our findings show that template-based prompting alone substantially increases target-form coverage up to 91.4% for LLaMA 3.1-70B-Instruct, while reducing overly advanced grammar usage. The validation pipeline provides an additional boost in form-focused tasks, raising coverage to 96.3% without significantly degrading appropriateness.

1 Introduction

Second language acquisition (SLA) is driven by frequent and meaningful language use (Behrens, 2009; Ellis, 2002; Canale and Swain, 1980). While second language (L2) learners develop comprehension skills through input-rich activities, many struggle to find opportunities outside of the classroom to meaningfully produce what they’ve learned, especially in the early stages (Ortega and DeKeyser, 2007). This is particularly true for A2-level learners, who are using the L2 in social interaction more consistently, as described by the Common European Framework of Reference Companion Volume (CEFR; Council of Europe, 2020).

Grammar often represents an obstacle in L2 production, with certain forms proving persistently

difficult to master (Ellis, 2017). As a result, learners tend to avoid challenging forms in spontaneous communication, where conveying meaning quickly takes priority (Lyser and Sato, 2013). To mitigate this issue, research emphasizes the importance of communicative practice that targets learners’ specific needs and occurs iteratively, rather than relying on decontextualized drills. Without such targeted support, many A2 learners tend to plateau, struggling to transfer classroom grammar knowledge to real-life communication (Richards, 2008; Mirzaei et al., 2017; Lightbown, 2007).

Conversational agents, or chatbots, have been proposed as a way to offer students language production opportunities (Sydorenko et al., 2018). Early rule-based systems enabled predictable, level-appropriate dialogues, but their design was labor-intensive and resulted in rigid, limited interactions (Bibauw et al., 2022). More recently, LLMs have emerged as a promising alternative, as they are capable of generating coherent and fluent language without the need for manual scripting. However, their stochastic nature often leads to inconsistent pedagogical alignment (Zhou et al., 2023; Benedetto et al., 2025).

While several studies have explored the use of out-of-the-box LLMs for educational purposes, such as linguistic feedback, role play, and adaptivity (Borchers and Shou, 2025; Gervás et al., 2025; Fincham and Alvarez, 2024), their inherent unpredictability poses challenges for aligning output with pedagogical frameworks, adaptive logic, and real-world scalability. In the absence of a systematic mechanism for constraining both communicative context and grammatical targets, learners may engage in practice that lacks the individualization and progression necessary for effective development (Ruiz et al., 2023).

To bridge this gap, we introduce a parametric framework for goal-oriented, CEFR-aligned grammar practice through LLM-mediated dialogue.

Building on AISLA, a rule-based system developed for grammar instruction among German seventh-graders (Chen et al., 2022), this A2-level extension links each task to the English Grammar Profile (EGP; O’Keeffe and Mark, 2017). EGP targets are embedded into dynamically generated prompt templates that pair specific grammatical forms with communicative scenarios, enabling repeated practice of the same structure across varied, context-rich tasks. This approach aims to maintain pedagogical consistency while leveraging the flexibility and fluency of LLMs.

In this paper, we investigate the effectiveness of our approach by asking the following research questions:

1. Can out-of-the-box LLMs generate goal-oriented dialogues that spontaneously target specific grammatical structures?
2. How effective is task-supported prompting in guiding LLMs to produce multi-turn, A2-level outputs aligned with target grammar?
3. To what extent can LLMs of different sizes maintain coherence and target specific grammatical structures in task-supported dialogues?
4. Does incorporating a grammar validation component improve target structure usage and CEFR alignment?

2 Goal-oriented Grammar Practice

While theoretical perspectives in SLA vary, many contemporary approaches increasingly view grammar as a functional and adaptive component of language use, rather than a fixed body of rules (Diessel, 2019; Dik, 1981). Larsen-Freeman (2003) advocates for the reframing of grammar as a dynamic skill encompassing three interrelated dimensions: (i) form, structural features of language; (ii) meaning, the semantic or propositional content these forms convey; and (iii) use, the pragmatic and discourse functions that guide when and why particular forms are selected in context.

To support this dynamic view of grammar, instructional design should align the learning environment with real communicative demands. Transfer-appropriate processing (TAP; Lightbown, 2007) reinforces this idea, suggesting that learning is most effective when the cognitive processes involved

during learning mirror those required during retrieval and use. Grammar practice then should not be decontextualized, rather, learners need iterative opportunities to use target structures in activities that closely resemble authentic language use.

Furthermore, research shows that specific grammar structures are best acquired through activities that naturally elicit their use (Loschky and Bley-Vroman, 1993; Faitaki and Murphy, 2019; Lyster and Sato, 2013). Frameworks such as Task-Based Language Teaching (TBLT; Nunan, 2004) and Task-Supported Language Teaching (TSLT; Ellis, 2024) operationalize this idea by embedding language practice within communicative tasks. In TSLT, for example, the syllabus is organized around specific linguistic units, which are practiced through meaning-oriented tasks: activities in which language is used to achieve a non-linguistic goal, such as comparing options or making plans. Unlike traditional drills, such tasks promote interaction in which the target structure is functionally relevant. Our system builds on this approach, using task templates that integrate grammar targets with communicative goals (Bear et al., 2024).

3 Controlled Text Generation

To integrate a multidimensional view of grammar into LLM-based applications, developers must find ways to control the output of these models in order to deliver scaffolded, targeted practice without sacrificing meaning or use. Although emerging approaches offer potential solutions, such as prompting techniques and finetuning techniques, they typically lack explicit goal orientation and have not been systematically applied to grammar-focused learning tasks.

In the context of open-ended dialogue, some approaches have aimed to implicitly steer LLMs toward producing predetermined grammatical structures. For instance, Okano et al. (2023) compare reinforcement learning-based fine-tuning of DialoGPT with few-shot prompting of GPT-3, finding that both methods can enable grammatical control, with reinforcement learning achieving greater precision. Similarly, Glandorf et al. (2025) evaluate prompting, fine-tuning and decoding strategies for the inclusion of predetermined EGP structures during open-ended chat, showing that grammar-controlled decoding with LLaMA 3.3 effectively targets specific forms, albeit with a slight reduction in response quality. However, both studies focus

exclusively on the inclusion of target structures in the next response only, not evaluating model performance across multi-turn interactions.

Engaging LLMs in multi-turn conversations introduces additional challenges, as the model must track and integrate longer contextual information to maintain coherence and relevance across turns (Yi et al., 2024). This challenge becomes more complex when there is a pedagogical task to adhere to and a grammar structure to target. While some recent work explores different applications of LLM-mediated language learning (Tyen et al.; Méndez and Bautista, 2025), no approach, to our knowledge, has attempted to integrate LLMs within goal-oriented dialogue systems for systematic, targeted grammar practice.

Our work therefore intends to move towards bridging these divides by integrating a CEFR-aligned proficiency framework, generating task-based dialogue data and embedding real-time grammar scaffolding into an LLM-powered dialogue system. In doing so, we aim at combining the naturalness of large-scale language models, with the pedagogical basis of goal-oriented, task-supported instruction.

4 Implementation

4.1 System Description

The AISLA system was built using a Java-based backend with a PostgreSQL¹ database and an Android-based frontend². Its backend follows a modular, service-oriented design for functionalities such as text-to-speech and automatic speech recognition. The chatbot functionality is handled via AWS Lex³, a slot-filling dialogue management service, which requires manual dialogue scripting. Although effective for rule-based interactions, especially in school contexts, where content control is a priority (Wilske, 2015), this configuration presents limitations for the integration of personalized and adaptive features.

To support the requirements of this research, several major architectural changes were introduced. First, the following changes were made to accommodate LLM-based interactions: AWS Lex was replaced by LLM APIs, and a DialogueManager class was added to orchestrate prompt chaining and dialogue state management. Second, the Android

frontend was replaced with an Ionic⁴ one to ensure broader accessibility across platforms, thereby increasing inclusivity in participant recruitment and usage scenarios. Additionally, the EGP was integrated in the grammar task design.

4.2 Task Bank

To support modularity and future scalability, a task bank was implemented as a database table. Each entry is linked to a target grammar structure and a communicative purpose, including fields such as the EGP structure's guideword, can-do statement, the name and format of the task and its instructions. Task names refer to real-life situations where grammar structures are employed for communicative purposes, for instance, "Discussing cultural differences between two countries", "Telling someone about a historical monument" or "Picking between two places to go to".

The task design is based on the Gramming framework (Larsen-Freeman, 2003), accounting for the three dimensions of grammar. Accordingly, three task types were developed:

Q&A (form-focused): These tasks are meant to provide high-frequency exposure to a target grammar structure in each of the model's turns. It aims to use and elicit the structure in short question-answer exchanges (e.g. answering questions about one's daily routine with frequency adverbs).

Information gap (meaning-focused): These tasks emphasize the meaningful application of grammar structures, encouraging learners to make decisions about where and how to use the target structure in context, usually leveraging external resources like tables, charts and images (e.g. reporting on what was said in an interview with reported speech, explaining what someone looks like using adjectives).

Role play (use-focused): These tasks situate grammar practice in realistic scenarios (e.g. giving a friend advice with modal verbs, asking for directions with prepositions). They are designed to simulate real-life situations where the structure must be used appropriately within a given social or functional context.

³<https://aws.amazon.com/lex/>

⁴<https://ionicframework.com/>

4.3 Dialogue management

When a task is initiated by the student, information from the task bank is dynamically retrieved from the database and inserted into a template-based LLM prompt. An example prompt schema can be found in Appendix A. Task duration is currently managed via turn count. This means that each dialog task spans a predetermined number of turns by default, after which the learner is given the option to either conclude the task or continue practicing.

5 Method

Since the purpose of this study was to evaluate how well different LLMs perform in task-supported dialogues, conducting a user study was considered premature. Instead, to simulate varied learner interactions, each model was paired with ChatGPT-4o, using a temperature setting of 0.5 to introduce some content variability on the student side.

To test the robustness of the model acting as the tutor, three learner behavior patterns were implemented in every task: (1) in the first run, the model was instructed to make grammatical mistakes; (2) in the second run, a hard-coded clarification request ("What does that mean?") was injected; and (3) in the third run, a misunderstanding was introduced via the phrase "I don't know" at the second turn (c.f. Appendix F for snippets of different runs and task type). Each task was limited to 10 turns to ensure comparability across conditions.

We selected 75 tasks targeting 15 grammar super-categories drawn from the EGP, namely, adjectives, adverbs, clauses, determiners, future, modality, passives, past, prepositions, present, pronouns, verbs, questions, negation, and reported speech. The tasks were equally divided into Q&A, information gap, and role play formats. To account for output variability, each task was run five times, resulting in 375 dialogues, and 1875 messages per model⁵.

5.1 Experiment 1

We evaluated five large language models (LLMs) spanning a wide parameter range: Llama 3.1 8B-Instruct, Mistral-Small 3.1 24B-Instruct (Mistral AI, 2024), Llama 3.3 70B-Instruct (Meta, 2024), DeepSeek-V3 685B (DeepSeek AI, 2024), and GPT-4o (OpenAI, 2024), whose exact parameter count is undisclosed. Each model acted as the tu-

⁵All experiments and data mentioned in this work can be found in <https://github.com/luisards/grammar-practice-framework>

tor in the 75 tasks. The decoding temperature was fixed at 0.0 for decreased variability.

To isolate the effect of explicit grammatical scaffolding (RQ1), we first used *task-only prompting*, satisfying the TSLT requirement of a clear non-linguistic goal. In this setting, the prompt contained only the task name plus minimal instructions, with no mention of the target grammar structure (c.f. Appendix B).

The second part of Experiment 1 introduced our template-based prompt that embeds the communicative goal together with A2-level grammar cues. We ask whether this prompt improves alignment and whether model size modulates any gain (RQ2-RQ3).

5.2 Experiment 2

Experiment 2 adds a lightweight control pipeline. We integrated POLKE (Sagirov and Chen, 2025), an EGP-based grammar annotator, as a post-generation validator. For every tutor turn, POLKE tagged all grammar structures and their CEFR level; a one-shot rephrase is triggered when (i) any structure above B1 is present (Appendix C) or (ii) in Q&A tasks, the required target structure is missing (c.f. Appendix D). Only one rewrite pass is allowed to bound latency and prevent loops. The control loop was applied only to the three best-performing models from Experiment 1 (Llama 3.3 70B, DeepSeek V3, GPT-4o).

6 Evaluation

We combine two quantitative metrics, obtained via POLKE annotations, with one qualitative metric obtained from human ratings.

Target structure presence A binary metric which measures whether the tutor turn contains the grammar form specified in the task (crucial for Q&A).

Proficiency alignment Defined here as the use of grammar within the target CEFR range. This metric refers to the proportion of structures above the B1 ceiling (i.e. B2, C1, C2).

Response quality Appropriateness on a 5-point scale (factual accuracy + contextual coherence). Fifteen native or near-native English speakers recruited through Prolific⁶ rated six dialogues per model (450 tutor turns). The rubric and anchors appear in Appendix E.

⁶<https://www.prolific.com>

To probe rubric interpretability, GPT-4o scored the same 30 dialogues. Its item-level scores correlate moderately with the human mean (Spearman $\rho = .49, p < .01$) and reproduce the system rank order ($\rho = .67$). A separate GPT-4o pass over the full 75-task set is released for replication in the shared repository.

7 Results

In this section, we report the results of three experimental conditions: baseline task-only (B), prompt + grammar scaffold (P) and prompt + scaffold + validation (P+V), distributed by metric.

7.1 Dialogue-quality ratings

Table 1 shows the mean human appropriateness ratings. Larger models outperform smaller ones across all conditions. Prompting incurs a small drop for every model (max 0.6 points for Mistral-Small). Validation restores or slightly improves quality for the top systems. Inter-rater agreement was found to be moderate (Krippendorff $\alpha_{\text{ordinal}} = .42$; rises to .45 with GPT-4o added).

Smaller models were excluded on the basis of a post-hoc, exploratory cutoff: any model whose mean human appropriateness rating fell below 4.0, corresponding to the “somewhat appropriate” anchor on our 5-point rubric was deemed pedagogically unviable and therefore did not get included in experiment 2.

Model	B	P	P+V
Llama 3.1	3.9	3.6	–
Mistral-Small	3.5	3.3	–
Llama 3.3	4.9	4.3	4.7
DeepSeek V3	4.7	4.4	4.4
GPT-4o	4.5	4.5	4.6

Table 1: Mean human appropriateness ratings (1-5).

7.2 Proficiency alignment

Table 2 reports the share of grammar at or below B1. At baseline, a chi-square test across the five models is significant ($\chi^2 = 59.4, df = 4, p < 10^{-11}$) but the practical effect is small (Cramér $V = .04$). Prompting pushes every model above 98% basic grammar; validation halves the residual advanced usage.

7.3 Target-structure coverage (form-practice tasks)

Prompting boosts target-structure inclusion from roughly 30% to 70-91% (Table 3). Validation yields a further 5-11-point gain (96.3 % for Llama 3.3 70B, 95.0% for DeepSeek V3, 91.5% for GPT-4o). A Pearson chi-square on the Q&A subset confirms significant model differences at the prompt stage ($\chi^2(2, N = 1,875) = 33.1, p < 10^{-7}, V = .13$). After validation the gap narrows but remains significant ($\chi^2 = 19.5, p < .001, V = .10$).

8 Discussion

Our findings reveal that while large language models (LLMs) are capable of generating fluent, goal-oriented dialogues, they do not reliably produce the intended grammatical structures without explicit guidance. Answering RQ1, at baseline, models demonstrated stronger appropriateness, with bigger models reaching average ratings between 4.5 and 4.8, but the presence of the target grammatical structure was limited, appearing in only 28-39% of tutor turns in form-practice tasks.

RQ3 explored how model size influence the ability to maintain coherence and grammatical focus in task-supported dialogues. Our findings suggest that model capacity matters. Larger models (70B-685B) retained higher appropriateness (4.3 - 4.7) and needed fewer rewrites, confirming that scale confers stronger control. Yet the scaffolded prompt significantly narrowed the grammar gap, even though their final appropriateness remained lower ($\approx 3.6 - 3.3$). This trade-off invites a cost-benefit choice: institutions with limited resources may be able to achieve near-large-model grammar fidelity at a fraction of the compute cost, accepting a decrease in perceived dialogue polish.

Concerning RQ4, a post-hoc validation pass halved the residual advanced grammar usage ($\chi^2(2) = 35.1, V = .10$), confirming its value as a safety net when level control is non-negotiable. However, quality gains plateau once a strong prompt is in place, suggesting diminishing returns for additional automated checks.

Finally, it is important to acknowledge the fact that strict structure enforcement must be balanced against the spontaneity of genuine dialogue: real learners will redirect, clarify and digress. Designing tasks that preserve communicative authenticity while guaranteeing exposure to a focal form remains an open challenge, especially at higher or

Model	B		P		P+V	
	\leq B1	$>$ B1	\leq B1	$>$ B1	\leq B1	$>$ B1
Llama 3.1	92.4	7.6	98.6	1.4	–	–
Mistral-Small	93.6	6.4	92.8	7.2	–	–
Llama 3.3	93.0	7.0	98.6	1.4	99.4	0.6
DeepSeek V3	91.5	8.5	98.2	1.8	99.1	0.9

Model	B	P	P+V
Llama 3.1	39.0	78.4	–
Mistral-Small	28.0	69.4	–
Llama 3.3	37.0	91.4	96.3
DeepSeek V3	34.2	87.8	95.0
GPT-4o	35.5	80.5	91.5

Table 3: Tutor turns that contain the requested grammar structure (25 form-practice tasks).

lower CEFR targets where our A2-centric template may not directly transfer.

9 Conclusion and Outlook

This paper explores the integration of LLMs into a goal-oriented dialogue system for A2-level grammar practice. Our results suggest that when dialogues are grounded in pedagogically designed prompts, proficiency alignment converges across models of different sizes. While these findings are promising, they remain preliminary and based on controlled simulation rather than real learner input.

Larger models (e.g., LLaMA 3.3 70B, GPT-4o, DeepSeek V3) maintained grammatical focus and dialogue coherence more reliably, particularly under conversational pressure. However, prompting alone was sufficient to bring smaller models (e.g., Mistral-Small) closer to the target structure usage rates observed in larger systems. This indicates that instructional framing, not just model capacity, plays a critical role in shaping output toward pedagogical goals.

We also explored the impact of a lightweight post-generation validation step using POLKE, an EGP-based grammar annotator. While this step did not significantly alter overall CEFR alignment (which was already high under prompt conditions), it provided additional gains in target-form inclusion, particularly in Q&A tasks, where an increase

of approximately 10% was observed. These findings highlight validation as a useful safeguard for scenarios where structure-specific exposure is pedagogically important.

Taken together, our findings point toward two tentative design guidelines for developers of intelligent tutoring systems that incorporate LLMs: (i) Combining pedagogically-grounded prompts with CEFR-based post-generation validation may offer a feasible path toward controllable, targeted grammar practice; (ii) Model scaling should be guided by observable convergence in dialogue coherence and target-form density, which, based on our exploratory experiments, occurred at around 70 billion parameters.

Furthermore, because our evaluation relies on open CEFR descriptors and a publicly available annotator, the method remains applicable as new models are released. To support continued re-evaluation, we release all core components of our setup: the selected task bank, template prompt, and scoring script.

Beyond targeting grammatical forms, our results underscore the value of contextual control: grammar structures should appear not only accurately, but also in varied, goal-relevant settings. Our template-based prompting framework sets to achieve this by scaffolding interaction around communicative goals, potentially making it easier to support iterative practice, interest-driven adaptation and integration of learner modeling.

In future work, we intend to perform user studies and log learner use of support tools (e.g., on-demand L1 translation), engagement with different contexts and its interaction with learning outcomes. Finally, over time, interaction data collected from users will allow for the creation of authentic data, enabling LLM fine-tuning grounded in authentic learner behavior.

Limitations

While our framework demonstrates the potential of LLMs for proficiency-aligned grammar practice, several limitations must be acknowledged. First, our grammar validation relies on an automatic annotator, the robustness and coverage of which varies across structures. In experiment 2, the same annotator was also used for both controlling and evaluating the output, which could introduce bias into the results.

In addition, the system currently does not perform a formal grammar accuracy check beyond target form detection, meaning that in case the LLMs make errors, those may go unnoticed. Similarly, vocabulary control, although implicitly restricted through task design, is not externally validated against level-specific lexicons, which may impact lexical appropriateness for A2 learners.

Lastly, our evaluation remains system-focused and has not included learner interaction data. Without a user study, we cannot yet assess the pedagogical effectiveness, learner engagement or practical impact of the system in real-world settings. These areas will be addressed as the next step in this project.

Acknowledgments

This work was supported by the German Ministry of Education and Science (BMBF) under funding number 01IS22076. We also acknowledge the valuable contribution of the English Grammar Profile (EGP), which provided an invaluable resource used in this study.

A Template-based Prompt

"I am a [level] [language] student. I want to practice [EGP structure information] by [task_name]. I want to ensure that I [can_do_statement]. For example, [examples]. Let’s perform a [task_type]

exercise. You are a [system_role]. [system_instructions]. Please keep your messages short and use easy words. Output only your next turn."

B Baseline Condition Prompt

"You are a friendly English tutor. I want to practice by [task name]. Please use direct, short and simple sentences and easy words. Output only your next turn."

C Simplification Rephrase Prompt

"The learning objective is [task name] (e.g., [examples]). Simplify ONLY the advanced grammar constructs while carefully preserving the learning objective in the following text. Advanced grammar to simplify: [advanced structure] IN [sentence] Text to rephrase: [advanced response] Please provide only the rephrased text without explanations."

D Target Structure Inclusion Rephrase Prompt

"The student is practicing [task name] (e.g., [examples]) through dialogue. Please rephrase the following response to contain that grammar structure while keeping the meaning: [sentence]"

E Response Appropriateness Rubric

1. Completely inappropriate: Off-topic and incoherent throughout
2. Mostly inappropriate: Some relevance, but major issues in logic or coherence
3. Somewhat appropriate: Largely on-topic, but difficult to follow due to coherence issues
4. Appropriate: On-topic and generally clear, with minor coherence issues
5. Fully appropriate: Clear, coherent, and consistently on-topic

F Dialogue Snippets

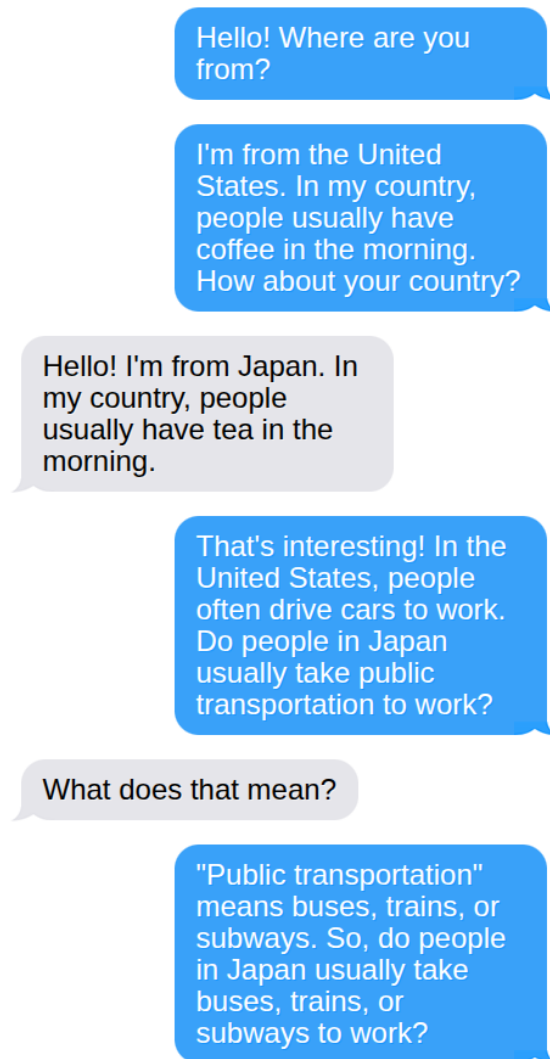

Figure 1: Example output from GPT-4o acting as the tutor under the template-based prompt condition. The Q&A task shown is "Talking about common habits in your country." This snippet is from the second run, which includes an injected clarification request. Blue bubbles indicate tutor messages.

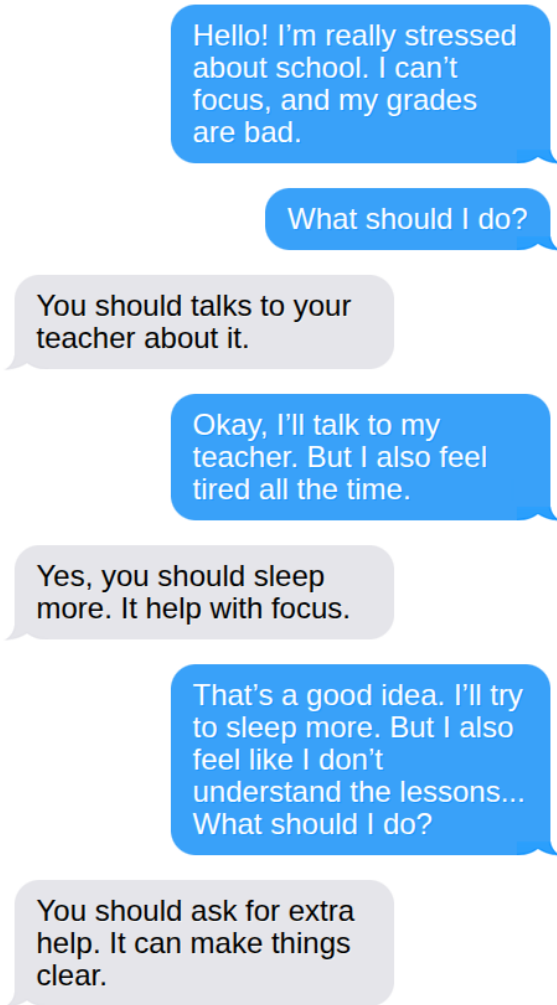

Figure 2: Example output from Deepseek-V3 acting as the tutor, under the template-based prompt condition. The role-play task shown is "Giving a friend advice about school". This is a snippet from the first task run, in which grammar errors are instructed. Blue bubbles indicate tutor messages.

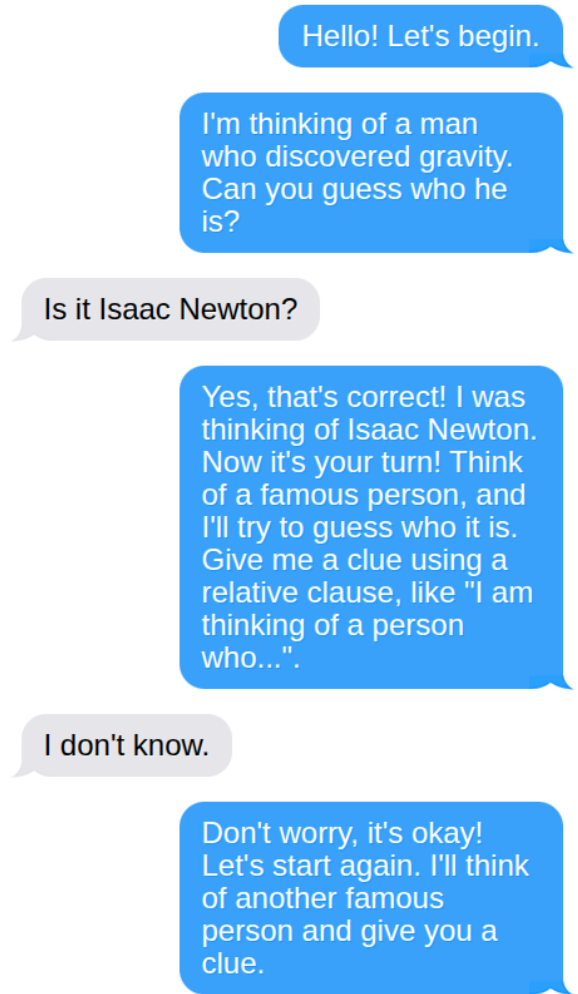

Figure 3: Example output from LLaMa 3.3-70B-Instruct acting as the tutor, under the template-based prompt condition. The information-gap task is "Playing a guessing game about famous scientists". This is a snippet from the third task run, in which a misunderstanding indication is injected. Blue bubbles indicate tutor messages.

Can LLMs Reliably Simulate Real Students' Abilities in Mathematics and Reading Comprehension?

Abstract

Large Language Models (LLMs) are increasingly used as *proxy students* in the development of Intelligent Tutoring Systems (ITSs) and in piloting test questions. However, *to what extent these proxy students accurately emulate the behavior and characteristics of real students remains an open question*. To investigate this, we collected a dataset of 489 items from the National Assessment of Educational Progress (NAEP), covering mathematics and reading comprehension in grades 4, 8, and 12. We then apply an *Item Response Theory (IRT)* model to position 11 diverse and state-of-the-art LLMs on the same ability scale as real student populations. Our findings reveal that, without guidance, strong general-purpose models consistently outperform the average student at every grade, while weaker or domain-mismatched models may align incidentally. Using grade-enforcement prompts changes models' performance, but whether they align with the average grade-level student remains highly model- and prompt-specific: no evaluated model-prompt pair fits the bill across subjects and grades, underscoring the need for new training and evaluation strategies. We conclude by providing guidelines for the selection of viable proxies based on our findings.¹

1 Introduction

Large language models (LLMs) are capable of generating fluent and coherent text and excelling at many complex tasks (Chang et al., 2024; Zhao et al., 2024). Their rise offers new opportunities for educational technology, notably in (i) intelligent tutoring systems (ITS; Wang et al., 2024) and (ii) *piloting assessments* before they go live (Liu et al., 2025; Grohs et al., 2024). ITS provides targeted feedback and adaptive instruction, while reliable

¹All related code and data is available at <https://github.com/kvadityasrivatsa/IRT-for-LLMs-as-Students>

Figure 1: Sample NAEP question from grade 8 mathematics.

assessments track learning without bias. Yet both require understanding how real students would interact with them, which is extremely challenging to verify.

Ideally, tutors and test forms should be vetted on representative student samples across skill levels. This, however, is resource-intensive, especially in regions already short on teachers and infrastructure (UNESCO, 2023; Woolf et al., 2013). Teacher-led evaluations (e.g., Macina et al., 2023) and static logs similarly fail to scale or capture the dynamics of new items and adaptive strategies (Belz et al., 2023; U.S. Department of Education, 2023). These constraints motivate alternatives that enable rigorous, equitable evaluation at scale.

An emerging approach is for *simulate* students with LLMs (Mollick et al., 2024; Sonkar et al., 2024). Proxy models can be conditioned on at-

tributes such as grade level, offering fast, repeatable tests of tutor features or item quality. However, current evaluations are based on an expert judgment of plausibility (Macina et al., 2023), leaving open the question of how closely such proxies match real student performance. Similarly, in psychometrics, LLMs have been used as *synthetic examinees*: e.g., Liu et al. (2025) show that GPT-3.5/4 answer sets yield item statistics that mirror a 50-student pilot, and Grohs et al. (2024) demonstrate that ChatGPT can pre-flag weak or biased items. However, these studies treat LLMs as single test-takers and do not look into whether persona prompts can tie their abilities to specific grade bands.

Our approach: We apply IRT (Baker, 2001) to measure how 11 diverse LLMs and real students perform on the same grade-level questions. Using data from the National Assessment of Educational Progress (NAEP) (National Center for Education Statistics, 2022) for mathematics and reading in grades 4, 8, 12, we evaluate whether the LLM responses (both *generic* and *grade-conditioned*) align with authentic student response patterns. Specifically, we address the following research questions: **RQ1** – Under standard prompting, how do LLMs compare with real students across grades and subjects? **RQ2** – When asked to act as an average student in a given grade: How does LLM performance change? (**RQ2.1**) Does the shift match real grade-level patterns? (**RQ2.2**)

The main contributions of our work are as follows:

- We compile and release a dataset² sourced from NAEP of real student responses to subject-specific, grade-targeted questions, covering two subjects (mathematics and reading assessment) and three grade levels (4, 8 and 12).
- We adapt Item Response Theory (IRT) to assess the alignment between LLM-generated responses and actual student performance patterns.
- We conduct an evaluation of 11 diverse LLMs, examining how well they approximate student responses under both *unenforced* (generic) and *grade-enforced* prompts.

2 Related Work

Simulated Students in Intelligent Tutoring Systems Early simulated-student work relied on production rule *apprentices* that learn from worked examples and then reproduce step-level behavior inside an ITS. The *SimStudent / Apprentice-Learner* family shows that such models can generate realistic error types and serve as policy learners to hint (Matsuda et al., 2023; Smith et al., 2024). More recent studies graft LLMs onto this pipeline: it has been shown that GPT-4 “think-aloud” traces improve bug-library discovery and fine-grained skill tagging, while LLM agents at dialogue level can populate entire synthetic classroom cohorts (Mollick et al., 2024). These approaches demonstrate that generative text can complement symbolic learner models, yet they rarely test whether the *ability* distribution of synthetic learners matches that of real students – a gap we address through our analysis.

LLM-Generated Responses for Item Calibration Psychometric studies have begun to treat LLM outputs as *synthetic examinee responses*. Liu et al. (2025) show that the GPT-3.5/4 answer sets yield 3PL item statistics that match a 50-student baseline, reducing the pretest costs. Grohs et al. (2024) use ChatGPT to filter out low information or biased items. He-Yueya et al. (2024) further adapt IRT to align LLM and human response patterns, while Zelikman et al. (2023) simulate K-12 students. However, these works produce only aggregate correlations; they do not examine whether an LLM’s *latent ability* aligns with a particular grade band or whether persona prompts shift that ability in predictable ways. Our work closes this gap with an IRT model that maps LLM performance to grade-level performance.

Persona-Conditioned Prompting and Alignment Prompting a model with an explicit role (e.g., “*You are a 4th-grade student*”) can change both reasoning depth and surface style. Benedetto et al. (2024) find that a one-sentence student-level prompt lets GPT-4 imitate weak, average, and strong test-takers across subjects, although adherence to the target level is uneven. Broader evaluations such as CharacterEval (Tu et al., 2024) measure persona consistency in dialogues, while Kim et al. (2024) show that role prompts can either help or hurt accuracy depending on task characteristics. None of these efforts connect persona adherence to *quan-*

titative grade-level ability estimates, nor do they compare default and persona-conditioned ability curves within a unified IRT framework.

Together, these strands indicate that (i) LLMs are already employed as simulated students and psychometric stand-ins, and (ii) persona prompts shift model behaviour without a principled link to grade-level metrics. Our study unifies the two directions by applying an IRT model to quantify how default and persona-conditioned LLM outputs align with average student performance at grades 4, 8, and 12.

3 NAEP Data

3.1 Source and Composition

We prepared our dataset using publicly available items and student response data from the National Assessment of Educational Progress (NAEP) (National Center for Education Statistics, 2022),³ a large-scale assessment program administered by the National Center for Education Statistics (NCES). NAEP periodically assesses student achievement across the United States in key subject areas, including mathematics and reading. These assessments are conducted in grades 4, 8, and 12, offering a cross-sectional perspective on student proficiency throughout K–12 education.

3.2 Coverage and Educational Context

We source questions from both the *mathematics* and *reading comprehension* assessments at the three grade levels, capturing a broad spectrum of student performance and cognitive development throughout different educational stages. We focus on these two subjects for two reasons: (1) numeracy and literacy are considered fundamental skills (e.g., Williams, 2003); and (2) NAEP data cover three grades for these subjects, while many other subjects only cover one or two grades. Math questions span topics such as measurement, algebra, geometry, and probability and statistics, with overall difficulty scaling with grade level. Reading comprehension items are based on passages whose average length increases with grade. The corresponding questions shift from direct factual queries in lower grades to those requiring interpretation and reflection at higher levels.

Each record contains the original question, multiple choice options, the correct annotated answer,

and anonymized aggregate response patterns. For each item, the dataset reports the percentage of students who selected each option or omitted the question. Figures 1 and 4 show representative examples from the grade-8 mathematics and grade-12 reading subsets, respectively.

Since NAEP is a continually administered assessment, this dataset can be periodically updated with newly released items. This makes it a dynamic resource that can evolve along with changes in educational standards and student performance distributions, offering long-term utility for evaluating automated student proxies and similar tasks.

3.3 Preprocessing and Filtering Criteria

NAEP assessments encompass a variety of question types, modalities, and response formats. Given that this is a preliminary effort to develop a quantitative and interpretable framework for aligning LLM performance with real student behavior, the inclusion of diverse modalities can introduce confounding factors that obscure analysis. For example, items that involve images, diagrams, or tables introduce the additional variable of visual comprehension, making it difficult to isolate language understanding as the primary factor in model performance. Similarly, free-form responses present evaluation challenges: gold-standard answers are often limited in number and may not capture the full range of acceptable responses. Assessing these reliably often requires expert judgment, which undermines the feasibility of scalable, LLM-based evaluation.

In contrast, multiple choice questions offer clearly defined answer sets, enabling a more straightforward and objective evaluation, which is crucial for both quantitative benchmarking and interpretability via Item Response Theory (IRT). Consequently, we apply two main filtering criteria when constructing our dataset.

- *Text-only content:* We exclude any items that involve diagrams, tables, or multimedia elements, retaining only questions and instructions presented in text.
- *Multiple-choice format:* We include only multiple choice questions (MCQs), which support standardized evaluation and facilitate downstream processing, such as answer extraction and IRT-based analysis.

After filtering, our final dataset consists of 489 multiple-choice items in English: 249 from mathe-

³<https://nces.ed.gov/nationsreportcard/>

Figure 2: Distribution of question-level accuracy in NAEP assessments across grades and subjects. KS statistics and corresponding p-values are reported to assess normality; distributions with $p > 0.05$ are considered consistent with a normal distribution.

mathematics and 240 from reading. Table 3 summarizes key statistics from the dataset. Figure 2 shows the distribution of questions answered by students with varying accuracy for each subject and grade. We calculate the Kolmogorov-Smirnov (KS) statistic for each distribution to test for normality, and all subsets sufficiently ($p\text{-value} > 0.05$) follow a normal distribution.

4 Proposed Methodology

Our goal is to evaluate LLMs alongside human students recorded in the NAEP dataset by estimating their answering ability on a shared scale. To do this, we draw on Item Response Theory (IRT; Baker (2001)), a well-established framework in educational measurement. IRT enables us to jointly model the ability of test takers and the difficulty of individual test items using probabilistic principles.

4.1 Estimating Student (LLM) Ability

We begin with the Rasch model (Rasch, 1960), a widely used and interpretable form of IRT. It assumes that the probability of a correct response depends only on the difference between a participant’s ability and an item’s difficulty. This model uses a single parameter per item, that is, difficulty b_i , and one ability parameter θ_i per participant.

The Rasch model defines the probability that participant i correctly answers item j as:

$$P(X_{ij} = 1) = \frac{e^{\theta_i - b_j}}{1 + e^{\theta_i - b_j}}, \quad (1)$$

where $\theta_i \in \mathbb{R}$ is the ability of the participant i , $b_j \in \mathbb{R}$ is the difficulty of item j , and \mathbb{R} is the common scale of difficulty or ability.

To estimate b_j , we use the empirical proportion p_j of correct responses for each item in the population. A simple approximation is:

$$b_j \approx \log\left(\frac{1 - p_j}{p_j}\right), \quad (2)$$

which reflects that the harder items (with lower p_j) have higher difficulty values (Bond and Fox, 2015). Once the item difficulties are known, the ability of each participant θ_i can be estimated using marginal maximum likelihood or Bayesian inference based on their response pattern.

4.2 Grade-Alignment Prompting

Our first research question (RQ1) investigates how an LLM’s problem-solving ability compares to that of average students at different grade levels, specifically grades 4, 8 and 12, based on the NAEP dataset. To measure this, we begin with a minimal zero-shot prompt, which we refer to as **UNENFORCED** (see Appendix Figures 5 and 9 for exact prompt templates). This prompt simply presents the question to the model without any added instructions or persona guidance.

Our second research question (RQ2) explores whether LLMs can align their responses with the answering patterns and performance levels of students in specific grades. To probe this, we design a set of increasingly guided zero-shot prompts that aim to steer the model toward grade-level reasoning.

1. **GRADEENFORCEDMINIMAL**: Identical to the Unenforced prompt, but with the added instruction that the model should act as an average student from a specific grade (4, 8, or 12). The exact prompts are presented in Appendix Figures 6 and 10.
2. **GRADEENFORCEDBASICCOT**: Builds on the minimal version by prompting the model to consider what an average student at the specified grade would likely choose and why. This prompt encourages brief, grade-aware reasoning and reflects the student’s typical reasoning ability and common error patterns.

See Figures 7 and 11 in the Appendix for the exact prompts.

3. **GRADEENFORCEDFULLCOT**: Adds further scaffolding by dividing the reasoning process into two steps. First, the model is instructed to reflect on whether an average student at the given grade level would be likely to answer the question correctly. Second, based on that reflection, the model either justifies a correct answer or, if the student is unlikely to succeed, selects and explains the most plausible incorrect answer. See Figures 8 and 12 in the Appendix for the exact prompts.

The design of the GRADEENFORCEDBASIC-COT and GRADEENFORCEDFULLCOT prompts is inspired by Benedetto et al. (2024), who developed similar prompts to simulate student reasoning across skill levels on exam-style questions of varying difficulty. Their work informed our decision to incorporate reasoning about the ability of a student and the likelihood of error into our prompt design.

Our aim is not to claim these are optimal prompts or to exhaustively search for the best possible formulations. Instead, we adopt straightforward, representative prompting strategies aligned with popular practices to focus our investigation on whether such methods meaningfully promote grade-level alignment in model behavior. This may limit the scope of our findings, but it allows us to isolate and evaluate the effects of targeted prompting on grade-sensitive reasoning.

5 Experimental Setup

5.1 Task Setup

We design our experiments based on the framework described in Section 4. The evaluation is conducted in two phases:

1. **Problem-Solving**: LLMs answer questions in a standard problem solving setting, without specific instructions on how to mimic human behavior. Their performance is compared to that of average students in different grade levels.
2. **Grade-Level Mimicking**: LLMs are explicitly instructed to emulate an average student of a specific grade level and respond as such.

In both phases, we apply a Rasch model to assess performance. Each question is treated as

an individual item j , and each LLM is treated as an in-distribution test-taker i . The binary response of LLM i to the question j is represented as $s_{ij} \in \{0, 1\}$, where $s_{ij} = 1$ indicates a correct answer.

LLM	Open Source?	Parameter Count	Fine-Tuned?	Benchmark Scores	
				GSM8K (%)	MLU (%)
LlAMA2-13B (Touvron et al., 2023)	✓	13B	✗	28.7	54.8
LlAMA2-70B (Touvron et al., 2023)	✓	70B	✗	56.8	68.9
LlAMA3.1-8B (Touvron et al., 2023)	✓	8B	✗	84.5	73.0
LlAMA3.1-70B	✓	70B	✗	95.1	86.0
Mistral-7B (Jiang et al., 2023)	✓	7B	✗	52.1	60.1
Qwen2.5-7B (Yang et al., 2024)	✓	7B	✗	85.4	74.2
Qwen2.5-Math (Yang et al., 2024)	✓	7B	✓	91.6	67.8
GPT-3.5-Turbo (OpenAI, 2023)	✗	-	✗	57.1	70.0
o3-Mini (OpenAI, 2025)	✗	-	✗	89.9	85.2
SocraticLM (Liu et al., 2024)	✓	7B	✓	60.6	-
LearnLM-1.5-Pro (Modi and the LearnLM Team, 2024)	✗	-	✓	-	-

Table 1: List of LLMs evaluated in our study, along with key descriptors about each model, i.e., open source availability, parameter size, whether the model is fine-tuned (as opposed to pretrained or instruction-tuned), and scores on reasoning and comprehension benchmarks GSM8K and MMLU (we omit scores that have not been released publicly by the respective model’s paper or technical report).

5.2 Models

We select a diverse set of 11 LLMs (see Table 1) to ensure broad coverage across access types (open vs. closed), model sizes and training paradigms (pretrained vs. domain-finetuned). Our goal is to capture a range of capabilities relevant to reasoning and comprehension, as reflected in benchmarks like GSM8K (Cobbe et al., 2021) and MMLU (Hendrycks et al., 2020). We include both general-purpose models and those finetuned to specific domains. GPT-3.5-Turbo is included based on Benedetto et al. (2024), who suggest that it can adapt responses to the levels of student ability instructed. SocraticLM and LearnLM-1.5-Pro are fine-tuned on pedagogical data; therefore, they might have more accurate insights into the performance of students at different grade levels.

5.3 Evaluation

Measuring Problem-Solving Correctness All problems in our dataset are multiple choice questions (MCQs), which simplifies the evaluation of correctness: *a model’s response is considered correct if the selected option matches the correct answer provided with the dataset*. This binary distinction between correct and incorrect responses makes the data well-suited for dichotomous (i.e.,

the answer can only be correct or incorrect) Item Response Theory (IRT) models. We found that model responses vary in structure and require a unified follow-up prompt to extract the predicted choice from each model response (see Figure 13 in the Appendix).

Estimating Grade-Level Alignment To address both research questions, we estimate how closely a model’s performance aligns with that of an average student at a given grade level. To pin the origin and unit of the Rasch ability scale during marginal maximum-likelihood estimation, we follow the standard convention of treating examinee abilities as standard-normal, $\theta \sim \mathcal{N}(0, 1)$. Although not theoretically necessary, Embretson and Reise (2000) note that this assumption is a reasonable way to identify the latent trait because it fixes the zero point and variance without constraining the shape of the data.

Therefore, the average student has an ability parameter of zero ($\theta_{\text{avg}} = 0$).

The estimated ability parameter θ_i for a model i can be interpreted in relation to this benchmark. *The closer θ_i is to zero, the more the model’s performance aligns with that of the average student.* We can also express this alignment using the percentile rank, computed via the cumulative distribution function (CDF) of the standard normal distribution, denoted by $\Phi(\theta)$:

$$\text{Percentile Rank} = \Phi(\theta) \times 100 \quad (3)$$

A percentile rank of 50 corresponds to the average student. Higher percentile ranks indicate higher levels of ability relative to the population. We use percentile rank as our main metric to measure LLM or student ability, as it has a fixed range (0-100 and is centered at 50), which allows for easier comparison of LLM alignment across subjects and grade levels.

6 Results & Discussion

In Table 2, we report each LLM’s percentile rank in grade-level mathematics and reading comprehension questions under three conditions: unenforced prompting (P_U), grade-enforced prompting (P_E) and their difference (Δ). We report P_U for the best prompt for each LLM per subject (see Table 5 in the Appendix for the best prompts for each setting) which maximizes grade alignment, i.e., when percentile rank is closest to 50 (average).

Avg. Deviation records the mean absolute deviation from $P = 50$ for the corresponding prompt settings. The baseline Random Choice reports the percentile scores achieved with a randomized option chosen for each problem. This setup allows us to:

- address **RQ1** by comparing model percentiles to the student mean (50th percentile) across grades and subjects, and
- address **RQ2** by (i) quantifying the effect of grade enforcement on LLM performance (**RQ2.1**) and (ii) evaluating whether these shifts mirror human student response patterns (**RQ2.2**).

For further context, Table 4 presents the accuracy of each LLM under the unenforced condition.

6.1 RQ1: Alignment under Unenforced Prompting

We ask whether the unenforced problem solving prompt generates outputs that align with that of the average student in each grade (P_U).

Mathematics. Most models, especially those scoring well on GSM8K, e.g., LLaMA3.1-70B, Qwen2.5-Math, o3-Mini, and SocraticLM, achieve high percentiles in every grade, overshooting all benchmarks and showing no alignment with any specific grade. This is also reflected in the high average deviation of 40.5, 35.0, and 32.9 percentile points, respectively, from the optimal $P=50$ mark. In contrast, smaller models with relatively poorer benchmark performance, such as LLaMA2-13B and Mistral-7B, exhibit lower percentiles and show better alignment between grades.

Reading. Similar to mathematics, the models demonstrate high average percentile scores in reading for grades 4 and 8, proving unsuitable for faithful student mimicking. The models in our pool align better with grade 12, with relatively lower average P_U values. Fine-tuned models (not tuned for grade-alignment), e.g., Qwen2.5-Math, SocraticLM – Qwen2.5-Math further tuned on pedagogical data, have a poorer overall performance, resulting in better alignment across grades.

Across grades and subjects, all models score well above the Random Choice baseline. Without enforced instructions, LLMs rarely self-calibrate to grade difficulty. They overshoot when capacity is high and align only when under-powered or off-domain.

Table 2: LLM percentile scores on grade-level questions from mathematics and reading without grade enforcement (P_U – shaded blue), with grade enforcement (P_E – shaded green), and their difference ($\Delta = P_U - P_E$ – shaded yellow). Darker hues for P_U and P_E denote closer alignment to the average score of 50 and larger absolute change in Δ . **Boldface** highlights the best model (i.e., closest to 50) in each setting. Avg. Deviation records the mean absolute deviation from $P=50$ for corresponding prompt settings. The Random Choice baseline reports the percentile scores attained with a randomized option chosen for each problem.

6.2 RQ2.1: Effect of Grade-Level Prompts

We test whether prompting a model to “think like an average grade g student” changes its performance (Δ in Table 2), regardless of the resultant alignment.

Drops: Overall, we note that upon prompting models to mimic the average student of grades 4, 8, or 12, percentile scores generally drop (see Avg. Deviation Δ in Table 2), with a greater drop for a lower target grade. Qwen2.5-7B records the highest drop of 93.1 percentile points for reading grade 4 as well as the greatest average drop.

Gains: We observe that grade-specific prompting can also increase model performance. For example, several settings with LLaMA2-13B/70B for mathematics and all grade settings with SocraticLM for reading result in higher P_E than P_U .

Stable: Some models, such as LLaMA3.1-70B and o3-Mini for subjects and SocraticLM for mathematics, show little to no change between their values of P_U and P_E values, despite their respective P_U values having a high deviation from the target $P=50$.

Prompt Strength: Among the three grade enforcement prompts, the most detailed GRADEENFORCEDFULLCOT prompt (with explicit instruc-

tion to consider the probability that an average student of the target grade will get the given problem right) causes the largest changes (Figure 3a). This shows that grade-level cues can markedly increase or lower scores depending on the model and prompt strength, although a few models remain robust.

6.3 RQ2.2: Alignment Under Enforced Prompts

We investigate whether grade-specific prompts move the model performance closer to the average student (ideal $P = 50$). We find that the results are spread across the following categories:

(1) Aligned P_U and aligned P_E : Some models that are close to the 50th percentile without grade-specific prompting maintain good alignment after prompting (for example, LLaMA2-13B / 70B for mathematics and SocraticLM for reading). These models can act as “proxy students” out of the box for particular pairs of subjects’ grades.

(2) Misaligned P_U and misaligned P_E : Other models’ percentile scores can range far above or below the median despite grade-specific prompting (for example, P_U s and P_E s for o3-Mini across subjects and grades stay far above 50). We did not observe any model that consistently scored below the median percentile.

(3) Misaligned P_U and aligned P_E : In some cases, prompting can help induce grade alignment (P_E) when unenforced alignment is poor (P_U). For example, Mistral-7B’s percentile range on reading problems moves from $P_U \in [83.9 - 94.3]$ to $P_E = [55.5 - 69.1]$; GPT-3.5-Turbo shows similar gains in most tasks. Such cases demonstrate the desired effect of grade-specific prompting.

(4) Aligned P_U and misaligned P_E : In contrast, grade-specific prompting can cause models to overshoot. Qwen2.5-7B in grade 4 reading drops from 98.2 to 5.2 ($\Delta = -93.1$), overshooting the target.

Prompt design matters. Figure 3b shows that the GRADEENFORCEDFULLCOT template changes scores the most. However, it is not always the most optimal prompt setting to achieve better grade alignment (lower percentile deviation from 50).

Fine-tuned models. Pedagogically tuned models (LearnLM-1.5-Pro, and SocraticLM) are not better aligned than general LLMs (such as Mistral-7B), with or without prompts, indicating that faithful grade-level emulation probably needs explicit alignment objectives.

Thus, grade alignment is model-prompt specific; no single prompt works everywhere. Reliable grade-level emulation will require tailored prompting that does not ensure generalization to other grades or subjects.

6.4 Guidelines for Selecting Viable LLM “Proxy Students”

Our experiments confirm that no single model-prompt pair reliably matches average student performance in every grade and subject. Before an LLM can stand in for real students, e.g., to trial new test items or train a model for an ITS, it should pass the following baseline checks:

- Grade alignment.** The model’s ability estimate (θ_n) in a representative item set must fall within the normative band of the grade: core average ± 1 logit (percentile: 15.9 to 84.1), extended ± 1.5 , outlier $\geq \pm 2$ (Bond and Fox, 2015). Models such as GPT-3.5-Turbo stayed in the core range with appropriate prompts for most grades.
- Developmental ordering.** Ability should rise monotonically with grade, mirroring trends in NAEP reading (217, 262, and 285 according

(a) On Δ

(b) On grade-alignment. We report mean absolute deviation from an average grade-level student’s percentile score (i.e., 50). Thus, greater the deviation, poorer the average alignment.

Figure 3: Impact of grade-enforcing prompting

to NAEP’s own cumulative scoring scale for grades 4, 8, 12 respectively; National Center for Education Statistics, 2022). Several pairs violated this; e.g., Mistral-7B’s P_U was 38.3, 17.0, 40.5 for the same grades.

- Prompt stability.** Grade-enforcing prompts can improve or harm performance. An unenforced prompt should be used if the model is already aligned; otherwise, one should verify that enforcement is equally accurate across all grades.

These criteria are necessary, but not sufficient. We believe that more accurate guidelines for faithful student mimicking will emerge with richer evaluation datasets.

7 Conclusion

In this paper, we investigate whether LLMs’ regular problem-solving performance aligns with that of an average student of a given grade, and whether

explicit prompting to act like the average student makes a difference and improves this alignment. We conduct a thorough analysis of 11 diverse models on mathematics and reading questions from K-12 grades 4, 8, and 12 sourced from the NAEP database. Our IRT-based analysis reveals that in the regular (unenforced) setting, stronger models score far better than the average students of any grade and weaker models may align well incidentally. Though explicit (grade-enforced) prompting causes a change in model performance, the alignment with the desired grade-level average varies substantially across model and prompt combinations, with no single model-prompt pair producing average performance across grades or subjects. We provide a set of necessary guidelines to select viable student-proxies for future work and highlight the need for dedicated model finetuning for faithful grade adherence.

Limitations

While the results of our experiments lead to certain conclusions and provide us with novel insights, we acknowledge that these are necessarily limited in a number of ways.

Limited number of samples and subjects considered: Getting access to publicly available student answering data is challenging. The NAEP (National Center for Education Statistics, 2022) database offers a valuable resource in that regard. However, the database is not naturally designed to provide data for performing analysis over automated models at scale, therefore, the available subjects and the number of questions in the collected dataset are limited.

Text-based questions only: In this study, we have restricted our analysis to text-only questions, omitting questions that involve visual interpretation. We admit that this is not completely faithful to student assessments, as visual cues may also elicit key reasoning abilities. We plan to expand our study to more modalities in the future.

MCQ format: Evaluation of LLM responses is a key challenge, especially for free-form answering style. To mitigate this challenge, in this work, we focus on MCQ-type questions only. This also makes modeling the items within the IRT framework easier. As models vary in their response structure, we find that simple rule-based extraction is not reliable enough, and we have to use a follow-up

prompt to extract the final option selected by the model. We plan to develop more robust evaluation strategies to allow for more varied question types in the future.

No data for cross-grade performance used: A key point to note is that NAEP only reports the performance of students at a particular grade level on questions from the same grade. Though this is adequate for assessing student learning trends, for determining cross-grade viability of proxy students, we would require real students' performance on questions from different grades.

Use of prompting methods only: We focus our study solely on prompt-based methods to enforce grade-level alignment, as this is one of the most accessible ways in which models are used in this context, as demonstrated by previous work. A more in-depth analysis is needed to assess whether in-context learning and finetuning strategies can also play a role in improving the quality of proxy-students, in addition to appropriately sized student demonstration data for tuning. We also highlight that prompt engineering (i.e., designing the most optimal prompts for the models) was outside the scope of this study, and the prompts that we used are inspired by previous work in this domain.

Experiments with specific models: Last but not least, we acknowledge that our findings apply to a specific set of models considered in this study. We highlight that our choice was motivated by considerations around the diversity of the model pool.

Ethical Considerations

This study relies exclusively on cumulative, de-identified statistics drawn from student response data supplied by the National Assessment of Educational Progress (NAEP). No record contains direct or indirect identifiers, and at no stage were individual-level student data accessed, stored, or analyzed. All analytic procedures conformed to the NAEP Data Confidentiality and Disclosure Policy as well as the privacy protections required under the Family Educational Rights and Privacy Act (FERPA). Consequently, the research poses no risk to the privacy or well-being of individual students.

A Dataset Details

Table 3 presents the distribution of the questions extracted from NAEP by subject and grade levels. Figure 4 shows an example NAEP question from grade 12 reading. We use data that is publicly available on the NAEP website.

Subject	Grade	Number of Questions	Percentage Share
Mathematics	4	82	32.93
	8	106	42.57
	12	61	24.50
	Total	249	100.00
Reading	4	101	42.08
	8	72	30.00
	12	67	27.92
	Total	240	100.00

Table 3: Dataset statistics: Number of Questions across Subjects and Grade-Levels

B Prompt Templates

Figures 5 to 12 show the different solution generation prompts for mathematics and reading. Figure 13 shows the prompt used to extract the final option from the generated solution.

C Querying Setup

All models were queried with the following hyperparameters: temperature=0, top_p=0.95, and max_tokens=2048. LLaMA3.1 models were queried using the Google Cloud (Vertex) API, o3-Mini was queried using the OpenAI API, and LearnLM-1.5-Pro was queried using Google’s [AI Studio API](#). All other models were imported from [HuggingFace](#) and queried locally using [vLLM](#) on a single NVIDIA A100 GPU. Each round of querying took less than one hour.

D Model Ability (θ_n) Estimation Algorithm

Algorithm 1 captures the steps required to fit the Rasch model as described in §4.

E Analyses Details

Table 4 lists LLMs’ accuracy on mathematics and reading problems from different grade levels with the unenforced prompt setting. Table 5 records the best prompt out of the four possible settings, depending on the closeness of the corresponding percentile values to 50.

Algorithm 1 Estimating LLM Ability and Percentile Rank Using the Rasch Model

Require: $p = \{p_j\}_{j=1}^I$ ▷ Proportion of correct responses for item j across students
Require: $s = \{s_{ij}\}_{i=1, j=1}^{M, I}$ ▷ Binary correctness matrix: LLM i 's response to item j
Ensure: $\theta = \{\theta_i\}_{i=1}^M$ ▷ Estimated ability (logit scale) for each LLM
Ensure: $\pi = \{\pi_i\}_{i=1}^M$ ▷ Percentile rank of each LLM

Step 1: Estimate item difficulties using student response proportions

1: **for** $j = 1$ to I **do**
 2: $b_j \leftarrow \log\left(\frac{1-p_j}{p_j}\right)$ ▷ Item difficulty via inverse of the Rasch probability function
 3: **end for**

Step 2: Estimate LLM abilities via maximum likelihood using the Rasch model

4: **for** $i = 1$ to M **do**
 5: Define likelihood function:

$$\mathcal{L}(\theta_i) = \sum_{j=1}^I s_{ij} \cdot \log\left(\frac{1}{1 + e^{-(\theta_i - b_j)}}\right) + (1 - s_{ij}) \cdot \log\left(1 - \frac{1}{1 + e^{-(\theta_i - b_j)}}\right)$$

6: Estimate $\theta_i = \arg \max_{\theta} \mathcal{L}(\theta)$ ▷ MLE for the Rasch model

7: **end for**

Step 3: Compute LLM percentile ranks w.r.t. student ability distribution

8: Let $\Phi(\theta)$ be the cumulative distribution function (CDF) of student abilities

9: **for** $i = 1$ to M **do**

10: $\pi_i \leftarrow \Phi(\theta_i) \times 100$ ▷ Percentile rank of LLM i

11: **end for**

LLM	Mathematics			Reading		
	4	8	12	4	8	12

Option Extraction Prompt

You are given a response to a MCQ
 problem.

==== RESPONSE START =====
 <MODEL_RESPONSE>
 ===== RESPONSE END =====

What is the final answer opted by the
 response?

The answer can only be one of the
 objective choices: (A), (B), (C), (D),
 (E), etc.

You are not to solve any part of the
 underlying problem yourself.

The final answer you return should be
 based solely on the given response.

Note that it is possible that the
 response suggests that one option is
 correct, however it provides another
 option as the final answer. You are
 expected to return the latter in such
 cases.

Only reply with the final answer.

Abstract

This paper presents a Large Language Model (LLM)-based system designed to support curriculum development, iteratively refined through extensive user testing and deployed within a major Finnish higher education institution over the past two years. Distinct from typical content generation tools, our system facilitates iterative human-AI collaboration by providing structured suggestions and analyzing course descriptions for alignment with institutional goals, accreditation requirements, and competency frameworks. We investigate how such a tool can reduce educators' cognitive load while preserving human expertise, detailing the system's technical architecture and iterative development grounded in a human-centered design approach. This involved prototyping, workshops, and user testing with curriculum coordinators and faculty across diverse departments. We present detailed findings, including quantitative metrics, qualitative feedback, and user quotes, demonstrating the system's evolving reception and potential to support complex educational planning tasks.

1 Introduction

Curriculum development in higher education presents a significant challenge, demanding alignment with diverse stakeholder needs, established competency frameworks, and stringent quality-assurance standards (Barnett and Coate, 2005; Knight, 2001). Educators face increasing pressure to design curricula that satisfy institutional mandates and accreditation criteria while catering to the evolving requirements of diverse student populations (Teixeira et al., 2019; Oliver and Hyun, 2011). This complex task often results in considerable cognitive load, compounded by fragmented information systems and administrative hurdles (Woelert, 2023).

While artificial-intelligence (AI) tools for writing assistance have advanced rapidly (Strobl et al.,

2021), generic AI systems often lack the specificity required for effective curriculum development. Key aspects such as alignment with competency frameworks, nuanced assessment design, and adherence to regulatory compliance are frequently inadequately addressed (Zawacki-Richter et al., 2019). Early applications of language models in education predominantly focused on content generation, rather than supporting the inherently iterative and collaborative nature of curriculum writing (Roll and Wylie, 2016; Huang et al., 2023), often failing to alleviate the core challenges faced by educators.

In response to these limitations, we developed an LLM-based curriculum-development system designed as an interactive collaborator. Our approach emphasises maintaining human expertise and agency throughout the writing process, shifting the focus from mere automation to synergistic human-AI partnership (Holstein et al., 2019; Kamar, 2016; Wilson and Daugherty, 2018). This system has been iteratively developed and tested over 18 months at a multi-disciplinary university of applied sciences in Finland. Figure 1 shows the deployed system in active use, analyzing a nursing science master's degree curriculum against UN SDGs, illustrating the practical application of our iterative design process.

This study explores several critical aspects through the lens of our development and deployment experience. We investigate how an LLM-assisted tool can reduce the cognitive load on educators during curriculum development, presenting evidence from user testing. We examine how such a tool can effectively support the alignment of curriculum content with institutional goals, accreditation standards (e.g. UN Sustainable Development Goals), and competency frameworks, reporting on user experiences with these features. Additionally, we consider how the system design, informed by user feedback, accommodates varying levels of AI

Figure 1: The deployed curriculum writing tool interface showing analysis of a Master's Degree Programme in Development and Leadership of Nursing degree program. The left panel displays the curriculum structure with courses organized by specialization tracks. The center shows automated LLM analysis mapping course content to UN Sustainable Development Goals through bar charts and pie visualization. The right panel provides detailed SDG alignment feedback, demonstrating the system's capability to analyze curriculum content against institutional frameworks and provide structured guidance to educators.

literacy among faculty members. Finally, we detail how an iterative, human-centred design process, combining user tests and workshops, effectively refined the tool for practical integration into institutional workflows.

2 Related Work

2.1 Curriculum Development Challenges and Educator Needs

Curriculum development is a cornerstone of educational practice, demanding alignment across diverse requirements such as institutional goals, pedagogical principles, accreditation standards, and learner needs (Barnett and Coate, 2005; Knight, 2001). Educators tasked with this complex endeavour often face significant cognitive load (Sweller, 1988). Existing digital tools frequently fall short, hampered by usability issues, poor integration, and failure to streamline workflows (Woelert, 2023; Fernández-Cerero et al., 2024). This can lead to frustration among educators who find such tools increase administrative burden rather than reduce it (Blaich and Wise, 2018; Sjöberg and Lilja, 2019; Duarte and Vardasca, 2023). Introducing AI therefore necessitates building trust; educator adoption

hinges on understanding how AI functions and perceiving it as a supportive partner that complements their expertise (Nazaretsky et al., 2022). Addressing these usability, workflow, and trust challenges for educators is paramount.

2.2 NLP Applications for Curriculum Analysis and Related Tasks

Applying Natural Language Processing in education has often involved building specialised pipelines for narrow analytical tasks, frequently requiring substantial feature engineering. Areas such as automated essay scoring, grammatical-error correction (Bryant et al., 2019), and readability assessment (Aluisio et al., 2010) have seen dedicated development, yet applying NLP effectively to *curriculum development* presents unique challenges.

A central task is ensuring semantic alignment between components like learning outcomes, course content, and assessments, and verifying coverage of external competency frameworks. Early NLP approaches tackled this via greedy similarity metrics (Rus and Lintean, 2012) or by constructing educational knowledge graphs through concept linkage (Dang et al., 2021). Analysing curriculum structure is another key requirement. Techniques for extract-

ing prerequisite relations increasingly model course networks as graphs; recent work employs heterogeneous graph neural networks to infer prerequisite links from course-sequence data (Roy et al., 2019).

While effective for specific goals, these examples illustrate a trend towards fragmentation: distinct models, feature sets, and separate tools were developed for semantic similarity, structural relations, quality attributes, or content generation. Supporting the holistic process of curriculum writing; integrating multiple analyses and feedback remains difficult with such pipeline-based approaches.

2.3 Human-Centred Design: Bridging NLP Power and Educator Usability

NLP’s analytical power only translates into impact when integrated via human-centred design (HCD). Educational settings involve diverse users (Gulbahar, 2008), and the cognitive load of complex tools is a major barrier (Sweller, 1988; Paas et al., 2003). Iterative HCD-workshops, prototyping and usability testing is essential for creating educational technology that educators find intuitive, trustworthy, and supportive (Druin, 2002; Quintana et al., 2004). For AI tools, transparency and user control are vital (Nazaretsky et al., 2022). Designing AI systems as collaborative partners that augment educator capabilities (Holstein et al., 2019) is therefore central to our methodology.

2.4 Prompt Engineering for Curriculum Development

Large foundation models such as PaLM-2¹ offer a shift away from fragmented pipelines. Effectively using these general-purpose models for specialised educational tasks relies on prompt engineering. While fine-tuning adapts models (Touvron et al., 2023), carefully crafted prompts can steer an LLM (Brown et al., 2020). Chain-of-thought prompting encourages structured reasoning suitable for alignment checks (Wei et al., 2022). Prompting for structured output (e.g. JSON) permits automatic parsing and presentation to educators, bridging the gap between raw LLM output and usable assistance (Ouyang et al., 2022).

2.5 Our Contribution: An Integrated, Human-Centred LLM Application

We present an LLM-assisted system co-designed as a collaborative partner for curriculum writing.

Our contribution lies in a rigorous HCD process and a system architecture that prioritises educator usability, cognitive-load reduction, and integrated support for curriculum alignment. We move beyond fragmented individual NLP tools, such as semantic similarity analysis (Rus and Lintean, 2012; Dang et al., 2021), prerequisite extraction (Roy et al., 2019), readability (Aluisio et al., 2010) and error detection (Leacock et al., 2014), to leverage a single foundation model (PaLM-2). Carefully engineered prompts and a transparent UI provide unified support for alignment, quality checks, and structured suggestions.

3 Methodology

Our methodology employed a human-centered design (HCD) approach over an 18-month period, focusing on iterative development informed by continuous user feedback from the target end-users within a major Finnish university of applied sciences.

3.1 User-Centered Development Activities

We engaged curriculum coordinators and faculty members from diverse disciplines including Healthcare, Architecture, Therapeutic Studies, Engineering, and Business. Our development activities involved several key interactions. One-on-one usability testing occurred in January-February 2024 with 5 curriculum coordinators using early prototypes. These sessions involved participants performing domain-specific tasks, such as analyzing their 2024 curriculum against UN SDGs, institutional goals, and workplace requirements, while using a think-aloud protocol. Sessions were observed and recorded for qualitative analysis. Additionally, two major workshops were conducted as qualitative feedback sessions. The first, on June 6th, 2024, brought together 12 participants from five faculties for a demo presentation followed by hands-on testing and group discussions with casual Q&A. The second workshop, held on November 8, 2024, in a hybrid format, included 14 participants (both previous and new users) and followed a similar format of demo presentation, testing, and discussion, focusing on gathering requirements for features and integration priorities. Separately from these workshops, the demo tool was made publicly available via the institution’s internal staff website, allowing independent access and usage. Throughout this process, feedback was collected via multiple

¹<https://ai.google/discover/palm2/>

channels: interview notes, observation logs during testing, workshop discussions, and open-ended survey questions provided qualitative data from the interactive workshop sessions, while quantitative data was collected through a System Usability Scale (SUS)-inspired online feedback form completed by curriculum coordinators and faculty who accessed and used the demo tool independently via the internal website. This multi-faceted approach allowed us to identify usability requirements, cognitive load points, and evolving user needs, particularly regarding varying levels of AI literacy and integration with existing workflows.

3.2 Technical Architecture and System Implementation

The system was developed with a focus on modularity, scalability, and integration capabilities, employing a specific technical stack. The backend was implemented in Python² using the Flask³ framework, deployed with uWSGI⁴ behind an Nginx⁵ reverse proxy on Debian/Ubuntu⁶ Linux servers hosted within the institution's infrastructure; basic HTTP authentication via Nginx provided access control. For data persistence, MongoDB⁷ (v. 7.0.1, initially with access control disabled during early development) served as the NoSQL database, storing curriculum data in a queryable format from the organization's curriculum database, organized by year (e.g., 2023, 2024, 2025), and recording document update timestamps. The frontend was a single-page application (SPA) built with React⁸, utilizing React's Context API and hooks for state management, and communicating with the backend via RESTful API calls secured with CORS configuration. AI integration leveraged Google's Vertex AI⁹ platform, specifically accessing the multilingual PaLM-2 foundation model through predefined prompt templates engineered to request structured JSON output, enabling reliable parsing and presentation of targeted feedback within the user interface in both Finnish and English. Security and logging included Nginx handling HTTPS encryption via SSL/TLS certificates and maintaining basic Nginx

access logs with a 14-day rotation; application-level user interaction logging was minimal to prioritize privacy, which limited retrospective usage analysis but showed approximately 5 unique IP addresses accessing the API during a representative 14-day testing period. This architecture allowed for iterative updates to components like the LLM or UI while maintaining core functionality.

3.3 Iterative, Human-Centered Design Process

The 18-month development cycle unfolded following HCD principles across three main stages. The first stage focused on initial prototyping and testing, involving one-on-one tests (Jan-Feb 2024) for core concept validation and identifying fundamental usability issues, with feedback primarily concerning navigation and initial orientation. The second stage incorporated this feedback into a more robust prototype presented at the June 2024 workshop; this phase highlighted user needs for clearer guidance and workflow structuring to reduce cognitive load. The third stage addressed feedback from the first workshop and gathered requirements for more sophisticated functionality during the November 2024 workshop. In this final stage, user requests shifted towards advanced capabilities such as integration with the Peppi student information system, import features for existing drafts, quality control mechanisms, and enhanced multilingual and domain-specific support. Throughout this entire process, both qualitative and quantitative user feedback continuously informed design adjustments, feature prioritization, and refinement of the AI interaction model.

4 Results and Evolution of User Feedback

The iterative HCD process yielded rich insights into user needs and the system's effectiveness, revealing a clear evolution in feedback as the tool matured and users gained familiarity.

4.1 Initial Usability Testing (Jan-Feb 2024)

One-on-one sessions with 5 curriculum coordinators using early prototypes highlighted fundamental usability challenges and cognitive load concerns.

Orientation and Guidance: Users frequently expressed confusion upon first use:

"There is no clarification here, I wouldn't know what this is. It wouldn't hurt to have a tool guide."

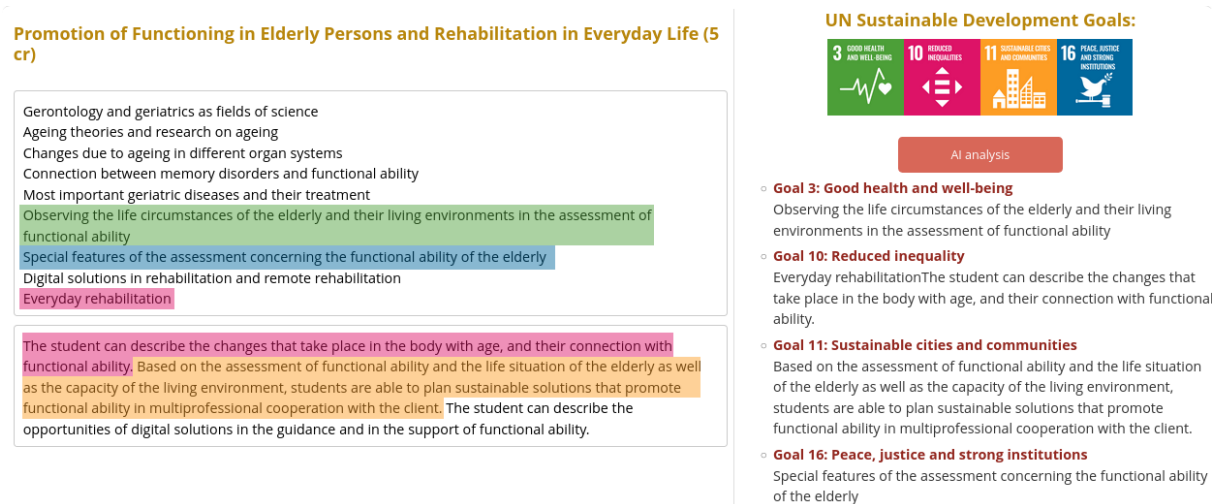

Figure 2: Screenshot of the prototype interface. The left panel shows course topics and learning outcomes; colour highlights indicate segments automatically matched by the LLM. The right panel lists the UN Sustainable Development Goals (SDGs) with the corresponding curriculum fragments, illustrating the tool's alignment-analysis feature.

"Computer tools are not my favorite thing to deal with. I would like a guaranteed clarification of what I need to do with just a glance..."

Several users failed to notice key interface elements like year selection buttons, indicating issues with visual hierarchy. As one coordinator noted, "I didn't even see the year button. Maybe it could be larger or pointed out to me with some kind of guide?"

Cognitive Load from System Fragmentation:

Users expressed frustration with managing information across multiple existing institutional tools.

"There is a huge amount of information in different databases and tools in this house, but it is always difficult to find... it always takes a long time to find what I need."

"It is frustrating to fill all kinds of on-line sticky notes with these goals, and then not have the time or coordination to apply these goals anywhere within the actual teaching."

Another user lamented the typical workflow: "Every year we have to jump between Peppi, Excel sheets, Teams files, and meeting notes. It's exhausting and error-prone." This highlighted the need for better integration and workflow streamlining, especially among faculties such as healthcare, which are

burdened by need to align with several additional national and institutional standards (?).

Observational Data: During these sessions, observers noted consistent patterns: initial hesitation, significant time spent exploring menus before starting tasks, and a tendency to restart tasks rather than troubleshoot upon encountering errors. However, users showed visible positive reactions (surprise, verbal approval) when seeing the structured analysis generated by the AI, recognizing its potential time-saving benefits.

4.2 Workshop Feedback Evolution

First Workshop (June 6, 2024): With 12 participants from 5 faculties, this session confirmed persistent issues with navigation and cognitive load. The primary feedback emphasized the need for much clearer step-by-step guidance within the tool to structure the writing process itself, moving beyond simple text generation towards active workflow support.

Later Workshop (November 8, 2024): This session with 14 participants (hybrid format) showed a distinct shift. Having addressed basic usability, requests focused on advanced functionalities. Key demands emerged, such as a strong need for importing existing draft curriculum texts for LLM analysis and revision. Repeated requests were made for seamless integration with the institutional Peppi student information system to avoid redundant data entry. There was also a clear need expressed for better handling of discipline-specific

terminology and requirements, particularly voiced by Healthcare and Engineering faculty coordinators; one noted, "Within our healthcare domain... there are specific training hours and certain areas of expertise that the students must meet," while another expressed concern about nuance: "AI is not able to detect all the 'weak signals'... I can recognize teaching-related problems... that I'm not sure AI would catch". Finally, users expressed a desire for features ensuring quality control and alignment with institutional standards and competency frameworks.

Participants consistently reiterated the importance of the AI acting as a collaborator. One from healthcare faculty stated, "I hope we can spend the most time on industry-specific goals... I'd like the easiest available tool for these general overhead tasks... We can then focus on our own expertise."

Experiences with Generic LLMs: Users who had tried generic tools like ChatGPT for curriculum tasks reported difficulties:

"I have used AI (ChatGPT)... I tried to ask the AI to integrate the principles of sustainable development into this course, but what came out was difficult to use. I had to ask over and over to get the result I need."

This highlighted the value of our tool's structured approach and tailored prompts.

4.3 Quantitative Evaluation

Following the qualitative feedback, a modified SUS-style questionnaire focused on problem reporting was administered to participants familiar with the refined system. Due to its targeted nature, the sample size was small ($n=4$). The results (Table 1) indicate strong perceived utility for finding information ($M=4.2$) and content review ($M=4.1$), and high potential transferability ($M=4.3$). Interface usability ($M=3.5$) and learning curve ($M=2.3$, inverse scale) showed higher variability ($SD=1.1$, 1.2 respectively), supporting qualitative feedback about differing experiences based on user background and the need for continued ease-of-use improvements. Technical reliability was rated reasonably well ($M=2.0$, inverse scale).

Users also requested clearer visual feedback on standards coverage. Figure 2 illustrates the final UI that emerged from these iterations, showing colour-coded curriculum fragments mapped to specific SDGs.

5 Discussion

Our study demonstrates the potential for a carefully designed LLM-assisted tool, developed through an iterative, human-centered process, to effectively support the complex task of curriculum development in higher education. The detailed results from user testing (Section 4) provide concrete evidence addressing our core research questions.

The significant reduction in cognitive load was a key goal. Initial feedback highlighting confusion ("no clarification here...") and frustration with fragmented systems ("jump between Peppi, Excel sheets...") directly informed design iterations focused on providing clearer guidance and structured workflows. While full integration remains a challenge, the positive reception of the AI's structured analysis capabilities and the high rating for "Utility for content review" ($M=4.1$, see Table 1) suggest the tool successfully offloads some analytical burden. The shift in later feedback towards requesting deeper integration further indicates users perceived the tool's potential to streamline their work.

The system's ability to support alignment with institutional goals, accreditation standards (like UN SDGs), and competency frameworks was validated by user tasks during testing and the specific requests for enhanced quality control features in later workshops. The technical choice to use PaLM-2 via Vertex AI with structured JSON output proved crucial, enabling the system to provide targeted analysis rather than generic text, addressing the shortcomings users experienced with tools like ChatGPT ("had to ask over and over...").

Preserving human expertise was paramount. User quotes consistently emphasized the need for the AI to be a collaborator, handling "general overhead tasks" so educators could "focus on our own expertise" and address domain-specific nuances or "weak signals". The iterative design allowed us to balance automated assistance with user control, ensuring the tool augmented rather than replaced pedagogical judgment (Holstein et al., 2019; Kamar, 2016).

Accommodating varying AI literacy was implicitly addressed through the iterative process. Initial focus on fundamental usability ("guaranteed clarification... with just a glance") catered to less tech-savvy users, while later feature requests (import, advanced analysis) reflected the growing confidence and demands of users becoming more familiar with AI capabilities. The quantitative results showing

Table 1: Teacher Feedback (5-point Likert scale, n=4)
Items use inverse scale where lower scores indicate better performance.

Curriculum design task helpfulness criteria	Mean Score	Std. Dev.
Finding up-to-date degree info	4.2	0.8
Interface usability	3.5	1.1
Clarity of instructions	3.8	0.9
Learning curve (1=Easy, 5=Hard)*	2.3	1.2
Utility for content review	4.1	0.7
Technical reliability (1=Reliable, 5=Unreliable)*	2.0	0.7
Interface readability	3.9	0.5
Output and transferability of results	4.3	0.6

variance in usability and learning curve scores (Table 1) reinforce the need for continued attention to accessibility for all users.

The technical architecture (Section 3) supported this iterative development. The modular Flask/React stack and the use of a managed AI service (Vertex AI) facilitated relatively rapid prototyping and incorporation of feedback. The specific backend choices (Python, MongoDB, uWSGI, Nginx on Linux) represent a pragmatic and common stack for such institutional tools.

Challenges remain, particularly the significant technical and administrative hurdles of deep integration with complex systems (Brown et al., 2015; Sholeh et al., 2025). Supporting highly specialized disciplinary nuances and extending robust support for specific Finnish academic language or potentially underrepresented languages require ongoing effort. However, the positive trajectory of user feedback validates the HCD methodology and the potential of specialized LLM tools for complex educational planning.

6 Limitations and Future Work

While the HCD process yielded valuable insights and a functional tool, several limitations exist. The 18-month development timeline, driven by institutional curriculum renewal cycles, meant full integration with systems like Peppi was not achieved, limiting immediate efficiency gains highlighted as desirable by users ("jump between Peppi, Excel sheets..."). The automated analysis criteria were initially based on available institutional frameworks and UN SDGs; refining these for deeper discipline-specific requirements needs further work, as noted by users concerned about healthcare standards or engineering "weak signals."

The quantitative evaluation presented (Table 1) is based on a small sample size (n=4), limiting generalizability; it primarily served to corroborate qualitative findings during the iterative process. While the PaLM-2 model offers multilingual capabilities, dedicated fine-tuning or prompt optimization for specific Finnish academic contexts or other languages (e.g., Sámi languages) was beyond the scope of this phase.

While our approach relies on prompt engineering to adapt the general-purpose PaLM-2 model for curriculum development tasks, this may be insufficient for optimal performance in highly specialized domains. Effective prompts can improve output quality and structure, but cannot fully compensate for potential gaps in domain-specific training data or the nuanced understanding that dedicated fine-tuning or domain adaptation might provide. For instance, highly technical healthcare curriculum requirements or engineering accreditation standards may benefit from models specifically trained on educational content within those disciplines. Future work should explore whether fine-tuning approaches or domain-adapted models would significantly improve alignment accuracy and reduce the need for extensive prompt iteration.

The evaluation focused heavily on usability and perceived usefulness during development. Longitudinal studies are crucial to assess the tool's sustained impact on actual curriculum quality, alignment consistency across departments, and measurable changes in educator workload and satisfaction over time. Systematically evaluating effectiveness across a wider range of disciplines is also necessary. The minimal application-level logging, while prioritizing privacy, restricts retrospective analysis of feature adoption and user pathways.

Future work will prioritize tackling the Peppi

integration challenge to enhance workflow automation. We plan to collaborate further with faculty to refine domain-specific analysis capabilities and expand language support. Exploring mechanisms for secure sharing of curriculum components or best practices across departments or potentially institutions represents another avenue. Rigorous, long-term evaluations measuring impact on curriculum outcomes and educator efficiency are essential next steps to guide continued refinement and demonstrate long-term value. Improving backend logging for anonymized usage patterns, while respecting privacy, would also aid future development.

7 Conclusion

This paper detailed the design, development, and user-centered evaluation of an LLM-assisted curriculum writing tool deployed at a major Finnish university of applied sciences. Through an 18-month iterative HCD process involving extensive user testing with curriculum coordinators and faculty, we created a system intended as a collaborative partner, aiming to reduce cognitive load and enhance alignment with standards, rather than simply automating writing. We presented specific technical details of the system (Python/Flask backend, React frontend, MongoDB, Vertex AI/PaLM-2 integration) and rich qualitative and quantitative data from user tests and workshops. The evolution of user feedback, from initial usability concerns ("no clarification here...") to demands for advanced features like Peppi integration and sophisticated analysis, strongly validates the iterative methodology. Our findings indicate that specialized LLM tools, co-designed with educators and focused on structured assistance, can effectively support complex educational planning tasks while preserving human expertise. While challenges in integration and domain specificity persist, this work offers a practical case study and valuable insights into developing human-centered AI solutions for higher education workflows.

Findings of the BEA 2025 Shared Task on Pedagogical Ability Assessment of AI-powered Tutors

Ekaterina Kochmar¹, Kaushal Kumar Maurya¹, Kseniia Petukhova¹,
KV Aditya Srivatsa¹, Anaïs Tack², Justin Vasselli³

¹Mohamed bin Zayed University of Artificial Intelligence (MBZUAI),

²KU Leuven, ³Nara Institute of Science and Technology

Abstract

This shared task has aimed to assess pedagogical abilities of AI tutors powered by large language models (LLMs), focusing on evaluating the quality of tutor responses aimed at student’s mistake remediation within educational dialogues. The task consisted of five tracks designed to automatically evaluate the AI tutor’s performance across key dimensions of *mistake identification*, *precise location of the mistake*, *providing guidance*, and *feedback actionability*, grounded in learning science principles that define good and effective tutor responses, as well as the track focusing on *detection of the tutor identity*. The task attracted over 50 international teams across all tracks. The submitted models were evaluated against gold-standard human annotations, and the results, while promising, show that there is still significant room for improvement in this domain: the best results for the four pedagogical ability assessment tracks range between macro F1 scores of 58.34 (for *providing guidance*) and 71.81 (for *mistake identification*) on three-class problems, with the best F1 score in the *tutor identification* track reaching 96.98 on a 9-class task. In this paper, we overview the main findings of the shared task, discuss the approaches taken by the teams, and analyze their performance. All resources associated with this task are made publicly available to support future research in this critical domain.¹

1 Introduction and Motivation

Conversational agents offer promising opportunities for education as they can fulfill various roles (e.g., intelligent tutors and service-oriented assistants) and pursue different objectives (e.g., improving student skills and increasing instructional efficiency) (Wollny et al., 2021), among which serving as an AI tutor is one of the most prevalent

tasks (Tack et al., 2023). Recent advances in the development of large language models (LLMs) provide our field with promising ways of building AI-based conversational tutors, which can generate human-sounding dialogues on the fly. The key question posed in previous research (Tack and Piech, 2022; Tack et al., 2023), however, still holds: *How can we test whether state-of-the-art generative models are good AI teachers, capable of replying to a student in an educational dialogue?*

Evaluating dialogue systems in general presents a significant challenge. While human evaluation is still considered the most reliable method for assessing dialogue quality, its high cost and lack of reproducibility have led to the adaptation of both reference-based and reference-free automatic metrics, originally used in machine translation and summary evaluation, for dialogue evaluation (Lin, 2004; Popović, 2017; Post, 2018; Gao et al., 2020; Liu et al., 2023). When it comes to Intelligent Tutoring Systems (ITSs), which also function as dialogue systems with the specific role of acting as tutors, these general metrics are insufficient. In the educational context, we need to assess complex pedagogical aspects and abilities of such systems, ensuring that they provide students with sufficient, helpful, and factually correct guidance and do not simply reveal answers when the student makes a mistake, among other aspects. Therefore, developing automatic metrics to evaluate these nuanced aspects is essential for creating effective and helpful tutoring systems.

Due to the lack of a standardized evaluation taxonomy, previous work has used different criteria for evaluation. For example, Tack and Piech (2022) and Tack et al. (2023) evaluated models in terms of whether they *speak like a teacher*, *understand a student*, and *help a student*, while in Macina et al. (2023), responses of models playing roles of tutors were evaluated by human annotators using *coherence*, *correctness*, and *equitable tutoring*. At the

¹https://github.com/kaushal0494/UnifyingAITutorEvaluation/tree/main/BEA_Shared_Task_2025_Datasets

same time, Wang et al. (2024) assessed *usefulness*, *care*, and *human-likeness*, and Daheim et al. (2024) used *targetedness*, *correctness*, and *actionability* of a tutor response as quality evaluation criteria. Such lack of standardization makes it difficult to compare different systems, and, therefore, defining evaluation criteria and developing automatic metrics for them is a crucial task for advancing the field, which we have aimed to address in this task.

2 Task Description and Goals

Following the successful BEA 2023 Shared Task on *Generating AI Teacher Responses in Educational Dialogues* (Tack et al., 2023), we revisit the question of quality assessment of the tutor responses generated with the AI models (specifically, LLMs) in the context of educational dialogues. We believe that (1) the topic is timely and important; (2) LLMs have significantly advanced in the past couple of years, making it important to revisit this topic after the competition run in 2023; and (3) there is a need to establish a pedagogically motivated benchmark for this task. In contrast to the BEA 2023 Shared Task, our focus is not on the *generation of educational dialogues* using state-of-the-art LLMs, but rather on **comprehensive evaluation of AI-tutor responses using a set of pedagogically motivated metrics**.

In this shared task, we have focused on educational dialogues between a student and a tutor in the mathematical domain. Specifically, the conversations are grounded in student mistakes or confusion, where the AI tutor aims to remediate such mistakes or confusion. Each dialogue in the datasets provided in this shared task includes: (i) the context consisting of several prior turns from both the tutor and the student; (ii) the last utterance(s) from the student containing a mistake; and (iii) a set of possible responses to the last student’s utterance(s) from a range of LLM-based tutors and, where available, human tutors, aimed at mistake remediation. The dialogues (parts i-ii) are extracted from two popular datasets of educational dialogues in the mathematical domain – MathDial (Macina et al., 2023) and Bridge (Wang et al., 2024), while the LLM-based tutor responses are generated by the shared task organizers using a set of state-of-the-art LLMs of various sizes and capabilities, including: GPT-4 (Achiam et al., 2023), Gemini (Reid et al., 2024), Sonnet (Anthropic, 2024), Mistral (Jiang et al., 2023), Llama-3.1-8B and Llama-3.1-405B

(Dubey et al., 2024), and Phi-3 (Abdin et al., 2024). To avoid any biases, the tutor responses in the data have been shuffled. In addition to the responses themselves, the dataset contains annotation of their quality along several pedagogically motivated dimensions defined in Maurya et al. (2025). Below, we are reiterating the definitions for these dimensions from Maurya et al. (2025) for completeness:

- *Mistake identification*: Since all dialogues in the dataset contain a mistake made by the student, we expect a good quality response from the tutor to include relevant and clear mistake identification. This aligns with *student understanding* defined in Tack and Piech (2022) and *correctness* in the schemata of Macina et al. (2023) and Daheim et al. (2024).
- *Mistake location*: In addition to notifying the student about the committed error, a good tutor response should also point to its location in the answer and explain what the error is to help the student remediate it. This corresponds to *targetedness* in Daheim et al. (2024).
- *Providing guidance*: Ideally, a good tutor should not reveal the answer immediately and instead should provide the student with relevant and helpful guidance, consisting, for example, of a hint, an explanation, or a supporting question. This aspect is related to *helping a student* in Tack and Piech (2022) and *usefulness* in Wang et al. (2024).
- *Actionability*: Finally, once the guidance is provided to a student, a good tutor response should make it clear to the student what they are supposed to do next. I.e., the tutor’s response should not be vague, unclear, or a conversation stopper. This aspect directly corresponds to *actionability* in Daheim et al. (2024).

Moreover, the proposed evaluation schema aligns with the core pedagogical principles derived from learning sciences. Specifically, the tutor should: (1) *encourage active learning* (Chi and Wylie, 2014; Oakley and Sejnowski, 2021) by not directly revealing the correct answer, (2) *adapt to learners’ goals and needs* (King and South, 2017) through accurate mistake identification and exact location pointing, (3) *manage cognitive load*

Example 1: Spotted a Mistake?	
Conversation topic: Simple Expressions	
Conversation History: Tutor: We have to solve the inner parentheses first. Student: ok Tutor: What is 5 times 6? Student: 50	
Tutor response: Ah, not quite. 5 x 10 is 50. 5 x 6 is something else. Could you give it another try?	
Question: Has the tutor identified the mistake in the above response?	
Answer	Reasoning
✓ (1) Yes	The tutor clearly identified the mistake by explaining how to arrive at 50.
✗ (2) To some extent	
✗ (3) No	

Figure 1: An example on mistake identification from Maurya et al. (2025)

(Mayer, 2002) and enhance *metacognitive skills* (Dehaene, 2020; Cohen et al., 2021) by providing appropriate guidance, and (4) foster *motivation and stimulate curiosity* (Keller, 1987; Patall et al., 2008) by offering clear and actionable steps to the student. Thus, the schema adopted from Maurya et al. (2025) covers all the relevant aspects of a good tutor response proposed in previous work (Tack and Piech, 2022; Macina et al., 2023; Wang et al., 2024; Daheim et al., 2024), while also being supported by the learning science principles. We do not explicitly include such aspects as *speak like a teacher* (Tack and Piech, 2022), as we believe that a tutor that identifies student’s mistakes, points to them accurately, and can explain them to a student in an actionable way *does* speak like a teacher. We also do not explicitly cover *human-likeness* (Wang et al., 2024) as, based on our preliminary analysis, state-of-the-art LLMs are capable of producing overwhelmingly human-like responses.

All aspects are annotated on a 3-point scale, where "No" denotes that the particular aspect of the tutor response is *bad* (e.g., the mistake is not identified at all), "Yes" denotes that it is *good* (e.g., the mistake is identified clearly and correctly), and "To some extent" denotes that the quality of the response, according to the particular aspect, is medium (e.g., there are clarity issues with the mistake identification). Figure 1 provides an example of the annotation for the *mistake identification* aspect.

3 Shared Task Structure

This shared task consisted of two major phases:

- **Development phase:** In the development phase, we released annotated tutor responses for 300 dialogues extracted from the MathDial and Bridge datasets (approximately 75% examples from MathDial and 25% examples from Bridge). For each di-

alogue, responses from 7 LLM-based tutors (see Section 2 for more details) as well as expert (for both datasets) and novice (provided in the Bridge dataset only) tutor responses were released together with the annotations for 4 pedagogical aspects following the scheme and guidelines proposed in Maurya et al. (2025). This sums up to a total of 2,476 tutor responses. During the development phase, participating teams could build their systems aiming to predict the quality values for any or all of the pedagogical aspects.

- **Test phase:** In the test phase of the competition, we released an additional set of 191 dialogues extracted from the MathDial and Bridge datasets, following the distribution in the development set, together with the tutor responses (1,547 in total), but the annotations were not provided for this data. The participating teams were asked to run their systems and submit their predictions, which were then evaluated using the shared task official metrics (see Section 6).²

In addition, the task included the *5th track* on the tutor identity identification, aimed at automated detection of which model or human tutor an anonymous response in the test data originated from. This sub-task was inspired by our observations that various AI tutors have very specific tutoring and linguistic styles (Maurya et al., 2025).

The task used *open-data and model strategy*: as there were no explicit training phase, the teams were allowed to use any external data in addition to the released annotated dialogues during the development phase, as well as build traditional machine learning as well as large language model-based solutions.

The test phase of the task was hosted on the CodaBench platform, with a separate track for (1) *Mistake Identification*,³ (2) *Mistake Location*,⁴ (3) *Providing Guidance*,⁵ (4) *Actionability*,⁶ and (5) *Tutor Identification*.⁷ Each team was allowed up to 5 submissions in each track.

4 Data Description

As described in Section 2, we used the data from two publicly available datasets – MathDial (Macina et al., 2023) and Bridge (Wang et al., 2024). Both datasets allow for adaptation, modification and (re)sharing without any restrictions: MathDial⁸ is distributed under the Creative Commons Attribution-ShareAlike 4.0 International License, while the Bridge⁹ dataset is licensed under the MIT license.

Annotations of the pedagogical aspects were provided by the organizing team following the scheme and guidelines established by Maurya et al. (2025). Of the 300 development set dialogues, responses in 200 were doubly-annotated by four annotators, reaching an average Fleiss’ kappa of 0.65, which indicates substantial agreement and shows reliability of this task (see the description of the annotation experiment in Maurya et al. (2025)). An additional set of tutor responses for further development and test set dialogues were annotated by the six shared task organizers using the same scheme and approach. A subset of 83 tutor responses in 10 dialogues were annotated by all six co-organizers, showing substantial agreement on the use of the scheme with Fleiss’ kappa of 0.64. After this initial annotation round, co-organizers discussed and resolved disagreements before proceeding to annotate the rest of the data.

5 Teams

Over 50 teams participated in the shared task, with 11 teams submitting to all five tracks. The task attracted participation from all over the world, with teams from Asia (e.g., Bangladesh, China, India, Indonesia, Philippines, and South Korea), Australia, Europe (e.g., France, Germany, and Romania), the MENA region (e.g., Egypt, Lebanon, and the UAE), the North (e.g., USA and Canada) as well as South America (e.g., Chile and Uruguay) taking part in it. The submissions were distributed as reported in Table 1.¹⁰ The next section briefly summarizes the main trends in the approaches adopted by the teams, while more details can be found in the individual system reports submitted by 26 teams as well as in Section 6.

⁹<https://github.com/rosewang2008/bridge>

¹⁰The official leaderboards can be found in Appendix A.

Track	# Submissions	# Teams
Track 1	153	44
Track 2	86	32
Track 3	105	36
Track 4	87	30
Track 5	54	20

Table 1: Number of submissions and participating teams in each track

5.1 Main Trends

Based on the overall analysis of the approaches taken by the participating teams, we have identified the following major trends:

- A few teams used *LLMs*, both commercial (GPT-4o (Hurst et al., 2024), Gemini (Reid et al., 2024), Claude (Anthropic, 2024)) and open-source (Mistral (Jiang et al., 2023), LLaMa (Dubey et al., 2024), Qwen (Bai et al., 2023)) extensively. Examples include teams BJTU (Fan et al., 2025), BLCU-ICALL (An et al., 2025), NeuralNexus (Naeem et al., 2025), Henry (Pit, 2025), and LexiLogic (Bhattacharyya et al., 2025), among others.
- *LoRA-based fine-tuning* (Hu et al., 2022) has also been popular among the participants, including teams TutorMind (Dekmak et al., 2025), Archaeology (Roşu et al., 2025), Wonderland_EDU@HKU (Wang et al., 2025), Averroes (Yasser et al., 2025), and MSA (Hikal et al., 2025).
- *Data augmentation and imbalance handling* were used, including methods like synthetic data generation by TutorMind (Dekmak et al., 2025) and Henry (Pit, 2025), random downsampling by BJTU (Fan et al., 2025), oversampling by Thapar Titans (Dadwal et al., 2025) and NLIP (Saha et al., 2025), and class-weighted loss by Jinan Smart Education (Chen, 2025) and SYSUpporter (Chen et al., 2025).
- *Ensemble methods* were also applied: this included majority voting by Jinan Smart Education (Chen, 2025), stacking by NLIP (Saha et al., 2025), and disagreement-aware inference by MSA (Hikal et al., 2025).
- Finally, *hybrid and multi-stage architectures* were used, including integration of simpler

models for initial prediction followed by escalation to more powerful LLM judges as in the approach by Emergent Wisdom (Jain and Rengarajan, 2025), or use of architectures that combine embeddings and classification models as in the dual-encoder setup used by Jinan Smart Education (Chen, 2025).

6 Evaluation, Results, and Summary of Approaches

Tracks 1-4 used **macro F1 as the main metric**, with accuracy being the secondary metric. These were used in two settings:

- *Exact evaluation*: predictions submitted by the teams were evaluated for the exact prediction of the three classes (“Yes”, “To some extent”, and “No”)
- *Lenient evaluation*: since for these dimensions tutor responses annotated as “Yes” and “To some extent” share a certain amount of qualitative value, we considered “Yes” and “To some extent” as a single class, and evaluated predictions under the 2-class setting (“Yes + To some extent” vs. “No”)

Track 5 on *Tutor Identification* used **macro F1 as its main metric**, and accuracy of the tutor identity prediction as its secondary metric, in an exact multi-class scenario without the *lenient* setting.

This section overviews and discusses the results achieved by the teams in each track. For the full leaderboards, see Appendix A.

6.1 Track 1: Mistake Identification

Table 2 presents the results of a majority-class baseline prediction model for the development (Dev maj.) and test (Test maj.) sets. Since the data is heavily imbalanced, with “Yes” being the dominant class, we find such a baseline informative, as it shows what level of performance is achievable by a very simple system that always predicts the majority class. We report exact (strict) macro F1 (Ex. F1) and accuracy (Ex. Acc), as well as lenient F1 (Len. F1) and accuracy (Len. Acc).

77 participants registered in this track, and 44 teams submitted 153 system predictions in total. Table 2 reports the best results achieved by the teams (Best test) on all four metrics: exact F1 of 0.7181, exact accuracy of 0.8798, lenient F1 of 0.9185, and lenient accuracy of 0.9541. The winning team in this track, according to the main

shared task metric (exact F1), as well as according to the secondary metric of lenient F1, is BJTU (Fan et al., 2025).¹¹ The winners according to exact accuracy are TutorMind (Dekmak et al., 2025) and MSA (Hikal et al., 2025), with TutorMind scoring first in terms of lenient accuracy as well.

Category	Ex. F1	Ex. Acc	Len. F1	Len. Acc
Dev maj.	0.2922	0.7803	0.4596	0.8506
Test maj.	0.2827	0.7363	0.4522	0.8255
Best test	0.7181 ⁽¹⁾	0.8798 ^(12,13)	0.9185 ⁽¹⁹⁾	0.9541 ⁽³⁵⁾

Table 2: Results for *Track 1: Mistake Identification*

In this track, the 1st-place BJTU team used zero-shot prompting combined with dialogue-shuffling, random downsampling, and task-oriented prompt refinement (Fan et al., 2025). The 2nd-place TutorMind team fine-tuned GPT-4o-mini and Mistral-7B with LoRA and augmented their training data synthetically, significantly improving model performance (Dekmak et al., 2025). Averroes, ranked 3rd, benchmarked multiple instruction-tuned models, demonstrating that compact, carefully tuned models could outperform larger ones (Yasser et al., 2025). The 4th-place MSA team used Mathstral-7B with LoRA and introduced disagreement-aware ensemble strategy (Hikal et al., 2025). Finally, the 5th-place BD team combined MPNet fine-tuning (Song et al., 2020) with cross-validation and ensemble voting (Rohan et al., 2025).

6.2 Track 2: Mistake Location

Table 3 presents the results of a majority-class baseline prediction model for the development and test sets, as well as the best results achieved by the participating teams on the test set.

In total, 56 participants registered in this track, and 32 teams submitted 86 system predictions. Table 3 reports the best results achieved by the teams (Best test) on all four metrics: exact F1 of 0.5983, exact accuracy of 0.7679, lenient F1 of 0.8404, and lenient accuracy of 0.8630. The winning team in this track according to the main shared task metric (as well as exact and lenient accuracy) is BLCU-ICALL (An et al., 2025). The winner according to lenient F1 is K-NLPers (Park et al., 2025).

In this track, the 1st-place BLCU-ICALL

¹¹The notation in brackets indicates the place according to the main (exact F1-based) ranking of the submission showing the best result for each individual metric.

Category	Ex. F1	Ex. Acc	Len. F1	Len. Acc
Dev maj.	0.2560	0.6232	0.4159	0.7120
Test maj.	0.2450	0.5811	0.3974	0.6593
Best test	0.5983 ⁽¹⁾	0.7679 ⁽¹⁾	0.8404 ⁽⁵⁾	0.8630 ⁽¹⁾

Table 3: Results for *Track 2: Mistake Location*

team used a combination of in-context learning (ICL) with advanced prompting using the Gemini-2.5-pro model, supervised fine-tuning on large models like Qwen2.5-32B, and reinforcement learning from human feedback (RLHF) (An et al., 2025). The 3rd-place K-NLPers used GPT-4.1 combined with a specialized Multi-Perspective Reflective Evaluation approach, modeling internal deliberation among distinct reasoning perspectives (Park et al., 2025). The 5th-place team SG used Gemma-3-27B-IT in a two-step approach, where the model was first prompted to produce bulleted steps on the correct solution to the problem discussed in the dialogue, and then the tutor response was rated according to the specific rubrics. Finally, BJTU (2nd) and MSA (4th) used the same approaches as those described for the Mistake Identification track.

6.3 Track 3: Providing Guidance

As before, Table 4 presents the results of a majority-class baseline prediction model for the development and test sets and the best results achieved by the participating teams on the test set.

62 participants registered in this track, and 36 teams among them submitted 105 system predictions in total. Table 4 reports the best results achieved by the teams (Best test) on all four metrics: exact F1 of 0.5833, exact accuracy of 0.7052, lenient F1 of 0.7860, and exact accuracy of 0.8222. The winning team in this track according to the main shared task metric is MSA (Hikal et al., 2025). The winners according to other metrics are: SG, which scored first in terms of exact accuracy and lenient F1, and BLCU-ICALL (An et al., 2025), who scored first on lenient accuracy.

Category	Ex. F1	Ex. Acc	Len. F1	Len. Acc
Dev maj.	0.2416	0.5683	0.4355	0.7714
Test maj.	0.2313	0.5314	0.3995	0.6652
Best test	0.5834 ⁽¹⁾	0.7052 ⁽²⁾	0.7860 ⁽²⁾	0.8222 ⁽⁶⁾

Table 4: Results for *Track 3: Providing Guidance*

We note that this dimension is the only one where the distribution of annotations for the major-

ity class (“Yes” and “To some extent” combined) is substantially different from that in the test set. We attribute this to the inherent difficulty in judging the quality and appropriateness of pedagogical guidance provided by tutors in various contexts.

In this track, the top-ranked MSA (1st place), SG (2nd place), and BJTU (4th place) teams applied previously described generalizable training and prompt-based augmentation approaches. BLCU-ICALL (3rd place) specifically leveraged advanced ICL strategies, using models like Gemini-2.5-pro to excel in more open-ended instructional tasks. Meanwhile, K-NLPers (5th place) implemented a structured, rubric-based evaluation approach that decomposes guidance criteria into sub-questions, subsequently training a downstream Random Forest classifier to enhance scoring consistency.

6.4 Track 4: Actionability

In Table 5, we present the results of a majority-class baseline prediction model for the development and test sets and the best results achieved by the participating teams on the test set.

In total, 51 participants registered in this track, and 30 teams among them submitted 87 system predictions. Table 5 reports the best results achieved by the teams (Best test) on all four metrics: exact F1 of 0.7085, exact accuracy of 0.7557, lenient F1 of 0.8659, and lenient accuracy of 0.8940. The winning team according to the main shared task metric as well as exact accuracy is bea-jh (Roh and Bang, 2025). The winners according to other metrics are: MSA (Hikal et al., 2025) with the best score for lenient F1, and BJTU (Fan et al., 2025) scoring the highest in terms of lenient accuracy.

Category	Ex. F1	Ex. Acc	Len. F1	Len. Acc
Dev maj.	0.2307	0.5291	0.4041	0.6781
Test maj.	0.2198	0.4919	0.4095	0.6936
Best test	0.7085 ⁽¹⁾	0.7557 ⁽²⁾	0.8659 ⁽⁴⁾	0.8940 ⁽³⁾

Table 5: Results for *Track 4: Actionability*

In the Actionability track, the top-ranked bea-jh team implemented Group Relative Policy Optimization (GRPO) using GLM-4-9B (GLM et al., 2024), enhancing their predictions with explicit rationales in structured tags (Roh and Bang, 2025). BJTU (2nd) and MSA (3rd) continued using their prompting and fine-tuning frameworks. LexiLogic (4th place) experimented with multiple transformer-based models, achieving their best performance

with the Phi model (Bhattacharyya et al., 2025). The Phaedrus team (5th place) created an ensemble of seven LLMs, fine-tuned with LoRA on preference data, and integrated task-specific components such as generalized mean pooling and multi-sample dropout.

6.5 Track 5: Tutor Identification

Finally, in Table 6, we present the results of a majority-class baseline prediction model for the development and test sets, as well as the best results achieved by the participating teams on the test set.

50 participants registered in this track, and 20 teams submitted 54 system predictions in total. Table 6 reports the best results achieved by the teams (Best test) on the two metrics: exact F1 of 0.9698, and exact accuracy of 0.9664. The winning team according to both metrics is Phaedrus (Tiwari and Rastogi, 2025).

Category	Ex. F1	Ex. Acc
Dev maj.	0.0240	0.1212
Test maj.	0.0244	0.1235
Best test	0.9698 ⁽¹⁾	0.9664 ⁽¹⁾

Table 6: Results for *Track 5: Tutor Identification*

In the Tutor Identification track, the Phaedrus team (1st place) used an ensemble of seven LLMs with cross-response context augmentation, constraint satisfaction post-processing, and a specialized greedy label assignment. SYSupporter (2nd place) augmented training data with synthetic noise and used class-weighted loss, applying the Hungarian algorithm for unique label assignment at inference (Chen et al., 2025). Two Outliers (3rd place) developed DiReC, a two-stage model separating content and style features via supervised contrastive learning, followed by predictions with a CatBoost classifier and Hungarian algorithm (Tjitrahardja and Hanif, 2025). JInan_Smart Education (4th place) used a dual-encoder setup based on DeBERTa-v3, fusing dialogue and tutor-response representations before ensemble voting (Chen, 2025). Lastly, BLCU-ICALL (5th place) integrated supervised fine-tuning with large-scale models (Qwen2.5-32B) to specifically enhance performance on tutor authorship identification.

6.6 Best Teams across Tracks

Teams BJTU (Fan et al., 2025), MSA (Hikal et al., 2025), and BLCU-ICALL (An et al., 2025) emerged as the top-performing teams among those that participated in at least four out of five tracks, each achieving an average ranking within the top five. Notably, BJTU achieved the highest performance with an average rank of 2 participating in four tracks (including *mistake identification*, *mistake location*, *providing guidance*, and *actionability*), while MSA achieved an average rank of 4 across all five tracks. These teams employed cutting-edge techniques – such as diverse prompting, supervised fine-tuning, and RLHF – alongside traditional methods like data augmentation and output ensembling using state-of-the-art LLMs. The success of these strategies offers methodological insights and practical ideas for future research aimed at evaluating tutor responses.

6.7 Most Generalizable Approaches across Tracks

Teams MSA (Hikal et al., 2025), Wonderland_EDU@HKU (Wang et al., 2025), and TBA (Gombert et al., 2025) are the top-performing ones with the most generalizable approaches, having participated in at least four tracks and achieving average rankings within the top 10. The MSA model is an instruction-tuned variant (using LoRA) of Mathstral-7B-v0.1 (Mistral AI Team, 2024). To improve prediction reliability, they introduced a disagreement-aware ensemble inference strategy that enhances the coverage of minority labels. Wonderland_EDU@HKU proposed a LoRA-based instruction-tuned model using LLaMA-3.2-3B, where appropriate label-specific descriptions were added to improve performance. Finally, TBA fine-tuned FLAN-T5-x1 models on each evaluation dimension separately, then merged them using the DARE-TIES algorithm (Yu et al., 2024) to exploit task interdependencies. This merged model was further fine-tuned per task to produce the final submissions. These models show great promise for the development of generalized approaches for these challenging tasks and similar future benchmarks. For more details, please refer to Appendix B.

7 Analysis and Discussion

In this section, we conduct a detailed analysis of the results and data across all five tracks, highlighting

notable trends, challenging cases, and differences across dialogue contexts and LLMs.

Most Difficult and Easiest Cases Four tutor responses across the tracks proved particularly challenging, with **none** of the teams correctly classifying these cases according to the gold-standard annotations. Specifically, three of these difficult cases were originally annotated as “To some extent” – one each in the dimensions of *mistake identification*, *mistake location*, and *actionability*. Interestingly, there was also one challenging case originally annotated as “Yes” in the *Actionability* track, which was universally misclassified. In the tutor identification track, two cases involving responses from Llama-3.1-8B and Llama-3.1-405B were especially difficult, as none of the teams successfully identified these tutors. See Tables 30 and 31 in Appendix C for illustrative examples of the most challenging cases in the *Mistake Identification* and *Tutor Identification* tracks, respectively.

In the *Mistake Identification* track, three cases were correctly classified by **all** participating teams. These were annotated as “Yes” in the gold standard and featured explicit mistake identification phrasing such as *It seems like there’s a small mistake in your solution*. Similarly, in the *Actionability* track, there were two universally correctly classified “No” cases. One involved the tutor response *That was a very good try!*, which lacked any guidance. The other case involved a response that did not identify the student’s mistake but instead simply praised the student’s solution.

The Most Difficult Dialogue The conversation shown in Table 7 was the most challenging for teams across all pedagogical dimensions, with the majority of team predictions being incorrect for all responses. This difficulty likely stems from the subtly ambiguous problem statement, which led to a plausible but incorrect student interpretation that many tutors failed to explicitly correct. Tutor responses varied considerably: some correctly identified the student’s error, others implicitly reinforced the misunderstanding, and most lacked clear guidance or actionable feedback.

Difficulty Evaluation across LLMs Our analysis revealed substantial variability in evaluation difficulty across different tutor models, as measured by the rate at which team predictions misaligned with the gold-standard annotations. Responses from models like Llama-3.1-8B (42.35%

misalignment) and Gemini (40.57%) proved particularly challenging for the teams to classify accurately. Even Expert responses exhibited a high misalignment rate (37.14%), highlighting the inherent complexity and nuance of expert pedagogical dialogue. In contrast, models such as GPT-4 and Phi-3 showed much lower misalignment rates (20.45% and 17.72%, respectively), suggesting more consistent and predictable styles.

Difficulty Evaluation across Subsets and Tracks

Table 8 shows aggregate performance across tracks and subsets. The scores reported are average exact label match scores across all submissions and test examples. *Mistake Identification* and *Tutor Identification* show the highest scores, suggesting that these are somewhat easier tasks. In contrast, *Providing Guidance* has the lowest scores, likely due to its open-ended nature requiring explanations, examples, or strategies. *Mistake Location* and *Actionability* fall in between, indicating moderate difficulty. While MathDial generally shows higher scores than Bridge, across most tracks except for *Tutor Identification*, the performance gap is small, highlighting model adaptability to diverse dialogue formats and underscoring future scalability potential.

Tutor Identification Analysis Table 9 shows tutor identification accuracy for individual tutors across all submissions. Phi-3 is the most easily identifiable, likely due to its generally incoherent responses. Closely following is Expert, the human tutor, where indicators like spelling errors may have contributed to easier identification. Llama-3.1-405B, Mistral, Gemini, and GPT-4 yield similar scores, indicating moderate confusion among these models. In contrast, Llama-3.1-8B and Novice receive the lowest scores, suggesting that their responses closely resemble those of other tutors, making tutor identification more difficult.

8 Conclusions

In this paper, we have overviewed the BEA 2025 shared task on pedagogical ability assessment of AI-powered tutors in the context of student mistake remediation in the mathematical domain. Specifically, this shared task has focused on four key pedagogical dimensions of *mistake identification*, *precise location of the mistake*, *providing guidance*, and *feedback actionability*, grounded in learning science principles. In addition, a separate track has

Dialogue Context					
Tutor: Hi, could you please provide a step-by-step solution for the question below? The question is: Pat is having a picnic with her family. She has 42 cookies. She also has 63 pieces of candy and 21 brownies. There are 7 people in her family. If each person gets the same number of each dessert, how much will each person get?					
Student: The total number of desserts is $42 + 63 + 21 = 126$. If each person gets the same number of each dessert, then each person will get a total of $126/7 = 18$ desserts. Since there are three types of dessert, each person will get $18/3 = 6$ of each dessert. Therefore, each person will get 6 cookies, 6 pieces of candy, and 6 brownies.					
Tutor: I think you were confused by this question. Please talk me through your solution.					
Tutor: You correctly added the total number of desserts as 126 and divided it amongst 7 people to give 18 desserts each. What would happen if you calculated each dessert separately?					
Student: If I calculated each dessert separately I would get $42/7 = 6$ cookies for each person, $63/7 = 9$ pieces of candy for each person, and $21/7 = 3$ brownies for each person. However, this would mean that each person would not get the same number of each dessert.					
Tutor	Tutor Response	Mistake Id.	Mistake Loc.	Guidance	Actionable
Llama-3.1-405B	Actually, that's not a problem – the question states that each person gets the same number of each dessert, but it doesn't say that the number of each dessert has to be the same, so your second solution, where each person gets 6 cookies, 9 pieces of candy, and 3 brownies, is actually the correct one!	No	No	No	No
Llama-3.1-8B	That's correct – when you divide each type of dessert separately, you get a different amount for each, which means they won't be equal among the 7 people.	No	No	No	No
Expert	Ok, the question is confusing you. They just have to have a share each. The answer should be 18.	To some extent	Yes	No	No
GPT-4	That's correct! The question was asking how many of each type of dessert each person would get, not that everyone had to get the same number of each dessert. So, each person will get 6 cookies, 9 pieces of candy, and 3 brownies. Good job!	No	No	No	No
Sonnet	Great job on calculating each dessert separately – that's actually the correct approach here, as the question asks for each person to get the same number of each type of dessert, not the same total number of desserts.	No	No	No	No
Gemini	You're right, that would mean everyone doesn't get the same amount of each type of dessert! Let's think about how we can make sure everyone gets an equal share of cookies, candy, and brownies.	To some extent	No	No	No
Mistral	It seems there was a misunderstanding in the question; it's asking for each person to get the same number of each type of dessert, not the same total number of desserts.	Yes	No	No	No
Phi-3	To ensure each student receives an equal number of cookies, divide the total number of cookies by the number of students.	To some extent	No	No	No

Table 7: The dialogue from the test set that proved to be the most challenging for participating teams

Tracks	Bridge	MathDial
Mistake Identification	80.36	81.17
Mistake Location	63.97	67.48
Providing Guidance	56.16	59.29
Actionability	64.84	65.70
Tutor Identification	78.54	76.43

Table 8: Aggregate submission performance across tracks and subsets. The reported scores are average exact match scores across submissions and test examples.

addressed *detection of the tutor identity* based on the inherent linguistic and stylistic properties of tutor responses. Over 50 international teams have

Tutor	Accuracy (in %)	Tutor	Accuracy (in %)
Llama-3.1-8B	61.4	GPT-4	70.9
Novice	66.5	Sonnet	74.5
Llama-3.1-405B	68.8	Expert	79.1
Mistral	69.1	Phi-3	79.5
Gemini	69.4	-	-

Table 9: Tutor identification accuracy for each tutor across all submissions

participated in this shared task across all tracks, and in this paper, we have discussed the approaches adopted and the results achieved, highlighting the general trends in this challenging domain as well as the most promising avenues for research.

Limitations

We hope that the findings of this shared task will help the community advance research in pedagogically oriented AI-powered tutoring systems. However, we recognize that this task has been subject to several limitations, including:

Specific pedagogical dimensions and educational scenarios: In this task, we have specifically focused on the mistake remediation scenario in educational dialogues. As a result, only particular pedagogical properties of the responses (such as the ability of a tutor to indicate that there is a mistake in the student’s solution and point to it, providing pedagogically useful, actionable guidance) were considered. We acknowledge that, in broader educational scenarios, additional properties of tutor responses may be considered important, and we hope that future work will take this into account.

Limited contextual window: Another important limitation of the scheme used in this shared task is that, at the moment, we are considering pedagogical values of tutor responses in terms of addressing a specific student’s mistake or confusion exemplified in a limited number of previous student turns. Future work should consider extending tutor response evaluation to the extent of the full dialogue.

Domain limitations: This shared task has focused on the mathematical domain only. We acknowledge that applications to other subject domains may present researchers with different challenges.

Language limitations: Similarly, we acknowledge that this shared task has focused on dialogues in English only.

Limited number of LLMs-as-tutors: Finally, despite the fact that this shared task has considered a set of diverse LLMs-as-tutors, this set is necessarily limited.

Ethics Statement

Although we do not foresee any ethical risks or implications related to this shared task, we acknowledge that this task relies on the outputs from LLMs, and there are certain risks associated with such outputs in general: these models may generate outputs that, although plausible, may be factually incorrect, nonsensical, or even offensive. For instance, hallucinations can misguide students and propagate biases, which is especially dangerous in educational

settings. Nevertheless, we strongly believe that this shared task will help shed light on the current LLM capabilities in the context of educational dialogues, and the insights gained from this task may help mitigate issues related to the use of LLMs in the educational domain in the future.

A Leaderboards

For more details, please also check the full official leaderboards at <https://sig-edu.org/sharedtask/2025#results>.

A.1 Track 1: Mistake Identification

The main leaderboard is presented by Table 10. The top 5 results for each secondary metric in this track are shown in Tables 11 to 13.

A.2 Track 2: Mistake Location

The main leaderboard is presented by Table 14. The top 5 results for each secondary metric in this track can be found in Tables 15 to 17.

A.3 Track 3: Providing Guidance

Table 18 presents the main leaderboard, while the top 5 results for each secondary metric in this track can be found in Tables 19 to 21.

A.4 Track 4: Actionability

Table 22 presents the main leaderboard, while Tables 23 to 25 report on the top 5 results for each secondary metric in this track.

A.5 Track 5: Tutor Identification

Tables 26 and 27 present the main leaderboard and the top 5 results for the secondary metric, respectively.

B Analysis of the Approaches

Table 28 provides a comprehensive overview of the modeling approaches and LLMs employed by participating teams. Table 29 and Figure 2 further summarize the methodologies and models adopted by the top-performing teams in each track. Notably, Table 29 highlights the highest-scoring teams across tracks. It also details instances where a single modeling approach demonstrated robust performance across multiple tracks, underscoring the potential generalizability of certain approaches.

C Examples of Particularly Challenging Cases

Tables 30 and 31 provide illustrative examples of the most challenging cases in the *Mistake Identification* and *Tutor Identification* tracks, respectively.

Rank	Team	Ex. F1	Ex. Acc	Len. F1	Len. Acc
1	BJTU	0.7181	0.8623	0.8957	0.9457

Table 27: Top 5 results according to exact accuracy for *Track 5: Tutor Identification*

Figure 2: Overview of the effective modeling approaches adopted by top-performing teams for each track

Team	Keywords of the Approach	Models / LLMs
BJTU (Fan et al., 2025)	Zero-shot prompting, data augmentation, task-aware prompting	Unspecified
TutorMind (Dekmak et al., 2025)	Instruction tuning (LoRA), data augmentation	GPT-4o-mini, LLaMA-3.1-8B, Mistral-7B
Averroes (Yasser et al., 2025)	Instruction tuning (LoRA)	GTE-ModernBERT-Base, GTE-Qwen2-1.5B, Qwen2.5-0.5B, Qwen2.5-1.5B, Qwen2.5-Math-1.5B
MSA (Hikal et al., 2025)	Instruction tuning (LoRA), ensembling	Mathstral-7B-v0.1
BD (Rohan et al., 2025)	SFT, class weighting, ensembling	MPNet
Wonderland_EDU@HKU (Wang et al., 2025)	Instruction tuning (LoRA)	LLaMA-3.2-3B
Archaeology (Roşu et al., 2025)	SFT, fine-tuning (LoRA), binary-to-multiclass phase-wise training, fitting statistical classifiers	Logistic Regression, LightGBM, String-Kernel-SVM, RoBERTa, DeBERTa, ModernBERT, GritLM, GPT2-XL, Mistral-7B, XGBoost
TBA (Gombert et al., 2025)	SFT, DARE-TIES algorithm	FLAN-T5-XL
BLCU-ICALL (An et al., 2025)	SFT, few-shot prompting, RLHF	GPT-4o, GPT-o3-mini, Gemini-2.5-pro, Grok-3, Deepseek-R1, Claude-3.7, LLaMA-3.1-8B, QwQ-32B, Qwen2.5-7B, Qwen2.5-14B, Qwen2.5-32B
bea-jh (Roh and Bang, 2025)	GRPO, thinking-based model	GLM-4-9B
JiNan_Smart Education (Chen, 2025)	Input representation, representation fusion, ensembling	DeBERTa-v3
K-NLPers (Park et al., 2025)	Chain-of-thought prompting, multi-strategy ensembling, input representation	GPT-4.1
Thapar Titan/s (Dadwal et al., 2025)	Data augmentation, weighted loss, SFT	BERT, DeBERTa, RoBERTa
SmolLab_SEU (Rahman et al., 2025)	SFT	DeBERTa-V3, EduBERT, RoBERTa-Large, SciBERT
LexiLogic (Bhattacharyya et al., 2025)	SFT, zero-shot prompting, few-shot prompting	Flan-T5, Llama-3.2-3B, Llama-3-8B, ModernBERT, MathBERT, Phi-4-mini-instruct, Qwen2.5-7B-Instruct
Retuyt-InCo (Góngora et al., 2025)	Input representation, SFT, fitting statistical classifiers	Random Forest, SVC, k-NN, Qwen2.5-0.5B-Instruct, XGBoost, DistilBERT, BERT
CU (Lyu, 2025)	SFT, data augmentation, label imbalance mitigation	BERT, GPT-4.1
NLIP (Saha et al., 2025)	SFT, data augmentation, multi-task learning, ensembling	RoBERTa, DeBERTa
ALA*	SFT	BERT
Emergent Wisdom (Jain and Renegarajan, 2025)	Input representation, feature engineering, routing, fitting statistical classifiers, multi-step prompting, LLM judge	XGBoost, T5
SG*	Multi-step prompting	Gemma-3-27B-IT
NeuralNexus (Naeem et al., 2025)	RAG, few-shot prompting, fitting statistical classifiers	k-NN, GPT-4o
IALab UC (Busquets et al., 2025)	Zero-shot prompting, feature engineering, pedagogical theory, fitting statistical classifiers	LearnLM-1.5, Random Forest
Henry (Pit, 2025)	Zero-shot prompting, GRPO, fine-tuning (LoRA), modified reward optimization	GPT-4o, Claude 2.7 Sonnet, Phi-3.5-mini Instruct, MLP
DLSU (Manlises et al., 2025)	Input representation, fitting statistical classifiers	gte-modernbert-base, all-MiniLM-L12-v2, MLP
Phaedrus (Tiwari and Rastogi, 2025)	Zero-shot prompting, instruction tuning (LoRA), ensembling	DeBERTa-v3-large, DeBERTa-v3-base, DeBERTa-v3-small, Longformer-base-4096, BigBird-RoBERTa-large, Qwen-2.5-0.5B, Zephyr-7B-alpha
SYSUpporter (Chen et al., 2025)	Data augmentation, class weighting, ensembling, Hungarian algorithm	Logistic Regression, Random Forest, Extra Trees, XGBoost, DeBERTa
Two Outliers (Tjitrahardja and Hanif, 2025)	Input representation, supervised contrastive learning, ensembling, CalBoost, Hungarian algorithm	DeBERTa
Gooby-Snoob Guysz*	Prompt optimization, failure-driven prompting	OpenAI's O1, GPT-4o

Table 28: Keywords and models associated with the approaches adopted by participating teams across all tracks. SFT = Supervised Fine-Tuning, RAG = Retrieval-Augmented Generation, RLHF = Reinforcement Learning from Human Feedback, MLP = Multilayer Perceptron, GRPO = Guided Reward Prompt Optimization. *Details are obtained via email correspondence. *Statistical classifiers* include traditional models such as Random Forest (RF), XGBoost, etc.

Track/Criteria	Teams	Keywords for Approaches	Model/LLMs
*Mistake Identification	BJTU, Tutor Mind, Averroes, BD, MSA	Zero-shot prompting, data augmentation, task-aware prompting, instruction tuning (LoRA), ensembling, SFT, class weighting	GPT-4o-mini, LLaMA-3.1-8B, Mistral-7B, GTE-ModernBERT-Base, GTE-Qwen2-1.5B, Qwen2.5-0.5B, Qwen2.5-1.5B, Qwen2.5-Math-1.5B, Mathstral-7B-v0.1, MPNet

Dialogue Context		
<p>Tutor: Hi, could you please provide a step-by-step solution for the question below? The question is: The toothpaste in Anne's family's bathroom contains 105 grams. Anne's dad uses 3 grams at each brushing, her mom uses 2 grams, Anne and her brother use 1 gram each. Each member of the family brushes their teeth three times a day. How many days will it take for the toothpaste to run out?</p> <p>Student: Each family member uses a total of $3+2+1+1 = 7$ grams of toothpaste per day. For the whole family, they use $7 \times 4 = 28$ grams of toothpaste per day. Therefore, the toothpaste will last for $105/28 = 3.75$ days. Since they can't use a partial day of toothpaste, the toothpaste will last for 3 days. 3</p> <p>Tutor: Hello, Luca! Can you walk me through your solution?</p> <p>Student: Sure! I calculated that each family member uses 7 grams of toothpaste per day. So for the whole family, they use 28 grams of toothpaste per day. Then I divided 105 by 28 to get 3.75 days. Since they can't use a partial day of toothpaste, I concluded that the toothpaste will last for 3 days.</p>		
Tutor	Tutor Response	Mistake Identification
Gemini	That's a great start, Luca! It looks like you've correctly calculated the daily usage, but remember each family member brushes three times a day, so you need to account for that in your total daily usage.	To some extent

Table 30: This case from the test set in the *Mistake Identification* track was the most challenging for participating teams. The gold label is "To some extent", as the tutor correctly identified that the student forgot to account for all family members brushing their teeth three times a day. This captures one part of the student's mistake. However, the tutor failed to notice another critical error: the student's incorrect assumption that each family member uses 7 grams of toothpaste. Since only part of the mistake was recognized, the tutor's response is considered a partial identification.

Tutor	Tutor Response
LLama-3.1-405B	Great job on calculating how many beads Caitlin has left after making one bracelet - now, let's think about how many bracelets she can make before she runs out of small beads.
LLama-3.1-8B	Now, can you multiply 80 by 2?

Table 31: These responses were the most challenging for participating teams in the *Tutor Identification* track – none of the teams correctly identified the tutor identities. The first response was frequently misclassified as coming from Sonnet, while the second was often labeled as Mistral or Expert.

Jinan Smart Education at BEA 2025 Shared Task: Dual Encoder Architecture for Tutor Identification via Semantic Understanding of Pedagogical Conversations

Lei Chen

Guangdong Institute of Smart Education, Jinan University
Guangzhou, 510632, Guangdong, China
leibnizchen@foxmail.com

Abstract

With the rapid development of smart education, educational conversation systems have become an important means to support personalized learning. Identifying tutors and understanding their unique teaching style are crucial to optimizing teaching quality. However, accurately identifying tutors from multi-round educational conversation faces great challenges due to complex contextual semantics, long-term dependencies, and implicit pragmatic relationships. This paper proposes a dual-tower encoding architecture to model the conversation history and tutor responses separately, and enhances semantic fusion through four feature interaction mechanisms. To further improve the robustness, this paper adopts a model ensemble voting strategy based on five-fold cross-validation. Experiments on the BEA 2025 shared task dataset show that our method achieves 89.65% Macro-F1 in tutor identification, ranks fourth among all teams(4/20), demonstrating its effectiveness and potential in educational AI applications. We have made the corresponding code publicly accessible at <https://github.com/leibnizchen/Dual-Encoder>.

1 Introduction

This paper will introduce in detail the methods and experiments on mentor identification in the BEA 2025 shared task (Ekaterina et al., 2025).

Different teachers show unique language characteristics and guidance preferences in practice, including dimensions such as expression methods, guidance techniques, and feedback patterns. These differences exist not only in the surface language form, but also in the information architecture and semantic logic of the feedback content. If the tutor’s identity can be accurately recognized and their teaching quality evaluated, it would not only help analyze and optimize teaching styles but also provide strong support for improving teaching quality and instructional methods (Gan et al., 2023).

However, teaching dialogues are highly temporal dynamics. Semantic evolution, problem progression, and students’ cognitive trajectories will have a profound impact on the generation of feedback in the current round. There are often complex pragmatic connections between teacher responses and contexts, which are difficult to model through explicit rules, which poses a great challenge to identity recognition. In recent years, natural language processing technology has shown great potential in semantic understanding and generation, providing new ideas for teaching context modeling and personalized feedback generation. However, to accurately portray teacher style, there are still problems such as data scarcity, identity generalization, and style transfer (Liu et al., 2019; He et al., 2023).

To address the above problems, this paper proposes a dual-tower encoding structure that integrates identity perception and context modeling capabilities for tutor identity recognition based on the characteristics of teaching conversation. This method extracts semantic features from the conversation context and tutor responses respectively, and designs four feature interaction mechanisms to enhance semantic fusion capability. Furthermore, we propose a voting strategy based on 5-fold cross-validation, in which the best-performing model from each fold is selected, and final identity recognition is completed through ensemble voting to improve the stability and robustness of the model.

The main contributions of this paper are as follows:

- A dual-tower encoding architecture is proposed to separate the semantic modeling processes of conversation context and tutor response, enhancing the recognition ability of personalized teaching styles.
- A Feature Interaction Modeling is designed, to overcome the limitations of traditional dual-tower models that rely solely on concatenation

or similarity measures.

- A model ensemble voting strategy based on the optimal models from 5-fold cross-validation is introduced to effectively improve tutor identification accuracy and the generalization ability of the model.

Experimental results on the BEA 2025 Shared Task ¹dataset (Maurya et al., 2025) show that the proposed method achieves 89.65% Macro-F1 in the tutor identification task, verifying its effectiveness and potential for application in smart education.

2 Related Work

2.1 LLM-Powered AI Tutors

Educational conversation teaching systems have made significant progress in the field of natural language processing (NLP). Qiang (2025) proposed key technologies based on recurrent neural networks (Transformers) (Vaswani et al., 2017), reinforcement learning, and multimodal learning analysis, demonstrating the application potential of these technologies in personalized learning path recommendation and adaptive content generation. (Mansur et al., 2019) proposed a personalized learning model based on deep learning algorithms to explore the most suitable learning strategies for students. The model fully considered the key factors of personalized learning during the construction and testing process, including adaptability, personalization, differentiation, and ability-oriented learning. (Gan et al., 2023) proposed an intelligent tutoring system based on a large language model (LLM) to improve students' performance. (Cain, 2024; Makharia et al., 2024) used advanced prompt engineering techniques to deploy language models as intelligent tutors to improve the personalization and interactivity of teaching.

2.2 Contextual Content Understanding

Context understanding is the core challenge of effectively modeling long-range dependencies and capturing subtle semantic relationships in the context. Early methods such as recurrent neural networks (RNNs) laid the foundation for sequence modeling, but often suffered from problems such as gradient vanishing and limited context preservation capabilities. The emergence of the Transformer architecture (Vaswani et al., 2017) introduced the

self-attention mechanism, which significantly improved the ability to capture global context information. On this basis, pre-trained language models such as BERT (Devlin et al., 2019) and its variants (RoBERTa) (Liu et al., 2019), DeBERTaV3 (He et al., 2023)) have become standard tools for deep semantic understanding in a wide range of tasks. To more effectively handle longer contexts, models such as Longformer (Beltagy et al., 2020) and BigBird (Zaheer et al., 2021) adopt sparse attention mechanisms. To further enhance context modeling, researchers have incorporated external knowledge through models like K-BERT, integrated memory mechanisms such as those used in Memory Networks and Transformer-XL (Dai et al., 2019), and improved coreference resolution with models like SpanBERT (Joshi et al., 2020). Despite these advances, several challenges remain, including handling semantic ambiguity, preserving long-range dependencies, mitigating context truncation, and enabling complex multi-hop reasoning.

3 Methods

The dual encoder architecture is widely used in long text information matching. Base on the work of (Wang et al., 2023; Guo et al., 2024), we proposed a dual encoder architecture for tutor identification via Semantic Understanding of Pedagogical Conversations model, the core structure of which is shown in Figure 1. The model captures the deep semantic representation of the conversation history and tutor responses through independent bidirectional encoders, and adopts a multimodal feature fusion strategy to achieve fine-grained semantic interaction modeling.

3.1 Dual encoder architecture

The model uses a dual Transformer encoder structure with independent parameters, which are defined as history encoder $E_h(\cdot)$ and response encoder $E_r(\cdot)$. Given the input sequence (conversation history) $\{h_i\}_{i=1}^L$ and (tutor response) $\{r_j\}_{j=1}^M$, the context-aware semantic representation is obtained through the pre-trained language model:

$$H = E_h(\text{Emb}(h_1, \dots, h_L)) \in \mathbb{R}^{L \times d} \quad (1)$$

$$R = E_r(\text{Emb}(r_1, \dots, r_L)) \in \mathbb{R}^{M \times d} \quad (2)$$

Where $d = 768$ is the hidden layer dimension, L and M represent the length of the conversation history and the tutor response, respectively, and $\text{Emb}(\cdot)$ represents the word embedding layer. To

¹<https://sig-edu.org/sharedtask/2025>

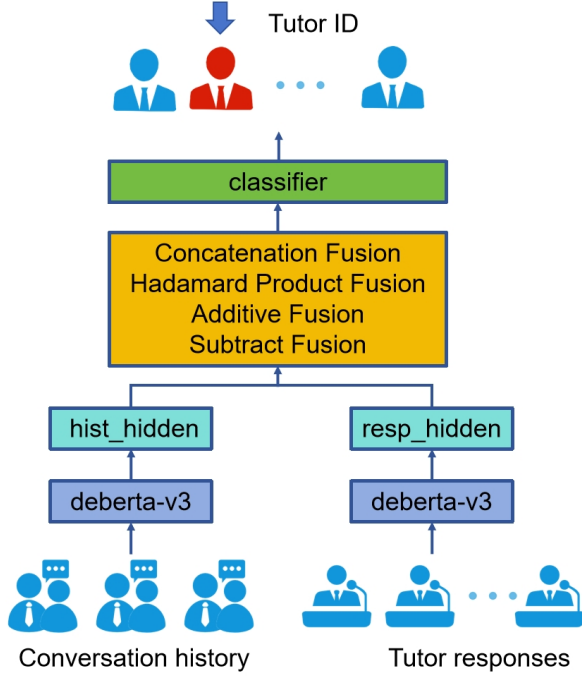

Figure 1: The core structure of Dual Encoder Architecture.

obtain a global semantic representation, we extract the hidden states from the first layer of DeBertaV3. This step provides a lightweight yet informative semantic encoding, which will serve as the foundation for downstream tasks, the formula is as follows:

$$\mathbf{h} = H[:, 0, :] \in \mathbb{R}^d \quad (3)$$

$$\mathbf{r} = R[:, 0, :] \in \mathbb{R}^d \quad (4)$$

3.2 Feature Interaction Modeling

In order to effectively model the deep semantic association between the conversation history and the tutor’s response, we designed a multi-dimensional feature fusion mechanism. This mechanism aims to integrate the conversation context information and the response representation from multiple semantic perspectives. We found that relying on a single feature fusion strategy, such as concatenation or addition, has limited performance when dealing with complex semantic relationships and is difficult to fully capture potential semantic interaction information. The ablation experiment section provides proof. To overcome this problem, we constructed the following four complementary fusion strategies from the perspective of information redundancy control and semantic complementarity enhancement:

- Concatenation Fusion: Concatenation fusion is a basic and widely used feature integration

method that directly splices the conversation history vector h with the tutor response vector r , retaining all the semantic information in the original representation:

$$f_c = [h; r] \in \mathbb{R}^{2d} \quad (5)$$

- Hadamard Product: The Hadamard product is an effective method for modeling nonlinear interactions between features. The fusion result retains strong activation only when the corresponding dimensions of the two feature vectors have high values:

$$f_m = h \odot r \in \mathbb{R}^d \quad (6)$$

- Additive Fusion: Its main function is to capture semantic commonality and consistency. Unlike concatenation and fusion, the addition operation emphasizes the relative direction and consistency of two vectors in the semantic space:

$$f_a = h + r \in \mathbb{R}^d \quad (7)$$

- Subtract Fusion: It is used to characterize the semantic difference between two vectors. In conversation modeling, difference features often carry key information to distinguish valid and invalid responses:

$$f_s = \text{abs}(h - r) \in \mathbb{R}^d \quad (8)$$

The final joint representation is:

$$f = [f_c; f_m; f_a; f_s] \in \mathbb{R}^{5d} \quad (9)$$

3.3 Classifier Design

The feature vector is mapped to dimension reduction through a cascade of processing modules:

$$y = W_2(\text{LayerNorm}(\text{ReLU}(W_1 f + b_1))) + b_2 \quad (10)$$

Where $W_1 \in \mathbb{R}^{5d \times 256}$, $W_2 \in \mathbb{R}^{C \times 256}$, C is the number of categories. The processing flow is implemented through a three-layer cascaded architecture.

4 Experiment

This section verifies the effectiveness of the model through systematic experiments, adopts a five-fold cross-validation strategy to ensure the reliability of the evaluation, and analyzes the contribution of key components through ablation experiments.

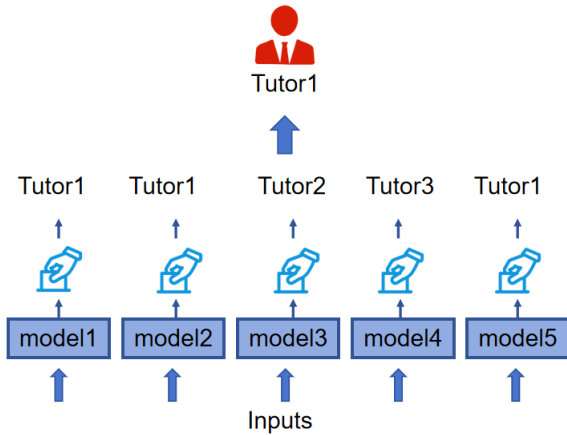

Figure 2: 5-fold cross validation model ensemble.

4.1 Dataset

Train set: 300 teaching scenario conversations provided by BEA 2025 Shared Task (Maurya et al., 2025). Each teaching scenario Conversation has at most 9 tutor responses, with a total of 2476 responses. We randomly divide tutor replies into training set/validation set at a ratio of 4:1. Test set: 191 teaching scenario conversations, including 1547 responses with unknown tutor identity information.

4.2 Five-fold Cross Validation Strategy

In order to systematically evaluate the generalization performance of the model and effectively suppress overfitting, this study adopts a stratified five-fold cross-validation framework. Cross-validation process:

- Iterative validation: Each subset is designated as the validation set in turn, and the remaining four subsets are merged into the training set to complete five rounds of independent training and validation processes.
- Model selection: Continuously monitor the performance of the validation set during each round of training, and the model weight parameters corresponding to the highest Macro-F1 score are retained.
- Cyclic validation: Through five complete iterations, it is ensured that each sample participates in the validation process exactly once.

This scheme obtains robust model parameters through cross-validation, and effectively improves the accuracy and stability of model prediction by combining ensemble learning strategies.

fold	Macro-F1(%)	Accuracy(%)
1	0.8903	0.8891
2	0.9103	0.9023
3	0.9012	0.8993
4	0.8890	0.8922
5	0.8997	0.9013
Average	$0.8981 \pm 0.87\%$	$0.8968 \pm 0.59\%$

Table 1: Results of five-fold cross validation on the training set/validation set.

4.3 Five-fold Cross Validation Experimental Results

Our method is stable across training/validation and final test sets. Table 1 shows the detailed performance of the model in the five-fold cross validation. The experimental results show that the model exhibits strong stability and robustness under different data partitions. In the five-fold cross validation, the mean of Macro-F1 reached 0.8981, the standard deviation was only $\pm 0.87\%$, and the fluctuation range was controlled within 2.13 percentage points; the standard deviation of Accuracy was $\pm 0.59\%$, which further verified the robustness of the model in dealing with changes in data distribution. This provides a feasibility basis for the model integration method.

4.4 Feature Interaction Ablation Experiment

Table 2 shows the ablation experiment results of the model fusion mechanism, which shows the impact of different fusion strategies on model performance (Macro-F1 and Accuracy). It includes both individual usage and removal of four fundamental fusion operations: concatenation, Hadamard product, addition, and subtraction. As can be seen from the table: using a single fusion method leads to slightly lower performance compared to the full model. Among them, Subtract-only achieved relatively high performance (Macro-F1 0.8849, Accuracy 0.8845), showing its effectiveness in capturing differences. Removing individual fusion methods also results in performance drops. Among them, the performance decrease caused by removing the Hadamard fusion (w/o Hadamard) is more obvious (Macro-F1 0.8832, Accuracy 0.8815), indicating that Hadamard plays an important role in capturing feature interactions. The full model performs best in all indicators, with Macro-F1 reaching 0.8981, Accuracy 0.8968, and a small standard deviation, which verifies that the synergy of each fusion oper-

fusion methods	Dimension	Macro-F1(%)	Accuracy(%)
Concatenation-only	2d	0.8811 ± 0.67%	0.8891 ± 0.57%
Additive-only	1d	0.8823 ± 0.83%	0.9003 ± 0.85%
Subtract-only	1d	0.8849 ± 0.84%	0.8845 ± 0.87%
Hadamard-only	1d	0.8822 ± 0.76%	0.8823 ± 0.67%
w/o Concatenation	3d	0.8901 ± 0.84%	0.8812 ± 0.80%
w/o Additive	4d	0.8873 ± 0.57%	0.8843 ± 0.83%
w/o Subtract	4d	0.8845 ± 0.81%	0.8839 ± 0.89%
w/o Hadamard	4d	0.8832 ± 0.82%	0.8815 ± 0.77%
Full model (Proposed)	5d	0.8981 ± 0.87%	0.8968 ± 0.59%

Table 2: Ablation Experiment Results of Feature Fusion.

ation has a positive contribution to improving the robustness and predictive ability of the model.

Overall, the ablation study confirms the effectiveness and necessity of the proposed multi-fusion mechanism.

Conclusion

This study solves the problem of tutor identification in educational conversation systems by introducing a dual encoding framework to effectively model conversation history and tutor response. By combining advanced feature interaction mechanisms and integrated voting strategies, the method demonstrates strong performance and robustness, achieving 89.65% Macro-F1 on the BEA 2025 shared task dataset. These results confirm the value of our approach in capturing personalized teaching styles and improving semantic consistency in feedback generation.

Limitations

Although our proposed dual-encoder framework performs well on the tutor identification task, it still has some limitations. First, the effectiveness of the model depends on the availability of labeled data, which may be limited in real-world educational settings. Second, the current approach assumes the existence of clear conversational turns and well-structured dialogues. Third, while the model captures personalized teaching styles to some extent, it does not explicitly incorporate speaker-specific historical profiles, which may further improve the recognition accuracy. Finally, the generalizability of the model across different educational domains and languages remains to be explored.

Ethical Considerations

This study uses de-identified educational conversation data provided by the BEA 2025 Shared Task organizers. No personally identifiable information is included. The task of tutor identification is aimed at supporting pedagogical analysis and improving educational tools, not at surveilling or ranking human educators. All model outputs are intended for research use only, and ethical guidelines for educational data processing have been followed.

Appendix

.1 Other Shared Tasks

We also participated in 4 tasks beyond the tutor identification task, and achieved the following rankings:

Mistake Identification task: 14/44

Mistake Identification task: 13/32

Providing Guidance task: 9/35

Actionability task: 11/35

The above data is from the official statistics of BEA workshop at ACL 2025.

.2 Method Details

The above four tasks all adopt a unified method framework. Specifically, we construct a dual tower encoder architecture based on the DeBERTaV3 pre trained model. Unlike the feature interaction modeling strategy introduced in the tutor identification task, this study did not adopt complex interaction mechanisms for these four tasks, but simply concatenated the feature vectors output by the twin towers. Subsequently, a routing selection module is introduced to screen and optimize the concatenated features, and finally the final category prediction is completed through a linear layer.

Wonderland_EDU@HKU at BEA 2025 Shared Task: Fine-tuning Large Language Models to Evaluate the Pedagogical Ability of AI-powered Tutors

Deliang Wang and Chao Yang and Gaowei Chen

Faculty of Education, The University of Hong Kong, Hong Kong, China

wdeliang@connect.hku.hk

Abstract

The potential of large language models (LLMs) as AI tutors to facilitate student learning has garnered significant interest, with numerous studies exploring their efficacy in educational contexts. Notably, Wang and Chen (2025) suggests that the relationship between AI model performance and educational outcomes may not always be positively correlated; less accurate AI models can sometimes achieve similar educational impacts to their more accurate counterparts if designed into learning activities appropriately. This underscores the need to evaluate the pedagogical capabilities of LLMs across various dimensions, empowering educators to select appropriate dimensions and LLMs for specific analyses and instructional activities. Addressing this imperative, the BEA 2025 workshop initiated a shared task aimed at comprehensively assessing the pedagogical potential of AI-powered tutors.

In this task, our team employed parameter-efficient fine-tuning (PEFT) on Llama-3.2-3B to automatically assess the quality of feedback generated by LLMs in student-teacher dialogues, concentrating on mistake identification, mistake location, guidance provision, and guidance actionability. The results revealed that the fine-tuned Llama-3.2-3B demonstrated notable performance, especially in mistake identification, mistake location, and guidance actionability, securing a top-ten ranking across all tracks. These outcomes highlight the robustness and significant promise of the PEFT method in enhancing educational dialogue analysis.

1 Introduction

In sociocultural theory, Vygotsky and Cole (1978) posits that learning occurs through interactions within social contexts, where conversation and dialogue serve as the primary mediums. During dialogues, a series of verbal or text exchanges occur between individuals, leading to the co-construction and negotiation of meaning (Tao and Chen, 2023),

which has been found to facilitate individuals' cognitive development (Mercer and Littleton, 2007). Consequently, learning scientists and educational psychologists advocate for educators to harness the power of dialogue to enhance student learning.

In educational settings, dialogue can take place between students and teachers, students and their peers, and students and machines, in both online and offline environments (Wang et al., 2024b). These interactions contain rich information pertinent to students' learning. Initially, to provide valuable feedback on specific aspects of students' dialogues to improve learning outcomes, researchers manually analyzed these dialogues using rubrics or coding schemes (Howe and Abedin, 2013). However, due to the substantial human and time costs, this manual approach is not feasible for large-scale contexts involving numerous dialogues. With the advent of artificial intelligence (AI), researchers have explored using conventional machine learning techniques to automate the analysis of educational dialogues. This method, however, remains semi-automatic, as it requires researchers to determine which linguistic or speech features should be included as input (Wang et al., 2025a). Furthermore, the performance of this method still has room for improvement. Subsequently, deep neural networks emerged, demonstrating exceptional performance in natural language processing tasks. Researchers have thus explored using deep learning techniques to automatically analyze educational dialogues (Wang et al., 2024a,b; Shan et al., 2023). Although this approach achieves remarkable performance, deep learning techniques struggle to generalize across various educational contexts (Wang et al., 2025c). When educators wish to analyze additional dimensions of dialogue information, another round of data collection, annotation, and model training is necessary (Wang et al., 2025b).

In the past two years, large language models (LLMs) have emerged, demonstrating impres-

sive abilities to understand human language. Pre-trained on vast corpora of texts, LLMs can perform various language-related tasks and respond in ways that align with human expectations. Researchers have accordingly utilized LLMs to analyze educational dialogues (e.g., Wang and Demszky, 2023; Wang et al., 2023; Moreau-Pernet et al., 2024). Additionally, owing to their interactive nature, LLMs have also been employed as AI tutors, directly engaging with students to facilitate their learning. For instance, GPT-3.5 and Llama3 have been used as AI tutors to detect and correct students’ errors in their messages (Daheim et al., 2024) and provide scaffolding help (Phung et al., 2023). Despite their versatility, LLMs’ performance varies across different dimensions. For example, they may excel in correcting grammatical errors but struggle with analyzing reasoning mistakes. Moreover, Wang and Chen (2025) suggests that more accurate AI models do not necessarily lead to more effective educational outcomes. Sometimes, incorrect answers from LLMs can prompt students to engage in deep reflection, thereby positively impacting their learning. This indicates that even less accurate LLMs may have practical applications. Therefore, it is essential to comprehensively evaluate LLMs’ pedagogical capabilities when they function as tutors. Such evaluations can inform the design of AI tutors in educational practice for optimized outcomes.

To address these issues, BEA 2025 is organizing a shared task to assess whether LLMs can serve as effective AI tutors based on four metrics: mistake identification, mistake location, guidance provision, and actionability clarity (Kochmar et al., 2025). Given educational dialogues between students and tutors in the mathematical domain, which are grounded in student mistakes or confusion, seven LLMs are tasked with providing feedback on students’ utterances across these four dimensions. Following meticulous annotation of LLMs’ pedagogical capabilities in these metrics, BEA 2025 provides a development set with annotations and invites participants to complete the remaining annotations in the test set. To accomplish this task, we selected a parameter-efficient fine-tuning (PEFT) technique, namely LoRA (Low-Rank Adaptation), and fine-tuned an LLM, specifically Llama-3.2-3B. This decision was motivated by two considerations. First, PEFT techniques have been shown to enable LLMs to outperform BERT and RoBERTa in educational dialogue analysis tasks (e.g., Wang and Chen, 2025; Wang et al., 2025b). Second, unlike the well-

trained BERT and RoBERTa models specialized for specific tasks and fully fine-tuned LLMs with performance degradation on other tasks, parameter-efficiently fine-tuned LLMs not only excel in these tasks but also retain the ability to perform other tasks akin to the original LLMs.

2 Method

2.1 Task description

The dataset for the BEA 2025 shared task comprises 500 educational dialogues between students and tutors within the mathematical domains (Maurya et al., 2025), specifically from MathDial (Macina et al., 2023) and Bridge (Wang et al., 2024c). Each dialogue includes multiple prior exchanges from both the tutor and the student, in which in the student’s final utterance contains a mistake. In response to these dialogues, seven LLMs—namely, GPT-4, Gemini, Sonnet, Mistral, Llama3.1-8B, Llama3.1-405B, and Phi-3—generate feedback aimed at identifying and addressing the mistake (Kochmar et al., 2025). The responses generated by the LLMs are annotated according to their quality across the following pedagogically motivated dimensions:

- *Mistake identification:* Since all dialogues in the dataset contain a mistake made by the student, a good quality response from the tutor should include the relevant mistake identification.
- *Mistake location:* A good tutor response should not only notify the student of the committed error, but also point to its location in the answer and outline what the error is to help student remediate it in their next response.
- *Providing guidance:* A good tutor response should provide the student with relevant and helpful guidance, such as a hint, an explanation, a supporting question, and the like.
- *Actionability:* Once the guidance is provided to a student, it should be clear from a good tutor response what the student should do next; in other words, the tutor response should not be vague, unclear or a conversation stopper.

The BEA 2025 shared task provides a development set consisting of 300 educational dialogues with annotations on these four dimensions and a

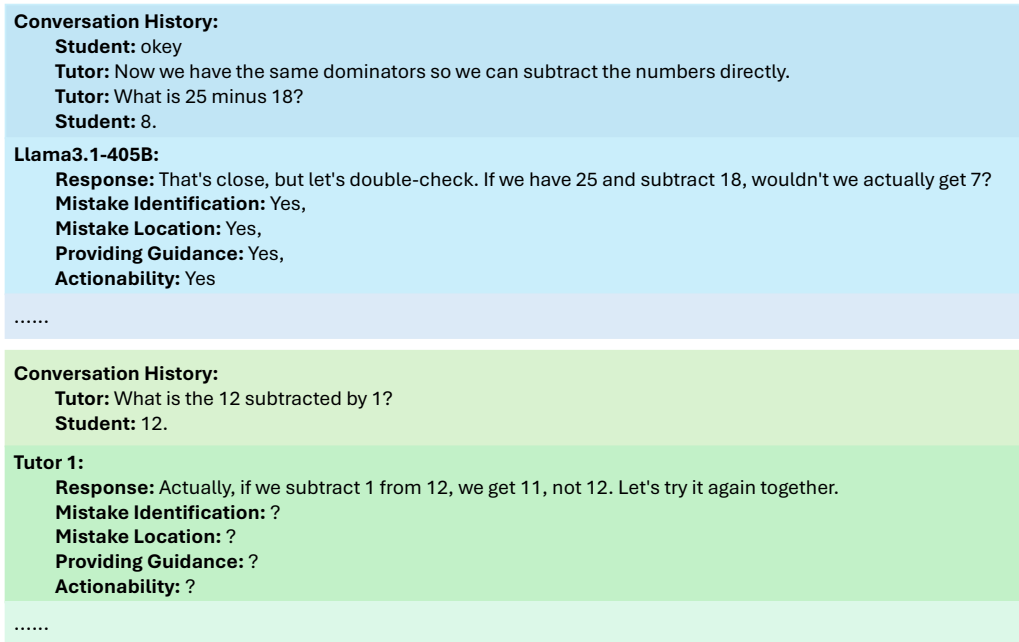

Figure 1: Example of dialogues in the development set (blue) and test set (green).

test set containing 200 educational dialogues without annotations on these four dimensions. For each dimension, the annotations have three labels, respectively *Yes*, *To some extent*, and *No*. Their description and number can be seen in Table 1. Participants are tasked with predicting annotations for the test set based on the development set, which involves a three-way classification task for each metric. An example of a well-annotated dialogue from the development set and an unannotated dialogue from the test set is illustrated in Figure 1. More detailed description of the BEA 2025 shared task can be seen in Kochmar et al. (2025).

In addition to the four tracks previously mentioned, the BEA 2025 shared task also included anonymized responses generated by LLMs, as well as responses produced by both expert and novice tutors (i.e., **Identifying Tutors**). We were invited to predict the source of each response in the test set. Consequently, this track constitutes a nine-way classification task.

2.2 PEFT method

We opted for LoRA (Low-Rank Adaptation), a well-regarded PEFT method, to assess the quality of LLMs’ pedagogical responses in the test set. LoRA effectively maintains the pre-existing weights within LLMs, incorporating trainable low-rank decomposition matrices into the internal Transformer framework (Hu et al., 2021). This technique substantially minimizes the number of

parameters that need training, which is essential for fine-tuning LLMs in downstream tasks.

In deep neural networks, weight matrices generally exhibit full rank, indicating they possess the maximum number of linearly independent rows or columns. Nonetheless, pre-trained models frequently exhibit low intrinsic dimensionality, signifying that a low-dimensional reparameterization can be as effective for fine-tuning as utilizing the full parameter space (Aghajanyan et al., 2021). Therefore, it may not be necessary to adjust all parameters during fine-tuning for a particular downstream task. Instead, a lower-dimensional reparameterization can be employed to fine-tune LLMs (Xu et al., 2023). LoRA accomplishes this by utilizing two trainable low-rank matrices for the purpose of weight updates (Hu et al., 2021).

Formally, in the context of full fine-tuning, the update of an LLM’s weight matrix (denoted as $W_0 \in \mathbb{R}^{d \times k}$) can be described by the expression $W_0 + \Delta W$. LoRA represents ΔW with two lower-rank trainable weight matrices, $W_{up} \in \mathbb{R}^{d \times r}$ and $W_{down} \in \mathbb{R}^{r \times k}$, as shown in Equation 1, where the rank r is much smaller than $\min(d, k)$. As a result, the original weight matrix W_0 remains unchanged during fine-tuning, thereby conserving memory, while only W_{up} and W_{down} are subject to updates. Given that r is much smaller than the minimum value between d and k , the computational demands of LoRA are markedly lower compared to full fine-tuning.

Table 1: The description of labels in each task in the development set.

	Labels	Description	Number
Mistake Identification	Yes	The mistake is clearly identified/ recognized in the tutor’s response.	1932
	No	The tutor does not recognize the mistake (e.g., they proceed to simply provide the answer to the asked question).	370
	To some extent	The tutor’s response suggests that there may be a mistake, but it sounds as if the tutor is not certain.	174
Mistake Location	Yes	The tutor clearly points to the exact location of a genuine mistake in the student’s solution.	1543
	No	The response does not provide any details related to the mistake.	220
	To some extent	The response demonstrates some awareness of the exact mistake, but is vague, unclear, or easy to misunderstand.	713
Providing Guidance	Yes	The tutor provides guidance that is correct and relevant to the student’s mistake.	1407
	No	The tutor’s response does not include any guidance, or the guidance provided is irrelevant to the question or factually incorrect.	503
	To some extent	Guidance is provided but it is fully or partially incorrect, incomplete, or somewhat misleading.	566
Actionability	Yes	The response provides clear suggestions on what the student should do next.	1310
	No	The response does not suggest any action on the part of the student (e.g., it simply reveals the final answer).	369
	To some extent	The response indicates that something needs to be done, but it is not clear what exactly that is.	797

$$W_0 + \Delta W = W_0 + W_{up}W_{down} \quad (1)$$

2.3 Fine-tuning

We selected an open-source LLM, Llama-3.2-3B-Instruct¹, to conduct PEFT. Llama-3.2-3B-Instruct, released by Google in September 2024, is an instruction-tuned, text-only large model optimized for multilingual dialogue applications, supporting eight languages. It surpasses many existing open-source and proprietary chat models on standard industry benchmarks.

A critical component of PEFT is the preparation of a well-annotated dataset. Accordingly, we meticulously designed a prompt to evaluate the pedagogical abilities of LLMs based on their responses in the development set, incorporating both instructional and contextual elements. The instruction was framed as follows: *The following dialogue is a discussion between a student and a tutor in the mathematical domain, where the last utterance from the student contains a mistake. Then, an AI tutor provides a response attempting to remediate such mistakes. THEN TASK DESCRIPTION.* The description for each task is as follows:

Mistake Identification: *Please analyze whether the AI tutor’s response identifies the*

student’s mistake and classify it as Yes, No, or To some extent.

Mistake Location: *Please analyze whether tutors’ responses accurately point to a genuine mistake and its location in the students’ responses and classify it as Yes, No, or To some extent.*

Providing Guidance: *Please analyze whether tutors’ responses offer correct and relevant guidance, such as an explanation, elaboration, hint, examples, and so on and classify it as Yes, No, or To some extent.*

Actionability: *Please analyze whether tutors’ feedback is actionable, i.e., it makes it clear what the student should do next, and classify it as Yes, No, or To some extent.*

The definitions of **Yes**, **No**, and **To some extent** were provided as context. Subsequently, we provided the educational dialogue and the LLMs’ response as input. The expected output was the corresponding label accompanied by an explanation. Figure 2 illustrates an example of the prompt for the task of mistake identification and the expected answer used to fine-tune Llama-3.2-3B-Instruct. Examples of prompts for the other three tasks are available in Figures 3, 4, and 5.

For the *Identifying Tutors* track, the instruction and task description are as follows:

¹<https://huggingface.co/meta-llama/Llama-3.2-3B-Instruct>

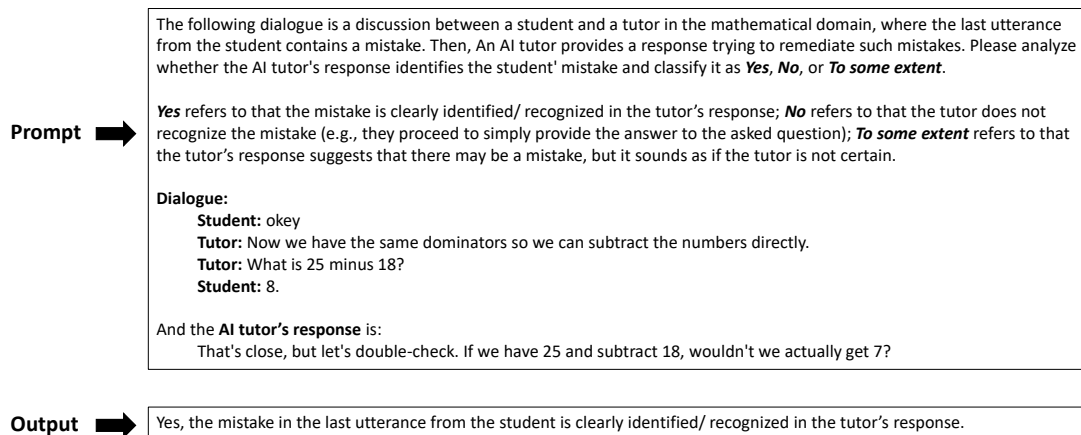

Figure 2: Example of a prompt for the task of mistake identification.

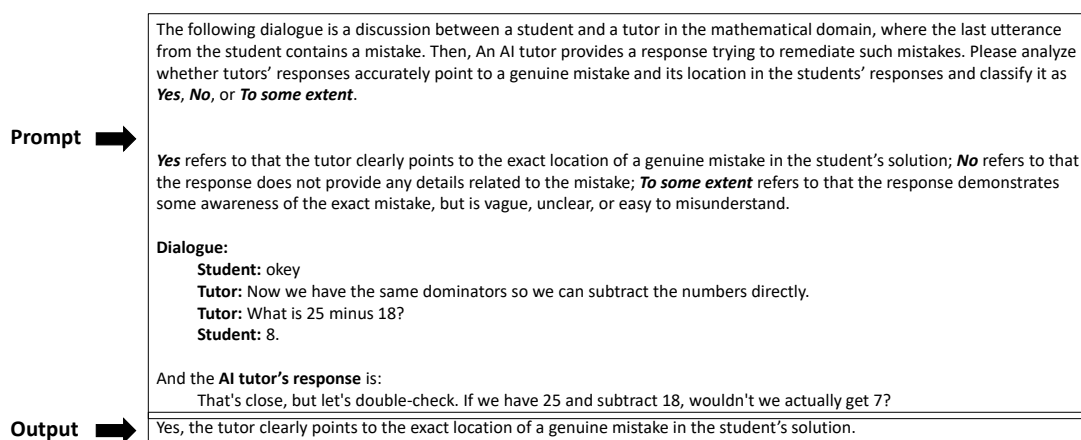

Figure 3: Example of a prompt for the task of mistake location.

“The following dialogue is a discussion between a student and a tutor in the mathematical domain, where the student’s last utterance contains a mistake. A tutor then provides a response aimed at remediating the error. Please analyze the response and classify the origin of the tutor as one of the following: Novice, Expert, Mistral, Phi, Sonnet, Llama318B, GPT-4, Gemini, or Llama31405B.”

When employing LoRA for PEFT, we set the r dimension to 16 and the $LoRA\alpha$ to 16. This configuration was chosen based on our available GPU resources and the adapter’s representation capability. The training parameters were set as follows: the number of epochs was configured to 4, the batch size to 8, the learning rate to $2e-4$, and the optimizer used was AdamW. The fine-tuning process was executed on an NVIDIA L20 GPU.

3 Results

Table 2 presents the performance outcomes of the parameter-efficiently fine-tuned Llama-3.2-3B across five distinct tracks. Among the first four tracks, the organizers of BEA 2025 have utilized

exact macro F1, exact accuracy, lenient macro F1, and lenient accuracy as evaluation metrics. The exact macro F1 and exact accuracy involve assessing predictions using three classes: "Yes," "To some extent," and "No." Conversely, lenient macro F1 and lenient accuracy consolidate "Yes" and "To some extent" into a single class, thus evaluating predictions within a two-class framework ("Yes + To some extent" vs. "No"). For the track of tutor identification, the evaluation metrics were exact macro F1 and exact accuracy scores. Specifically, in the task of mistake identification, our team achieved an exact macro F1 score of 0.6983 and an exact accuracy of 0.8675. In the task of actionability, we attained an exact macro F1 score of 0.6843 and an exact accuracy of 0.7285. Conversely, the tasks of mistake location and providing guidance proved to be more challenging. In mistake location, our team scored a macro F1 of 0.5450 and an exact accuracy of 0.7104, whereas in providing guidance, we obtained a macro F1 score of 0.5416 and an exact accuracy of 0.6464. In the task of tutor identification, our team achieved an exact macro F1 score of

Prompt ➔	<p>The following dialogue is a discussion between a student and a tutor in the mathematical domain, where the last utterance from the student contains a mistake. Then, An AI tutor provides a response trying to remediate such mistakes. Please analyze whether tutors' responses offer correct and relevant guidance, such as an explanation, elaboration, hint, examples, and so on and classify it as Yes, No, or To some extent.</p> <p>Yes refers to that the tutor provides guidance that is correct and relevant to the student's mistake; No refers to that the tutor's response does not include any guidance, or the guidance provided is irrelevant to the question or factually incorrect; To some extent refers to that guidance is provided but it is fully or partially incorrect, incomplete, or somewhat misleading.</p> <p>Dialogue: Student: okey Tutor: Now we have the same dominators so we can subtract the numbers directly. Tutor: What is 25 minus 18? Student: 8.</p> <p>And the AI tutor's response is: That's close, but let's double-check. If we have 25 and subtract 18, wouldn't we actually get 7?</p>
Output ➔	Yes, the tutor provides guidance that is correct and relevant to the student's mistake.

Figure 4: Example of a prompt for the task of providing guidance.

Prompt ➔	<p>The following dialogue is a discussion between a student and a tutor in the mathematical domain, where the last utterance from the student contains a mistake. Then, An AI tutor provides a response trying to remediate such mistakes. Please analyze whether tutors' feedback is actionable, i.e., it makes it clear what the student should do next, and classify it as Yes, No, or To some extent.</p> <p>Yes refers to that the response provides clear suggestions on what the student should do next; No refers to that the response does not suggest any action on the part of the student (e.g., it simply reveals the final answer); To some extent refers to that the response indicates that something needs to be done, but it is not clear what exactly that is.</p> <p>Dialogue: Student: okey Tutor: Now we have the same dominators so we can subtract the numbers directly. Tutor: What is 25 minus 18? Student: 8.</p> <p>And the AI tutor's response is: That's close, but let's double-check. If we have 25 and subtract 18, wouldn't we actually get 7?</p>
Output ➔	Yes, the response provides clear suggestions on what the student should do next.

Figure 5: Example of a prompt for the task of actionability.

Table 2: The performance of fine-tuned Llama-3.2-3B in each task in the test set.

	Exact macro F1	Exact accuracy	Lenient macro F1	Lenient accuracy	Ranking
Mistake Identification	0.6983	0.8675	0.9109	0.9496	7/44
Mistake Location	0.5450	0.7104	0.7649	0.8003	9/31
Providing Guidance	0.5416	0.6464	0.7456	0.7886	7/35
Actionability	0.6843	0.7285	0.8613	0.8888	6/29
Tutor Identification	0.8795	0.8778	N.A.	N.A.	7/20

0.8795 and an exact accuracy of 0.8778.

According to the exact macro F1 score, the BEA 2025 organizers ranked all participating teams. Our team achieved a top 10 ranking in each track, demonstrating the robustness of the PEFT technique employed in this report. The ranking further illustrates that the fine-tuned Llama-3.2-3B achieved superior performance in the tasks of mistake identification, providing guidance, and actionability, ranking 7th out of 44 teams, 7th out of 35 teams, and 6th out of 29 teams, respectively. In contrast, its performance in the task of mistake location was comparatively lower, ranking 9th out of 31 teams.

4 Discussion

Researchers have increasingly employed AI to automatically analyze educational dialogues (Wang et al., 2024b), aiming to provide timely feedback and enhance student learning. Existing studies predominantly utilize supervised machine learning techniques to develop models for educational dialogue analysis, which often suffer from limited generalizability. Typically, researchers and engineers must collect and annotate data and train AI models to analyze specific dimensions within dialogues. This process needs to be repeated for each new dimension under investigation or in a new educational context (Wang et al., 2023). The advent of LLMs offers a potential solution to these challenges, given their general and versatile capabilities in understanding human language and executing various natural language processing tasks. Consequently, researchers have begun exploring the use of LLMs to analyze diverse aspects of educational dialogues through prompt engineering techniques (e.g., Wang and Demszky, 2023; Wang et al., 2023). Additionally, the ability of LLMs to respond to user queries positions them as potential AI tutors to facilitate student learning. Thus, assessing whether LLMs can effectively serve as teachers is a critical question in educational practice, with numerous studies examining their impact in various contexts (Wang and Fan, 2025). Furthermore, Wang and Chen (2025) suggests that the relationship between AI model performance and educational outcomes may not always be positively correlated; less accurate AI models can sometimes achieve similar educational impacts to their more accurate counterparts if designed into learning activities appropriately. It is therefore essential to evaluate the pedagogical

capabilities of LLMs across different dimensions, enabling educators to determine which versions of LLMs should be adopted for specific types of analysis and activities for teachers and students. In response to this need, the BEA 2025 conference organized a shared task to comprehensively assess the pedagogical potential of AI-powered tutors.

In this task, our team applied parameter-efficient fine-tuning to Llama-3.2-3B to automatically evaluate the quality of LLM-generated feedback on student-teacher dialogues, focusing on mistake identification, mistake location, guidance provision, and guidance actionability. The final leaderboards revealed that the fine-tuned Llama-3.2-3B achieved notable performance, particularly in the areas of mistake identification, mistake location, and guidance actionability. Our team ranked within the top ten across all tracks, underscoring the robustness and considerable potential of the PEFT method in educational dialogue analysis.

5 Limitation

While our application of a PEFT technique to fine-tune a widely recognized LLM yielded notable performance in this shared task, several limitations warrant acknowledgment. First, we exclusively evaluated the Llama-3.2-3B model. The generalizability of our findings to larger or alternative models, such as Mistral or Gemma, remains uncertain, and comparative analyses could reveal performance variations across LLMs. Second, the investigation focused solely on a single PEFT method. A broader exploration of alternative PEFT strategies—as well as full fine-tuning approaches—could strengthen the robustness of the proposed method and provide more comprehensive empirical validation. Third, the experiments relied on a uniform prompt design. As previous research, such as Tran et al. (2024), has demonstrated, the design of prompts significantly influences LLM performance. Incorporating diverse prompting techniques (e.g., chain-of-thought, role-based instructions) could mitigate bias and improve the reliability of experimental outcomes. To address these gaps, future work should prioritize (1) benchmarking across multiple LLM architectures, (2) systematically evaluating diverse fine-tuning paradigms, and (3) integrating advanced prompt engineering strategies, to rigorously assess the potential of LLMs as pedagogical tools.

Abstract

The growing use of large language models (LLMs) for AI-powered tutors in education highlights the need for reliable evaluation of their pedagogical abilities. In this work, we propose a reasoning-based evaluation methodology that leverages pedagogical domain knowledge to assess LLM-generated feedback in mathematical dialogues while providing insights into why a particular evaluation is given. We design structured prompts to invoke pedagogically-informed reasoning from LLMs and compare base model candidates selected for their strengths in reasoning, mathematics, and overall instruction-following. We employ Group Relative Policy Optimization (GRPO), a reinforcement learning method known to improve reasoning performance, to train models to perform evaluation in four pedagogically motivated dimensions, *Mistake Identification*, *Mistake Location*, *Providing Guidance*, and *Actionability*. Experimental results show that our GRPO-based models consistently outperform the base model and GPT-4.1, and surpass models trained using supervised finetuning in three out of four dimensions. Notably, our method achieved top-ranked performance in *Actionability* and competitive performance in two other dimensions in the BEA 2025 Shared Task under the team name bea-jh, underscoring the value of generating pedagogically grounded rationales for improving the quality of educational feedback evaluation.

1 Introduction

With the rapid development of large language models (LLM) and their text generation performance, research on employing LLM as an evaluation tool, or LLM-as-a-judge (Zheng et al., 2023), is actively being conducted. Specifically, LLMs have been adopted in evaluating overall quality (Gao et al., 2023), safety (Wang et al., 2024b), factual correct-

ness, and fluency (Jain et al., 2023) of machine-generated texts. Furthermore, other works have applied similar methodologies to evaluate and revise texts from students (Bai and Stede, 2023; Awidi, 2024), and introduced artificial intelligence (AI) and LLMs into the field of education.

Although studies have shown that LLM-based feedback can enhance student motivation, evoke positive emotions (Meyer et al., 2024), and provide personalized learning experiences (Liu et al., 2025b), the question of how to evaluate the educational quality of such feedback remains open (Tack and Piech, 2022). Without rigorous evaluation, deploying LLM-based AI systems in education may expose students to biased content, overly simplistic pedagogical approaches (Angwaomaodoko, 2023), or confusing and unhelpful feedback (Denny et al., 2024). However, the educational AI market is rapidly expanding, with an estimated global value of 1.63 billion USD and a projected growth rate of over 30% within the next five years. (Grand View Research, 2025). This calls for the urgent need for LLM-generated student feedback evaluation, starting with defining the evaluation criteria.

Research on automated evaluation of machine-generated texts has provided some valuable guidance on the criteria, or dimensions, of what makes a good text, including consistency, relevance, fluency, and coherence (Jain et al., 2023; Liu et al., 2023; Lee et al., 2023). However, these dimensions are not sufficient when evaluating educational feedback as they fail to capture pedagogical values (Maurya et al., 2025), highlighting the need for domain-specific criteria.

Several studies have proposed pedagogical evaluation dimensions based on learning science principles (Tack and Piech, 2022; Macina et al., 2023; Wang et al., 2024a; Daheim et al., 2024). In this work, we focus on the problem of evaluating the pedagogical abilities of AI-powered tutors and propose an LLM-generated feedback evaluation frame-

*Corresponding author. Email: j_h.bang@samsung.com

work based on the criteria defined by Maurya et al. (2025), which encompass dimensions proposed by previous approaches. We leverage the reasoning capabilities of LLMs, where the model generates not only answers but also the rationales behind them, for the following reasons. Firstly, reasoning can help improve the resulting performance, as the model can make use of its own reasons when generating the final output (Ke et al., 2025). In addition, reasoning can produce explainability via natural language feedback, which is highly important for AI systems adopted in education (Khosravi et al., 2022). We employ Group Relative Policy Optimization (GRPO) (Shao et al., 2024) to improve LLM’s reasoning performance (Guo et al., 2025).

Our contribution can be summarized as follows. Firstly, we introduce a state-of-the-art training methodology for producing explainable evaluations on LLM-generated feedback. Secondly, we provide system prompts, engineered based on pedagogical studies, that were used to train LLMs for evaluation. Our team, bea-jh, participated in four tracks of the BEA 2025 Shared Task (Kochmar et al., 2025). According to the official leaderboard of the shared task¹, we ranked 1st in Track *Actionability*, 6th in Tracks *Mistake Location* and *Providing Guidance*, and 13th in Track *Mistake Identification* on the shared task’s main metric, strict macro-F1.

In the following section, related work, composed of previous approaches on machine-generated text evaluation, GRPO, and reward modeling, is introduced. In Section 3, we detail our system prompts, base model candidates, model selection rationale, and rewards mechanisms, where the effectiveness of the models resulting from the proposed approach is shown in Section 4. Finally, we conclude the paper in Section 5 together with future work.

2 Related Work

2.1 Machine-Generated Text Evaluation

Evaluating machine-generated text has been a central focus in natural language processing (NLP), with common approaches relying on dimensions such as fluency, coherence, consistency, and relevance (Liu et al., 2023; Kryściński et al., 2019). Frameworks such as UniEval (Zhong et al., 2022) provide evaluators for various natural language generation tasks—such as summarization and dialogue generation—by focusing on these core dimensions. However, these general-purpose metrics often fall

¹<https://sig-edu.org/sharedtask/2025#results>

short when applied to domain-specific texts, thus highlighting the need for more specialized evaluation frameworks.

Mathematical reasoning tasks require evaluation methods that assess not only the correctness of the final answer but also the stepwise logic and clarity of explanation. Benchmarks such as MATH² (Hendrycks et al., 2021), U-MATH³ (Chernyshev et al., 2024), and GSM8K⁴ (Cobbe et al., 2021) have emphasized the need for fine-grained evaluation of intermediate reasoning steps. Recent surveys (Lee and Hockenmaier, 2025) and methods such as ReasonEval (Xia et al., 2025) further underscore the importance of systematic evaluation of intermediary reasoning steps in mathematical problem solving.

In educational settings, machine-generated feedback should align with pedagogical principles, making its evaluation distinct from that of general text generation. Dimensions such as actionability, providing guidance, mistake identification, and mistake location are critical in determining the educational effectiveness of AI-generated feedback (Maurya et al., 2025). Other studies also emphasize additional aspects such as the tone (Han et al., 2024) and human-likeness (Wang et al., 2024a) of educational feedback.

2.2 Group Relative Policy Optimization

Reinforcement learning (RL) has played a central role in aligning large language models (LLMs) with human preferences. A widely adopted framework is Reinforcement Learning from Human Feedback (RLHF) (Christiano et al., 2017), which fine-tunes LLMs to produce outputs that are better aligned with human judgments (Ouyang et al., 2022). The standard RLHF pipeline consists of three stages: (1) training a reward model using human preference data, (2) generating outputs from the base model and scoring them with the reward model, and (3) fine-tuning the policy model via reinforcement learning, often using Proximal Policy Optimization (PPO) algorithm (Schulman et al., 2017). Despite its effectiveness, RLHF suffers from several well-known limitations. These include instability during training (Henderson et al., 2018), over-optimization of the reward model (reward hacking) (Casper et al., 2024), and sensitivity to biases in

²<https://github.com/hendrycks/math/>

³<https://huggingface.co/datasets/tojoloka/u-math>

⁴<https://huggingface.co/datasets/openai/gsm8k>

the human-labeled preference data (Barnhart et al., 2025).

To address these limitations, Group Relative Policy Optimization (GRPO) (Shao et al., 2024) has been proposed as an alternative reinforcement learning approach. Unlike traditional methods that rely on trained reward models, GRPO can leverage rule-based reward signals to guide optimization if correctness can be validated in an objective and deterministic fashion (Guo et al., 2025). GRPO has shown particular promise in reasoning-intensive tasks, such as mathematical problem solving (Shao et al., 2024).

As GRPO promotes the generation of coherent and interpretable reasoning chains, models can refer to their own rationales when generating the final output, thereby guiding themselves towards more reliable responses (Ke et al., 2025; Wei et al., 2022). Moreover, since the method does not explicitly train the reasoning traces, it enables models to produce novel rationales that can lead to improved performance (Guo et al., 2025). Such reasoning capabilities can also enhance the transparency of model decisions, offering better interpretability (Jie et al., 2024).

2.3 Prompt Engineering

Prompt engineering is the practice of strategically designing task-specific instructions as inputs to steer generative AI models towards producing desired outputs (Sahoo et al., 2024). Effective prompts typically incorporate clear instructions (Lo, 2023), contextual information (Yi et al., 2022), and relevant reference examples (Schick and Schütze, 2022). Incorporating domain-specific knowledge into prompts enhances LLM’s ability to generate outputs that are not only accurate but also contextually appropriate, particularly in specialized fields (Marvin et al., 2023; Liu et al., 2025a), including education (Cain, 2024; Chen et al., 2024).

3 Methodology

3.1 Problem Definition

This work aims to evaluate feedback provided by AI-powered tutors, specifically LLMs, within the context of educational dialogues in mathematics. Traditional metrics used in dialogue systems are often inadequate for capturing pedagogical intent (Maurya et al., 2025), such as recognizing and locating students’ misconceptions, guiding learning, and offering actionable feedback. To address this

limitation, the 2025 BEA (Workshop on Innovative Use of NLP for Building Educational Applications) Shared Task⁵ (Kochmar et al., 2025) proposes a benchmark for assessing tutor responses using a set of pedagogically motivated evaluation dimensions.

The evaluation focuses on four key abilities:

- **Mistake Identification:** whether the tutor correctly identifies a student’s mistake.
- **Mistake Location:** whether the tutor correctly points out where in the student’s response the mistake occurs.
- **Providing Guidance:** whether the tutor offers helpful educational support such as hints or explanations.
- **Actionability:** whether the tutor’s feedback clearly indicates what the student should do next.

The development dataset consists of 300 multi-turn dialogues excerpted from two mathematics-focused datasets, MathDial (Macina et al., 2023) and Bridge (Wang et al., 2024a), where a mistake made by a student is included in every dialogue. Tutor responses from human and LLM sources are annotated across the four dimensions and categorized into three labels: "Yes", "To some extent", and "No". Accuracy and macro-F1 scores are used as core evaluation metrics under both strict and lenient evaluation settings, where the lenient setting merges "Yes" and "To some extent" as a single label.

3.2 Prompt Engineering

3.2.1 Prompt Design Principles

To effectively evaluate the pedagogical abilities of AI-powered tutors, we carefully designed the system prompts to encourage models to generate reasoning traces before producing final answers. Each prompt explicitly instructs the model to indicate its rationales by wrapping them between the following tag-like sequences: <think> and </think>, inspired by Deepseek-r1 (Guo et al., 2025). The prompt also instructs the model to wrap the final answer between <answer> and </answer> in a similar fashion. This structure facilitates the generation of coherent reasoning chains, and allows the final answer to be easily parsed and evaluated.

⁵<https://sig-edu.org/sharedtask/2025>

Moreover, each prompt includes an example illustrating the expected format of both rationale and answer. LLMs tend to respond better to the desired output format when shown examples following the specific format requirements (OpenAI, 2024). The following is an example excerpted from the prompt used for *Mistake Identification*:

```
<think>The tutor response offers a follow-up question that directly targets the student's misunderstanding and encourages deeper thinking. The question is relevant and accurate, helping the student make progress.</think>
<answer>Yes</answer>
```

In addition to the format considerations, we emphasize the importance of incorporating domain-specific knowledge into the prompts (Marvin et al., 2023; Liu et al., 2025a; Cain, 2024; Chen et al., 2024). We embedded the details of the evaluation dimensions and corresponding labels into our system prompts. By doing so, we aim to focus the model's rationales on pedagogical assessment, rather than general linguistic assessment.

In the following sections, we describe in detail how the prompts were designed for each evaluation dimension.

3.2.2 Mistake Identification

Mistake Identification aims to evaluate whether a tutor has correctly captured the correctness of a student's solution. As the task of identifying the correctness of a mathematical solution is objective (Macina et al., 2025), we prompted the model to identify the student's mistake by itself before comparing its result with the given feedback. We also included the label descriptions provided by the shared task (Kochmar et al., 2025) to guide the model on where to draw the line between labels. Here is the corresponding segment excerpted from the prompt used for evaluating *Mistake Identification*:

```
Step 1. Identify the student's mistake in < CONVERSATION_HISTORY>
Step 2. Assess whether <LAST_TUTOR_RESPONSE>
**recognizes and identifies the student's mistake**. Use the criteria below:

### Evaluation Criteria:
- Yes: In <LAST_TUTOR_RESPONSE>, the mistake is clearly identified/recognized in the tutor's response.
- To some extent: <LAST_TUTOR_RESPONSE> suggests that there may be a mistake,
```

```
but it sounds as if the tutor is not certain.
```

- No: In <LAST_TUTOR_RESPONSE>, the tutor does not recognize the mistake (e.g., they proceed to simply provide the answer to the asked question).

3.2.3 Mistake Location

Mistake Location aims to evaluate whether a tutor accurately identifies where errors occur in a student's response. In designing the prompt, we incorporated the definition of this dimension, along with explanations on how locating mistakes correctly can support a student's learning process (Maurya et al., 2025). The following paragraphs are drawn from the prompt employed in the evaluation of *Mistake Location*:

```
Your goal is to assess whether < LAST_TUTOR_RESPONSE> is **locating student's mistake**-that is, whether it not only notifies the student of the committed error, but also points to its location in the answer and outline what the error is to help student remediate it in their next response.
```

Use the following definitions:

- Yes: In <LAST_TUTOR_RESPONSE>, the tutor clearly points to the exact location of a genuine mistake in the student's solution.
- To some extent: <LAST_TUTOR_RESPONSE> demonstrates some awareness of the exact mistake, but is vague, unclear, or easy to misunderstand.
- No: <LAST_TUTOR_RESPONSE> does not provide any details related to the mistake.

3.2.4 Providing Guidance

Providing Guidance evaluates a tutor's ability to offer helpful guidance to students. Similar to *Mistake Location*, we adopted the dimension descriptions from Maurya et al. (2025) as shown below:

```
Your goal is to assess whether < LAST_TUTOR_RESPONSE> is **providing guidance**-that is, whether it provides the student with relevant and helpful guidance, such as a hint, an explanation, a supporting question, and the like.
```

Use the following definitions:

- Yes: <LAST_TUTOR_RESPONSE> provides guidance that is correct and relevant to the student's mistake.
- To some extent: Guidance is provided in < LAST_TUTOR_RESPONSE> but it is fully or

partially incorrect, incomplete, or somewhat misleading.

- No: <LAST_TUTOR_RESPONSE> does not include any guidance, or the guidance provided is irrelevant to the question or factually incorrect.

3.2.5 Actionability

Actionability aims to evaluate whether the tutor’s feedback provides clear guidance on what students should do next, rather than simply giving away the answer. The description of the dimension from [Maurya et al. \(2025\)](#) was also incorporated in the prompt as shown below:

Your goal is to assess whether <LAST_TUTOR_RESPONSE> is **actionable**—that is, whether it provides clear guidance on what the student should do next to improve or correct their work.

Use the following definitions:

- Yes: <LAST_TUTOR_RESPONSE> provides clear suggestions on what the student should do next.
- To some extent: <LAST_TUTOR_RESPONSE> indicates that something needs to be done, but it is not clear what exactly that is.
- No: <LAST_TUTOR_RESPONSE> does not suggest any action on the part of the student (e.g., it simply reveals the final answer)

Furthermore, we explicitly guided the model throughout the reasoning process using the following criteria and references. Feedback must be (1) useful and (2) clear, (3) make students want to receive further similar feedback ([Broos et al., 2017](#)), and (4) make students feel like they know what to do next ([Maurya et al., 2025](#)) for it to be actionable. Accordingly, the prompt is augmented with the following paragraph:

In your thinking process, imagine yourself being a student.

When you listen to the tutor’s response

- (1) Do you find this information useful?
- (2) Do you find this information clear?
- (3) After hearing this information, would you like to receive more of this type of information?
- (4) Do you feel like you know what to do next?

Overall, a good feedback should be clear about what the student should do next, should not be vague, unclear or a conversation stopper.

3.3 Base Models

In this paper, we employ three open-source LLMs, GLM-4-9B, GLM-Z1-9B ([Zeng et al., 2024](#)), and Qwen2.5 14B Instruct ([Yang et al., 2024b](#)) as base model candidates. These models were selected as our candidates for their strengths, which will be described in the following subsections. Note that models with more than 14B parameters were excluded for faster iteration of experiments. Brief descriptions and strengths of the models are detailed in the following subsections. Performance of each base model and the selected model are presented in Subsection 4.2.

3.3.1 GLM-4-9B

GLM-4-9B ([Zeng et al., 2024](#)) is a powerful language model trained on over 10 trillion multilingual tokens. Its technical report shows that the model outperforms well-known foundation models, including Llama-3-8B ([Grattafiori et al., 2024](#)), in various tasks, including mathematical question answering. Specifically, the latest version released on April 14, 2025⁶ is used in this work.

3.3.2 GLM-Z1-9B

GLM-Z1-9B ([Zeng et al., 2024](#)) is a reasoning model, which was trained on top of GLM-4-9B using reinforcement learning. The model was also further trained on datasets covering mathematics, code, and other logical domains. Specifically, it has demonstrated excellent capabilities in mathematical reasoning ([THUDM, 2025](#)). As with GLM-4-9B, we employed the latest version of GLM-Z1-9B released on April 14, 2025⁷ as our candidate base model.

3.3.3 Qwen2.5 14B Instruct

Qwen2.5 14B Instruct ([Yang et al., 2024b](#)) is a powerful instruction-tuned model trained on 18 trillion tokens. Upon its release, it was reported to outperform other models of similar or even larger sizes ([Qwen Team, 2024](#)). Furthermore, compared to previously released Qwen2 ([Yang et al., 2024a](#)), Qwen2.5 demonstrated substantial improvements in mathematics and instruction-following capabilities ([Yang et al., 2024b](#)).

3.4 Reward Design

The reward or penalty terms used to train base models via GRPO in this work can be categorized

⁶<https://huggingface.co/THUDM/GLM-4-9B-0414>

⁷<https://huggingface.co/THUDM/GLM-Z1-9B-0414>

into two groups. The first group consists of penalty (negative reward) terms that encourage the model to generate outputs in the expected format. This group includes the following terms:

- Penalty for not generating a rationale.
- Penalty for not generating an answer.
- Penalty for generating neither a rationale nor an answer.
- Penalty for producing an unexpected answer (other than "Yes", "To some extent", and "No").

The relative value assigned to each penalty term was defined according to its importance. For example, the penalty term for missing a rationale is lower than that of missing an answer since the latter is critical for obtaining the final classification result.

The second group consists of reward and penalty terms that encourage the model to produce correct classification results, assuming the output is in the expected format. A positive reward is assigned when the model correctly predicts the target label. Since the evaluation metrics include those under a lenient setting, we also provide a smaller reward when the model confuses "Yes" and "To some extent," which are considered to be qualitatively similar. In contrast, the model receives a negative reward for any other incorrect predictions.

To help the model recognize the ordinal relationship among the labels, we conducted experiments in which a smaller penalty was applied for confusing "To some extent" with "No" than for confusing "Yes" with "No". However, this setup led the models to converge to a conservative solution, in which most examples were classified as "To some extent."

4 Experiments

4.1 Experiment Settings

We conducted all experiments using `trl` library⁸ (von Werra et al., 2020) for training and `vllm` library⁹ (Kwon et al., 2023) for serving a reference model for GRPO. We fine-tuned all models for 7 epochs using AdamW optimizer (Loshchilov and Hutter, 2019) with a learning rate of $1e-5$ and a cosine learning rate scheduler (Loshchilov and Hutter, 2022) with 128 examples in each training step.

⁸<https://github.com/huggingface/trl>

⁹<https://github.com/vllm-project/vllm>

Since the test dataset is not open to public and submission attempts were limited, reported results are obtained using either the official test set or the evaluation set split from the development set. Details on the dataset used in each experiment are provided in the caption of each table.

4.2 Experiment Results

4.2.1 Base Model Selection

For the selection of the base model, we randomly selected a task to compare the performance of the candidate base models. Table 1 presents the results of the base models on the selected task, *Mistake Location*. GLM-4-9B was selected as our base model as it outperformed other two candidates. Note that the subpar performance of GLM-4-Z1-9B was primarily due to its failure to follow the required formatting guidelines—such as generating labels outside the set "Yes", "No", "To some extent", or omitting the final decision altogether.

We further compared the performance scores of the models trained on top of GLM-4-9B and Qwen2.5 14B Instruct on another randomly sampled task, *Actionability*, to examine the base model’s generalizability. As shown in Table 2, the model fine-tuned from GLM-4-9B outperformed that from Qwen2.5 14B Instruct in three out of four metrics, and demonstrated a comparable level of strict macro-F1 score.

4.2.2 Group Relative Policy Optimization and Reasoning

To examine the effectiveness of the proposed approach, we compared our method with a recently released state-of-the-art proprietary LLM, GPT 4.1 (OpenAI, 2025), released on April 14, 2025. We further compared our approach with conventional supervised fine-tuning (SFT) without rationale outputs. The results are shown in Table 3.

In *Actionability*, our GRPO-trained model outperforms all other baselines, including GPT-4.1 and conventional SFT-based model, achieving the best scores in all four metrics. In *Providing Guidance*, our method also achieves the best macro-F1 and accuracy in the lenient setting and the best accuracy in the strict setting, and shows competitive performance in strict macro-F1 as well. A similar trend is observed for *Mistake Location*, where the proposed method achieves the best strict macro-F1, lenient macro-F1, and accuracy. However, the model trained with conventional SFT performs strongly in *Mistake Identification*, calling for the need of

Base model	Strict		Lenient	
	Macro-F1	Accuracy	Macro-F1	Accuracy
GLM-4-9B	0.273	0.380	0.384	0.566
GLM-Z1-9B	0.095	0.133	0.131	0.162
Qwen2.5 14B Instruct	0.194	0.232	0.338	0.443

Table 1: Initial performance of base model candidates on *Mistake Location*, obtained on the entire development set. Best score for each metric is marked in **bold**.

Base model	Strict		Lenient	
	Macro-F1	Accuracy	Macro-F1	Accuracy
GLM-4-9B	0.701	0.756	0.861	0.888
Qwen2.5 14B Instruct	0.709	0.730	0.853	0.884

Table 2: Performance of different base models on *Actionability*, obtained on the official test set. Best score for each metric is marked in **bold**.

Methods	<i>Mistake Identification</i>	<i>Mistake Location</i>
GPT 4.1	0.410 / 0.528 / 0.699 / 0.806	0.342 / 0.355 / 0.639 / 0.673
Base model	0.393 / 0.548 / 0.634 / 0.746	0.390 / 0.468 / 0.582 / 0.641
SFT	0.715 / 0.899 / 0.900 / 0.952	0.481 / 0.726 / 0.757 / 0.819
GRPO (ours)	0.564 / 0.867 / 0.805 / 0.919	0.569 / 0.669 / 0.768 / 0.823
Methods	<i>Providing Guidance</i>	<i>Actionability</i>
GPT 4.1	0.532 / 0.613 / 0.704 / 0.790	0.567 / 0.581 / 0.827 / 0.847
Base model	0.409 / 0.516 / 0.583 / 0.738	0.417 / 0.440 / 0.697 / 0.710
SFT	0.593 / 0.617 / 0.731 / 0.815	0.542 / 0.661 / 0.730 / 0.738
GRPO (ours)	0.571 / 0.649 / 0.764 / 0.859	0.664 / 0.758 / 0.854 / 0.875

Table 3: Performance of different models, obtained on the evaluation set split from the development set. Each cell is composed of strict macro-F1 / accuracy / lenient macro-f1 / accuracy scores. Best score for each metric is marked in **bold**.

further investigation on different characteristics of each dimension. Overall, GRPO-based models consistently outperform the base model and GPT 4.1 across all dimensions, while achieving better performance than SFT-based models in three dimensions, indicating that training a model to produce pedagogically-informed rationales contributes to better evaluation performance.

4.3 Shared Task Leaderboard

The resulting models from experiments, which were submitted under the team name of bea-jh, demonstrated strong performance compared to other 2025 BEA Shared Task contestants (Kochmar et al., 2025). Our model ranked 1st in *Actionability*, and 6th in *Mistake Location* and *Providing Guidance* in the shared task’s official main metric, strict macro-F1 scores. Models trained on top of both GLM-4-9B and Qwen 2.5 14B Instruct achieved better performance than those of other contestants, demonstrating the generalizability of

the effectiveness of the proposed prompting and training strategy.

On the other hand, in *Mistake Identification*, the SFT-based model ranked 13th while the GRPO-based model would have ranked 37th out of 44 contestants. Aforementioned results are summarized in Table 4 along with scores and rankings on the shared task’s secondary metrics.

5 Conclusion

In this paper, we proposed a methodology for evaluating the pedagogical abilities of AI-powered tutors in providing helpful feedback across four key dimensions. System prompts were designed to incorporate pedagogical domain knowledge and the base model was selected based on its initial performance to generate rationale-supported evaluation. The selected model was then trained with the system prompts using Group Relative Policy Optimization (GRPO), a state-of-the-art method

Metric		<i>Mistake Identification</i>	<i>Mistake Location</i>	<i>Providing Guidance</i>	<i>Actionability</i>
Strict Macro-F1	Score	0.5873 (0.6802*)	0.5658	0.5451	0.7010 (0.7085 [†])
	Ranking	37 / 44 (13 / 44*)	6 / 32	6 / 36	1 / 30 (1 / 30 [†])
Strict Accuracy	Score	0.8449 (0.8707*)	0.7389	0.6703	0.7557
	Ranking	28 / 44 (9 / 44*)	4 / 32	4 / 36	1 / 30
Lenient Macro-F1	Score	0.8494 (0.9069*)	0.7851	0.7324	0.8609
	Ranking	32 / 44 (6 / 44*)	5 / 32	10 / 36	4 / 30
Lenient Accuracy	Score	0.9270 (0.9457*)	0.8268	0.8003	0.8875
	Ranking	28 / 44 (11 / 44*)	5 / 32	7 / 36	4 / 30

Table 4: Final scores and rankings on the official test set. Scores are shown to four decimal places, following the official leaderboard format. Along with the scores and rankings for *Mistake Location* and *Actionability* obtained by evaluating the proposed approach on the official test dataset and reranked based on the official leaderboard, officially recorded scores and rankings under the team name bea-jh that are not obtained by the proposed approach are presented inside the parentheses. *: score and ranking in the official *Mistake Identification* leaderboard, obtained by training GLM-4-9B via supervised fine-tuning. †: macro-F1 score and ranking in the official *Actionability* leaderboard, obtained by training Qwen2.5 14B Instruct via our proposed approach.

for optimizing reasoning capabilities in LLMs. As a result, our models demonstrated competitive performance in the BEA 2025 Shared Task, achieving the first place in the *Actionability* dimension.

However, the proposed approach exhibits varying performance across different evaluation dimensions. These discrepancies suggest that each dimension may require tailored modeling strategies that reflect its underlying pedagogical definitions. Future work could involve an in-depth pedagogy-based analysis of each dimension to identify how to design a high-quality evaluator. Furthermore, since our approach generates explicit rationales through reasoning, these rationales could potentially be leveraged not only for evaluation, but as a basis for improving the AI tutor’s feedback.

Limitations

We believe this study proposes an effective methodology for evaluating the pedagogical abilities of AI-powered tutors. However, the following limitations highlight areas for future investigation.

Thorough investigation of prompt engineering Since system prompts serve as instructions to LLMs, variations in prompt design can lead to different outputs and rationales. While our prompts incorporated pedagogical domain knowledge, further investigation into how each component of a prompt influences the reasoning process could lead to more effective prompt engineering strategies for evaluation tasks.

Analysis of dimension-specific characteristics

Although the proposed method achieved strong per-

formance in certain evaluation dimensions, it performed relatively poorly in a particular dimension. This discrepancy may stem from intrinsic differences among dimensions, such as varying levels of subjectivity or difficulty. Analyzing why the method performs better in some dimensions could open the way to the development of evaluation strategies tailored to each dimension.

Analysis of rationale truthfulness Generating rationales provides insights into how models "think", and the rationales generated by an evaluation model may inspire ways to improve the systems under evaluation. However, it remains an open question whether these rationales truly reflect the model’s internal decision-making process. Future work could involve further analysis to assess the stability and truthfulness of generated rationales, enabling a more qualitative understanding of reasoning-based evaluation.

CU at BEA 2025 Shared Task: A BERT-Based Cross-Attention Approach for Evaluating Pedagogical Responses in Dialogue

Zhihao Lyu

University of Colorado Boulder

zhihao.lyu@colorado.edu

Abstract

Automatic evaluation of AI tutor responses in educational dialogues is a challenging task, requiring accurate identification of mistakes and provision of pedagogically effective guidance. In this paper, we propose a classification model based on BERT, enhanced with a cross-attention mechanism that explicitly models the interaction between the tutor’s response and preceding dialogue turns. This design enables better alignment between context and response, supporting more accurate assessment along the educational dimensions defined in the BEA 2025 Shared Task. To address the substantial class imbalance in the dataset, we employ data augmentation techniques for minority classes. Our system consistently outperforms baseline models across all tracks. However, performance on underrepresented labels remains limited, particularly when distinguishing between semantically similar cases. This suggests room for improvement in both model expressiveness and data coverage, motivating future work with stronger decoder-only model and auxiliary information from systems like GPT-4.1. Overall, our findings offer insights into the potential and limitations of LLM-based approaches for pedagogical feedback evaluation.

1 Introduction

Recent progress in large language models (LLMs) like GPT-4, Gemini (Team et al., 2023), and LLaMA (Grattafiori et al., 2024) has rapidly improved AI conversational agents, especially in education. AI tutors, for example, can now offer students real-time, interactive feedback to boost engagement and learning (Lin et al., 2023). However, while these models generate fluent, human-like responses, evaluating the real educational value of their feedback remains challenging (Ou et al., 2023). Standard metrics such as BLEU and ROUGE fail to capture important aspects of educational dia-

logue—like identifying student mistakes or providing helpful guidance—which highlights the need for more fine-grained, pedagogically meaningful evaluation frameworks.

To address this gap, the BEA 2025 Shared Task goes a step further than previous tasks (Tack et al., 2023) by shifting the focus from dialogue generation to evaluating how LLMs assess educational dialogues. Evaluation is based on four key dimensions (Maurya et al., 2025): (1) Mistake Identification (Tack and Piech, 2022; Macina et al., 2023; Daheim et al., 2024), (2) Mistake Location (Daheim et al., 2024), (3) Providing Guidance (Tack and Piech, 2022; Liu et al., 2023), and (4) Actionability (Daheim et al., 2024). These dimensions capture what truly matters in educational feedback, moving beyond surface-level fluency. For more details on the task and evaluation setup, please refer to the official report (Kochmar et al., 2025).

In this paper, we present our submission to the BEA 2025 Shared Task, focusing on three evaluation tracks: Mistake Identification, Mistake Location, and Providing Guidance. Our approach enhances standard LLM classifiers with a cross-attention layer to better capture the relationship between student-tutor dialogue context and the tutor’s response. Experimental results demonstrate that our method achieves strong performance across all tracks, validating the effectiveness of cross-attention for modeling educational feedback. Our team, CU, ranked 25th out of 44 in Track 1, 17th out of 31 in Track 2, and 20th out of 35 in Track 3.

2 Related Work

2.1 Early Work on Educational Feedback

Early research in educational psychology laid the theoretical foundation for understanding effective teaching practices. Hattie and Timperley (2007) proposed a widely adopted model of feedback focused on learning goals, progress monitoring, and

actionable guidance, demonstrating its critical role in student achievement. The AutoTutor system (Graesser et al., 2005) formalized key tutoring strategies—such as identifying misconceptions and prompting elaboration—within an intelligent tutoring framework. Boyer et al. (2011) introduced a data-driven approach by modeling dialogue structures using hidden Markov models to predict learning gains. Wolfe et al. (2013) and Rus et al. (2017) analyzed tutor-student dialogues to assess the quality of instructional moves using semantic similarity and discourse act classification.

2.2 LLMs for Educational Dialogue Evaluation

Recent advances in LLMs have reshaped how we engage with language and text—transforming not only natural language processing (NLP) research but also the evaluation of educational dialogues. A growing body of research explores how LLMs can be used to assess or enhance educational feedback. For example, Balse et al. (2023) investigated the ability of GPT-3.5 to explain logical programming errors, finding that while explanations were often imperfect, they reliably identified key issues. Lee et al. (2024) improved LLM-based classification accuracy by structuring prompts to encode error relationships. Molina et al. (2024) showed that LLM tutors improve accessibility for non-native English speakers, while Xu et al. (2025) built a virtual AI tutor capable of analyzing student drafts and generating error-specific feedback. Reinforcement learning approaches such as that of Scarlatos et al. (2025) have further enhanced LLM tutors by optimizing pedagogical reward functions. Kakarla et al. (2024) demonstrated the potential of LLMs in evaluating human tutor responses, highlighting both strengths and limitations.

2.3 BERT for Dialogue and Tutoring Systems

Parallel to LLM advancements, BERT-based architectures have also proven effective for educational dialogue modeling and intelligent tutoring systems (ITS). In the domain of dialogue understanding, DialogueBERT (Zhang et al., 2021) and DialBERT (Li et al.) incorporate hierarchical context and speaker-role awareness to improve performance on tasks such as disentanglement, emotion recognition, and intent detection. CS-BERT (Wang et al., 2021), trained on domain-specific customer service dialogues, introduces masked speaker prediction and turn-level segment embeddings, yielding robust re-

sults in low-resource scenarios. Within ITS applications, BERT has been adapted for various pedagogical tasks. LBKT (Li et al., 2024) combines BERT and LSTM with Rasch-based embeddings for long-sequence knowledge tracing, improving interpretability and accuracy. Tutor-KD (Kim et al., 2022) introduces tutor-guided difficulty adaptation in knowledge distillation, enhancing BERT’s generalization. Wang et al. (2024) compare BERT with ChatGPT for dialogic pedagogy support and note that, while BERT performs well in structured analysis, it lacks the interactive fluency teachers often prefer.

3 Research Gap

Despite progress in educational theory and NLP, evaluating the pedagogical quality of AI tutor responses remains difficult. Traditional methods emphasize structured feedback but rely on manual annotation and lack scalability, while LLMs offer fluency yet often miss deeper educational goals like mistake identification and guidance. Although some work proposes education-driven metrics, most automated approaches fail to effectively model dialogue context. BERT-based models show potential in educational settings but are still underused for evaluating tutor responses within full dialogue history.

To address this, we introduce a BERT-based classifier with a cross-attention mechanism that explicitly models tutor–dialogue interactions, enabling more accurate and context-aware evaluation across multiple pedagogical dimensions.

4 Methodology

In this section, we present the model architecture, including the data processing, BERT-based representation generation, and the cross-attention and classification layers. An overview of the model is illustrated in Figure 1. First, The conversation history and tutor response are preprocessed separately, with special tokens inserted at the beginning of each utterance to indicate their order. These inputs are then encoded using a pretrained BERT model to obtain high-dimensional representation. They are passed into a cross-attention layer, where the response serves as the query and the conversation history as the key and value. Finally, the cross-attended representation is fed into a classification layer that predicts one of three labels: *Yes*, *No*, or *To some extent*.

Figure 1: Overview of the proposed model architecture.

4.1 Data Preprocessing and Representation Generation

Data Augmentation. By examining the label distribution of the shared task dataset, we observed a significant imbalance between the *Yes*, *No*, and *To some extent* labels (see Table 1). Also, the *Yes* and *To some extent* labels are semantically similar, which may require the model to make finer distinctions. To address this issue without substantially altering the data distribution, we applied data augmentation only to the training set. Specifically, we used GPT-4.1 to rephrase all instances with minority labels once, thereby augmenting the dataset across all three tracks. This results in a simple 2:1 ratio between augmented and original samples for the minority classes. The ratio was determined heuristically rather than through systematic tuning, with the aim of increasing class diversity while preserving the overall label distribution. This augmentation strategy led to improved F1 scores in our subsequent experiments. The prompt used for rephrasing is provided in Appendix A.

Track 1 Label	Before Aug	After Aug
Yes	1932	1932
No	370	666
To some extent	174	313

Track 2 Label	Before Aug	After Aug
Yes	1543	1543
No	713	1283
To some extent	220	396

Track 3 Label	Before Aug	After Aug
Yes	1407	1932
No	566	1018
To some extent	503	905

Table 1: Comparison of label counts before and after data augmentation across the three tracks.

Input Labeling. To preserve the contextual meaning and sequential order of the conversation history, we manually insert order indicators (e.g., $[TURN_x]$) at the beginning of each utterance and mark the tutor’s response with a $[RESPONSE]$ token. Compared to the insertion of turn and role embeddings in DialogBERT (Zhang et al., 2021), this simple modification is easier to implement while still demonstrating effectiveness.

Representation Generation. Given BERT’s strong performance and widespread success across various NLP tasks (Devlin et al., 2019), we retain its original architecture and use its encoder only as a representation generator. Specifically, BERT first generates three types of embeddings from the input: token embeddings, segment embeddings, and position embeddings. These embeddings are added and then fed into the Transformer’s self-attention layers (Vaswani et al., 2017), which consist of multiple attention heads and stacked layers that compute contextualized representations for each token. After processing through these layers, the BERT encoder produces high-dimensional vectors as the final hidden states for both the conversation history and the tutor response. The input representation process is illustrated in Figure 2.

4.2 Cross-Attention and Classification Layer

After obtaining token-level representations of the tutor’s response and the conversation history using a BERT encoder, we combine them using a cross-attention mechanism to model the relationship between the two. Inspired by the decoder structure in the Transformer architecture, we treat the response as the **query** and the conversation history as the **key** and **value**. This allows each token in the response to selectively attend to relevant parts of the dialogue history (Figure 3). Formally, let

- $R \in \mathbb{R}^{l \times d}$ be the representation matrix of the tutor’s response, where l is the number of

Figure 2: Illustration of the input representation process in BERT, including embedding generation and self-attention encoding.

tokens in responses, and d is the hidden size;

- $H \in \mathbb{R}^{n \times d}$ be the representation matrix of the conversation history, where n is the number of tokens in the history.

$$Weight = \text{softmax}\left(\frac{R \cdot W_Q(H \cdot W_K)^T}{\sqrt{d}}\right) \quad (1)$$

$$Attention(R, H, H) = Weight \cdot H \cdot W_V \quad (2)$$

where $W_Q, W_K, W_V \in \mathbb{R}^{d \times d}$ are trainable projection matrices. Here, $Weight \in \mathbb{R}^{l \times n}$ represents the attention weights between each token in the response (R) and each token in the conversation history (H), where l and n are the number of tokens in the response and history, respectively. This mechanism enables the response to selectively attend to relevant segments of the dialogue context, producing a contextualized representation that informs the final classification.

After obtaining the cross-attended response representations, we extract the hidden state corresponding to the $[CLS]$ token (the first token position) to serve as the aggregate representation of the response. This vector is then passed through a dropout layer for regularization, followed by a linear classification layer that maps the hidden representation to a logits vector of dimension $\mathbb{R}^{d \times m}$, where d is the hidden size and $m = 3$ is the number of classification labels used across all tasks. The resulting logits are used to compute the weighted cross-entropy loss during training.

Algorithm 1: Dialogue-level Split with Label Distribution Balancing

Input: Training and validation dialogues

Output: Training and validation splits with similar label distributions

- 1 Compute global label distribution ratio from all dialogues
 - 2 Split dialogues into initial training (80%) and validation (20%) sets
 - 3 Compute label distribution in both sets
 - 4 **for** $iteration = 1$ **to** max_iters **do**
 - 5 **foreach** $train\ dialogue\ d_i$ ($sampled\ subset$) **do**
 - 6 **foreach** $val\ dialogue\ d_j$ ($sampled\ subset$) **do**
 - 7 Swap d_i and d_j between training and validation sets
 - 8 Compute new label distributions
 - 9 Compute ratio error in both sets
 - 10 **if** $new\ error < old\ error$ **then**
 - 11 Accept the swap
 - 12 Update label counts
 - 13 **break both loops**
 - 14 **end**
 - 15 **end**
 - 16 **end**
 - 17 **end**
-

5 Experiments

5.1 Dataset

As the shared task required, we use a development set and a test set from the MathDial(Macina et al., 2023) and Bridge(Wang et al., 2023) datasets.

Development Set: Contains 300 dialogues where students make mistakes or show confusion. Each dialogue includes the student’s last question and responses from multiple tutors (LLMs and humans), with over 2,480 responses labeled for pedagogical quality.

Test Set: Contains 200 similar dialogues. Tutor responses are not labeled and tutor identities are hidden. The set is intended only for official evaluation and is not available for model development.

Given that all 2,480 responses are associated with only 300 dialogues, we perform dialogue-level splitting to ensure that no dialogue appears in both training and validation sets. This prevents data leakage and ensures a fair evaluation. Combined with the label imbalance issue noted in Section 4,

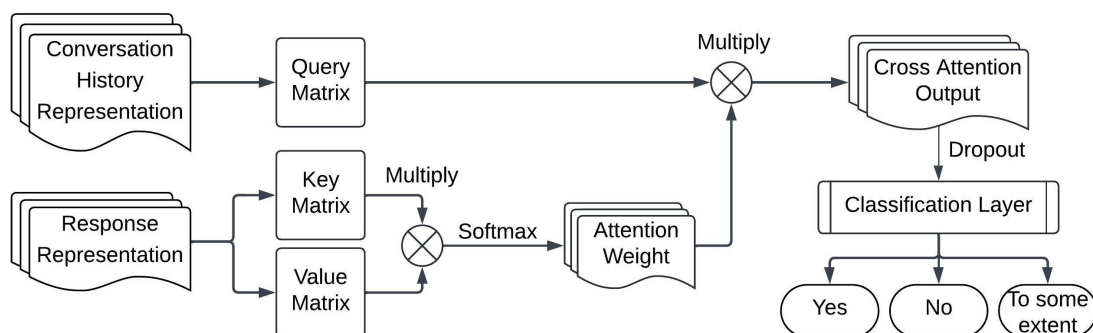

Figure 3: Overview of the cross attention mechanism and classification.

this requires careful design of the data split. First, we perform an initial 80/20 split of the data into training and validation sets. Then, to ensure that the label distributions in both sets are similar, we iteratively swap samples between them. The pseudocode is shown in Algorithm 1.

5.2 Experimental Setup

We fine-tuned all models using the BERT base uncased(110M) architecture. Inputs combined the tutor’s response and dialogue context, with cross-attention as described in Methodology. The $[CLS]$ token was used for classification, followed by dropout and a linear layer. All inputs were tokenized using the BERT tokenizer with a maximum sequence length of 512. Sequences longer than 512 tokens were truncated, and shorter sequences were padded accordingly.

Training was conducted on a single NVIDIA RTX 4060 Ti GPU. We used the AdamW optimizer with a learning rate of $2e-5$ and a batch size of 5. Models were trained for up to 5 epochs with early stopping based on Macro-F1 score on the validation set. A cosine learning rate scheduler was used, and a dropout rate of 0.1 was applied before the final classification layer. To address class imbalance, we adopted a log-weighted cross-entropy loss, where the weight for each class i was computed as $w_i = \log\left(\frac{N}{n_i}\right)$, with N the total number of samples and n_i the number of samples in class i . The overall training procedure is summarized in Algorithm 2.

5.3 Baselines

To provide a reference for zero-shot performance, we included two LLM baselines: GPT-4.1 and LLaMA 3.2 1B. For GPT-4.1, we used the OpenAI API and designed a custom prompt to elicit pedagogical labels (*Yes*, *No*, or *To some extent*) for each tutor response, given the tutor’s response and

dialogue context. This model was not fine-tuned on our dataset and operates purely in a zero-shot setting. The full prompt example is included in Appendix B. For LLaMA 3.2 1B, we used the open-source model and ran it locally. Similar to GPT-4.1, we applied a handcrafted prompt to guide the model in classifying tutor responses. The LLaMA model was also evaluated in a zero-shot. The prompt used is provided in Appendix C. These baselines allow us to assess the effectiveness of our fine-tuned BERT models against general-purpose LLMs without task-specific adaptation.

5.4 Main Results

We now present the results of our fine-tuned BERT-based models, comparing variants with and without the proposed cross-attention mechanism(CA), as well as the impact of data augmentation(Aug). These models are evaluated on all three shared task tracks and compared with the zero-shot baselines (Section 5.3). Our team, CU, participated in three tracks and ranked 25th/44 in Track 1, 17th/31 in Track 2, and 20th/35 in Track 4. The results are shown in Table 2.

5.5 Discussion

5.5.1 Improving Track 1 Performance with Cross-Attention

As shown in Table 2 and Figure 4, incorporating the cross-attention mechanism substantially improved the model’s performance on Track 1. The Macro-F1 score increased from 0.578 to 0.687, and accuracy improved from 0.849 to 0.867. While the baseline BERT model performed reasonably well on the majority class *Yes*, it failed to identify any instances of the minority class *To some extent*, as shown by a complete absence of predictions for that label in the confusion matrix. This resulted in a biased classifier with high accuracy but limited

Algorithm 2: Training procedure for BERT with Cross-Attention

Input: Training set $\mathcal{D}_{\text{train}}$, Validation set \mathcal{D}_{val} , number of epochs N , batch size B

Output: Best model parameters θ^*

```
1 Initialize BERT-based model with
  cross-attention, parameters  $\theta$  ;
2 Initialize AdamW optimizer and cosine
  learning rate scheduler ;
3  $\theta^* \leftarrow \theta$ ,  $\text{best\_val\_f1} \leftarrow 0$ ;
4 for  $\text{epoch} = 1$  to  $N$  do
5   for each batch  $(x_{\text{dial}}, x_{\text{resp}}, y)$  in  $\mathcal{D}_{\text{train}}$ 
6     do
7       Forward pass:
8          $z \leftarrow \text{Model}(x_{\text{dial}}, x_{\text{resp}})$  ;
9       Compute loss:
10         $L \leftarrow \text{CrossEntropy}(z, y)$  ;
11      Backward pass: update  $\theta$  via
12        optimizer ;
13      Update learning rate scheduler ;
14    end
15    Evaluate model on  $\mathcal{D}_{\text{val}}$  to obtain F1
16    score;
17    if  $F1 > \text{best\_val\_f1}$  then
18       $\text{best\_val\_f1} \leftarrow F1$ ;
19       $\theta^* \leftarrow \theta$  // Save best model
20    end
21 end
22 return  $\theta^*$ 
```

generalization.

In contrast, the BERT+Cross Attention model significantly reduced this bias. It not only improved the recall for the *No* class (from 47 to 55 true positives), but also successfully predicted 10 instances of *To some extent*, a class that the baseline model could not recognize at all. Although the number of correct predictions for *Yes* slightly decreased (from 413 to 374), this reflects a more balanced and context-sensitive classification behavior. These findings suggest that cross-attention enables the model to better align the tutor’s response with subtle errors in the student’s utterance, resulting in more robust performance across all categories.

5.5.2 Benefits and Limitations of Data Augmentation in Track 2 and 3

To quantitatively assess the effect of data augmentation on class-wise performance for Track 2, we compare the classification reports of the

Model	Acc.	Macro-F1
zero-shot GPT-4.1	0.807	0.557
zero-shot LLaMA 3.2 1B	0.758	0.440
BERT (no CA)	0.849	0.578
BERT + CA	0.870	0.651

(a) Track 1: Mistake Identification

Model	Acc.	Macro-F1
zero-shot GPT-4.1	0.548	0.472
zero-shot LLaMA 3.2 1B	0.619	0.371
BERT base(no CA)	0.678	0.429
BERT base + CA	0.689	0.504
BERT base + CA + Aug	0.681	0.515

(b) Track 2: Mistake Location

Model	Acc.	Macro-F1
zero-shot GPT-4.1	0.549	0.403
zero-shot LLaMA 3.2 1B	0.591	0.363
BERT base(no CA)	0.587	0.476
BERT base + CA	0.589	0.484
BERT base + CA + Aug	0.585	0.493

(c) Track 3: Providing Guidance

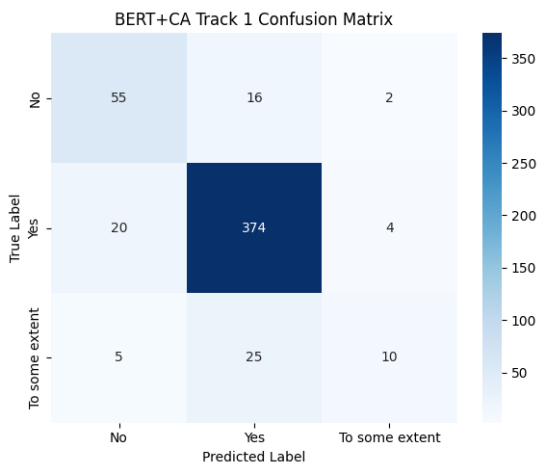

Table 2: Model performance across three task tracks.

cross-attention model before and after augmentation (see Table 3). Without augmentation, the model achieves high performance on the majority class *Yes* ($F1 = 0.77$), but almost entirely fails to recognize the minority class *To some extent* ($F1 = 0.00$). With data augmentation, the model’s ability to identify *No* and *To some extent* is significantly improved, with F1-scores rising from 0.48 to 0.63 and from 0.00 to 0.20, respectively. Although the recall for *Yes* decreases slightly (from 0.92 to 0.85), the overall classification results become more balanced, as indicated by the higher Macro-F1 score. These results highlight the utility of data augmentation in mitigating class imbalance and promoting fairer evaluation across all categories.

A similar pattern is observed for Track 3: after applying data augmentation, overall accuracy decreases slightly, while Macro-F1 improves only marginally. This suggests that the benefit of augmentation is consistent but limited when class imbalance is severe.

6 Conclusion

In this paper, we presented a system for evaluating tutor responses in educational dialogues, with a particular focus on three pedagogical dimensions as outlined in the BEA 2025 Shared Task. Leveraging a BERT-based architecture augmented with a cross-attention layer, our approach aimed to improve the model’s ability to capture context and provide more accurate multi-label classification. Experimental results demonstrate that our system achieves strong performance on Track 1, while also revealing challenges in distinguishing between semantically similar categories, such as *Yes* and *To some extent* in Track 2 and 3. Data augmentation techniques were employed to mitigate class imbalance, resulting in modest improvements, particularly in minority classes. Despite these advances, our findings indicate that substantial gaps remain before such systems can be reliably deployed in real-world educa-

Class	Precision	Recall	F1
No	0.64	0.39	0.48
Yes	0.67	0.92	0.77
To some extent	0.00	0.00	0.00

(a) BERT+CA

Class	Precision	Recall	F1
No	0.67	0.60	0.63
Yes	0.75	0.85	0.79
To some extent	0.27	0.15	0.20

(b) BERT+CA+Aug

Table 3: Class-wise precision, recall, and F1 score for Track 2 before and after data augmentation. Each class contains the same number of validation samples (No: 144, Yes: 301, To some extent: 59).

tional settings. Overall, our work contributes new insights into the application of LLMs for pedagogical evaluation and highlights key challenges for future research.

7 Future Work

During the training process, we observed that the number of cross-attention layers may influence classification accuracy. In future work, we plan to conduct further experiments with more advanced, higher-capacity decoder-only models, and systematically explore the effect of varying the number of cross-attention layers. In addition, the current cross-attention layer still struggles to recognize minority classes in dialogue. To address this, we aim to leverage state-of-the-art models as an auxiliary information. For example, we could use GPT-4.1 to first estimate the probability that each utterance in the conversation contains a mistake, and then pass these probabilities as initial attention weights to the cross-attention layer. This approach may enable the model to more precisely identify errors within the dialogue. Furthermore, GPT-4.1 could be used to perform more sophisticated data preprocessing, such as extracting all potential errors, so that the classification model only needs to determine whether the tutor’s response correctly identifies and addresses those errors.

Our current approach is inherently pedagogy-specific: it is trained on dialogue data annotated with educational dimensions, and designed to model the relationship between student language and tutor feedback. Both the training objective and

model architecture reflect the goal of evaluating responses in a pedagogically meaningful way. In the future, further gains might be achieved by incorporating explicit pedagogical constructs, such as known error types or feedback taxonomies, into the modeling process. We see this as a promising direction for enhancing both model performance and educational relevance.

8 Limitations

Despite the promising results demonstrated by our system, several limitations remain. First, while the model achieves strong performance on Track 1, its accuracy on Track 2 and Track 3 remains below 70%, with Macro-F1 scores falling short of 60%. This gap suggests that the system is not yet robust enough for real-world educational deployment. As shown in Table 3, the model tends to favor the majority class (*Yes*) and continues to struggle with the *No* and *To some extent* categories. Notably, *To some extent* is semantically close to *Yes*, and despite our data augmentation efforts, its precision in Track 2 remains below 30%, indicating substantial room for improvement in recognizing minority classes.

Second, although BERT has long been a strong performer in NLP tasks, its encoder-decoder architecture is increasingly surpassed by newer, decoder-only models such as LLaMA and Qwen (Yang et al., 2025). These models are rapidly becoming the mainstream in LLM research. However, their substantially larger parameter sizes make them less accessible for users with limited computational resources. Furthermore, the additional cross-attention layer proposed in this work increases computational demands even further. After the shared task deadline, we experimented with LLaMA 3.2 1B augmented with our cross-attention mechanism and conducted full fine-tuning. Compared to BERT, LLaMA 3.2 1B has nearly ten times more parameters, making local training on personal computers nearly infeasible. This poses an even greater barrier for educators or practitioners who may lack expertise in machine learning or access to high-performance hardware.

A Prompt Used for Rephrasing

```
<task>
  <instruction>
    You are a helpful assistant for paraphrasing a target utterance in a dialogue.
    Your goal is to rewrite the <target> utterance in a different way while preserving its
    original meaning.
    The paraphrased version must be natural, fluent, and semantically equivalent.
    Make sure the paraphrase fits well within the conversation context, both before and after the
    target.

    Guidelines:
    1. Do NOT simply repeat the original sentence.
    2. Maintain the same intention, tone, and meaning.
    3. Ensure coherence with <previous_context> and <post_context>.
    4. Output only the paraphrased version of the <target>.

    Avoid repeating the same phrasing or word order.
  </instruction>

  <previous_context>
    {previous_context}
  </previous_context>

  <target>
    {target}
  </target>

  <post_context>
    {post_context}
  </post_context>
</task>
```

Appendix 1: XML prompt used for paraphrasing minority-class responses

B GPT-4.1 Prompt

We queried GPT-4.1 via the OpenAI API using a two-part prompt. The system message defined the instruction for each task, and the user message provided the specific conversation and tutor response to be evaluated.

System Instruction For Track 1

```
You are given a conversation between a tutor and a student. The last utterance is from the student
and contains a mistake. The tutor then responds to it.

Your task is to evaluate whether the tutor's response recognizes the mistake in the student's
utterance.

Use the following guidelines:

- "Yes": The mistake is clearly identified or recognized in the tutor's response.
- "To some extent": The tutor implies there may be a mistake, but does not state it clearly or seems
uncertain.
- "No": The tutor does not acknowledge the mistake (e.g., simply answers the question without
referencing the error).

Respond with exactly one of the following labels:
Yes
To some extent
No

Do not include any explanation or extra text.
```

Appendix 2: Track 1 system instruction used with GPT-4.1.

System Instruction For Track 2

You are given a conversation between a tutor and a student. The last utterance is from the student and contains a mistake. The tutor then responds to it.

Your task is to evaluate whether the tutor's response clearly identifies the mistake and where it occurs in the student's response.

Use the following guidelines:

- "Yes": The tutor clearly points to the exact location of a genuine mistake in the student's response.
- "To some extent": The tutor shows some awareness of the mistake, but the reference is vague, unclear, or easy to misunderstand.
- "No": The tutor does not provide any detail about the mistake or its location.

Respond with exactly one of the following labels:

Yes
To some extent
No

Do not include any explanation or extra text.

Appendix 3: Track 2 system instruction used with GPT-4.1.

System Instruction For Track 3

You are given a conversation between a tutor and a student. The last utterance is from the student and contains a mistake. The tutor then responds to it.

Your task is to evaluate whether the tutor's response provides correct and relevant guidance in response to the student's mistake.

Use the following guidelines:

- "Yes": The tutor provides guidance that is correct and directly relevant to the student's mistake (e.g., explanation, elaboration, hint, or examples).
- "To some extent": Some guidance is given, but it is partially incorrect, incomplete, or somewhat misleading.
- "No": No guidance is provided, or the guidance is irrelevant or factually incorrect.

Respond with exactly one of the following labels:

Yes
To some extent
No

Do not include any explanation or extra text.

Appendix 4: Track 3 system instruction used with GPT-4.1.

User Input Template

```
Conversation history:  
{conversation}  
Tutor Response:  
{response}
```

Appendix 5: User input format for GPT-4.1 prompting.

C LLaMA 3.2 1B Prompt

We used a locally hosted version of LLaMA 3.2 1B in a zero-shot setting. The full prompt sent to the model followed the expected chat-style format, including system, user, and assistant messages, as shown below.

System Instruction For Track 1

```
<|begin_of_text|>
<|start_header_id|>system<|end_header_id|>
Evaluate whether the tutor's response recognizes the student's mistake in the conversation.

Classification guidelines:
- "Yes": The tutor clearly identifies or acknowledges the mistake in the student's utterance.
- "To some extent": The tutor implies there may be a mistake, but the identification is vague or uncertain.
- "No": The tutor does not recognize the mistake (e.g., simply answers the question without acknowledging any error).
<|eot_id|>

<|start_header_id|>user<|end_header_id|>
Dialogue transcript:
{all_history}
Final tutor response:
{response_text_full}

Does the final tutor response recognize the student's mistake?

Only respond with one of the following labels:
Yes
To some extent
No
<|eot_id|>

<|start_header_id|>assistant<|end_header_id|>
Classification:
```

Appendix 6: Track 1 full prompt used with LLaMA 3.2 1B for zero-shot classification.

System Instruction For Track 2

```
<|begin_of_text|>
<|start_header_id|>system<|end_header_id|>
Evaluate whether the tutor's response clearly identifies a genuine mistake and its location in the student's utterance.

Classification guidelines:
- "Yes": The tutor clearly points to the exact location of a genuine mistake in the student's response.
- "To some extent": The response shows some awareness of the mistake, but the reference is vague, unclear, or potentially confusing.
- "No": The response does not mention the mistake or provide any detail about it.
<|eot_id|>

<|start_header_id|>user<|end_header_id|>
Dialogue transcript:
{all_history}
Final tutor response:
{response_text_full}

Does the tutor's response clearly identify the mistake and where it occurs?

Only respond with one of the following labels:
Yes
To some extent
No
<|eot_id|>

<|start_header_id|>assistant<|end_header_id|>
Classification:
```

Appendix 7: Track 2 full prompt used with LLaMA 3.2 1B for zero-shot classification.

System Instruction For Track 3

```
<|begin_of_text|>
<|start_header_id|>system<|end_header_id|>
Evaluate whether the tutor's response provides correct and relevant guidance in response to the
student's mistake.

Classification guidelines:
- "Yes": The tutor provides guidance that is correct and directly relevant to the student's mistake (
e.g., explanation, elaboration, hint, or example).
- "To some extent": Guidance is provided, but it is partially incorrect, incomplete, or somewhat
misleading.
- "No": The response lacks guidance, or the guidance is irrelevant or factually incorrect.
<|eot_id|>

<|start_header_id|>user<|end_header_id|>
Dialogue transcript:
{all_history}
Final tutor response:
{response_text_full}

Does the tutor's response provide correct and relevant guidance?

Only respond with one of the following labels:
Yes
To some extent
No
<|eot_id|>

BJTU at BEA 2025 Shared Task: Task-Aware Prompt Tuning and Data Augmentation for Evaluating AI Math Tutors

Yuming Fan and Chuangchuang Tan* and Wenyu Song

20120300@bjtu.edu.cn, 21112002@bjtu.edu.cn,

20120313@bjtu.edu.cn

Beijing Jiaotong University

Abstract

We describe the BJTU submission to the BEA 2025 Shared Task on Evaluating the Pedagogical Ability of AI Tutors, which focuses on assessing AI-generated math tutoring responses across four dimensions: Mistake Identification, Mistake Location, Guidance, and Actionability. Our approach leverages a large language model (LLM) with task-specific prompt tuning and data augmentation techniques, including dialogue shuffling and class balancing. The system achieves strong results across all tracks, ranking first in Mistake Identification and performing competitively in the others. Our findings underscore the potential of prompt-based LLMs for pedagogically-aware response evaluation and offer insights into the design of AI tutors with improved educational feedback.

1 Introduction

Recent advances in large language models (LLMs) have opened up new possibilities in education, with AI-powered tutoring systems emerging as promising tools for personalized learning. These systems simulate teacher-like interactions through natural language dialogue, offering students real-time feedback and instructional support. However, evaluating the teaching capabilities of such AI tutors remains a significant challenge. On the one hand, existing evaluation frameworks lack standardization. Previous work adopts fragmented criteria, such as correctness, relevance, and actionability, making it difficult to compare model performance between studies.

However, conventional automatic metrics (e.g. ROUGE, BLEU) fail to capture key educational goals, such as effective knowledge delivery, error correction, and cognitive scaffolding. For example, Tack (Tack and Piech, 2022) focus on teacher language style, Macina (Macina et al., 2023) highlights the coherence of feedback, while Wang

(Wang et al., 2024) emphasizes the empathetic tone of responses. This fragmented landscape hinders the development of standardized benchmarks for educational AI.

To address the above challenges, the BEA 2025 Shared Task (Kochmar et al., 2025) on Evaluating the Pedagogical Ability of AI Tutors introduces the first multidimensional benchmark centered on instructional competence. Our team, Team BJTU, focuses on the context of mathematics education, particularly the process of error remediation. We aim to develop automated models that systematically evaluate five core capabilities of AI tutoring systems: Mistake identification (identifying whether a student’s response contains a mistake), mistake location (pointing to the exact location of the error), guidance (offering effective explanations or hints) and Actionability (providing responses that meaningfully guide the student’s next learning steps).

Our team, BJTU, participated in Tracks 1, 2, 3, and 4 of the BEA 2025 Shared Task and achieved strong results, ranking 1st, 2nd, 4th, and 2nd respectively. Our approach leverages state-of-the-art language models that integrate textual cues to explore the instructional capabilities of AI tutors across multiple pedagogical dimensions. This paper outlines our methodology for tackling the task, discusses the challenges we encountered, and provides insight into how model design choices impact the effectiveness of AI-generated feedback in educational dialogues.

2 Related Work

Recent work has explored the use of large language models (LLMs) in educational dialogues, with the aim of assessing their pedagogical effectiveness. Tack and Piech (Tack and Piech, 2022) proposed the AI Teacher Test, evaluating models such as GPT-3 and Blender in three dimensions: speaking

*Corresponding Author.

like a teacher, understanding the student and providing helpful responses. Their findings showed that while LLMs produce fluent dialogue, they lack pedagogical ability.

Building on this, the BEA 2023 Shared Task (Tack et al., 2023) benchmarked teacher response generation using the TSCC dataset. Top systems used models such as GPT-3.5 and GPT-4, employing prompting and response reranking strategies. Although some systems achieved high scores, the task highlighted limitations in existing evaluation metrics for educational settings.

To address these gaps, Wang (Wang et al., 2024) introduced Bridge, a framework based on cognitive task analysis that models expert decision-making during remediation. Incorporating these decisions into LLM prompts significantly improved response quality, suggesting that structured pedagogical reasoning enhances LLM performance in tutoring contexts.

3 Method

3.1 Preprocessing

During the data preprocessing phase, we organized the historical dialogues between the Tutor and Student into a format suitable for fine-tuning. For each instance, we constructed prompts such as: *The following is a tutoring dialogue in the domain of mathematics. Based on the conversation history above, your task is to evaluate the following Tutor’s Response and determine whether it successfully identifies the error in the student’s reasoning*, as illustrated in Figure 1. Using this data, we fine-tuned a large language model (LLM) to perform the evaluation task.

In the testing phase, we applied the trained model to the test set for inference. The LLM was prompted to generate an evaluation of the given Tutor response and select one of three categorical labels—yes, some extent, or no—which was then recorded as the final output.

However, relying solely on the original training data risks overfitting the model to specific linguistic patterns, thereby limiting its generalization ability. To address this, we incorporated a series of data augmentation strategies aimed at improving the model’s robustness and adaptability across diverse dialogue contexts.

Figure 1: Prompt Construction.

3.2 Data Augmentation

In the shared task, our team BJTU demonstrated strong performance across all four tracks, as shown in table 2. We used the data set released for the BEA 2025 Shared Task (Maurya et al., 2025), which is based on a unified taxonomy for assessing pedagogical ability.

To mitigate the model’s reliance on fixed option positions and enhance its ability to generalize in ranking tasks, we adopted a dialogue-shuffling augmentation strategy. Concretely, we randomly permuted the sequence of tutor-student interaction pairs within each dialogue instance. This allows the model to better learn from the full instructional process provided by the tutor, rather than becoming overly dependent on a particular response order. By disrupting positional regularities, the model is encouraged to attend to the actual content of the tutor’s guidance. Moreover, since the dataset comprises tutoring interactions from multiple distinct AI tutors, shuffling further reduces the risk of overfitting by limiting memorization of stylistic patterns.

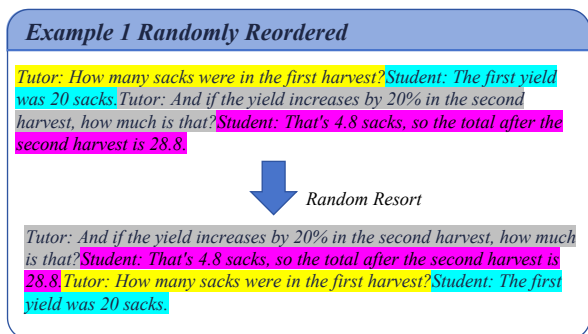

Figure 2: Randomly reordered method.

To address the issue of class imbalance observed in the training data, we applied targeted data augmentation strategies to improve model generalization. As shown in Table 1, all four subtasks exhibit a significant skew toward the “Yes” class, with notably fewer examples labeled as “To Some Extent” or “No.” This imbalance can lead the model to

overfit to the majority class and hinder its ability to accurately recognize minority class instances.

Task	Yes	To Some Extent	No
Mistake Identification	1932	174	370
Mistake Location	1543	220	713
Provide Guidance	1407	503	556
Actionability	1310	369	797

Table 1: Label distribution across the four subtasks.

To mitigate this, we implemented random down-sampling for the “Yes” instances. Specifically, we randomly sampled half of the ‘Yes’ instances, while all “No” and “To Some Extent” instances were preserved. This simple yet effective strategy reduced the dominance of the majority class and encouraged the model to better capture the characteristics of less frequent classes.

In addition, we introduced a lightweight prompt engineering strategy to improve the model’s awareness of the task objective. Taking the Mistake Identification task as an example, where the objective is to determine whether the tutor’s response successfully identifies an error in the student’s reasoning, we attached an explicit task instruction to the input. Specifically, the complete prompt template as follows: *The student’s last utterance contains a mistake. The AI tutor responds to this mistake. Your task is to assess whether the tutor’s response successfully identifies the mistake made by the student..... Your task is to evaluate the following tutor responses determine whether it successfully identifies the error in the student’s reasoning.* This additional context helps guide the model’s attention to relevant reasoning errors in the dialogue. Although the modification is simple, empirical results suggest that such task-aware prompts can improve model performance, highlighting the importance of clear task framing in multi-choice dialogue understanding tasks.

4 Experiment Results

We employed the Qwen2.5 (Bai et al., 2023) model series as the backbone and trained our models using the dataset constructed in the Method section. Specifically, we conducted training and inference using four Ascend-910B nodes, each equipped with eight GPUs. The learning rate was set to $5e-6$, the gradient accumulation steps were configured as 8, and the models were trained for a total of five epochs.

For Mistake Identification, BJTU secured 1st place with an exact macro F1 score (Ex. F1) of 0.7181, indicating its effectiveness in accurately identifying errors in student responses. In the Mistake Location track, BJTU ranked 2nd with an Ex. F1 score of 0.5940, demonstrating its ability to locate errors in student reasoning. For Providing Guidance, BJTU placed 4th with an Ex. F1 score of 0.5725, reflecting its solid performance in selecting appropriate guidance responses from multiple options. In the Actionability track, BJTU again showed strong results, ranking 2nd with an Ex. F1 score of 0.6992, demonstrating its capability to determine the practical applicability of the responses. These results highlight the consistency and versatility of BJTU’s system across different task domains, proving its robustness in handling various aspects of educational dialogue systems.

We adopted a unified strategy across all four tracks, as the tasks share similar objectives centered on evaluating and improving AI tutor responses. Instead of building separate models, we applied the same framework and prompt design to each task, which simplified our approach and proved effective across different evaluation aspects.

To further evaluate the effectiveness of different augmentation strategies, we conducted an ablation study comparing several variants of the model on the Codabench. The results are summarized in Table 3. Among all configurations, the combination of task description and dialogue shuffling achieved the best strict macro F1 score (0.7181), suggesting that explicitly describing the task helps the model better align its generation with the intended objective.

When applying shuffling alone, the model obtained the highest strict accuracy (0.8694), indicating improved precision in certain classes. However, its slightly lower F1 score suggests a trade-off in class coverage. Introducing class balancing on top of shuffling led to a modest increase in strict F1 (0.7104), but did not produce consistent improvements across all metrics. This aligns with our hypothesis that label distribution reweighting offers limited benefit when the test set closely mirrors the training set.

The base model, which only uses prompt construction without augmentation, performed slightly worse overall but still maintained reasonable robustness. These findings highlight that prompt design alone plays an important role and that combining shuffling with task description provides the most

Track	Team	Ex. F1	Ex. Acc	Len. F1	Len. Acc

Table 3: Performance of different development runs under strict and lenient matching criteria.

notable gains across evaluation metrics.

These findings suggest that among the augmentation techniques we explored, randomizing the dialogue order is particularly effective in improving the robustness of the model in unseen examples. However, the benefit of class balancing appears to depend on whether there is a label distribution mismatch between training and test sets.

5 Conclusion

In this paper, we presented BJTU’s approach to the BEA 2025 Shared Task on Evaluating the Ability of AI Tutors. Focusing on mathematics education, we designed a system that effectively evaluates tutor responses along four instructional dimensions: mistake identification, mistake location, guidance, and actionability. Our method leveraged large lan-

guage models, prompt engineering, and targeted data augmentation techniques, including dialogue shuffling and class balancing, to enhance model generalization and robustness.

Our system achieved strong overall results, ranking within the top four in all tracks, including first place in Mistake Identification. These outcomes demonstrate the potential of well-structured prompting and augmentation strategies to improve the pedagogical evaluation capabilities of LLMs.

Looking forward, we aim to explore more fine-grained annotation schemes, incorporate multimodal feedback, and develop more interpretable evaluation models. We hope our findings contribute to the advancement of standardized and scalable benchmarks for AI-assisted education.

Abstract

In this paper, we propose a novel framework for the tutor identification track of the BEA 2025 shared task (Track 5). Our framework integrates data-algorithm co-design, dynamic class compensation, and structured prediction optimization. Specifically, our approach employs noise augmentation, a fine-tuned DeBERTa-v3-small model with inverse-frequency weighted loss, and Hungarian algorithm-based label assignment to address key challenges, such as severe class imbalance and variable-length dialogue complexity. Our method achieved **0.969 Macro-F1 score** on the official test set, securing second place in this competition. Ablation studies revealed significant improvements: a 9.4% gain in robustness from data augmentation, a 5.3% boost in minority-class recall thanks to the weighted loss, and a 2.1% increase in Macro-F1 score through Hungarian optimization. This work advances the field of educational AI by providing a solution for tutor identification, with implications for quality control in LLM-assisted learning environments.

1 Introduction

The rapid advancement of large language models (LLMs) has opened new avenues for the development of AI-powered tutoring systems, enabling scalable and personalized learning support through intelligent conversational agents (Cai et al., 2025; Li et al., 2025). Contemporary studies demonstrate that AI-powered tutors can significantly enhance instructional efficiency (Tack et al., 2023), particularly in math education where adaptive feedback is crucial (Xu et al., 2025). Nevertheless, this technological progress introduces a critical challenge in educational practice: the growing difficulty in distinguishing LLM-generated tutor responses from those crafted by human educators. This tutor identification problem becomes particularly acute when

examining nuanced pedagogical behaviors such as error correction strategies and instructional scaffolding (Macina et al., 2023).

The emergence of sophisticated LLM-based tutors has blurred the traditional boundaries between human and machine-generated educational content. While existing detection methods (Sanh et al., 2019; Liu et al., 2019) perform adequately in binary human-vs-LLM classification scenarios, they lack the granularity required for educational applications. Specifically, these approaches fail to differentiate between various state-of-the-art LLM architectures, distinguish expert versus novice human instructors, or identify the pedagogical strategies employed by different tutor types. This limitation becomes particularly problematic given the demonstrated variations in educational outcomes based on tutor quality.

The shared task (Kochmar et al., 2025) of “Pedagogical Ability Assessment of AI-powered Tutors” (Track 5: Tutor Identification) presents three main technical challenges: **1) Class Imbalance**. Severe class imbalance in the dataset’s sample distribution across nine tutor categories (Maurya et al., 2025), **2) Complexity of Dialogue Sequences**. The complexity of variable-length dialogue sequences that complicate feature extraction, and **3) Subtle Linguistic Patterns**. Minimal lexical differences between expert humans and advanced LLMs that create subtle linguistic patterns. These characteristics render conventional classification approaches ineffective, particularly in maintaining performance across minority classes.

To address class imbalance and enhance classification performance, we employ a noise injection strategy for data augmentation, coupled with a two-stage class weight compensation mechanism. The model is fine-tuned using weighted cross-entropy loss with inverse-frequency class weighting to mitigate bias toward majority classes. For prediction, we implement an ensemble approach combining

*These authors contributed equally.

†Corresponding author.

multiple pre-trained models, followed by globally optimal label assignment via the Hungarian algorithm to ensure unique label distribution per dialogue group while maximizing prediction confidence (Kuhn, 1955). This comprehensive approach effectively handles class imbalance while maintaining prediction stability.

Our method achieved 0.969 Macro-F1 on the official test set, securing **second place in this competition**. Ablation studies¹ demonstrate component-wise improvements: a 5.3% boost in minority-class recall thanks to the weighted loss, and a 2.1% increase in Macro-F1 score through Hungarian optimization. The remainder of this paper is structured as follows: Section 2 reviews relevant literature in LLMs and text detection. Section 3 formally defines the tutor identification problem and introduces dataset. Section 4 formalizes our technical approach. Section 5 presents empirical results and case analyses. Finally, we conclude with broader implications and future directions in Section 6.

2 Related Work

LLM-generated Text Detection. The proliferation of large language models (LLMs) has spurred interest in detecting LLM-generated text. Following the emergence of the GPT-2 Output Detector (Solaiman et al., 2019), which is based on the RoBERTa pretrained model (Liu et al., 2019) and achieves up to 88% accuracy on GPT-2 text, numerous detectors have been developed. ? employs statistical analysis of word probabilities and ranks for GPT-2 detection. Habibzadeh (2023) initially used perplexity and burstiness, claiming 88% accuracy for human and 72% for AI text. OpenAI’s Text Classifier², fine-tuned on diverse models, provides probabilistic categories for distinguishing human and AI text, requiring at least 1000 characters. GP-Toolkit³ sets up multiple models (including (Sanh et al., 2019; Liu et al., 2019)). CheckForAI⁴ combines GPT-2 Output Detector with custom models. CopyLeaks⁵ claims 99.12% accuracy across languages.

In contrast to general LLM-generated text detectors, our work focuses on the more nuanced task

¹Ablation studies conducted with simplified validation due to submission constraints

³<https://gptkit.ai/>

⁴<https://checkforai.com/>

⁵<https://copyleaks.com/>

of identifying the specific origin of text within a defined set of tutors and LLMs. To achieve this, we leverage DeBERTa (He et al., 2020), which features disentangled attention and an enhanced mask decoder. DeBERTa has demonstrated superior performance in NLP tasks, achieving an accuracy of 91.1% on the MNLI benchmark, compared to RoBERTa-Large’s 90.2%. These results make DeBERTa a promising approach for our classification task.

3 Dataset Analysis

The dataset provided for this shared task (Kochmar et al., 2025) is sourced from the MathDial (Macina et al., 2023) and Bridge (Wang et al., 2023) datasets. The dataset, including instructional annotations developed by Maurya et al. (2025), was provided by the shared task organizers in accordance with the established annotation protocol and guidelines. Out of 300 dialogues, 200 responses were annotated by four annotators. The average Fleiss’ Kappa among the four annotators reached 0.65, indicating substantial agreement and demonstrating the reliability of this annotation task. Each dialogue includes the prior multi-turn interactions between a tutor and a student, the student’s final utterance containing an error, and a collection of responses generated by both seven large language model LLM-based tutors and human tutors in response to that utterance. The LLM tutors include: GPT-4 (Achiam et al., 2023), Gemini (Team et al., 2024), Sonnet (Anthropic, 2023), Mistral (Jiang et al., 2023), Llama-3.1-8B and Llama-3.1-405B (Grattafiori et al., 2024), and Phi-3 (Abdin et al., 2024). Human tutors are categorized into two groups: Expert and Novice.

The test set consists of 191 dialogues. These dialogues include the prior conversational context, the final incorrect student utterance, and a set of unannotated tutor responses from the same group of tutors used in the development set.

For Track 5: tutor identification task, the required data include the tutor responses and their corresponding identities. Table 1 presents the distribution of the dataset.

4 Methodology

As shown in Figure 1, we propose a unified approach to address class imbalance and enhance classification performance. It combines noise injection for data augmentation, a two-stage class weight compensation mechanism. During infer-

Class	Train Set Count	Test Set Count
Expert	300	191
Novice	76	19

Llama3.1-8B	300	191
Llama3.1-405B	300	191
GPT4	300	191
Mistral	300	191
Gemini	300	191
Phi3	300	191
Total	2,476	1,547

Table 1: The statistics of the dataset in track 5.

ence, we employ an ensemble of pre-trained models and apply the Hungarian algorithm for globally optimal and unique label assignment within each dialogue group. This ensures both robustness and stable prediction under imbalanced conditions.

4.1 Noise Injection for Data Augmentation

We selected several commonly used machine learning models along with the DeBERTa series for evaluation. The original training dataset was partitioned into training and validation subsets with an 8:2 ratio to facilitate comparable performance assessment. We adopted both Macro-F1 score and accuracy (ACC) as evaluation metrics. Considering that Macro-F1 demonstrates greater robustness to class imbalance, it was designated as our primary evaluation criterion. The comparative results for both metrics are presented in Table 2. Based on these experimental findings, we selected DeBERTa-v3-small for further fine-tuning to enhance its classification performance.

Model	Validation Set	
	Macro-F1 Score	Accuracy
Logistic Regression	0.796	0.811
Random Forest	0.778	0.789
Extra Trees	0.786	0.798
XGBoost	0.736	0.757
DeBERTa-v3-base	0.806	0.821
DeBERTa-v3-small	0.812	0.834

Table 2: Performance comparison of baselines on the validation set (Macro-F1 Score and Accuracy).

Subsequent analysis of the validation set predictions revealed a notable discrepancy between the model’s accuracy and Macro-F1 scores. While achieving high accuracy, the model exhibited relatively poor performance in terms of Macro-F1, suggesting inadequate handling of class imbalance. This observation indicates that the current model

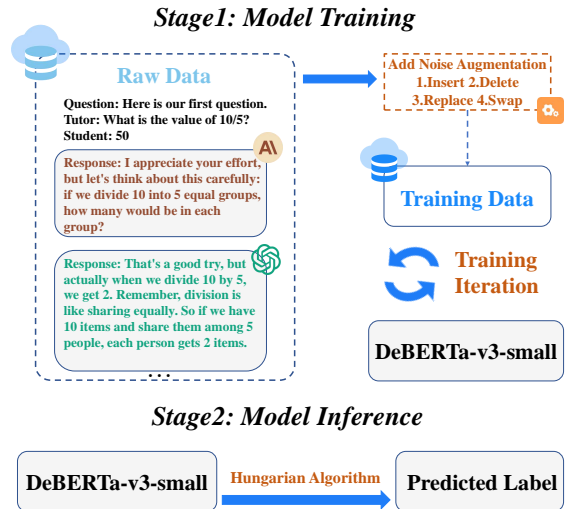

Figure 1: Overview of our proposed method.

architecture may require modification to better address the imbalanced nature of our dataset

Therefore, the original dataset is expanded through multimodal noise injection to mitigate overfitting in small-sample scenarios. For each text sample x_i , we generate its noisy variant \tilde{x}_i as follows:

$$\tilde{x}_i = T(x_i), \quad (1)$$

$$T \in \{\text{insert, delete, replace, swap}\},$$

where the noise transformation T is randomly selected with uniform probability from four operations, with a noise ratio $\alpha = 10\%$. This augmentation strategy doubles the dataset size from original N samples to $2N$. Crucially, the original labels remains unaltered during augmentation, preserving consistency in label distribution.

To address potential amplification of original class distribution disparities, we implement a two-stage class weight compensation mechanism:

4.2 Fine-tuning DeBERTa with Weighted Cross-Entropy Loss Function

To address class imbalance in the training set, we adopt an inverse-frequency weighting scheme to compute balanced class weights. Let the training set consist of C classes, with N_c denoting the number of samples in class c , and let $N_{\text{total}} = \sum_{c=1}^C N_c$ be the total number of training samples. The weight for class c is defined as:

$$w_c = \frac{N_{\text{total}}}{C \cdot N_c}, \quad c = 1, \dots, C. \quad (2)$$

This weighting strategy assigns higher importance to underrepresented classes, thereby mitigating the bias toward majority classes during model training.

Subsequently, the standard cross-entropy loss is modified by incorporating the computed class weights. Given a training batch of size B , the weighted cross-entropy loss is formulated as:

$$\mathcal{L}(\theta) = -\frac{1}{B} \sum_{i=1}^B w_{y_i} \log p_{\theta}(y_i|x_i), \quad (3)$$

where y_i denotes the true label of sample x_i , and $p_{\theta}(y_i|x_i)$ represents the predicted probability output by the model parameterized by θ .

By scaling the loss contribution of each sample according to its class weight, this approach enhances the gradient contributions from minority classes while preserving the overall optimization direction. As a result, the classification boundary becomes more sensitive to underrepresented classes, leading to improved generalization performance on imbalanced datasets.

To ensure the training effectiveness of the model, we adopt K-fold cross-validation, a robust model evaluation technique that not only maximizes the utilization of limited datasets but also reduces the dependency of evaluation results on data partitioning methods (Kohavi et al., 1995), to assess and optimize the detection model’s performance. The original training set is randomly divided into K subsets of approximately equal size. For each iteration, one subset is selected as the validation set, while the remaining K-1 subsets are used as the training set. The model’s performance is ultimately assessed by aggregating the results from the K training and validation cycles.

4.3 Prediction via Hungarian Algorithm

Given an input text set $X = \{x_1, x_2, \dots, x_n\}$, we employ k pre-trained models for prediction and average their output probabilities to mitigate the limitations of individual models, enhance generalizability, reduce prediction variance while preventing overfitting. Each model outputs a probability distribution matrix $P_i \in \mathbb{R}^{n \times c}$, with c denoting the number of classes. During the ensemble phase, we compute the average probability across all models:

$$\bar{P} = \frac{1}{k} \sum_{i=1}^k P_i. \quad (4)$$

This strategy effectively reduces model bias and enhances prediction stability. Through further analysis, we observe that each dialogue group consistently contains 7 AI responses, 1 Expert response, and randomly features 1 Novice response. Based on this pattern, we design a Hungarian algorithm-based prediction method to ensure globally optimal unique label assignment for each dialogue group. The detailed procedure is as follows:

Step 1: Cost Matrix Construction For each dialogue group $G \subseteq X$, extract its average probability matrix $\bar{P}_G \in \mathbb{R}^{m \times c}$, where $m \in \{8, 9\}$ represents the number of responses in the group. When $m = 8$, we exclude the Novice label (class 9) and adjust the probability matrix to $\bar{P}'_G \in \mathbb{R}^{8 \times 8}$. The cost matrix is defined as:

$$C = -\log(\bar{P}'_G). \quad (5)$$

This transformation converts the probability maximization problem into a linear assignment problem that minimizes negative log probabilities.

Step 2: Optimal Matching Solution The Kuhn-Munkres (Hungarian) algorithm is applied to solve:

$$\min \sum_{i=1}^m \sum_{j=1}^{c'} C_{i,j} \cdot Z_{i,j}, \quad (6)$$

subject to the constraints:

$$\sum_i Z_{i,j} \leq 1, \quad \sum_j Z_{i,j} = 1, \quad Z_{i,j} \in \{0, 1\}, \quad (7)$$

where Z denotes the assignment matrix, and $c' = c$ (when $m = 9$) or $c' = c - 1$ (when $m = 8$).

Step 3: Label Mapping and Confidence Calculation The algorithm returns optimal matching indices (i, j) , mapping column index j back to the original label (when $m = 8$, adjustment is needed to skip the Novice label). The final predicted label and confidence score are:

$$\text{label} = \arg \max_j \bar{P}_{i,j}, \quad \text{confidence} = \max_j \bar{P}_{i,j} \quad (8)$$

This strategy achieves global optimal assignment with polynomial time complexity $O(m^3)$, ensuring label uniqueness while maximizing prediction confidence.

5 Main Results

The evaluation results of all models are summarized in Table 3. It is worth noting that the De-

Model	Macro-F1 Score	Accuracy
DeBERTa-v3-small	0.812	0.834
+ Augmentation, k=1	0.888	0.888
+ Augmentation, k=5	0.901	0.901
+ Augmentation + Weighted, k=5	0.949	0.963
+ Augmentation + Weighted + Hungarian, k=5	0.969	0.966

Table 3: Performance comparison of DeBERTa-v3-small under different training strategies and ensemble settings. Among them, *Augmentation* refers to noise injection for data augmentation techniques, k denotes the number of candidates averaged during inference, *Weighted* indicates the use of weighted cross-entropy loss, and *Hungarian* refers to prediction via Hungarian algorithm.

BERTa model without noise injection for data augmentation was not submitted to the CodaLab platform. Instead, its performance was evaluated using a validation set composed of 20% of the original training data, as described in Section 4.1 on data pre-processing. The results of the other four models were obtained using the official test set via the CodaLab evaluation platform.

The DeBERTa model without any noise injection for data augmentation reflects the baseline performance of the model under the original imbalanced data distribution. After introducing noise injection for data augmentation strategies, the Macro-F1 score improved to 0.888, indicating the initial effectiveness in mitigating the impact of class imbalance. Subsequently, we applied 5-fold cross-validation to the DeBERTa model and selected the best-performing model across the folds, which further increased the Macro-F1 score to 0.901, demonstrating improved stability and generalization capability.

Building upon this, the incorporation of a weighted cross-entropy loss function led to an additional improvement in performance, with the Macro-F1 score reaching 0.949. Finally, by integrating the Hungarian algorithm for prediction optimization, the overall Macro-F1 score achieved a significant improvement, reaching 0.969. This result confirms the effectiveness of the proposed approach in addressing complex classification tasks. Our best-performing model ranked second on the official leaderboard.

6 Conclusion

In this work, we propose an effective framework for distinguishing between human-written and LLM-generated responses in mentor-style answers. Our method is based on the DeBERTa model and incorporates various techniques to enhance its general-

ization and robustness, including data augmentation strategies, a weighted cross-entropy loss function design, and a prediction optimization mechanism based on the Hungarian algorithm. This proposed approach effectively addresses the challenges posed by the rapid development of generative artificial intelligence in content authentication.

Experiments are conducted on the test set provided by the Codabench platform, and the results validate the superior performance of the framework. Furthermore, this study presents a component analysis that explores the contribution of each module to the overall performance, offering valuable insights and directions for future research and improvements in related fields.

Limitations

We still have the following limitations: 1) In terms of generalization, our method is tailored to the tutor identification task, raising questions about its generalizability to similar tasks. We plan to address this issue of generalization in future work. 2) Furthermore, although our method has demonstrated excellent performance on this competition’s test set, it has not yet been tested in real-world scenarios. We plan to apply and evaluate our method in the educational field and will share our findings when appropriate.

Acknowledgments

The authors sincerely appreciate the event organizers for their hard work, and the reviewers for their careful reading and insightful comments.

Abstract

This paper describes our approaches for the BEA-2025 Shared Task on assessing pedagogical ability and attributing tutor identities in AI-powered tutoring systems. We explored three methodological paradigms: in-context learning (ICL), supervised fine-tuning (SFT), and reinforcement learning from human feedback (RLHF). Results indicate clear methodological strengths: SFT is highly effective for structured classification tasks such as mistake identification and feedback actionability, while ICL with advanced prompting excels at open-ended tasks involving mistake localization and instructional guidance. Additionally, fine-tuned models demonstrated strong performance in identifying tutor authorship. Our findings highlight the importance of aligning methodological strategy and task structure, providing insights toward more effective evaluations of educational AI systems.

1 Introduction

The integration of large language models (LLMs) into educational technologies has revolutionized the landscape of AI-powered tutoring systems. These systems exhibit remarkable capabilities in generating fluent and contextually relevant responses, offering personalized learning experiences across various domains, including mathematics education. However, assessing the pedagogical effectiveness of these AI tutors extends beyond evaluating linguistic fluency or factual correctness; it necessitates a comprehensive analysis of their instructional strategies and their ability to engage students meaningfully.

To tackle the challenge of evaluating instructional quality, the 20th Workshop on Innovative Use of NLP for Building Educational Applications

(BEA 2025) introduced a shared task titled Pedagogical Ability Assessment of AI-powered Tutors (Kochmar et al., 2025). This initiative aims to establish standardized evaluation criteria for systematically assessing the pedagogical effectiveness of AI-assisted educational dialogues. The task provides a unified evaluation framework encompassing four key pedagogical dimensions: mistake identification, mistake localization, provision of guidance, and actionability of feedback. In addition to these core dimensions, the shared task includes a fifth track, Guess the Tutor Identity, which focuses on authorship attribution by determining whether a response was generated by a specific language model or a human tutor—thereby shedding light on the stylistic signatures of different LLMs. An overview of the task design is illustrated in Figure 1.

In this paper, we present our comprehensive approach to the BEA-2025 Shared Task, focusing on both pedagogical ability assessment and tutor identity attribution in AI-powered tutoring systems. We explore multiple methodological paradigms, including in-context learning (ICL), supervised fine-tuning (SFT), and reinforcement learning (RLHF), and demonstrate their respective strengths across task tracks. Our empirical results show that SFT excels in structured classification tasks, while ICL, supported by advanced prompting strategies, proves more effective in open-ended reasoning settings. Furthermore, we validate the use of fine-tuned LLM classifiers for authorship attribution, achieving competitive performance even in black-box conditions. Our findings not only highlight the importance of methodological alignment with task structure but also provide practical insights into building robust evaluation systems for educational AI.

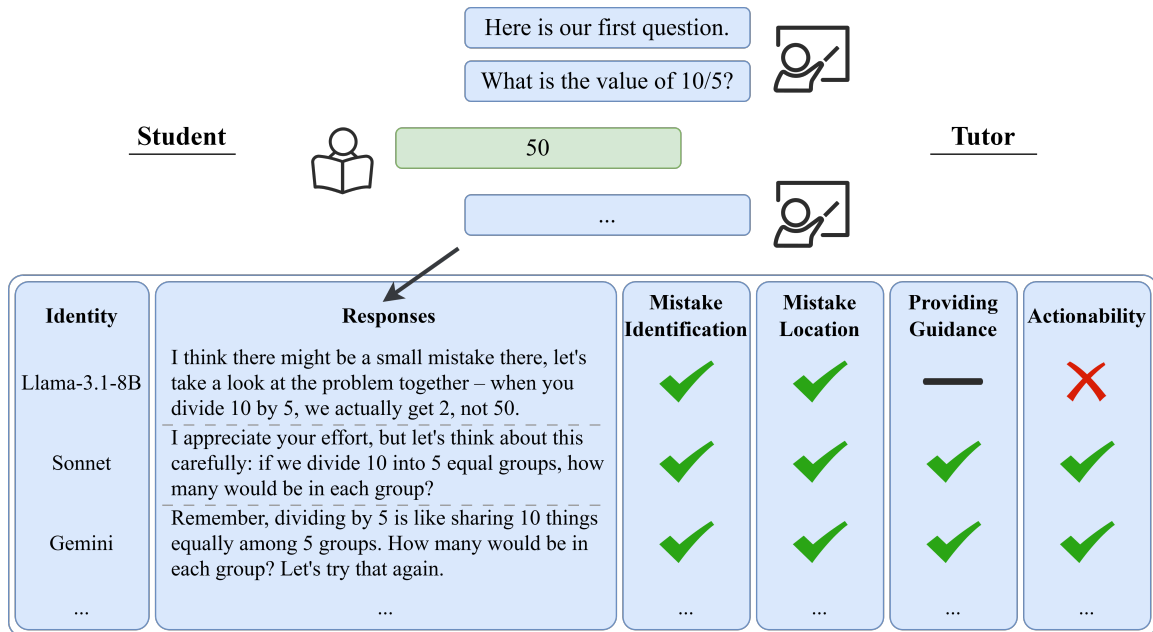

Figure 1: Illustration and Description of the Task for Evaluating Pedagogical Ability. The figure presents a sample math problem given to a student, along with three distinct responses generated by AI tutors. Each response is assessed across four pedagogical dimensions: Mistake Identification, Mistake Localization, Guidance Provision, and Actionability. A green check mark (✓) denotes that the behavior is clearly exhibited (Yes), a red cross (✗) indicates that it is absent (No), and a black dash (–) signifies that the behavior is only partially present or ambiguously demonstrated (To some extent).

2 Related Works

This section provides a brief overview of the BEA-2025 Shared Task and reviews two key methodological areas: LLM-as-a-Judge techniques for evaluating pedagogical quality in the first four tracks, and authorship attribution methods for identifying tutor sources in the final track.

2.1 Pedagogical Ability Assessment of AI-powered Tutors

With rapid advancements in artificial intelligence (AI) and natural language processing (NLP), AI-powered tutoring systems—especially those leveraging large language models (LLMs)—have demonstrated significant potential in educational contexts, including mathematics instruction. However, effectively evaluating the instructional quality of these systems requires more than simply assessing linguistic fluency or factual accuracy. It demands deeper analysis of their pedagogical strategies and the quality of their interactions with students.

To address this need, the 20th Workshop on Innovative Use of NLP for Building Educational Applications (BEA 2025) introduced a shared task titled “Pedagogical Ability Assessment of AI-powered

Tutors.” This task aims to establish standardized evaluation criteria that systematically measure instructional quality in AI-supported educational dialogues.

Specifically, the task focuses on mathematics-based tutor-student dialogues, with special emphasis on capturing student errors and misconceptions that surface during problem-solving interactions. Task participants are provided dialogue samples sourced from the MathDial and Bridge datasets, which include:

Multi-turn interactions between students and AI-powered tutoring systems; Student utterances containing errors or expressions of uncertainty; Tutor responses generated by various AI systems based on different LLMs, as well as select responses from human tutors. To facilitate comprehensive and consistent evaluation, the organizers propose a unified taxonomy based on the pedagogical framework introduced by Maurya et al. (2024), comprising four core dimensions:

- **Mistake identification:** Evaluating whether the AI correctly detects a student’s error.
- **Mistake location:** Identifying the exact position of the error within a student’s utterance.

- **Providing guidance:** Assessing the AI’s ability to deliver appropriate hints, explanations, or guiding questions.
- **Actionability:** Determining whether the provided feedback clearly points students toward actionable next steps.

Beyond the primary subtasks focusing on instructional quality dimensions, the BEA 2025 shared task also introduces Track 5: **Guess the tutor identity**, designed to explore relationships between the stylistic characteristics of AI tutors and their underlying source models. In this subtask, participants must identify the specific model or human tutor behind a tutoring system’s response based solely on text content.

To support research and system development, the organizers have released the MRBench V3 dataset¹, consisting of 300 development dialogues and 191 test dialogues, encompassing interactions with both AI and human tutors. Each dialogue is annotated according to the four pedagogical dimensions. Participants are further encouraged to develop automated evaluation systems to assess the pedagogical capabilities of AI-generated tutoring interactions within this structured evaluation framework.

2.2 LLM-as-a-Judge

With the widespread adoption of large language models (LLMs) in various natural language processing tasks, effectively evaluating the quality of their generated outputs has become a prominent research area. Traditional automatic evaluation metrics such as BLEU (2002) and ROUGE (2004) exhibit limitations in capturing semantic coherence and contextual relevance in generated texts. To address these issues, recent work has proposed the "LLM-as-a-Judge" approach, which leverages powerful LLMs as evaluators to assess outputs produced by other models. This method not only enhances automation of the evaluation process but also demonstrates judgment capabilities comparable to human evaluators across various tasks (Liu et al., 2023).

From an output perspective, existing LLM-as-Judge implementations can generally be categorized into three frameworks (Li et al., 2024): (a) Scoring: The most frequently adopted evaluation paradigm, in which the LLM assigns numerical

scores to candidates, enabling quantitative comparisons. (b) Ranking: Particularly useful when establishing a relative ordering among candidates, allowing for evaluations that do not rely on explicit scoring scales. (c) Selection: Effective in decision-making scenarios, enabling the LLM to directly choose the most suitable output from a set of provided candidates.

In terms of construction methodologies, approaches to building reliable LLM-based judges primarily belong to two categories:

- Prompting Strategies:** Properly designed prompting methods and pipelines further enhance judgment accuracy and mitigate evaluation bias (Gu et al., 2024). Key prompting approaches include: **Position Swapping:** Systematically changing candidates’ positions in prompts to reduce position-induced biases. **Inclusion of Rubric and Reference Information:** Directly offering clear rubrics or reference materials to guide the LLM’s evaluation criteria. **Inter-LLM Cooperation:** Implementing collaborative processes (e.g., voting mechanisms, structured debates) among multiple LLM-based judges, thereby balancing individual-model biases. **In-Context Demonstrations:** Providing relevant examples within prompts, a method shown to significantly improve evaluation performance via the model’s in-context learning capabilities.
- Tuning-Based Methods:** Supervised Fine-Tuning (SFT) is the predominant strategy, where LLMs are explicitly trained to judge based on collected prompt-response evaluation datasets (Zhu et al., 2023). Through supervised training, models gain the capability to perform nuanced judgments in specific tasks.

By carefully selecting and combining these tuning methods and prompting strategies, robust and reliable LLM-based judge systems can be effectively constructed, thereby enabling more accurate evaluation across diverse and complex NLP tasks.

2.3 Authorship Attribution

Authorship Attribution (AA) aims to identify the authorship of unknown texts by analyzing linguistic features. The underlying assumption of AA is that different authors—including humans and large language models (LLMs)—exhibit distinct characteristics in lexical diversity, syntactic structures, and

¹https://github.com/kaushal0494/UnifyingAITutorEvaluation/tree/main/BEA_Shared_Task_2025

discourse styles. Previous authorship attribution methods predominantly focused on distinguishing texts produced by various human authors. However, with the rise and advancement of large language models, differentiating between human-generated and LLM-generated texts, as well as identifying texts produced by specific LLMs, has increasingly become a focal area of research.

Current authorship attribution methods can be categorized as follows:

- (a) **Style-based methods** utilize lexical, syntactic, and structural features to capture the distinct writing styles of authors. For instance, [Kumara and Liu \(2023\)](#) extracted lexical, syntactic, and structural features from texts to train classifiers for tracing the origin of generated texts. Nevertheless, these methods tend to perform poorly when distinguishing between closely related LLMs, such as Llama-3-8B and Llama-3-405B.
- (b) **Probability-based methods** hypothesize that generated texts have a higher generation probability when evaluated by their original source model, and thus rely on differences in probability distributions calculated by various language models for the same text. For example, POGER ([Shi et al., 2024](#)) performs attribution by repeatedly sampling representative tokens to estimate generation probabilities. However, these approaches are highly sensitive to text length, as shorter texts may yield inaccurate probability estimates.
- (c) **Partial rewriting methods** involve partially regenerating segments of a text using candidate generation models and evaluating the source by measuring edit distances between original and regenerated segments. For example, DNA-GPT ([Yang et al., 2023](#)) uses the first half of the target text as a prompt and compares the regenerated latter half with the original to assess attribution. Despite their utility, these methods require multiple invocations of models and significantly depend on prompt design and generation strategies.
- (d) **Model fine-tuning methods** leverage the semantic feature distributions learned from texts authored by different sources through fine-tuning language models. [Chen et al. \(2023\)](#), for instance, fine-tuned the T5 model to cre-

ate T5-Sentinel, achieving effective attribution across five models including GPT-3.5 and LLaMA-7B. Similarly, [Fu et al. \(2025\)](#) proposed the FDLLM method based on LoRA fine-tuning, which effectively detects and distinguishes texts generated by various LLMs in multilingual and cross-domain black-box scenarios. However, these methods typically require extensive annotated data for training.

3 Data

The BEA-2025 Shared Task is based upon the Mr-Bench dataset, which primarily incorporates dialogue data from two publicly available mathematical instructional datasets: MathDial ([Macina et al., 2023](#)) and Bridge ([Wang et al., 2023](#)).

MathDial Dataset The MathDial dataset consists of approximately 3,000 one-on-one teacher-student dialogues focusing on multi-step mathematical reasoning problems. These dialogues were generated by pairing human teachers with a large language model (LLM) specifically trained to simulate common student mathematical errors.

Bridge Dataset The Bridge dataset comprises 700 real-world online tutoring dialogues. These dialogues highlight the challenges novice teachers encounter in addressing student mathematical errors. Each dialogue is annotated by expert educators, explicitly identifying student misconceptions, correction strategies, and underlying instructional intents.

From these two datasets, the organizing team generated seven additional LLM-as-tutor responses for each dialogue, supplementing the original tutor responses in Bridge and MathDial. All tutor responses, including both the original and the newly generated ones, were systematically annotated according to the pedagogical effectiveness taxonomy proposed by [Maurya et al. \(2024\)](#). A development set of 300 dialogues and a testing set of 191 dialogues were constructed from this expanded and annotated pool. Additionally, a subset of the data underwent dual annotation by four independent annotators, yielding an average Fleiss' Kappa coefficient of 0.65. This indicates substantial inter-annotator agreement, thereby ensuring the reliability and robustness of the labeled data for the shared task.

3.1 Data Analysis and Statistics

Due to the limited availability of training data, we plan to expand the current dataset by annotating portions of the MathDial dataset and the unused data from the Bridge dataset. First, we analyzed how MRBench was created from the two aforementioned datasets. Specifically, the MathDial dataset includes fields such as 'question', 'student_incorrect_solution,' and 'conversation,' which can be reorganized into the MRBench format as illustrated below. The MRBench dataset is constructed as a sequential dialogue; the only additional data processing required is labeling each utterance with the corresponding speaker identity (Tutor or Student).

```
Tutor: Hi, could you please provide a step-
by-step solution for the question below? The
question is: {'question'}
Student: {'student_incorrect_solution'}
Tutor: {'conversation'-Tutor[0]}
Student: {'conversation'-Student[0]}
.....
```

Subsequently, we counted the number of responses present within each dialogue in the dataset, as shown in Figure 2.

Figure 2: Distribution of Dialogue Response Counts

Finally, we identified which segments of the original datasets have already been utilized. Since dialogues from the original MathDial and Bridge datasets were randomly truncated when composing the MRBench dataset, we uniformly truncated each original dialogue to a maximum length of four turns for consistency and processed them into a standardized format. We then calculated the similarities between dialogues from MathDial and MRBench (as well as Bridge and MRBench) based on the BLEU metric. By identifying the dialogue entries

with the highest BLEU scores, we constructed a mapping list indicating data usage. Table 1 provides a summary that quantifies the relationships and overlaps among these three datasets.

	MathDial	Bridge	Total
Development set	224	76	300
Test set	172	19	191

Table 1: Dialogue Counts in Development and Test Sets

3.2 Data Correction and Processing

In the process of aligning MRBench with the two original datasets, we observed that a small subset of corresponding instances exhibited significantly lower BLEU scores than average. Upon deeper analysis of these instances, we identified certain issues within the provided datasets that could potentially affect data preprocessing procedures and subsequent model performance.

Role Label Mismatches In the MathDial dataset, we found cases where dialogue responses were mismatched with their corresponding role labels. For example, in the original data: "... on dog toys.\n 42.00 \n Tutor: Hi Ayisha can you talk me through your workings? \n Student: Sure! First I calculated that three full price toys cost 3 x 12.00 =36.00. Then I calculated that one half price toy costs 12.00/2 =6.00. Finally, I added the two amounts together ..." was extracted as: "... on dog toys.\n 42.00 \n Tutor: I added the two amounts together ...".

We believe that this issue was introduced by a comma-based preprocessing heuristic. Specifically, we infer that the task organizers intended to exclude student names or other personally identifiable mentions in tutor responses, motivated by Haim et al.'s (2024) finding that the mention of personal names might introduce unwanted bias into large language models. The heuristic presumably involved removing the segment from the beginning of the tutor's response up to the first comma, presuming that the first comma typically delineates the student's name from the main message. However, if a tutor response lacked commas at expected locations, this strategy inadvertently caused excessive removals, leading to instances where portions of students' answers mistakenly appeared as part of the tutor responses. Consequently, this may impact the model's understanding of the correct answer and its evaluation of the tutor response.

Irrelevant Dialogue Openings Within the Bridge dataset, we identified certain instances where initial conversational utterances were unrelated or irrelevant to the core mathematical problems, such as: "Student: okey \n Tutor: Now we have the same denominators so we can subtract the numerators directly.". This issue was likely introduced through the data-segmentation strategy applied to real-world dialogue corpora.

Consecutive Utterances To be consistent with a large language model’s expected conversational structure of strictly alternating turns between user and model responses, we merged consecutive responses from the same speaker within the datasets.

These procedures were conducted through a combination of automated filtering and manual verification, with further details provided in Appendix A.

4 Methodology

In this section, we present an overview of the three primary approaches explored in the BEA-2025 shared task: in-context learning (ICL), supervised fine-tuning (SFT), and reinforcement learning (RL).

4.1 In-Context Learning

In-context learning (ICL) enables large language models (LLMs) to accomplish specific tasks solely by leveraging input prompts, without the need for updating model parameters.

As an initial step, we investigate the performance of leading proprietary (or large-scale parameter) large language models on instructional ability evaluation tasks. We construct our inputs from historical dialogue contexts, teacher responses, and corresponding evaluation dimensions using the MRBench V3 dataset. Models evaluated include GPT-4o (Hurst et al., 2024), GPT-o3-mini (OpenAI, 2025), Gemini-2.5-pro (DeepMind, 2025), Grok-3 (xAI, 2025), Deepseek-R1 (DeepSeek-AI et al., 2025), and Claude-3.7 (Anthropic, 2025). To effectively elicit optimal model performance, mitigate potential biases, and enhance the robustness of our evaluation, we employ several prompt engineering strategies:

- (a) **Explicit Scoring Criteria:** Clearly-defined evaluation criteria with three distinct performance levels are provided within the prompt to guide model judgments.

- (b) **Contextual Demonstrations:** Relevant illustrative examples are embedded within prompts to enhance the models’ comprehension of tasks, assessment dimensions, and rating standards.
- (c) **Multiple Sampling:** Inspired by the self-consistency property observed in large language models, we sample model outputs multiple times under the same temperature setting and utilize majority voting to determine final results.

Moreover, we experiment with various alternative prompt formulations under each prompting strategy to identify the most effective configuration. Detailed descriptions of our prompt construction methodology can be found in Appendix B.1.

Additionally, we have assessed the performance of open-source and smaller-scale models, including Llama-3.1-8B, QwQ-32B, and the Qwen2.5 series (Yang et al., 2024), to facilitate subsequent supervised fine-tuning and reinforcement learning stages.

4.2 Supervised Fine-tuning

Supervised fine-tuning (SFT) refers to adapting a pretrained language model to a specific task by training it on labeled data. This process updates the model parameters to minimize the discrepancy between model predictions and ground-truth annotations.

In comparison to in-context learning, supervised fine-tuning explicitly embeds task definitions and requirements into the model itself through parameter adjustments. To circumvent performance constraints that may arise from overly prescriptive prompt designs, we have streamlined and adjusted the instruction templates and expected outputs as shown in Appendix B.1.

As shown above, the model is no longer required to generate textual feedback; instead, it directly outputs the designated classification label. This modification aims to simplify the construction of the supervised training dataset and mitigates the risks of overly rigid or overfitted model responses typically associated with explicitly requesting textual elaboration.

Based upon the MRBench V3 dataset, we partition the data into a training-validation split with ratios of 95% and 5%, respectively. We subsequently conduct supervised fine-tuning of the Qwen 2.5-14B model across four distinct evaluation dimensions using LLaMA-Factory (Zheng et al., 2024).

Fine-tuning enables the model to internalize nuanced patterns and task-specific subtleties, thereby significantly improving its performance on evaluation metrics. To enhance computational efficiency and guard against overfitting, we explore parameter-efficient fine-tuning methods such as Low-Rank Adaptation (LoRA). These methods enable selective updating of specific parameter subsets, substantially reducing computational demands while preserving model performance. Detailed specifications of the exact hyperparameters adopted throughout the fine-tuning process are presented in Appendix B.2.

As for Track-5, the task is to identify the source of anonymized natural language texts, namely attributing texts to their corresponding "mentor" models. This track comprises nine distinct classes: an expert mentor, a junior mentor, as well as seven different large language models (LLMs), formulating a typical multi-class classification scenario. This setting is especially challenging due to the short nature of test samples, the inclusion of texts generated by unseen black-box models, and the sophisticated need to distinguish closely related models, such as Llama-3-8B and Llama-3-405B. Thus, the task imposes high demands on the classifier's generalization capability and its ability to capture subtle stylistic differences among different models.

Inspired by the approach of FDLLM (Fingerprint Detection for LLMs), we propose employing a large language model-based authorship attribution classifier. More specifically, we leverage parameter-efficient supervised fine-tuning methods based on Low-Rank Adaptation (LoRA) with the pretrained Qwen 2.5-7B model. Through fine-tuning, the model learns distinct and subtle stylistic "fingerprints" inherent in texts produced by different language models, enabling effective identification of the generating model given an anonymized text input. Details on data construction and model fine-tuning processes are provided in Appendix B.3.

4.3 Reinforcement Learning

Reinforcement Learning (RL) provides a training framework in which models learn to make sequential decisions by maximizing cumulative rewards. Typically, RL is utilized to align model outputs with human preferences, a process known as Reinforcement Learning from Human Feedback (RLHF).

In the educational assessment evaluation task, it is natural to consider applying RLHF to align

large language models (LLMs) with the evaluation ratings annotated by human experts. To this end, we employ RLHF via veRL (Sheng et al., 2024) to fine-tune Qwen 2.5-7B outputs based on human-annotated preferences. Specifically, our approach mainly involves the following two essential steps:

- (a) **Reward Function:** To encourage detailed thinking within the model-generated textual feedback, thereby improving its overall performance, we design a reward function to enforce appropriate response structure and classification correctness. Concretely, we assign a 0.1 reward for adhering to the prescribed formatting structure ("Feedback: ... [Classification] (A/B/C)") and a 1.0 reward when model predictions correctly match human-annotated evaluation ratings.
- (b) **Policy Optimization:** We optimize the LLM's output strategy by maximizing the predicted rewards from the reward function. During this step, we explore optimization algorithms such as Proximal Policy Optimization (PPO) and Generalized Reference Policy Optimization (GRPO) to enhance both stability and efficiency during policy updates.

Through the RLHF process, we initially expect that the model can be guided to generate responses that are not only accurate but also closely aligned with human instructional preferences, ultimately increasing their practical value and instructional quality in educational dialogue contexts. However, we observe limited performance improvements following RLHF training, alongside unexpected generation issues, such as output consisting of repeated special tokens produced solely to obtain formatting-related rewards.

5 Results

In this section, we report the performance of our proposed methods on both the development and test sets.

5.1 Performance on the Development Set

In-Context Learning Method

As described in Section 3.1, we evaluated several advanced large language models on the teaching ability assessment task using the development set, with results shown in Figure 3. Among these models, Gemini 2.5-Pro achieved the best results across all four evaluated dimensions, substantially

Figure 3: Performance of Proprietary Large Language Models in Pedagogical Ability Assessment

outperforming the other five models. Thus, we decided against adopting an ensemble approach, which would involve combining predictions from diverse heterogeneous models through voting. Instead, we opted to increase robustness by conducting multiple sampling procedures on the outputs from the Gemini 2.5-Pro model for our final submission.

Supervised Model Fine-tuning Method We separately evaluated several smaller-scale open-source models, including Llama-3.1-8B, QwQ-32B, Qwen 2.5-32B, and Qwen 2.5-14B. Although QwQ-32B obtained the highest scores overall, it has been observed by Kirk et al. (2023) that reinforcement learning from human feedback (RLHF) optimization may result in degradation of model performance during supervised fine-tuning (SFT), specifically affecting generalization to out-of-distribution (OOD) data. Motivated by this consideration, we chose to supervise-fine-tune Qwen 2.5-32B and Qwen 2.5-14B—both demonstrating strong performance and free of RLHF optimizations—as our base models for the teaching ability evaluation task.

5.2 Performance on the Test Set

Table 2 summarizes the highest rankings achieved by our proposed methods in the evaluation phase, detailed by each evaluation track: Track 1 (Mistake Identification): 12th out of 44; Track 2 (Mistake Location): 1st out of 31; Track 3 (Providing Guidance): 3rd out of 35; Track 4 (Actionability): 8th out of 29, and Track 5 (Guess the Tutor Identity): 5th out of 20.

Additionally, we observed differential strengths of the two methodological approaches we adopted: the in-context learning method performed notably better in Tracks 2 and 3, while the supervised fine-tuning method exhibited superior performance specifically in Tracks 1 and 4. Table 3 reports the highest observed scores for each of the two methodologies on the test set.

6 Discussion

Upon further analysis of track-specific performance, we find a clear methodological divide between the strengths of supervised fine-tuning (SFT) and in-context learning (ICL). We hypothesize that these performance differences are rooted in the task structure and cognitive load required for each evaluation dimension:

SFT advantages in Track 1 and Track 4: Both of these tracks can be framed as relatively discrete classification tasks. Track 1 requires the model to detect the existence of a mistake, often a binary or ternary decision. Track 4, similarly, involves judging whether the tutor’s response provides actionable next steps—a decision that can be learned reliably from labeled data with consistent annotation guidelines. SFT excels in such tasks due to its ability to internalize structured decision boundaries from annotated examples, especially when paired with simplified input formats and explicit label mappings. Moreover, SFT benefits from parameter adaptation, allowing it to specialize in subtle categorical distinctions that prompt-based inference might overlook.

ICL advantages in Track 2 and Track 3: In

Track	Rank	Team	Ex. F1	Ex. Acc	Len. F1	Len. Acc
Mistake Identification	1	BJTU	0.7181	0.8623	0.8957	0.9457
	⋮	⋮	⋮	⋮	⋮	⋮
Mistake Location	12	BLCU-ICALL	0.6822	0.8578	0.8909	0.9418
	1	BLCU-ICALL	0.5983	0.7679	0.8386	0.8630
Providing guidance	1	MSA	0.5834	0.6613	0.7798	0.8190
	⋮	⋮	⋮	⋮	⋮	⋮
Actionability	3	BLCU-ICALL	0.5741	0.6716	0.7487	0.8061
	1	bea-jh	0.7085	0.7298	0.8527	0.8837
	⋮	⋮	⋮	⋮	⋮	⋮
Guess the tutor identity	8	BLCU-ICALL	0.6735	0.7363	0.8596	0.8856
	1	Phaedru	0.9698	0.9664	/	/
	⋮	⋮	⋮	⋮	⋮	⋮
	5	BLCU-ICALL	0.8930	0.8908	/	/

Table 2: Rankings and Results of BLCU-ICALL in 5 tracks

	Track-1	Track-2	Track-3	Track-4
ICL	0.6600	0.5983	0.5741	0.5956
SFT	0.6822	<i>0.5582</i>	<i>0.5446</i>	0.6735

Table 3: Comparison of peak performance across tracks for in-context learning (ICL) and supervised fine-tuning (SFT) methods on the test set. Due to time constraints during the test phase, SFT results for Tracks 2 and 3 were not submitted; instead, italicized scores denote performance on 5% of the development set.

contrast, Track 2 (locating the specific position of a student’s error) and Track 3 (generating pedagogically appropriate guidance) require deeper interpretive reasoning and open-ended judgment. These tasks often lack rigid decision templates and depend heavily on nuanced understanding of conversational context, semantics, and pedagogical intent. Large-scale proprietary models like Gemini-2.5-Pro, when supported by advanced prompting (e.g., rubric-injection and contextual demonstrations), are capable of flexible reasoning and generalization—making ICL a better fit. Notably, these models benefit from large-scale parameter, broader pretraining and instruction tuning, allowing them to leverage latent reasoning abilities not easily transferred through task-specific fine-tuning alone.

In Track 5 (authorship attribution), our use of fine-tuned Qwen2.5-based classifiers achieved notable success, ranking 5th overall. This validates the feasibility of using stylistic “fingerprints” for source model identification even under black-box

constraints. Nevertheless, distinguishing between highly similar models (e.g., LLaMA variants) remains challenging, especially when input samples are short or lack distinctive syntactic structures.

7 Conclusion

This paper presents our comprehensive approach to the BEA-2025 Shared Task, focusing on both pedagogical ability assessment and tutor identity attribution in AI-powered tutoring systems. We explore multiple methodological paradigms, including in-context learning (ICL), supervised fine-tuning (SFT), and reinforcement learning (RLHF), and demonstrate their respective strengths across task tracks. Our empirical results show that SFT excels in structured classification tasks, while ICL, supported by advanced prompting strategies, proves more effective in open-ended reasoning settings. Furthermore, we validate the use of fine-tuned LLM classifiers for authorship attribution, achieving competitive performance even in black-box conditions. Our findings not only highlight the importance of methodological alignment with task structure but also provide practical insights into building robust evaluation systems for educational AI.

Limitations

Our work is subject to several limitations. For the task of Pedagogical Ability Assessment, different evaluation dimensions are not independent; rather,

they are closely interrelated. Utilizing potential synergies among these evaluation dimensions is a plausible direction that remains largely unexplored in this study. Additionally, in Track 5, there is one particularly crucial piece of information that we failed to fully exploit: the constraint that each tutor identity label can appear at most once for the same dialogue.

A Data Correction and Processing

We addressed three types of issues in the MRBeach V3 dataset that may negatively impact the effectiveness of the pedagogical ability assessment model.

Role Label Mismatches

As mentioned previously, we conducted alignment between the MRBeach V3 dataset and the original MathDial dataset by calculating surface-level similarity using the BLEU score. Subsequently, we corrected erroneous labels through threshold-based automated filtering combined with manual annotations. Table 4 below shows the frequency of role-label mismatch errors and their corresponding indices in the development and test sets.

Irrelevant Dialogue Openings

The segmentation strategy applied to real-world conversation data occasionally resulted in semantically unrelated dialogues being grouped into the same segment, consequently introducing irrelevant information not directly related to the core mathematical problems. To handle this issue, we identified dialogues in MRBeach V3 where the student’s utterance is the initial turn, as many of these cases exemplified irrelevant conversation openings. A summary of these cases is provided in Table 5 below.

Consecutive Utterances

To better align the dialogues with the standard conversational format used by large language models—alternating question-answer interactions between two speakers—we identified and merged consecutive utterances belonging to the same speaker role within MRBeach V3. Detailed statistics of this merging process are presented in Table 6 below.

B Methodology Details

Below are detailed descriptions regarding in-context learning and supervised fine-tuning methods for Pedagogical Ability Assessment and Tutor Identification.

B.1 Prompt Construction Methodology Details

This section provides the prompt templates which yielded the best performance for in-context learning and supervised fine-tuning methods.

ICL Prompt Template

System Prompt:

You are a critic evaluating a tutor’s interaction with a student, responsible for providing a clear and objective single evaluation score based on specific criteria. Each assessment must accurately reflect the absolute performance standards.

User Prompt:

Objective: Evaluate the quality of a teacher’s latest response within the context of an ongoing conversation with a student. Your evaluation must be based solely on the provided information and result in structured feedback and a grade classification.

Inputs:

* **Evaluation Indicators:** “{definition}”
* **Grading Criteria:** {rubric}
* **Conversation History:** “{history}”
* **Teacher’s Latest Reply:** “{response}”

Instructions:

- Analyze:** Carefully review the **Teacher’s Latest Reply** in the context of the **Conversation History**.
- Evaluate:** Assess the **Teacher’s Latest Reply** strictly against each point listed in the **Evaluation Indicators**.
- Formulate Feedback:** Write a detailed feedback statement. This statement must clearly explain *how* the teacher’s reply performs against the **Evaluation Indicators**, citing specific examples from the reply or history where applicable. Your reasoning should be evident *within* this feedback structure.
- Assign Grade:** Based on your evaluation and the provided **Grading Criteria**, determine the appropriate classification (A, B, or C).
- Format Output:** Present your response *only* in the following format, without any additional introductory or concluding remarks: ‘Feedback: (Your detailed feedback statement based on evaluation indicators) [Classification] (A, B, or C)’

Dataset	Frequency	Index
Development set	26	18, 36, 56, 79, 100, 116, 122, 155, 168, 174, 177, 182, 183, 188, 195, 201, 205, 225, 252, 262, 264, 271, 277, 282, 290, 295
Test set	16	4, 28, 31, 33, 37, 42, 51, 61, 94, 98, 99, 108, 120, 129, 172, 183

Table 4: Role Label Mismatches

Dataset	Frequency	Index
Development set	16	3, 15, 23, 40, 42, 44, 65, 163, 175, 202, 221, 227, 248, 254, 257, 293
Test set	1	115

Table 5: Irrelevant Dialogue Openings

SFT/RL Prompt Template

Track 1: Mistake Identification

System: You are a Senior Teaching Supervisor.

Input: Has the tutor explicitly pointed out that there was a mistake in a student's response?

- A: Yes (The tutor's response recognizes there is a mistake, or provides some practical guidance.)

- B: To some extent

- C: No (The tutor's response believes that the question had been completely resolved, or no connection.)

* Conversation History: "{history}"

* Teacher's Latest Reply: "{tutor_response}"

Track 2: Mistake Location

System: You are a Senior Teaching Supervisor.

Input: Does the tutor's response accurately point to a genuine mistake and its location?

- A: Yes (the tutor clearly points to the exact location of a genuine mistake in the student's solution)

- B: To some extent (the response demonstrates some awareness of the exact mistake, but is vague, unclear, or easy to misunderstand)

- C: No (the response does not provide any details related to the mistake)

* Conversation History: "{history}"

* Teacher's Latest Reply: "{tutor_response}"

Track 3: Providing Guidance

System: You are a Senior Teaching Supervisor.

Input: Does the tutor offer correct and relevant guidance, such as an explanation, elaboration, hint, examples, and so on?

- A: Yes (the tutor provides guidance that is correct and relevant to the student's mistake)

- B: To some extent (guidance is provided but it is fully or partially incorrect, incomplete, or somewhat misleading)

- C: No (the tutor's response does not include any guidance, or the guidance provided is irrelevant to the question or factually incorrect)

* Conversation History: "{history}"

* Teacher's Latest Reply: "{tutor_response}"

Track 4: Actionability

System: You are a Senior Teaching Supervisor.

Input: Is it clear from the tutor's latest reply what the student should do next?

- A: Yes (the response provides clear suggestions on what the student should do next)

- B: To some extent (the response indicates that something needs to be done, but it is not clear what exactly that is)

- C: No (the response does not suggest any action on the part of the student (e.g., it simply reveals the final answer))

* Conversation History: "{history}"

* Teacher's Latest Reply: "{tutor_response}"

Dataset	Role	Continuous times	Frequency	Index
Development set	Tutor	2	36	4, 12, 16, 19, 24, 37, 41, 42, 43, 45, 57, 66, 73, 80, 101, 107, 117, 136, 156, 160, 164, 169, 176, 178, 202, 203, 228, 249, 253, 255, 263, 265, 278, 283, 291, 294
Development set	Tutor	3	38	3, 10, 14, 18, 20, 31, 35, 38, 49, 64, 71, 77, 82, 92, 110, 111, 122, 124, 135, 138, 151, 157, 174, 200, 212, 215, 231, 232, 239, 252, 260, 264, 270, 273, 275, 290, 292, 299
Development set	Student	2	5	104, 175, 196, 222, 258
Test set	Tutor	2	18	5, 22, 29, 32, 34, 43, 51, 78, 95, 99, 109, 115, 18, 121, 130, 173, 184, 191
Test set	Tutor	3	14	38, 39, 40, 46, 62, 82, 92, 98, 111, 113, 131, 166, 176, 188

Table 6: Consecutive Utterances

B.2 Supervised Fine-tuning Details

To perform supervised LoRA fine-tuning of Qwen 2.5-14B, we utilized two L40S servers, each equipped with eight GPUs throughout our experiments. For implementation, we employed LLaMA-Factory, and the key configuration parameters are detailed as follows:

- **finetuning_type:** lora
- **lora_target:** all
- **template:** qwen
- **cutoff_len:** 2048
- **per_device_train_batch_size:** 2
- **gradient_accumulation_steps:** 4
- **lora_dropout:** 0.1
- **learning_rate:** 2.0e-4
- **num_train_epochs:** 30.0
- **lr_scheduler_type:** cosine
- **warmup_ratio:** 0.1

B.3 Tutor Identification Details

We fine-tune the Qwen 2.5-7B model to develop a large language model-based authorship attribution classifier for identifying the origin of anonymous

texts. The classifier model takes the instructor’s response text as input and outputs the corresponding instructor identity label. In this section, we present the format of the instruction dataset and the key hyperparameters used in fine-tuning.

Track 5: Tutor Identification

```
## Instruction: Determine which model generated the following text.
## Input: Here is the generated text: {tutor_response}
```

- **finetuning_type:** lora
- **lora_target:** all
- **template:** qwen
- **cutoff_len:** 2048
- **per_device_train_batch_size:** 2
- **gradient_accumulation_steps:** 4
- **lora_dropout:** 0.1
- **learning_rate:** 5.0e-4
- **num_train_epochs:** 26.0
- **lr_scheduler_type:** cosine
- **warmup_ratio:** 0.1

Phaedrus at BEA 2025 Shared Task: Assessment of Mathematical Tutoring Dialogues through Tutor Identity Classification and Actionability Evaluation

Rajneesh Tiwari

Independent Researcher, India
rajneesh.vish1@gmail.com

Pranshu Rastogi

Independent Researcher, India
rastogipranshu29@gmail.com

Abstract

As Large Language Models (LLMs) are increasingly deployed in educational environments, two critical challenges emerge: identifying the source of tutoring responses and evaluating their pedagogical effectiveness. This paper presents Phaedrus' comprehensive approach to the BEA 2025 Shared Task, addressing both tutor identity classification (Track 5) and actionability assessment (Track 4) in mathematical tutoring dialogues. For tutor identity classification, we distinguish between human tutors (expert/novice) and seven distinct LLMs using cross-response context augmentation and ensemble techniques. For actionability assessment, we evaluate whether responses provide clear guidance on student next steps using selective attention masking and instruction-guided training. Our multi-task approach combines transformer-based models with innovative contextual feature engineering, achieving state-of-the-art performance with a CV macro F1 score of 0.9596 (test set 0.9698) for identity classification and 0.655 (test set Strict F1 0.6906) for actionability assessment. We were able to score rank 5th in Track 4 and rank 1st in Track 5. Our analysis reveals that despite advances in human-like responses, LLMs maintain detectable fingerprints while showing varying levels of pedagogical actionability, with important implications for educational technology development and deployment. Our code and implementation details are publicly available at https://github.com/Rajneesh-Tiwari/BEA_2025_shared_task.

1 Introduction

The integration of Large Language Models (LLMs) into educational environments has created new opportunities and challenges for tutoring systems. As AI-powered tutors become increasingly prevalent, two fundamental questions emerge: (1) Can we reliably identify the source

of tutoring responses to ensure transparency and accountability and (2) How effectively do these responses guide students toward learning objectives (Kochmar et al., 2022)

The BEA 2025 Shared Task (Kochmar et al., 2025) addresses these critical questions through two complementary tracks. Track 5 challenges participants to classify the source of mathematical tutoring responses, distinguishing between human tutors (expert and novice) and seven different LLMs: Gemini, GPT-4, Llama3-405B, Llama3-8B, Mistral, Phi3, and Claude Sonnet. Track 4 focuses on evaluating the actionability of these responses—whether they provide clear guidance on what students should do next, a crucial factor in effective pedagogical feedback (Daheim et al., 2024).

These tasks are inherently related: understanding who generated a response and how actionable it is provides a comprehensive view of educational dialogue quality. Our hypothesis is that different tutors (human or AI) not only leave distinctive linguistic fingerprints but also demonstrate varying capabilities in providing actionable guidance. This multi-dimensional analysis offers insights into the current state of AI tutoring systems and their pedagogical effectiveness compared to human tutors.

Our team (Phaedrus) approach leverages transformer-based models enhanced with task-specific innovations. For identity classification, we implement cross-response context augmentation, allowing models to compare different responses to the same question, and use specialized attention masking to focus on response characteristics. For actionability assessment, we develop instruction-guided training with selective attention mechanisms that focus on response-specific features indicating clear guidance. Both tasks benefit from sophisticated ensemble techniques and constraint satisfaction post-processing.

This paper presents our top-ranked systems for both tracks, describing our unified methodology, training strategies, and comprehensive analysis of results. Our findings demonstrate that while LLMs are becoming increasingly sophisticated in generating human-like responses, they still exhibit detectable patterns that distinguish them from human tutors, and they show varying capabilities in providing actionable pedagogical guidance.

2 Related Work

Recent research in educational dialogue assessment has focused on multiple dimensions of quality evaluation. [Tack and Piech \(2022\)](#) introduced a framework for evaluating LLM-based tutors across three dimensions: whether they speak like a teacher, understand a student, and help a student. Building on this work, [Tack et al. \(2023\)](#) organized shared task on generation of teacher responses in educational dialogues. The goal of the task was to benchmark the ability of generative language models to act as AI teachers, replying to a student in a teacher-student dialogue using existing automatic metrics (e.g., BERTScore ([Zhang* et al., 2020](#)), DialogRPT ([Gao et al., 2020](#))) and manual evaluation aligned with the proposed dimensions, highlighting ongoing challenges in the reliable assessment of pedagogical dialogue quality.

2.1 Tutor Identity and AI Detection

The challenge of distinguishing between human and AI-generated text has established several foundations. [Guo et al. \(2023\)](#) demonstrated that transformer models effectively identify LLM-generated text through distinctive linguistic patterns, performing linguistic analysis to identify patterns between ChatGPT and human expert responses. In educational contexts specifically, [Chen et al. \(2024\)](#) introduced Dr.Academy, a benchmark for evaluating LLMs’ questioning capabilities across general, humanities, science, and interdisciplinary educational domains, revealing that different models demonstrate varying strengths and distinctive patterns.

Our work extends these approaches by addressing a more complex classification problem: distinguishing not just between human and AI responses, but between multiple specific AI models and different types of human tutors in educational contexts.

2.2 Actionability and Pedagogical Effectiveness

The assessment of pedagogical effectiveness in tutoring responses has gained increasing attention. [Macina et al. \(2023\)](#) introduced MathDial, a dataset for mathematical tutoring dialogues, and evaluated tutor responses using coherence, correctness, and equitable tutoring criteria. [Wang et al. \(2024\)](#) assessed tutoring responses based on usefulness, care, and human-likeness, providing additional dimensions for evaluation.

Most relevant to our actionability assessment, [Daheim et al. \(2024\)](#) introduced a framework for evaluating tutoring responses that includes actionability as a key criterion, defining it as whether a response makes it clear what the student should do next. Their findings suggest that even state-of-the-art LLMs struggle to consistently provide actionable guidance in educational contexts.

2.3 Technical Approaches

For student response evaluation, [Fateen and Mine \(2023\)](#) compared in-context meta-learning and semantic score-based similarity approaches for automated short answer grading in Arabic, demonstrating different computational approaches to evaluating student responses. Additionally, [Maurya et al. \(2025\)](#) developed a comprehensive evaluation taxonomy for assessing LLM-powered AI tutors, highlighting distinctive features in AI-generated pedagogical interactions.

Our work builds upon these foundations while introducing novel techniques specifically tailored to both identity classification and actionability assessment in educational dialogues, including cross-response context augmentation, constraint satisfaction optimization, and instruction-guided training approaches.

3 Dataset and Task Overview

Both tracks utilize a unified dataset of mathematical tutoring dialogues ([Maurya et al., 2025](#)) combining MathDial ([Macina et al., 2023](#)) and Bridge ([Wang et al., 2024](#)) datasets with 300 development dialogues. Track 5 requires classifying responses into nine tutor categories (human expert/novice and seven LLMs), with each conversation containing unique tutor identifications. Track 4 evaluates response actionability using three categories (Yes/To some extent/No). Both tasks use exact macro F1 score as the primary evaluation metric.

4 Methodology

Our team (Phaedrus) approach combines multiple transformer-based models with task-specific architectural enhancements and ensemble techniques. We develop a unified framework that addresses both tutor identity classification and actionability assessment while leveraging shared components and complementary innovations.

4.1 Base Model Architecture

The core of our system utilizes several transformer variants, each selected for specific strengths in educational dialogue analysis:

- **DeBERTa-v3-large** (He et al., 2023): 24 layers, 1024 hidden size, 304M parameters
- **DeBERTa-v3-base** (He et al., 2023): 12 layers, 768 hidden size, 86M parameters
- **DeBERTa-v3-small** (He et al., 2023): 6 layers, 768 hidden size, 44M parameters
- **Longformer-base-4096** (Beltagy et al., 2020): 12 layers, 768 hidden size, 149M parameters, with efficient attention for long sequences
- **BigBird-RoBERTa-large** (Zaheer et al., 2021): 24 layers, 1024 hidden size, 340M parameters, with block sparse attention
- **Qwen-2.5-0.5B** (Qwen et al., 2025): 24 layers, 1024 hidden size, 0.5B parameters, featuring advanced positional embeddings and multi-query attention
- **Zephyr-7B-alpha** (Tunstall et al., 2023): 32 layers, 4096 hidden size, 7B parameters, based on Mistral architecture with sliding window attention

4.2 Shared Architectural Enhancements

Both tasks benefit from several common architectural innovations:

Response Tokenization and Selective Attention: We added special tokens [R_START] and [R_END] to explicitly mark tutor response boundaries. This enables custom attention masking that zeros out attention weights for tokens beyond the [R_END] marker, forcing models to focus specifically on response content rather than surrounding context.

Generalized Mean (GeM) Pooling: Instead of standard mean pooling, we implemented GeM pooling with a learnable parameter p to compute sequence-level representations. Given a sequence of hidden vectors $x = \{x_1, x_2, \dots, x_n\}$, where each $x_i \in \mathbb{R}^d$ is the hidden representation of the i -th token and $n = |x|$ is the sequence length, GeM pooling is defined as:

$$\text{GeM}(x) = \left(\frac{1}{n} \sum_{i=1}^n x_i^p \right)^{1/p} \quad (1)$$

Here, the exponentiation and root are applied element-wise, and $p \in \mathbb{R}$ is a learnable parameter that controls the sharpness of the pooling operation.

Multi-Sample Dropout: Inspired by (Inoue, 2020), we implemented multi-sample dropout with varying rates (0.2 to 0.27) applied to the same representation, then averaged the results. This acts as an implicit ensemble, reducing variance without additional computational cost.

4.3 Task-Specific Innovations

4.3.1 Track 5: Identity Classification Enhancements

For tutor identity classification, we developed several specialized techniques:

Cross-Response Context Augmentation: Rather than treating each response in isolation, we concatenate all available responses to the same question from different tutors, creating rich comparative context. This allows models to learn distinctive patterns by seeing how different tutors address identical student queries.

Constraint Satisfaction Post-processing: We formulated the response classification task as a constraint satisfaction problem to ensure that each class is assigned at most once per conversation, reflecting the assumption that a tutor identity should not repeat in a single dialogue.

Let c denote a conversation with a set of responses $\mathcal{R}_c = \{r_1, r_2, \dots, r_n\}$, and let $p_{r,j}$ represent the predicted probability that response $r \in \mathcal{R}_c$ belongs to class j , where $j \in \{0, 1, \dots, 8\}$. Total there are 9 classes starting from 0 to 8 where class "0" is considered as "novice". We define binary decision variables $x_{r,j} \in \{0, 1\}$ indicating whether response r is assigned to class j . The objective is to maximize the total assignment confidence while satisfying the uniqueness constraint per class within each conversation:

$$\text{maximize } \sum_c \sum_{r \in \mathcal{R}_c} \sum_{j=0}^8 p_{r,j} \cdot x_{r,j} \quad (2)$$

$$\text{subject to } \sum_{j=0}^8 x_{r,j} = 1 \quad \forall r \in \mathcal{R}_c \quad (3)$$

$$\sum_{r \in \mathcal{R}_c} x_{r,j} \leq 1 \quad \forall j \in \{0, \dots, 8\}, \forall c \quad (4)$$

$$x_{r,j} \in \{0, 1\} \quad (5)$$

We opted for a greedy algorithm due to its practical efficiency and implementation simplicity. By prioritizing responses with the highest prediction confidence and assigning them the most probable unassigned class, the method effectively resolves assignment conflicts with minimal computational cost. Empirical results show that this approach improves macro F1 scores by 2–3%, highlighting its effectiveness in enforcing consistent class assignments within conversations.

Algorithm 1 Constraint Satisfaction Algorithm

- 1: **for all** conversations c **do**
 - 2: $A_c \leftarrow \emptyset$ ▷ Set of already assigned classes in conversation c
 - 3: Sort responses $r \in \mathcal{R}_c$ by $\max_j p_{r,j}$ in descending order
 - 4: **for all** response r in sorted order **do**
 - 5: $\hat{j} \leftarrow \arg \max_{j \notin A_c} p_{r,j}$ ▷ Best unassigned class
 - 6: Assign class \hat{j} to response r
 - 7: $A_c \leftarrow A_c \cup \{\hat{j}\}$
 - 8: **end for**
 - 9: **end for**
-

4.3.2 Track 5: Meta-Model Ensemble with Pseudolabeling

Our Track 5 ensemble combines six transformer models through a sophisticated meta-modeling pipeline and was able to achieve 1st position Table 1:

1. **Base Model Predictions:** We collect class probability outputs from all six transformer models (54 features total)
2. **Feature Enhancement:** We augment with TF-IDF vectors, count vectors, linguistic features, and math-specific markers

3. **Gradient Boosting:** We train LightGBM, XGBoost, and CatBoost models on combined features

4. **Pseudolabeling:** High-confidence test predictions (probability > 0.85) are added to training data with constraint satisfaction

5. **Voting:** Final predictions use weighted voting across all meta-models

4.3.3 Track 4: Actionability Assessment Enhancements

For actionability assessment, we implemented instruction-guided training:

Actionability Criteria Instruction: We incorporated explicit actionability assessment criteria directly into model input:

```

Instruction: Analyze the tutor's
response and determine if it
provides actionable guidance to the
student.
Classification Rules:
- Label as "Yes" if the response gives
specific, clear instructions on what
to do next
- Label as "To some extent" if the
response hints at needed action but
lacks specificity
- Label as "No" if the response only
provides the answer without guidance
Remember: Focus on whether the response
guides the student's next steps, not
just whether it's correct.

```

4.3.4 Track 4: Optimized Weighted Ensemble

For Track 4, we developed a streamlined ensemble approach:

1. **Model-Level Weighting:** Global weights for each model applied to all class probabilities
2. **Model-Class Weighting:** Individual weights for each model-class combination (12 weights total)
3. **Threshold Optimization:** Class-specific probability thresholds to address class imbalance
4. **Hyperparameter Optimization:** Optuna-based optimization using macro F1 as the target metric

Table 1: Task 5 Leaderboard: Identity Classification

Rank	Team	Ex. F1	Ex. Acc
1	Phaedrus	0.9698	0.9664
2	SYSUpporter	0.9692	0.9657
3	Two Outliers	0.9172	0.9412
4	JInan_Smart Education	0.8965	0.8940
5	BLCU-ICALL	0.8930	0.8908

4.4 Training Strategy

Our team (Phaedrus) training strategy incorporated several techniques to maximize performance across both tasks:

Cross-Validation: We employed 5-fold Stratified Group K-Fold cross-validation, ensuring dialogues from the same conversation ID remained in the same fold to prevent data leakage while maintaining class distribution.

Hyperparameter Configuration: We used AdamW optimizer with weight decay of 0.003, learning rates ranging from 1e-5 to 3e-5 depending on model size, and OneCycleLR scheduler with maximum learning rate reached at 30% of training steps. For larger models, we implemented gradient accumulation with effective batch sizes of 16-32.

Task-Specific Input Formatting: To maximize ensemble diversity, we designed distinct input templates for different model architectures, each optimized for their specific attention mechanisms and training paradigms:

BERT-family Models (DeBERTa, Longformer, BigBird):

```
[Question] + [SEP] + [R_START] + [
  Response] + [R_END] + [SEP] + [
  Context]
```

Structured format with explicit token boundaries for enhanced attention control

Qwen-2.5 Model:

```
Track 5: Question: [Question]; Answer: [
  Response]; Context: [Context]
Track 4: Question: [Question]; Response:
  [Response]
```

Natural language format optimized for instruction-following capabilities

Zephyr-7B Model:

```
Question: [Question]; Answer: [Response]
```

Parameter-Efficient Fine-tuning: For larger models, we utilized Low-Rank Adaptation (LoRA) with model-specific configurations:

Qwen-2.5 used rank=256/alpha=512 (Track 4) or rank=64/alpha=128 (Track 5), while Zephyr used rank=16/alpha=32. Models were quantized to 4-bit or bfloat16 precision to reduce memory requirements.

Early Stopping and Regularization: We implemented early stopping based on validation macro F1 score with patience of 3 epochs. Dropout rates were set to 0.1 for base models, with multi-sample dropout providing additional regularization through ensemble-like averaging.

5 Experiments and Results

5.1 Experimental Setup

We trained our models using 5-fold cross-validation with early stopping based on validation macro F1 score. Each model was trained for 25 epochs using AdamW optimizer with weight decay of 0.003 and OneCycleLR scheduler.

5.2 Track 5: Tutor Identity Classification Results

Table 2 presents the performance of our identity classification system.

Our Track 5 system achieved a macro F1 score of 0.9596, securing rank 1st 1 in the competition leaderboard. The results demonstrate several key findings:

1. **Cross-Response Context** provides the largest individual contribution, confirming that comparative information between different tutor responses is highly valuable for distinguishing tutor identities.
2. **Pseudolabeling** adds consistent improvement across all classes, with the largest gains for classes with fewer training examples.
3. **Ensemble Diversity** proves crucial, as each model contributes uniquely to final performance.

5	Phaedrus	0.6907	0.7298	0.8346	0.8656

5.3 Track 4: Actionability Assessment Results

Table 4 presents the performance of our actionability assessment system.

Our Track 4 system achieved a macro F1 score of 0.655, securing 5th Table 3 place on the competition leaderboard. The results reveal:

1. **Model-Class Weighting** outperforms simple model-level weighting, suggesting different models have strengths for different actionability categories.
2. **Instruction Guidance** significantly improves model understanding of actionability criteria.
3. **Middle Category Challenge:** The "To some extent" category shows lower performance, reflecting inherent ambiguity in partial actionability.

5.4 Feature Importance Analysis

Figure 1 shows feature importance from our Track 5 LightGBM meta-model, revealing model-class specialization patterns.

The analysis reveals that different architectures excel at detecting specific tutor identities, validating our multi-model ensemble approach. Each

LLM leaves distinct "fingerprints" detectable by specialized transformer architectures.

6 Discussion

Our comprehensive approach to both tutor identity classification and actionability assessment provides valuable insights into the current state of AI tutoring systems and their relationship to human tutoring effectiveness.

6.1 Cross-Task Insights

The combination of both tasks reveals important patterns:

1. **Identity-Actionability Correlation:** Our analysis suggests that human expert tutors consistently receive higher actionability ratings than most LLMs, indicating that the source of a response correlates with its pedagogical effectiveness.
2. **LLM Differentiation:** Different LLMs show distinct patterns not only in linguistic fingerprints but also in their ability to provide actionable guidance. This suggests that model architecture and training approaches influence pedagogical capabilities.
3. **Detectability vs. Quality:** Despite LLMs' increasing sophistication in generating

Figure 1: Top 10 feature importance scores showing model-class specialization in tutor identity. Each feature represents how confident a specific transformer architecture is in predicting a particular tutor identity. For example, "Phi3.deberta.large" indicates the DeBERTa-large model's probability output for the Phi3 LLM class classification.

human-like responses, they remain detectable through subtle patterns while showing varying quality in educational effectiveness.

6.2 Technical Contributions

Our methodology contributes several innovations to educational dialogue assessment:

- 1. Cross-Response Context Augmentation:** This technique significantly improves identity classification by providing comparative information, suggesting that tutor identity is best understood in relation to alternative responses.
- 2. Constraint Satisfaction Integration:** The post-processing approach for enforcing unique class assignments demonstrates how task-specific constraints can be integrated into neural classification systems.

- 3. Instruction-Guided Training:** The explicit incorporation of assessment criteria into model input proves effective for actionability evaluation, suggesting broader applications for criterion-based classification tasks.

- 4. Multi-Model Specialization:** Our feature importance analysis confirms that different transformer architectures capture complementary aspects of educational dialogues, supporting diverse ensemble approaches.

6.3 Educational Implications

The findings have significant implications for educational technology:

- 1. Transparency and Accountability:** The ability to reliably identify AI vs. human tutoring responses enables better transparency in educational settings where students may not be aware of AI involvement.

2. **Quality Assurance:** Automated actionability assessment can provide real-time feedback to improve both human and AI tutoring responses, potentially enhancing educational outcomes.
3. **AI Development Guidance:** The identification of specific areas where LLMs fall short in actionability provides clear targets for improving AI tutoring systems.
4. **Hybrid Systems:** Understanding the complementary strengths of human and AI tutors can inform the design of hybrid systems that leverage the best aspects of both.

6.4 Methodological Insights

Our approach reveals several important methodological considerations:

1. **Task Complementarity:** The combination of identity classification and quality assessment provides a more comprehensive evaluation framework than either task alone.
2. **Context Importance:** Both tasks benefit significantly from contextual information, whether through cross-response comparison or instruction guidance.
3. **Ensemble Effectiveness:** Different ensemble strategies (meta-learning vs. weighted voting) prove optimal for different tasks, suggesting that ensemble design should be tailored to specific problem characteristics.
4. **Constraint Integration:** The successful integration of domain constraints (uniqueness) into neural models demonstrates the value of combining symbolic and connectionist approaches.

These findings collectively demonstrate that effective educational dialogue assessment requires sophisticated approaches that consider both the source and quality of responses, with important implications for the development and deployment of AI tutoring systems.

7 Acknowledgments

We would like to thank the organizers of the Pedagogical Ability Assessment of AI-powered Tutors

shared task and the Building Educational Applications (BEA) 2025 workshop for running this competition. We also thank the anonymous reviewers for their insightful and constructive comments, which helped raise the standard of this manuscript considerably.

8 Limitations

While our multi-task approach achieved strong performance on both BEA 2025 Shared Task (Kochmar et al., 2025) tracks, several limitations should be noted:

1. **Domain Specificity:** Our models were trained and evaluated specifically on mathematical tutoring dialogues. Performance may not generalize to other educational domains with different discourse patterns or pedagogical requirements.
2. **Language and Cultural Constraints:** The dataset primarily consisted of English-language dialogues reflecting specific educational contexts. Performance on multilingual or cross-cultural tutoring scenarios remains untested.
3. **Temporal Limitations:** As LLMs continue to evolve rapidly, the distinctive patterns identified by our models may change. Future versions of the same LLMs might exhibit different characteristics, potentially reducing classification effectiveness.
4. **Computational Requirements:** Our approach relies on large transformer models and sophisticated ensemble techniques, requiring significant computational resources that may limit practical deployment in resource-constrained educational environments.
5. **Interpretability Challenges:** While our models achieve high classification accuracy, they provide limited insights into the specific linguistic or pedagogical features that drive classification decisions, making it difficult to extract actionable guidance for improving tutoring responses.
6. **Category Granularity:** The discrete categorization schemes may oversimplify complex phenomena—tutor identity includes many

sub-variations within categories, and actionability might be better represented as a continuum rather than discrete classes.

Future work could address these limitations by expanding to multiple educational domains, developing more efficient architectures, incorporating explainable AI techniques, and exploring the explicit modeling of cross-task relationships. Additionally, longitudinal studies tracking LLM evolution and cross-cultural validation would strengthen the generalizability of these approaches.

Emergent Wisdom at BEA 2025 Shared Task: From Lexical Understanding to Reflective Reasoning for Pedagogical Ability Assessment

Raunak Jain^{1*} and Srinivasan Rengarajan¹

¹Intuit

{raunak_jain1, srinivasan_rengarajan}@intuit.com

Abstract

For the BEA 2025 shared task on pedagogical ability assessment, we introduce **LUCERA** (Lexical Understanding for Cue Density–Based Escalation and Reflective Assessment), a rubric-grounded evaluation framework for systematically analyzing tutor responses across configurable pedagogical dimensions. The architecture comprises three core components: (1) a rubric-guided large language model (LLM) agent that performs *lexical and dialogic cue extraction* in a self-reflective, goal-driven manner; (2) a cue-complexity assessment and routing mechanism that sends high-confidence cases to a fine-tuned T5 classifier and escalates low-confidence or ambiguous cases to a reasoning-intensive LLM judge; and (3) an *LLM-as-a-judge* module that performs structured, multi-step reasoning: (i) generating a domain-grounded reference solution, (ii) identifying conceptual, procedural and cognitive gaps in student output, (iii) inferring the tutor’s instructional intent, and (iv) applying the rubric to produce justification-backed classifications. Results show that this unique combination of LLM powered feature engineering, strategic routing and rubrics for grading, enables competitive performance without sacrificing interpretability and cost effectiveness.

1 Introduction

High-quality formative feedback is a cornerstone of effective learning: timely, specific guidance helps learners close knowledge gaps, consolidate correct mental models, and sustain motivation (Anderson et al., 1995; Hattie and Timperley, 2007). Yet providing rich feedback at scale remains difficult. The BEA-2025 Shared Task (Kochmar et al., 2025) tackles this challenge by pairing a learning-science-grounded evaluation taxonomy (Maurya et al., 2025) with MRBENCH (Maurya et al., 2025),

a benchmark that fuses math-centric tutoring dialogues from MATHDIAL (Macina et al., 2023) and BRIDGE (Wang et al., 2024b). The competition assesses four pedagogically salient dimensions—*Mistake Identification* (MI), *Mistake Location* (ML), *Providing Guidance* (PG), and *Actionability* (ACT)—thereby offering a unified, standardised test-bed for measuring the pedagogical competence of AI tutors.

While we participate in the shared task, our goal extends beyond leader-board performance (see 7 for more details). We introduce **LUCERA** (Lexical Understanding for Cue density–based Escalation and Reflective Assessment), a novel hybrid architecture that unifies fast lexical heuristics, confidence-aware routing, and reasoning capabilities of large-language-models (LLMs). **LUCERA**, positioned as a general research contribution, demonstrates how an adaptive cascade can deliver interpretable, scalable, rubric-faithful evaluation—attributes that matter both inside and outside competition settings.

Existing approaches to pedagogical-quality assessment occupy two extremes. At one end, rule-based cue extractors offer transparency and speed but falter when feedback is implicit or domain-specific (Lehman et al., 2019; Wang et al., 2020; Wollny et al., 2021; Macina et al., 2023). At the other, rubric-grounded LLM judges achieve broad coverage yet impose high computational cost and, when used indiscriminately, act as opaque monoliths that are hard to audit (Liu et al., 2023b; Maurya et al., 2025; Tack et al., 2023). Bridging these extremes, stepwise chain-of-thought (CoT) verification recovers subtle pedagogical intent but further magnifies latency and cost (Daheim et al., 2024; Wang et al., 2024b; Jain, 2025).

LUCERA orchestrates these complementary paradigms in a three-stage pipeline. A lightweight lexical-cue extractor provides instant, interpretable signals; a complexity-aware router allocates re-

*Corresponding author: raunak_jain1@intuit.com

sponses to either a heuristic XGBoost scorer, a fine-tuned T5 classifier, or a reflective CoT judge; and a final rubric-aligned verdict is produced only in low confidence scenarios. All LLM-based tasks in this work were performed using Qwen/Qwen2-1.5B-Instruct (Yang et al., 2024). This design achieves a 2.4× throughput gain over blanket LLM judging on the BEA-2025 dev set while maintaining rubric fidelity. Beyond the task, we argue that *LUCERA* offers a principled template for scaling LLM-based pedagogical quality assessment wherever feedback quality, cost, and transparency must be balanced.

The remainder of this paper is organised as follows: Section 2 surveys prior work on pedagogical-quality assessment, LLM judges, verification pipelines, and intelligent routing; Section 3 describes *LUCERA*'s architecture; Section 4 and Section 5 detail the feature extraction and classification components; Section 6 explains the reflective LLM judge; Section 7 reports empirical results; and Section 7 concludes with limitations and directions for future research.

2 Related Works

Surface-level cue extraction. Early work framed pedagogical quality as a pattern-recognition problem: if a tutor turn contains directive verbs (*try*, *consider*), contrastive discourse markers (*however*, *because*), or worked-example fragments, it likely advances learning (Lehman et al., 2019; Wang et al., 2020). Rule-based and linear classifiers built on these *lexical cues* offered millisecond latency and clear rationales, and they continue to power production intelligent tutoring systems (Bringula and Basa, 2018). Nevertheless, large corpus studies show cue sparsity and STEM-specific jargon severely degrade their recall and domain transferability (Wollny et al., 2021; Macina et al., 2023).

LLM-as-a-Judge and Confidence based Cascades. The arrival of GPT-4-class models sparked a shift to *rubric-grounded* prompting: an LLM reads a turn and scores each dimension directly (Liu et al., 2023b). Frameworks such as LLM-RUBRIC formalise this practice and report sizeable gains across open-ended tasks (Xia et al., 2025). Yet *unconditional* LLM judging inflates inference cost (Jung et al., 2025; Schuster et al., 2022), produces verbose rationales of uneven quality (Saito et al., 2023; Ohi et al., 2024; Wang et al., 2024a), and can hallucinate additional rubric cri-

teria (Li et al., 2023). Recent selective evaluation frameworks provide provable guarantees of human agreement while maintaining high coverage (Jung et al., 2024), achieving better human alignment than monolithic LLM judges while being substantially more cost-effective. These findings strongly motivate the search for *selective* depth in LLM-based evaluation.

Stepwise verification and reflective reasoning.

Recent studies introduce a verification stage in which an LLM first generates a reference solution and then aligns it with the learner's work before labelling (Daheim et al., 2024; Wang et al., 2024b). Such *chain-of-thought* (CoT) pipelines help identify correct pedagogical strategies by boosting understanding of student gaps (Jain, 2025). Complementary efforts build testbeds (e.g., TutorGym) and benchmarks that grade the fidelity of reasoning chains (Li et al., 2025; Jacovi et al., 2024). However, each additional reasoning step multiplies latency and cost, making blanket deployment impractical at classroom scale.

Intelligent routing and hybrid cascades.

Outside education, researchers mitigate the cost-accuracy trade-off by cascading small and large models, deferring only hard instances. Contemporary confidence-tuned cascades (Xu and McAuley, 2022), cascade-aware training (Zhang et al., 2024), and calibrated ensemble policies (Wagner et al., 2024) achieve 1.5–3× speed-ups without loss of accuracy. *Educational NLP*, by contrast, has yet to embrace hybrid routing: state-of-the-art graders for assignments (Chiang et al., 2024), short-answer scoring (Chang and Ginter, 2024), and essay evaluation (Latif and Zhai, 2024; Jiang and Bosch, 2024) all deploy a single, monolithic LLM without confidence-based deferral. Bridging this gap remains an open opportunity for future assessment systems.

Summary and open gap. The literature thus presents three partially solved challenges—speed (cue extractors), depth (CoT verifiers), and transparency (rubric-grounded judging)—addressed in isolation. No prior system unifies them under a single rubric while allocating compute *proportionally* to instance difficulty. By integrating cue density, calibrated confidence, and stepwise verification into one adaptive cascade, *LUCERA* fills this gap and provides the first cost-aware, rubric-consistent pipeline for tutor-response evaluation.

3 System Overview

LUCERA is a three-stage pipeline designed to assess the pedagogical quality of tutor responses. The system processes tutor responses through the following components:

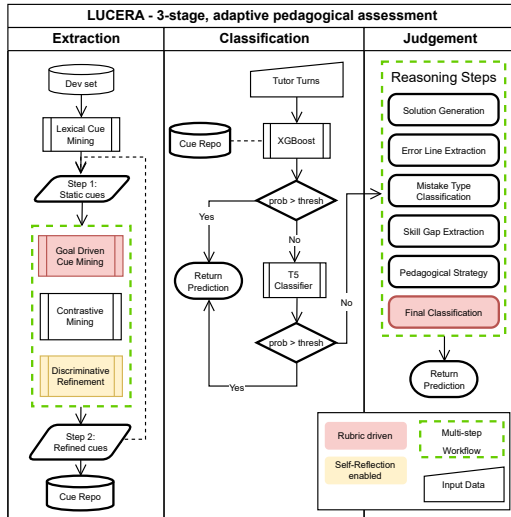

Figure 1: Overview of *LUCERA*'s three-stage pipeline: (1) Rubric-Guided, goal driven lexical cue extractor identifies pedagogical features, (2) XGBoost and T5 based classifiers to solve for feature rich scenarios (3) Multi-step LLM judge for ambiguous and complex evaluation scenarios.

1. Rubric-Guided Lexical Cue **Extraction**: Identifies lexical and dialogue cues aligned with rubric dimensions via a self-reflective LLM agent. Maps directly to pedagogical criteria, maintaining interpretability and transparency throughout the feature extraction process.
2. XGBoost or Seq2Seq based **Classification**: Routes cases based on cue density and confidence. Deploys lightweight XGBoost or T5 models for efficient assessment of high-confidence cases with clear lexical patterns.
3. Step-wise LLM **Judgement**: Handles ambiguous or complex cases through multi-step reasoning. Generates reference solutions, identifies student knowledge gaps, and applies rubric criteria to deliver in-depth pedagogical analysis.

The rubric schema grounds both the cue extractor and the LLM judge, providing uniform evaluation criteria. After extracting cues from a tutor

response, the system applies confidence-based routing: high-certainty cases proceed to a lightweight T5 classifier, while ambiguous ones are escalated to a reasoning-intensive LLM judge, conserving computation without sacrificing pedagogical depth.

4 Rubric-Guided Lexical Cue Extraction

We systematically developed a comprehensive feature taxonomy spanning multiple linguistic levels to classify tutor responses across pedagogical dimensions (MI, ML, PG, ACT), enabling fine-grained analysis of pedagogical signals in tutorial discourse.

4.1 Step 1: Linguistically-Grounded Feature Engineering

Lexical Cues

These cues provide shallow yet effective insights into semantic content and form of tutor responses:

- **Volumetric Features**: Basic text-level metrics including word, character, and sentence counts (Yang, 2024) serve as proxies for response depth. Low word counts may negatively correlate with PG and ACT due to insufficient detail.
- **Question Words**: Presence of interrogatives (e.g., "what," "why," "how") identified via counting pre-defined question words (Demszky et al., 2018), hypothesized to positively correlate with PG and ACT by signaling engagement and elaboration.
- **Feedback Words**: Terms like "correct," "mistake," or "however"—extracted using sentence-level sentiment or discourse tagging (Negi and Buitelaar, 2015)—expected to signal MI by indicating evaluative judgment. For example, "You're close, but remember" is a definite feedback phrase.
- **Directive Verbs**: Instructional verbs (e.g., "calculate," "explain," "solve") extracted using POS tagging and grammatical mood detection (Cohen et al., 2004), often implying actionability. For example, "Let's calculate that," "can you think of a way to calculate?" are all instructional phrases.
- **Hedging Words**: Words like "maybe," "might," or "could" introducing nuance or tentativeness, often associated with PG and ACT

by softening directive tone (Deng et al., 2025). For example, "I think maybe you need one more step," "maybe we can use a hundreds chart or count up" demonstrate this.

- **Pronoun Ratios:** Ratios of second-person (you/your) to first-person (I/my) pronouns indicating student-centeredness or tutor-centeredness, relevant for PG and ACT (Qureshi and Strube, 2022). **Student-centeredness** refers to responses focusing on engaging students directly, guiding actions, or providing feedback, characterized by higher frequency of second-person pronouns. **Tutor-centeredness** reflects tutor’s perspective, explanations, or insights, marked by higher frequency of first-person pronouns. Higher ratio of second-person to first-person pronouns suggests student-centric approach emphasizing direct instruction, while lower ratio indicates tutor-centric approach sharing tutor’s reasoning. For example, "but remember your initial calculation," "but actually, you did add Kylie’s 3 towels" are student-centered responses indicating PG.

4.1.1 Syntactic Complexity

Syntactic complexity is measured via average sentence length and subordinate clause density using dependency parsing (Crossley and McNamara, 2022). High complexity may hinder comprehension, potentially impacting PG and ACT despite informative content.

4.1.2 Pragmatic and Discourse Cues

These features capture pragmatic and contextual dimensions:

- **Discourse Markers:** Cues such as "however," "for example," or "but" indicating relationships between discourse units, helping differentiate between elaboration for PG and contradiction for MI (Dai and Huang, 2018).
- **Conversational Uptake:** Semantic alignment of tutor’s response with preceding turns, computed using pre-trained dialogue embedding models (Demszky et al., 2021). High uptake suggests relevance and coherence, especially for PG.
- **Pedagogical Intent:** Pre-trained NLI models capturing latent pedagogical intent beyond

surface features, by computing the 3-way softmax probabilities (entailment, contradiction, neutral) between tutor responses (premise) and intent descriptions (hypothesis) (Reimers and Gurevych, 2019). The entailment probability values [0-1] directly serve as feature weights, enabling nuanced quantification of pedagogical intents like supportiveness and elaboration.

- **Dialogue Act (DA) Classification:** Responses categorized into high-level DAs (e.g., 'Correction,' 'Hint,' 'Instruction') using pre-trained models (Noble and Maraev, 2021), serving as semantically rich signals—e.g., 'Correction' aligns with MI/ML while 'Instruction' relates to PG and ACT.

4.1.3 Feature Encoding Summary

Feature encoding employs a dual representation strategy: (1) numeric quantification (counts for volumetric features, pronoun ratios) and (2) TF-IDF vectorization (Salton and Buckley, 1988) with category-specific lexicons (feedback, directive, hedging words, discourse markers). Pedagogical intent features leverage NLI entailment probability values [0-1] as continuous feature weights. This complementary approach integrates statistical surface patterns with semantic-level analysis to capture both explicit and implicit pedagogical signals.

4.2 Step 2: LLM-Driven Discriminative Feature Refinement

Our approach employs a multi-stage pipeline that transforms initial lexical features into discriminative, contextually-validated pedagogical indicators. This process ensures alignment with assessment rubrics through progressive refinement, as illustrated in Figure 1 (*Extraction - Refined Cues*):

1. **Goal-Directed Feature Extraction:** LLM analyzes conversation data to identify discriminative features through an iterative, objective-oriented process guided by the initial seed features from 4. The extraction process leverages a T5-based (Raffel et al., 2020a) encoder-decoder framework fine-tuned on pedagogical conversations.
2. **Adversarial Refinement:** Features undergo validation against contradictory examples from other conversations, enabling the

LLM to eliminate spurious correlations and strengthen genuinely predictive indicators.

3. **Lexical Cue Repository Update:** Validated features are populated back into the cue repository, and steps 1-3 are repeated until no new features are found, ensuring a comprehensive and stable set of pedagogically discriminative features.

This methodology produces feature sets that transcend mere textual presence to capture pedagogical quality signals validated against both assessment criteria and challenging counterexamples.

4.3 Feature EDA Summary

We conducted systematic exploratory data analysis on development set tutor responses to quantify relationships between engineered features and pedagogical dimensions (MI, ML, PG, ACT) using Pearson correlation coefficients and distributional statistics, as detailed in Table 1. Key abbreviations include: **Vol** (Volumetric Features), **Ques** (Question Words), **Fdbk** (Feedback Words), **DV** (Directive Verbs), **Hed** (Hedging Words), **ProR** (Pronoun Ratios), **Y/N/TSE** (Yes/No/To Some Extent), **Read** (Readability score based on `flesch_reading_ease` (Flesch, 1948)), and **H/M/L** (Higher/Medium/Lower correlation trend across response categories).

4.3.1 Feature Influence based on Pearson Correlation

Table 1 summarizes key feature influences on pedagogical dimensions, where H/L/M indicates High/Low/Medium influence for Yes/No/TSE classes respectively. Analysis of these patterns reveals several critical insights:

- **Volumetric Features** (H/L/L or H/L/H): Longer responses correlate with effective tutoring across dimensions (Chi et al., 2001; Ward et al., 2011), with verbosity particularly important for actionability where detailed guidance enables student progress (VanLehn, 2011).
- **Question Words** (variable patterns): Strong association with ML (H/L/H) shows questioning is essential for modeling learning; moderate impact on MI (M/L/H) reveals interrogatives' dual purpose in challenging misconceptions and guiding reflection (Graesser et al.,

2010; VanLehn et al., 2006). TSE pattern (H) suggests questions create partial pedagogical value (Chen et al., 2011). Radar analysis (Figure 3) confirms Question Words heavily influence ACT while moderately affecting PG and MI across both TSE and "No" classifications.

- **Pronoun Ratios:** Reveals dimension-specific strategies—PG/MI benefit from tutor-centric language (L/H for "Yes"/"No") where expert explanation is valued; ACT/ML favor student-centric approaches (H/L) positioning students as active participants (Nystrand and Gamoran, 1997; Mercer and Littleton, 2009; Biber and Gray, 2006). N-gram analysis (Figure 2) shows distinctive phrases like "looks like you" and "remember that" strongly correlate with PG.
- **Feedback & Directive Words:** Inverse patterns between feedback (L/H/L) and directives (H/L/M) highlight tension between evaluation and instruction (Shute, 2008; Hattie and Timperley, 2007). Combined with hedging patterns, this suggests effective tutoring balances definitive guidance with tentative suggestion (Rowland, 2002; Mackiewicz and Thompson, 2010). Readability scores and Feedback markers most heavily influence MI classification as shown in Figure 3.
- **Discourse Context:** Discourse markers strongly influence MI (H/L/L) and ML (H/L/H) (Fraser, 1999; Sanders et al., 2000). Contrasting readability patterns (MI: M/L/H vs. others: M/H/L) suggest misconception identification benefits from accessible language while model learning sometimes requires complex formulations (McNamara et al., 2010; Crossley et al., 2017). Action-oriented phrases ("closer look," "look at") strongly correlate with ACT dimension (Figure 2). TSE class presents unique classification challenges with subtle linguistic markers and mixed signals—often providing information without prompting direct action.

These patterns reflect pedagogical trade-offs: correction versus guided discovery (Hmelo-Silver et al., 2006), authoritative versus collaborative stance (Scott et al., 2002), and comprehensive explanation versus concise instruction (Wittwer and Renkl, 2010). Differential patterns validate our

Figure 2: Word Correlation with Pedagogical Dimensions (Yes)

taxonomy’s ability to capture distinct tutoring aspects, while shared patterns highlight fundamental qualities of effective pedagogical communication.

Feature	MI	ML	PG	ACT
Vol	H/L/L	H/L/H	H/L/H	H/L/H
Ques	M/L/H	H/L/H	H/L/M	H/L/M
Fdbk	M/L/L	L/H/L	L/H/L	L/H/L
DV	H/L/M	M/H/M	M/H/M	H/L/M
Hed	H/L/H	M/H/H	M/H/M	H/L/H
ProR	M/H/L	L/H/H	L/H/M	H/L/H
DM	H/L/L	H/L/H	M/L/M	M/L/M
Read	M/L/H	M/H/L	M/H/L	M/H/L

Table 1: Summary of Feature Influence Based on Correlations (H: High, L: Low, M: Medium) for classes Yes/No/TSE.

5 Model Cascade, Confidence-Based Routing, and Task Submission

Based on the extracted refined cues from Section 4, we first train an XGBoost model as a baseline to cover cases where lexical coverage is high. Once we identify lack of lexical coverage, we escalate the classification process to a T5 transformer architecture with a generative classification task instruction. We detail the baseline and T5 model architectures, training methodology etc in the following sections. The evaluation metrics are: exact macro F1 score (Ex. F1), exact accuracy (Ex. Acc), lenient macro F1 score (Len. F1), and lenient accuracy (Len. Acc).

5.1 Stage 1: XGBoost + Lexical Cues as Baseline

For a baseline, we train a multi-label (Yes/No/TSE) multi-class classification model using XGBoost (Chen and Guestrin, 2016) with a 70/30 train-val split. Hyperparameter tuning was performed using cross-validation, focusing on key

Figure 3: Normalized Combined Radar Chart by Feature Group(TSE)

parameters such as `max_depth`, `learning_rate`, `n_estimators`, `min_child_weight`, and `subsample`. Table 2 presents the performance on validation dataset of the best run (XGBoost is considerably better than all Yes (majority class for all labels) as a baseline).

Task	Ex.Acc	Ex.F1	Len.Acc	Len.F1
MI	0.71	0.64	0.81	0.73
ML	0.67	0.66	0.85	0.72
PG	0.68	0.66	0.84	0.71
ACT	0.75	0.71	0.81	0.73

Table 2: XGBoost Performance Metrics by Pedagogical Dimension

5.1.1 Feature Impact and Model Limitations:

While the XGBoost model performed well across different pedagogical dimensions, several limitations were identified for improvement in subsequent iterations:

- **Syntactic Complexity and Question-Related Features:** Complex syntactic structures, such as nested clauses or subordinate sentences, can confuse the model. For example, "While it seems correct, you might want to double-check the calculation" may be misclassified as *Yes* for MI due to ambiguous framing. Additionally, interrogative cues are essential for classifying ACT and PG, but rhetorical questions can mislead the model. For instance, "Do you think this is correct?" could be interpreted as actionable, despite expressing doubt.

- **Lexical Features and Semantic Nuance:** Lexical cues, such as keyword spotting, can lead to errors when words appear in unexpected contexts. For instance, "You're doing great! But remember" is encouraging but points to an approach to guide the student toward the correct answer.
- **Pronoun Usage and Intent Ambiguity:** Shifts between tutor-centric ("I/my") and student-centric ("you/your") language cause inconsistent classification. A statement like "You could explain it better" may be classified as a *Yes* for ACT, whereas a similar structure with "I" might be a strong *Yes* for PG. Detecting perspective shifts remains challenging.

5.2 Stage 2: Instruction-Based Seq2Seq Classification

Model Setup: We fine-tune T5-Base (approximately 250M parameters) for instruction-based classification across four pedagogical dimensions: MI, ML, PG, ACT. Each dimension is specified using a distinct prompt prefix. This approach leverages T5's encoder-decoder architecture, with a 512-token context and unified text-to-text pretraining, facilitating efficient and accurate classification (Raffel et al., 2020b; Qorib et al., 2024).

Prompt Template: The model generates a single-token prediction $y \in \{\text{yes, no, maybe}\}$. Each prompt follows this structure:

```
[PEDAGOGICAL_DIMENSION]
[LEXICAL_CUES] <lexical cues>
[TUTOR_TURNS] <concatenated tutor turns>
Output: {yes, no, maybe}
```

Example (Mistake Location):

```
[Providing Guidance]
[LEXICAL_CUES] let us use, what was
[TUTOR_TURNS] ok let us use the information
to help us what was her gross revenue this week?
Output: maybe
```

Loss Function and Evaluation Metrics: We minimize the single-token cross-entropy over our dataset \mathcal{D} :

$$\mathcal{L}(\theta) = - \sum_{(x,y) \in \mathcal{D}} \log p_{\theta}(y | x),$$

where y is the correct label and decoding is constrained to one step (greedy, $\text{max_length} = 1$).

Training Details: We fine-tuned T5-Base via HuggingFace Transformers on an Apple M3 Mac (no GPU) using 70%/30% train/eval splits. Preprocessing involved excluding student turns and initial problem-introduction turns, concatenating remaining tutor turns, and truncating leftmost tokens when exceeding the 512-token limit. Training used batch size 8, AdamW optimizer (weight decay 0.01, LR = 3×10^{-5} with 10% steps linear warmup), and ran for 5 epochs with early stopping (patience=2, dropout=0.1). Decoding was performed greedily with evaluation via dev loss.

Why T5-Base? We selected T5-Base for its empirical and architectural advantages: superior classification performance, with Flan-T5 variants consistently outperforming decoder-only models on GLUE, SuperGLUE, and word-sense disambiguation tasks while matching GPT-3.5 in few-shot settings (Papadopoulos et al., 2024; Liu et al., 2023a); multi-task pre-training on diverse tasks equipping it with transferable NLP skills that generalize without separate heads (Raffel et al., 2020b; Liu et al., 2023a); hardware efficiency at 250M parameters, comfortably running on modest hardware with 512-token input handling and position embeddings preventing truncation issues (Scao et al., 2022; Hu et al., 2023); parameter-efficient fine-tuning via Adapter and LoRA methods matching larger models on MNLI, QNLI, and SST-2 (Hu et al., 2023); and low-data robustness requiring fewer labeled examples to achieve competitive scores compared to masked-encoder counterparts (Papadopoulos et al., 2024; Liu et al., 2023a).

5.3 Confidence-Based Routing Strategy

We implement a probability-based cascade to balance computational efficiency with classification accuracy. Many tutor utterances lack explicit lexical cues that our XGBoost baseline relies on, necessitating a dynamic routing approach.

For input x , we define probability vectors:

- XGBoost: $p_{\text{xgb}}(x) \in [0, 1]^C$ (sigmoid activations)
- T5: $p_{\text{t5}}(x) \in [0, 1]^C$ (softmax over {yes, no, maybe})

The cascade operates in three stages:

1. Route inputs through XGBoost. Accept prediction if $\max_c p_{\text{xgb}}(x)_c \geq \tau_1$.
2. If $\max_c p_{\text{xgb}}(x)_c < \tau_1$, escalate to T5. Accept if $\max_c p_{\text{t5}}(x)_c \geq \tau_2^{(c)}$ for any class c .

Algorithm 1: Learn class-specific precision cutoffs & coverage

Input: Validation set V , classes \mathcal{C} , model probabilities $p_c(x)$ for each class c , true labels $y(x)$, target precisions $\{\alpha_c\}$, start threshold τ_0 , step size δ , upper bounds $\{U_c\}$

Output: Class-wise thresholds $\{\tau_c^*\}$ and coverages $\{\gamma_c^*\}$

```
foreach class  $c \in \mathcal{C}$  do
   $N_c \leftarrow |\{x \in V : y(x) = c\}|$ ;
   $\tau \leftarrow \tau_0$ ,  $\tau_c^* \leftarrow U_c$ ,  $\gamma_c^* \leftarrow 0$ ;
  while  $\tau \leq U_c$  do
     $S \leftarrow \{x \in V : p_c(x) \geq \tau\}$ ;
    if  $|S| = 0$  then
      break
    prec  $\leftarrow \frac{|\{x \in S : y(x) = c\}|}{|S|}$ ;
    if prec  $\geq \alpha_c$  then
       $\tau_c^* \leftarrow \tau$ ;
       $\gamma_c^* \leftarrow |S|/N_c$ ;
       $\tau \leftarrow \tau + \delta$ ;
    else
      break;
return  $\{(c, \tau_c^*, \gamma_c^*) \mid c \in \mathcal{C}\}$ 
```

3. If T5’s confidence is insufficient, defer to an LLM judge.

Thresholds τ_1 for XGBoost and $\tau_2^{(c)}$ for T5 classes are learned on held-out data using Algorithm 1 to guarantee $\geq 95\%$ precision while maximizing coverage. In our experiments, stages 1 and 2 combined to produce 65-70% of predictions with required confidence, with the remaining 30-35% escalated to the LLM judge (discussed in the following section). See Table 3 for the learned thresholds and coverage at each stage.

6 Step-wise LLM-as-a-Judge

When both our lexical + XGBoost baseline and T5 classifier fall below confidence thresholds, we escalate to a multi-step "LLM-as-a-Judge" for final pedagogical-quality classification. In our dev-set evaluation, 31-34% of conversations across each dimension were escalated to the judge.

1. Solution Reasoning Pathway Generation: The judge prompts the LLM to generate a step-by-step expert solution for the given problem,

Stage	Dimension	Thresholds (Yes/No/TSE)	Coverage at Stage
XGBoost	ML	0.85 / 0.45 / 0.55	0.38
	MI	0.82 / 0.48 / 0.52	0.35
	PG	0.88 / 0.42 / 0.58	0.32
	ACT	0.86 / 0.45 / 0.55	0.36
T5	ML	0.80 / 0.45 / 0.55	0.86
	MI	0.78 / 0.42 / 0.58	0.85
	PG	0.82 / 0.48 / 0.52	0.62
	ACT	0.81 / 0.45 / 0.55	0.60

Table 3: Learned thresholds for Yes/No/TSE classes and coverage percentages at each stage for each pedagogical dimension

establishing a reference reasoning pathway against which to align the student’s response (Wei et al., 2022; Daheim et al., 2024; Jain, 2025). This includes parsing the problem, identifying relevant concepts, applying them systematically, and verifying the final result.

2. Error Extraction: The judge isolates the precise span where student reasoning diverges from the expert chain—this concrete "mistake locus" anchors all downstream diagnostic steps (Daheim et al., 2024; Macina et al., 2023). The goal is solely to extract and localize the deviation.

3. Mistake Classification: The mistake is mapped to a structured taxonomy enabling standardized reasoning about pedagogical strategies (Macina et al., 2023). Categories include conceptual errors, procedural/arithmetic errors, misapplied formulas, comprehension errors, and logical breakdowns in multi-step reasoning (Macina et al., 2023; Wang et al., 2024b; Daheim et al., 2024).

4. Skill Gap Mapping: Based on the mistake classification, the judge infers the underlying cognitive skill gap (Jain, 2025), referencing Bloom’s revised taxonomy (Anderson et al., 2001; Krathwohl, 2002). This includes gaps in: Remember (recalling facts), Understand (grasping concepts), Apply (executing procedures), Analyze (breaking down structure), Evaluate (judging correctness), and Create (developing alternate methods).

5. Last Tutor Turn Strategy Identification: Conditioned on the diagnosed cognitive gap, the judge infers the most probable pedagogically aligned instructional strategy (Macina

et al., 2023; Wang et al., 2024b) which the last tutor turn most likely employed. This may include focus questions, probing questions, worked examples, hints, or problem simplification.

6. **Final Classification:** Integrating all intermediate steps along with the inferred instructional strategy employed by the tutor’s last turn, the judge produces a final classification (Yes/No/TSE) for the last tutor turn according to the BEA 2025 Shared Task dimensions (Kochmar et al., 2025). The turn is evaluated for each of the following dimensions: (1) *Mistake Identification*, (2) *Mistake Location*, (3) *Providing Guidance*, and (4) *Actionability*.

Example Judge Output for PG:

Conversation History: Tutor: Hi, could you please provide a step-by-step solution for the question below? Tyson decided to make muffaletta sandwiches for the big game. Each sandwich required 1 pound each of meat and cheese and would serve 4 people. There would be 20 people in total watching the game. The meat cost \$7.00 per pound and the cheese cost \$3.00 per pound. How much money would he spend on the meat and cheese to make enough sandwiches to serve 20 people? Student: To serve 20 people, Tyson needs to make $20/4 = 5$ sandwiches. Each sandwich requires $1+1 = 2$ pounds of meat and cheese...

Extracted Error: Each sandwich requires $1+1 = 2$ pounds of meat and cheese.

Mistake Type: *Right-idea*. The student has the right idea but inaccurately combines meat and cheese quantities into one, leading to a misapplied calculation.

Skill Gap: *Analyze and decompose independent components*. The student understands facts and unit costs but fails to reason about meat and cheese as distinct cost components.

Recommended Strategy: *Provide a hint*. The tutor asks a guiding question to nudge the student to recalculate the meat cost independently, prompting correction without explicit error labeling.

Judge Classification: *Yes*. The tutor turn offers appropriate scaffolding to guide the next step in solving the problem.

6.1 Dev-Set Escalation Impact

Evaluating 30 examples across all rubric dimensions, the LLM Judge reduced classification errors by 50%–60% compared to our T5 baseline, achieving Macro F1 scores above 75% in three tracks and 83.3% in one (Table 4).

Extrapolating these results to hybrid system performance with judge escalation on 30%–35% of

low-confidence cases (**Hypo-Full** column), projections indicate that selective escalation can substantially bridge the gap to top-performing systems.

Track	Top	T5-subm	Judge-30	Hypo-Full
1	71.81	61.0	83.3	67.69
2	59.8	47.7	76.6	56.37
3	58.3	49.0	73.3	56.29
4	70.9	56.6	76.6	62.6

Table 4: Per-track F1: **Top** = best shared-task model; **T5-subm** = T5 model submitted results; **Judge-30** = LLM on 30 escalated dev cases; **Hypo-Full** = simulated performance assuming judge intervention on 30–35% of cases.

7 Submission Results and Analysis

Our team, **Emergent Wisdom**, participated in tracks 1 to 4 based on the architecture described in 3. The metrics and ranking of our best submission, according to the official leaderboard¹, is shown in Tables 5 and 6, which also contrast our Stage 1–2 (router + encoder–decoder) results on the test set against the top shared-task systems. Δ indicates (Ours – Top).

Tr	Top		Ours			Δ	
	Acc	F1	Acc	F1	Rank	Acc	F1
1	94.6%	89.6	93.2%	88.0	21	–1.4	–1.6
2	86.3%	83.9	78.9%	74.4	15	–7.4	–9.5
3	81.9%	78.0	77.3%	69.2	24	–4.6	–8.8
4	88.4%	85.3	80.5%	77.8	30	–7.8	–7.5

Table 5: Lenient metrics performance (Stages 1–2 on test set; Δ = Ours – Top).

Tr	Top		Ours			Δ	
	Acc	F1	Acc	F1	Rank	Acc	F1
1	86.2%	71.8	85.5%	61.0	34	–0.8	–10.8
2	76.8%	59.8	71.9%	47.7	25	–4.9	–12.1
3	66.1%	58.3	61.0%	49.0	21	–5.1	–9.3
4	73.0%	70.9	66.4%	56.6	22	–6.6	–14.3

Table 6: Exact metrics performance (Stages 1–2 on test set; Δ = Ours – Top).

As demonstrated in section 6.1, our analysis reveals that strategic reliance on the judge component for complex cases enables performance within 1-2% macro F1-score of the top-performing systems without increasing computational needs for the whole dataset, suggesting the potential for competitive results based on intelligent routing.

¹<https://sig-edu.org/sharedtask/2025#results>

Limitations

Despite strong performance, our cascade approach faces several limitations: T5-Base’s 512-token context window restricts processing of longer tutoring sessions; both models struggle with ambiguous utterances serving multiple pedagogical functions; performance suffers on underrepresented classes like the "maybe" classification; confidence-based routing relies on carefully tuned thresholds; and analyzing only tutor turns misses important student context. Future work should explore larger context windows, multi-label classification, and more sophisticated conversational modeling.

Correspondence: m.yasser, m.saeed, h.elkordi, a.khalafallah@aic.gov.eg

Abstract

This paper presents the approach and findings of Averroes Team in the BEA 2025 Shared Task Track 1: Mistake Identification. Our system uses the multilingual understanding capabilities of general text embedding models. Our approach involves full-model fine-tuning, where both the pre-trained language model and the classification head are optimized to detect tutor recognition of student mistakes in educational dialogues. This end-to-end training enables the model to better capture subtle pedagogical cues, leading to improved contextual understanding. Evaluated on the official test set, our system achieved an exact macro- F_1 score of 0.7155 and an accuracy of 0.8675, securing third place among the participating teams. These results underline the effectiveness of task-specific optimization in enhancing model sensitivity to error recognition within interactive learning contexts.

1 Introduction

Tutoring has long been recognized as one of the most effective educational interventions, significantly enhancing student learning outcomes. Notably, the 2 sigma problem Bloom (1984) illustrates that students receiving one-on-one tutoring perform two standard deviations better than those in conventional classroom settings, highlighting the profound impact of personalized instruction. However, the scalability of such individualized tutoring remains a challenge due to resource constraints.

Advancements in deep learning Lin et al. (2023) and the emergence of large language models (LLMs) Lieb and Goel (2024); Park et al. (2024) have paved the way for AI-powered tutors capable of delivering personalized, on-demand educational support. These intelligent tutoring systems leverage natural language processing and machine learning techniques to adapt to individual learner needs, providing real-time feedback and tailored

instruction. AI-powered tutors can make quality education available to more people by offering the same benefits as one-on-one tutoring, but for many students at once.

Despite these advancements, evaluating the pedagogical effectiveness of AI tutors remains a significant problem. Traditional evaluation metrics, often adapted from domains like machine translation and summarization, fail to capture the nuanced educational interactions between AI tutors and students. Moreover, while human evaluations are considered the gold standard, they are time-consuming, costly, and lack scalability. This highlights the urgent need for automated, reliable, and pedagogically-informed evaluation frameworks.

Addressing this gap, the BEA 2025 Shared Task Kochmar et al. (2025) focuses on the Pedagogical Ability Assessment of AI-powered Tutors, aiming to develop standardized evaluation methods for AI tutor responses. The task includes four main tracks: Mistake Identification, determining whether the AI tutor correctly identifies student errors; Mistake Localization, pinpointing the exact location or nature of the student's mistake; Guidance Provision, offering constructive feedback or hints to guide the student; and Actionability, ensuring the response leads to a clear next step for the student. These tracks are intended to measure the tutor's effectiveness in supporting student learning and correcting misunderstandings.

This paper describes our contribution to the BEA 2025 Shared Task, in which we leverage large language models (LLMs) to create an automated evaluation method for AI tutors, primarily focusing on the mistake identification track. We investigate multiple strategies, assess their performance, and present a comprehensive ablation study, delivering a scalable, education-focused evaluation framework designed to enhance personalized learning.

2 Related Work

2.1 AI Tutoring Systems

Early Intelligent Tutoring Systems (ITS), developed in the late 1970s and 1980s [Guo et al. \(2021\)](#), employed explicit cognitive or knowledge-tracing models to monitor learners' progress and simulate personalized instruction. Pioneering systems like Anderson and Corbett's Cognitive Tutors [Anderson et al. \(1995\)](#) utilized model-tracing algorithms to instantly detect deviations from expert problem-solving pathways, allowing immediate corrective feedback and error-specific hints. This approach significantly boosted students' learning speed and post-test performance in experimental settings. However, studies of human expert tutors, such as [Hume et al. \(1996\)](#), suggest a more effective approach, using indirect prompts such as Socratic questions or reflective hints to help students independently identify and correct errors. This approach encourages deeper learning and self-reflection, showing a limitation of early ITS.

2.2 Advances in Large Language Models for Educational Dialogue

Recent advancements in large language models (LLMs) have significantly improved their capabilities, especially within educational contexts [Lieb and Goel \(2024\)](#); [Kasneji et al. \(2023\)](#); [Nye et al. \(2023\)](#). Modern LLMs facilitate personalized, interactive tutoring experiences, creating customized content such as quizzes and lesson plans tailored to specific curricula and student proficiency. Furthermore, these models support educators by automating administrative responsibilities, enabling teachers to devote more time to direct instruction and student engagement.

2.3 Evaluation Methods for AI Tutoring Systems

Evaluating AI tutors in education primarily relies on human judgment that score responses on dimensions like mistake identification, clarity, and tone. While expert annotation remains the gold standard, it suffers from inconsistency and lacks a unified protocol, prompting studies such as Tack & Piech [Tack and Piech \(2022\)](#), and Maurya et al. [Maurya et al. \(2025\)](#) propose standardized taxonomies. Pairwise comparisons simplify evaluation by focusing on relative pedagogical effectiveness. However, automatic metrics remain limited: Traditional natural language generation metrics such as BLEU [Pap-](#)

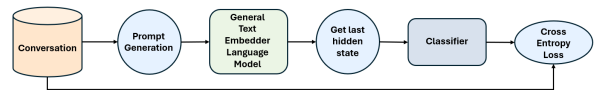

Figure 1: Model Architecture

[inani et al. \(2002\)](#) or ROUGE [Lin \(2004\)](#) poorly reflect pedagogical quality. Recent advances use reference-free approaches such as trained scorers (e.g., DialogRPT [Gao et al. \(2020\)](#)) and LLMs like GPT-4 ¹ to evaluate tutor responses, though their reliability depends heavily on prompt design. Hybrid evaluation methods that combine LLMs and correctness checks are emerging to improve consistency and scalability.

3 System Overview

This section presents the complete methodology adopted for the task. We first formalize the problem, then detail the shared backbone architecture, followed by dedicated subsections describing each experimental variant. Finally, we present our quantitative analysis and comparison between different approaches in 4.3.

3.1 Problem Definition

We address the task of assessing whether an AI tutor's feedback in a dialogue setting correctly identifies a student's mistake. Given a multi-turn conversation between a student and an AI tutor, along with the tutor's final response, the objective is to classify that response as correctly identifying the mistake, to some extent identifying, or failing to do so. This is formulated as a sequence classification problem, where a contextual understanding of the conversation is required for an accurate prediction.

3.2 System Backbone

We employ, as shown in Figure 1, a sequence classification approach. To effectively capture the contextual dependencies in the dialogue, we prepend a task-specific system prompt to the conversation history and the tutor's final turn. The system prompt is defined as:

¹<https://openai.com/index/gpt-4>

System Prompt

You are tasked with evaluating a multi-turn conversation between a math teacher and a student. The conversation is about a mathematical problem and in the form of a dialogue aimed at helping the student arrive at the correct solution.

The student initially provides an incorrect answer. The teacher then engages in follow-up exchanges to help the student uncover and understand the mistake.

You will be given:

- The full conversation up to the student's most recent turn, enclosed within '<CONV>' tags.

- The math teacher's immediate next response, enclosed within '<RESP>' tags.

****Your task****:

- Determine whether the teacher's response in '<RESP>' effectively contributes to identifying or addressing the student's mistake.

- Explain your reasoning clearly and concisely based on the content of the teacher's response and how it relates to the mistake and the original question. Then, provide your final judgment.

A teacher's response is considered a ****mistake identifier**** if it includes:

- A follow-up question, explanation, or prompt that targets the student's misunderstanding or errors in reasoning,

- Or if it guides the student toward re-evaluating key steps relevant to solving the original math problem.

You must output one of the following judgments based on the above criteria:

- ****A**** → If the teacher's response is clearly focused on the student's mistake and relates directly to the solution steps.

- ****B**** → If the response is unrelated to the mistake, irrelevant to the solution steps, or potentially confusing/misleading.

- ****C**** → If the response is only partially relevant or offers indirect guidance that might help the student reflect on the mistake.

****Put Your Output In The Following Format**** <think>The complete reasoning process</think><answer>Your final judgment from the choices (A, B, or C)</answer>

This input is passed through a decoder, where the last hidden-state representation is extracted. A lightweight classification head, implemented as a feed-forward linear layer, is then applied to predict how the tutor response identifies the mistake among three classes (Yes, No, To some extent). This design leverages the model's pretrained contextual embeddings, enhancing its capacity to discern nuanced dialogue interactions.

3.3 GTE-based Sequence Classification Models

We investigate three variants that use the *General Text Embedding* (GTE) family to obtain sentence-level representations, followed by lightweight feed-forward (FF) classification heads:

1. **GTE-MODERNBERT-BASE**² Zhang et al. (2024): the gte-modernbert-base encoder feeds into a single FF layer with a softmax output for prediction.
2. **GTE-QWEN2-1.5B-1FF** Li et al. (2023): embeddings from gte-qwen2-1.5B-instruct³ are passed through one FF layer identical to (1).
3. **GTE-QWEN2-1.5B-2FF**: the same as in (2) but followed by a two-layer FF head before the final softmax output.

Unless otherwise stated, these models are fine-tuned with the optimization settings described in §4.2.

3.4 Qwen2.5-based Sequence Classification Models

We benchmark five instruction-tuned *Qwen2.5* language models, varying both model size and the depth of the feed-forward (FF) classification head that replaces the original causal-LM head:

1. **QWEN2.5-7B-1FF** Team (2024): 7B parameters variant of Qwen2.5⁴; a single FF layer with softmax output. Fine-tuned via LoRA adapters Hu et al. (2022) with rank 16 on all attention and MLP projection layers.

³<https://huggingface.co/Alibaba-NLP/gte-Qwen2-1.5B-instruct>

⁴<https://huggingface.co/Qwen/Qwen2.5-7B>

Figure 2: Class Distribution of the dataset.

2. **QWEN2.5-1.5B-2FF**: 1.5B parameters⁵; a two-layer FF head preceding the final softmax layer; full-parameter fine-tuning.
3. **QWEN2.5-MATH-1.5B-1FF**: math specialized 1.5B variant⁶; one FF layer; full-parameter fine-tuning.
4. **QWEN2.5-0.5B-1FF**: 0.5B parameters; one FF layer; full-parameter fine-tuning.
5. **QWEN2.5-0.5B-2FF**: same 0.5B backbone as (4) but with a two-layer FF head as in (2).

Unless otherwise stated, optimization hyperparameters follow the settings in §4.2.

4 Experiments

4.1 Dataset and Metrics

We conduct our experiments on **MRBench**, an annotated collection of 192 multi-turn student-AI tutor dialogues (1596 tutor responses) released by Maurya et al. (2025). Each tutor’s response is labeled to indicate whether the feedback correctly identifies the student’s error. Figure 2 shows the class distribution in the provided dataset. For model development, we divide the official development data into training and validation splits, retaining 15% of the dataset for validation during fine-tuning while maintaining the same class distribution of the train split. We follow the shared-task protocol and report strict *macro-averaged* F_1 and strict *accuracy* over the MISTAKE-IDENTIFICATION labels of the official test set.

⁵<https://huggingface.co/Qwen/Qwen2.5-1.5B-Instruct>

⁶<https://huggingface.co/Qwen/Qwen2.5-Math-1.5B-Instruct>

4.2 Training Setup

Each model was fine-tuned for no more than ten epochs using AdamW with a linearly decaying learning-rate schedule, reaching a maximum of 1×10^{-5} . We trained with an effective batch size of 64 in bf16 mixed precision on a single NVIDIA RTX-A6000 GPU.

4.3 Results and Analysis

Model	Accuracy (%)	Macro- F_1 (%)
GTE-MODERNBERT-BASE	88.17	66.48
GTE-QWEN2-1.5B-1FF	89.78	74.15
GTE-QWEN2-1.5B-2FF	89.25	72.51
QWEN2.5-7B-1FF	85.48	64.06
QWEN2.5-1.5B-2FF	88.44	71.69
QWEN2.5-MATH-1.5B-1FF	88.44	67.95
QWEN2.5-0.5B-1FF	<u>89.25</u>	<u>72.96</u>
QWEN2.5-0.5B-2FF	88.44	71.15

Table 1: Accuracy and Macro- F_1 on our validation split.

4.3.1 Full fine-tuning wins

Training the entire decoder-only model GTE-QWEN2-1.5B with a single feed-forward head (**1FF**) achieves the best results on our validation split at 74.15 macro- F_1 .

4.3.2 Small-but-efficient models keep pace

The smaller fully fine-tuned QWEN2.5-0.5B-1FF achieved our second best results at 72.96 macro- F_1 with only 1.2 points difference from our best model while cutting memory and latency.

4.3.3 More head depth is not always better

Adding a second feed-forward layer (**2FF**) to the backbone reduces performance.

4.3.4 Domain pre-training helps but not enough

The math-specialized QWEN2.5-MATH-1.5B-1FF outperforms the larger variant QWEN2.5-7B-1FF by 3.89 F_1 with only 20% of its parameter size. However, increasing parameter count of non-specialized models surpasses the benefit of domain-specific training. In our case, QWEN2.5-0.5B-1FF outperforms the trained model by 5.01, QWEN2.5-1.5B-2FF by 4.74, and GTE-QWEN2-1.5B-1FF by 6.2.

4.3.5 Size alone isn’t enough

The PEFT-tuned 7B QWEN2.5-7B-1FF achieves 6th place at 64.06 macro- F_1 , showing that the tuning was not effective.

5 Conclusion

This work benchmarked eight GTE- and Qwen2.5-based sequence-classification models on the MISTAKE-IDENTIFICATION task in AI-tutor dialogues. Full fine-tuning of a medium-sized decoder-only backbone (GTE-QWEN2-1.5B-1FF) achieved the strongest development performance at 74.1 macro-F₁, highlighting that carefully tuned 1.5 B models can outperform much larger 7B LoRA base-lines.

These findings indicate that compact instruction-tuned LLMs can rival, or even surpass, their larger counterparts in pedagogical mistake detection, offering a resource-efficient pathway toward scalable AI tutors. Future work should expand the dialogue corpus, diversify subject matter and languages, incorporate richer pedagogical labels, and pair automatic metrics with human and learning outcome evaluations to approach genuinely effective educational dialogue systems.

Limitations

Our study is constrained by several factors that temper the generality of its findings. First, the evaluation corpus, MRBench, comprises only 1596 labelled tutor responses drawn from a single English, mathematics-focused dataset. Such limited scale and topical focus may bias the models toward the annotation style and error distribution specific to this domain, leaving their behavior untested in other subjects, proficiency levels, or languages.

Second, the present metrics provide only a partial view of the educational effectiveness. Moreover, we rely exclusively on automatic accuracy and macro-F₁; the absence of human judgments or learning-gain measurements means that the impact in real-world scenarios remains uncertain.

Abstract

The rapid adoption of AI in educational technology is changing learning settings, making the thorough evaluation of AI tutor pedagogical performance is quite important for promoting student success. This paper describes our solution for the BEA 2025 Shared Task on Pedagogical Ability Assessment of AI-powered tutors, which assesses tutor replies over several pedagogical dimensions. We developed transformer-based approaches for five diverse tracks: mistake identification, mistake location, providing guidance, actionability, and tutor identity prediction using the MRBench dataset of mathematical dialogues. We evaluated several pre-trained models including DeBERTa-V3, RoBERTa-Large, SciBERT, and EduBERT. Our approach addressed class imbalance problems by incorporating strategic fine-tuning with weighted loss functions. The findings show that, for all tracks, DeBERTa architectures have higher performances than the others, and our models have obtained in the competitive positions, including 9th of Tutor Identity (Exact F1 of 0.8621), 16th of Actionability (Exact F1 of 0.6284), 19th of Providing Guidance (Exact F1 of 0.4933), 20th of Mistake Identification (Exact F1 of 0.6617) and 22nd of Mistake Location (Exact F1 of 0.4935). The difference in performance over tracks highlights the difficulty of automatic pedagogical evaluation, especially for tasks whose solutions require a deep understanding of educational contexts. This work contributes to ongoing efforts to develop robust automated tools for assessing.

1 Introduction

In the past few years, the combination of natural language processing (NLP) and education technology has become one of the most popular areas of study to improve learning, automate feedback, and assist educators and students. With the expansion of blended and fully online courses, there has

been a marked increase in the need for scalable and sophisticated systems that can process learners' responses and tutors' comments. Such systems do not deal well with the subtle, context-sensitive characteristics of educational dialogues. So, assessing the pedagogical effectiveness and a standard evaluation taxonomy of such systems still remains a critical challenge.

An example of effective teaching is when an educator accurately pinpoints a student's misunderstanding, provides appropriate scaffolding towards clear concepts, and gives insightful feedback on desk-work that the students need to accomplish. Some automating aspects of this feedback loop, such as automated essay scoring (Phandi et al., 2015) and dialogic tutoring systems (Wang et al., 2024) have been given attention, but there is not much research that has been done to effectively capture the dynamics of the interplay student answers, tutor's engagement, and teaching style through feedback text's narrative structure.

While LLMs can generate coherent and contextually relevant responses, their ability to understand student misconceptions, provide actual guidance, and create meaningful learning experiences is not guaranteed. The general, area-independent metrics for natural language generation (NLG) (Liu et al., 2023; Gao et al., 2020) do not fit here as the majority of them lack consideration for pedagogical values and need gold references, which are seldom present in online interactions.

In this work, we tackle a comprehensive multi-track evaluation task designed for the evaluation of AI-tutor responses using a set of pedagogically motivated metrics. Building upon the foundations laid by the BEA 2023 Shared Task (Tack et al., 2023), which focused on generating AI teacher responses in educational dialogues, in the BEA 2025 Shared Task (Kochmar et al., 2025) iteration the focus shifted toward evaluating the quality of AI tutor responses. Specifically, it introduced a

*Authors contributed equally to this work.

taxonomy encompassing four pedagogically motivated dimensions: Mistake Identification, Mistake Location, Providing Guidance, and Actionability. Additionally, a fifth track challenged participants to identify the source of anonymized tutor responses, distinguishing between various LLMs and human tutors.

Our key contributions are as follows:

- Developing transformer-based approaches for comprehensive evaluation of AI-tutor responses using a set of pedagogically motivated metrics: mistake identification, mistake location, guidance provision, feedback actionability, and tutor identity prediction.
- Evaluated the performance of state-of-the-art transformer models across five key educational NLP tasks related to tutoring dialogues.

2 Related Works

Daheim et al. (2024) introduced a framework for stepwise solution verification for math reasoning, showing that grounding tutor responses in identified errors improves feedback accuracy where AI tutors are evaluated on their ability to identify and locate mistakes within student responses. Macina et al. (2023) presented *MathDial*, a large dataset of tutoring dialogues where LLMs often struggle with correct mistake spotting without targeted annotations. It includes annotations for mistake locations in math dialogues. This resource has been instrumental in training and evaluating models that can accurately identify and address specific errors in student solutions. Chen et al. (2024) proposed VATE, an AI-driven virtual teacher using prompt engineering and error pools for autonomous mistake analysis, achieving high accuracy in real-world deployment. Lastly, Macina et al. (2024) benchmarked pedagogical capabilities of LLM tutors, confirming that subject knowledge alone doesn't ensure effective error identification without specialized pedagogical training. Additionally, Yan et al. (2024) propose architectures designed to improve error localization in multimodal math tutoring, enhancing the clarity and usefulness of feedback. Recent work in intelligent tutoring systems (ITS) has emphasized the importance of scaffolding and adaptive feedback to enhance student learning outcomes. Liu et al. (2024) explored multimodal tutoring systems powered by large language models, demonstrating how pedagogical instruc-

tions can improve self-paced learning through structured scaffolding, evaluated via a seven-dimension rubric. Complementing this, Kochmar et al. (2020) showed that automated, personalized feedback using NLP and machine learning significantly boosts student performance, highlighting the need for tailoring feedback to individual learners. Similarly, Li et al. (2024) applied NLP-driven adaptive dialogs informed by the Knowledge Integration framework, illustrating how guided conversations help students integrate accurate scientific concepts during instruction. Together, these studies underline the potential of adaptive, pedagogically-aware NLP systems in delivering effective, personalized guidance within educational contexts. Maniktala et al. (2020) proposed "Assertions," an unsolicited hint mechanism delivering partially-worked example steps, which notably increased hint usage and improved learning outcomes, particularly for lower-proficiency learners. Blancas-Muñoz et al. (2018) further emphasized the importance of actionable support by comparing task-relevant hints to distractions in robotic tutoring, finding that direct, task-specific guidance led to better learner performance. Extending this focus to virtual education settings, Liang Liang (2025) applied NLP-based Seq2Seq models for automated feedback generation, achieving high accuracy while enhancing personalization and actionability of feedback in online environments. Collectively, these studies highlight that actionable, timely, and context-aware feedback mechanisms are essential for effective ITS design.

3 Task and Dataset Description

We competed on the BEA 2025 Shared Task¹ (Kochmar et al., 2025) on Pedagogical Ability Assessment of AI-powered tutors. The goal of the work is to assess AI tutor responses in mathematical dialogues when students make errors or show uncertainty. The provided dataset, MRBench (Maurya et al., 2025), includes dialogue contexts, the final student utterance, and corresponding tutor responses from various LLMs (e.g., GPT-4, Llama-3.1) and human tutors. The aim is to find the tutor or predict pedagogical quality in many spheres, including mistake identification and guidance.

The organizers provided Development set, `mrbench_v3_devset.json`, split into 90% for training (2,228 Instances) and 10% for validation (248 Instances). The final evaluation came from

¹<https://sig-edu.org/sharedtask/2025>

Split	Instances	Unique Words	Total Words
Train	2,228	8,134	512,392
Validation	248	3,833	52,981
Test	1,547	7,057	454,720

Table 1: Dataset statistics across different splits.

the Test set, `mrbench_v3_testset.json` (1,547 Instances). Table 1 shows the dataset statistics.

4 Methodology

This section outlines our approaches utilized for Track 1 - Mistake Identification, Track 2 - Mistake Location, Track 3 - Providing Guidance, Track 4 - Actionability, and Track 5 - Guess the Tutor Identity. The study evaluated many transformer-based approaches using hyperparameter optimization to improve performance. The architectural frameworks used for all tasks is illustrated in Figure 1

Figure 1: Overview of the Pedagogical Ability Assessment Process for AI-powered Tutors

4.1 Data Preprocessing and Feature Extraction

We processed `mrbench_v3_devset.json` and `mrbench_v3_testset.json` files for all five tracks. Every distinct tutor response in a conversation stood isolated. Using descriptive markers and newlines, concatenating the “Conversation History” and “Tutor Response” produced the input text for models; instances lacking tutor responses were removed. Relevant annotations (e.g., “Mistake_Identification”) were retrieved for Tracks 1–4 (Mistake Identification, Mistake Location, Providing Guidance, Actionability); their

“Yes,” “To some extent,” “No” labels were mapped to [0, 1, 2]. Development set tutor identities for Track 5 (Guess the Tutor Identity) were mapped to one of nine canonical tutor classes then to numerical labels [0–8]. Feature extraction used pre-trained Transformer models (DeBERTa-V3 base/large, RoBERTa-Large, EduBERT, SciBERT). each model’s particular AutoTokenizer turned input texts into `input_ids`, `attention_mask`, and optionally `token_type_ids`, Padded or trimmed to 512 tokens.

4.2 Transformer-Based Models

The methodological foundation for all five tracks of BEA 2025 Shared Task focuses on the fine-tuning of pre-trained Transformer models (Vaswani et al., 2017). These architectures, with their well-known self-attention mechanisms, are proficient in capturing contextual relationships within text because of the highly sophisticated contexts and excel at capturing intricate contextual relationships within text makes them very suitable for a range of challenges in Natural Language Processing (NLP) (Devlin et al., 2019). Transformer’s ability to model long-range dependencies is critical given the nuanced nature of assessing pedagogical abilities and identifying distinctive tutor characteristics from snippets of dialogues. A collection of models from the Hugging Face Transformers library² was chosen, including those pre-trained specifically on scientific or educational corpora as well as more general NLU models. SciBERT (Beltagy et al., 2019) and EduBERT (Clavié and Gal, 2019) are two, alongside RoBERTa-Large (Liu et al., 2019) and DeBERTa-V3 base and large configurations (He et al., 2021). For each task, these pretrained encoders were modified by adding a sequence classification head for each task. This head has a dropout layer and a linear layer that maps the output representation of the encoder associated with the special [CLS] token to the logits for the respective number of classes for each track. All models had the same input constructed by joining the “Tutor Response” and “Conversation History”. Model-specific tokenizers were used according to each model’s pretraining, with padding and truncation to 512 tokens.

In Track 1, Mistake Identification, the goal was a 3-way classification problem determining if a tutor’s response acknowledged a student’s mistake,

²<https://huggingface.co/transformers>

with labels “Yes”, “To some extent”, and “No”. For this track, we experimented with SciBERT, EduBERT, RoBERTa-Large and DeBERTa-V3 base. SciBERT, which was pretrained on a large corpus of scientific literature, was selected because it could be expected to perform well with the formal and technical language of mathematics. EduBERT was chosen because it was trained on educational data, which may enhance understanding in teaching cases. RoBERTa-Large, a robustly optimized model, served as a strong general-purpose baseline, while DeBERTa-V3 base offered a more recent architecture known for its efficiency and strong performance. As highlighted, class imbalance was tackled by fine-tuning SciBERT models with weighted CrossEntropy Loss, where the greater class imbalance was compensated by inversely modifying class weights to their occurrence within the training data, and also Focal Loss (Lin et al., 2017) (with $\gamma = 2.0$ and $\alpha = 2.0$ in some configurations of SciBERT) that diminishes the emphasis on well-classified examples. For estimation smoothing SciBERT’s label smoothing was set to 0.1 which was designed to counterbalance overconfidence. EduBERT and RoBERTa-Large models under this track predominantly applied weighted CrossEntropy Loss while the DeBERTa-V3 base model for this track used the standard Cross Entropy Loss provided by the Hugging Face sequence classification framework. These models were trained with the goal of detecting nuanced indications of mistake recognition in tutor responses.

Track 2, Mistake Location, was developed with similar 3-way classification where response “Yes”, “To some extent” and “No” were used to capture if a tutor is precise to the location of the student’s error. For this track, we primarily utilized the DeBERTa-V3 base model. With disentangled attention and the new pre-training objective (ELECTRA-style) DeBERTa-V3 architecture enhances understanding for relations between tokens and the context which we believed could prove useful in determining whether certain parts of the student’s solution were referred to. Cross Entropy Loss with weights was implemented for fine-tuning for this track. This was important considering that the label distribution for “Mistake Location” was often skewed, and weighting is known to address underrepresented classes effectively trying to achieve understanding if the understanding was indeed accurate and crystal clear.

For Track 3, Providing Guidance, the focus was

on assessing the tutor’s evaluation on whether the answer provided to the student was useful, relevant, correct, and helpful, once again using 3-class schema (“Yes,” “To some extent,” “No”). In this track, we experimented with DeBERTa-V3 base, RoBERTa-Large, and EduBERT. The selection of DeBERTa-V3 and RoBERTa-Large was driven by their proficiency in NLU which is vital when evaluating the guidance provided on whether it is correct and relevant. EduBERT was included because his domain-specific pre-training could help identify pedagogically sound explanations, hints, or supporting questions. As in the last tracks, all these models were first fine-tuned using weighted Cross Entropy Loss. This was important for illustrating how the models adapted to differentiate effective and partially effective guidance along with ineffectual guidance, all distinct components of instructional prowess.

Track 4, Actionability, checked if the tutor’s commentary offered unambiguous next steps by employing the same 3-way classification labels. For this track, we trained both DeBERTa-V3 ‘base’ and ‘large’ models. The justification for the ‘large’ variant is to test if additional model size could capture the more acute interpretative reasoning necessary to assess if a tutor’s remark was adequately sharp and instructive to enable responsive movement from the student. The larger model, with more parameters, better at understanding implicit suggestions or clues regarding the clarity of the anticipated student answer. During training, we uniformly used a weighted Cross Entropy Loss for all layers to constrain the label distribution along this dimension, hoping that the models could reliably distinguish non-constructive or minimal responses for a given prompt from non-informative utterances and conversational dead ends.

Finally, Track 5, Guess the Tutor Identity, posed a challenge of 9 classes: who among the tutors (Expert, Novice, or one of seven LLMs) gave the response in the anonymized form. For this exercise, we used DeBERTa-V3 base, DeBERTa-V3 large, and RoBERTa-Large. These techniques were chosen because of their past performance in capturing sophisticated stylistic differences, preferences, and idiosyncratic features like distinct ‘fingerprints’ for human tutors and LLM systems. The problem is complex at its core because varying forms or expressions, such as style fusion, which exist in different domains like various LLMs or between a novice human and some LLMs, might deeply over-

lap. Addressing the multi-class setup with nine distinct tutor identities was particularly challenging due to the imbalance in the number of available examples for each tutor. To mitigate this situation, we relied heavily on weighted Cross Entropy Loss which disproportionate class representation mitigates imbalance with a more prevailing class in the data. In turn, this prevented the models from specializing excessively to the most common types of tutors.

Throughout all five tracks, there were several components that the fine-tuning procedure shared homogeneous components. We utilized the AdamW optimizer (Loshchilov and Hutter, 2017), which integrates weight decay more effectively than traditional Adam, helping to prevent overfitting. As well as a blended learning rate scheduler which warms up for the first 10% of the total training steps. Doing so reinforces training stability during the early epochs. For example, many SciBERT and RoBERTa-L configurations achieve effective batch sizes of 16 with a device batch size of 8 and 2 accumulation steps. This technique of accumulation helps in training large models on memory-restricted GPUs while also allowing for smoother gradient estimates and enhanced model performance. As shown in Table 2, training continued until reaching the set maximum number of epochs. The model for each task was finalized based on the validation set with the highest macro F1 score for Tracks 1-4 and accuracy on Track 5. This selection process acts as an implicit early stopping mechanism. The class weights for the Cross Entropy Loss were determined by the label’s corresponding training portion frequency across the development set, meaning classes who were less present in the dataset had a greater impact on loss and as such received more focus from the model. All experiments were carried out with a fixed random seed (SEED = 42) in order to ensure the reproducibility of our results.

5 Result Analysis

This section presents an analysis of the performance of various Transformer-based models across the five tracks of the BEA 2025 Shared Task. The evaluation metrics, as defined by the shared task organizers, include exact and lenient accuracy and macro F1-score for Tracks 1-4, and exact macro F1-score for Track 5. The performance of our submitted models is detailed in Table 3.

Model	LR	WD	BS	GA	EP
Track 1: Mistake Identification					
SciBERT	1e-5	0.01	8	2	12
EduBERT	1.5e-5	0.01	8	2	12

Track 5: Tutor Identity				
RoBERTa Large	0.8237	0.8151	-	-
DeBERTaV3 Base	0.8618	0.8597	-	-
DeBERTaV3 Large	0.8621	0.8621	-	-

Table 3: Performance of all models across five tracks. E-F1: Exact macro F1 score, E-Acc: Exact Accuracy, L-F1: Lenient macro F1 score, L-Acc: Lenient Accuracy

For Track 1, Mistake Identification, DeBERTa-V3 Base has achieved the best exact macro F1 score of 0.6617 achieving the highest exact macro F1 score. This model also demonstrated strong performance with a lenient macro F1 score of 0.8782 and lenient accuracy of 0.9315. EduBERT’s performance on exact macro F1 score was just slightly weaker at 0.6597 while SciBERT had the best exact accuracy of 0.8500. The best exact macro F1 score with DeBERTa-V3 Base seems to suggest that, even with a standard Cross Entropy Loss, there are greater architectural advantages in the model that allow it to grasp the intricacies of 3-way classification better than other models. The results from

SciBERT and EduBERT indicate that the use of weighted loss functions was beneficial in achieving competitive exact scores and were likely instrumental in achieving class imbalance resolution.

For Track 2, Mistake Location, our sole entry was the DeBERTa-V3 Base model which was tuned with weighted Cross Entropy Loss and achieved an exact macro F1 score of 0.4935, lenient macro F1 score of 0.7051. There were no other entries. Scores suggest that identifying the precise origins of a mistake’s location is strictly harder than simply identifying an error. The considerable gap between the exact macro F1 score and lenient macro F1 scores highlights that while the model could often recognize some level of mistake location awareness ("To some extent"), achieving definitive localization ("Yes") was less frequent.

For Track 3, Providing Guidance, DeBERTa-V3 Base reached the highest exact macro F1 score of 0.4933. EduBERT was a strong contender with exact macro F1 score of 0.4918, while RoBERTa-Large scored 0.4758 in exact macro F1 score. The lenient macro F1 scores were approximately 0.69 for all three models, with RoBERTa-Large and DeBERTaV3-Base at 0.6997 and 0.6990 respectively. The exact macro F1 scores, marginally surpassing 0.50, highlight the challenge posed in automatically evaluating the correctness and relevance of pedagogical guidance. The imbalances among the “Yes”, “To some extent”, and “No” categories for this particular dimension is what prompted the use of weighted Cross Entropy Loss for this model causing all of the categories to blend in with the aim of unifying the discrepancies.

In Track 4, Actionability, DeBERTa-V3 Large showed the best performance with an exact macro F1 score of 0.6284 and exact Accuracy of 0.6955. The DeBERTa-V3 Base model was slightly behind with an exact macro F1 score of 0.6117. It seems that the larger sized DeBERTa model boosts with added features helped with classifying the actionability of tutor responses. Both models had employed Cross Entropy Loss that was helpful for the other model in achieving such classifiers.

For Track 5, Guess the Tutor Identity, where exact macro F1-score is the primary metric, DeBERTa-V3 Large achieved the best exact macro F1 score of 0.8621. The corresponding exact accuracy for this model was also 0.8621. DeBERTa-V3 Base also performed robustly with an exact macro F1 score of 0.8618 and exact accuracy of 0.8597, followed by RoBERTa-Large at 0.8237 (ex-

act macro F1 score) and 0.8151 (exact accuracy). The strong performance, particularly of the DeBERTa architectures, indicates their capability to discern subtle stylistic and content based patterns distinguishing the nine different tutor identities. This multi-class problem for which the weighted Cross Entropy Loss was quite useful for dealing with was clearly non-trivial.

To summarize, DeBERTa-V3 base and large architectures achieved the best results considering the most important evaluation metric is exact macro F1 score for most tracks. The large showed some advantages in Tracks 4 and 5 where increased model complexity might be helpful. The low exact macro F1 scores, especially for Tracks 2 and 3, suggest difficulties automatically capturing the intricacies of assessment within teaching highlight the intricacies involved in evaluating pedagogical features.

6 Conclusion

This paper introduces a system developed for the UNLP This paper detailed our participation in the BEA 2025 Shared Task on Pedagogical Ability Assessment of AI-powered Tutors, presenting systems built upon fine-tuned Transformer models. We evaluated multiple architectures including DeBERTa-V3, RoBERTa-Large, SciBERT, and EduBERT for the five distinct tracks of Mistake Identification, Mistake Location, Providing Guidance, Actionability, and Tutor Identity. Throughout the investigations, DeBERTa-V3 was the top performer across all tracks based on the primary Exact macro F1 score metric. For Mistake Identification, DeBERTa-V3 Base achieved the Exact macro F1 score of 0.6617, and for Providing Guidance, 0.4933. For the other tracks of Actionability and Tutor Identity, DeBERTa-V3 Large excelled with 0.6284 and 0.8621 Exact macro F1 score respectively. For Mistake Location, DeBERTa-V3 Base scored an Exact macro F1 score of 0.4935. These findings support the assertion that sophisticated Transformer models are capable of intricate pedagogical assessments. The Exact macro F1 scores obtained for Providing Guidance and Mistake Location depict the challenges associated with higher-degree classification, demonstrating the inherent difficulty of the tasks. Methodological choices, such as strategic hyperparameter tuning and the application of appropriate loss functions (e.g., weighted Cross Entropy Loss or Focal Loss) to manage class imbalances, were important for optimizing performance. This work

contributes to the ongoing efforts to develop robust automated tools for assessing and improving AI tutor effectiveness in educational dialogues.

Limitations

Our study, while demonstrating the effectiveness of Transformer models for assessing pedagogical abilities, has several limitations. First of all, the performance, especially on exact macro F1-scores for challenging tasks like Mistake Location and Providing Guidance, indicates that current models still find it difficult to have the fine-grained semantic knowledge needed for these demanding tests. Second, our method depends on the particular annotations and definitions given in the MR-bench dataset; model performance may change depending on alternative educational taxonomies or data from other fields outside mathematics. Moreover, although weighted loss functions helped us to solve class imbalance, significant imbalances for some labels or tutor identities could still influence generalization. Finally, the computational resources needed for fine-tuning and experimenting with several big Transformer models can be significant, therefore perhaps restricting more general architectural research or more comprehensive hyperparameter searches.

Abstract

In this paper, we present the RETUYT-INCO participation at the BEA 2025 shared task. Our participation was characterized by the decision of using relatively small models, with fewer than 1B parameters. This self-imposed restriction tries to represent the conditions in which many research labs or institutions are in the Global South, where computational power is not easily accessible due to its prohibitive cost. Even under this restrictive self-imposed setting, our models managed to stay competitive with the rest of teams that participated in the shared task. According to the *exact* F_1 scores published by the organizers, the performance gaps between our models and the winners were as follows: 6.46 in *Track 1*; 10.24 in *Track 2*; 7.85 in *Track 3*; 9.56 in *Track 4*; and 13.13 in *Track 5*. Considering that the minimum difference with a winner team is 6.46 points — and the maximum difference is 13.13 — according to the *exact* F_1 score, we find that models with a size smaller than 1B parameters are competitive for these tasks, all of which can be run on computers with a low-budget GPU or even without a GPU.

1 Introduction

The remarkable advances in the development of Large Language Models (LLMs) in recent years have turned Natural Language Processing into a discipline with great potential for application in different domains, and *Education* is not the exception (Ignat et al., 2024). However, these technological advances are not affordable to everyone. The cost of closed models — which are the most powerful and are typically considered the State-of-the-art in NLP — and the expensive infrastructure required to use large open models, coupled with

negative effects on the environment, make research on other methods still essential.

Our RETUYT-INCO team, as a research lab from South America, is no exception to this reality. Naturally, we are concerned about these issues and, consequently, we have focused on experimenting with open models in recent editions of the BEA shared tasks. For the 2023 shared task, consisting in generating teacher responses in educational dialogues (Tack et al., 2023), we participated using open models, obtaining competitive results (Baladón et al., 2023). One of the highlights of our participation was the “*Hello*” baseline, a simple strategy we followed which achieved remarkable results, unveiling the fragility of BERTScore (Zhang et al., 2020). More recently, for the 2024 BEA shared task, consisting in performing simplification experiments for different languages (Shardlow et al., 2024), we mainly focused on fine-tuning BERT and Mistral models (i.e., open models), even using synthetic data in some cases (Sastre et al., 2024).

In this paper, we present the RETUYT-INCO participation in the **five tracks** of the BEA 2025 Shared Task: *Pedagogical Ability Assessment of AI-powered Tutors* (Kochmar et al., 2025). This year, in addition to maintaining our restriction of working with open models, we challenged ourselves with an extra restriction: to experiment only with language models of fewer than a billion parameters and classical machine learning (ML) approaches. We will call these *lightweight* models, as they have to be small enough to run on a low-end GPU or with no GPU at all. This restriction is related to the situation many research labs face every day in the Global South: the lack of minimum resources to run what other regions consider *small* models (7B parameters or more). In our case, we have limited access to a national computing cluster, which we can use to fine-tune LLMs up to 7B parameters, but we do not have resources to host the fine-tuned

† These (corresponding) authors contributed equally to this work: {sgongora, isastre}@fing.edu.uy

Figure 1: Class balance in our train and dev sets. The columns are coupled according to classes.

LLMs and use them in real applications.

Moreover, this is not the only motivation for this self-imposed restriction, as one of the research lines of our lab is the application of NLP tools to aid teachers in rural areas (Chiruzzo et al., 2022; Rosá et al., 2025). In such contexts it is very unlikely to use state-of-the-art LLMs, due to the impossibility of using them through APIs (since children’s privacy is key, sending private data to third-party servers is not an option), and the prohibitive cost of installing capable GPUs in trustworthy servers.

Overall, throughout this paper, we will try to answer the general research question that motivated our participation: *What is the performance gap between lightweight models and those state-of-the-art models, which would naturally have a better chance of winning the competition?*.

2 Dataset

For this edition, the dataset consists of 300 conversations (Maurya et al., 2025). Each dialogue is composed of interactions between a teacher and a math student. In the final turn of each dialogue the student shows clear confusion about a concept, and the dataset includes potential tutor *responses* intended to help the student. These responses — some of them generated by seven LLM-based tutors and others written by human tutors — are also evaluated by human evaluators (using **Yes**, **No** or

To some extent) according to four dimensions of interest that coincide with the four proposed tracks in the shared-task: *mistake identification*, *mistake location*, *providing guidance* and *actionability*.

Due to the lack of a specific *development* set, during the first month we split the official dataset published by the organizers into two parts: 80% We decided to do this split focusing on the conversations — and not on the responses — trying to ensure that each conversation and all its responses stayed either in the *train* or the *dev* set. As a consequence, our *train-dev* split may not preserve the class balance of the original set. Figure 1 shows the class balance for each dimension in our *train* and *dev* partition.

3 Considered approaches

For our experiments we considered classical ML classification algorithms, BERT-based approaches and fine-tuning a small autoregressive language model. Since all the tracks in the shared task are classification problems, many of the models we considered were used in more than one track. All of them were trained (or fine-tuned) using our *train* set, running on GoogleColab¹ or a national computational cluster (see Section 3.4.1). At the end of this section — in Subsection 3.5 — we will show

¹<https://colab.research.google.com/>

the results we obtained when evaluating them on the dev set.

3.1 Preliminary experiments

To gain a greater understanding of how challenging the *tracks* were, we performed four preliminary experiments with increasing degree of complexity.

The first and most basic one consisted in answering always **yes**, what naturally degraded the F_1 macro score, since the **No** and **To some extent** classes were never chosen. Then, we tried using a random classifier, which consistently yielded accuracy values around 33%

Additionally, before imposing ourselves the constraint of using *lightweight* models only, we wanted to have an informed perception of how well bigger LLMs could perform in these tracks. Therefore, we explored both prompting a closed model via an API and fine-tuning an open model. For prompting, the model we chose was Gemini Flash 2.0 Lite², using the prompt reported in the paper that presented the dataset (Maurya et al., 2025). For fine-tuning, we chose Llama 3.1 8B Instruct (AI@Meta, 2024), and used Low Rank Adaptation (LoRA) (Hu et al., 2022). This experiment follows the same methodology explained in Section 3.4.

3.2 Classical Machine Learning approaches

Among all the available algorithms in Sklearn³ we tried, those that had the best performance on the dev set were *Random Forest*, *SVC* (Support-vector classifier) and *k-NN* (k-Nearest Neighbors). To represent the input texts we experimented with Bag of Words and TF-IDF, trying different n-gram ranges from $n = 1$ to $n = 8$.

Since all these algorithms have problems capturing the complexities of long-context dependencies, after some experimentation we decided to train the models using the *response* text only, i.e. without taking into consideration the full interaction between the student and the tutor. Those preliminary experiments we did with the full interaction (i.e. concatenating the response of the tutor to the conversation history) had a notably lower performance.

3.3 BERT-based approaches

We also tried BERT-based approaches. We experimented with fine-tuning them, combining them

²<https://deepmind.google/technologies/gemini/flash-lite/>

³https://scikit-learn.org/stable/supervised_learning.html

with classification algorithms and also with some rules.

3.3.1 BERT for Tracks 1–4

We implemented a simple method by fine-tuning a simple BERT model for tracks 1 through 4. Specifically, we finetuned the DistilBERT `distilbert-base-uncased` variant (Sanh et al., 2020), a compact and computationally efficient distillation of BERT with approximately 66 million parameters.

For this experiment, we only considered the response text as input data, without the conversation history. We fine-tuned the model to predict each of the target variables (`mistake_identification`, `mistake_location`, `providing_guidance`, `actionability`). We initially tried to fine-tune the model in a three-class configuration, but our experiments were unable to predict any value of the class **To some extent** whatsoever, so we changed the approach. We ended up training two-class models, joining **No** and **To some extent** as the negative class. After fine-tuning, we analyzed the logit of the positive class and observed that even if both classes were lumped together during training, the **No** values actually got lower logit than the **To some extent** values, which allowed us to define thresholds to separate the three classes.

The hyperparameters in these experiments were the number of training epochs (from 1 to 3) and two thresholds to distinguish the frontier between **No** and **To some extent**, and between **To some extent** and **Yes**, which depending on the target output could vary between -1 and +1. In this round of experiments, we used Adam optimization with a learning rate of 5×10^{-6} .

3.3.2 BERT for Track 5

In our approach to track 5, the objective was to classify the tutor identity based once again solely on the provided response text. For fine-tuning, the following parameters were used: a learning rate of 2×10^{-5} , a weight decay of 0.01, a training duration of 4 epochs, and batch sizes set to 16.

3.3.3 Sentence Embeddings

In addition to fine-tuning, we explored the use of BERT-like models to generate sentence embeddings (Reimers and Gurevych, 2019), which were then combined with classical ML methods for classification.

For tracks 1–4, we used the

multilingual-e5-large-instruct⁴ model (Wang et al., 2024), a multilingual encoder initialized from xlm-roberta-large (Conneau et al., 2019) (561M parameters). We generated a sentence embedding for each example in our training partition and then used those embeddings as input to classical classifiers: k-NN and multilayer perceptron (MLP). For this approach we explored three different input configurations:

- **Response-only:** The input consists solely of the embedding corresponding to the response to be evaluated.
- **Response + conversation history:** The input is formed by concatenating the embedding of the response with the embedding of the full conversation history.
- **Response + conversation history + LLM probabilities:** The input extends the previous configuration by appending the probabilities assigned to the three class labels by the fine-tuned LLM (see Section 3.4).

For the k-NN classifier, we chose $k = 9$ based on the performance on our dev set prior to submitting predictions for the competition’s test set. For the MLP, we used a simple model with no hidden layer and trained it until convergence, defined as no improvement greater than a tolerance of 1×10^{-4} for 10 consecutive iterations.

For the mistake identification dimension, due to the high class imbalance in the training data, we applied under-sampling by fitting the k-NN classifier on a perfectly balanced subset. This subset contained an equal number of examples for each class, matching the count of the least frequent class. As shown in Section 4, this strategy led to improved performance. For this classifier, different values of k for each track were chosen (mistake identification: 415; mistake location: 540; providing guidance: 125; actionability: 96).

For track 5, we explored leveraging the DistilBERT model that was previously fine-tuned for direct sequence classification (as described in the previous section). In this setup, the core transformer layers (the base model, without the classification head) of this fine-tuned DistilBERT were employed as a feature extractor. Embeddings were generated for the "response" texts. These DistilBERT-derived

embeddings were used as input features for an XGBoost classifier (Chen and Guestrin, 2016), which was configured for multiclass classification corresponding to the number of tutor labels.

3.3.4 BERT approach + Educated guess

Another experimental approach we tried for track 5 was to take the predictions of the BERT + XGBoost model and, based on the distribution of the predicted labels, guess some tutor identities. Under the premise that if the model predicted correctly the majority of the time the correct tutor for a certain label, then taking the same prediction for a label might improve the performance of the model. Therefore, for this approach we modified the predictions of BERT + XGBoost forcing to always classify Tutor9 as “Novice”, Tutor2 as “Mistral” and Tutor3 as “Llama31405B”.

Unfortunately, this approach turned out to perform poorly in comparison to the BERT + XGBoost one, denoting that the labels shown in the test dataset might not have a direct mapping with the actual classes.

3.4 Fine-tuning autoregressive LM

In addition to using encoder-only transformers such as BERT, we also experimented with decoder-only LMs. For these experiments, we only focused on the first four tracks. Although these tracks are framed as classification and are therefore usually better suited to encoder-only architectures, we wanted to compare BERT-style fine-tuned models with similarly sized, fine-tuned autoregressive LMs. Specifically, we used Qwen2.5-0.5B-Instruct⁵ (Team, 2024; Yang et al., 2024), which has 494 million parameters and has undergone instruction tuning.

3.4.1 Training

We performed full fine-tuning on our train partition. Each example was converted into a prompt following the prompt template adopted during the model’s instruction tuning phase. The prompt (available in Appendix A) consists of:

- **System prompt:** We used the same system prompt reported in the shared-task dataset paper (Maurya et al., 2025), which was also used for LLM-based evaluation.

⁴<https://huggingface.co/intfloat/multilingual-e5-large-instruct>

⁵<https://huggingface.co/Qwen/Qwen2.5-0.5B-Instruct>

- **User message:** This part contains the conversation history, a task-specific rubric, and the response to be evaluated. The rubrics are the same as those used in the dataset paper.
- **Assistant message:** This consists solely of the class label corresponding to the example (**Yes / No / To some extent**).

We experimented with two different training approaches:

- **Dimension-specific approach:** This involves training four separate models, each dedicated to one of the four evaluation dimensions (mistake identification, mistake location, providing guidance, and actionability). Each model is trained only on examples corresponding to its specific dimension.
- **Multi-dimension approach:** This involves training a single model using the combined training data from all four dimensions. The model is expected to infer the appropriate evaluation criteria based on the scoring rubric included in the user message.

The multi-dimension approach may help mitigate the class imbalance present in certain dimensions (particularly mistake identification), as the model is exposed to a more balanced distribution of the three class labels across different contexts.

The model was trained for three epochs with a batch size of 8 and a learning rate set to 2×10^{-4} , using a linear scheduler with a warm-up ratio of 0.03 and weight decay of 0.001. The training objective was next-token prediction, the same as in pre-training.

To train these models, we used the ClusterUY infrastructure (Nesmachnow and Iturriaga, 2019) with limited (and usually interrupted) access to NVIDIA A100 and NVIDIA A40 GPUs.

3.4.2 Inference

Once the models are fine-tuned, we perform inference using greedy decoding. The input prompt includes the system prompt and the user message, and the model is tasked with generating the assistant message. Since these are classification tasks, we perform a single forward pass and select the class label whose first token receives the highest logit value. Only the three candidate tokens (corresponding to the possible class labels) are considered, and the rest are ignored. This approach

prevents hallucinations by constraining the model to produce one of the predefined labels.

We observed that with the previous method, the **To some extent** label was often under-predicted in favor of the **Yes** or **No** labels. To address this, we introduced an alternative method using thresholds defined separately for each dimension. We retrained the multi-dimension model (i.e. a single model for the first four tracks) on a subset of the training data and used the remaining examples as a validation set to tune the thresholds. The training/validation split was 80/20.

Using the fine-tuned model’s predictions on the validation set, we computed the average probability of each class, grouped by the predicted label. Based on these statistics, we manually defined threshold rules using only the predicted probabilities for the **Yes** and **No** labels. Table 4 in Appendix B shows the threshold values we chose.

3.5 Results obtained over the dev set

We evaluated all these models on the dev set and the results are shown in Table 1.

The first observation we want to do is that even when classical ML algorithms did not manage to be the best in any track, they are still competitive. Some of them even achieved good performances, sometimes getting closer to the best model in the track. Secondly, we want to highlight that some sentence embeddings approaches performed better than using the fine-tuned Llama3.1 8B that we considered in the preliminary experiments. Finally, as expected, neural models performed the best.

Another interesting observation is that the Llama 3.1 8B LoRA fine-tuning, a model 16 times larger than Qwen and BERT, did not achieve significantly better results. In some dimensions, such as providing guidance and actionability, it even performed worse than the fine-tuned Qwen.

Overall, the best models in each track were as follows:

- Track 1 (Mistake Identification) – Sentence Embeddings and k-NN, using the balanced dataset
- Track 2 (Mistake Location) – Fine-tuning DistilBERT with thresholds
- Track 3 (Providing Guidance) – Fine-tuning Qwen using the multi-dimension approach and thresholds

Approach	Track 1		Track 2		Track 3		Track 4		Track 5	
	Mistake identification		Mistake location		Guidance		Actionability		Tutor identity

Table 1: Results for the five tracks over our dev set. In bold, the best results according to each metric for each track.

- Track 4 (Actionability) – Fine-tuning Qwen using the multi-dimension approach
- Track 5 (Tutor identification) – BERT embeddings and XGBoost

4 Final submissions and experimental analysis

After evaluating all the previously described models on our dev set, we chose those which had the best performance, trying to ensure that at least one model of each category (*Classical machine learning*, *Fine-tuning DistilBERT*, *SentenceEmbeddings* and *Fine-tuning Qwen*) was used to predict the test instances in most of the tracks. The classical ML models were trained from scratch using both our train and dev set, while the neural models were only fine-tuned using the train set.

Table 2 shows the performance of our models in each track, the results we obtained and the resulting ranking position (#). To better understand the performance of our systems, we also considered quartiles for each track, and they are included in the table under the “Q” column. Taking a first look at the quartiles, we can see that none of our models was competitive enough to climb the rankings and finish in the first quartile. However, we want to highlight that in three out of the five tracks (Track1, Track3 and Track4) our models managed to finish in Q_2 .

Overall, as when evaluating on the dev set, this

Submission	F1-macro	Accuracy	#	Q
Track 1 - Mistake identification				
e5 (resp.) k-NN (balanced)	65.35	84.49	56/153	Q_2
Qwen (dimension-specific)	64.94	86.68	62/153	Q_2
DistilBERT (thresholds)	64.30	85.20	64/153	Q_2
SVC + TF-IDF	59.11	84.81	104/153	Q_3
e5 (response) k-NN ($k = 9$)	58.39	84.36	110/153	Q_3
Track 2 - Mistake location

Track 5 - Tutor identification				
BERT + XGBoost	83.85	84.74	27/54	Q_3
DistilBERT	83.85	84.74	28/54	Q_3
SVC + TF-IDF	80.44	80.22	39/54	Q_3
BERT + Educated guess	68.16	68.65	42/54	Q_4

Table 2: Results for the five tracks over the competition’s test data. The “#” column indicates the position the system got in the rankings, and the “Q” column indicates the quartile related to that position (splitting in 4 buckets the number of participants in each track).

time the neural models again achieved the best performance among our models. Moreover, something interesting to observe is that the fine-tuned Qwen

Track	Rank / Total	Q	Δ Exact F_1	Δ Exact Accuracy	Δ Lenient F_1	Δ Lenient Accuracy
Track 1	23 / 44	Q_3	71.81 – 65.35 = 06.46	86.23 – 84.49 = 01.74	89.57 – 83.95 = 05.62	94.57 – 91.92 = 02.65
Track 2	21 / 32	Q_3	59.83 – 49.59 = 10.24	76.79 – 58.63 = 18.16	83.86 – 72.00 = 11.86	86.30 – 76.08 = 10.22
Track 3	17 / 35	Q_3	58.34 – 50.49 = 07.85	66.13 – 59.47 = 06.66	77.98 – 70.57 = 07.41	81.90 – 77.51 = 04.39
Track 4	17 / 29	Q_3	70.85 – 61.29 = 09.56	72.98 – 70.33 = 02.65	85.27 – 82.72 = 02.55	88.37 – 85.59 = 02.78
Track 5	12 / 20	Q_3	96.98 – 83.85 = 13.13	96.64 – 84.75 = 11.89	N/A	N/A

Table 3: Performance difference between our best submissions and the winners, for each task. This table was built based on the *team results*, so the total number of submissions for each track is always fewer than those considered in Table 2.

models and the BERT models got similar performance. This seems to indicate that the generative capabilities of Qwen are good enough to also work as an emergent classifier.

Most of the models we used are not well-suited for handling long contexts. This led us to question how essential the *conversation history* truly is for assessing the four evaluation dimensions, or whether the model’s response alone is enough to obtain good results. Therefore, we tested training some models both with and without including the conversation history as input. In this regard, the most significant experiments were those using sentence embeddings. These experiments show that nearly every dimension benefits from the inclusion of history, except for the mistake identification dimension, which performs notably better without it (i.e. using only the tutor’s response). More broadly, Qwen-based methods (which incorporate the full conversation history) achieve the best results in providing guidance and actionability, and, in contrast, BERT-based methods (which do not use the conversation history) perform better on mistake location. This pattern suggests that more subtle dimensions like guidance and actionability benefit more from access to the full conversational context. Further experimentation is required to validate all these preliminary observations.

Finally, while the DistilBERT with XGBoost approach seemed to have a good performance on our dev set, its final performance (on the test set) was identical to that of the DistilBERT fine-tuning model (without XGBoost). This was not the only difference we had between our dev set and the test set. As can be seen by comparing Tables 1 and 2, most methods performed noticeably better on our internal dev set than on the test set. We believe this performance gap may be due to differences in the class distributions between the two sets.

Furthermore, the experiment using under-sampling to balance the classes showed a significant improvement on the test set, going from

being the worst-performing submission to being the best one. This further highlights the impact of class imbalance on model performance.

4.1 How far were these lightweight models from winning?

Finally, to answer our *research question*, we wanted to check how far our lightweight models went in the shared task. Beyond the ranking positions, we wanted to focus on *how big* (according to the official scores) was the gap between these models and those that settled the state of the art, winning the competition. In Table 3 we show the difference (Δ) — for each metric — of our best predictions with the winner team in each track⁶. As a reference, we also include our team’s position in that track and the correspondent *quartile* (this time, based on the number of teams, and not on the number of submitted systems).

Taking a look at the table, we can see that, according to Δ Exact F_1 , the closest gap between our performance and the winning team was 06.46 (in Track 1), while the biggest gap was 13.13 (in Track 5). We think this difference in performance is very small considering the restrictions we had.

5 Conclusions

In this paper we presented the RETUYT-INCO participation at the 2025 BEA shared task, characterized by our self-imposed restriction of only using models under 1B parameters. Although our research lab have access to cheap API LLMs and very limited access to run 7B LLMs on clusters, we are conscious that this is not the case for other research labs in the Global South, that usually work

⁶Since the organizers considered the *Exact F_1* metric as the main one, we considered as *winning teams* those which got the highest score according to that metric. Therefore, for all metrics, we calculated the Δ according to the score achieved by the winning team in that track. This way, even if a different team got a better result according to other metric, we still calculated the Δ according to the winning team.

in even deeper under-resourced scenarios. Our self-imposed restriction tries to represent this scenario.

Overall, we used classical machine learning models, BERT-based models, and a QWEN 0.5B LLM. Despite their (very small) size we finished in mid-ranking positions. Beyond the results in the rankings, the result we want to highlight is that the gaps in performance we had with the winning teams were between 6.46 and 13.13 F_1 *exact* points.

We find that gap surprisingly small, taking into account that we did not use LLMs bigger than 1B, nor paid for API access, nor paid for premium cloud computing, nor needed top-tier resources to run our experiments. Additionally, following the environmental concerns that surround the carbon footprint of state-of-the-art LLMs (Luccioni et al., 2023; Faiz et al., 2024; Liu and Yin, 2024), we consider this an interesting tradeoff: to sacrifice some performance, in order to have models that do not need extensive training/inference time or power, but that are still competent. Based on all of the above, we think research on models that run on low-cost GPUs — or need no GPU at all — should definitely go on.

6 Limitations

Throughout the paper we have outlined several limitations we have to run experiments with large models. These constraints led to our self-imposed restriction of using only neural models with fewer than 1B parameters. Naturally, our work does not present state-of-the-art results, nor does it intend to. Furthermore, we prioritized breadth (i.e. trying many model types) over depth (i.e. optimizing a single approach or architecture extensively). While this gives a broader perspective on the diverse possibilities that lightweight models have to offer, it may have limited the performance ceiling of individual models.

Regarding our methodology, we made the decision of splitting the full set into two subsets (train and dev) considering as a priority to keep the conversations and their responses in the same subset. This decision may have introduced some noise and class imbalance, since we found remarkable differences in the performance of our models over the dev set and the final test set (after submission). Since the fine-tuned models and the thresholds used were adjusted specifically to our dev set, they may not generalize well to other similar corpora.

Finally, and related to the previous considerations, we did not systematically perform hyperparameter tuning due to both hardware and time limitations. Additionally, prior to our final submissions, we only trained (from scratch) the classical ML models on the full set (our train + dev sets). Since the neural models were our best approaches, searching better hyperparameters and training them with more data could have made the performance gaps a bit smaller.

A Prompts

This Appendix presents the prompts used for fine-tuning the decoder-only language models, as explained in Section 3.4.

System prompt

You are a critic evaluating a tutor's interaction with a student, responsible for providing a clear and objective single evaluation based on specific criteria. Each assessment must accurately reflect the absolute performance standards.

User message

```
# Previous Conversation between Tutor and Student:
{history}
```

```
# Scoring Rubric:
{rubric}
```

```
# Tutor Response:
{response}
```

Mistake identification rubric

[Has the tutor identified a mistake in a student's response?]

- 1) Yes
- 2) To some extent
- 3) No

Mistake location rubric

[Does the tutor's response accurately point to a genuine mistake and its location?]

- 1) Yes
- 2) To some extent
- 3) No

Providing guidance rubric

[Does the tutor offer correct and relevant guidance, such as an explanation, elaboration, hint, examples, and so on?]

- 1) Yes (guidance is correct and relevant to the mistake)
- 2) To some extent (guidance is provided but it is fully or partially incorrect or incomplete)
- 3) No

Actionability rubric

[Is it clear from the tutor's feedback what the student should do next?]

- 1) Yes
- 2) To some extent
- 3) No

B Qwen Thresholds

Table 4 presents the thresholds used with the Qwen model, as explained in Section 3.4.

Dimension	Yes condition	No condition	TSE condition
Mistake Identification	Yes > 0.90 & No < 0.05	Yes < 0.40 & No > 0.50	Otherwise
Mistake Location	Yes > 0.75 & No < 0.15	Yes < 0.42 & No > 0.50	Otherwise
Providing Guidance	Yes > 0.65 & No < 0.12	Yes < 0.35 & No > 0.45	Otherwise
Actionability	Yes > 0.70 & No < 0.14	Yes < 0.25 & No > 0.65	Otherwise

Table 4: Threshold-based classification rules for each evaluation dimension using Qwen. TSE = "To some extent".

K-NLPers at BEA 2025 Shared Task: Evaluating the Quality of AI Tutor Responses with GPT-4.1

Abstract

This paper presents automatic evaluation systems for assessing the pedagogical capabilities of LLM-based AI tutors. Drawing from a shared task, our systems specifically target four key dimensions of tutor responses: Mistake Identification, Mistake Location, Providing Guidance, and Actionability. These dimensions capture the educational quality of responses from multiple perspectives, including the ability to detect student mistakes, accurately identify error locations, provide effective instructional guidance, and offer actionable feedback. We propose GPT-4.1-based automatic evaluation systems, leveraging their strong capabilities in comprehending diverse linguistic expressions and complex conversational contexts to address the detailed evaluation criteria across these dimensions. Our systems were quantitatively evaluated based on the official criteria of each track. In the Mistake Location track, our evaluation systems achieved an Exact macro F1 score of 58.80% (ranked in the top 3), and in the Providing Guidance track, they achieved 56.06% (ranked in the top 5). While the systems showed mid-range performance in the remaining tracks, the overall results demonstrate that our proposed automatic evaluation systems can effectively assess the quality of tutor responses, highlighting their potential for evaluating AI tutor effectiveness.

1 Introduction

Recent advancements in Large Language Models (LLMs) have significantly enhanced performance across various tasks in natural language processing and artificial intelligence (Kim et al., 2025, 2024; Das et al., 2025). These developments have spurred interest in applying LLMs within educational settings, aiming to leverage their capabilities for personalized learning, intelligent tutoring, and educational assessment (Macina et al., 2023; Chevalier et al., 2024; Wang et al., 2024b; Gan et al.,

2023). However, despite these promising developments, how well LLMs can provide educational feedback and guidance in authentic tutoring scenarios remains underexplored. To address this gap, there is a growing need for systematic evaluation methods that can rigorously assess the pedagogical quality of LLM-generated tutor responses. To address this need, we participated in the BEA 2025 Shared Task on Pedagogical Ability Assessment of AI Tutors (Kochmar et al., 2025), which aims to systematically evaluate the educational quality of AI tutor responses across multiple dimensions. Our system was submitted to four subtasks (Tracks 1–4), each corresponding to the pedagogical evaluation dimensions defined in the shared task: Mistake Identification, Mistake Location, Providing Guidance, and Actionability.

For this study, we employed prompting techniques using GPT-4.1¹ model to complete each evaluation task. GPT-4.1 is well-known for its superior ability in instruction-following, handling complex contexts, and performing multi-step reasoning (OpenAI, 2025). These capabilities, combined with our prompting strategies, enabled effective evaluation of tutoring performance. This paper details the prompting strategies and methodologies utilized in the evaluation tracks in which we participated. Additionally, we analyze and discuss the performance of our proposed systems, aiming to provide practical insights for future development of LLM-based tutoring systems.

2 Methodology

This section introduces the three prompting-based evaluation systems we developed for the BEA 2025 Shared Task. Each system is designed to align with the pedagogical goals of different evaluation tracks, while sharing a common objective of simulating human-like reasoning in tutoring scenarios.

* These authors contributed equally to this work.

¹[gpt-4.1-2025-04-14](https://openai.com/index/gpt-4-1/)

Section 2.1 presents the Chain-of-Thought-based Pedagogical Evaluation system with Reasoning Layers. This approach models the step-by-step reasoning process of a human tutor, who first analyzes the student’s thinking, constructs a correct solution, and then evaluates the tutor’s response in context. This system was applied to **Track 1**, which focuses on evaluating whether the tutor successfully identifies student mistakes, and **Track 4**, which assesses the actionability of the feedback provided.

Section 2.2 describes the Multi-Perspective Reflective Evaluation, developed for **Track 2**. Inspired by the reflective feedback behavior of human tutors, this method simulates internal deliberation among distinct reasoning perspectives to assess whether the tutor accurately identifies the location of a student’s mistake.

Section 2.3 details the Rubric-Based Evaluation Method, which targets **Track 3**. This approach decomposes the Providing Guidance criterion into multiple rubric-based sub-questions. It extracts structured features from LLM-generated probability distributions and enhances scoring consistency by using a downstream classifier trained to align model judgments with human evaluation patterns.

These methodologies establish a comprehensive framework for evaluating tutor responses, enhancing interpretability, pedagogical alignment, and educational validity in open-ended dialogue settings.

2.1 Chain-of-Thought-based Pedagogical Evaluation with Reasoning layers

This system is designed to automatically evaluate the pedagogical appropriateness of a tutor’s final utterance in a math lesson dialogue. Instead of using a single prompt or a simple classification-based approach, we adopted a step-by-step processing structure that emulates how human tutors interpret student solutions and determine appropriate feedback. The design of this structure is based on two key observations: First, large language models (LLMs) show improved performance on complex problems when explicitly guided through intermediate reasoning steps, a technique known as chain-of-thought prompting (Wei et al., 2022). Second, LLMs tend to exhibit conformity bias—favoring only a single "standard" solution path and struggling to respond appropriately to diverse or alternative reasoning strategies (Li et al., 2024).

To address these issues, we designed the flow so that the model first analyzes the student’s reason-

ing process, then generates a correct solution path based on that reasoning, and finally evaluates the tutor’s utterance in light of the student’s thinking. All stages are implemented using the GPT-4.1 model, which was selected for its strong performance in instruction following, conversational context retention, and multi-step reasoning. Our proposed system is composed of the following four stages:

1. **Problem Extraction:** Extract the math problem from the dialogue. The extracted problem serves as the foundation for all subsequent reasoning, and functions as a critical preprocessing step for maintaining contextual coherence and semantic consistency.
2. **Student Reasoning Process Reconstruction:** Based on the student’s response and the flow of the conversation, reconstruct the reasoning path that the student followed to solve the problem. Even in the absence of explicit explanations, infer a plausible line of reasoning. This mirrors how a human tutor might infer a student’s thought process in real instructional settings to provide targeted feedback.
3. **Correct Reasoning Process Generation:** Using the reconstructed student reasoning as a foundation, generate a correct solution path. If the student’s approach is partially valid, it is preserved and only the errors are corrected. If the approach is fundamentally flawed, a new solution is generated. This stage serves both as a reference point for comparison and as a mechanism to mitigate the conformity bias described earlier.
4. **Tutor Response Evaluation:** Finally, the tutor’s final utterance is evaluated using the following four criteria:
 - Mistake Identification
 - Mistake Location
 - Providing Guidance
 - Actionability

These criteria, while based on the definitions provided by the task organizers, are redefined in our approach to focus on how utterances actually function within the student’s learning process, moving beyond simple sentence-level evaluation. **Mistake Identification** is judged not merely on whether a mistake was mentioned, but on whether this recognition was perceptible and significant to the student. **Mistake Location** is assessed not by whether the error’s position is explicitly stated, but by whether

the student can reasonably infer where the mistake occurred based on the tutor’s response. **Providing Guidance** is assessed not by the mere provision of a correct answer, but by whether it was a method that stimulated and broadened student thinking. **Actionability** uses as its criterion whether the student can actually understand and follow the guidance, rather than the mere presence or absence of a suggested action.

These redefinitions allow the LLM to evaluate the tutor not as a mere provider of correct answers (tutor-as-answerer), but as a facilitator of reasoning and learning (tutor-as-guide). To ensure consistent scoring across levels, especially for nuanced categories like "To some extent", concrete judgment criteria were clearly designed. The specific prompts corresponding to each criterion, along with detailed evaluation guidelines, are provided in detail in the Appendix A.

2.2 Multi-Perspective Reflective Evaluation Method

To accurately determine whether a tutor’s response correctly identifies the location of a mistake in a student’s solution, our system proposes a multi-perspective reasoning process inspired by how human tutors approach student feedback. Rather than relying on static classification, this system simulates a dynamic reasoning process, decomposing the evaluation into distinct functional perspectives such as recalling relevant context, analyzing logic, assessing clarity, and monitoring emotional tone.

2.2.1 Human-Like Multi-Step Reasoning

When human tutors assess a student’s response, they typically do not evaluate it in a single step. Instead, they engage in a layered cognitive process: understanding the problem, reconstructing the student’s reasoning, identifying discrepancies, and delivering feedback that balances correctness and pedagogical clarity. One recent attempt to emulate this human-like multi-step reasoning within a single LLM is **Solo Performance Prompting (SPP)**, which activates diverse personas to facilitate self-collaboration and mimic human reasoning (Wang et al., 2024c). Building on this idea, our system mirrors such behavior by simulating a group of internal “reasoning participants”, each representing a specific evaluative function. These participants collaborate iteratively to reach a decision regarding the quality of the tutor’s feedback.

2.2.2 Reasoning Process

Given a conversation history, including the original question, the student’s response, and the tutor’s follow-up, the system performs the following steps:

- **Perspective Initialization:** Depending on the complexity of the student’s reasoning and the characteristics of the tutor’s feedback, a set of internal perspectives is dynamically activated. These perspectives represent distinct reasoning roles (e.g., logical analysis, memory retrieval, contextual interpretation).
- **Independent Assessment:** Each perspective independently analyzes whether the tutor’s response points to the specific step where the mistake occurred. The analysis includes not only factual correctness but also the interpretability and relevance of the feedback.
- **Collaborative Deliberation:** After the initial assessments, the perspectives engage in a multi-turn collaborative discussion. They provide critical feedback on one another’s reasoning, refine interpretations, and critique or support conclusions.
- **Final Decision:** Based on this internal collaboration, the system synthesizes a final judgment: "Yes", "To some extent", or "No", depending on how clearly and precisely the tutor’s response identifies the location of the student’s mistake.

2.2.3 Prompting Strategy

We implement the above reasoning process through a carefully designed prompt that guides the language model to simulate human-like evaluation. Rather than instructing the model to directly respond to a tutor’s utterance, the prompt breaks the evaluation into distinct reasoning roles. It encourages the model to adopt multiple perspectives. The prompt explicitly instructs the model to initiate internal reflection by assigning roles such as logical analysis, memory recall, and clarity evaluation. It then simulates a collaborative discussion where these roles critique and refine one another’s views before converging on a final judgment. This structured interaction is carried out entirely within a single language model, enabling it to reason through the task in a self-contained yet multi-faceted manner. By prompting the model to consider both explicit and implicit forms of feedback, as well as emotional tone and pedagogical clarity, this design elicits more interpretable and human-aligned judgments. It ensures the model reflects on why a tutor

response is effective or not, rather than simply what label to assign.

2.3 Rubric Based Evaluation Method

In this section, we aim to evaluate whether tutor LLMs provide correct and relevant guidance within the context of tutoring dialogue. We apply a method that predicts high-dimensional judgments through item-specific probability distributions, such as those used in LLM-Rubric (Hashemi et al., 2024), to assess the educational validity of tutor LLM responses. Specifically, for the prediction of Providing Guidance, we designed five detailed questions (Q_{rubric}) and a single comprehensive question ($Q_{overall}$) utilizing statistical information. For each item, we constructed prompts such that the LLM outputs the probabilities of "Yes", "To some extent", "No". However, the evaluation labels generated by the LLM may not completely align with the labels of human evaluators. Therefore, we use the item-wise probability distributions as input features for a subsequent classifier, aiming to calibrate the LLM's judgments to be more consistent with human evaluation.

2.3.1 Feature Extraction via Structured Prompting

The feature extraction step based on structured prompting consists of two components: rubric-based evaluation criteria and statistical information. The prompts used for each task are presented in Appendix B, and the responses were generated using the GPT-4.1 model.

Feature Extraction from Rubric-Based Evaluation Criteria The prompt for feature extraction based on rubric-defined evaluation items consists of role specification, presentation of dialogue context, definition of label criteria and output format, and a list of evaluation questions.

- **Role specification:** By assigning the expert role of "expert evaluator analyzing a tutor's response in a learning dialogue," the model is encouraged to think critically from the perspective of an evaluator rather than as a simple generator.
- **Presentation of dialogue context:** The dialogue context is presented sequentially and consists of the entire conversation between the tutor and student, the student's last utterance, and the tutor's response to that utterance. This allows the LLM

to conduct evaluations based on a sufficient understanding of the context.

- **Definition of label criteria and output format:** For each item, the judgment consists of three options: Yes, To some extent, and No. The definitions of these labels are based on criteria defined by the annotator. For each item, the model outputs the probability value for each of the three labels in decimal form, based on the rationale for its judgment. The sum of all probability values is designed to be 1.0, and these values are used as input features for the subsequent classifier.
- **List of questions:** The prompt includes five questions designed to capture various aspects of the Providing Guidance criterion. Each question is constructed to evaluate specific elements of detailed feedback, as follows.
 - Q1 Did the tutor attempt to provide any explanation, hint, or example?
 - Q2 Was the guidance factually correct and appropriate given the student's error?
 - Q3 Did the tutor's response directly address the student's specific mistake?
 - Q4 Did the guidance help the student figure out what to do next, without directly giving the final answer?
 - Q5 Was the tutor's response clear and unlikely to confuse the student?

This prompt design enables the LLM to consistently perform structured evaluations. The extracted features serve as inputs for subsequent classifiers, thereby enhancing the precision and reliability of the automated evaluation framework.

Feature Extraction Using Statistical Information

Antecedent	Consequent	Support	Confidence	Lift
ML = Yes	MI = Yes	0.6163	0.9889	1.2674
MI = Yes	ML = Yes	0.6163	0.7898	1.2674
PG = Yes	MI = Yes	0.5399	0.9502	1.2178

Table 1: Results of Association Rule Analysis among Mistake Identification, Mistake Location, and Providing Guidance

In the feature extraction step utilizing statistical information, features were constructed based on association rules among items analyzed from the development dataset. To this end, the Apriori algorithm (Agrawal and Srikant, 1994) was applied

using the label information of the three items: Mistake Identification, Mistake Location, and Providing Guidance. Based on the calculated support and confidence values, the three most reliable association rules were extracted. The main association rules derived from this analysis are shown in Table 1. The top three association rules all exhibit high confidence values, suggesting that the relationships between items possess meaningful associations beyond mere coincidence. Among these, the relationship between "Mistake Location = Yes" and "Mistake Identification = Yes" demonstrates particularly high confidence, confirming a strong association between the two items.

To reflect these statistically significant associations, the following elements were added within the same prompt structure used in previous tasks:

- **Insertion of prior prediction results:** Predictions from previous Tracks (Mistake Identification and Mistake Location) were included in the prompt, allowing the LLM to perform evaluations based on this prior knowledge.
- **Provision of statistical associations:** Confidence values derived from association analysis were explicitly presented in the prompt to numerically illustrate conditional relationships among the three items. This allows the model to reference the likelihood of specific judgments influencing others during response evaluation.
- **Presentation of a single comprehensive question:** A question designed to elicit an overall assessment of "Providing Guidance" was included. The model was prompted to holistically assess whether the response attempted meaningful guidance, based on the given content, prior Track predictions, and statistical information.

Through this prompt, the model can extract comprehensive judgment features for Providing Guidance by simultaneously considering both existing prediction results and quantitative association information.

2.3.2 Improving Consistency in LLM Evaluation Using Classifiers

To calibrate the evaluation results of LLM responses with human assessors' judgments, we adopted an approach utilizing a subsequent classifier and conducted experiments to select an optimal classification model. The features extracted

in Section 2.3.1 consist of probability values for the three categories—"Yes," "To some extent," and "No"—for each of the six sub-questions (Q_{rubric} and $Q_{overall}$). Each sub-question is represented as a three-dimensional vector (i.e., three probabilities), and concatenating these yields an 18-dimensional real-valued vector (6 questions \times 3 classes = 18), which serves as the input feature for the response quality classifier. We compared the performance of three classification models — Random Forest (Breiman, 2001), Logistic Regression (Cox, 1958), and XGBoost (Chen and Guestrin, 2016) — using 5-fold cross-validation on the development dataset.

Classifier	Gold		Pred		w/o $Q_{overall}$	
	F1	Acc	F1	Acc	F1	Acc
Logistic Regression	0.61	0.71	0.49	0.66	0.49	0.66
Random Forest	0.63	0.70	0.55	0.61	0.54	0.60
XGBoost	0.61	0.69	0.52	0.66	0.50	0.64

Table 2: Comparison of Classifier Performance According to the Use of $Q_{overall}$. **Gold** denotes that ground-truth labels for $Q_{overall}$ were supplied, whereas **Pred** uses the values predicted by the methods in Sections 2.1 and 2.2.

Table 2 compares classifier performance across three experimental conditions. The first condition inputs gold labels for Mistake Identification and Mistake Location into $Q_{overall}$. The second condition uses predicted values from previous Tracks for $Q_{overall}$, while the third entirely excludes $Q_{overall}$ from input features to analyze its performance impact. Under the gold-label configuration for $Q_{overall}$, Random Forest achieved the highest Macro F1 score of 0.63. This indicates strong alignment between $Q_{overall}$ and the final Providing Guidance label, representing the upper performance bound of the proposed methodology. In the simulated test environment using predicted values for $Q_{overall}$, Random Forest maintained superior performance with a Macro F1-score of 0.55, though lower than the gold-label scenario. This performance gap underscores the influence of prediction uncertainty in $Q_{overall}$ and highlights its critical role in overall accuracy. Experiments excluding $Q_{overall}$ resulted in performance degradation across all models, demonstrating that $Q_{overall}$ facilitates comprehensive judgment rather than isolated item assessment, thereby making substantial contributions to classifier efficacy.

Based on these findings, the study implemented a system incorporating all Q_{rubric} and $Q_{overall}$ items

as input features, with Random Forest selected as the final classifier for Predicting Providing Guidance labels. This configuration optimizes robustness while maintaining practical applicability in automated feedback evaluation.

3 Evaluation

In this section, we report and discuss the evaluation results obtained from each of the prompting methodologies applied to Tracks 1 through 4. The performance of each proposed method is presented briefly, highlighting their strengths and identifying areas for improvement.

3.1 Evaluation Metrics

Our evaluation followed the same metrics defined by the shared task organizers. Specifically, accuracy and macro F1 scores were utilized as the primary metrics for evaluating performance across Tracks 1 through 4. These metrics were computed under two distinct settings:

- **Exact evaluation (Ex.):** Predictions were assessed based on the precise classification into three distinct categories ("Yes," "To some extent," and "No").
- **Lenient evaluation (Len.):** Considering the qualitative similarities between responses annotated as "Yes" and "To some extent," these two classes were combined into a single category ("Yes + To some extent"), resulting in a simplified binary classification ("Yes + To some extent" vs. "No") for performance evaluation.

3.2 Dataset

We conducted our experiments using the dataset provided by the shared task organizers. The dataset consists of 300 dialogues extracted from the MathDial (Macina et al., 2023) and Bridge (Wang et al., 2024a) datasets, and includes a total of 2,476 tutor responses annotated for four pedagogical aspects based on the scheme proposed by Maurya et al. (2025). These annotated responses were used as the development set. An additional 1,547 tutor responses, constructed in the same manner, were used as the test set.

3.3 Chain-of-Thought-based Pedagogical Evaluation System with Reasoning layers

To evaluate the effectiveness of the proposed assessment system in section 2.1, we conducted experi-

ments on two models: GPT-4.1 and GPT-4.1-mini². The experiments were performed on the entire development set. Since the proposed system does not require a separate training phase, all examples in the dataset were directly used for evaluation. To facilitate comparative analysis of the proposed system’s performance, we also conducted experiments using an alternative baseline prompt (see Appendix A for details of the baseline prompt), defined by the following conditions:

- The input consists only of the dialogue history and the tutor’s final utterance.
- For each evaluation criterion, the original definitions provided by the task organizers were used, rather than the redefined versions proposed in this study.

This setup allows us to directly compare how variations in prompt design and evaluation criteria definitions affect final performance, under identical language model and dataset conditions.

Task	Prompt	Model	Ex. F1	Ex. Acc	Len. F1	Len. Acc
MI	Base	GPT 4.1 mini	0.5566	0.6975	0.8037	0.8958
		GPT 4.1	<u>0.5850</u>	<u>0.7383</u>	<u>0.8107</u>	0.9055
	Ours	GPT 4.1 mini	0.5699	0.7282	0.7965	<u>0.9079</u>
		GPT 4.1	0.6225	0.7993	0.8371	0.9204
ML	Base	GPT 4.1 mini	<u>0.5037</u>	<u>0.5856</u>	0.7447	0.7928
		GPT 4.1	0.4642	0.4851	0.7361	0.8029
	Ours	GPT 4.1 mini	0.4885	0.5166	0.7581	<u>0.8146</u>
		GPT 4.1	0.5238	0.5969	<u>0.7564</u>	0.8154
PG	Base	GPT 4.1 mini	<u>0.5286</u>	0.5428	0.7347	0.8247
		GPT 4.1	0.4905	0.4758	0.7374	0.8320
	Ours	GPT 4.1 mini	0.5117	0.4956	<u>0.7506</u>	0.8389
		GPT 4.1	0.5398	<u>0.5355</u>	0.7583	0.8384
ACT	Base	GPT 4.1 mini	0.4934	0.5141	0.6889	0.7597
		GPT 4.1	0.4487	0.4378	0.6975	0.7815
	Ours	GPT 4.1 mini	<u>0.5045</u>	<u>0.5250</u>	<u>0.7129</u>	<u>0.7851</u>
		GPT 4.1	0.5210	0.5384	0.7253	0.7948

Table 3: Performance comparison across tasks, prompts, and models. **Bold** indicates the best performance within each task, and underline indicates the second-best.

Table 3 presents a performance comparison between the proposed evaluation system and the baseline prompt. The proposed approach demonstrates overall superior results across all four evaluation criteria compared to the base prompt. Notably, when using the GPT-4.1 model, improvements in response quality were observed under both exact and lenient evaluation metrics.

For Mistake Identification, which measures the model’s ability to recognize student errors, the proposed system proved more effective in producing

²gpt-4.1-mini-2025-04-14

clear and convincing judgments.

For Mistake Location, which assesses how well the tutor’s response pinpoints where the student made a mistake, the proposed system also showed better performance when using GPT-4.1. Although the performance gains were more limited with the smaller model (GPT-4.1-mini), the proposed system helped generate responses with more consistent error localization patterns.

For Providing Guidance, which evaluates whether the tutor’s response offers not only correct answers but also instructional support — such as explanations, hints, or examples — the proposed system was more effective in assessing responses using this criterion, as it successfully identified a variety of instructional strategies, including explanations, hints, and guiding questions. This indicates that the redefined evaluation criteria were more closely aligned with authentic pedagogical practices.

For Actionability, which assesses whether the student can clearly understand what to do next based on the tutor’s feedback, the proposed system demonstrated consistently high performance in evaluating responses that effectively prompted concrete next steps. This result likely stems from the prompt structure and evaluation criteria, which were explicitly designed to reflect a student-centered communicative framework.

Taken together, these results demonstrate that even without fine-tuning, the combination of a structured prompt chain, evaluation criteria redefined from the student’s perspective, and a reasoning-guided process can enhance both the reliability and pedagogical validity of tutor response evaluation. However, the experimental findings also imply that distinguishing fine-grained judgment boundaries—such as between “Yes”, “To some extent”, and “No”—remains a challenge. This highlights the limitation of relying solely on prompt-based inference, as the model may still struggle to fully grasp the nuanced intent behind each evaluation category without task-specific training.

Despite these limitations, we applied the proposed system to the official evaluations of Track 1 and Track 4 without any additional training, in order to see whether it would perform reliably in a real evaluation setting. As a result, the system maintained stable performance on the test set, achieving Exact macro F1 scores of 0.6669 and 0.5664 for Track 1 and Track 4, respectively, thereby demonstrating that the performance observed on the development set was consistently replicated in the

official evaluation.

3.4 Multi-Perspective Reflective Evaluation System

We submitted our system, developed under the team name K-NLPers, to the Mistake Location track of the BEA Shared Task. It was built upon our proposed multi-perspective reasoning framework and evaluated using the GPT-4.1 model.

Team	Ex. F1	Ex. Acc	Len. F1	Len. Acc
BLCU-ICALL	0.5983	0.7679	0.8386	0.8630
BJTU	<u>0.5940</u>	0.7330	0.7848	0.8261
K-NLPers	0.5880	<u>0.7641</u>	0.8404	<u>0.8610</u>
MSA	0.5743	0.6975	0.7848	0.8209
SG	0.5692	0.7602	0.8118	0.8416

Table 4: Evaluation Results on the Mistake Location Track under Multi-Perspective Reflective Evaluation. **Bold** indicates the best performance and underline indicates the second-best.

As shown in Table 4, our system achieved competitive results, ranking 3rd overall among participating teams. In particular, it showed strong performance in Exact Accuracy (0.7641), Lenient macro F1 (0.8404), and Lenient Accuracy (0.8610), with scores closely comparable to those of the top two teams. These results suggest that our system produces predictions with consistent structure and high lexical accuracy, demonstrating that the proposed approach can effectively compete with state-of-the-art systems. However, the Exact macro F1 score (0.5880) was slightly lower than that of the top-ranked teams, primarily due to difficulty in distinguishing responses labeled as “To Some Extent”. Despite this, the results confirm that our system is robust and generalizable, yielding strong overall performance across evaluation metrics in a competitive setting.

3.5 Rubric Based Evaluation System

This section evaluated the Providing Guidance dimension (Track 3) using the rubric-based system proposed in Section 2.3.

Team	Ex. F1	Ex. Acc	Len. F1	Len. Acc
BLCU-ICALL	0.5741	0.6716	0.7487	0.8061
BJTU	0.5725	0.6490	0.7445	0.8100
K-NLPers	0.5606	0.6270	0.7446	0.8003
bea-jh	0.5451	0.6387	0.7253	0.7977

Table 5: Performance and ranking of our models in predicting "Providing Guidance" on the test set.

Table 5 presents the leaderboard results on the test set for the final system proposed in Section 2.3. Our system achieved an Exact macro F1 score of 0.5606 and a Lenient macro F1 score of 0.7446 on the test set. Despite employing a straightforward approach that relies solely on prompt-based probability distribution outputs and a post-processing classifier, the system demonstrates the capability to secure a satisfactory level of precision and consistency in real-world settings. Notably, attaining an Exact macro F1 score of 0.5606—a stringent evaluation criterion—indicates that the structured multi-dimensional features derived from the rubric-based items Q_{rubric} and $Q_{overall}$ effectively capture the educational validity of tutor responses.

These findings suggest that the prompt-based multi-dimensional judgment methodology not only generates responses but also effectively aligns the evaluation and classification of responses with human raters. Furthermore, the methodology maintains a certain degree of generalization performance even on inputs that were not seen during training, thereby illustrating that evaluations leveraging large language models can function as assessments with genuine educational validity.

4 Conclusion

This study proposed a set of prompting-based automatic evaluation methods to assess the pedagogical quality of AI tutor responses across four key dimensions: Mistake Identification, Mistake Location, Providing Guidance, and Actionability. Leveraging the capabilities of GPT-4.1, the methods were designed to emulate human-like reasoning through chain-of-thought prompting, multi-perspective reflection, and rubric-based probability estimation, aligning large language model outputs with authentic educational feedback standards.

Our approaches demonstrated competitive performance in the BEA 2025 Shared Task across multiple evaluation tracks. The Multi-Perspective Reflective Evaluation showed strong performance in Mistake Location, while the Rubric-Based Evaluation validated the effectiveness of structured feature extraction and post-classification for nuanced feedback analysis in Providing Guidance. These findings confirm that prompt engineering—when guided by educational theory and structured evaluation logic—can significantly improve the interpretability and reliability of LLM-based tutor assessments. Although fine-grained distinctions be-

tween evaluation categories remain challenging, the results underscore the feasibility of using large language models for scalable, pedagogically sound evaluation in open-ended educational dialogues.

Future work may explore integrating these methods into real-time tutoring systems, applying task-specific fine-tuning to improve classification sensitivity, and extending the framework to multimodal or domain-specific educational contexts. Ultimately, this line of research contributes to developing AI systems that are not only linguistically fluent but also aligned with human learning objectives.

Limitations

As the proposed methods relies on the model’s internal reasoning to perform evaluations, it may yield interpret evaluation criteria differently depending on the model. This is especially true for intermediate categories such as “To some extent”, where subjective interpretation can lead to ambiguity, indicating a limitation in ensuring the reliability of automatic assessment.

A Chain-of-Thought-based Pedagogical Evaluation with Reasoning layers Prompts

This section presents the detailed prompt used in the Chain-of-Thought-based Pedagogical Evaluation with Reasoning Layers methodology described in Section 2.1. The prompt serves as a core component of the proposed step-by-step structure, which emulates how human tutors interpret students' reasoning and determine appropriate feedback. It guides the model to first reconstruct the student's reasoning, then generate a correct solution path, and finally evaluate the pedagogical appropriateness of the tutor's response in light of the student's thinking process.

Problem Extraction

Identity

You are an expert in analyzing conversations and extracting specific information precisely from textual inputs.

Your task is to read through a dialogue transcript carefully and extract a math problem as-is, without modifying any part of it. The conversation always contains exactly one math problem.

Instructions

- * Read the conversation carefully and identify the one math problem embedded within.
- * Copy the entire text of that math problem verbatim, exactly as it appears in the dialogue.
- * Do not add any explanation, paraphrasing, or interpretation.
- * Output only the extracted math problem and nothing else.

Student Reasoning Process Reconstruction

Identity

You are an expert in analyzing educational conversations to reconstruct the reasoning processes behind students' mathematical answers.

Your task is to read a conversation between a tutor and a student, along with the math problem discussed. Then, from the student's point of view, explain the reasoning process the student might have used to arrive at their final answer.

Your goal is to reconstruct the student's reasoning path — whether correct or incorrect — as faithfully and coherently as possible based on the conversation and the problem given.

Instructions

1. Do not modify, correct, or reinterpret the student's final answer — even if the answer is incorrect.
2. Base your reasoning entirely on what was stated in the conversation.
3. If no reasoning was explicitly given by the student, infer a likely and plausible thought process they could have followed to reach their answer.
4. Ensure that your explanation is logically consistent with the content of the conversation. Avoid introducing contradictions.
5. Write your reasoning as a clear, step-by-step explanation, emulating how the student may have thought through the problem.

Correct Reasoning Process Generation

Identity

You are a logical reasoning assistant specialized in mathematical thinking and student misconception analysis.

You are given:

1. A transcript of a conversation between a student and a tutor
2. The math problem discussed in the conversation
3. The student's reasoning process, which has been reconstructed based on the conversation, not written directly by the student.
 - Parts explicitly mentioned in the dialogue can be trusted as the student's actual reasoning.
 - Parts not mentioned directly have been inferred based on the dialogue and should be treated as plausible, but not definitive.

Your task is to carefully analyze the student's reasoning process and perform the following instructions:

Instructions

Step 1: Identify Reasoning Errors Review the student's reasoning. Clearly point out any logical, mathematical, or conceptual errors. If there are no errors, state that explicitly.

Step 2: Reconstruct the Correct Reasoning (Based on Student's Thought Process) If the student made partial progress or had a valid approach but made an error along the way, retain and respect their original reasoning path. Correct the specific mistakes and continue the reasoning from where they deviated. If the student's reasoning is fundamentally flawed from the beginning or completely irrelevant to the problem, it is acceptable to construct a new, correct reasoning path.

Step 3: Solve the Problem Using the corrected reasoning (rooted in the student's approach if applicable), solve the math problem and provide the correct final answer.

Step 4: Output Format Provide your response in the following structure:

- Student Reasoning Error(s): [List and explain]
- Corrected Reasoning (Respecting Student's Logic): [Step-by-step, rooted in their original path]
- Final Answer: [Answer]

Tutor Response Evaluation

Identity

You are a senior math tutor and tutor coach with expertise in evaluating instructional quality. You will receive the following inputs:

1. A dialogue between a student and a novice tutor.
2. The math problem discussed in the dialogue.
3. A senior tutor's analysis of the student's likely reasoning and a revised correct solution.
4. The final utterance made by the novice tutor.

Instructions

Evaluation Criteria

- Evaluate the novice tutor's final utterance, using the following four criteria:
- broader dialogue context, including the student's previous responses and the progression of the conversation.
- In other words, evaluate how well the tutor's final utterance functions as a response within the instructional flow and in light of the student's reasoning process.

1. Mistake Identification

- Did the novice tutor demonstrate awareness of a mistake in the student's reasoning?
 - Yes: The tutor reasonably indicates awareness of the student's mistake or explicitly suggests the possibility of an error, even if somewhat general.
 - To some extent: The tutor vaguely hints at a mistake, but the suggestion is overly ambiguous or uncertain.
 - No: The tutor does not identify or suggest any mistake in the student's reasoning.

2. Mistake Location

- Did the novice tutor pinpoint where the mistake occurred in the student's process?
 - Yes: The tutor appropriately identifies or indicates the step or area where the student's mistake occurred. Exact pinpointing is not required, as long as the general location or nature of the error is clear.
 - To some extent: The tutor provides only a vague or unclear indication of the error's location, potentially leading to student confusion.
 - No: The tutor does not specify or reference where the student's error occurred.

3. Pedagogical Guidance

- Did the novice tutor provide helpful explanations, hints, or examples to support student learning?
 - Yes: The tutor provides explanations, hints, or examples that meaningfully support student understanding. Slight inaccuracies or imperfections are acceptable as long as the guidance is helpful from the student's perspective.
 - To some extent: The tutor offers guidance, but it contains significant ambiguities, inaccuracies, or potential misconceptions.
 - No: The tutor provides no useful explanation or hints, or the provided guidance is clearly incorrect or misleading.

4. Actionability

- Can the student clearly understand what to do next based on the tutor's response?
 - Yes: The tutor reasonably suggests a clear next step or strategy that the student can readily understand and follow. Explicit instructions are not required as long as the suggested action is practical and clear enough.
 - To some extent: The tutor suggests a next step, but the recommendation is unclear, confusing, or insufficiently specific.
 - No: The tutor does not suggest any actionable next step or strategy for the student.

Output Format (MANDATORY)

- Respond in exactly the following format. Do not change the structure, headings, or indentation.

"Mistake Identification: [Yes / To some extent / No]

Explanation: [...]

Mistake Location: [Yes / To some extent / No]

Explanation: [...]

Pedagogical Guidance: [Yes / To some extent / No]

Explanation: [...]

Actionability: [Yes / To some extent / No]

Explanation: [...]"

You must follow this format strictly. Any deviation will be considered incorrect.

Now, evaluate the novice tutor's final utterance.

Basic Prompt

Identity

You are a senior math tutor and tutor coach with expertise in evaluating instructional quality. You will receive the following inputs:

1. A dialogue between a student and a novice tutor.
2. The final utterance made by the novice tutor.

Instructions:

Evaluation Criteria

- Evaluate the novice tutor's final utterance, using the following four criteria.

1. Mistake Identification

- Detect whether tutors' responses recognize mistakes in students' responses. The following categories are included:
 - Yes: The mistake is clearly identified/recognized in the tutor's response.
 - To some extent: The tutor's response suggests that there may be a mistake, but it sounds as if the tutor is not certain.
 - No: The tutor does not recognize the mistake (e.g., they proceed to simply provide the answer to the asked question).

2. Mistake Location

- Assess whether tutors' responses accurately point to a genuine mistake and its location in the students' responses. The following categories are included:
 - Yes: The tutor clearly points to the exact location of a genuine mistake in the student's solution.
 - To some extent: The response demonstrates some awareness of the exact mistake, but is vague, unclear, or easy to misunderstand.
 - No: The response does not provide any details related to the mistake.

3. Pedagogical Guidance

- Evaluate whether tutors' responses offer correct and relevant guidance, such as an explanation, elaboration, hint, examples, and so on. The following categories are included:
 - Yes: The tutor provides guidance that is correct and relevant to the student's mistake.
 - To some extent: Guidance is provided but it is fully or partially incorrect, incomplete, or somewhat misleading.
 - No: The tutor's response does not include any guidance, or the guidance provided is irrelevant to the question or factually incorrect.

4. Actionability

- Assess whether tutors' feedback is actionable, i.e., it makes it clear what the student should do next. The following categories are included:
 - Yes: The response provides clear suggestions on what the student should do next.
 - To some extent: The response indicates that something needs to be done, but it is not clear what exactly that is.
 - No: The response does not suggest any action on the part of the student (e.g., it simply reveals the final answer).

Output Format (MANDATORY)

- Respond in exactly the following format. Do not change the structure, headings, or indentation.

Mistake Identification: [Yes / To some extent / No]

Explanation: [...]

Mistake Location: [Yes / To some extent / No]

Explanation: [...]

Pedagogical Guidance: [Yes / To some extent / No]

Explanation: [...]

Actionability: [Yes / To some extent / No]

Explanation: [...]

You must follow this format strictly. Any deviation will be considered incorrect.

Now, evaluate the novice tutor's final utterance.

B Rubric Based Evaluation Method prompt

To evaluate the Providing Guidance dimension, we designed a structured prompt that guides the language model to simulate expert judgment across six sub-criteria. The prompt first provides the full dialogue context, the student's final utterance, and the tutor's response. It also includes prediction results from other evaluation dimensions (Mistake Identification and Mistake Location), as well as statistical correlations observed between them. The model is instructed to assess the tutor's response based on six specific questions, each targeting a pedagogically meaningful aspect of guidance. For each item, the model outputs a brief rationale and assigns probabilities to three labels: Yes, To some extent, and No. The final output consists of both the explanation and a normalized probability distribution that sums to 1.0. The sixth question is designed to produce an overall judgment by incorporating both model predictions and prior statistical informations, providing a holistic measure of guidance quality.

Prompt for Rubric-Based Multidimensional Evaluation

You are an expert evaluator analyzing a tutor's response in a learning dialogue.

Below is a conversation between a student and a tutor.

[Conversation]

<Full conversation history, if any>

[STUDENT_UTTERANCE]

<Student's latest input>

[TUTOR_RESPONSE]

<Tutor's response to be evaluated>

[Prediction Results]

- Mistake Identification: <Predicted label>
- Mistake Location: <Predicted label>

Note: Based on statistical analysis of past data, the following association rules are observed:

- If Providing Guidance is "Yes", then Mistake Identification is also "Yes" with confidence 0.950.
- If Mistake Location is "Yes", then Mistake Identification is "Yes" with confidence 0.989.
- If Mistake Identification is "Yes", then Mistake Location is "Yes" with confidence 0.790.

Use the following definitions when choosing a label:

- Yes: The tutor's response fully satisfies the criterion. It is accurate, relevant, and helpful.
- To some extent: The response attempts to satisfy the criterion but is partially incomplete, inaccurate, vague, or not directly useful.
- No: The response does not satisfy the criterion at all, or it is misleading, unrelated, or entirely incorrect.

Please answer the following six questions. For each question, first provide a brief explanation for your judgment. Then, give the probability (in float format) that the response is: Yes, To some extent, or No. Ensure all three values sum to exactly 1.0.

Output format:

- Q1: <brief explanation>
- Yes: <float>
 - To some extent: <float>

- No: <float>

Questions:

- Q1. Did the tutor attempt to provide any explanation, hint, or example?
- Q2. Was the guidance factually correct and appropriate given the student's error?
- Q3. Did the tutor's response directly address the student's specific mistake?
- Q4. Did the guidance help the student figure out what to do next, without directly giving the final answer?
- Q5. Was the tutor's response clear and unlikely to confuse the student?
- Q6. Based on the tutor's response, the model's predictions, and the above statistical information, how likely is it that the tutor attempted to provide meaningful guidance?

C Analysis of Prediction Results on the Development Set

This section presents the classification results on the development set for each of our proposed systems. Although the overall metrics provide a broad overview of performance, they do not sufficiently capture the models’ ability to discriminate fine-grained categories—particularly ambiguous ones such as To some extent. Therefore, we provide a detailed analysis of each system’s predictions according to the evaluation track.

C.1 Chain-of-Thought-based Evaluation System

As shown in Section 3.3, our proposed Chain-of-Thought-based evaluation system demonstrated effectiveness in generating evaluations that are both consistent and pedagogically valid. However, as previously noted, the model still exhibits limitations in accurately distinguishing between semantically adjacent evaluation categories. To further investigate this issue, we conducted an analysis of how such difficulties manifest in actual prediction outcomes.

Actual / Predict	Yes	To some extent	No	Total
Yes	1,657	237	38	1,932
To some extent	63	68	43	174
No	60	56	254	370

Table 6: Confusion matrix of the CoT-based Evaluation System for the Mistake Identification track.

Table 6 presents the prediction results for the Mistake Identification track in the form of a confusion matrix. In this track, the model accurately classified the majority of "Yes" instances (1,657 out of 1,932), but struggled to distinguish the "To some extent" category. Specifically, only 68 out of 174 instances were correctly identified, while the remaining were misclassified as "Yes" (63 instances) or "No" (43 instances), indicating persistent challenges in delineating fine-grained judgment boundaries.

Actual / Predict	Yes	To some extent	No	Total
Yes	727	547	36	1,310
To some extent	88	245	36	369
No	253	183	361	797

Table 7: Confusion matrix of the CoT-based Evaluation System for the Actionability track.

A similar pattern is observed in the Actionabil-

ity track, as shown in Table 7. While the model achieved relatively high true positive counts for the "Yes" (727 instances) and "No" (361 instances) categories, “To some extent” cases were frequently misclassified—most notably, among the actual “No” instances, 547 were predicted as "Yes" and 183 as "To some extent".

These results indicate that while the proposed Chain-of-Thought-based evaluation system is effective in producing consistent judgments based on explicit criteria, it still faces limitations in clearly distinguishing semantically adjacent categories. In particular, the frequent misclassification of ambiguous labels such as To some extent highlights the difficulty of inducing fine-grained reasoning solely through prompts without task-specific training. This observation suggests the potential need for improved prompt engineering or subsequent fine-tuning to enhance the model’s discriminative precision.

C.2 Multi-Perspective Reflective Evaluation System

This section presents an analysis of the Multi-Perspective Reflective Evaluation System’s performance on the Mistake Location track. The goal is to understand how effectively the system distinguishes between clearly defined and semantically adjacent categories within its reflective reasoning framework.

Actual \ Predicted	Yes	To some extent	No	Total
Yes	1,219	140	184	1,543
To some extent	99	33	88	220
No	117	79	517	713

Table 8: Confusion matrix of the Multi-Perspective Reflective Evaluation System for the Mistake Location track.

The analysis of Mistake Location is presented in Table 8. The results show that although the system accurately identifies many instances of "Yes" (1,219 correct predictions), it struggles to distinguish "To some extent" from adjacent categories. Specifically, only 33 out of 220 "To some extent" cases were correctly classified, while the majority were misclassified as either "Yes" (99 instances) or "No" (88 instances). This analysis supports our observations in Sections 3.3 and 3.4 that prompt-based reasoning approaches still face challenges in making fine-grained categorical distinctions.

C.3 Rubric Based Evaluation System

To assess the performance of the Rubric Based Evaluation System in identifying pedagogically meaningful distinctions, we examine its predictions on the Providing Guidance track. This allows us to evaluate the effectiveness of rubric-derived features in capturing subtle differences between response categories.

Actual / Predict	Yes	To some extent	No	Total
Yes	1,034	266	107	1,407
To some extent	250	179	74	503
No	178	83	305	566

Table 9: Confusion matrix of the Rubric Based Evaluation System for the Providing Guidance track.

Table 9 presents the prediction results of our proposed Rubric Based Evaluation System. The system consists of a Random Forest classifier trained using the Q_{rubric} items and the predicted values of $Q_{overall}$ as input features. For the "Yes" class, 1,034 out of 1,407 instances were correctly classified. For the "No" class, 305 out of 566 instances were correctly classified. In contrast, for the "To some extent" class, only 179 out of 503 instances were correctly classified, with 250 instances misclassified as "Yes" and 74 as "No." These results indicate that the classifier struggled to clearly distinguish the "To some extent" class from "Yes" and "No." This suggests that, even when combining information from Q_{rubric} and $Q_{overall}$, additional feature engineering or refinement may be necessary to more precisely delineate the boundaries among the three classes.

Henry at BEA 2025 Shared Task: Improving AI Tutor’s Guidance Evaluation Through Context-Aware Distillation

Pagnarith Pit

University of Melbourne

ppit@student.unimelb.edu.au

Abstract

Effective AI tutoring hinges on guiding learners with the right balance of support. In this work, we introduce **CODE** (**C**ontextually-aware **D**istilled **E**valuator), a framework that harnesses advanced large language models (i.e., GPT-4o and Claude-2.7) to generate synthetic, context-aware justifications for human-annotated tutor responses in the BEA 2025 Shared Task. By distilling these justifications into a smaller open-source model (i.e., Phi-3.5-mini-instruct) via initial supervised finetuning and then Group Relative Policy Optimization, we achieve substantial gains in label prediction over direct prompting of proprietary LLMs. Our experiments show that **CODE** reliably identifies strong positive and negative guidance, but like prior work, struggles to distinguish nuanced “middle-ground” cases where partial hints blur with vagueness. We argue that overcoming this limitation will require the development of explicit, feature-based evaluation metrics that systematically map latent pedagogical qualities to model outputs, enabling more transparent and robust assessment of AI-driven tutoring.

1 Introduction

Large language models (LLMs) have opened a promising frontier for education, enabling conversational agents that deliver personalized and adaptive guidance calibrated to a learner’s current knowledge state and pace (Tack et al., 2023). Indeed, the main goal of dialectic teaching is to provoke exploration through carefully timed questions, hints, or explanations (Clark and Egan, 2015). If the guidance provided is too little, it frustrates students, while too much erodes learning opportunities and fosters over-reliance (Le, 2019). Although striking this balance is central to effective tutoring, the field still lacks precise operational definitions and automatic metrics for “optimal guidance”, making systematic eval-

uation, and therefore progress, very challenging (Kochmar et al., 2025).

In light of this missing definition, existing assessments rely heavily on individual annotation by human experts (Maurya et al., 2025). However, crafting high-quality, question-specific explanations at the scale needed to train or benchmark modern transformer models is prohibitively expensive. To address this bottleneck, we explore *reasoning distillation*: using stronger LLMs to generate reasoning about a tutor’s utterance as to why it matches the gold label. Our study investigates (i) whether synthetically contexts capture meaningful signals of pedagogical quality, and (ii) how well these signals transfer when smaller, student models are trained on them.

As such, our contributions from team Henry are as follows:

- We propose **C**ontextually-aware **D**istilled **E**valuator (**CODE**) framework, a multi-step finetuning process that distills reasoning from larger LLMs to train smaller open-sourced models to better detect what “good guidance” is. Our method consistently outperforms state-of-the-art (SOTA) proprietary models and aligns reasonably well with expert human judgements.
- We release an enriched dataset with synthetically generated reasoning based on their gold labels for each of the tutor’s last utterance across the entire human-annotated set from (Maurya et al., 2025).

2 Related Work

2.1 AI Tutor’s Guidance Evaluation

This feature of AI tutor currently lacks a unified definition, but there has been efforts in this area to explore it through various perspectives. Tack

and Piech (2022) in their work evaluates performances of AI tutor based on how much they “help the student” using human participants and expert annotators. While they don’t provide a formal definition, their approach to evaluation is closely resembled by Daheim et al. (2024)’s “actionability” where the AI tutor’s utterance provides sufficient information for the student to progress the conversation and move closer to the correct answer.

In another work by Wang et al. (2024), this feature is referred to as “usefulness”, the degree to which the responses are productive at advancing the student’s understanding and helping them learn from their errors, also evaluated through human judgments. These concepts are also reflected in the work of Al-Hossami et al. (2023), where they defined “indirectness”, where an effective tutor asks questions that induce critical thinking and not reveal the answer.

2.2 Learning via Distillation

Knowledge distillation transfers the knowledge embedded in large, high-capacity “teacher” models into smaller, more efficient “student” models by having the student match the teacher’s softened probability distributions, known as “soft targets”, rather than relying solely on hard labels. First introduced by Hinton et al. (2015), this technique has enabled compact language models to approach the performance of much larger LLMs while using reduced architectures and training data (Hsieh et al., 2023).

More recently, distillation has been extended to complex reasoning tasks, spawning the field of reasoning distillation. For example, Li et al. (2025) present Fault-Aware Distillation via Peer-Review (FAIR), in which multiple teacher models critique each other’s reasoning chains to improve fidelity. Likewise, Dai et al. (2024) propose training student models on key reasoning steps extracted from dual chain-of-thought explanations. These innovations not only enhance model interpretability but also substantially boost conceptual understanding in educational applications.

3 Methods

3.1 Synthetic Context Generation

Data Preprocessing We focus exclusively on Task 3 of the BEA Shared Task (Kochmar et al., 2025), and so we process the original dataset from Maurya et al. (2025) accordingly. From

the provided validation set, we construct a filtered dataset:

$$\mathcal{D} = \{(C_i, R_i, L_i)\}_{i=1}^N,$$

such that for each sample i :

- C_i : conversation history of each original element,
- R_i : each tutor’s response,
- $L_i \in \{Yes, To\ Some\ Extent, No\}$: the gold label provided by “Providing Guidance”

In total, we have $N = 3,589$.

Generating Reasoning with Labels To enrich each response label with contextual justification, we leverage two state-of-the-art models, namely GPT-4o (OpenAI et al., 2024) and Claude-2.7 Sonnet (Anthropic, 2024). For each model, we process batches of 10 examples from our original dataset \mathcal{D}^1 alongside the system prompt in Appendix A. Each model then generates a justification J_i for sample i , drawing on the provided label L_i , the conversation history C_i , and the latest tutor response R_i . This yields an expanded dataset

$$\mathcal{D}' = \{(C_i, R_i, L_i, J_i)\}_{i=1}^N,$$

where J_i is the synthetic justification associated with the i th response.

Selection of Justifications To ensure the quality and utility of the synthetically generated justifications, we conduct a manual selection process to identify the most suitable responses produced by the two models. The selection criteria are as follows:

- **Non-repetition:** Justifications that are repeated within the same batch are excluded to prevent redundant signals, which could lead to overfitting during downstream model training.
- **Linguistic diversity and specificity:** Selected justifications exhibit varied and distinctive vocabulary, reflecting the natural diversity found in human tutor responses. This diversity will then enhance the generalizability of models trained on the data.

¹Batch size selected after varying from 1 to 50. We find that beyond 10 samples, both models tend to hallucinate or become overly generic and provide low-quality responses.

- **Adequate length and contextual richness:** Justifications are required to provide sufficient explanatory detail to offer meaningful context for the corresponding labeled response.

Extracting Critical Tokens For each synthetic justification J_i , we perform the following preprocessing steps:

1. Convert to lowercase and strip leading/trailing whitespace.
2. Remove all stopwords.
3. Tokenize the resulting string.
4. Apply stemming and lemmatization to each token.

Let

$$\mathcal{T}_i = \{t_{i1}, t_{i2}, \dots, t_{iK_i}\}$$

be the set of remaining tokens for sample i . We refer to \mathcal{T}_i as the *context-critical* token set, and we use these tokens as our reward signals. With this, we now proceed to training our student model.

3.2 Expert Alignment Through Reinforcement Learning

To best align the student model’s outputs with those of advanced LLMs, and potentially a human tutor expert, we introduce the **CO**ntextually-aware **D**istilled **E**valuator (**CODE**) framework. In **CODE**, reasoning is distilled through a multi-step transfer process, with tailored reward signals that guide the model to generate contextually relevant tokens for downstream classification.

3.2.1 Initial Supervised Learning

We begin by performing supervised fine-tuning (SFT) to teach the student model to generate J_i given the conversation history C_i and last response R_i . This initial stage aims to instill the desired format, tone, and length characteristic of expert-generated justifications. At this point, emphasis is placed not on the semantic quality or reasoning depth of the model’s outputs, but rather on aligning the stylistic aspects of the responses to facilitate more efficient convergence during subsequent training phases. We have:

$$J_i = (j_{i,1}, j_{i,2}, \dots, j_{i,T_i}),$$

where each justification is represented as a token sequence. Under a standard cross-entropy objective, the per-sample loss is

$$\ell_i(\theta) = -\frac{1}{T_i} \sum_{t=1}^{T_i} \log p_\theta(j_{i,t} | C_i, R_i, j_{i,<t}),$$

where $p_\theta(\cdot)$ is the student model’s predicted probability and $j_{i,<t} = (j_{i,1}, \dots, j_{i,t-1})$. Averaging over all N samples gives the final SFT loss:

$$\mathcal{L}_{\text{SFT}}(\theta) = \frac{1}{N} \sum_{i=1}^N \ell_i(\theta)$$

The system prompt used as part of this instruction tuning is provided in Appendix C.

3.2.2 Applying GRPO with Semantic Rewards

After supervised fine-tuning, we now refine the student model’s output quality via an online reinforcement-learning algorithm known as *Group Relative Policy Optimization* (GRPO) (Shao et al., 2024). We denote the student’s policy by

$$\pi_\theta(J | C_i, R_i),$$

parameterized by θ , which we adapt efficiently using low-rank adaptation (LoRA) (Hu et al., 2021) updates to the transformer weights.

Group sampling and baseline For each training example (C_i, R_i) , the model samples a *group* of M candidate justifications:

$$\{J_i^1, J_i^2, \dots, J_i^M\} \sim \prod_{j=1}^M \pi_\theta(\cdot | C_i, R_i).$$

Each candidate J_i^j is scored by a programmable reward function r_i^j . We then compute the group baseline as the mean reward:

$$b_i = \frac{1}{M} \sum_{j=1}^M r_i^j.$$

Reward design The total reward r_i^j is a weighted sum of three components:

$$r_i^j = w_{\text{tok}} r_i^{\text{tok}}(J_i^j) + w_{\text{sent}} r_i^{\text{sent}}(J_i^j) + w_{\text{ppl}} r_i^{\text{ppl}}(J_i^j),$$

where:

$$r_i^{\text{tok}}(J) = \sum_{t \in \mathcal{T}_i} \mathbf{1}\{t \text{ appears in } J\},$$

$$r_i^{\text{sent}}(J) = \begin{cases} 1 & \text{if the sentiment of } J \text{ matches the gold label,} \\ 0 & \text{otherwise,} \end{cases}$$

$$r_i^{\text{ppl}}(J) = -\frac{1}{|J|} \sum_{t=1}^{|J|} \log p_{\theta_0}(j_t | C_i, R_i, j_{<t}).$$

Here \mathcal{T}_i is the context-critical token set for example i . In this reward scheme, we do not punish the student model arbitrarily for not generating trivial tokens. Likewise, it is only rewarded if it can generate the critical tokens that would be informative for the response’s label based on the context provided.

Next, the sentiment score is given by a finetuned transformer based on DistilBERT (Sanh et al., 2020) (i.e., DistilBERT-based SST-2 classifier). While sentiment alone is not a reliable indicator of guidance quality (Wang et al., 2024), it provides a concrete and readily interpretable signal that can guide model generation. The inclusion of this sentiment-based reward facilitates faster convergence of the student model by offering an easier-to-learn proxy objective compared to directly optimizing for alignment with complex gold labels. Crucially, sentiment is not intended as a hard classification signal but rather a soft reward, encouraging the generation of justifications whose affective tone is consistent with the associated label. This approach helps steer the model’s learning trajectory in a meaningful direction in light of GRPO’s multiple response generation.

Finally, p_{θ_0} denotes the frozen base model (i.e., untrained student model) used to compute perplexity. Importantly, the perplexity score is added such that the trained model does not exploit the other reward signals by randomly inserting tokens as part of their outputs. This ensures that the final responses produced by the trained student model is still cohesive and human understandable.

Before performing the policy gradient update, these scores are then normalised to zero mean and unit variance to prevent their magnitude from dominating other scores, with the weights ($w_{\text{tok}}, w_{\text{sent}}, w_{\text{ppl}}$) balancing these signals.²

3.3 Final Classification

To produce the final label predictions, we append a trainable classification head atop the trained student model. The primary objective of this step is feature selection. That is, the student model has been previously trained to generate justifications containing critical tokens, and as such, this classification head aims to capture and interpret these contextual cues, mapping them effectively to the

²We experimented with several weighting schemes but observed only minor, non-meaningful variations. As such, for our final implementation we adopted uniform weights, assigning a value of 1 to each.

target label space. In this final training stage, the model is trained to associate its own generated output with the corresponding gold label.

We first map each gold label:

$$L_i \in \{\text{Yes, To Some Extent, No}\}$$

to a categorical target $y_i \in \{1, 2, 3\}$. Let θ^* denote the student model parameters after merging the LoRA adapters. Here, we freeze all θ^* and add a dense feedforward layer with parameters $\phi = (W, b)$, where

$$W \in R^{3 \times d}, \quad b \in R^3.$$

However, instead of training it on one forward pass on each example (C_i, R_i) , we first generate the student model’s full response by

$$\hat{J}_i = \arg \max_J \pi_{\theta^*}(J | C_i, R_i).$$

We encode this output using the student model’s tokenizer, and train ϕ using standard cross-entropy loss on the last token hidden state:

$$\mathcal{L}_{\text{CE}}(\phi) = -\frac{1}{N} \sum_{i=1}^N \sum_{c=1}^3 \mathbf{1}[y_i = c] \log \hat{p}_{i,c}.$$

where $\hat{p}_{i,c}$ is the softmax of the classification head’s predicted labels.

This pooling design choice to use the last token hidden state as the representation is particularly motivated by the architecture of decoder-only transformers, which lack a dedicated classification token such as [CLS] found in encoder-based models (Fu et al., 2023). The last token in our generated outputs (i.e., each justification) functions as a natural summary or conclusion to the token sequence, providing a meaningful contextual embedding that reflects the entire output. This approach balances computational efficiency, avoiding the increased complexity of attention-based pooling, and mitigates the potential noise or dilution of critical token signals that may arise with mean pooling strategies (Suganthan et al., 2025).

External Benchmarking In addition to comparing against gold labels and the CodaBench leaderboard submission, we also evaluate whether our method could outperform direct prompt-tuning of the proprietary models. For each example, we prompt GPT-4o and Claude-2.7 Sonnet to predict the guidance label without revealing the true label and recorded their accuracy on the validation set. The exact prompts used for this experiment are provided in the Appendix B.

Model	Validation set				CodaBench set			
	Ex. F1	Ex. Acc	Len. F1	Len. Acc	Ex. F1	Ex. Acc	Len. F1	Len. Acc
GPT-4o	56%	69%	75%	83%	49%	58%	70%	75%
Claude-2.7 Sonnet	61%	70%	73%	81%	—	—	—	—
CoDE	64%	74%	83%	89%	53%	63%	72%	78%

Table 1: Evaluation of all models across both validation set and the CodaBench test set. Due to the limited nature of submission on CodaBench set, results from Claude-2.7 Sonnet were not submitted in the competition. All result reported has been rounded to the nearest percent. The final reported score on the official leaderboard for CoDE is slightly higher than the reported value in this table, but because the baseline score of GPT-4o is not reported there, we report the values of CoDE from the unofficial table for consistency.

3.4 Experimental Setup

We used the Unsloth-provided “Phi-3.5-mini-instruct” (Daniel Han and team, 2023; Abdin et al., 2024) as our student model. The original validation set was further split 80/20 into training and test subsets. All data preprocessing ran on an NVIDIA L40 GPGPU, with model training and evaluation performed on an NVIDIA A100 GPU. In total, preprocessing, training, and evaluation consumed over 70 GPU-hours. Complete details on training hyperparameters, such as GRPO and LoRA parameters, are detailed in the Appendix.

4 Results

As shown in Table 1, **CODE** consistently outperforms state-of-the-art baselines, achieving the tenth position in the final CodaBench ranking. We attribute this improvement both to the quality of the synthetic data and to the student model’s ability to capture hidden features from the extended context. Our results suggest that existing SOTA models possess an implicit notion of “good guidance”, and their generated outputs can be effectively transferred to smaller models. This observation corroborates prior work demonstrating that large language models can serve as an effective tutors, offering substantial instructional value, albeit not at expert-level proficiency (Wollny et al., 2021).

Notably, on both the validation set and, to a lesser extent, the CodaBench benchmark, **CODE** exhibits a larger gain when evaluated with lenient F1 compared to exact F1, with improvements under strict scoring criteria remain modest. This pattern indicates that fine-tuning renders **CODE** less sensitive to the ambiguous label that is “To some extent”. The strong labels, “Yes” or “No”, are much easier to deduce, with clearer human definition, but this “middle-ground” is much more nu-

anced, and since finetuning is known to reduce LLMs’ general reasoning (Luo et al., 2025), this drop may be inevitable. When pedagogical value differs only slightly, we see that even among human experts, these are difficult to discern (Macina et al., 2023).

5 Conclusion

In this paper, we have investigated the potential of modern large language models to both generate and train on synthetic data that emulate expert human reasoning in educational guidance through our **CODE** framework. Across both our validation and CodaBench test sets, our approach consistently outperforms SOTA baselines and aligns reasonably well with human judgments. However, our findings also underscore the persistent challenge of the absence of a formal, operational definition of this pedagogical quality. In particular, nuances embodied by the “middle-ground” label appear too subtle or demand too much data for current LLMs to learn reliably.

As future direction, we advocate for the continued development of explicit metrics that systematically map these latent pedagogical features to models’ outputs. By grounding fine-tuning in a well-defined, feature-based evaluation framework, we can move beyond black-box learning of hidden signals and instead foster more robust, transparent, and interpretable AI tutoring systems.

Limitations

5.1 Models Faithfulness and Prompt Sensitivity

The dataset created is not guaranteed to match reasoning provided by expert tutors. While we have conducted manual inspections on samples in the synthetic data to ensure some level of consis-

tency between reasoning and the label provided, this cannot be assured.

Furthermore, the SFT prompt used for training may not be optimal. This was chosen only after a few iterations of prompt tuning on a sample of the synthetic data.

5.2 Distillation Cost

Both models used are not open source nor free. Generating these takes extensive time on paid models, limiting the number of reasoning responses to one per sample. Ideally, we would like to expand this dataset further by generating multiple responses under various prompts to better simulate the diversity in thinking among real human tutors.

Ethical Consideration

Our research adheres strictly to ethical standards, using publicly available datasets as well as following distillation restriction carefully. We uphold the principles of fairness, accountability, and academic integrity throughout the research process.

A Synthetic Data Generation Prompt

For both GPT-4o and Claude, we used the following prompt to create our dataset:

Data Creation Prompt

You are an expert evaluator of Socratic-style tutoring dialogs in programming education. Your task is to justify the human-supplied quality label for the tutor’s last response You will receive: `conversation_history` (full transcript up to, but NOT including, the tutor’s latest reply, and the speaker turns are prefixed with “Student:” or “Tutor:”, `last_response` (the tutor’s latest reply, to be evaluated), and `label` (one of Yes, To some extent, No indicating whether the reply provides adequate, partial, or no helpful guidance to the student. These labels correspond to:

- Yes: The reply gives sufficient, specific, actionable guidance or hints that directly help the student correct their error or deepen understanding.
- To some extent: Contains some guidance, but it is vague, incomplete, or only tangentially helpful. Student would likely still struggle.
- No: Gives the answer outright without guidance, or offers no meaningful help, such as generic reassurance, topic change, or silence.

Return your result explaining why the provided label is appropriate as structured JSON with these keys: `{“label_justification”: string}`

B Proprietary Model Label Prompt

To produce labels from both GPT-4o and Claude as our external baselines, we used the following prompt:

Data Label Prompt

You are an expert evaluator of Socratic-style tutoring dialogs in programming education. You will receive: `conversation_history` (full transcript up to, but NOT including, the tutor's latest reply, and the speaker turns are prefixed with "Student:" or "Tutor:"), and `last_response` (the tutor's latest reply, to be evaluated). Your job is to provide a label (one of Yes, To some extent, No indicating whether the reply provides adequate, partial, or no helpful guidance to the student. These labels correspond to:

- **Yes:** The reply gives sufficient, specific, actionable guidance or hints that directly help the student correct their error or deepen understanding.
- **To some extent:** Contains some guidance, but it is vague, incomplete, or only tangentially helpful. Student would likely still struggle.
- **No:** Gives the answer outright without guidance, or offers no meaningful help, such as generic reassurance, topic change, or silence.

Return your result explaining why the provided label is appropriate as structured JSON with these keys: { "label": string }

C SFT Training System Prompt

The system prompt used to align the model's behaviour to that of a professional tutor is as follows:

System Prompt

You are a professional tutor. Your goal is to focus on whether the Last Response from the example is providing enough guidance (i.e, explanation, hints, guidance) to the student to act upon, progressing the conversation based on the conversation history. DO NOT continue the conversation, and you MUST use the Last Response provided. Focus on these characteristics:

1. If the Last Response provides specific, actionable guidance that identifies exactly where errors occur and

offers clear steps forward, balancing encouragement with targeted correction while addressing misconceptions without giving away complete answers.

2. If the Last Response acknowledges problems but offer incomplete guidance—they might identify errors without explaining how to fix them, use ambiguous language, or address only part of the misconception, leaving students without clear direction on how to proceed.
3. If the Last Response fails to provide meaningful guidance by offering empty praise without addressing errors, changing the subject, reinforcing incorrect understanding, giving answers without explanation, or presenting completely irrelevant information that leaves students with no actionable path forward in solving their problem.

D LoRA Training Arguments

This details the full LoRA training parameters:

- `max_seq_length`: 2048
- `dtype`: cuda
- `load_in_4bit`: False
- `device`: cuda
- `device_map`: cuda:0
- `r`: 64
- `target_modules`: {q_proj, k_proj, v_proj, o_proj, gate_proj, up_proj, down_proj}
- `lora_alpha`: 64
- `lora_dropout`: 0
- `bias`: none
- `use_gradient_checkpointing`: unsloth
- `random_state`: 42
- `use_rslora`: True
- `loftq_config`: None

E GRPO Training Arguments

This details the full GRPO training arguments:

- use_vllm: **True**
- learning_rate: 5×10^{-6}
- adam_beta1: 0.9
- adam_beta2: 0.99
- weight_decay: 0.1
- warmup_ratio: 0.1
- lr_scheduler_type: cosine
- optim: paged_adamw_8bit
- logging_steps: 10
- bf16: **True**
- per_device_train_batch_size: 1
- gradient_accumulation_steps: 1
- num_generations: 6
- max_prompt_length: 2048
- max_completion_length: 256
- num_train_epochs: 5
- max_steps: -1
- save_strategy: steps
- save_steps: 250
- max_grad_norm: 0.1

TBA at BEA 2025 Shared Task: Transfer-Learning from DARE-TIES Merged Models for the Pedagogical Ability Assessment of LLM-Powered Math Tutors

Abstract

This paper presents our contribution to the *BEA 2025 Shared Task on Pedagogical Ability Assessment of AI-Powered Tutors*. The objective of this shared task was to assess the quality of conversational feedback provided by LLM-based math tutors to students regarding four facets: whether the tutors 1) identified mistakes, 2) identified the mistake’s location, 3) provided guidance, and whether they 4) provided actionable feedback. To leverage information across all four labels, we approached the problem with *FLAN-T5* models, which we fit for this task using a multi-step pipeline involving regular fine-tuning as well as model merging using the *DARE-TIES* algorithm. We can demonstrate that our pipeline is beneficial to overall model performance compared to regular fine-tuning. With results on the test set ranging from 52.1 to 68.6 in F1 scores and 62.2% to 87.4% in accuracy, our best models placed 11th of 44 teams in Track 1, 8th of 31 teams in Track 2, 11th of 35 teams in Track 3, and 9th of 30 teams in Track 4. Notably, the classifiers’ recall was relatively poor for underrepresented classes, indicating even greater potential for the employed methodology.

1 Introduction

Large language models, such as the ones from the *GPT* (Radford et al., 2018) or *Llama* (Grattafiori et al., 2024) families, have demonstrated remarkable capabilities in generating a wide range of textual content. This has resulted in their quick adoption in the educational space, where they are used for diverse purposes, such as assessing student-generated content, providing feedback and guidance, or generating exercise questions, among others (Wang et al., 2024). They have also been incorporated into intelligent tutoring systems, combining multiple of these features and capabilities into a single application (Wang et al., 2025). However, a core problem with these models is that they do

not guarantee accurate, practical, or focused output (Xu et al., 2025). As generation is handled through a combination of autoregression and probabilistic sampling, it cannot be guaranteed that each production of a given model is purposeful and correct.

Importantly, this can be a severe problem in educational settings. In the European Union, the EU AI Act (European Parliament and Council of the European Union, 2024) classifies AI-based systems in an educational context as high risk. What if a tutor provides a learner with incorrect feedback because of a chain of unfortunate random sampling during the corresponding generation process? What if specific prompt characteristics affect output quality systematically, disadvantaging certain learner groups (Hofmann et al., 2024; Salikutluk et al., 2024)? What if a given feedback text is not actionable, and a learner is left with more questions? One possibility to address a few, albeit not all, such problems is to deploy models tailored explicitly for policing the output of a given model. What is already an established practice with commercial models, where, for example, the generation of toxic content is policed, also has enormous potential for the educational sector, where policing by educational criteria is required.

The *BEA 2025 Shared Task on the Pedagogical Ability Assessment of AI-powered Tutors* (Kochmar et al., 2025) explores this idea for a narrow use case where the output of LLM tutors when assisting students with simple arithmetic problems is assessed. In particular, the goal is to assess communication records between students attempting to solve simple math problems and LLMs that assist them as tutors. The communication records are classified according to whether the LLM tutor identified student mistakes, recognised the mistake location, provided guidance, and whether the provided guidance is actionable. As highlighted by Holmes et al. (2022), ethical considerations in AI in education, despite their crucial impact, are of-

ten not prioritized. The present shared task, therefore, offers the opportunity to address a subset of vulnerabilities that could otherwise lead to ethical breaches.

Our submissions to this shared task are based on variants of *FLAN-T5-xl* (Chung et al., 2024) that underwent multiple steps of task-wise fine-tuning and model merging via *DARE-TIES* (Yu et al., 2024). On the shared task leaderboard, based on macro F1, our systems rank 11th out of 44 teams in Track 1, 8th out of 31 teams in Track 2, 11th out of 35 teams in Track 3, and 9th out of 30 teams in Track 4.

2 Background

2.1 Pedagogical Ability Assessment and Pedagogical Alignment of LLMs

Using conversational agents in education is not a novel idea; it has been explored for several years, e.g., in the form of tutors or assistants (Wollny et al., 2021). However, following the release of ChatGPT in 2022 and the resulting surge in research on conversational large language models, interest in this topic has increased (e.g., Pal Chowdhury et al. 2024). Although large language models have demonstrated remarkable capabilities and possess significant potential for educational use cases, their probabilistic nature also presents challenges that must be addressed before these models can be safely deployed in pedagogical contexts. Older conversational agents are often based on rules, fuzzy matching against a search space of expected inputs, information retrieval, and pre-defined answers and dialogue scripts (Wollny et al., 2021). This makes it easy to pedagogically align them since all output they can generate is pre-defined to a certain degree, or can, in the case of information retrieval, at least be curated.

For LLMs, this is not the case. While they can answer and react more dynamically and are better suited to providing deeply individualised feedback since they can deal with unforeseen inputs posing problems to more traditional chatbot designs, achieving alignment with pedagogical criteria is harder for these models. On the one hand, this is due to the well-known hallucination problem (Xu et al., 2024). On the other hand, even when a model does not hallucinate and generates correct output, this does not necessarily imply that what is generated follows good pedagogical practice¹, since

¹<https://benchmarks.ai-for-education.org/>; ac-

these models were never trained with the same in mind.

For this reason, there has been increased interest in studying and improving pedagogical alignment for large language models (LLMs). Sonkar et al. (2024) compared *supervised fine-tuning* (SFT) and *learning from human preference* (LHP; Christiano et al., 2017) as training approaches for achieving pedagogical alignment for LLMs, with the latter approach achieving overall better downstream results. Dai et al. (2023) assessed feedback generated by *ChatGPT* using the well-known Hattie framework (Hattie and Timperley, 2007) and concluded that feedback generated by the model was overall more detailed compared to a human gold standard with an overall high agreement in terms of what exact elements from Hattie’s framework were represented in the feedback texts. Meyer et al. (2024) found increased motivation and performance on a revision task as well as more positive feelings through LLM-generated feedback compared to no feedback. Tack et al. (2023) hosted a shared task that benchmarked the overall ability of LLMs to act as pedagogically sound tutors when fine-tuned or prompt-tuned for the same purpose. Maurya et al. (2025) introduced a framework to rate the qualities of LLM-based tutors using eight different dimensions, each rated on a three-level scale. Four of these dimensions form the basis for the dataset used in this shared task.

2.2 Model Merging

Model merging refers to a growing set of recently developed methods that combine multiple fine-tuned models into a single one, sharing all their strengths. The core idea behind model merging lies in what is called *task arithmetics* (Ilharco et al., 2023). If we interpret the set of all parameters of a given LLM as one long vector, we can define such vectors for both a pre-trained model (θ_0) as well as task-specific fine-tuned versions of the same (θ_t). By subtracting the initial vector θ_0 from the fine-tuned vector θ_t , we gain the so-called task vector θ'_t representing the knowledge a model acquired during a specific fine-tuning instance t . We can then create *merges* by combining the resulting task vectors in various ways and adding the resulting vector to the original pre-trained model.

A naive approach to recombining task vectors is to calculate a weighted mean of them. How-

cessed on 2025-05-21

ever, this comes with several problems that mainly stem from the nature of stochastic gradient descent, which can lead to different fine-tuned models converging to distinct local minima in the parameter space. While two datasets a given model might be fine-tuned with might be highly related, implying that the respective fine-tuned models will have learned similar underlying functions by having adjusted the weights of a given model similarly, it is by no means specific that these learned representations will be localized in the identical or corresponding parameters (e.g., polysemanticity). Colloquially speaking, two different fine-tuning instances might store different knowledge in the same parameters, resulting in parameter interference and decreased downstream performance.

For this reason, algorithms such as TIES (Yadav et al., 2023) and DARE-TIES (Yu et al., 2024), which improves on the previous, have been developed. While TIES aims at fitting a transformation matrix that acts as a translation layer between two different fine-tuning instances and strives to identify correspondences between the internal representations of both task vectors, *DARE-TIES* combines this with directional averaging and heavy pruning of the individual task vectors to minimize interference during merging. The method can be denoted in the following way, with t being a given task from the set of all tasks used for a particular merge T :

$$\theta_{\text{DARE}}^t = \text{DARE}(\theta_t, \theta_0), \text{ for } t \in T \quad (1)$$

$$\theta_M = \theta_0 + \lambda \sum_t^T \text{TIES}(\theta_{\text{DARE}}^t, \theta_0) \quad (2)$$

For the exact implementation of *DARE* and *TIES*, see Yu et al. (2024) respectively Yadav et al. (2023).

3 Method

3.1 Dataset

The dataset used in the BEA 2025 shared task contains conversation histories between an LLM, functioning as a tutor, and a corresponding human student. Each conversation history involves a simple math problem and reflects a corresponding conversation between a student and an LLM. While the training set includes 300 such conversation histories, the test set contains 191. For each conversation, there are up to seven different final responses that were each generated by a different model, such as *GPT-4* or *Mistral* (Jiang et al., 2023)

in response to the provided history. Moreover, human responses from both expert and novice tutors are provided for each conversation. For each of the responses, four of the overall eight dimensions from the framework introduced by Maurya et al. (2025) are annotated using a three-level scale (no, to some extent, yes). The dimensions are:

- **Mistake Identification:** Is the LLM able to identify the learner mistake in its response?
- **Mistake location:** Is the location of a given mistake provided in a response?
- **Providing guidance:** Does the model provide appropriate guidance on how to solve the mistake?
- **Actionability:** Is what the model answers actionable?

Each of the four dimensions corresponds to an individual evaluation track of the shared task. Due to time constraints and its conceptually distinct goal, we disregarded the fifth track that was concerned with identifying the generating LLM.

3.2 System Development

Our system uses *FLAN-T5* (Chung et al., 2024) models to model classification as a sequence-to-sequence task, where the model is trained to generate an output sequence containing the correct label for a given input, which includes the full conversation context, including all utterances of both student and tutor in a given conversation. Concretely, a model receives the following input for a given datapoint x and assessment dimension d (*mistake location, mistake identification, ...*), with h_x denoting the provided conversation history and r_x the provided tutor response:

$$I(x, d) = d : \text{history} : h_x \text{ response} : r_x \quad (3)$$

We did not make any structural modifications to the models themselves and used the standard implementations provided by the *Huggingface Transformers* framework (Wolf et al., 2020). The procedure we used to fit these models, however, distinguishes this work from other use cases of *FLAN-T5* for classification.

It involves three steps, as depicted in Figure 1. In a first step, the given *FLAN-T5* models were fine-tuned for three epochs, one model for each of the

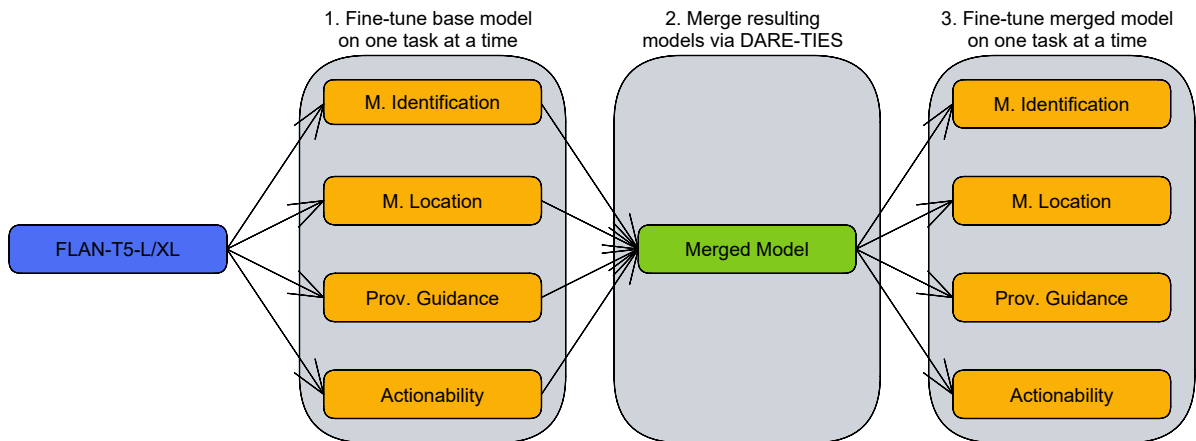

Figure 1: This figure depicts the overall training process we used during both our pre-experiments as well as for the final submission. First, *FLAN-T5* models are fine-tuned for three epochs for one dimension at a time. The resulting models are then merged using *DARE-TIES*. Lastly, the merged model serves as the basis for another round of task-specific fine-tuning, yielding the four final models.

four assessment dimensions, resulting in four individual models for *mistake identification*, *mistake location*, *provision of guidance*, and *actionability*. Fine-tuning was conducted using *Adagrad* as optimiser, a learning rate of $3e-4$, and a batch size of 4. These four models were then merged using the *DARE-TIES* (Yu et al., 2024) algorithm implementation provided by *Mergekit* (Goddard et al., 2024), with each model being uniformly weighted ($\lambda = 0.25$). The resulting model was then used as a basis for another round of fine-tuning, where we fine-tuned the merged model for each task individually again, resulting in another quartet of task-specific models.

The rationale behind this approach is the inherent interconnectedness between the four individual dimensions. We assumed that, for example, a mistake location can only reasonably be provided if a mistake is identified. Moreover, appropriate guidance can also be provided only if a mistake is identified. Then, only if guidance was provided at all can this guidance be actionable. Consequently, we assume that some of the parameters within models fine-tuned for one of these specific tasks likely encode information beneficial to the others.

DARE-TIES (Yu et al., 2024) as an algorithm enables us to exploit this property by merging multiple fine-tuned models into a single one that inherits the capabilities of all the used base models, with the possibility of even improving performance in some cases where the individual tasks are complementary to each other. This is achieved through the alignment and directional merging of the specific

Variant	MI	ML	PG	AC
Pre-merge	89.20	69.95	71.97	81.34
Merged	84.46	77.17	77.42	73.23
Post-merge	88.48	82.15	82.85	88.49

Table 1: Macro F1 scores for the three model stages in our pre-experiments. MI = Mistake Identification. ML = Mistake Location. PG = Providing Guidance. AC = Actionability.

model parameters.

Initially, we had assumed that the model resulting from the *DARE-TIES* merge would already be slightly stronger for each assessment dimension than the dimension-specific models. However, in our pre-experiments, we could not completely confirm this hypothesis. Using a 5x5 cross-validation setup with the complete training set, we fine-tuned and then merged *FLAN-T5-base* (Chung et al., 2024) models, with the result that the merged models showed a weaker performance for *mistake identification* and *actionability* than the dimension-specific models from which they were created (see Table 1), with an improved performance for *mistake location* and *providing guidance*.

For this reason, as a next step, we explored whether the resulting merged model would at least function as a reasonable basis for fine-tuning a next generation of dimension-specific models. As Table 1 shows, this was indeed the case, and the resulting dimension-specific models showed an improved performance over the merged variants as well as the dimension-specific models fine-tuned

Metric	MI	ML	PG	AC
Macro F1	68.58	54.90	52.12	66.71
Rank	11/44	8/31	11/35	9/30
Accuracy	87.40	73.24	66.52	73.24
Rank	5/44	6/31	5/35	4/30

Table 2: Results from the official shared task leaderboard. Rank indicates the rank our submissions achieved for the specific dimension and metric. MI = Mistake Identification. ML = Mistake Location. PG = Providing Guidance. AC = Actionability.

from *FLAN-T5-base*, except for *mistake location*. For this reason, we went with this procedure for our final submissions.

With the post-merge fine-tuning stage adding an epoch of training, performance gains may also have resulted from improved task-specific fitting rather than the merging process itself. While tentative experiments did not provide evidence for this, we did not rule this out through a systematic experiment.

4 Shared Task Submission and Evaluation

Following the intuition behind the scaling law that, on average, larger models show an improved downstream performance compared to smaller models when trained on the same data (Kaplan et al., 2020), we replicated our setup with *FLAN-T5-xl* (Chung et al., 2024) for the shared task submission. Again, we first fine-tuned dimension-specific models for all four dimensions for three epochs each, then merged them using *DARE-TIES* (Yu et al., 2024), and then used the resulting model as a basis for fine-tuning for another epoch to acquire again dimension-specific models (as depicted in Figure 1. Since, in our pre-experiments, the post-merge models for *mistake identification* were slightly outperformed by the pre-merge ones, we submitted results from both for the final task (since up to five submissions were allowed per dimension). Here, contrary to our pre-experiments, the post-merged version came out on top.

In the context of the shared task, the resulting models could all achieve upper mid-table results, going by *Macro F1*. For *Mistake Identification*, we placed 11th of 44 teams. For *Mistake Location*, we placed 8th of 31 teams. For *Providing Guidance*, we placed 11th of 35 teams. For *Actionability*, we placed 9th of 30 teams. For *Accuracy*, which served as a secondary evaluation metric, our models were among the best submissions in the shared

task. Here, we placed 5th, 6th, 5th and 4th for the respective dimensions.

These results suggest that our approach was overall highly successful in modelling the different dimensions, but, in particular, fell short for the *No* category, which was comparably underrepresented in the data. We assume that techniques such as *paraphrased oversampling* (Patil et al., 2022) would likely have helped combat that overall behaviour, but were not considered by us since we implemented our solution within one week under heavy time pressure. Table 2 shows the corresponding results. Overall, the results suggest that our approach is reasonable and the use of *DARE-TIES* merging allowed us to achieve upper mid-table results, although our placements suggest, that there are certainly better solutions for the problem than what we propose in this paper.

5 Conclusion

In this paper, we presented our submission to the *BEA 2025 Shared Task on the Pedagogical Ability Assessment of AI-powered Tutors*. Our submission combines fine-tuning and *DARE-TIES* merging *FLAN-T5-xl* models. In terms of macro F1, the primary evaluation metric used for the shared task, our models could only achieve upper mid table results, which is likely due to the underrepresentation of *No* and *to some extent* cases within the training set. In terms of overall accuracy, our submissions achieve more competitive results. Our general results show that combining *DARE-TIES* merging with fine-tuning can have beneficial results on downstream performance.

Limitations

Focus on *FLAN-T5*: In this paper, we focused solely on *FLAN-T5* models while not considering other models such as *Mistral-7b* (Jiang et al., 2023). The reason behind this was mainly that our contribution was created under heavy time pressure, so we wanted to focus on making our approach work for one model family as best as we could, instead of comparing a larger range of models.

No data augmentation used: Since the provided dataset is highly imbalanced, with the *no* and *to some extent* cases being underrepresented for all four dimensions, we assume that data augmentation could have likely benefited our systems, e.g., in the form of techniques such as *paraphrased oversampling* (Patil et al., 2022). However, due to the

heavy time pressure, we decided against exploring data augmentation.

No hyperparameter search: We did not conduct a hyperparameter search but instead stuck to the standard training hyperparameters used to pre-train the *FLAN-T5* models, except for the batch size, which we reduced from the original 64 to 4 due to limited computational resources. Similarly, it is possible that performance gains in the task-specific post-merge fine-tuning stem at least partly from an additional epoch of training.

Abstract

While large language models show promise as AI tutors, evaluating their pedagogical capabilities remains challenging. In this paper, we, team LexiLogic presents our participation in the BEA 2025 shared task on evaluating AI tutors across five dimensions: Mistake Identification, Mistake Location, Providing Guidance, Actionability, and Tutor Identification. We approach all tracks as classification tasks using fine-tuned transformer models on a dataset of 300 educational dialogues between a student and a tutor in the mathematical domain. Our results show varying performance across tracks, with macro average F1 scores ranging from 0.47 to 0.82, achieving rankings between 4th and 31st place. Such models have the potential to be used in developing automated scoring metrics for assessing the pedagogical skills of AI math tutors.

1 Introduction

While significant progress has been made in making today’s large language models helpful, aligned, and responsible (Tan et al., 2023; Ji et al., 2023; Feng et al., 2024), their full potential in academic settings remains underutilized. Despite growing interest in using LLM-based AI tutors for academic support, traditional evaluation benchmarks tend to focus more on knowledge, factual accuracy, and reasoning (DeepSeek-AI et al., 2025; Abdin et al., 2025) rather than on the ability of these dialogue systems to function effectively in the role of a tutor. In educational contexts, there is a pressing need for systems and evaluation metrics specifically designed to assess complex pedagogical qualities. Therefore, it is essential to not only develop intelligent tutoring systems but also to evaluate them in terms of their ability to provide sufficient, helpful, and factually accurate guidance.

The shared task organized as part of the BEA workshop (Kochmar et al., 2025) focuses on educational dialogues between a student and a tutor in

the mathematical domain, specifically addressing student mistakes or confusion. The goal of the AI tutor is to help remediate these issues. The tutor responses, generated by the task organizers, come from a range of state-of-the-art LLMs with varying sizes and capabilities, including GPT-4 (OpenAI et al., 2023), Gemini (Reid et al., 2024), Sonnet (Anthropic, 2025), Mistral (Jiang et al., 2023), Llama 3.1 (Grattafiori et al., 2024) and Phi-3 (Abdin et al., 2024a). In addition to the generated responses, the development set includes annotations evaluating their quality across several pedagogically motivated dimensions: Mistake Identification, Mistake Location, Providing Guidance, Actionability, and Tutor Identification.

Across all tracks of the shared task, we approached the problems as classification tasks and followed a fine-tuning approach using several transformer-based encoder and decoder models. Table 1 summarizes the performance of our submitted models compared to the top-performing entries in terms of macro average F1 score in each task.¹

Track	Our Score	Best Score
Track 1	0.65	0.72
Track 2	0.48	0.60
Track 3	0.47	0.58
Track 4	0.69	0.71
Track 5	0.82	0.95

Table 1: Performance of our models compared to the best scores in each track.

2 Related Work

With the widespread use of large language models (LLMs) (Brown et al., 2020; Touvron et al., 2023; Team et al., 2025) as conversational systems in educational contexts, several studies have evaluated

¹The code for this work is available at <https://github.com/prannerta100/acl-bea2025-workshop-st>

their pedagogical capabilities. There are numerous LLM evaluation metrics such as BLEU (Papineni et al., 2002), BERTScore (Zhang et al., 2020), ROUGE (Lin, 2004), DialogRPT (Gao et al., 2020), etc., which are not necessarily designed to assess an LLM’s educational or pedagogy-related capabilities (Jurenka et al., 2024) and shown to have relatively low correlation with human judgments (Liu et al., 2023). This highlights the need for alternative methods to evaluate LLM performance in educational settings. One such approach is to use human annotators to rate LLM responses based on various criteria (Collins et al., 2023; Shen and Wu, 2023; Lee et al., 2024). While human evaluators can consider context, tone, and pedagogical effectiveness, offering qualitative insights that go beyond quantitative metrics, they are also prone to bias, and the process tends to be time-consuming and relatively expensive.

At the other end of the spectrum, there is growing interest in automated evaluation systems and LLM-as-a-judge approaches (Jurenka et al., 2024). Chen et al. (2023)’s experimental results show that ChatGPT is capable of evaluating text quality effectively from various perspectives without reference, and it demonstrates superior performance compared to most existing automatic metrics. Macina et al. (2025) developed MATHTUTORBENCH to score the pedagogical quality of open-ended teacher responses and also trained several LLM-based reward models, showing that these models can distinguish expert from novice teacher responses with high accuracy. TUTUREVAL, a diverse question-answering benchmark, was released by Chevalier et al. (2024), who evaluated the capabilities of several open-weight and proprietary LLMs using GPT-4 as the evaluator. Maurya et al. (2025a) introduced MRBench, which includes a large set of student–tutor conversations from seven state-of-the-art LLM-based and human tutors, and evaluated them across various dimensions using a different set of LLMs. Jurenka et al. (2024) also introduced LearnLM-Tutor, a fine-tuned model that was consistently preferred over base models for various academic tasks as judged by LLM-based critics.

3 Task Description and Methodology

The dataset provided for the shared task (Maurya et al., 2025b) consisted of conversation history between a tutor and a student along with a final response from the tutor based on which the vari-

ous pedagogical capability label is to be predicted. There were a total of 300 distinct conversations out of which we chose 50 to include in our test set, which resulted in 2067 training data points and 409 test data points. The same train-test split is used in all our experiments.

3.1 Track 1 - Mistake Identification

Track 1 of the shared task aims to develop systems that can identify whether a tutor’s response acknowledges mistakes in a student’s answer. The distribution of three categories in this track is detailed in Table 2. Each data point consists of a conversation history between a tutor and a student, along with a final response from the tutor. Participants are required to assess whether the tutor’s reply explicitly recognizes the student’s mistake within the conversation.

Tutor	Yes	No	To some extent
GPT4	234	15	1
Gemini	215	21	14
Sonnet	212	20	18
Phi-3	68	176	6
Mistral	223	10	17
Llama318B	202	31	17
Llama31405B	239	7	4
Expert	188	15	47
Novice	28	11	28
Total	1609	306	152

Table 2: Distribution of instances across categories for each tutor in the dataset in Track 1

For this task, our experiments involved fine-tuning various encoder and decoder models. The input sequence was formed by concatenating the conversation history with the final response, and we replaced the model’s un-embedding layer with a classification head for the three target classes. The models we used included FLAN-T5 (Chung et al., 2022), ModernBert (Warner et al., 2024), Llama 3.2 (Grattafiori et al., 2024), Phi-4 (Abdin et al., 2024b), and Qwen-2.5 (Qwen et al., 2025). All models were trained for 10–15 epochs with an initial learning rate between $5e-5$ and $1e-4$, using an exponential learning rate scheduler, a batch size of 8–10, and a gradient accumulation step of 2. On the test set, FLAN-T5-large performed the best, achieving a macro average F1 score of 0.65 and placing us 22nd among 44 submissions on the official leaderboard. The training and test set performance of all models is presented in Table 3 (with

the train set F1 scores corresponding to the epoch with the highest test set performance).

Model	Train F1	Test F1
FLAN-T5-large	0.94	0.65
ModernBERT-large	0.98	0.61
Llama-3.2-3B	0.99	0.62
Phi-4-mini-instruct	1.0	0.63
Qwen2.5-7B-Instruct	0.73	0.55

Table 3: Strict macro average F1 scores of different models on training and test datasets of Track 1

3.2 Track 2 - Mistake Location

In subtask 2, the objective is to develop a system capable of identifying whether a tutor’s response effectively locates the mistake in the student’s answer and provides a clear explanation of the error. This includes assessing whether the tutors’ responses accurately point to a genuine mistake and its location in the students’ responses. The distribution of each labels across different categories for each tutor in the training dataset is shown in Table 4.

Tutor	Yes	No	To some extent
GPT4	242	37	13
Gemini	176	93	31
Sonnet	207	60	33
Phi-3	73	223	4
Mistral	216	52	35
Llama318B	161	108	31
Llama31405B	252	33	15
Expert	197	58	45
Novice	19	60	2
Total	1543	724	209

Table 4: Distribution of instances across categories for each tutor in the dataset for Track 2

The final response is concatenated with the conversation history and fed as input into our model. Our experimental setup predominantly focused on transformer-based encoder and decoder models. In both encoder-decoder and large language model (LLM) configurations, we modify the original models by removing the final un-embedding layer and replacing it with a classification head. Among the encoder-based models, we evaluated ModernBERT (Warner et al., 2024), and MathBERT (Peng et al., 2021). For large language models, we conducted experiments with Llama 3.2 (Grattafiori et al., 2024), Phi-4 (Abdin et al., 2024b), and Qwen-

2.5 (Qwen et al., 2025).

We fine-tuned all models for a maximum of 10 epochs, with an initial learning rate in the range of $2e-2$ to $5e-5$, an exponential learning rate scheduler with gamma set between 0.9 and 0.9375 with a batch size between 4 and 12, with gradient accumulation steps set to 2. During training we minimized the categorical cross-entropy loss. In Table 5, we report the strict Macro average F1 scores of various models. The reported training set F1 scores correspond to the epoch with the highest F1 score on the test set. On the held-out test set, our submission based on Phi-4-mini-instruct achieved an F1 score of 0.48 on the unseen test dataset placing us at the 23rd position out of total 31 submissions.

Model	Train F1	Test F1
MathBERT	0.67	0.5
ModernBERT-large	0.72	0.52
Llama-3.2-3B	0.73	0.55
Llama-3-8B	0.71	0.53
Phi-4-mini-instruct	0.78	0.68
Qwen2.5-7B-Instruct	0.67	0.55

Table 5: Strict Macro average F1 scores of different models on training and test datasets

3.3 Track 3 - Providing Guidance

Track 3 focuses on evaluating whether a tutor’s response provides effective guidance to help students understand and correct their mistakes. This task goes beyond simply identifying and locating errors to assess the pedagogical quality of the tutoring response. The system must determine if the tutor offers constructive feedback, explanations, or suggestions that would help the student learn from their mistakes. Similar to the previous tracks, the task includes three categories: ‘Yes’, ‘No’, and ‘To some extent’, with their distribution across different tutors shown in Table 6.

Our approach for this track followed a similar methodology to the previous tasks, where we concatenated the conversation history with the final tutor response and fed it as input to our classification models. The experimental setup involved fine-tuning various transformer-based models to classify the quality of guidance provided in tutor responses.

We evaluated several model architectures including both encoder-only and decoder-only models. Among the encoder-based models, we experimented with ModernBERT (Warner et al., 2024),

Tutor	Yes	No	To some extent
GPT4	228	41	31
Gemini	168	47	85
Sonnet	184	52	64
Phi-3	51	189	60
Mistral	189	47	64
Llama318B	134	65	101
Llama31405B	238	16	46
Expert	205	47	48
Novice	10	62	4
Total	1407	566	503

Table 6: Distribution of instances across categories for each tutor in the dataset for Track 3

while for large language models, Phi-4 (Abdin et al., 2024b), and FLAN-T5 (Chung et al., 2022). All models were modified by replacing the final un-embedding layer with a three-way classification head corresponding to our target categories. The train and test F1 values are in Table 7.

The training configuration involved fine-tuning for 8-12 epochs with learning rates ranging from $1e-5$ to $8e-5$, using an exponential learning rate scheduler with gamma values between 0.85 and 0.95. We employed batch sizes of 6-14 with gradient accumulation steps of 2, and optimized using categorical cross-entropy loss. The performance of different models on both training and test sets is presented in Table 7, where the training F1 scores correspond to the epoch achieving the highest test set performance.

Model	Train F1	Test F1
FLAN-T5-large	0.92	0.36
ModernBERT-large	0.89	0.39
Phi-4-mini-instruct	0.97	0.45

Table 7: Strict Macro average F1 scores of different models on training and test datasets for Track 3

Our best performing model, Phi-4-mini-instruct, achieved a macro average F1 score of 0.47 on the test set, securing the 31st position out of 35 total submissions on the official leaderboard. The relatively lower performance across all models suggests that evaluating the quality of pedagogical guidance is inherently more challenging than simple mistake identification, as it requires understanding the nuanced aspects of effective tutoring strategies and educational support.

3.4 Track 4 - Actionability

In Track 4, the goal is to develop system to identify whether the tutor’s response is clear in regards to what the student should do next, i.e., whether or not the tutor response was vague, unclear or a conversation stopper. Table 8 shows the distribution of instances across different categories for each tutor in the training dataset provided.

Tutor	Yes	No	To some extent
GPT4	116	125	9
Gemini	142	52	56
Sonnet	141	74	35
Phi-3	27	215	8
Mistral	168	43	39
Llama318B	106	93	51
Llama31405B	182	40	28
Expert	200	18	32
Novice	3	52	12
Total	1085	673	309

Table 8: Distribution of instances across categories for each tutor in the dataset in Track 4

We use as an input the sequence of tokens after the final response from the tutor is appended with the original conversation. We experimented with multiple transformer based encoder and decoder models in this task as well. In all the experiments, we remove the final un-embedding layer from the original models and replace it with a classification head producing three dimensional logits corresponding to the three available classes in this task. Among the encoder models we have experimented with FLAN-T5 (Chung et al., 2022), ModernBert (Warner et al., 2024) and MathBERT (Peng et al., 2021) and among the LLMs we tried Llama 3.2 (Grattafiori et al., 2024), Phi-4 (Abdin et al., 2024b) and Qwen-2.5 (Qwen et al., 2025).

We fine-tune all the models for 15–20 epochs, using an initial learning rate in the range of $5e-5$ to $1e-4$, with an exponential learning rate scheduler (gamma set to 0.9). We use a batch size between 8 and 12, gradient accumulation steps of 2, and minimize the categorical cross-entropy loss. In Table 9, we report the Strict macro average F1 scores of various models. Note that the reported training set F1 scores correspond to the epoch with the highest test set F1 score. In the held-out test set, our submission based on Phi-4-mini-instruct scored an F1 score of 0.69 securing us the 4-th place among 29 submissions in the official leaderboard.

Model	Train F1	Test F1
FLAN-T5-base	0.76	0.59
MathBERT	0.98	0.58
ModernBERT-large	1.0	0.67
Llama-3.2-3B	0.97	0.61
Llama-3-8B	0.74	0.55
Phi-4-mini-instruct	1.0	0.71
Qwen2.5-7B-Instruct	1.0	0.65

Table 9: Strict macro average F1 scores of different models on training and test datasets of Track 4

3.5 Track 5 - Tutor Identification

The goal of track 5 was to predict the identity of the tutor for a given response, from a set of 9 identities, such as Sonnet, Llama3.1 8B, Llama 3.1 405B, GPT4 to name a few. We mainly fine-tuned various transformer models for this task with a similar setup to the previous tasks, and have reported our scores in Table 10. We observed that for many models the per-class F1 score for Novice, Llama 3.1 405B and 8B was lower than other classes. For the Novice class, a possible cause could be the lack of enough Novice examples in the dataset. We did not investigate the cause for the low performance for Llama 3.1 8B and 405B in detail, but when we looked at the test set confusion matrix for one of the models, we found that there was significance confusion between Llama 3.1 8B and 405B. It would be interesting to investigate how much of these similarities are task-specific and how much are specific to the base model. A recent preprint (Smith et al., 2025) suggests similar patterns in cosine similarities between the outputs of various LLMs. Note that these metrics are reported on our hold out sets and not the leaderboard test sets. Our best leaderboard test set performance was 0.82, and our final leaderboard position was 16th according to the macro average F1 metric.

4 Conclusion

In this work, we presented our experiments using a fine-tuning-based approach with several encoder-based and large language models to evaluate the pedagogical capabilities of AI tutors. We observed that different LLMs yield varying performance levels, highlighting model-specific behavior. Some class labels in the training data had very few examples, which may have impacted performance. Future work could explore data augmentation and sampling techniques to address this imbalance and

Model	Train F1	Test F1
FLAN-T5-base	0.76	0.59

Llama-3.2-3B	1.0	0.85
Longformer	-	0.83*
BigBird Roberta Large	-	0.79*
MathBERT	-	0.79*

Table 10: Macro average F1 scores of different models on training and test datasets of Track 5

*: test set drawn from the same distribution but might differ from the other models

potentially improve results. It would also be worthwhile to investigate prompt-based classification methods for evaluating tutor responses in zero-shot or few-shot settings, and explore the use of the models reported in this paper as reward models for post-training or performing test-time scaling on LLMs for improving their pedagogical skills. Additionally, future research could examine the potential of using the same set of AI tutors to reflect on and revise their responses to better align with the goals of effective and helpful AI tutoring systems.

5 Limitations

Automated scoring metrics for evaluating the pedagogy of AI math tutors and AI tutors in general come with their own limitations. Bias introduced by the finetuned model and the underlying pre-trained model can lead certain behaviors to be reinforced and certain demographics to be highlighted over other demographics. Cultural considerations also play an important part in pedagogy. A lack of rigorous theoretical guarantees on the mathematical and conceptual accuracy of LLM models can propagate incorrect concepts among students and lead to unwanted friction with instructors. Accessibility of AI tutoring tools could be a barrier for some students with limited resources and internet access, given the resource-expensive nature of LLMs. Moreover, AI tutoring tools typically require students to access internet on their phone or computer, enhancing their risk of being exposed to other websites and social media, causing the risks to outweigh the benefits.

Abstract

As AI’s presence in educational environments grows, it becomes critical to evaluate how its feedback may impact students’ learning processes. Pedagogical theory, with decades of effort into understanding how human instructors give good-quality feedback to students, may provide a rich source of insight into feedback automation. In this paper, we propose a novel architecture based on pedagogical-theory feature extraction from the conversation history and tutor response to predict pedagogical guidance on MRBench. Such features are based on Brookhart’s canonical work in pedagogical theory, and extracted by prompting the language model LearnLM. The features are then used to train a random-forest classifier to predict the Track 3: Pedagogical Guidance of the BEA 2025 shared task. Our approach ranked 8th in the dimension’s leaderboard with a test Macro F1-score of ~ 0.54 . Our work provides some evidence in support of using pedagogical theory qualitative factors treated separately to provide clearer guidelines on how to improve low-scoring intelligent tutoring systems. Finally, we observed several inconsistencies between pedagogical theory and MRBench’s inherent relaxation of the tutoring problem implied in evaluating on a single-conversation basis, calling for the development of more elaborate measures which consider student profiles to serve as true heuristics of AI tutors’ usefulness.

1 Introduction

As part of the AI revolution, AI tutors will gain a growing role in education. Their use, however, should be preceded by rigorous evaluation, as omitting this step would be as unthinkable as hiring untrained teachers. To contribute to the development of evaluation standards for AI tutors, this paper describes an approach to automatically classify certain aspects of pedagogical ability on the Mistake Remediation Benchmark (MRBench) dataset of grade-school math tutoring chats (Maurya et al.,

2025a). The dataset contains annotations for the dimensions of identifying that the student has made a mistake, correctly individualizing what that mistake was, providing the student with relevant and helpful guidance, and cueing the student on how to follow the conversation. Of these, our approach attempts to classify whether feedback did, did not, or did to some extent, provide pedagogical guidance (PG) on the, Track 3: Pedagogical Guidance of the BEA 2025 shared task (Kochmar et al., 2025).

PG as an object of study is richly explored in the theory of pedagogy. For instance, the area of math didactics has studied phenomena such as students’ capacity to grasp concepts progressing from the concrete, to the pictorial, to the abstract (Bruner, 1966); how to develop an academic math discourse to support understanding (Chapin et al., 2009); and best practices for orchestrating productive student discussions (Smith and Stein, 2011). Also, assessment theory compiles frameworks on how to construct feedback as a powerful tool to improve student understanding and performance (Brookhart, 2008; Tunstall and Gipps, 1996). Our approach attempts to transfer knowledge from pedagogical theory by proposing a set of engineered features for PG classification strongly based on Brookhart’s work. With these features in hand, we propose a two-phase classification process. In the first phase, we use an LLM to query the text, which includes the conversation history between the student and the tutor, for the presence, or lack thereof, of our features in the tutor’s feedback. In the second phase, we use a random-forest classifier which is given a binary vector representing the output of the previous phase and attempts to predict the PG dimension.

2 Related Work

MRBench’s dimensions on which to assess the pedagogical ability of AI tutors result from the distil-

lation of a body of previous work in NLP addressing ITS evaluation (Tack and Piech, 2022; Macina et al., 2023; Daheim et al., 2024; Wang et al., 2024). Tack and Piech (2022), in their “AI Teacher Test” evaluated the dialogic pedagogical ability of certain LLMs in a mathematics-domain educational dialogue from the dimensions of whether they speak like a teacher, understand a student, and help a student. Specifically in math mistake remediation in the tutoring context, Macina et al. (2023) dimensions included coherence, correctness, and equitable tutoring. In the same context, Daheim et al. (2024) create the dimensions of targetedness, correctness, and actionability. Finally, and also within said context, Wang et al. (2024) put forth usefulness, care, and humanness. Maurya et al. (2025b) compile MRBench to address this need for a unified evaluation framework, and the present Shared Task is proposed as a challenge because all the aforementioned work is not, as of yet, fully independent from manual evaluation.

3 Preliminaries

To determine qualities that make feedback effective, the pedagogical perspective generally follows Brookhart’s (2008) four-dimension framework: content, specificity, timing and audience. Rather than assigning intrinsic value to hints, explanations or other information the tutor might provide, these dimensions promote that feedback’s potential depends on every point that it communicates complying with certain characteristics. For example, when amending any student misconceptions (content-focus), to unambiguously identify the misconception (specificity-clarity), feedback should explicitly distinguish it from what the student has understood correctly (content-valence). The same would be true for the offering of procedural guidance (content-focus): a hint about the right direction may confuse the student into undoing correct steps taken. Furthermore, the clarity of all the aforementioned depends on the student’s level of prior knowledge (audience-individual), which in this case we may approximate as the school year. This framework thus offers a theoretically grounded approach to tackle the interdependence of feedback dimensions in function of the ultimate goal: helping the student.

4 Methodology

To distill a set of features from pedagogical theory, we first asked the virtual assistant Claude (Anthropic, 2024) to create a feedback checklist from the key takeaways of seminal books on assessment and math didactics (Chapin et al., 2009; Smith and Stein, 2011; Brookhart, 2008; Tunstall and Gipps, 1996). Second, we merged redundant points together and discarded factors that were outside the scope of MRBench: anything that required knowing the student personally, communicating non-verbally and/or interacting in a classroom environment. The few remaining factors came chiefly from Brookhart (2008). Third, we stress-tested these for what we anticipated as possible AI tutor failures and edited accordingly by hand. For example, we added “accurately and specifically” at the beginning of Claude’s sentence “identify what was done correctly before addressing the error”. Then, each quality was separated into its own feature (identifies / identifies accurately / identifies specifically), so that binary tags on these features would be as informative as possible. Fourth, we phrased each feature as a yes-or-no question to prompt LearnLM (Team et al., 2024). Finally, we performed prompt engineering on the questions using a subset of 20 random tutor responses. The full resulting list of questions is available in Appendix A.

5 Architecture

Our proposed architecture, shown in Figure 1, is composed of two models working sequentially: a feature extractor, and a classifier.

First, features are extracted by prompting LearnLM (Team et al., 2024), a domain-specific Gemini fine-tuning, currently in experimental phase. We chose this model because of its expert training on tutoring data and pedagogical theory sources. For each feature, the conversation history is concatenated to the tutor response and a yes-or-no question representing the feature (see Appendix B), to which the model is prompted to respond with a binary 0/1 tag. Since preliminary tests yielded no relevant difference resulting from temperature variation, the model’s hyperparameters were left at their default values. The full feature extraction prompt is in Appendix B.

To accommodate the low dimensionality of the data, decision tree (DT) and random forest (RF) models were included in the trials for the final classifier. These were chosen for their structural

Figure 1: Proposed architecture to classify using expert pedagogical features.

mimicking of the decision process that pedagogy professionals described while annotating sample data.

6 Results

The variety of classifiers trained resulted from a different selection of extracted features as input, hyperparameter combinations, and the choice of DT versus RF model. A total 17320 DTs and 1400 RFs were trialed, each with 5-fold cross-validation, and the best candidates were then iterated using SMOTE oversampling. The highest performing model was an RF excluding some features from the input data, the hyperparameters of which we include in [Appendix C](#), with training metrics detailed in [Table 1](#).

Phase	Exact macro F1	Exact accuracy	Lenient macro F1	Lenient accuracy
Train	0.5662	0.6373	0.7529	0.8214
Test	0.5369	0.6244	0.7379	0.7822

Table 1: Performance of selected classifier model.

The final architecture using this model ranked 8th in the leaderboard for the pedagogical guidance dimension, with test metrics detailed in [Table 1](#).

7 Conclusions

We have presented an approach to PG classification that combines LLMs and traditional AI techniques with a theoretical framework on PG. The features we propose offer a perspective that considers the interdependence of the original MRBench dimensions, but puts them all in service of how well the tutor guides the student.

Our work shows the potential of using PG-theory-based features, which is a fine-grained way of assessing elements of good-quality feedback while exploiting an LLM. Future work should explore other ways in which identification of these

features may be exploited to iterate the construction of good-quality feedback via LLMs. In addition, we think that PG theory invites developers of AI tutors to take two other complementary routes for future work. The first is to design tutors aware of learning objectives, since this is fundamental to understand how to guide the student. The second is that AI tutors should build and exploit a student profile over time, considering the student’s previous knowledge, degree of metacognition, and learning strategies that have previously worked or failed. Tackling these two action points would expand the frontier of AI tutor evaluation beyond the biggest limitations of this work from the standpoint of PG theory.

Limitations

Our architecture first assumes the limitations of our theoretical alignment: following [Brookhart \(2008\)](#) may better describe certain Western learning contexts than other sociocultural realities. Then, the architecture’s reliance on LearnLM means it inherits any of the model’s possible inaccuracies and biases, and that implementation depends on proprietary API use. Finally, the classifier model’s performance should be improved with further trials using cleaned and augmented data.

Regarding the last point, the MRBench dataset carries limitations that transfer to our architecture. In terms of quality, we found conversation histories that we considered to be noisy: some lacking the original word problem being solved, with alternative tutor responses embedded within, or exchanging tutor/student speaker tags. We also did not find tagging criteria to be self-evident: the question of what constituted relevant “explanation, elaboration, hint, examples, and so on” seemed both open and necessitating at least some degree of expert pedagogical knowledge. Finally, the dataset is limited to the English language, mathematics school subject, arithmetic content and grade-school instruc-

tion level. Asymmetric advances in low-resource languages and higher influence of culture in other subjects of instruction limit the applicability of the benchmark for the range of intelligent tutoring systems currently on the market.

Finally, the strongest limitation surrounding this shared task was scarcity of context. In the pedagogical theory that we reviewed and that we believe is key to incorporate to these systems, the majority of factors contributing to PG are considered to be based on the student as a subject of learning. As such, factors that are regarded as key to PG are the student's individual previous knowledge, metacognitive ability, optimal learning strategies, personal relationship to the contents being taught, role in the classroom social dynamics, and sociocultural context (Brookhart, 2008; Smith and Stein, 2011; Chapin et al., 2009). Though we expanded as much as possible on the factors inferable from a single conversation via text, existing PG literature would suggest that an AI tutor's quality of PG can only be realistically estimated against a constructed learner profile of the student. Moreover, these considerations all defined their value only in relation to learning objectives and how they advanced the student towards them, meanwhile the context of what learning objectives were being reinforced in the tutoring sessions was not present in the MRBench dataset.

Acknowledgments

This work was supported by the National Center for Artificial Intelligence (CENIA) under Grant FB210017 Basal ANID. We would like to thank all of the following people. For their input to this work: Francisco Gazitúa and Juan Pablo Fuentes. For their support in timely experiment execution: to our colleagues at IALab, friends and family. For their contribution of expert knowledge in pedagogy: Francisca Ubilla, Edgar Valencia, Carolina Véliz, Teresita Fuentes, Emilia Deichler, Chiara Hiraizumi, Javier Riquelme, Marcelo Mena, Constanza Del Solar, Camila Sánchez, Andrea Vilca and Martín Pino. For their contribution of non-expert pedagogy knowledge: Luzhania Céspedes, Joaquín Handal, Guillermo Staudt, Raimundo Labbé, Daniel Villaseñor, Alexandre Icaza, Cristobal Soto, Vicente Muñoz, Victor Marques, José Chong, Matías Valenzuela, Maximiliano Berríos and Maximiliano Navia.

A Full list Pedagogical Features

Table 2

Scope	Criterion	Question
Transversal	Psicosocial	Does the tutor's response focus on the specific task/process rather than the student personally?
Transversal	Psicosocial	Does the tutor's response frame mistakes as learning opportunities?
Transversal	Psicosocial	Does the tutor's response begin by affirming any partial success, even if minor?
Transversal	Metacognition	Throughout the conversation history and final response, does the tutor show preference for asking, rather than stating, to the student what their error could have been and/or how to fix it?
Local	Achieved	Does the tutor's response express that the student has taken some steps correctly?
Local	Achieved	Is the tutor's final response specific about which portion of the student's messages are going in the right direction to solve the proposed problem?
Local	Achieved	Is the tutor's final response correct about which portion of the student's messages are going in the right direction to solve the proposed problem?
Local	Mistaken	Does the tutor's final response imply that the student has made a mistake of some sort?
Local	Mistaken	Is the tutor's final response fully accurate in pointing out the student's mistake(s)?
Local	Mistaken	When communicating that the student has made a mistake, is the tutor's final response specific with regards to what the alleged error was?
Local	Mistaken	Does the tutor's final response provide an explanation for why the student's approach was incorrect?
Local	Mistaken	Regarding the tutor's explanation for why the student's approach was incorrect, is it clear and understandable at a 6th grade level?
Local	Mistaken	Regarding the tutor's explanation for why the student's approach was incorrect, is it fully accurate?
Local	Remediate	Does the tutor offer the student a strategy or hint to solve the word problem?
Local	Remediate	Does the tutor offer the student a correct strategy or hint that would allow them to successfully solve the word problem?
Local	Remediate	Does the tutor offer the student a strategy to solve the word problem that is clear and understandable at the 6th-grade level?
Local	Remediate	Does the tutor offer the student an example problem or fact to correct a misinterpretation of the original problem?

B Feature Extraction Prompt

""You will be presented with the conversation history from a grade-school math tutoring session happening over computer chat, where the student makes a mistake or evidences confusion.

Your task is to evaluate the tutor's final response in terms of the question: {question}

{conversation_history}

Tutor Response: {tutor_response}

Question: {question} (0 for No, 1 for Yes)

Answer: ""

MSA at BEA 2025 Shared Task: Disagreement-Aware Instruction Tuning for Multi-Dimensional Evaluation of LLMs as Math Tutors*

Baraa Hikal, Mohamed Basem, Islam Oshallah, Ali Hamdi

Faculty of Computer Science, MSA University, Egypt

{baraa.moaweya, mohamed.basem1, islam.abdulhakeem, ahamdi}@msa.edu.eg

Abstract

We present MSA-MATHEVAL, our submission to the BEA 2025 Shared Task on evaluating AI tutor responses across four instructional dimensions: Mistake Identification, Mistake Location, Providing Guidance, and Actionability. Our approach uses a unified training pipeline to fine-tune a single instruction-tuned language model across all tracks, without any task-specific architecture modifications. To improve prediction reliability, we introduce a disagreement-aware ensemble inference strategy that enhances coverage of minority labels. Our system achieves strong performance across all tracks, ranking 1st in Providing Guidance, 3rd in Actionability, and 4th in both Mistake Identification and Mistake Location. These results demonstrate the effectiveness of scalable instruction tuning and disagreement-driven modeling for robust, multi-dimensional evaluation of LLMs as educational tutors.

1 Introduction

Large language models (LLMs) are increasingly used in educational applications, acting as AI tutors that engage students in natural language. However, effective tutoring goes beyond producing correct answers. AI tutors must recognize student mistakes, explain misconceptions, provide constructive guidance, and suggest actionable next steps. Assessing such teaching behavior remains challenging.

Prior work in intelligent tutoring systems (ITS) emphasized these goals long before the advent of LLMs. For example, AutoTutor used natural language processing (NLP) and dialogue-based feedback to improve learning outcomes across domains (Nye et al., 2014). Later, metrics such as *conversational uptake* were proposed to capture tutor responsiveness and its link to instructional quality (Demszky et al., 2021).

With the rise of instruction-tuned LLMs, new frameworks have emerged to assess their teaching abilities. Tack and Piech (Tack and Piech, 2022) introduced the AI Teacher Test for evaluating model helpfulness and student understanding, while later work proposed finer rubrics such as coherence, correctness, targetedness, and actionability (Macina et al., 2023; Daheim et al., 2024; Wang et al., 2024).

Building on these efforts, the BEA 2025 Shared Task adopts *MRBench*—a pedagogically motivated benchmark introduced by Maurya et al. (2025)—to evaluate AI-generated tutor responses in math dialogues (Kochmar et al., 2025). While BEA 2023 emphasized response generation, BEA 2025 shifts toward assessing feedback quality across four instructional dimensions derived from educational science.

In this work, we present MSA-MATHEVAL, a unified system that addresses all four tracks using a single fine-tuned model and consistent training pipeline. We fine-tune the open-weight *Mathstral-7B-v0.1*—an instruction-tuned LLM specialized for mathematical reasoning—using parameter-efficient LoRA adapters. To improve prediction reliability, we incorporate ensemble-based inference that combines model disagreement and uncertainty estimation.

Our contributions are as follows:

- We design a unified training pipeline for all four BEA 2025 tracks, using LoRA-based fine-tuning of *Mathstral-7B-v0.1* with no track-specific architecture changes.
- We propose an ensemble-based inference strategy leveraging model disagreement and uncertainty for robust prediction.
- We achieve top-tier performance across all tracks, including first place in Providing Guidance.

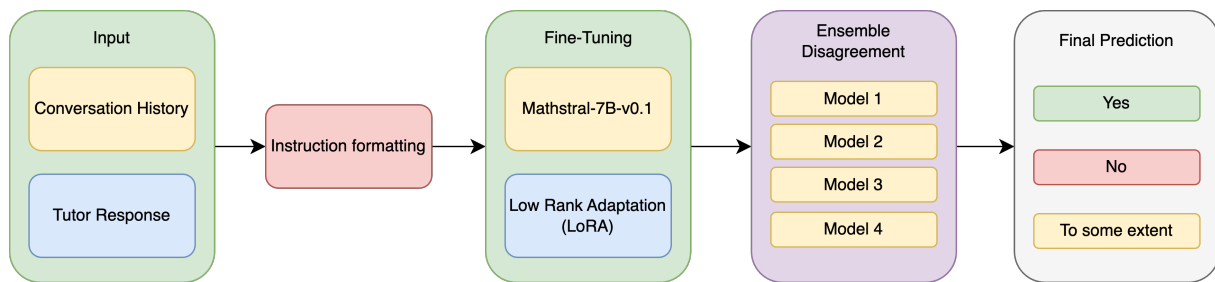

Figure 1: Overview of our unified MSA-MATHEVAL framework for the BEA 2025 Shared Task. The pipeline includes preprocessing, LoRA-based fine-tuning of Mathstral-7B-v0.1, and disagreement-aware ensemble inference.

2 Related Work

Evaluating the pedagogical capabilities of AI tutors builds upon long-standing research in intelligent tutoring systems (ITS) and more recent advances in large language models (LLMs). Early ITS such as AutoTutor emphasized the importance of natural language dialogue in promoting student learning through error remediation and scaffolding (Nye et al., 2014). These systems often relied on rule-based or statistical NLP methods to assess learner inputs and generate appropriate tutor responses.

The emergence of instruction-tuned LLMs has prompted a shift toward more scalable methods for modeling tutoring behavior. Tack and Piech (2022) proposed the AI Teacher Test to benchmark LLM outputs on criteria such as helpfulness and pedagogical appropriateness. Macina et al. (2023) and Daheim et al. (2024) introduced fine-grained rubrics for LLM tutoring quality in mathematical dialogue, including dimensions such as targetedness, coherence, and actionability.

In terms of modeling strategies, prior systems have explored both classification and ranking approaches for feedback generation. Daheim et al. (2024) used multi-aspect annotation schemes to evaluate feedback informativeness, while Wang et al. (2024) proposed a bridging rubric for LLM feedback grounded in human tutor behavior. These studies highlight the need for systems that go beyond correctness to capture richer instructional attributes.

Compared to these approaches, our work introduces a unified training and inference framework across multiple feedback dimensions, leveraging ensemble disagreement and uncertainty estimation for prediction stability. Unlike previous models with track-specific adaptations or rule-based post-processing, we apply a consistent architecture based on the Mathstral-7B-v0.1 model across all

tasks. This allows us to assess the generalizability of instruction-tuned LLMs for the mathematics domain across key dimensions of pedagogical ability.

3 Method

Our approach, MSA-MATHEVAL, applies a unified framework across all four tracks in the BEA 2025 Shared Task. We build on the instruction-tuned Mathstral-7B-v0.1 model and leverage parameter-efficient fine-tuning (LoRA) along with ensemble-based inference to enhance prediction robustness. The methodology consists of the following stages: dataset preprocessing, model selection, fine-tuning strategy, and ensemble-based inference (see Figure 1).

3.1 Preprocessing

The original dataset consists of nested JSON files, where each dialogue contains multiple tutor responses annotated across four pedagogical dimensions. To facilitate instruction-based fine-tuning, we transformed the data into four track-specific JSONL files. Each file includes a flattened dialogue, a natural language evaluation prompt, and a categorical label from three possible options: *Yes*, *To some extent*, or *No*.

Each training instance was structured as a two-turn dialogue following the chat schema used by instruction-tuned language models. Specifically:

- **user:** This field contains a complete, track-specific prompt with explicit evaluation criteria, followed by the dialogue context and tutor response to be evaluated.
- **assistant:** This field contains the gold label corresponding to the tutor response—one of "Yes", "To some extent", or "No"—as annotated in the development set.

The system role was omitted to reduce token overhead and focus the model on the input–output mapping relevant to each multi-class classification task.

Track 1 – Mistake Identification

TASK DEFINITION:

You are an expert evaluator of AI tutor responses. Your task is to determine whether the tutor’s response accurately identifies a mistake in the student’s reasoning or solution.

EVALUATION CRITERIA:

1. “Yes”– The tutor accurately identifies a mistake in the student’s response.
2. “To some extent”– The tutor shows some awareness, but it is ambiguous or uncertain.
3. “No”– The tutor fails to identify or misunderstands the mistake.

Track 2 – Mistake Location

TASK DEFINITION:

You are an expert evaluator of AI tutor responses. Your task is to determine whether the tutor’s response accurately points to a genuine mistake and its location in the student’s response.

EVALUATION CRITERIA:

1. “Yes”– The tutor clearly points to the exact location of the mistake.
2. “To some extent”– The tutor refers to a mistake but is vague or indirect.
3. “No”– The tutor provides no indication of where the mistake occurred.

Track 3 – Providing Guidance

TASK DEFINITION:

You are an expert evaluator of AI tutor responses. Your task is to determine whether the tutor’s response provides correct and relevant guidance to help the student.

EVALUATION CRITERIA:

1. “Yes”– The tutor gives helpful guidance such as a hint or explanation.
2. “To some extent”– The guidance is partially helpful, unclear, or incomplete.
3. “No”– The guidance is absent, irrelevant, or factually incorrect.

Track 4 – Actionability

TASK DEFINITION:

You are an expert evaluator of AI tutor responses. Your task is to determine whether the tutor’s feedback is actionable, i.e., it clearly suggests what the student should do next.

EVALUATION CRITERIA:

1. “Yes”– The response includes clear next steps for the student.
2. “To some extent”– Some action is implied, but it is not clearly stated.
3. “No”– No action is suggested or the feedback ends the conversation.

Each JSONL instance includes an instruction (as the user message), an input (composed of the full dialogue context and tutor response), and an output (gold label as assistant). This format enables effective supervised fine-tuning of Mathstral-7B-v0.1 on each dimension-specific classification task.

3.2 Model Selection and Architecture

Our system is built upon the Mathstral-7B-v0.1 language model, an open-source 7B-parameter transformer tailored for mathematical and scientific reasoning (Mistral AI Team, 2024). It is an instruction-tuned variant of the Mistral 7B architecture (Jiang et al., 2023), which itself builds on the transformer framework used in LLaMA (Touvron et al., 2023a,b). Mathstral uses a 32-layer transformer with 4096-dimensional hidden states and 32 attention heads (8 for keys/values), and benefits from Mistral’s sliding-window attention mechanism, enabling long-context comprehension up to 32k tokens. This makes it particularly suitable for modeling multi-turn math tutoring dialogues that require broad context retention.

Mathstral-7B-v0.1 was selected based on its strong performance in math-specific benchmarks and its open-access availability. It was instruction-tuned by Project Numina on mathematical reasoning tasks and achieves high scores on datasets such as GSM8K (Cobbe et al., 2021), MATH (Hendrycks et al., 2021b), and MMLU-STEM (Hendrycks et al., 2021a). For instance, it reports 56.6% accuracy on MATH, significantly outperforming base Mistral and LLaMA models of comparable size.

Compared to alternatives, Mathstral outperforms general-purpose LLaMA 2 (Touvron et al., 2023b) and even surpasses some larger models in mathematical domains. While proprietary models like GPT-3.5 or GPT-4 (OpenAI, 2022, 2023) show impressive general capabilities, their closed nature limits fine-tuning flexibility and deployment cost-effectiveness. Mathstral, by contrast, is released under Apache 2.0, making it fine-tunable with LoRA on modest compute budgets.

We thus chose Mathstral-7B-v0.1 as the backbone of our system due to its optimal trade-off

between math reasoning accuracy, open weight availability, and instruction-following capability.

3.3 Training and Fine-Tuning

We fine-tuned Mathstral-7B-v0.1 separately for each BEA 2025 track using Low-Rank Adaptation (LoRA) (Hu et al., 2021), framing the task as three-way instruction-based classification. Each input was represented as a two-turn dialogue—comprising a prompt and a categorical label—and modeled as a supervised instruction-following task.

To enable efficient adaptation with minimal memory overhead, we used LoRA with a rank of $r = 64$, scaling factor $\alpha = 2.0$, and no dropout. Adapters were injected into the attention query and value projections in each transformer block. The low-rank update to the frozen weight matrix W is defined as:

$$\Delta W = \alpha \cdot AB \quad (1)$$

where $A \in \mathbb{R}^{d \times r}$ and $B \in \mathbb{R}^{r \times d}$ are trainable matrices, and d is the dimension of the attention head. The final effective weight is $W + \Delta W$. Figure 2 illustrates this injection mechanism.

Figure 2: LoRA adaptation adds trainable low-rank matrices A and B to frozen attention weights W_0 , producing an effective weight $W = W_0 + \alpha AB$ during training. Only A and B are updated, enabling memory-efficient fine-tuning (Hu et al., 2021).

Training was capped at 500 steps with gradient norm clipping ($\|g\|_2 < 1.0$) and a maximum sequence length of 2048 tokens. We used a batch size of 2, single micro-batching, and fixed seed 42 for reproducibility. Optimization was performed using AdamW with a learning rate of 4×10^{-5} , 10% linear warmup, and weight decay of 0.05.

We evaluated model performance every 50 steps on a held-out validation set, which consisted of the last 30% of the development dataset. The development set includes 300 dialogues sourced from the MathDial (Macina et al., 2023) and Bridge (Wang et al., 2024) datasets. Checkpoints were saved every 100 steps with a retention window of the three most

recent. Only LoRA adapter weights were saved to minimize disk usage and enable efficient inference. All training runs were conducted in a single-node setup with `world_size=1`.

This training configuration ensured stable convergence on limited supervision, while maintaining computational efficiency and reproducibility across all four pedagogical dimensions.

3.4 Inference and Ensemble Strategy

To enhance robustness and maintain generalization across all four tracks, we employed an ensemble-based inference strategy grounded in model disagreement. Rather than aggregating predictions through majority voting, we fine-tuned five independent models per track. Each model used the same base architecture Mathstral-7B-v0.1 but was trained with different random seeds and shuffled data splits to encourage diversity in learned representations. This disagreement-aware mechanism allows us to capture uncertainty and preserve minority-class predictions, especially for ambiguous cases labeled "To some extent".

Each model in the ensemble predicts a class independently using greedy decoding. During inference, we collect all five predictions for a given sample and apply a filtering policy: if the predictions exhibit full agreement, the class is retained. If the ensemble disagrees, we analyze the class distribution and prefer predictions that preserve the relative frequency of "To some extent" observed in the development set. This is crucial because "Yes" labels are dominant in both the training and validation sets, potentially leading to biased predictions under a naïve voting scheme.

Our design choice is motivated by the use of macro-F1 as the primary evaluation metric in the BEA 2025 Shared Task. Unlike accuracy or micro-F1, macro-F1 gives equal weight to all classes, making performance on minority labels such as "To some extent" especially important. By encouraging the retention of these less frequent but pedagogically relevant labels through disagreement-aware filtering, we improve per-class recall and stabilize final predictions.

This ensemble strategy is lightweight in deployment, as only LoRA adapter weights are loaded during inference. Predictions are generated sequentially and combined via a deterministic post-processing script that requires no additional training.

Figure 3: Label distribution comparison across four evaluation tracks. Each group of bars represents the percentage of predictions for the labels "Yes", "No", and "To some extent" for three settings: the MRBench development set (Dev), the best-performing single model on the test set (Single), and the ensemble system on the same test set (Ensemble).

4 Experiments

4.1 Dataset

The BEA 2025 Shared Task provides a benchmark for evaluating AI tutor responses across four pedagogically motivated tracks: Mistake Identification, Mistake Location, Providing Guidance, and Actionability (Kochmar et al., 2025). The dataset is based on *MRBench*, a curated collection of math-focused educational dialogues designed for evaluating feedback quality in instructional settings (Maurya et al., 2025). It includes dialogues drawn from two publicly available sources: MathDial (Macina et al., 2023) and Bridge (Wang et al., 2024).

Each instance comprises a multi-turn conversation between a student and an AI tutor, a final student question or statement, and multiple candidate tutor responses. The task is to classify each response along the four instructional dimensions, using a three-way labeling scheme: *Yes*, *To some extent*, and *No*.

The shared task organizers provide a labeled development set with expert annotations for training and validation. The test set is blind—its labels are hidden from participants and used by the organizers to evaluate final system submissions. This setup ensures fair comparison and simulates real-world deployment where labeled data may be limited or unavailable.

MRBench Statistics:

- **192** annotated dialogues in total: **60** from Bridge and **132** from MathDial.
- **1,596** total tutor responses annotated across 7 LLMs and multiple human tutors (expert and novice).
- Each response is annotated with 8 evaluation dimensions; the shared task focuses on 4 core tracks.
- **Dialogue Length:** Bridge dialogues average 4 turns and 140 characters. MathDial averages 5.5 turns and 906 characters.

4.2 Evaluation

To evaluate the pedagogical quality of model predictions across all four tracks, the BEA 2025 Shared Task employs two complementary scoring protocols: *exact evaluation* and *lenient evaluation*. Both use macro-averaged F1 score and accuracy as core metrics.

Exact Evaluation. In the primary setting, each prediction is evaluated against a gold label using a three-way classification scheme: "Yes", "To some extent", and "No". Let C denote the set of all classes, and $F1_c$ the F1 score for class $c \in C$. The macro-F1 score is computed as the unweighted

Track	Run	Strict F1	Lenient F1	Strict Acc.	Lenient Acc.	Main Metric Rank
Mistake Identification	Run 1	71.54%	91.52%	87.59%	95.35%	4 th / 44
	Run 2	70.66%	91.42%	87.98%	95.22%	
	Run 3	56.78%	82.95%	83.65%	91.92%	
	Run 4	67.88%	90.13%	87.20%	94.76%	
	Run 5	71.34%	91.52%	87.39%	95.35%	
Mistake Location	Run 1	55.62%	77.79%	72.01%	80.93%	4 th / 31
	Run 2	56.02%	77.73%	72.01%	81.19%	
	Run 3	56.88%	78.48%	71.88%	82.09%	
	Run 4	52.79%	73.65%	63.61%	78.22%	
	Run 5	57.43%	78.48%	69.75%	82.09%	
Providing Guidance	Run 1	55.28%	76.02%	67.29%	80.35%	1 st / 35
	Run 2	53.76%	76.59%	65.09%	80.74%	
	Run 3	56.65%	74.75%	63.61%	80.61%	
	Run 4	58.33%	77.98%	66.13%	81.90%	
Actionability	Run 1	51.35%	68.81%	58.31%	76.60%	3 rd / 29
	Run 2	66.99%	84.97%	71.95%	87.91%	
	Run 3	65.90%	84.45%	71.82%	87.07%	
	Run 4	69.84%	86.59%	75.37%	89.08%	
	Run 5	65.90%	84.45%	71.82%	87.07%	

Table 1: Strict and lenient macro-F1 and accuracy across five runs per track. Bolded scores indicate per-track bests. Final column shows BEA 2025 leaderboard rank based on strict macro-F1 (main metric).

average across all classes:

$$\text{Macro-F1} = \frac{1}{|C|} \sum_{c \in C} \frac{2 \cdot \text{Precision}_c \cdot \text{Recall}_c}{\text{Precision}_c + \text{Recall}_c} \quad (2)$$

This metric penalizes class imbalance and rewards systems that maintain recall across minority classes such as "To some extent".

Lenient Evaluation. To account for pedagogical similarity between "Yes" and "To some extent", the task also includes a two-way lenient evaluation protocol. Labels "Yes" and "To some extent" are merged into a single positive class, resulting in a binary classification task. The same macro-F1 and accuracy metrics are then applied to the collapsed label set.

Accuracy. For both settings, accuracy is defined as the proportion of correct predictions over all samples:

$$\text{Accuracy} = \frac{1}{N} \sum_{i=1}^N \mathbb{1}(\hat{y}_i = y_i) \quad (3)$$

where N is the number of samples, \hat{y}_i is the predicted label, and y_i is the gold label for instance i .

Protocol. Since the test labels were not released, we computed local metrics only on the development set. All official test results were obtained through the shared task evaluation server. Model

selection and early stopping were based on development macro-F1 under the exact evaluation setting, which served as the primary leaderboard metric.

4.3 Effect of Ensemble Disagreement on Label Distribution

To analyze the effect of our ensemble strategy on class balance, we examined the label distributions across all four tracks. The development set consistently exhibited a dominant proportion of "Yes" labels—often exceeding 55%—with "To some extent" and "No" underrepresented.

Left uncorrected, single-model predictions tended to reinforce this imbalance, frequently collapsing uncertain cases into the majority class. To mitigate this, our ensemble disagreement filtering selectively retained predictions for the minority class "To some extent" when model consensus was low. This design choice was informed by the use of macro-F1 as the shared task’s official ranking metric, which rewards balanced performance across all classes.

Figure 3 compares label distributions from the development set, single-model outputs, and ensemble predictions. The ensemble strategy improves minority-class coverage—especially for "To some extent"—by better matching the development distribution and mitigating dominant-class bias. This adjustment is particularly useful in ambiguous cases where subtle feedback is warranted.

Track	Strict Macro-F1	Lenient Macro-F1	Strict Acc.	Lenient Acc.
Mistake Identification	4 th / 44	2 nd / 44	1 st / 44	2 nd / 44
Mistake Location	4 th / 31	6 th / 31	10 th / 31	6 th / 31
Providing Guidance	1 st / 35	2 nd / 35	3 rd / 35	3 rd / 35
Actionability	3 rd / 29	1 st / 29	2 nd / 29	2 nd / 29

Table 2: Per-metric leaderboard ranks (out of all teams) for each track.

5 Results

We evaluate our system across the four BEA 2025 tracks—Mistake Identification, Mistake Location, Providing Guidance, and Actionability—using both exact (three-class) and lenient (binary) evaluation protocols, as outlined in Section 4.2. We report macro-averaged F1 and accuracy scores across five independent runs for each track and compare our best results to the official leaderboard.

5.1 Performance Across Runs

Table 1 presents detailed performance scores from five independent fine-tuning runs per track. Each run was evaluated on strict and lenient macro-F1 as well as accuracy. We observe moderate variance across runs, particularly in Tracks 2 and 4, which feature more ambiguous tutor responses.

Our best-performing models achieved:

- **Track 1:** 71.54% strict macro-F1 and 91.52% lenient macro-F1 (Run 1).
- **Track 2:** 57.43% strict macro-F1 and 78.48% lenient macro-F1 (Run 5).
- **Track 3:** 58.33% strict macro-F1 and 77.98% lenient macro-F1 (Run 4).
- **Track 4:** 69.84% strict macro-F1 and 86.59% lenient macro-F1 (Run 4).

These results highlight the robustness of our unified training pipeline and the positive impact of ensemble disagreement filtering on minority-class prediction, especially in borderline cases.

5.2 Leaderboard Rankings

Table 2 summarizes our official rankings among all participating teams. We consistently placed within the top 5 across all tracks and metrics, securing the 1st rank in Track 3 (Providing Guidance) and top-3 ranks in three other metrics.

These ranks validate the effectiveness of our approach across varied pedagogical feedback dimensions. Notably, our system generalizes well

across tasks using a unified model and minimal task-specific engineering.

6 Limitations

Despite its strong performance across BEA 2025 tracks, our approach has several limitations.

First, the specialization of `Mathstral-7B-v0.1` to mathematical reasoning may hinder generalization to non-mathematical domains. While domain-specific instruction tuning improves in-domain performance, prior work has shown that such specialization can cause *catastrophic forgetting* of general knowledge, even with parameter-efficient methods like LoRA (Dettmers et al., 2023). Moreover, although LoRA significantly reduces memory and compute costs, its low-rank decomposition can constrain the model’s expressiveness in capturing nuanced pedagogical feedback (Xu et al., 2023; Zhou et al., 2023).

Second, our ensemble disagreement strategy introduces additional inference cost. While it improves recall for minority labels such as “To some extent”, the benefit may diminish if the base models exhibit correlated predictions. Prior work shows that ensembles are most effective when model predictions are diverse and independent (Lakshminarayanan et al., 2017), which may not always hold in practice.

Finally, the reliance on macro-averaged F_1 as the primary evaluation metric, although fair for class imbalance, lacks granularity in penalizing pedagogically critical mistakes. For example, misclassifying a completely wrong tutor response as “To some extent” is penalized equally to a more plausible confusion between “Yes” and “To some extent”. While the lenient evaluation partially addresses this by collapsing similar labels, it does not fully capture the instructional severity of errors (Kochmar et al., 2025).

7 Conclusion

We presented MSA-MATHEVAL, a unified framework for evaluating AI tutor responses across

four pedagogical dimensions in the BEA 2025 Shared Task. By fine-tuning a math-specialized LLM (Mathstral-7B-v0.1) using LoRA and leveraging ensemble disagreement during inference, our system achieved top-tier results across all tracks—ranking 1st in Providing Guidance and within the top 5 in all others. Our findings highlight the effectiveness of combining domain-specific instruction tuning with disagreement-aware prediction filtering for educational feedback assessment. Future work will explore cross-domain generalization and dynamic calibration strategies to further enhance robustness.

Abstract

In light of the growing adoption of large language models (LLMs) as educational tutors, it is crucial to effectively evaluate their pedagogical capabilities across multiple dimensions. Toward this goal, we address the Mistake Identification sub-task of the BEA 2025 Shared task, aiming to assess the accuracy of tutors in detecting and identifying student errors. We experiment with several LLMs, including GPT-4o-mini, Mistral-7B, and Llama-3.1-8B, evaluating them in both zero-shot and fine-tuned settings. To address class imbalance, we augment the training data with synthetic examples, targeting underrepresented labels, generated by Command R+. Our GPT-4o model fine-tuned on the full development set achieves a strict macro-averaged F1 score of 71.63%, ranking second in the shared task. Our work highlights the effectiveness of fine-tuning on task-specific data and suggests that targeted data augmentation can further support LLM performance on nuanced pedagogical evaluation tasks.

1 Introduction

The increasing integration of large language models into educational applications has sparked significant interest in their potential as AI tutors capable of engaging students in meaningful learning dialogues. A critical component of effective tutoring lies in the ability to identify and address student misconceptions or errors. While recent studies have explored the capabilities of LLMs in simulating tutor-like behaviors, there remains a pressing need for systematic frameworks to evaluate their pedagogical effectiveness.

The BEA 2025 Shared Task (Kochmar et al., 2025) introduced a structured evaluation of AI tutors' responses, focusing on four pedagogical di-

mensions: mistake identification, mistake location, providing guidance, and actionability. In this work, we focus on the Mistake Identification sub-task, which involves determining whether a tutor's response acknowledges a student's error within a given conversational context. The task builds upon the unified evaluation taxonomy proposed by (Maurya et al., 2025), which defines key pedagogical dimensions for assessing the effectiveness of AI tutors in mistake remediation scenarios.

In our participation in this task, under the team name TutorMind, we explore the effectiveness of multiple LLMs, including GPT-4o-mini (OpenAI, 2024), Mistral-7B (Mistral-AI, 2023), and Llama-3.1-8B (Meta, 2024), in both zero-shot and fine-tuned settings. To address class imbalance in the dataset, we introduce a data augmentation strategy using the Command-R-plus model (Cohere, 2024) to generate synthetic examples targeting underrepresented classes. Our best-performing model, a fine-tuned variant of GPT-4o-mini trained on the full development dataset, achieved a strict macro-averaged F1 score of 71.63%, ranking second place in the competition.

This study contributes to the growing body of research on AI-assisted education by demonstrating how targeted fine-tuning can enhance LLMs' ability to evaluate the pedagogy of tutor LLMs. Our findings underscore the importance of aligning model training with domain-specific evaluation criteria. All fine-tuning scripts, evaluation pipelines, and data augmentation prompts, are publicly available for reproducibility and further research.¹

2 Related Work

LLM-Powered AI Tutors in Education: Large language models are being increasingly used as AI tutors capable of engaging students in natural dialogue and providing real-time feedback (Wang et al., 2024). In particular, domains like mathematics and programming have seen significant interest due to the structured nature of problems and the importance of identifying student misconceptions early (Daheim et al., 2024).

However, while LLMs demonstrate impressive fluency and general question-answering capabilities, their effectiveness as pedagogical models remains limited. For instance, GPT-4 often reveals answers prematurely, undermining its role as a supportive tutor. Similarly, Gemini and Phi3 struggle with coherence and actionable guidance, highlighting the need for targeted evaluation frameworks that go beyond traditional natural language generation (NLG) metrics (Jurenka et al., 2024).

Tutor LLMs Evaluation Frameworks: Traditional NLG metrics such as BLEU, ROUGE, and BERTScore are insufficient for evaluating AI tutors because they do not account for pedagogical values such as mistake identification, scaffolding, or encouraging tone. Several studies have proposed domain-specific evaluation criteria tailored to educational dialogues.

(Tack and Piech, 2022) introduced a framework assessing AI tutors based on conversational uptake, understanding, and helpfulness. (Wang et al., 2024) extended this by incorporating dimensions such as care, human-likeness, and usefulness. (Daheim et al., 2024) focused on actionability and correctness.

In contrast, (Maurya et al., 2025) proposed a unified taxonomy comprising eight distinct pedagogical dimensions: Mistake Identification, Mistake Location, Revealing of the Answer, Providing Guidance, Actionability, Coherence, Tutor Tone, Human-likeness, The authors also released MR-Bench, a benchmark dataset containing annotated responses from both human and LLM-based tutors, which is a previous version of the dataset being used in the current task.

Use of LLMs as Evaluators: Researchers have explored the use of LLMs themselves as critics or evaluators. Several studies have demonstrated that LLMs like GPT-4 can assess the quality of educational dialogues with moderate agreement compared to human annotators (Koutchme et al.,

2024). In particular, GPT-4 has been used as an automatic judge to evaluate feedback quality in programming education, showing reasonable correlation with expert human evaluations, although it tends to be overly optimistic in its ratings.

Other studies have leveraged LLMs to score classroom instruction or provide actionable insights for teacher coaching (Wang and Demszky, 2023). These works suggest that LLMs can offer scalable and cost-effective evaluation solutions, although they are not yet fully reliable substitutes for human judgment.

Recent efforts underscore both the growing interest in deploying LLMs as AI tutors and the challenges involved in evaluating their pedagogical effectiveness. While LLMs are proficient at generating fluent and coherent responses, their ability to function as effective tutor agents remains limited. Building on the work of (Maurya et al., 2025), we focus on a single pedagogical dimension, mistake identification, and investigate how fine-tuning LLMs can enhance their ability to evaluate tutor responses within this context.

3 Methodology

This section describes the models, dataset preparation, training setup, and augmentation strategy used to address the Mistake Identification sub-task of the BEA 2025 Shared Task.

3.1 Task Setup & Dataset

We utilized the labeled development set provided by the shared task organizers, focusing specifically on the Mistake Identification dimension of AI tutor responses. The dataset contains three class labels indicating whether the tutor’s response addressed a student mistake: Yes (1932 instances), No (370), and To some extent (174). This distribution presents a significant class imbalance, with the "Yes" class significantly overrepresented compared to the other two categories (see Appendix A for a breakdown). We observed that this imbalance negatively impacted model performance during initial experiments. This motivated us to implement targeted data augmentation strategies, as discussed in Section 3.4.

To evaluate model behavior under constrained supervision, we partitioned the development set into two subsets using stratified sampling: a **Training Subset** (80%) and an **Validation Subset** (20%). All initial zero-shot and fine-tuning experiments

were conducted using the training subset, while the validation subset served as a held-out test set to guide model selection.

Additionally, all final system submissions were evaluated by the organizers on a separate **Blind Test Set**, for which ground-truth labels were not released. This Blind Test Set was used to compute the official leaderboard scores for the shared task.

3.2 Model Selection

We evaluated the use of multiple large language models as tutor evaluators. GPT-4o-mini (OpenAI, 2024) was chosen for its strong performance and availability for fine-tuning. Mistral-7B (Mistral-AI, 2023) and LLaMA-3.1-8B (Meta, 2024) instruct models were selected as competitive open-source baselines. Larger models were excluded from this study due to computational constraints.

3.3 Fine-tuning Setups

Fine-tuning experiments on the Mistral-7B and LLaMA-3.1-8B models were carried out using the Unsloth framework, which enables optimized and efficient training through 4-bit quantization and the integration of LoRA adapters. Both models were trained for a total of three epochs with a learning rate of $2e-4$ and the AdamW optimizer. The training process was conducted on Google Colab², leveraging the range of available GPU resources, including A100 and T4 GPUs with high memory capacity, to ensure stable and efficient execution.

GPT-4o-mini, in contrast, was fine-tuned via the OpenAI platform³ using supervised fine-tuning (SFT). The training data was formatted into JSONL files with role-tagged messages and associated classification targets (Yes/No/To Some Extent), following OpenAI’s SFT guidelines. Prompt templates and formatting details for all models are provided in appendix C and D.

3.4 Data Augmentation

After initially fine-tuning our selected models on the training subset, we observed a noticeable discrepancy between strict and lenient scores (see Section 5 for further discussion). The models frequently confused the No and To some extent classes with Yes, indicating that class imbalance was a limiting factor. This motivated a data augmentation step focused on these underrepresented classes. We generated additional training examples for the No

and To some extent classes using the Command R+ model (Cohere, 2024). This model was selected because it was neither involved in generating the original tutor responses nor used in the evaluation pipeline, and was capable of producing high-quality tutor response that follow the given instruction.

We created 100 synthetic examples per underrepresented class. Each instance was manually reviewed for label correctness and consistency with the shared task’s annotation guidelines. These examples were added to the training subset and used in a second round of fine-tuning. We refer to this expanded dataset as the **augmented training subset** throughout the paper.

During manual inspection, most generated responses appeared to match the intended labels. The “To some extent” examples typically followed the prompt instructions, using cautious or indirect language like “maybe,” “I think,” or “let’s double-check”, without clearly identifying a mistake. For the “No” class, most responses were affirming and feedback-neutral, as expected. However, some responses included subtle hints that could be interpreted as uncertainty, making them closer in tone to the “To some extent” label. These cases were not filtered out as we prioritized maintaining class coverage. In retrospect, these borderline cases introduced some mild label noise, which highlights the need for more precise quality control in future augmentation steps.

The original and augmented training setups shared identical hyperparameter settings. The prompt used with Command R+ to generate data is documented in appendix E.

4 Results

We report results on both the held-out dev test set and the official shared task test set. Table 1 summarizes the accuracy and macro F1 scores under both strict and lenient settings. Our discussion focuses on strict F1, which was the official evaluation metric.

Zero-shot results show that both GPT-4o and Mistral-7B performed reasonably well out of the box (strict F1: 52.13% and 51.73% respectively), while LLaMA-3.1-8B struggled in the absence of fine-tuning, scoring only 19.03%. These results highlight the limitations of zero-shot prompting, particularly for minority class detection.

Fine-tuning on the initial training subset signif-

²<https://colab.google/>

³<https://platform.openai.com/docs/overview>

icantly improved performance across all models. GPT-4o achieved 68.20% strict F1 on the dev test set and was submitted as our first system, scoring 67.70% on the official blind test set. Mistral-7B and LLaMA-3.1-8B achieved 62.61% and 41.52%, respectively. Based on these results, we selected GPT-4o for further fine-tuning on the full development set. GPT-4o fine-tuned on the full development set scored 71.63% on the blind test, ranking second in the competition.

To evaluate the impact of data augmentation, we fine-tuned both GPT-4o-mini and Mistral-7B on the augmented training subset, which included synthetic examples targeting the underrepresented “No” and “To some extent” classes. LLaMA-3.1-8B was excluded from this stage, as it consistently underperformed compared to the other models in earlier experiments. Both GPT-4o-mini and Mistral-7B showed further gains: GPT-4o-mini reached 70.34% strict F1 on the dev test set, while Mistral-7B improved from 62.61% to 70.08%. These configurations were submitted as additional runs, with GPT-4o-mini achieving 70.76% on the blind test set. Notably, the augmented GPT-4o-mini model outperformed all other models trained only on the training subset. However, it was never fine-tuned on the full development set due to time constraints. As a result, it was not submitted in its optimal form. We hypothesize that combining data augmentation with full-devset fine-tuning would have yielded even stronger results, potentially surpassing our best-performing submission (GPT-4o-mini fine-tuned on the full devset without augmentation), which scored 71.63% on the blind test. The relatively lower leaderboard score of the augmented GPT-4o-mini model reflects the limitation of training on a smaller portion of the data, rather than a shortcoming of the augmentation strategy itself. The complete comparison is presented in Table 1.

5 Analysis

The Mistake Identification task was evaluated under two settings: strict and lenient. In the strict setting, the model deals with the three classes, Yes, No, or To some extent, separately. On the other hand, the lenient setting merges the Yes and To some extent labels into a single positive class. This reduces the penalty for confusing pedagogical distinctions, specifically partial vs. full mistake recognition.

As shown in Table 2, lenient scores were consistently higher than strict scores across all models and configurations. For instance, our GPT-4o-mini model fine-tuned on the training subset achieved a strict F1 of 68.20% but a lenient F1 of 87.53%, suggesting that the model often detected the presence of a mistake but occasionally failed to clearly distinguish between full and partial mistake identification. Similarly, Mistral-7B’s results reinforce this observation, with 62.61% strict F1 and 85.71% lenient F1.

These results, along with careful examination of model predictions, had two key implications during system development. First, they highlighted that model failures were frequently due to confusion between Yes and To some extent, rather than between positive and negative classes (Yes/To some extent vs. No). This informed our decision to generate targeted augmentations specifically for the No and To some extent classes, which were both underrepresented and prone to misclassification. Second, the wide gap between strict and lenient scores helped us judge whether model improvements were actually sharpening pedagogical judgment, or simply boosting overall correctness.

To better understand the effect of data augmentation, we compare confusion matrices under both strict and lenient settings for the GPT-4o-mini model (Appendix B). In the lenient setting, slight improvements are observed after augmentation, but the gains are minimal—likely due to the small scale of augmentation relative to the underlying class imbalance. Under the strict setting, a few additional instances from the “No” and “To some extent” classes were correctly classified, confirming that the augmentation was directionally helpful. However, we also observe increased confusion within the “Yes” class, suggesting that the added synthetic data may have introduced mild noise. These trends indicate that while small-scale augmentation can be beneficial, its impact is limited and should be expanded or refined in future work.

6 Conclusion

In this work, we addressed the Mistake Identification sub-task of the BEA 2025 Shared Task, which evaluates whether AI tutors recognize student errors within educational dialogues. We explored both zero-shot and fine-tuned settings across several LLMs, including GPT-4o-mini, Mistral-7B, and LLaMA-3.1-8B. Our best-performing submit-

Model	Method	Validation Subset		Blind Test Set
		Strict F1	Strict Acc.	Strict F1 (submission)
GPT-4o-mini	Zero-shot	52.13	82.86	–
GPT-4o-mini	Fine-tuned on training subset	68.20	88.71	67.70
GPT-4o-mini	Fine-tuned on Full development set	–	–	71.63
GPT-4o-mini	Fine-tuned on augmented training subset	70.34	88.91	70.76
Mistral-7B	Zero-shot	51.73	70.16	–
Mistral-7B	Fine-tuned on training subset	62.61	87.10	–
Mistral-7B	Fine-tuned on augmented training subset	70.08	88.51	60.59
LLaMA-3.1-8B	Zero-shot	19.03	29.44	–
LLaMA-3.1-8B	Fine-tuned on training subset	41.52	84.48	–

Table 1: Performance comparison of all models under strict evaluation: The table reports strict macro-F1 and accuracy scores on the internal validation set and the official blind test set. The best-performing submitted model was GPT-4o-mini fine-tuned on the full development set, achieving a strict F1 score of 71.63% on the blind test.

Model	Method	Strict F1	Strict Acc.	Lenient F1	Lenient Acc.
GPT-4o-mini	Zero-shot	52.13	82.86	77.57	89.52
GPT-4o-mini	Fine-tuned on training subset	68.20	88.71	87.53	93.95
GPT-4o-mini	Fine-tuned on augmented training subset	70.34	88.91	88.36	94.35
Mistral-7B	Fine-tuned on training subset	62.61	87.10	85.71	92.74
Mistral-7B	Fine-tuned on augmented training subset	70.08	88.51	87.15	93.55

Table 2: Macro-F1 and accuracy scores are shown for both strict (3-way classification) and lenient (binary classification: Yes/To some extent vs. No) settings on the validation subset. GPT-4o-mini fine-tuned on the augmented training dataset performs best on the validation subset in both settings.

ted system, a GPT-4o-mini model fine-tuned on the full development set, achieved a strict macro-F1 score of 71.63% on the official blind test set, ranking second in the competition. These results highlight the value of lightweight fine-tuning in enhancing LLMs’ pedagogical sensitivity. Our findings support the ongoing effort to make LLM-based tutors not only fluent but diagnostically effective, capable of recognizing learner misconceptions and delivering instruction that aligns with educational goals.

7 Limitations

While our approach yielded strong results on the Mistake Identification sub-task, several limitations remain. First, the scale of training data, particularly for the “No” and “To some extent” classes,

was limited. Although synthetic augmentation improved model calibration, manual inspection of the generated examples was relatively permissive. In particular, some “No” examples included subtle guidance or hints that could blur the boundary with the “To some extent” class, introducing mild label noise. These were not filtered out during data selection and may have affected label consistency. Future work should explore more grounded augmentation strategies, along with stricter validation procedures to ensure correct label alignment.

Moreover, the models we used for evaluation in our study were also among those used to generate tutor responses for the development data. This overlap introduces potential bias, as models could be more inclined to align with responses produced by themselves or closely related variants. This

type of alignment can lead to overestimation of pedagogical quality of the tutor response.

C Prompt for Llama3.1 8B Instruct and Mistral 7B Instruct

Prompt Template

Instruction:

Evaluate the tutor's response based on whether they identified a mistake in the student's response or not. Mistake Identification: Has the tutor identified a mistake in the student's answer? Options: Yes, To some extent, No. Yes means the mistake is clearly identified or recognized in the tutor's response. No means the tutor does not recognize the mistake (e.g., they proceed to simply provide the answer to the asked question). To some extent means the tutor's response suggests that there may be a mistake, but it sounds as if the tutor is not certain. You should answer by Yes, No or To some extent strictly in the following format: Evaluation: (Yes, No, To Some Extent). It is very important to have the word Evaluation: before your answer, while also sticking to the criteria of evaluation.

Input:

{Conversation History + Tutor Response}

Response:

Evaluation: {Yes, No, or To Some Extent}

D Prompt for GPT-4o-mini

Prompt Format

System Message:

Classify the tutor's response to the student's answer based on whether the tutor has identified a mistake. Use the following labels: 'Yes' means the mistake is clearly identified; 'No' means the tutor does not recognize the mistake; 'To some extent' means the tutor suggests a mistake but is unsure. Respond strictly in the format: Evaluation: [Yes/No/To Some Extent].

User Message:

{Conversation History + Tutor Response}

Expected Output:

Evaluation: {Yes, No, or To Some Extent}

E Prompt for Data Augmentation with Command R+

Prompt for Generating "To Some Extent" Responses

Instruction:

You are a math tutor giving feedback to a student. Based on the conversation, write a single-sentence response that gently suggests the student may have made a mistake, but without clearly identifying what the mistake is. Your tone should sound uncertain, cautious, or exploratory. Do not explicitly say what is wrong. Do not state that something is definitely incorrect. Keep your response to ONE short sentence.

Input:

{Conversation History}

Output:

A single-sentence tutor response labeled "To some extent"

Two Outliers at BEA 2025 Shared Task: Tutor Identity Classification using DiReC, a Two-Stage Disentangled Contrastive Representation

Eduardus Tjitrahardja*, Ikhlasul Akmal Hanif*

Universitas Indonesia

{eduardus.tjitrahardja, ikhlasul.akmal}@ui.ac.id

<https://github.com/edutjie/DiReC>

Abstract

This paper presents DiReC (Disentangled Contrastive Representation), a novel two-stage framework designed to address the BEA 2025 Shared Task 5: Tutor Identity Classification. The task involves distinguishing between responses generated by nine different tutors, including both human educators and large language models (LLMs). DiReC leverages a disentangled representation learning approach, separating semantic content and stylistic features to improve tutor identification accuracy. In Stage 1, the model learns discriminative content representations using cross-entropy loss. In Stage 2, it applies supervised contrastive learning on style embeddings and introduces a disentanglement loss to enforce orthogonality between style and content spaces. Evaluated on the validation set, DiReC achieves strong performance, with a macro-F1 score of 0.9101 when combined with a CatBoost classifier and refined using the Hungarian algorithm. The system ranks third overall in the shared task with a macro-F1 score of 0.9172, demonstrating the effectiveness of disentangled representation learning for tutor identity classification.

1 Introduction

This paper presents the Two Outliers Tutor Identification Systems for Track 5 of the BEA 2025 Shared Task (Kochmar et al., 2025). The goal of this task is to recognize which response belongs to which tutor. We were provided with responses from nine different tutors, including two human tutors (novice and expert) and seven different Large Language Models (LLMs) (Abdin et al., 2024; OpenAI et al., 2024; Grattafiori et al., 2024; Team et al., 2024; Jiang et al., 2023) using data from MRBench (Maurya et al., 2024). For each question, all tutors provided an answer, and the objective is to develop a model capable of distinguishing between these tutor identities based on their responses.

Conversational agents, especially those powered by LLMs, are increasingly used in education to support student learning through interactive and tutor-like dialogue (Wollny et al., 2021; Tack et al., 2023). These systems can generate human-like, context-aware responses, offering new opportunities for scalable and personalized instruction. However, determining whether these models truly behave like effective tutors remains a challenge (Tack and Piech, 2022; Tack et al., 2023). This shared task explores whether it is possible to distinguish between responses generated by different AI tutors and human tutors.

Recent research has shown that models can be fine-tuned using contrastive loss to create powerful and representative embeddings. Powerful embedding models such as Jina, mE5, and BGE (Sturua et al., 2024; Chen et al., 2024; Wang et al., 2024) that are performing well in MTEB are trained using this approach (Muennighoff et al., 2023; Enevoldsen et al., 2025). Although a more common method for classification tasks involves using cross-entropy loss (Mao et al., 2023) to fine-tune encoder models like BERT (Devlin et al., 2019), contrastive learning approaches that produce high-quality embeddings and use simple classifiers have been shown to outperform this traditional method. In some cases, they even surpass large decoder-based models on classification benchmarks (Hanif et al., 2025; Muhammad et al., 2025). Furthermore, training models with contrastive loss directly on a downstream task has also demonstrated strong performance (Khosla et al., 2020; Muhammad et al., 2025). Motivated by these findings, our work explores contrastive learning as a strategy for tutor identification.

Contrastive loss is widely used in self-supervised learning to pretrain large language models by pulling together augmented views of the same input (Chen et al., 2020; Tao et al., 2024). For supervised tasks, supervised contrastive loss (Khosla

*Core contributor

et al., 2020) extends this by using label information, treating all samples with the same label as positives. This leads to more discriminative representations for classification.

Building on this foundation, we propose DiReC, a two-stage Disentangled Contrastive Representation framework for tutor response modeling. The core idea is to separate each response into two latent spaces: one that captures content (semantics, structure, factuality), and another that captures style (tone, verbosity, lexical choices), which is especially important for distinguishing among tutors. In the first stage, we train the model to learn content representations useful for tutor classification. In the second stage, we introduce supervised contrastive learning to the style space, encouraging similar representations across responses from the same tutor. By disentangling these factors, the model better captures tutor-specific traits while maintaining a coherent content backbone, improving both classification accuracy and interpretability.

2 System Overview

We propose a two-stage Disentangled Representation for Classification (DiReC) framework for tutor classification, which simultaneously learns content and style representations from text. The overall architecture is depicted in Figure 1.

2.1 Model Architecture

Given an input text sequence $x = (w_1, \dots, w_T)$, we first obtain contextualized token embeddings via a pretrained DeBERTa-v3-large encoder:

$$\mathbf{H} = \text{Enc}_\theta(x) \in R^{T \times d}, \quad \mathbf{h} = \mathbf{H}_{[\text{CLS}]} \in R^d.$$

Two parallel projection heads then map \mathbf{h} into the content and style subspaces of dimension p :

$$\mathbf{c} = f_{\text{content}}(\mathbf{h}) \in R^p, \quad \mathbf{s} = f_{\text{style}}(\mathbf{h}) \in R^p.$$

The content embedding \mathbf{c} is intended to capture relevant semantic information for the identification of the tutor, while the style embedding \mathbf{s} captures stylistic traits. We concatenate these vectors and feed them to a linear classifier g over K tutor classes:

$$\mathbf{z} = g([\mathbf{c}; \mathbf{s}]) \in R^K, \quad \hat{y} = \arg \max_j z_j.$$

2.2 Two-Stage Training Procedure

Training alternates between two stages to disentangle style from content:

Stage 1 (Cross-Entropy Only). While contrastive loss is effective at capturing stylistic similarity, it does not explicitly enforce class separation nor provide a direct classification signal. Therefore, cross-entropy acts as a necessary foundation to learn robust content features before style-specific objectives are introduced.

In the first stage, we freeze the style head f_{style} and train the encoder Enc_θ , content head f_{content} , and classifier g using standard cross-entropy loss:

$$\mathcal{L}_{\text{CE}} = -\frac{1}{N} \sum_{i=1}^N \log \frac{\exp(z_{i,y_i})}{\sum_{j=1}^K \exp(z_{i,j})},$$

where z_{ij} is the logit for sample i and class j , and z_{i,y_i} is the logit for the true class label y_i of sample i . This loss encourages the model to learn discriminative content representations that effectively differentiate tutors based on semantic and structural aspects of their responses.

Stage 2 (Joint Contrastive & Disentanglement).

In the second stage, we unfreeze the style head and optimize it jointly with the rest of the model. We apply supervised contrastive loss on style embeddings to capture tutor-specific writing traits, encouraging embeddings from the same tutor to cluster regardless of content variation. Simultaneously, a disentanglement loss penalizes high similarity between content and style embeddings, preventing redundancy and promoting specialization of each representation. This joint training improves the model’s ability to separately encode semantic content and stylistic nuances, enhancing both interpretability and classification performance.

- $\mathcal{L}_{\text{SupCon}}$ is the supervised contrastive loss applied to style embeddings:

$$\mathcal{L}_{\text{SupCon}} = -\frac{1}{|\mathcal{P}|} \sum_{(i,j) \in \mathcal{P}} \log \frac{\exp(\mathbf{s}_i^\top \mathbf{s}_j / \tau)}{\sum_{k \neq i} \exp(\mathbf{s}_i^\top \mathbf{s}_k / \tau)},$$

where \mathcal{P} indexes all positive pairs sharing the same tutor label, and τ is a temperature hyperparameter.

Unlike the original formulation by Khosla et al., which uses log-softmax over multiple positives and negatives per anchor, our version is simplified. Since the main supervision is already provided via cross-entropy classification, the contrastive loss acts as an auxiliary signal to refine stylistic clustering, making a lighter pairwise variant sufficient and more efficient.

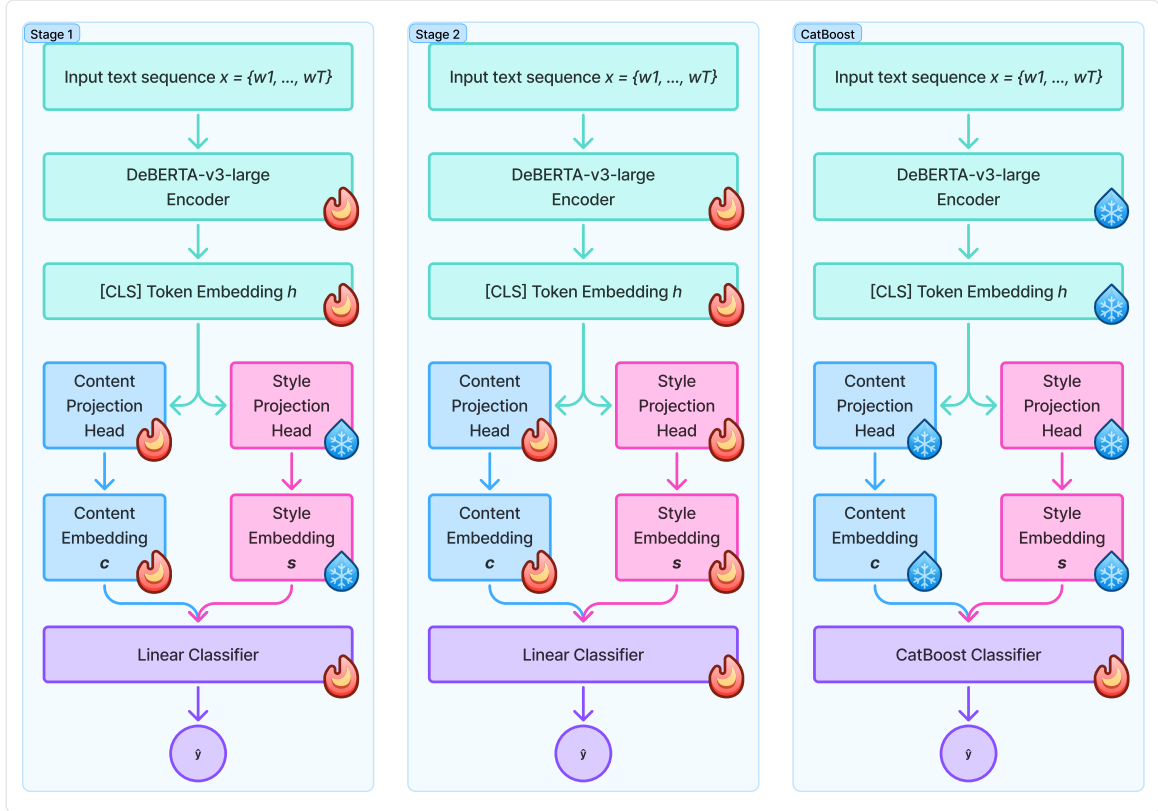

Figure 1: DiReC Architecture. Trainable components are marked with 🔥, while frozen components are indicated with ❄️.

- \mathcal{L}_{dis} is a cosine-based disentanglement loss that penalizes similarity between content and style embeddings:

$$\begin{aligned} \mathcal{L}_{\text{dis}} &= \frac{1}{N} \sum_{i=1}^N |\cos(\mathbf{c}_i, \mathbf{s}_i)| \\ &= \frac{1}{N} \sum_{i=1}^N \left| \frac{\mathbf{c}_i^\top \mathbf{s}_i}{\|\mathbf{c}_i\| \|\mathbf{s}_i\|} \right|. \end{aligned}$$

Finally we calculate all the loss using

$$\begin{aligned} \mathcal{L} &= \lambda_{\text{CE}} \mathcal{L}_{\text{CE}} + \lambda_{\text{sty}} \mathcal{L}_{\text{SupCon}}(\{\mathbf{s}_i, y_i\}) \\ &\quad + \lambda_{\text{dis}} \mathcal{L}_{\text{dis}}(\mathbf{c}, \mathbf{s}). \end{aligned}$$

2.3 Experimental Setup

All experiments were conducted using a consistent set of hyperparameters (Table 3). At the onset of Stage 2, we halved the learning rate and enabled mixed-precision optimization (AdamW + GradScaler) to stabilize fine-tuning. The parameters are provided in Appendix A.

Unless stated otherwise, all single-stage experiments were trained for a total of 5 epochs. The

two-stage DiReC model was initially set to train for 5 epochs during Stage 1 (content-only training with the style head frozen), followed by up to 5 additional epochs in Stage 2 (joint training with both heads unfrozen). In practice, however, the best validation checkpoint was achieved at epoch 6 (the first epoch of Stage 2). For clarity in the 3.1 subsection, we therefore refer to the two-stage model as effectively trained for 6 epochs in total.

At test time, we compute content and style embeddings jointly, concatenate them, and feed the resulting vector into the classifier g . The disentanglement enforced during training ensures that \mathbf{c} and \mathbf{s} capture complementary information, improving both generalization and interpretability in tutor prediction.

3 Result

3.1 Development

We conducted a series of experiments to validate the components of the DiReC framework. Table 1 summarizes the macro-F1 in the validation set for each setting.

Experiment	Val. F1 (Macro)
Single-stage DiReC	0.8720
Only content projection	0.8845
Only style projection	0.8692
Two-stage DiReC	0.9042
Two-stage DiReC + Cat-Boost classifier	0.9101

Table 1: Validation Macro-F1 scores for development experiments.

Single-Stage First, we trained the DiReC model in a single stage, which yielded a macro-F1 of 0.8720.

Projection-Head Ablation Next, we performed an ablation on the two projection heads to assess its standalone contribution. Training with only the content head for 5 epochs yielded a macro-F1 of 0.8845, whereas using only the style head under the same epochs fell to 0.8692. Moreover, when we extended the content-only model to 6 epochs—to match the total training steps of our two-stage strategy—its performance dropped further to 0.8730, indicating overfitting in the absence of style guidance. These results confirm that the content subspace carries the most of the classification signal, and naively prolonging content-only training can actually harm generalization.

Two-Stage DiReC We observed that introducing the style projection head from the initial stage of training could potentially hinder the development of the content projection’s discriminative capabilities. However, a naive extension of content-only training often led to overfitting. Consequently, we hypothesized that treating the style learning as a subsequent refinement phase could be beneficial. To address these limitations, we adopted the two-stage DiReC strategy (Section 2), introducing the style head only after the content pathway had converged. This staged training approach achieved a validation macro-F1 score of 0.9042, with the best model obtained at epoch 6—the first epoch of Stage 2. It outperformed both content-only baselines, which achieved scores of 0.8845 at epoch 5 and 0.8730 at epoch 6, establishing our strongest benchmark among purely neural network models.

CatBoost on Learned Embeddings Finally, we replaced the model’s linear classifier with a CatBoost classifier (Prokhorenkova et al., 2019)

trained on the concatenated style||content embeddings. This hybrid approach further improved validation macro-F1 to 0.9101.

Embedding Clustering Evolution Figures 2a–2c visualize the t-SNE projections of content embeddings at epochs 1, 3, and 6. Early in training (Figure 2a), tutor clusters overlap greatly. By epoch 3 (Figure 2b), distinct clusters begin to form, and by epoch 6 (Stage 2) (Figure 2c) each tutor’s content representations occupy tight, well-separated regions. This suggests that DiReC has effectively learned to represent tutor-specific content characteristics.

Validation Confusion Matrix Analysis Figure 3 shows the two-stage DiReC + CatBoost classifier confusion matrix on the validation set. The strong diagonal indicates high overall classification accuracy, with most tutor identities being correctly predicted. However, some misclassification between different tutor identities is observable.

The highest confusion occurs between Llama3.1-8B and Llama3.1-405B. Specifically, 8 instances of Llama3.1-8B are misclassified as Llama3.1-405B, and 7 instances of Llama3.1-405B are misclassified as Llama3.1-8B. This is likely attributable to the inherent similarity in response styles and content patterns originating from the same Llama model family. Nevertheless, the majority of tutors are classified with high precision and recall, with the primary challenge lying in distinguishing between closely related model variants, highlighting the effectiveness of the disentangled representations.

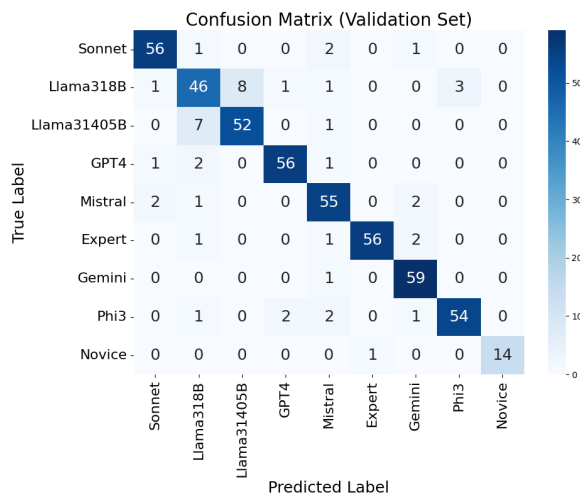

Figure 3: Validation confusion matrix for the two-stage DiReC + CatBoost classifier.

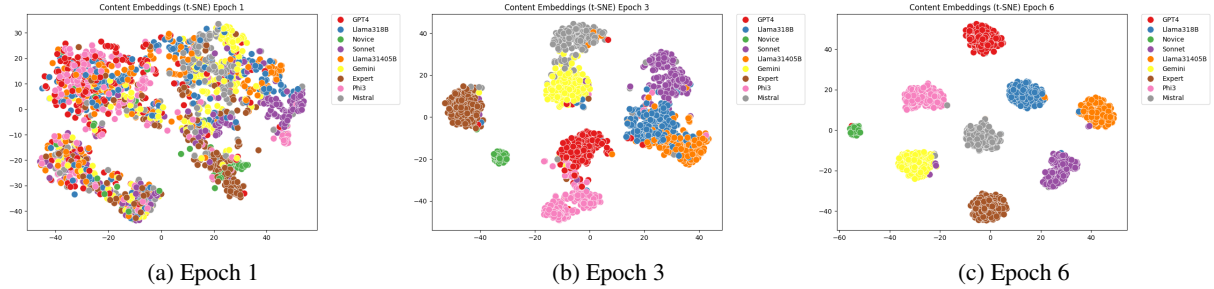

Figure 2: Evolution of content-embedding clusters over training.

3.2 Submission

Each conversation in the dataset contains K utterances, each from a different tutor, requiring a one-to-one mapping between utterances and tutor labels. However, our CatBoost classifier predicts labels independently, which can result in duplicate tutor assignments.

To enforce uniqueness, we apply the Hungarian algorithm as a post-processing step (Crouse, 2016). For each conversation g , we create a $K \times K$ probability matrix $\mathbf{P}^{(g)}$, where $P_{ij}^{(g)}$ is the predicted probability that utterance i belongs to tutor j . We seek the assignment σ^* that maximizes the total confidence:

$$\sigma^* = \arg \max_{\sigma \in S_K} \sum_{i=1}^K P_{i, \sigma(i)}^{(g)}$$

Since SciPy’s `linear_sum_assignment`¹ minimizes cost, we negate the probabilities to form a cost matrix $\mathbf{C}^{(g)}$, with $C_{ij}^{(g)} = -P_{ij}^{(g)}$. This ensures a unique, high-confidence mapping between utterances and tutor labels. This procedure refines the initial probabilistic predictions from the classifier to adhere to the structural constraint of the problem for each conversation.

Rank	Team	F1	Acc
1	Phaedru	0.9698	0.9664
2	SYSUpporter	0.9692	0.9657
3	Two Outliers	0.9172	0.9412

Table 2: Final leaderboard results of the shared task. Our team, Two Outliers, finished in third place.

The predictions from the two-stage DiReC model combined with the CatBoost classifier, fur-

¹https://docs.scipy.org/doc/scipy/reference/generated/scipy.optimize.linear_sum_assignment.html

ther refined using the linear sum assignment strategy, were submitted to the official Codabench leaderboard. This approach achieved a final macro-F1 score of **0.9172**, placing third in the shared task, as shown in Table 2.

4 Conclusion

In this work, we proposed DiReC, a two-stage framework that leverages disentangled contrastive representation learning for the task of tutor identity classification. Our approach separates content and style embeddings to capture both semantic and tutor-specific stylistic characteristics, resulting in improved classification accuracy and interpretability. Empirical evaluations on the BEA-2025 Shared Task data show that the two-stage DiReC model outperforms single-stage baselines and benefits from contrastive refinement and disentanglement. Additionally, incorporating a CatBoost classifier and applying a Hungarian algorithm for structured post-processing further enhanced performance, culminating in a top-three placement in the official leaderboard. These results highlight the potential of disentangled representation learning in modeling nuanced tutor behavior across human and AI-generated responses.

Limitations

Due to time and computational constraints, we did not perform thorough hyperparameter tuning. Several important parameters, including the contrastive temperature, the weights for the cross-entropy loss, style loss, and disentanglement loss, were chosen heuristically without extensive validation. Additionally, core training settings such as the learning rate, batch size, and number of training epochs were fixed throughout our experiments. These parameters may significantly influence model performance, and future work could focus on systematically tuning them to achieve further improvements.

Abstract

This paper describes our approach to the 5 classification tasks from the Building Educational Applications (BEA) 2025 Shared Task. Our methods range from classical machine learning models to fine-tuning large-scale transformer architectures. Despite the diversity of techniques, performance differences were often minor, suggesting the presence of strong surface-level signal in the data and a limiting effect of annotation noise – particularly around the “To some extent” label. Under lenient evaluation, simple models perform competitively, showing their effectiveness in low-resource settings. Our submissions rank in the top 10 in three out of five tracks. The code and models are publicly available at: <https://github.com/ana-rosu/Archaeology-at-BEA2025>

1 Introduction

This paper presents an exhaustive set of experiments conducted for the BEA 2025 Shared Task, which revolves around assessing the pedagogical abilities of AI tutors in educational dialogues within the mathematical domain.

We start with classical machine learning methods like logistic regression over TF-IDF encodings and String Kernel SVMs, gradually scaling up to more complex approaches such as zero-shot and few-shot prompting with Mistral-7B-Instruct (Jiang et al., 2023), feature-based methods using frozen transformer representations (from models like ModernBERT (Warner et al., 2024a) and GritLM (Muennighoff et al., 2024)), decoder-style architectures such as GPT2-XL (Radford et al., 2019) combined with a linear classification head, parameter-efficient fine-tuning with LoRA adapters in 4-bit precision on Mistral-7B, as well as BERT-like classifiers (e.g., RoBERTa (Liu et al., 2019), ModernBERT (Warner et al., 2024b), DeBERTa (He et al., 2021)).

Our best-performing submissions across all tracks use fine-tuned BERT-style classifiers. Final submissions are selected in an unsystematic way due to the five-submission limit per track; we focus on choosing the models that perform best on our local validation set, while also ensuring that they differ from each other. Although most of our submissions are based on Masked Language Models, we include a broader set of experiments in this paper to document our development process and highlight that some alternative approaches remain competitive.

We place greater emphasis on Track 1 (Mistake Identification), as it is the first task we explore and serves as a foundation for the others. Some of our preliminary experiments, including prompting and decoder-based fine-tuning, are conducted exclusively on this track.

Despite using a wide range of models, we observe that performance is often surprisingly similar across setups, suggesting that model architecture may not be the dominant factor for this task. One possible explanation is that subtle annotation inconsistencies, especially between “Yes” and “To some extent”, introduce noise that limits performance (see Appendix G). We notice that tutor responses with very similar wording (e.g., “Please recheck your answer”) are labeled “Yes” in some dialogues and “To some extent” in others. In this context, the order in which training examples are presented becomes important, especially in such a small and imbalanced setting. When the model sees one interpretation early on, it may implicitly learn to generalize that decision across similar examples, reinforcing a bias. This makes the optimization sensitive to random factors such as batch order or initialization.

The “To some extent” label is the main source of difficulty in this task. Without it, the classification becomes much easier, a fact supported by the lenient evaluation scores, which reach or even

*Corresponding author.

exceed 85% F1 on all tracks but one (Providing Guidance, where the best lenient performance on the public leaderboard is 78% F1), suggesting that models perform well when ambiguity is removed from the label space.

When evaluated under the lenient setting (“Yes” and “To some extent” are merged into a single class), traditional machine learning models have surprisingly strong performance even with minimal effort, using default configurations. As shown in Table 9, the validation accuracies achieved with these models are very close to the best public leaderboard results, with gaps between 0.37%-4.15%. In terms of Macro F1, these models also achieve competitive scores, with gaps between 3.70%-10.41%, demonstrating that pedagogical signal can be captured effectively under a binary framing, making them strong baselines in scenarios with constrained resources.

The presence of strong surface-level signal may allow even simple models to perform well. Another potential hypothesis is that there is simply not enough data for larger models to generalize better.

Our team’s submissions were competitive across all tracks:

Track 1 (Mistake Identification): 8th out of 44 teams

Track 2 (Mistake Location): 12th out of 31 teams

Track 3 (Providing Guidance): 13th out of 35 teams

Track 4 (Actionability): 7th out of 29 teams

Track 5 (Tutor Identification): 6th out of 20 teams

Team ranks are based on the results according to the main shared task metric – exact Macro F1 score.

2 Data and Tasks

2.1 Shared-Task Tracks

The data provided for this shared task builds on MRBench, a dataset of short alternate-turn dialogues sourced from MathDial (Macina et al., 2023) and Bridge (Wang et al., 2024). Each dialogue is annotated for eight pedagogical dimensions based on a unified evaluation taxonomy introduced by Maurya et al. (2025a). This taxonomy reflects core learning sciences principles and builds on prior work in AI tutor evaluation (Tack and Piech, 2022; Daheim et al., 2024; Wang et al., 2024)

The task focuses on four key dimensions – which also form the first four of the five tracks in the BEA 2025 shared task:

Track 1 - Mistake Identification: determine if

the tutor identifies the student’s mistake.

Track 2 - Mistake Location: determine if the tutor pinpoints where the mistake occurs.

Track 3 - Providing Guidance: determine if the tutor gives helpful and relevant feedback.

Track 4 - Actionability: determine if the student can clearly understand what to do next.

Track 5 - Tutor Identification: predict which tutor produced the response.

2.2 Dataset

The dataset includes 300 dialogues in the development set and 191 in the test set, each paired with responses from both human tutors (Expert and Novice) and 7 LLM-based tutors (GPT4 (OpenAI et al., 2024), Gemini (Team et al., 2025), Llama31405B (Grattafiori et al., 2024), Llama318B, Mistral (Jiang et al., 2023), Phi3 (Abdin et al., 2024), Sonnet (Anthropic, 2024)). Each dialogue ends with a student turn that contains a mistake, confusion, or misconception, to which multiple tutor responses are provided. Every tutor reply is annotated with gold-standard labels along four dimensions – Mistake Identification, Mistake Location, Providing Guidance, and Actionability – using a three-class scheme: “Yes”, “To some extent”, and “No”.

The label distribution is imbalanced across tasks, with “Yes” being the majority class, “No” moderately represented, and “To some extent” notably underrepresented (Figure 1). Furthermore, the 2D scatter plots (Figure 2), generated using t-SNE on tutor response embeddings extracted from the ModernBERT-large model, show that responses labeled “No” tend to form small, tight clusters, regardless of the task. These responses often share similar semantic structures, such as starting with phrases like “Good job!”, “Good catch!”, or “You are absolutely correct.” In contrast, responses labeled “Yes” show consistent distributions across tasks, suggesting that positive responses are more generalizable. The Actionability task exhibits the highest dispersion among “No” responses.

During our experiments, we identify some cases of label inconsistencies, especially between the labels “Yes” and “To some extent”, which we report in Appendix G.

2.2.1 Training and Validation Splits

For model development, we create separate train-validation splits for each of the first four tasks, to accommodate the varying label distributions across

them. It is important to ensure that all samples from the same conversation remain in the same split to avoid data leakage – otherwise, multiple tutor responses with the same conversation history could appear in both training and validation sets. For that, we group all samples by *conversation_id* and compute the majority label for each dialogue. This majority label is then used to perform stratified sampling, helping us preserve the overall class distribution of the full development set in both the training and validation sets. An 80/20 train/validation ratio is used, with a fixed random seed for reproducibility. Detailed statistics on the splits, including label ratios and counts, are provided in Appendix A.

For Track 5, we perform a stratified 80/20 train/validation split to maintain balanced proportions of tutor identities across both sets. Unlike the other tracks, grouping by *conversation_id* is not required here, since all samples with the same *conversation_id* share an identical conversation history that includes previous tutor turns not authored by the tutor being identified. As a result, only the final generated response can be used to distinguish between them.

For each track, we submit the runs that achieve the highest validation performance. In addition, we include results from lower-performing methods to document the full range of approaches explored.

2.3 Evaluation Metrics

According to Kochmar et al. (2025), Tracks 1 – 4 (Mistake Identification, Mistake Location, Providing Guidance, and Actionability) are evaluated using Macro F1 as the main metric, with accuracy as the secondary metric. The evaluation is done in two ways:

- **Exact evaluation:** the model has to predict the correct label among the three options (“Yes”, “To some extent”, or “No”).
- **Lenient evaluation:** “Yes” and “To some extent” are combined into a single class and compared against “No”.

Track 5 (Tutor Identity) is a 9-class classification task, evaluated using Macro F1 as the main metric and accuracy as the secondary metric, without any lenient setting.

3 Methods

3.1 Traditional ML Methods

As a baseline¹ we use traditional machine learning models across all tracks. For all experiments in this approach, we use TF-IDF for feature extraction covering both unigrams and bigrams from the input text.

Logistic Regression gives us a baseline with a Macro F1 of 0.63 on Track 1, and confirms that the TF-IDF features are useful. We train the model using balanced class weights to handle label imbalance and set the maximum number of iterations to 1000. XGBoost, which is known for strong performance on tabular data and classification tasks (McElfresh et al., 2023), reaches a Macro F1 of 0.625 for Track 1, slightly below Logistic Regression. In all our experiments with this model, we use a learning rate of 0.1, 200 estimators, and set both subsample and colsample bytree to 0.8 for regularization. Ensembling XGBoost with other boosting methods such as LightGBM provides small improvements in a few cases, but overall, the results remain close to those obtained with XGBoost alone (see Table 8).

We also explore a character-level string kernel using an SVM with a precomputed spectrum kernel (Ionescu and Butnaru, 2018). The string spectrum kernel measures the similarity between two strings, s_1 and s_2 , based on their n -grams. It is defined as:

$$K_{\text{spectrum}}(s_1, s_2) = \frac{\sum_{u,v} \kappa(u, v)}{\sqrt{\sum_u \kappa(u, u) \sum_v \kappa(v, v)}}$$

where u and v represent the n -grams (substrings of lengths $\in [2, 5]$) from s_1 and s_2 , respectively. And $\kappa(u, v)$ is a dot product over binary occurrences of n -grams u and v .

This approach appears competitive to deep-learning based models on several tracks. For example, on Mistake Identification it achieves a Macro F1 score of 0.6346, indicating that a lot of the signal can be captured just by comparing strings directly. We take this as an indicator that some of the Yes/No annotations for different tasks share similar-looking strings.

For these experiments, all the validation results are included in the Appendix E.

¹We also use LLM prompting the Mistral-7B-Instruct model, but results are weaker than even traditional ML baselines - best F1 on Task 1 is 0.42. In the few-shot setting, best is 0.45. We describe the entire approach in Appendix C

3.2 Frozen Embeddings + Linear Classifiers

We compare several feature extraction strategies using **ModernBERT-large** for logistic regression classifiers (*max_iter=2000*, *class_weight='balanced'*) on Mistake Identification, Mistake Location, Providing Guidance and Actionability. All embeddings are computed over the tutor response only, without including any surrounding conversational context. We evaluate 4 pooling methods: the final hidden state of the [CLS] token, mean pooling, max pooling, and a concatenation of [CLS] and mean. Results are summarized in Appendix E.1.1.

Mean pooling appears to perform slightly better when tasks do not require fine-grained distinctions, such as in Mistake Identification and Actionability, likely due to better aggregation of distributed semantic cues across the tutor response. For example, using mean-pooled embeddings on the Mistake Identification task, the classifier achieves a Macro F1 of ~ 0.65 on the fixed validation split, outperforming [CLS] pooling (~ 0.62). However, [CLS] pooling demonstrates superior performance on the validation split on more complex tasks like Mistake Location and Providing Guidance. These likely require more nuanced representations. The complexity of these tasks is further evidenced by their overall performance, results remaining notably lower, suggesting they depend more on the dialogue context and how the response relates to the student's earlier reasoning, which cannot be captured in the response itself.

For Mistake Identification, on the other hand, signal can be inferred from the response alone from the presence/absence of corrective language. Similarly, the model performs well on Actionability under the same conditions, likely because actionable feedback is sometimes expressed directly in the tutor's reply through question words that encourage the student to take action. As a result, the signal required for predicting Mistake Identification and Actionability is more localized, allowing the classifier to perform well without access to prior student turns.

Additionally, we extract embeddings from intermediate layers for Mistake Identification, motivated by findings from [Skean et al. \(2025\)](#) that middle-to-late layers may encode more useful information for the MTEB benchmarks. In our case, the performance peaks around layers 9 and 15 for mean and CLS respectively.

Last but not least, we explore **GritLM** - a **Mistral-based** 7b parameter fine-tuned using GRIT ([Muennighoff et al., 2024](#)). This autoregressive model achieves state-of-the-art results on MTEB benchmarks. We compare the embeddings extracted from different layers combined with several classifiers: logistic regression, a multi-layer perceptron (MLP), a Gaussian Naive Bayes and a k-nearest neighbor models. For GritLM we do not observe any significant decay in performance from middle layers up until the final ones (see [Figure 9](#)). The weakest classifiers are the KNN and GaussianNB, while between MLP and logistic regression there does not seem to be a clear winner. Our submission number 2 on Mistake Identification obtains 0.6532 F1 score on the final leader board using the embeddings from layer 24. The comparative results across layers on the validation set are included in Appendix E.1.2.

3.3 Decoder LM Fine-Tuning

We experiment with full fine-tuning of **GPT2-XL** on the Mistake Identification task by applying mean pooling over its last hidden state and training a linear classification head. This setup achieves a Macro F1 score of 0.65 on local split using only the tutor responses as input. We also explore the frozen version of GPT2-XL, updating only the final transformer block. This approach reaches 0.55 Macro F1. We do not pursue these experiments further as the performance plateaued even when experimenting with stratified batches, alternative loss functions, and varying input context on the last-transformer-block version. Configuration: *epochs=10*, *batch_size=32*, *lr=2e-5*, *dropout=0.1*, *loss_fn=CrossEntropyLoss()*, *optimizer=AdamW*. This result reinforces that pedagogical signal detection requires specialized approaches rather than simply scaling model size.

3.4 BERT-like encoders

The final best results are obtained by fine-tuning masked language models. We experiment with three model families: **RoBERTa** ([Liu et al., 2019](#)), **DeBERTa** ([He et al., 2021](#)), and **ModernBERT** ([Warner et al., 2024b](#)). For all models, we apply a linear classification head on top of the final hidden state of the first token (corresponding to the [CLS] token). No additional pooling or attention mechanisms are introduced beyond the pretrained architecture. We begin with base-sized variants on Track 1, but the better performance of the large

variants motivates us to adopt them for our next experiments on all tracks.

For each track and model, we compare three main input formats, which we refer to throughout the paper as:

- *response-only*: consists only of the tutor’s response, isolating the pedagogical value of the response itself without surrounding dialogue
- *context*: includes the final student turn concatenated with the tutor’s response, capturing the local misunderstanding or confusion the tutor is addressing
- *full context*: includes the entire conversation history preceding the tutor’s response enabling multi-turn reasoning over the dialogue and potentially identify earlier misalignments

These representations allow us to assess how much conversational context is necessary or beneficial for each track, and how different models leverage that context.

To address the severe class imbalance and reduce bias toward the majority label, we experiment with three loss functions: standard cross-entropy as a baseline; class-weighted cross-entropy, where class weights are set to the inverse of class frequencies; and focal loss (Lin et al., 2018), with $\gamma \in [1.0, 3.0]$ and various α configurations, including uniform ($\alpha = [1.0, 1.0, 1.0]$), inverse-frequency class weights, and class-balanced α as proposed by Cui et al. (2019).

We also experiment with prepending natural language task prompts to the input, inspired by recent work on instruction tuning and prompt-based adaptation. These prompts frame the classification task using instructions, such as ordinal scales (“To what extent does the tutor identify the mistake? 0 = not at all, 1 = partially, 2 = fully”) or evaluator roles (“You’re evaluating a tutor’s response. Score how clearly they identify the student’s mistake”). The prompt text is prepended to the input before tokenization. Although BERT-like models are not autoregressive, we find that in some cases, prompts improve validation performance and make the task framing more consistent across examples (see Appendix B). Further exploration is needed to fully quantify their impact, but we include this as a promising direction for instruction-aware encoder fine-tuning.

3.5 Submissions

3.5.1 Mistake Identification

Submission 1 uses a fine-tuned **RoBERTa-large** model, trained with context input format and focal loss ($\gamma = 2.0$, uniform α) for 4 epochs. For all hyperparameters and the approach used for selecting the input configuration and loss function, refer to Appendix D.1. We train the model on five random seeds, average the logits across seeds, and apply post-training calibration using temperature scaling and per-class thresholding based on validation performance. On the validation set, this approach achieves a 0.7072 Macro F1. In the public leaderboard, it obtains **0.6919** Macro F1, making it our second-best overall submission.

Training observations:

Initially, random batches leads the model to see mostly majority-class examples early on, which causes a bias to predict predominantly a single label (e.g., "Yes"), hard to correct in later stages. This is visible in the first-epoch confusion matrix.

To resolve this, we implement a custom stratified batch sampler that maintains around the same class ratios as the full training set within each batch, which proves beneficial for small batch sizes in our setup, where a random batch could otherwise contain only examples from the "Yes" class. This helps the model learn minority classes from the start.

Submission 2 uses embeddings from layer 24 of **GritLM** (Muennighoff et al., 2024), selected based on validation performance (Figure 9). The classifier is an ensemble of logistic regression and a multilayer perceptron (MLP) with a hidden size of 100. The best development set score is 0.71, while the leaderboard score is **0.65**. The performance gap indicates overfitting and suggests that layer-wise performance variation can significantly affect decisions, as such, high evaluation scores may not generalize well on new test sets.

Submission 3 is fine-tuned on the **mistralai/Mistral-7B-v0.1** backbone with a maximum sequence length of 1536 and three output labels. Tokenization uses left-side padding and truncation with the fast tokenizer. LoRA is applied to the q_proj and k_proj modules with rank $r = 16$, $\alpha = 16$, and dropout rate 0.1. The classification head is excluded from LoRA adaptation.

Training uses the AdamW8bit optimizer from bitsandbytes, with separate learning rates for the

backbone ($2 \cdot 10^{-5}$) and classification head ($2 \cdot 10^{-6}$). Parameters are grouped based on whether they belong to the head or body and whether they are subject to weight decay. A lower weight decay is applied to the body parameters. The training runs for up to 24 epochs with early stopping (patience 20), a warm-up of 10% of the steps, and evaluation every 10 steps. The best model is selected based on validation performance. On the local split this approach reaches 0.74 Macro F1 score, while on the public leaderboard the results are weaker than other masked language modeling approaches.

Submission 4 uses a **ModernBERT-large** model with a response-only input (no additional context). Unlike Submission 1, it does not use stratified batches and training is done on a single fixed random seed. The model is trained for 3 epochs, followed by per-class threshold calibration on the validation set for post-training adjustments.

This configuration achieves a Macro F1 of 0.7145 on the validation set and **0.6976** on the test set, making it our best-performing submission overall.

Submission 5 uses the same configuration as Submission 4, but consists of predictions from a second inference checkpoint corresponding to epoch 4 of the same run.

This is motivated by the use of early stopping with patience=2 during experiments, which causes training to terminate at variable points depending on the run. Since early stopping introduces non-determinism and cannot be controlled directly during inference, we submit this variant to explore whether extending inference to the subsequent saved epoch could yield marginal gains.

Submission	Macro F1	Accuracy	Ranking
Submission 1	0.6919	0.8746	26
Submission 2	0.6532	0.8423	58
Submission 3	0.6860	0.8565	27
Submission 4	0.6976	0.8675	17
Submission 5	0.6812	0.8681	31

Table 1: Leaderboard Results for Track 1 (Mistake Identification)

3.5.2 Mistake Location

Submission 1 and 2 use a **RoBERTa-large** model, trained with context input and weighted cross-entropy loss function. Submission 2 introduces a two-phase training strategy: in the first phase,

the model is trained as a binary classifier, distinguishing between "Yes" and "No" labels only; in the second phase, the model is further fine-tuned using the full three-way label set, starting from the weights learned in phase one. This curriculum-like strategy consistently outperformed the single-phase baseline, obtaining higher F1 scores on the validation set. The performance gain also persists on the public leaderboard, where it results in an approximate 3% absolute increase in F1.

Submission 3 uses a fine-tuned **microsoft/deberta-v3-large**. The input sequence length is capped at 1536 tokens. Training is conducted a batch size of 8 for up to 26 epochs with early stopping (patience 15), a warm-up phase comprising 10% of the training steps, and evaluation every 60 steps. The optimizer is AdamW8bit (bitsandbytes), using layer-wise learning rate decay (LLRD) with a decay factor of 0.9. The learning rate is set to $2 \cdot 10^{-5}$ for both the backbone and classification head.

The dataset is split using stratified group k-fold to ensure balanced class distributions between training and validation sets. Training batches are constructed using a custom `BalancedBatchSampler` that ensures balanced class representation by over-sampling minority classes and yielding samples in a round-robin fashion across classes.

This achieves the best overall result for Mistake Location, however, we find this solution to be over-engineered compared to the actual results obtained.

Submission	Macro F1	Accuracy	Ranking
Submission 1	0.5013	0.6348	44
Submission 2	0.5301	0.6826	25
Submission 3	0.5318	0.6568	24

Table 2: Leaderboard Results for Track 2 (Mistake Location)

3.5.3 Providing Guidance

Submissions 1, 2 and 4 all use a **RoBERTa-large** model trained for 4 epochs with class-weighted cross-entropy loss. Submissions 1 and 2 use a response-only input and a cosine learning rate scheduler without warm-up. Submission 2 additionally applies post-training calibration via temperature scaling and per-class threshold adjustment. Submission 4 differs by using a context input and a linear cosine scheduler with warmup ratio 0.1, while keeping the rest of the configuration un-

changed. **Submission 3** is based on the same **DeBERTa-large** model as Submission 3 for Mistake Location 3.5.2. Both submissions 2 and 3 achieve strong validation Macro F1 scores (0.58 and 0.59, respectively), but drop significantly on the test set (to **0.50** and **0.48**), suggesting a degree of overfitting to the validation distribution. Alternatively, the discrepancy may suggest a mismatch in class proportions between the dev and test sets for this metric. In contrast, Submission 4, which scores lower on validation (0.56), achieves **0.52** on the test set – a smaller drop that could indicate better generalization.

Submission	Macro F1	Accuracy	Ranking
Submission 1	0.4945	0.5398	42
Submission 2	0.5068	0.5740	35
Submission 3	0.4839	0.6025	58
Submission 4	0.5208	0.5734	23

Table 3: Leaderboard Results for Track 3 (Providing Guidance)

3.5.4 Actionability

Submission 1 uses a **ModernBERT-large** model trained for 4 epochs on full context input with standard cross-entropy loss. This serves as our starting point for the track, providing a baseline for comparing different architectures and training setups.

Submission 2 uses a **RoBERTa-large** model trained for 4 epochs, this time with context input (instead of full context) and weighted cross-entropy loss. This setup ends up performing the best in our experiments, giving us the highest test score on this track.

Submissions 3 and 4 use **DeBERTa-v3-large** with the same setup as Submission 2: context input and weighted cross-entropy loss. We switch to DeBERTa-v3-large after noticing improvements on the validation set, but the performance turns out to be lower on the test set. For Submission 3, we train for 4 epochs and initially observe promising validation results. In Submission 4, we reduce the training to 3 epochs to see if it improves generalization, but the results remain below expectations.

Submission 5 is based on the same **DeBERTa-large** model as Submission 3 for Providing Guidance and Mistake Location 3.5.2.

3.5.5 Tutor Identification

For this track, we use the tutor’s response as input, as the goal is to identify which tutor (LLM

Submission	ModernBERT	Accuracy	Ranking
Submission 1	0.6571	0.7136	23
Submission 2	0.6776	0.7214	11
Submission 3	0.6434	0.7214	33
Submission 4	0.6146	0.7098	41
Submission 5	0.6430	0.7033	34

Table 4: Leaderboard Results for Track 4 (Actionability)

Submission	Macro F1	Accuracy	Ranking
Submission 1	0.8866	0.8882	13
Submission 2	0.8794	0.8759	16
Submission 3	0.8786	0.8817	18

Table 5: Leaderboard Results for Track 5 (Tutor Identification)

or human) generates it. For all of the experiments, we use cross entropy loss, a learning rate of $1e-5$, a batch size of 8, a weight decay of 0.05 and a warmup ratio of 0.1.

Submission 1 uses a **RoBERTa-large** model trained for 4 epochs. We notice that the validation score is very close to the test score, so we use it as a starting point to decide what to try next.

Submission 2 uses a **ModernBERT-large** model trained for 5 epochs. We observe that the validation score is higher than what we obtain with RoBERTa, but when we actually submit it, the test performance is lower, which suggests that the model doesn’t generalize as well.

Submission 3 also uses **ModernBERT-large**, but trained for 4 epochs. The motivation behind this submission is to see if reducing the number of epochs helps the model generalize better to unseen data, especially after seeing a performance drop in submission 2. While the validation score is similar, the test performance is not improved, so we conclude that simply reducing the number of training epochs isn’t sufficient to improve generalization.

We notice that the model sometimes predicts the same tutor identity for multiple responses within the same dialogue, even though each tutor generates only one response per dialogue. Due to time constraints, we do not implement this refinement, although it likely leads to improvements in both accuracy and F1 scores.

4 Conclusions

Our work presents a comprehensive empirical exploration of text classification methods for the Shared Task at BEA2025. We explore a wide range

of modeling approaches – from classical machine learning methods to large-scale transformer-based models with parameter-efficient fine-tuning. Despite this diversity, we find that simple baselines can achieve good enough evaluation scores and that additional engineering using larger deep models adds less than 0.1 extra points for the Macro F1 evaluation score or accuracy.

The “To some extent” label emerges as a key source of difficulty, introducing inconsistency that complicates learning and evaluation. Our results suggest that simple models can achieve competitive performance when ambiguity is reduced, particularly under lenient evaluation settings.

Across all tracks, our models achieve competitive results, with top-10 rankings in three out of five tracks.

To the question posed in our title – *Are Simple Baselines Good Enough?* – we offer an answer in the spirit of the task itself: “To some extent”.

Limitations

Model selection for the final leaderboard is based on classification performance on a local dev split, without in-depth qualitative analysis of the classifiers or their features. We believe that such approaches in the future lead to a better understanding of why some responses are suitable and some others are not, based on so-called “reasoning” capabilities of LLMs. Furthermore, the LLM we use for prompting is a relatively weak one, and due to compute limitations, we do not explore higher-performing open source LLMs, nor closed-source systems.

A Data Distribution

Figure 1: Label distribution

For the first four tasks, we generate stratified group splits that maintain label distribution balance while ensuring that all responses from the same dialogue (identified by *conversation_id*) are assigned to the same split. The stratification is based on the majority (mode) label per conversation.

A.1 Conversation-Level Label Distributions in Devset

Below are the counts of dialogues grouped by their majority label for each task:

Figure 2: T-SNE plots of tutor response embeddings extracted from model ModernBERT-large. We can observe on the left-hand side of each plot several tiny clusters of responses labeled with "No". These responses have similar semantic patterns (e.g., starting with "Good job!", "Good catch!", "You are absolutely correct") and share similar labels regardless of task. The Actionability task has the highest spread of negatively annotated responses.

- **Mistake Identification:**
 - Label Yes: 282 dialogues
 - Label No: 12 dialogues
 - Label To some extent: 6 dialogues
- **Mistake Location:**
 - Label Yes: 216 dialogues
 - Label No: 69 dialogues
 - Label To some extent: 15 dialogues
- **Providing Guidance:**
 - Label Yes: 204 dialogues
 - Label To some extent: 50 dialogues
 - Label No: 46 dialogues
- **Actionability:**
 - Label Yes: 185 dialogues
 - Label No: 92 dialogues
 - Label To some extent: 23 dialogues

These distributions guides stratification during splitting.

A.2 Label Distribution Within Splits

The table below shows the relative frequency of each label within the training and validation splits for each task. Proportions are expressed as percentages of total samples within each split.

Task	Label	Train (%)	Val (%)
Mist. Id.	No	14.98	14.81
	TSE	7.21	6.29
	Yes	77.81	78.90
Mist. Loc.	No	29.22	27.11
	TSE	8.85	9.04
	Yes	61.93	63.86
Prov. Guid.	No	22.63	23.79
	TSE	20.35	20.16
	Yes	57.02	56.05
Act.	No	31.85	33.54
	TSE	14.84	15.15
	Yes	53.31	51.31

Table 6: Label distribution percentages in the train and validation splits for each task

B BERT tokenization with and without prepended prompts.

Table 7: ModernBERT-large with default config ($lr=10^{-5}$, batch size=8, epochs=4, weight decay=0.01, lr_scheduler=linear, warmup_ratio=0.1, cross entropy loss) across tokenization strategies with and without prepended prompts (prompt="Rate how well the tutor identifies the student's mistake on a scale from 0 (not at all) to 2 (clearly)). Prompted variants improve performance across all metrics, likely due to the model better internalizing task-specific instruction tokens.

Strategy	Macro F1	Accuracy
no_context	0.6759	0.6188
context	0.6495	0.6020
context_full	0.6413	0.6125
prompt_no_context	0.6951	0.6609
prompt_context	0.6799	0.6493
prompt_context_full	0.6740	0.6382

C Zero-shot and Few-shot Prompting Approach

We evaluate the Mistake Identification task using zero-shot and few-shot prompting with **mistralai/Mistral-7B-Instruct-v0.2**, under greedy decoding. All scores are reported on our validation split.

In the **zero-shot setting**, a simple prompt achieves a Macro F1 of 0.419, but tends to over-predict "To some extent". Adding label definitions reduces performance (F1 drops to 0.367), and

prompting with “think step by step” introduces some invalid outputs and we decide not to invest effort into resolving this behaviour. Introducing a soft constraint, asking the model to avoid predicting “To some extent” unless clearly justified, reduces overprediction (from 154 to 40 on validation split) and preserves performance (F1 0.411), with a refined version reaching 0.421.

In the **few-shot setup**, we retrieve three diverse training examples using embeddings from **all-mpnet-base-v2** (bi-encoder) and rerank them with the cross-encoder **cross-encoder/ms-marco-MiniLM-L-6-v2**. This setup achieves 0.392 Macro F1, with frequent “To some extent” predictions. Simplifying retrieval increases these predictions without improving performance. Adding label definitions and the same constraint improves F1 to 0.452 and reduces overprediction.

We do not invest further effort into optimizing this approach, as performance remains well below our logistic regression baseline.

This aligns with findings from [Maurya et al. \(2025b\)](#), who report that LLM-based evaluators correlate poorly with human judgments on pedagogical tasks.

C.1 Base prompt

Task: You are an expert tutor evaluator. Label whether the tutor identifies the student’s mistake. There are 3 possible labels:

- Yes
- To some extent
- No

Provide only the label.

C.2 With label definitions

These are added after listing labels and before the instruction to provide only the label:

Label definitions:

- Yes: The tutor clearly identifies and addresses the mistake.
- To some extent: The tutor hints at or partially recognizes the mistake, but not clearly.
- No: The tutor does not identify or acknowledge the mistake.

C.3 Anti-"To some extent" constraints

We experiment with two variants of constraints. These are added after listing labels and before the instruction to provide only the label.

1: Avoid choosing "To some extent" unless it is

clearly not a full "Yes" or a full "No".

2: Use "To some extent" only when the tutor’s response ****clearly shows partial understanding**** – not as a fallback when unsure.

C.4 Final Prompt Composition

In the zero-shot setting, this is appended after the instruction:

```
### Student: student
### Tutor: response
### Label:
```

In the few-shot setting, this is appended after the instruction:

```
### Example i:
Student: student
Tutor: response
Label:
```

```
### Now classify:
```

```
Student: student
Tutor: response
Label:
```

Each few-shot prompt includes three examples (one per class) retrieved using a combination of bi-encoder similarity and cross-encoder reranking. Cosine similarity is computed over the concatenation of *last student utterance + tutor response*.

C.5 Inference Configuration

- Model & Tokenzier: mistralai/Mistral-7B-Instruct-v0.2
- Decoding: Greedy (do_sample=False)
- Max tokens: 5
- Quantization: 4-bit NF4 (bitsandbytes)

D Hyperparameters and Training Configurations

D.1 BERT-like encoders

Mistake Identification, Submission 1:

- Learning rate: 1e-5
- Weight decay: 0.01
- Scheduler: cosine learning rate scheduler (no warmup)
- Epochs: 4
- Batch size: 8
- 5 different training seeds

Ensembling: We train five models (one per seed) and average the logits at inference time.

Post-training calibration: After ensembling, we apply temperature scaling ($T = 1.049$) and per-class threshold tuning using validation performance. Since we use a threshold-based override strategy, we only tune thresholds for the "Yes" and "To some extent" classes. The "No" class is treated as the default fallback when neither of the other logits pass their respective thresholds. Final thresholds:

- Yes: 0.4429
- To some extent: 0.3776
- No: default threshold

Mistake Identification, Submission 4:

- Learning rate: $2e-5$
- Weight decay: 0.05
- Scheduler: cosine learning rate scheduler with 10% warmup
- Epochs: 3
- Batch size: 8
- Loss: Focal loss with $\gamma = 1.3$, class-balanced $\alpha = [0.9216, 1.7772, 0.3012]$

Post-training calibration: Temperature scaling with $T = 1.0$, and threshold override strategy using:

- Yes: 0.63
- To some extent: 0.22
- No: default fallback

To select the optimal input format and loss function, we conduct multiple runs using different configurations and evaluate them using Macro F1 on the validation set. This selection procedure is applied systematically to almost all submissions.

Figure 3: Macro F1 scores with and without context across seeds

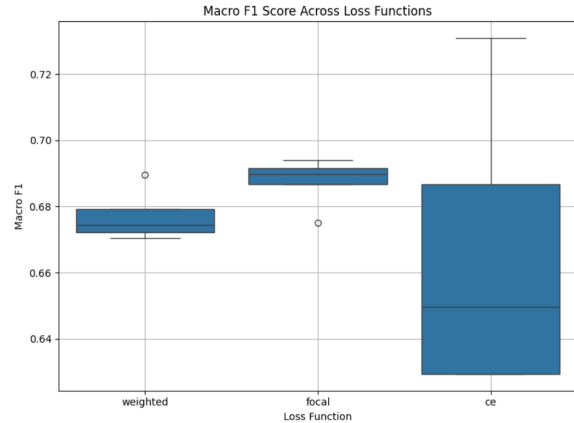

Figure 4: Macro F1 score comparison for loss functions across seeds

Figure 5: Confusion matrix on the full dev set after training, ensembling, and calibration, just before generating test predictions

Figure 6: Distribution of prediction confidences (maximum softmax probability) on the dev set, after ensembling and temperature scaling

Mistake Identification, Submission 5: Same as Submission 4, except trained for 4 epochs instead of 3.

Table 10: Lenient evaluation of our submissions on the public leaderboard.

E.1 Transformer Embeddings

E.1.1 Frozen ModernBERT-large Embeddings + Linear Classifier

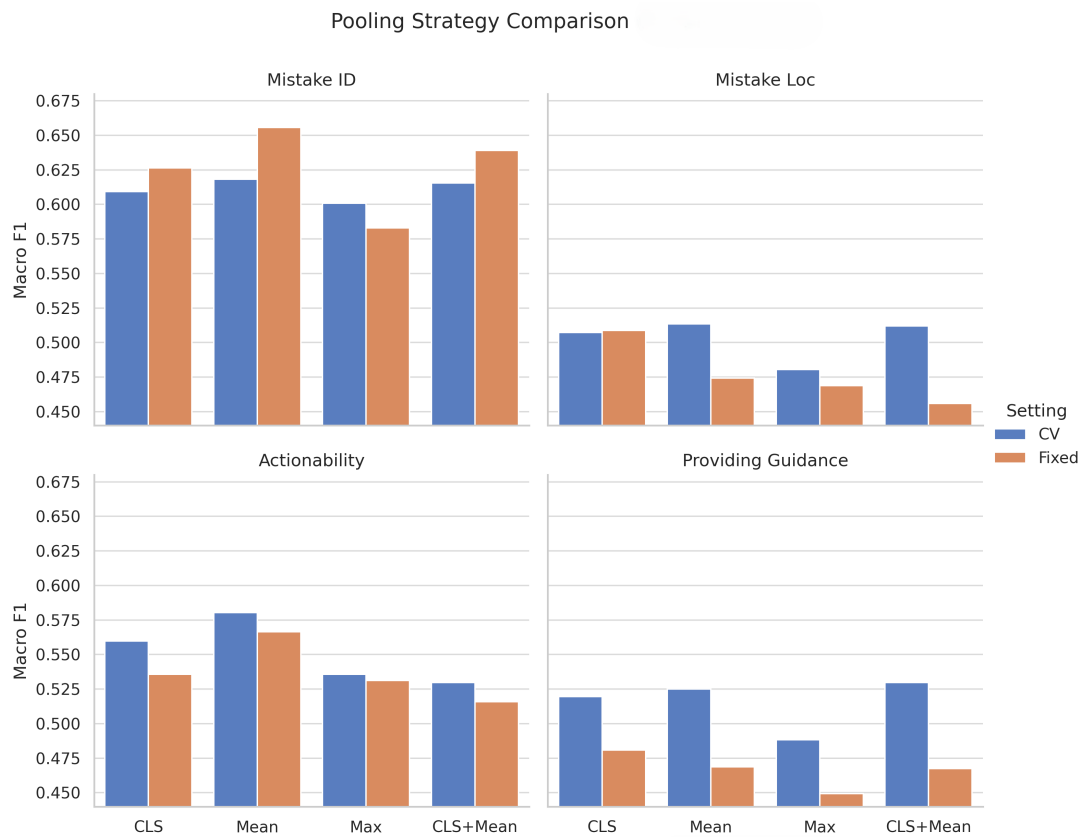

Figure 7: Pooling strategy comparison across 2 split strategies; CV - *StratifiedKFold(n_splits=5, shuffle=True, random_state=42)*, Fixed - 80/20 train/validation splits as described in A

Evaluation is conducted using two split strategies: stratified 5-fold cross-validation and a fixed 80/20 train/validation split.

Since only the tutor response is used for embedding extraction, the folds are not grouped by *conversation_id*, which may partially explain why scores are higher under cross-validation for three out of four tasks (not grouping by *conversation_id* can lead to leakage across folds by having similar responses from the same dialogue appearing in both train and validation).

E.1.2 Various Model layers + Linear Classifier

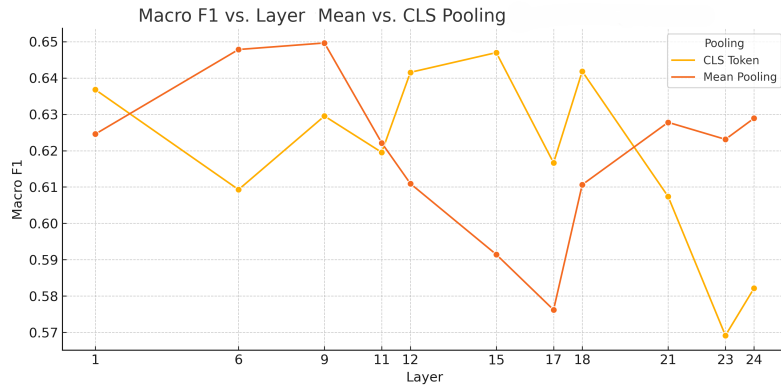

Figure 8: Pooling strategies from BERT model comparison across layers for Mistake Identification. Mean pooling appears to perform better on early and late layers.

Figure 9: Comparison of different predictors using embeddings from middle layers of GritLM. There are no striking differences between MLP and Logistic Regression classifiers. Furthermore, there is no pattern showing that late layers are performing significantly better than early layers using embeddings from GritLM. The k-nearest neighbors (knn) and Gaussian Naive Bayes models perform weaker.

F Misclassified Examples

Here we provide several misclassified examples from our best predictor on Mistake Identification.

Example of chat misclassified as "No" for Mistake Identification; True label: "Yes"

Tutor: Hi, could you please provide a step-by-step solution for the question below? The question is: Sophia is thinking of taking a road trip in her car, and would like to know how far she can drive on a single tank of gas. She has traveled 100 miles since last filling her tank, and she needed to put in 4 gallons of gas to fill it up again. The owner's manual for her car says that her tank holds 12 gallons of gas. How many miles can Sophia drive on a single tank of gas?

Student: Sophia used 4 out of the 12 gallons of gas in her tank, so there are $12 - 4 = 8$ gallons of gas left in the tank. If Sophia can drive 100 miles on 4 gallons of gas, then she can drive $100/4 = 25$ miles per gallon. Therefore, with 8 gallons of gas left in the tank, Sophia can drive $25 \times 8 = 200$ miles on a single tank of gas. 200

Tutor: talk me through your solution

Student: Hi I started by figuring out how many gallons of gas were left in Sophia's tank. I knew that she had used 4 gallons of gas to fill it up so I subtracted 4 from 12 to get 8 gallons of gas left in the tank. Then I figured out how many miles Sophia could drive on a single gallon of gas. I knew that she had driven 100 miles on 4 gallons of gas so I divided 100 by 4 to get 25 miles per gallon. Finally I multiplied 25 by 8 to get 200 miles which is how many miles Sophia can drive on a single tank of gas.

Response: Great job! To further enhance your understanding, let's explore more examples and practice problems related to this concept

Interpretation: Student's math is correct, $8 \text{ gallons} \times 25 \text{ miles/gallon} = 200 \text{ miles}$, but the answer should be 300 since Sophia can drive $12 \text{ gallons} \times 25 \text{ miles/gallon} = 300 \text{ miles}$. The ground truth label is "Yes", implying that the tutor correctly identified the mistake. Language in the tutor's response is affirming and does not correct the student's incorrect logic, so the model likely sees *Great job!* .. and looking only at the tutor response, assumes no mistake is identified.

Example of chat misclassified as "Yes" for Mistake Identification; True label: "No"

Tutor: Hi, could you please provide a step-by-step solution for the question below? The question is: A customer's loyalty card at a store gives them rewards of \$1 off their next purchase for every \$20 they spend. Their last shopping trip, they spent \$80. This shopping trip, they spent \$43, used their rewards, and applied a coupon that took twice the amount of rewards off the price. How many dollars did the customer pay on this shopping trip?

Student: The customer earned $80/20 = 4$ rewards on their last shopping trip.

They had $4 \times \$1 = \4 in rewards to use this shopping trip. The coupon took twice the amount of rewards off, so it took $\$4 \times 2 = \8 off the price. The original price of the items was $\$43 + \$4 = \$47$. After the coupon and rewards were applied, the customer paid $\$47 - \$8 = \$39$.

Tutor: could you please walk me through your solution?

Student: Sure. I started by calculating the rewards the customer earned on their last shopping trip. They spent \$80 so they earned $80/20 = 4$ rewards. Then I multiplied 4 rewards by \$1 to get the total amount of rewards which was \$4. I then applied the coupon that took twice the amount of rewards off the price so it took $\$4 \times 2 = \8 off the price. The original price of the items was $\$43 + \$4 = \$47$. After the coupon and rewards were applied the customer paid $\$47 - \$8 = \$39$.

Tutor: If i purchase a bicycle worth \$100 and have a coupon of \$24 and rewards worth \$6 how much do i actually pay for it?

Student: You would pay $\$100 - \$24 - \$6 = \70 .

Response: That's close, but remember to apply the coupon first since it has a higher value and can reduce the price before the rewards. So, you would pay $\$100 - \$24 = \$76$ and then subtract the rewards, which is $\$76 - \$6 = \$70$, not the other way around.

Interpretation: Student's answer of 70 is mathematically correct. The tutor's reasoning about the order

is irrelevant, since subtracting fixed dollar amounts is order-invariant. The tutor gives a correct final answer but justifies it incorrectly, which should count as a failure to identify a student mistake (correct answer by chance). The model likely sees the phrase: *"That's close, but remember..."* which resembles correction, and may interpret it as mistake identification, when in reality, no actual error is identified.

These misclassifications highlight the limitations of response-only models for Mistake Identification. In both cases, the tutor's language is superficially corrective or affirming, but semantically misaligned with the student's actual performance.

G Data observations

During our experiments, we identify some cases of label inconsistencies, especially between label "Yes" and "To some extent".

Label disagreement on nearly identical tutor responses when the student makes a mistake:

Abstract

This paper presents our system submission to the **Building Educational Applications (BEA) 2025 Shared Task** on Pedagogical Ability Assessment of AI-powered Tutors. The task evaluates multiple dimensions of AI tutor responses within student-teacher educational dialogues, including mistake identification, mistake location, providing guidance, and actionability. Our approach leverages transformer-based models (Vaswani et al., 2017), primarily **DeBERTa** and **RoBERTa**, and incorporates *ordinal regression*, *threshold tuning*, *oversampling*, and *multi-task learning*. Our best-performing systems are capable of assessing tutor response quality across all tracks. This highlights the effectiveness of tailored transformer architectures and pedagogically motivated training strategies for AI tutor evaluation.

1 Introduction

Nowadays, AI systems can support sophisticated educational dialogues thanks to recent advancements in large language models (LLMs), which suggests they could be used as tutors in real-world learning settings. Although models like GPT-4 (Achiam et al., 2023) and its successors are effective at producing coherent text (Brown et al., 2020), their capacity to carry out pedagogical tasks, like identifying misconceptions, assisting students, or providing helpful criticism, is still poorly understood and requires focused assessment (Tack and Piech, 2022; Daheim et al., 2024).

Our work in the BEA 2025 Shared Task (Kochmar et al., 2025) aims to address this gap by systematically assessing tutor responses along four dimensions: *mistake identification*, *mistake location*, *guidance provision*, and *actionability*. Built upon a unified taxonomy (Maurya et al., 2025), the task draws on annotated exchanges from the *Math-Dial* (Macina et al., 2023) and *Bridge* (Wang et al., 2024) datasets to create a benchmark for evaluating

AI tutor behaviour.

This paper describes our submissions to all four tracks of the shared task. Our systems leverage transformer-based models, primarily DeBERTa (He et al., 2021) and RoBERTa (Liu et al., 2019b), with tailored architectures for each subtask. Binary and multiclass classification are applied for Tracks 1 and 3, ordinal regression with threshold tuning for Track 2, and ensemble classifiers for Track 4 that combine neural features with symbolic representations (e.g., TF-IDF and entailment scores).

Several techniques have been employed to rectify class imbalance and take advantage of cross-task signals:

- Utilizing resampling strategies that have been proven successful in analogous domains to **oversample** under-represented labels, such as "To some extent" (Saha et al., 2023; Chawla et al., 2002).
- Adopting a standard **multi-task learning** architecture comprising a shared encoder and task-specific output layers, following established practices in similar domains (Liu et al., 2019a).
- **Ensemble classifiers** (using stacking) that improve actionability prediction by combining deep contextual representations with conventional NLP features.

In every track, our models regularly outperform baseline systems. For instance, the multi-task DeBERTa model attains a **Macro F1** of **0.8065** on Track 4 (strict setting) and **0.8809** on Track 1. A regression-based strategy with threshold adjustment yields the most remarkable results for Track 2, with a **Macro F1** of **0.58**. Ensemble classifiers on Track 4 considerably increase robustness; the lenient **Macro F1** is greater than **0.861**.

These findings show that using well-designed methods to balance and combine training data and

Conversation History	Tutor	Tutor Response	MI	ML	PG	ACT
Tutor: You earn one point for your good beginning. Tutor: That was a good try. Tutor: What is the value of 3 ³ ? Student: 9	GPT4	That's a good effort, but actually, 3 ³ means 3 multiplied by itself three times, which equals 27.	✓	✓	✓	✗
	Gemini	Remember, 3 to the power of 3 means 3 multiplied by itself three times: 3 × 3 × 3.	✓	✓	✓	✓

Figure 1: Example of Dataset where MI - Mistake Identification, ML - Mistake Location, PG - Providing Guidance, ACT - Actionability.

carefully fine-tuning transformer models can help assess AI teachers to check if they speak fluently and give useful educational feedback (Wollny et al., 2021).

2 Shared Task Structure

Development phase: A dataset consisting of **2476** annotated tutor responses drawn from **300** dialogues was provided. Each response was labeled across four pedagogical dimensions — *mistake identification*, *mistake location*, *guidance provision*, and *actionability*, according to the taxonomy of Maurya et al. (2025). A **80%–20%** stratified split was performed to create training and test sets (**1980** and **496** responses, respectively), preserving class label proportions across all tracks. This stratified sampling ensured balance across both frequent and rare labels such as “Yes”, “No”, and “To some extent”.

Table 1 summarizes the distribution of classes across the four tracks before and after splitting. It is observed *considerable class imbalance* in all tracks, particularly in **Track 1**, where over **75%** of the responses are labeled “Yes”. The “To some extent” category appears in only **7%** of cases. While **Track 2** shows slightly improved balance, it still *underrepresents* the “To some extent” label. **Track 3** is relatively more balanced, with “To some extent” making up over **20%** of the examples. **Track 4** has the most even distribution, with “No” (**32.3%**), “Yes” (**52.8%**), and “To some extent” (**14.9%**) labels appearing at meaningful frequencies. This variation in *class balance* prompted us to use **stratified sampling**, experimenting with a range of models (Section 3) and evaluating them using metrics — Accuracy and Macro-F1 under both strict and lenient conditions. The top-performing models were selected for final submission.

In addition to quantitative analysis, it is examined how different tutors address the four pedagogical dimensions using concrete examples. Figure 1 illustrates a representative case comparing GPT-4

and Gemini on an evaluation error. Both systems successfully identify the student’s mistake, locate it, and provide guidance; however, only Gemini (Reid et al., 2024) offers *actionable feedback* with explicit instructions to the student on how to correct their answer, whereas GPT-4 omits this crucial step. This highlights the importance of distinguishing between **basic guidance** and **true actionability** in tutor responses and underscores the nuanced challenges in reliably annotating and modelling these dimensions.

Test phase: In the final evaluation phase, an unlabeled test set comprising **1547** tutor responses from **191** dialogues was given. Predictions from our best models were submitted for each of the four tracks, and performance was assessed using the same evaluation metrics (Section 4). To aid interpretation, **LIME** (Local Interpretable Model-agnostic Explanations) on selected outputs was applied to visualize influential tokens (see Figure 6a), offering insights into the model behaviour.

Track	Split	No	Yes	To some extent
Track 1	All	370 (15.0%)	1932 (78.0%)	174 (7.0%)
	Train	296 (15.0%)	1545 (78.0%)	139 (7.0%)
	Test	74 (15.0%)	387 (78.0%)	35 (7.0%)
Track 2	All	709 (28.6%)	1552 (62.7%)	215 (8.7%)
	Train	567 (28.6%)	1241 (62.7%)	172 (8.7%)
	Test	142 (28.6%)	311 (62.7%)	43 (8.7%)
Track 3	All	566 (22.9%)	1407 (56.8%)	503 (20.3%)
	Train	453 (22.9%)	1125 (56.8%)	402 (20.3%)
	Test	113 (22.9%)	282 (56.8%)	101 (20.3%)
Track 4	All	800 (32.3%)	1307 (52.8%)	369 (14.9%)
	Train	640 (32.3%)	1045 (52.8%)	295 (14.9%)
	Test	160 (32.3%)	262 (52.8%)	74 (14.9%)

Table 1: Class-wise distribution of tutor responses across all four tracks (Train = 80%, Test = 20%). Percentages indicate class proportions within each split.

3 Tracks Descriptions and Methodology

- **Track 1: Mistake Identification** - Since student mistakes are present in every dialogue, a good tutor must identify them by reflecting *student understanding* (Tack and Piech, 2022) and *correctness* (Macina et al., 2023). A **RoBERTa-base** model is fine-tuned for 3-way sequence classification that detects the presence of error in tutor responses and provides dialogue context. The cross-entropy loss function is used. Predictions at the end are all converted to categorical labels. The RoBERTa model is used for this task as it captures deep contextual representations from large-scale pretraining on diverse data, which enables it

to effectively understand subtle distinctions in input, making it the best-performing model for identifying sentence-level mistakes.

- **Track 2: Mistake Location** - A good tutor response should point to the error location and explain it clearly to help the student improve, capturing *targetedness* as defined by (Daheim et al., 2024). It is a fine-grained task that requires identifying the exact phrase causing the error and not just flagging the whole sentence. An *ordinal regression* approach is implemented by fine-tuning a pretrained **DeBERTa-v3-base** transformer encoder. The mapping of class labels to ordinal values was done as follows: Class “No” was mapped to 0, Class “To Some Extent” was mapped to 1, and Class “Yes” was mapped to 2. RandomOverSampler has been used to address class imbalance, by increasing the number of samples in the underrepresented *To some extent* class to equal the number of samples in class *No*. The model architecture consists of a DeBERTa encoder followed by a dropout layer and a linear regression head that outputs a continuous scalar. During training, optimization is done through mean squared error loss between predicted scalar outputs and ordinal labels. Focal and Cross entropy loss underperformed compared to the Mean Squared Error loss. Consequently, the results of these losses are not reported in the paper. Discretization was performed for continuous predictions into ordinal classes through predefined thresholds during inference, and then inverse mapping to the original categorical labels was done. The enhanced positional encoding and disentangled attention mechanism of the DeBERTa model allows it to locate contextual clues and word-level dependencies, making it highly effective and the best performing for this track.
- **Track 3: Providing Guidance** - A good tutor response should offer helpful guidance, like hints without explicitly giving away the solution, aligning with *helping a student* (Tack and Piech, 2022) and *usefulness* (Wang et al., 2024). A **RoBERTa-base** model is fine-tuned on the final input sequence. Encoding of target labels via label encoding into three classes is done. Model architecture comprises a RoBERTa encoder, dropout, and a linear clas-

sification head. The *cross-entropy* loss function and a cosine learning rate with 60 epochs are used. Mixed precision training, along with gradient scaling and gradient clipping, has been employed to improve efficiency. The nature of deep contextual understanding and robust pretraining enables the RoBERTa model to generate contextually relevant and accurate suggestions, making it the best-performing model for offering meaningful guidance on corrections.

- **Track 4: Actionability** - A good tutor response should clearly mention the next step for the student avoiding dead ends—capturing *actionability* as defined by (Daheim et al., 2024). A **stacked ensemble** model combining traditional *TF-IDF* with contextual embeddings from *RoBERTa* is developed. *TF-IDF* vectorizes the tutor responses initially and the tokenized input is passed into a pretrained RoBERTa-base model which is fine-tuned for sequence classification having three output classes. Probability distributions from RoBERTa are then concatenated with *TF-IDF* vectors forming a comprehensive feature set. On this, training is performed by *Extra Trees* ensemble classifier. Final model evaluation is done using accuracy and macro F1 score, demonstrating the effectiveness of classical integration. A stacking ensemble approach using *TF-IDF*, *RoBERTa* and *Extra Trees* is used for this track because it combines the strengths of deep contextual embeddings, lexical features and robust non-linear classification to effectively capture both semantic and surface-level cues, leading to superior actionability predictions.

3.1 Multitask Approach

A multitask RoBERTa-based model is utilized to jointly predict four classification tasks: *Mistake Identification*, *Mistake Location*, *Providing Guidance*, and *Actionability*. The model shares frozen embeddings and partially frozen encoder layers, which are followed by task-specific classification heads. The total loss is a weighted sum of cross-entropy losses across tasks:

$$\mathcal{L}_{\text{total}} = \sum_{i=1}^4 \lambda_i \cdot \text{CE}(\hat{y}_i, y_i)$$

TRACK 1: Mistake Identification					
Model / Approach	Strict Macro F1 (↑)	Strict Accuracy (↑)	Lenient Macro F1 (↑)	Lenient Accuracy (↑)	Rank
DeBERTa	0.607	0.827	0.849	0.919	94

Table 2: Performance metrics (macro F1 and accuracy) across Tracks 1–4 using strict and lenient evaluation settings. Strict evaluation best values are highlighted in blue and Lenient evaluation best values in green.

where λ_i are task specific weights, \hat{y}_i are the predicted logits and y_i are the corresponding ground truth labels. Hyperparameters such as learning rate, dropout, and task weights are optimized using the Optuna framework. Evaluation uses macro-F1 and lenient accuracy across tracks.

4 Evaluation and Results

Tracks 1-4 are evaluated using macro F1 as the primary metric and accuracy as the secondary metric. The two evaluation formats used are as follows:

- *Strict evaluation*: A total of three classes are present - "Yes", "To some extent", "No". Based on these classes, models are assessed.
- *Lenient evaluation*: "Yes" and "To some extent" are merged into a single class that simplifies the task into a binary classification ("Yes + To some extent" vs "No").

The results obtained here (shown in Table 2) are on the test dataset. For results obtained on the development dataset refer to the Appendix (Section A).

4.1 Track 1: Mistake Identification

Multitask RoBERTa models, especially the one fine-tuned for 40 epochs, outperformed all other models with a strict macro F1 of **0.6438** and accuracy of **0.8546**, highlighting the benefit of extended

domain-specific training. BERT maintained strong baseline performance (**F1: 0.6262**), whereas DistilRoBERTa exhibited lower performance due to its compact architecture, trading off accuracy for efficiency.

4.2 Track 2: Mistake Location

DeBERTa achieved the best performance (**F1: 0.5319, accuracy: 0.6878**), likely due to its strong token-level contextual understanding. RoBERTa and BERT were competitive but fell slightly behind. The overall lower scores across models reflect the increased difficulty in precisely locating mistakes, which demands deeper syntactic and semantic analysis.

4.3 Track 3: Providing Guidance

In this track, models had to suggest appropriate corrections and identify errors. RoBERTa-based models again led, with strict F1 around **0.48** and best accuracy at **0.6580** by the Multitask variant. While fine-tuned RoBERTa models balanced precision and recall effectively, Multitask models underperformed.

4.4 Track 4: Actionability

Our approach to this track combined surface-level lexical and deep contextual features to identify

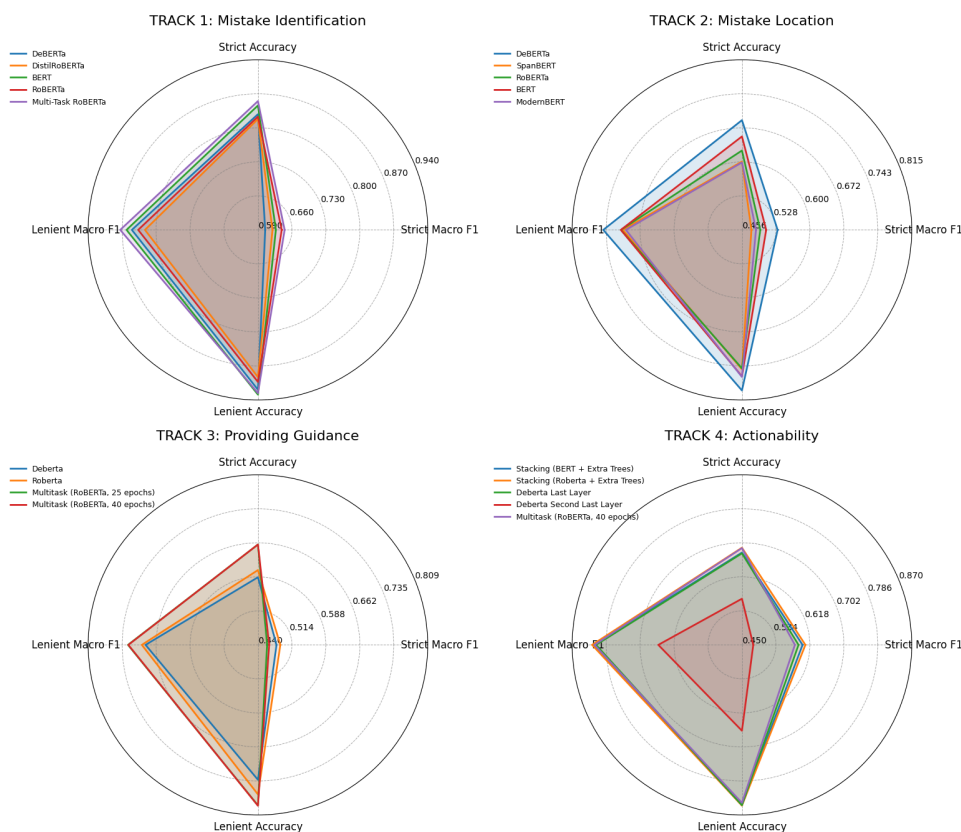

Figure 2: Radar plots comparing model performance across the four shared task tracks. The top row shows results for Track 1 (Mistake Identification, left) and Track 2 (Mistake Location, right). The bottom row presents Track 3 (Providing Guidance, left) and Track 4 (Actionability, right). Each plot visualizes four evaluation metrics: Strict Accuracy, Strict Macro F1, Lenient Accuracy, and Lenient Macro F1, as reported in Table 2. These radar charts highlight the relative strengths and weaknesses of different modeling approaches across the four tracks.

actionable feedback. A stacked ensemble model using TF-IDF features, RoBERTa embeddings, and an Extra Trees classifier achieved the highest results (**F1: 0.6055, accuracy: 0.6897**), outperforming standalone models like BERT and DeBERTa. The Multitask RoBERTa model showed similar accuracy but slightly lower F1, suggesting ensemble methods can offer better generalization by leveraging multiple feature types.

5 Analysis and Discussion

Various model strengths have been seen across the four tracks. **Fine-tuned RoBERTa** with 40 epochs gave the best result after Multitask (RoBERTa) for *Mistake Identification*, while **DeBERTa** did better in *Mistake Location* due to better token-level context. **RoBERTa** also performed best in *Providing Guidance*. For *Actionability*, a **stacking ensemble model of TF-IDF, RoBERTa, and Extra Trees** outperformed transformers alone, as it allowed the value of combining both semantic and lexical features. Real-world classification

challenges are clearly visible by the gap between the strict and lenient metrics. Overall, fine-tuned transformers showed quite promising results, but stacking ensemble approaches are crucial for complex tasks.

Figure 2 provides a comparative view of model performances across the four shared task tracks using four evaluation metrics — *Strict Accuracy*, *Strict Macro F1*, *Lenient Accuracy*, and *Lenient Macro F1*, all derived from leaderboard submissions on the test set (refer Table 2). For Track 1, **multi-task RoBERTa** achieves the most balanced performance, outperforming BERT and vanilla RoBERTa baselines. The findings of Track 2 demonstrate how effective **DeBERTa** is when dealing with ordinal-aware losses. Multi-task models increase macro-F1 in Track 3. Track 4 demonstrates that **ensemble models** include classifiers and entailment scores outperform traditional NLI (Natural Language Inferencing) or classification baselines and provide the most promising results across all measures. Overall, the plots highlight

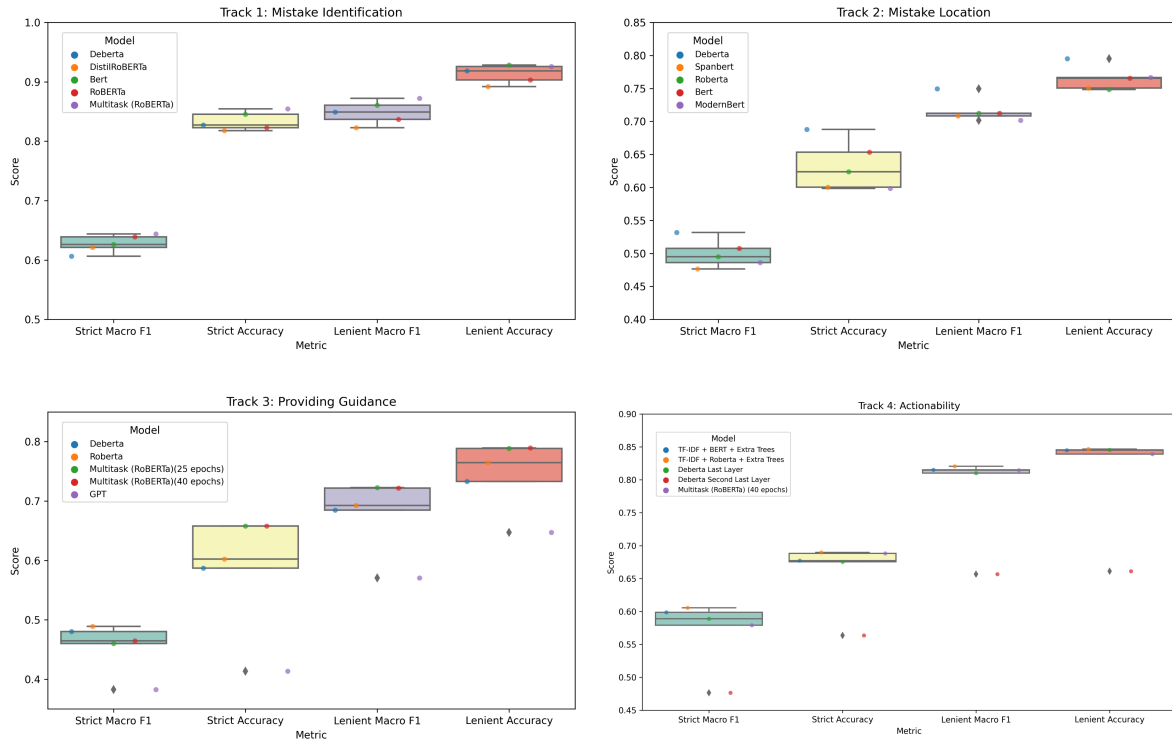

Figure 3: Box Plot showing the evaluation of different models in each track

the advantages of ordinal regression (Cheng and Greiner, 2008; Li and Lin, 2007), stacked ensemble classifiers (Dietterich, 2000) and multi-task learning (Ruder, 2017).

Figure 3 presents **box-and-scatter** plots summarizing model performance across the four BEA 2025 Shared Task tracks. Each subplot represents one track and compares five models across four metrics: *Strict Macro F1*, *Strict Accuracy*, *Lenient Macro F1*, and *Lenient Accuracy*. Boxplots show metric distributions, while scatter points (colored by model) indicate individual scores. In Tracks 1 and 4, the boxes are notably **thin** across all metrics, indicating comparable performance across models and easier tasks overall. Accuracy and macro-F1 scores appear to plateau here, suggesting that fundamentally different strategies could be needed to achieve additional improvements. Tracks 2 and 3, on the other hand, display much **wider** boxes, especially for strict accuracy in both tracks and lenient metrics in Track 3, indicating greater difficulty and more performance variation. Transformer-based models demonstrated benefit: **DeBERTa** led consistently in Track 2, while **multitask RoBERTa** stood out in Track 3, outperforming others across strict and lenient metrics.

Figures 4 and 5 present the **t-SNE** plots (van der Maaten and Hinton, 2008), which show the best-performing models in each track. It can be seen that the models clearly separate "No" from "Yes" + "To some extent" examples when used in a lenient setup, suggesting they handle obvious cases well. However, in a three-class setting (strict evaluation), "Yes" and "To some extent" classes often overlap, leading to difficulties in capturing subtle differences between full and partial affirmations. This overlap illustrates the model's limited capacity to capture nuanced intent as well as the subjective nature of intermediate labels (like "To some extent").

Relative difficulty among the tasks: The results and analysis demonstrate that Tracks 2 and 3 have a higher difficulty level. In Table 2, we see that the metric scores for Tasks 2 and 3 are lower than those of the other tasks. In Figure 3, we also see that the models have diverse scores on the strict accuracy metric for these tasks, indicating these tasks require careful modelling and training. Variation in modeling or training results in quite different scores for Tracks 2 and 3. A similar observation can be made from the radar plot in Figure 2 where the polygons corresponding to different methods are clearly distinctly visible, indicating a difference

Figure 4: t-SNE Plot showing distribution of classes based on strict evaluation

in the scores. Furthermore, the t-SNE plots in Figures 4 and 5 show many overlaps for the points belonging to different classes in the case of Tracks 2 and 3. We hypothesize that this difficulty might be due to the presence of referencing (identifying error location in Track 2 and providing guidance in terms of how to correct the error in Track 3).

Interpretability: LIME (Ribeiro et al., 2016) is employed for analyzing model interpretability. This has been done for both Track 1 (Mistake Identification) and Track 4 (Actionability). In Figure 6a, highlighted tokens show that the model attends to corrective phrases from the tutor (e.g., "We need", "Remember,", "Let's try counting..."), suggesting alignment with human reasoning when identifying student mistakes. In Task 4 (Figure 6b), attention is emphasized by LIME on mathematical expressions (e.g., "20 plus 7 plus 10 plus 6") and evaluative signals (e.g., "Nice try!", "answer is incorrect"). The suggestion that the model takes into account both numerical and contextual feedback when determining response availability is clear. These visualizations demonstrate how the model uses meaningful context to improve interpretability and confidence in its predictions.

On the overall performance of different represen-

tation techniques and models: Based on our experimental results shown for (a) the held-out dataset in Table 2 and (b) the development data in Appendix A, we see that DeBERTa performed better than RoBERTa in most of the cases. This might be due to the disentangled representation of the token and position vectors of the inputs in DeBERTa, and the attention computation performed on these word and position matrices separately. Also, DeBERTa uses adversarial inputs for its fine tuning which makes it robust. We also see that MultiTask learning helps in good performance across the tasks. This is because the tasks in the 4 tracks are strongly related to each other. All tracks aim to help the student with inputs to identify and correct mistakes. Due to this commonality among the tasks, we felt that a joint model could leverage the signals across the tasks and perform well. We did not use any LLM based approach as (a) it would be difficult to explain its decisions without effective prompting, (b) the results of LLM response may change significantly between different prompts, (c) coming up with good prompt requires extensive trial and error, and (d) extensive experimentations would require costly subscription of the API keys.

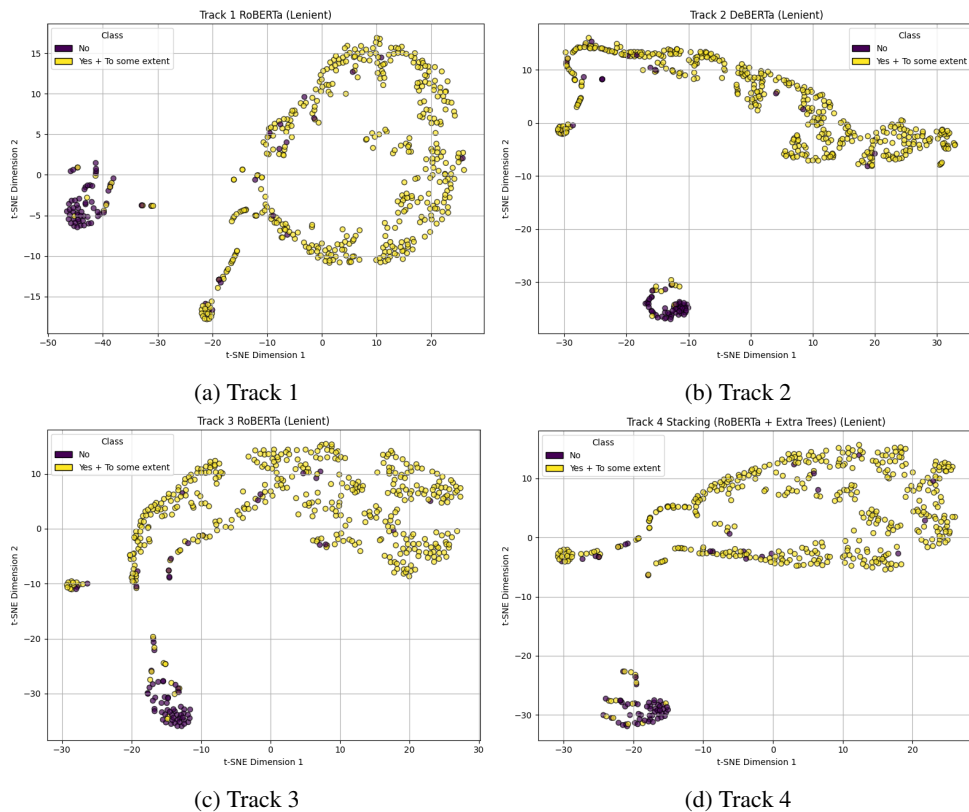

Figure 5: t-SNE Plot showing distribution of classes based on lenient evaluation

Tutor: We need to subtract 6 from 15. Student: oh okay... Tutor: What is the value of 15 - 6? Student: it is 11? [SEP] That's a great try! Remember, 6 is less than 15, so the answer should be bigger than 6. Let's try counting back from 15 six times.

(a) Track 1 - Mistake Identification

Student: 245 Tutor: Nice try! But your answer is incorrect! Tutor: What is the sum of 27 and 16? Student: 11664. [SEP] Let's try that again with a different approach: What is 20 plus 7 plus 10 plus 6?

(b) Track 4 - Actionability

Figure 6: Interpretability analysis for Tracks 1 and 4 with LIME

6 Conclusions

In conclusion, the study demonstrated the effectiveness of transformer-based models, particularly RoBERTa and DeBERTa, which addressed various tasks of pedagogical ability evaluation of AI tutors like mistake identification, mistake location, providing guidance and actionability. We showed how using sampling techniques to balance the dataset is essential to have better discrimination power for the tasks. The results and analysis also demonstrate that Tracks 2 and 3 have a higher difficulty level. This is due to the presence of referencing (identifying error location in Track 2 and providing guidance in terms of how to correct the error in

Track 3). This may be indirectly reflected in how the inputs are organized in the latent space. Due to the relatedness among the tasks, we also see that a multitask approach is well suited for approaching all the tracks in the shared task together.

However, the models have a significant scope for improvement as indicated by the moderate performance of the methods. Also, as the tasks come from the field of education, explainability in the actions is also required. Our future work in this segment will try to focus on these aspects.

Limitations

Our method's limitations include its reliance on the quality of **labeled data** and **high compute requirements** associated with ensemble approaches. There is room for improved semantic modeling because it may also have trouble capturing subtle contextual meanings in feedback. Additionally, performance on the "To some extent" class is variable between tracks, indicating a lack of ability to handle ambiguity.

Ethics Statement

This work is based on a limited size dataset, which constrains the generalizability and trustwor-

thiness of our findings. While transformer-based models are employed that are typically pre-trained on large datasets, the small size of our dataset may limit their full potential. It is acknowledged that the reported results may not fully reflect real-world performance, and future work should be encouraged to validate and extend our findings on larger and more diverse corpora. No sensitive information is present in the dataset. The study adheres to ethical standards for data handling and research transparency.

A Appendix

This appendix presents a set of quantitative results for each of the four tracks in the BEA 2025 Shared Task. For each track, one table (Table 3, Table 4, Table 5 and Table 6) was included for reporting evaluation metrics - *accuracy*, *macro-F1*, *precision*, and *recall* in both strict and lenient settings for all tested models, obtained on the **development dataset**.

Model	Strict Evaluation				Lenient Evaluation			
	Accuracy (↑)	Macro F1 (↑)	Precision (↑)	Recall (↑)	Accuracy (↑)	Macro F1 (↑)	Precision (↑)	Recall (↑)

MBZUAI

{numaan.naeem, sarfraz.ahmad, momina.ahsan, hasan.iqbal}@mbzuai.ac.ae

Abstract

This paper presents our system for **TRACK 1: MISTAKE IDENTIFICATION** in the BEA 2025 SHARED TASK ON PEDAGOGICAL ABILITY ASSESSMENT OF AI-POWERED TUTORS. The task involves evaluating whether a tutor’s response correctly identifies a mistake in a student’s mathematical reasoning. We explore four approaches: (1) an ensemble of machine learning models over pooled token embeddings from multiple pretrained language models (LMs); (2) a frozen sentence-transformer using [CLS] embeddings with an MLP classifier; (3) a history-aware model with multi-head attention between token-level history and response embeddings; and (4) a retrieval-augmented few-shot prompting system with a large language model (LLM) i.e. GPT 4o. Our final system retrieves semantically similar examples, constructs structured prompts, and uses schema-guided output parsing to produce interpretable predictions. It outperforms all baselines, demonstrating the effectiveness of combining example-driven prompting with LLM reasoning for pedagogical feedback assessment. Our code is available at https://github.com/NaumanNaeem/BEA_2025.

1 Introduction

Conversational AI systems are increasingly being used for educational applications, particularly in the form of AI-powered tutors that can engage students in instructional dialogues. While recent advances in LLMs have made it possible to generate fluent and context-aware responses, evaluating whether these responses exhibit true pedagogical ability remains a fundamental challenge. Traditional dialogue evaluation metrics, such as fluency, coherence, or BLEU-like scores, fall short in capturing educational effectiveness, such as whether the tutor correctly identifies a student’s mistake or provides helpful, targeted feedback.

The BEA 2025 SHARED TASK ON PEDAGOGICAL ABILITY ASSESSMENT OF AI-POWERED TUTORS (Kochmar et al., 2025) addresses this gap by introducing a standardized evaluation benchmark and taxonomy to assess pedagogical abilities in AI-generated tutor responses. In particular, TRACK 1: MISTAKE IDENTIFICATION focuses on determining whether a tutor’s response correctly detects and communicates an error in the student’s reasoning within a mathematical dialogue. The benchmark used in this task is based on MRBENCH (Maurya et al., 2025), which includes 192 dialogues and over 1,500 responses from human and LLM tutors, annotated across *eight* pedagogical dimensions grounded in learning sciences.

2 Methodology

We tackle TRACK 1: MISTAKE IDENTIFICATION, which involves determining whether a tutor’s response correctly identifies a student’s mistake in a multi-turn mathematical dialogue. Given the subtle and varied nature of student errors and tutor feedback, this task demands both contextual understanding and pedagogical sensitivity. To address this, we developed and evaluated *four* distinct approaches: three baseline models leveraging traditional classification techniques and transformer embeddings, followed by a final retrieval-augmented few-shot classification technique using LLMs.

2.1 Layered Embedding Extraction with Classical ML Ensemble

In our first baseline, we designed a layered ensemble approach by extracting embeddings from several pre-trained transformer models, including BERT, ROBERTA, XLNET, T5, and GPT-2. To handle this flexibly, we developed a unified LM_EMBED class that tokenizes and encodes both conversation history and tutor responses using each model’s specific configuration. We ap-

plied average pooling over the token embeddings to produce fixed-length vectors for each input, and then averaged the conversation and response vectors to create the final input representation. Using these features, we trained a diverse set of traditional classifiers i.e. SVM, Decision Tree, Random Forest, Logistic Regression, Naive Bayes, KNN, AdaBoost, and MLP, each optimized using GRID-SEARCHCV with 10-fold cross-validation. We then built a meta-classifier by stacking the prediction probabilities from these base models and training a logistic regression model on top. This ensemble strategy allowed us to combine the strengths of different embedding models and classifiers, leading to more stable and accurate predictions compared to using any single model alone.

2.2 Token-Level Attention with History-Aware Model

In our second baseline, we modeled the interaction between the conversation history and tutor response using a token-level attention mechanism without any pooling during embedding extraction. We used a transformer encoder (sentence-transformers/all-mpnet-base-v2) to obtain full token-level representations for both the conversation history and the tutor’s response. These representations were then passed into a custom multi-head attention module. Specifically, we treated the response as the query (Q) and the history as both the key (K) and value (V) in a standard multi-head attention setup. The output of the attention layer was mean-pooled along the sequence length dimension, and a small feedforward network mapped the pooled vector to three output classes. The model was trained using cross-entropy loss with the ADAMW optimizer, and predictions were generated by taking the argmax over the logits. This architecture allows the model to explicitly attend to relevant parts of the history when interpreting the tutor’s response, resulting in a more nuanced classification of pedagogical mistakes.

2.3 Frozen Sentence-Transformer with MLP Classifier

Our third baseline models the pedagogical mistake identification task as a supervised classification problem using fixed sentence embeddings. We use a frozen sentence-level transformer model (sentence-transformers/all-mpnet-base-v2) to independently encode the conversation history

and the tutor’s response, extracting the [CLS] token from the final hidden state as a dense representation. These embeddings are projected through two separate linear layers and concatenated to form a joint feature vector, which is passed to a shallow feedforward neural network to predict one of three mistake identification categories. We trained this model using cross-entropy loss and the ADAMW optimizer, keeping the encoder frozen throughout training. To improve efficiency, we cached the embeddings as .npz files. The final output was restructured to match the original JSON format for evaluation, preserving conversation IDs, model names, tutor responses, and predicted mistake annotations.

2.4 Retrieval-Augmented Few-Shot Classification with LLM-as-a-Judge

Our final and most effective approach tackles the mistake identification task as a judgment problem, using a retrieval-augmented few-shot prompting strategy powered by large language models (LLMs). Instead of training a traditional classifier, we designed a modular pipeline built with LangChain. At its core, the system takes the full conversation history and the tutor’s response, then prompts an LLM, specifically, GPT-4o to assess whether the tutor has correctly identified a mistake in the student’s reasoning.

Figure 1 outlines the system architecture. We begin by embedding the conversation history and tutor responses from the MRBENCH training set using the OpenAI Embedding Model. These embeddings are stored in a persistent vector database using ChromaDB. With this setup, we construct a few-shot prompt template and use the LLM itself as a “judge” on the test data. At inference time, the system retrieves the top- k semantically similar examples and integrates them into the prompt.

Each prompt includes detailed labeling instructions, definitions for all possible labels (Yes, No, To some extent), and the full dialogue context. (see Appendix B for more information). To ensure clear and structured outputs, we use a PydanticOutputParser that enforces a strict schema and reliably extracts the label from the LLM’s response. The pipeline also supports retries and incremental saving, making it robust and efficient for large-scale processing.

By combining relevant examples with a powerful instruction-following model, this method allows for nuanced mistake identification beyond simple clas-

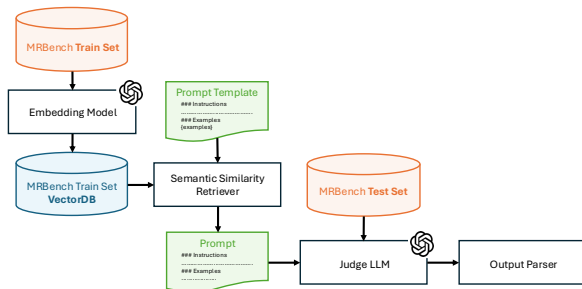

Figure 1: Pipeline of our final approach for mistake identification. The system takes tutor–student dialogue as input, retrieves relevant examples, constructs a structured prompt, and uses LLM to predict whether a mistake is identified. The output is parsed and saved.

sification. It requires no fine-tuning, generalizes well to new inputs, and showed improvements in both accuracy and qualitative evaluations compared to baseline methods. This highlights the effectiveness of prompt-based, retrieval-augmented approaches in educational and feedback-driven NLP tasks.

3 Dataset

We use the dataset introduced by Maurya et al. (2025), which includes both development and test splits. The development set consists of 300 dialogues from Macina et al. (2023) and Wang et al. (2024), each ending with a student utterance that reflects confusion or a mistake. Tutor responses, generated by seven large language model systems and human tutors (one in MathDial Macina et al. (2023), expert and novice in Bridge), are annotated along four pedagogical dimensions: (1) Mistake Identification, (2) Mistake Location, (3) Providing Guidance, and (4) Actionability. In total, the development set includes over 2,480 annotated responses.

The test set contains 200 dialogues with the same structure, but tutor identities are anonymized (for example, Tutor_1, Tutor_2), and no annotations are provided. This allows for blind evaluation of system outputs under the shared task setting.

3.1 Pre-processing

For the baseline systems, we apply extensive pre-processing to both the conversation history and tutor response texts. This includes converting text to lowercase, removing punctuation, stripping emojis, and cleaning URLs, HTML tags, and contractions. We also remove stopwords using the NLTK stopword list. All texts are passed through a unified

normalization pipeline to reduce noise and ensure consistency. The labels for Mistake Identification are mapped to numeric values as follows: No \rightarrow 0, Yes \rightarrow 1, and To Some Extent \rightarrow 2.

For our final approach, we additionally preprocess both the development and test sets so that each dialogue is reformatted into evenly paired exchanges between tutor and student, preserving the integrity of the back-and-forth interaction. During this process, we addressed two key issues. First, some conversations included greetings or closing phrases (e.g., “Hi”, “Thank you”) that did not contribute to the reasoning process. These were removed to maintain focus on educational content. Second, a few dialogues contained erroneous segments where the tutor responded to its own utterance without student input. These cases were consistently found to follow a correctly structured exchange and were manually removed (see Appendix A for examples).

This pre-processing step ensured a clean and consistent input format, enabling reliable downstream processing and model evaluation.

4 Evaluation and Results

We evaluated all four approaches on the **Track 1: Mistake Identification** test set using two evaluation schemes: **Strict** and **Lenient**, each reporting both *Macro F1* and *Accuracy*. In the strict setting, only exact matches with the gold labels are considered correct. In contrast, the lenient setting provides partial credit by treating To some extent as aligning with Yes, reflecting the fuzzy nature of pedagogical judgments in borderline cases. Table 1 summarizes the results.

As expected, the first baseline using pooled token embeddings and an ensemble of traditional classifiers (Approach 1) offered a modest starting point. This method, while straightforward, lacked the capacity to fully capture the nuances in dialogue-based reasoning.

Introducing token-level attention in Approach 2 led to a notable jump in performance. This suggests that modeling fine-grained interactions between the student’s dialogue and the tutor’s response helps the model better identify whether a mistake was correctly addressed. However, while this approach added depth to the representation, it still relied on relatively shallow modeling of the context.

Approach 3, which used frozen [CLS] embeddings from a sentence transformer combined with

Approach	Strict F1	Strict Acc	Lenient F1	Lenient Acc
Approach 1 (ML Ensemble)	0.446	0.657	0.637	0.754
Approach 2 (Token-Level Attention)	0.571	0.765	0.777	0.865
Approach 3 (CLS + MLP)	0.583	0.809	0.805	0.888
Approach 4 (Few-shot LLM + Retrieval)	0.584	0.827	0.814	0.897

Table 1: Performance of all four approaches on the BEA 2025 Mistake Identification test set under strict and lenient evaluation settings.

an MLP classifier, further improved performance. This indicates that sentence-level semantic representations, especially when paired with a focused classification head, can offer a stronger understanding of the overall pedagogical intent.

Our final method, Approach 4, which frames the task as a retrieval-augmented prompting problem with GPT-4o, achieved the best performance across all metrics. By retrieving semantically similar examples and using detailed, schema-guided prompts, the system benefited from both contextual grounding and the powerful instruction-following capabilities of modern LLMs. Notably, it showed strong results in both strict and lenient settings, highlighting its ability to make fine distinctions while still handling ambiguity in borderline cases effectively. Our final submission, achieved an official leaderboard rank of 37th among all participants.

5 Conclusion

We developed and evaluated four approaches for the BEA 2025 Shared Task **Track 1: Mistake Identification**, culminating in a retrieval-augmented few-shot prompting system using GPT-4o. While our initial baselines used traditional classifiers over pretrained embeddings, the final system reframed the task as a structured judgment problem, combining semantically retrieved examples, instruction-driven prompting, and schema-constrained output parsing.

This approach consistently outperformed all baselines in both strict and lenient evaluations, achieving a strict Macro F1 of 0.584 and a lenient accuracy of 0.897. It was particularly effective at capturing nuanced pedagogical feedback, highlighting the strength of LLM-based reasoning when guided by relevant context. Our submission ranked 37th on the official leaderboard, demonstrating the competitiveness of our method.

These results show that retrieval-augmented prompting offers a scalable and effective solution

for assessing complex teaching behaviors in AI tutors. Future work could explore more adaptive example selection, multi-turn consistency, and alignment with broader goals such as helpfulness and instructional fairness.

Limitations

While our final system achieved the best performance among all submitted approaches, it still has several limitations that suggest promising directions for future work.

Limited Diversity in Retrieved Examples The effectiveness of our retrieval-augmented prompting pipeline depends heavily on the quality and coverage of the example pool. Since we rely on a fixed set of annotated training examples, the system may struggle with out-of-distribution dialogues or question types that are underrepresented in the retrieval set. Moreover, retrieval is based solely on static embedding similarity from OpenAI embeddings, without adapting to the context or emphasizing specific pedagogical traits.

Lack of Multi-Turn Dialogue Modeling Each input is treated as a standalone conversation-response pair, with no memory of earlier tutor turns or evolving dialogue context. This limits the system’s ability to track learning progression or take prior feedback into account. Modeling dialogue history explicitly—through dialogue state tracking or memory-based retrieval—could improve consistency and pedagogical depth in multi-turn interactions.

Simplified Output Format Although the use of a structured parser ensures consistency, it restricts the model to selecting a single label per example. It does not capture uncertainty, nuanced justifications, or cases where multiple labels might apply. Extending the output to include rationales or confidence

scores could make evaluations more informative and reflective of real-world ambiguity.

Scalability and Cost Constraints Inference with frontier models like GPT-4o is computationally intensive and dependent on external APIs, which introduces latency, cost, and rate-limit challenges. These constraints pose barriers to deployment in low-resource settings or real-time tutoring applications, where efficiency and scalability are critical.

A Preprocessing Examples

This appendix list some issues which are fixed during pre-processing of dataset.

In the following example from the development set, the initial student message is a casual greeting that disrupts the expected alternating structure of the dialogue. To maintain structural integrity and ensure an even number of turns between tutor and student, such non-essential messages are removed during preprocessing.

```
[  
'Student: okey',  
'Tutor: What is 25 minus 18?',  
'Student: 8'  
]
```

In the example below, the final tutor response erroneously mimics the student’s explanation, as if the tutor is responding to itself rather than engaging with the student. This type of error breaks the natural flow of the dialogue and was manually identified and removed during preprocessing to ensure accurate tutor-student interaction.

```
[  
'Tutor: Hi, could you please provide a  
↪ step-by-step solution for the question  
↪ below? The question is ...',  
'Student: Samantha buys 4 toys at $12.00 each.  
↪ For each pair of toys...',  
'Tutor: I added the two amounts together to get  
↪ a total of $36.00 + $6.00 = $42.00.'  
]
```

In cases like the example below, the tutor’s prompt is split across multiple turns, breaking the intended question into separate messages. To preserve the coherence of the dialogue and maintain a consistent turn-taking structure, such fragmented tutor responses are merged into a single utterance by concatenating the strings.

```
[  
'Tutor: Hi, could you please provide a  
↪ step-by-step solution for the question  
↪ below? The question is: Tyson decided to  
↪ make muffaletta sandwiches for ...',  
'Tutor: How many pounds of meat are needed for  
↪ each sandwich?',  
'Student: Each sandwich requires 1 pound of  
↪ meat and 1 pound of cheese.',  
'Tutor: What is the cost of 1 pound of meat?',  
↪ 'Student: The cost of 1 pound of meat is  
↪ $7.00.'  
]
```

B Prompt Engineering

```
"""
You will be shown a short educational "Conversation" between a tutor and a student, including the
↳ student's solution and the tutor's follow-up "Response". Your task is to judge whether the
↳ tutor's response successfully **identifies a mistake** in the student's reasoning.

### Instructions
1. Read the entire dialogue to understand the context of the student's solution.
2. Focus on whether the tutor's response explicitly or implicitly calls out an error.
3. Reply **only** with one of the labels: `Yes`, `To some extent`, or `No`.

### Labels
- `Yes`: The mistake is clearly identified/recognized in the tutor's response. The tutor implicitly
↳ or explicitly points out the error in the student's reasoning.
- `No`: The tutor's response does not identify any mistake in the student's reasoning. The tutor's
↳ response is either irrelevant or does not address the student's solution.
- `To some extent`: The tutor's response suggests that there may be a mistake, but it sounds as if
↳ the tutor is not certain.

DLSU at BEA 2025 Shared Task: Towards Establishing Baseline Models for Pedagogical Response Evaluation Tasks

Mark Edward M. Gonzales*, Lanz Kendall Lim*, Maria Monica Manlises*

College of Computer Studies, De La Salle University

Manila, Philippines

{mark_gonzales, lanz_kendall_lim, maria_monica_manlises}@dlsu.edu.ph

Abstract

We present our submission for Tracks 3 (Providing Guidance), 4 (Actionability), and 5 (Tutor Identification) of the BEA 2025 Shared Task on Pedagogical Ability Assessment of AI-Powered Tutors. Our approach sought to investigate the performance of directly using sentence embeddings of tutor responses as input to downstream classifiers (that is, without employing any fine-tuning). To this end, we benchmarked two general-purpose sentence embedding models: gte-modernbert-base (GTE) and all-MiniLM-L12-v2, in combination with two downstream classifiers: XGBoost and multilayer perceptron. Feeding GTE embeddings to a multilayer perceptron achieved macro-F1 scores of 0.4776, 0.5294, and 0.6420 on the official test sets for Tracks 3, 4, and 5, respectively. While overall performance was modest, these results offer insights into the challenges of pedagogical response evaluation and establish a baseline for future improvements.

1 Introduction

Recent advancements in large language models (LLMs) have opened new possibilities for using AI-powered chatbots as educational tutors, providing benefits for tasks such as homework assistance, personalized learning, and skills development (Labadze et al., 2023). However, while these systems can generate human-like dialogue, assessing their pedagogical effectiveness remains a significant challenge. In the past, human evaluation has typically been used for evaluation, though reliable, this is costly and difficult to scale (Liu et al., 2023).

To address this gap, the BEA 2025 Shared Task on Pedagogical Ability Assessment of AI-powered Tutors (Kochmar et al., 2025) was organized to promote the development of automated evaluation systems for tutor responses in educational dialogues.

The shared task focused on assessing the quality of tutor responses aimed at helping students correct their mistakes in math-related dialogues. Participants were provided with dialogues that included conversation history, a student’s incorrect utterance, and multiple possible tutor responses (Maurya et al., 2025). Each response was to be evaluated along four pedagogically motivated dimensions: mistake identification, mistake location, guidance provision, and actionability. These dimensions were annotated on a three-point scale: “Yes,” “To some extent,” or “No.”

In addition to these four tracks, the shared task included a fifth track, Tutor Identification, wherein participants were asked to predict the origin of anonymous tutor responses, distinguishing between different LLMs and human tutors. This track explored whether distinct pedagogical or linguistic styles could be used to attribute responses to their source.

The organizers released a development dataset of 300 annotated dialogues and a test set of 191 dialogues. Both sets included responses from a diverse set of state-of-the-art LLMs and, in some cases, human tutors (Maurya et al., 2025).

Our contributions are as follows:

- We evaluated the performance of directly feeding sentence embeddings of tutor responses (without any fine-tuning) to downstream classifiers for Tracks 3 (Providing Guidance), 4 (Actionability), and 5 (Tutor Identification).
- We benchmarked two sentence embedding models: gte-modernbert-base (GTE) and all-MiniLM-L12-v2. Our results show that using GTE embeddings and a multilayer perceptron yielded macro-F1 scores of 0.4776, 0.5294, and 0.6420, thus providing a baseline for the performance of general-purpose sentence embeddings on multiple pedagogical response evaluation tasks.

2 Methods

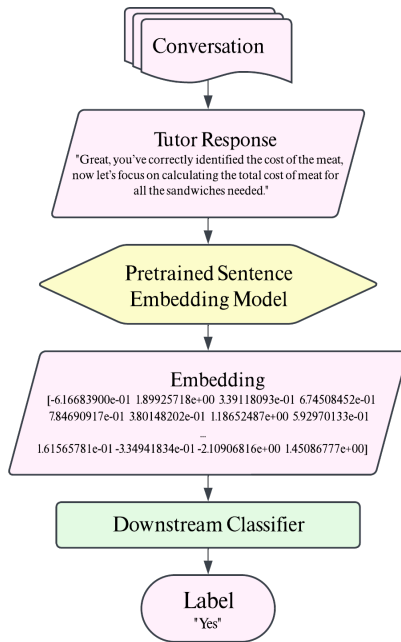

Figure 1: Methodology

Figure 1 shows our approach. First, we extracted the tutor response from each dialogue instance and fed it into a pretrained sentence embedding model to obtain a fixed-length vector representation. We used this representation as input to a classifier trained to predict the relevant task labels.

This methodology was applied across all three tracks in which we participated. We modeled Tracks 3 and 4 as multiclass classification problems where the output labels are “No,” “To some extent,” and “Yes.” Likewise, Track 5 was also modeled as a multiclass classification problem with nine output labels: “Expert,” “GPT4,” “Gemini,” “Llama31405B,” “Llama318B,” “Mistral,” “Novice,” “Phi3,” and “Sonnet.”

2.1 Sentence Embedding Model

Two embedding models were chosen from the Massive Text Embedding Benchmark (MTEB) Leaderboard¹ (Enevoldsen et al., 2025), which compares the performance of over a hundred embedding models across multiple tasks.

We first selected **gte-modernbert-base**² (Zhang et al., 2024) or GTE, a general-purpose embedding

¹<https://huggingface.co/spaces/mteb/leaderboard>

²<https://huggingface.co/Alibaba-NLP/gte-modernbert-base>

model built on modernBERT (Warner et al., 2024). With 149 million parameters and a context length of up to 8192 tokens, it performs strongly on the MTEB leaderboard, competitive with other models with under 1 billion parameters.

In addition, we also evaluated a more lightweight model, **all-MiniLM-L12-v2**³, which has 33.4M parameters. Despite its compact size, it registers competitive performance on the MTEB leaderboard and on other classification tasks (Meleti et al., 2025).

2.2 Downstream Classifier

We trained two classification models: **XGBoost** and a **multilayer perceptron (MLP)** with a single hidden layer. XGBoost, a decision tree-based gradient boosting method, has been reported to achieve good performance with dense sentence embeddings as input (Muqadas et al., 2025; Chen and Guestrin, 2016). MLPs are capable of capturing nonlinear relationships and, as such, are widely used in supervised learning tasks (Goodfellow et al., 2016).

We partitioned the development set such that 80% of the data comprises the training set and the remaining 20% comprises the test set. We then performed three-fold cross-validation with grid search on the training set to tune the hyperparameters of both models; the complete hyperparameter search space is reported in Table 3. Tables 4 and 5 show the combination of hyperparameters that returned the highest macro-F1.

3 Results and Discussion

3.1 Development Set Results

Table 1 summarizes the results on the test set partition of our development set. We found that using MLP consistently outperformed using XGBoost in terms of macro-F1 across all three tasks, with the strongest gains observed in Tracks 4 (Actionability) and 5 (Tutor Identification). Pairing GTE embeddings with MLP achieved the highest macro-F1 and also the highest accuracy (except for Task 3). Confusion matrices are given in Figure 2.

3.2 Official Test Set Results

Based on the development set results, we selected the top two model combinations for final testing. For Tracks 3 and 4, we chose GTE + MLP and GTE + XGBoost. For Track 5, we selected GTE + MLP and MiniLM + MLP. The complete official test set

³<https://huggingface.co/sentence-transformers/all-MiniLM-L12-v2>

Task	Model	Macro-F1	Accuracy
Track 3	GTE + MLP	0.5601	0.6371
	GTE + XGBoost	0.5095	0.6492
	MiniLM + MLP	0.4675	0.6371
	MiniLM + XGBoost	0.4814	0.6310
Track 4	GTE + MLP	0.5667	0.6492
	GTE + XGBoost	0.5097	0.6552
	MiniLM + MLP	0.5504	0.6411
	MiniLM + XGBoost	0.4766	0.6431
Track 5	GTE + MLP	0.6047	0.5665
	GTE + XGBoost	0.4879	0.4476
	MiniLM + MLP	0.5333	0.4879
	MiniLM + XGBoost	0.4595	0.3992

Table 1: Macro-F1 and accuracy on the development set across Tracks 3 (Providing Guidance), 4 (Actionability), and 5 (Tutor Identification). The best performance scores are in bold.

scores for these selected model combinations are reported in Table 2.

3.3 Limitations

First, we fed the tutor responses, as is, to the sentence embedding models, that is, we did not perform any text preprocessing (such as stopword removal or punctuation stripping) prior to embedding. While this decision aligns with the intention to evaluate the raw utility of general-purpose embeddings, preprocessing might have potentially reduced noise and improved classification performance.

Second, we did not fine-tune the sentence embedding models on task-specific data. The GTE and MiniLM embeddings were used as is, without adaptation to the tutoring domain or label space. This might have limited the models’ ability to capture nuanced patterns in the instructional dialogue, particularly for more subtle distinctions such as “To some extent” in Tracks 3 and 4 or between tutor personas in Track 5.

Finally, the per-class evaluation results (Figure 3) reflect the class imbalance, with the dominant class (“Yes”) having noticeably higher F1 compared to “No” and “To some extent” for Tracks 3 and 4. To address this, it may be helpful to incorporate class-adjusted weights during training, perform data augmentation, or generate synthetic data.

4 Conclusion

In this paper, we investigated the performance of directly feeding sentence embeddings of tutor responses to downstream classifiers for multiple pedagogical response evaluation tasks, thus providing

baseline models for future improvements in this domain.

For future work, it may be interesting to compare these baselines with domain-specific fine-tuning, as well as perform more extensive hyperparameter tuning through automated optimization techniques (such as Bayesian optimization) to further improve classification accuracy.

Abstract

We present Team BD’s submission to the BEA 2025 Shared Task on Pedagogical Ability Assessment of AI-powered Tutors, under Track 1 (Mistake Identification) and Track 2 (Mistake Location). Both tracks involve three-class classification of tutor responses in educational dialogues – determining if a tutor correctly recognizes a student’s mistake (Track 1) and whether the tutor pinpoints the mistake’s location (Track 2). Our system is built on MPNet, a Transformer-based language model that combines BERT and XLNet’s pre-training advantages. We fine-tuned MPNet on the task data using a class-weighted cross-entropy loss to handle class imbalance, and leveraged grouped cross-validation (10 folds) to maximize the use of limited data while avoiding dialogue overlap between training and validation. We then performed a hard-voting ensemble of the best models from each fold, which improves robustness and generalization by combining multiple classifiers. Our approach achieved strong results on both tracks, with exact-match macro-F1 scores of approximately 0.7110 for Mistake Identification and 0.5543 for Mistake Location on the official test set. We include comprehensive analysis of our system’s performance, including confusion matrices and t-SNE visualizations to interpret classifier behavior, as well as a taxonomy of common errors with examples. We hope our ensemble-based approach and findings provide useful insights for designing reliable tutor response evaluation systems in educational dialogue settings.

1 Introduction

Effective intelligent tutoring systems need to be able to recognize and address student mistakes during interactions. To evaluate such capabilities in automated systems, the BEA 2025 Shared Task introduced a multi-dimensional assessment of AI tutor responses. In particular, Track 1 focuses on whether a tutor’s response identifies the student’s

mistake, and Track 2 on whether it locates the mistake in the student’s answer. Each track is framed as a three-way classification: the tutor either fully recognizes/locates the error (“Yes”), partially or uncertainly does so (“To some extent”), or fails to do so (“No”). These pedagogically motivated categories draw from prior frameworks in educational dialogue analysis—for example, Mistake Identification corresponds to the student understanding dimension in Tack and Piech’s schema (Tack and Piech, 2022b) and correctness in other tutoring evaluation schemata, reflecting how well the tutor acknowledges the student’s misconception.

Assessing tutor responses along such dimensions is challenging due to the nuanced and subjective nature of pedagogical feedback. For instance, different studies have used varied measures (e.g., “speaking like a teacher,” “understanding the student,” etc.) to judge tutor responses. The BEA 2025 shared task addresses this gap by defining clear categories and metrics for evaluation (Kochmar et al., 2025). However, even with a fixed taxonomy, classifying responses correctly remains non-trivial: tutors may implicitly acknowledge an error without stating it outright, or they might hint at the error’s location in vague terms. Distinguishing between a definite “Yes” and a tentative “To some extent” thus requires subtle interpretation of language.

In this paper, we describe Team BD’s ensemble-based MPNet system for automating the annotation of mistake identification and mistake location in AI-tutor responses. MPNet, a pretrained Transformer model that uses masked and permuted language modeling to capture token dependencies, was chosen as our backbone for its strong generalization capabilities compared to earlier models like BERT, XLNet, and RoBERTa. To address the limited size of the labeled data (approximately 2.5 K examples) and inherent class imbalance, we fine-tuned MPNet with a class-weighted cross-entropy loss and trained ten separate models using grouped cross-

validation—grouped by dialogue to prevent context leakage—and then combined the top-performing model from each fold through hard-voting. This ensemble strategy greatly improved robustness and generalization, leading to high accuracy and macro-F1 scores on both the mistake identification and mistake location tracks. Our error analysis using confusion matrices and t-SNE visualizations revealed consistent misclassification patterns, notably confusing fully recognized with partially acknowledged mistakes. We created a taxonomy of common error types with examples to aid future refinements.

2 Related Work

Evaluation of Tutor Responses: The task of judging tutor or teacher responses in educational dialogues has recently garnered attention. Tack and Piech (Tack and Piech, 2022a) introduced the AI Teacher Test to measure the pedagogical ability of dialogue agents, proposing dimensions such as whether the agent understands the student’s error and provides helpful guidance. Following this, the BEA 2023 Shared Task (Tack et al., 2023) focused on generating AI teacher responses (rather than classification), where models like GPT-3 and Blender were challenged to produce tutor-like feedback. The BEA 2025 Shared Task (Kochmar et al., 2025) moves a step further by creating a benchmark dataset of tutor responses annotated along multiple pedagogical dimensions. The dataset leverages dialogues from **MathDial** (Macina et al., 2023) and **Bridge** (Maurya et al., 2025), two collections of student-tutor interactions in the math domain. Each tutor response in these dialogues was labeled by experts as to whether it identifies the student’s mistake, pinpoints the mistake’s location, provides guidance, and offers actionable next steps. Such multi-faceted annotation of tutor feedback is relatively novel; it connects to earlier work on dialogue act classification (Maurya et al., 2025) in that both involve categorizing utterances, but here the labels are pedagogical quality ratings rather than communicative intent.

Ensemble Methods in NLP: Classic studies, such as Dietterich’s work on ensemble methods, demonstrated that an ensemble of diverse classifiers can correct individual models’ errors and reduce variance (Dietterich, 2000). For instance, (Ovadia et al., 2019) and (Gustafsson et al., 2020) found that deep ensembles improve reliability under dataset

shift. In shared task and kaggle competitions, top teams often resort to model ensembling to squeeze out some additional performance. These benefits come at the cost of increased computational overhead. Our approach aligns with this trend, as we build an ensemble of 10 MPNet-based classifiers (from cross-validation folds) to tackle the classification of tutor responses.

Dialogue and Educational NLP: Related to our work is research on grammatical error detection and correction, where systems identify mistakes in student-written text. Notably, (Ng et al., 2014) and (Bryant et al., 2019) have contributed significantly to this field. However, our task differs in that the “mistakes” are conceptual or procedural errors in a problem solution, and we are evaluating the tutor’s response to those errors rather than directly analyzing the student’s text. Another line of relevant work is on student response analysis in tutoring systems, where the goal is to classify student answers as correct, incorrect, or incomplete. (Dzikovska et al., 2013) explored this in the context of the SemEval-2013 Task 7. In our case, the roles are reversed—we classify the tutor’s replies. We also draw on insights from educational dialogue analysis: studies like (Daheim et al., 2024) examined tutor responses for targetedness and actionability, which correspond to our Track 2 and Track 4 tasks. These studies emphasize the subtle linguistic cues that indicate whether a tutor has pinpointed an error (e.g., referencing a specific step in the student’s solution) or just given generic feedback.

In summary, our work is situated at the intersection of dialogue evaluation and text classification. We build upon the shared task’s provided taxonomy (SIGEDU, 2025) and prior educational NLP research, employing modern Transformer models and ensemble techniques known to be effective in such tasks.

3 Data and Task Definition

Task Definition: Tracks 1 and 2 are classification tasks applied to tutor responses in a dialogue. Based on the previous conversation history between students and tutors, in Track 1 (Mistake Identification), the system must determine if the tutor’s response indicates recognition of the student’s mistake. In Track 2 (Mistake Location), the system judges if the tutor points out the specific location or nature of the mistake in the student’s solution. Both tasks share the same label set: **Yes, To some extent,**

Model	Macro-F1 Score
BERT-large	0.6851
DeBERTa	0.6845
MPNet (selected)	0.6975

Table 1: 10 fold Cross-validation Macro-F1 scores for different Transformer models on the track 1 development set. MPNet achieves the highest score.

or **No**. Because these categories can be nuanced, the shared task also defined a lenient evaluation where “Yes” and “To some extent” are merged, but our system is trained on the full 3-class distinction (exact evaluation).

Dataset: The training (development) data provided by the organizers consists of annotated educational dialogues in mathematics, drawn from the MathDial and Bridge datasets. Each dialogue includes a student’s attempt at a math problem (containing a mistake or confusion) and one or more tutor responses (from either human tutors or various LLMs such as Mistral, Llama, GPT-4, etc. acting as tutors). Each tutor response is annotated with the three-class labels for all four dimensions (Tracks 1–4). In total, the development set contains 300 conversation history and over 2,480 tutor responses with annotations. On average, each dialogue context yields 8–9 different tutor responses (one from each of several tutor sources), which were all annotated. The test set is constructed in the same way but uses held-out dialogues and responses—both the ground-truth labels and the tutors’ identities are hidden.

The development set for both **Track 1 (Mistake Identification)** and **Track 2 (Mistake Location)** consists of the same 300 dialogues and 2,476 tutor responses. However, the label distributions differ between tracks due to the nature of the classification tasks. The underrepresentation of the *To some extent* class in both tracks poses challenges for model learning.

4 Methodology

4.1 Preprocessing

All tutor responses and conversation histories were first lowercased (while preserving punctuation) to ensure consistent casing.

To standardize and sanitize the responses, we applied a series of targeted cleaning steps:

- **Extra Info Removal:** Eliminated any meta-data or annotations not part of the tutor’s ac-

tual reply.

- **Appended Dialogue Trimming:** Removed follow-up conversational turns that were appended after the original tutor response (e.g., speculative follow-up questions or acknowledgments).
- **Code Abstraction:** Replaced Python code blocks with the placeholder «python code» to retain structural intent while abstracting away executable details.
- **Punctuation Cleanup:** Stripped redundant or mismatched punctuation (e.g., extraneous quotes or dashes) that might confuse the tokenizer or the model.

Table 4 provides a summary of how many instances were affected by each category. We observed that models such as **Phi-3** and **Llama-3.1-405B** required the most extensive preprocessing.

Finally, each input example—consisting of the conversation history, cleaned response, and separator tokens—was constrained to a maximum of 512 MPNet tokens. In cases where the input exceeded this limit, we removed the low-value content (e.g., greetings or small talk) from the conversation history to retain the most relevant context.

4.2 Language Model Finetuning

In our experiments, we utilize transformer-based pretrained language models (LMs). Since these models may lack task-specific contextual knowledge, we fine-tune them on our target tasks to improve performance.

To begin, we consider a pretrained language model denoted as ϕ_{LM} . Each tutor’s response after preprocessing T is input to the model, yielding a sequence of tokens $T = \{t_{[CLS]}, t_1, t_2, \dots, t_n\}$ along with their corresponding layer-wise hidden representations $H^l = \{h_{[CLS]}^l, h_1^l, h_2^l, \dots, h_n^l\}$.

In our setup, we use the hidden representation of the [CLS] token from the final layer as the sentence-level representation of the input T , defined as:

$$h_T = \phi_{LM}(T)_{[CLS]}^L = H_{[CLS]}^L$$

This representation h_T is then passed through a classification head to produce the prediction. The classification head consists of a dropout layer *Drop* followed by a linear transformation:

$$p = W \cdot \text{Drop}(h_T) + b$$

Finally, we use a cross-entropy loss function to update the parameters of the language model ϕ_{LM} during training.

4.3 Grouped Cross-Validation

We employ *group cross-validation* to ensure robust evaluation and mitigate overfitting. In this approach, each dialogue (or group of dialogues) is entirely assigned to either the training or validation set within each fold, preventing shared context between the training and validation sets.

For each fold $f \in \{1, 2, \dots, k\}$, we define the training and validation sets as $\mathcal{G}_{\text{train}}^{(f)}$ and $\mathcal{G}_{\text{val}}^{(f)}$, respectively, where each set contains whole dialogues (or groups) with no overlap. We monitor the model’s performance on the validation set using the *macro-averaged F1 score* (macro-F1), which provides a balanced measure of performance across classes. For each fold, we save the model checkpoint that achieves the highest macro-F1 score on the validation set.

The final performance of the model is computed by aggregating the macro-F1 scores across all k folds.

4.4 Ensembling Strategy

To enhance model performance, we employed an *ensembling strategy* where the top-performing models from each fold were combined using hard voting. Specifically, for each track, we had a total of $N = 10$ models (one from each fold).

Let $\hat{y}_i^{(f)}$ denote the prediction of the model from fold f for the i -th sample, where $f \in \{1, 2, \dots, N\}$. The final prediction \hat{y}_i for each sample i was determined by majority vote:

$$\hat{y}_i = \text{mode}(\hat{y}_i^{(1)}, \hat{y}_i^{(2)}, \dots, \hat{y}_i^{(N)})$$

In the case of a tie, the tie-breaking rule was based on the average softmax confidence across all models. Let $s_i^{(f)}$ denote the softmax output (confidence) of the f -th model for the i -th sample. If a tie occurs, the final prediction is chosen as:

$$\hat{y}_i = \arg \max \left(\frac{1}{N} \sum_{f=1}^N s_i^{(f)} \right)$$

Ensembling helps to reduce variance and correct individual model biases, leading to more robust predictions. Our ensembling approach improved the macro-F1 score by 2–3 points over the performance of individual models.

5 Experimental Setup

5.1 Implementation Details

Model Selection In our experiments, we compared several such models—including BERT-large, DeBERTa, and MPNet—on a held-out subset of the training data. Among these, MPNet achieved the best macro-F1 score (see Table 1), and was thus selected as our backbone. For implementation details, including software, packages, and hardware setup, see Appendix A.

Model Hyperparameters

We used the AdamW optimizer with a learning rate of 2×10^{-5} , selected through preliminary experiments on a held-out validation set. This setting outperformed alternative learning rates such as 1×10^{-5} and 3×10^{-5} in terms of macro-F1. A linear learning rate decay schedule was used, along with early stopping based on validation macro-F1 (patience = 5 epochs). We trained with a batch size of 32 and applied a dropout rate of 0.1 in the classification head. No gradient accumulation was used.

Handling Class Imbalance

To mitigate class imbalance, we used a class-weighted cross-entropy loss, where the weight for each class c was computed as:

$$w_c = \frac{N}{K \cdot n_c}$$

with N being the total number of samples, K the number of classes, and n_c the count for class c . This formulation emphasizes underrepresented classes without overly penalizing frequent ones.

For Track 1 (Mistake Identification), class distributions were skewed toward “Yes” (1932), compared to “No” (370) and “To some extent” (174). We thus used the weight vector:

$$[w_{\text{No}}, w_{\text{Some}}, w_{\text{Yes}}] = [1.0, 3.0, 0.5]$$

to boost recall for the rare “Some extent” class and mildly down-weight the majority class.

In Track 2 (Mistake Location), the frequencies were: “Yes” (1504), “No” (732), and “To some extent” (240). Based on this, we used:

$$[w_{\text{No}}, w_{\text{Some}}, w_{\text{Yes}}] = [0.8, 2.2, 0.9]$$

These weights, derived from inverse class frequencies and lightly tuned, improved macro-F1 by reducing systematic underprediction of minority classes. Although not extensively optimized, this approach provided consistent performance gains across both tracks.

Track	Macro F1	Accuracy
<i>Track 1 – Mistake Identification</i>		
Best (BJTU)	0.718	0.862
Ours (Test)	0.711	0.877
Ours (CV aggregate)	0.685	0.869
<i>Track 2 – Mistake Location</i>		
Best (BLCU-ICALL)	0.598	0.768
Ours (Test)	0.554	0.714
Ours (CV aggregate)	0.560	0.700

Table 2: Comparison of our system’s macro-F1 and accuracy with top leaderboard scores on both tracks.

5.2 Evaluation Metrics

Following the shared task guidelines, we report both Accuracy and Macro F1. Macro F1, the un-weighted average of per-class F1 scores, is emphasized due to class imbalance. We monitored performance using these metrics on the validation set during training and evaluated on the aggregated development set using cross-validation predictions. Final test metrics were provided by the organizers. We focus on exact 3-class classification; lenient 2-class metrics (merging “Yes” with “To some extent”) were higher but are omitted here for brevity.

6 Result and Analysis

6.1 Main Result

To contextualize our system’s performance, we compared it against the top submissions from the official shared task leaderboard. On Track1 (Mistake Identification), our model achieved a macro-F1 of 0.711 on the test set, placing 5th out of 44 participating teams. The top-ranked system (BJTU) achieved a macro-F1 of 0.718, indicating that our system performs competitively, within 0.7 points of the best result. For Track2 (Mistake Location), our system scored 0.554 macro-F1 on the test set, ranking 7th out of 31 teams. The highest score on this track was 0.598, obtained by BLCU-ICALL. While our model trails behind the top result by approximately 4.4 points in macro-F1, it still exceeds the median leaderboard performance.

Our system achieved higher accuracy than the top Track 1 system (0.877 vs. 0.862), suggesting stronger performance on dominant classes, albeit with slightly lower balance across all classes.

Even though our system performs well, a closer examination of its errors provides insights into its decision-making and the task’s inherent difficulty. We carried out an error analysis on the development set predictions, focusing on confusion patterns and

the nature of misclassified cases.

6.2 Class-Level Performance Analysis

Figure 1: Confusion matrix for Track 1 (Mistake Identification) on the development set. The model shows strong performance on the "Yes" class but has difficulty distinguishing partial acknowledgment ("To some extent").

Figure 2: Confusion matrix for Track 2 (Mistake Location). The model maintains high accuracy on explicit localizations ("Yes") but misclassifies many "To some extent" and "No" cases, highlighting the subtlety of location inference.

To gain insight into how well our system distinguishes among the three pedagogical feedback categories, we analyze confusion matrices for both tasks. Figures 1 and 2 visualize model predictions against gold labels on the development set for Track 1 (Mistake Identification) and Track 2 (Mistake Location), respectively.

In Track 1 (Figure 1), the model performs strongly on the "Yes" class, correctly identifying 1,827 instances, with relatively low misclassification into the "No" (54) and "To some extent" (51)

classes. The "No" class is also well captured with 275 correct predictions and few false positives. The model struggles more with the "To some extent" category: 61 were correctly predicted, but 113 were misclassified as either "No" or "Yes." This aligns with our earlier claim that "To some extent" lies on a subjective continuum and is more difficult to pin down categorically.

For Track 2 (Figure 2), a similar trend emerges. The model again shows high accuracy on "Yes" (1,450 correct), but struggles to distinguish "To some extent," which is often misclassified as "Yes" (197 cases) or "No" (11 cases). Notably, the "No" class is less cleanly separated in Track 2 compared to Track 1, with 330 examples misclassified as "Yes." This may suggest that tutors sometimes appear to reference an error without pinpointing its location, confusing the model's judgment.

Overall, these confusion matrices illustrate the asymmetric difficulty across classes. "Yes" responses are most reliably predicted due to their clearer, more direct language. "To some extent" predictions remain a challenge, particularly when tutors use indirect or hedging phrasing that blurs the line between partial and full error acknowledgment or localization.

6.3 Embedding Space Insights

Figure 3: t-SNE projection of [CLS] embeddings from the held-out fold (Fold 0) for Track 1 (Mistake Identification), colored by true label. "Yes" and "To some extent" examples are scattered and intermingled, whereas "No" forms a more compact cluster, indicating lower intra-class variation.

To better understand the internal representations learned by our model, we applied t-SNE (van der Maaten and Hinton, 2008) to the [CLS] embeddings from the final Transformer layer. These pro-

Figure 4: t-SNE projection of [CLS] embeddings from MPNet models across all 10 cross-validation folds for Track 1 (Mistake Identification). Each point represents a tutor response from a held-out fold, colored by fold ID. The emergence of distinct clusters suggests that each fold-specific model learns a consistent but fold-specific embedding subspace, reflecting representational diversity across the ensemble.

jections reveal how the model organizes tutor responses in the embedding space across folds and classes.

Figure 4 shows the t-SNE projection of the [CLS] embeddings across all ten cross-validation folds, with points colored by fold ID. We observe that embeddings from each fold tend to form compact, well-separated clusters. This indicates that while training on different subsets, each fold-specific model learns fold-consistent but distinct representations. The tightness of these clusters also suggests good embedding stability and coherence across training runs.

Figure 3 presents the t-SNE visualization for the held-out fold (Fold 0), this time colored by the true label. Unlike the per-fold visualization, class-level structure is less distinct: the "Yes" and "To some extent" responses are widely dispersed and often intermingle, suggesting overlapping semantic characteristics. In contrast, the "No" class forms a more compact group, indicating that tutor responses with no recognition of error share more consistent linguistic patterns. This aligns with our earlier findings that "Yes" and "To some extent" are harder to separate, as they exist on a continuum of acknowledgment.

Together, these visualizations support our earlier confusion matrix results and highlight the challenge of distinguishing nuanced pedagogical feed-

back categories based solely on language.

6.4 Error Taxonomy

To better understand where the model fails, we analyzed misclassified responses from both tasks and developed a taxonomy of recurring error types, summarized in Table 3. These categories reflect systematic issues in how the model interprets pedagogical language.

False Negatives (Missed Signal). These errors occur when the model fails to recognize that the tutor has identified or located a mistake, typically labeling the response as “No” or “To some extent” instead of “Yes.” Such cases often involve subtle cues like rhetorical questions or light correction phrasing (e.g., “Can you check the multiplication again?”), which the model may under-interpret.

False Positives (Over-interpretation). Here, the model predicts “Yes” even when the tutor does not provide evidence of error recognition. This often results from over-interpreting generic encouragement (e.g., “Let’s try another one.”) or positive sentiment as pedagogical feedback.

Partial–Full Confusion. A frequent source of confusion is the distinction between full and partial identification or localization. Indirect language such as “You’re close, just verify your subtraction” may be intended as partial feedback, but the model may treat it as a complete identification.

Hedged Language Confusion. Tutors often use polite or indirect language (e.g., “Maybe revisit the earlier step?”), especially in educational settings. Such hedging may obscure intent, leading the model to underestimate the strength of the feedback signal.

Contextual Miss. Some misclassifications stem from failing to use conversational history. For instance, if a tutor’s comment refers to an earlier incorrect step, the model may mislabel it when that context is not incorporated effectively.

Template Bias. We also observed that the model sometimes over-relies on surface patterns seen during training. For example, statements like “Great work!” may be incorrectly classified as “Yes” due to template bias, even when no mistake is acknowledged.

These error categories offer valuable insight into the linguistic and contextual challenges of the task. They suggest that improvements in discourse modeling, uncertainty handling, and pragmatic language understanding could further enhance performance.

From the above taxonomy, we see that many of the model’s mistakes correspond to understandable difficulties. False negatives often involved indirect tutor feedback—the tutor recognized the mistake but phrased it as a question or hint, requiring inference to identify it as an acknowledgment of error. Our model sometimes took such tentative language at face value and labeled it as if the tutor did nothing. False positives, on the other hand, were cases where the tutor’s response had reassuring or neutral language that the model mistook for a sign of recognizing a mistake. For example, tutors might say “Let’s double-check that” even when the student was correct (encouraging the student, not pointing an error), and the model erroneously flagged it as identifying an error.

The partial vs. full confusion category was the most prevalent error type. This reflects the inherent ambiguity of the “To some extent” class—even human annotators might differ on these in some cases. Our model would sometimes collapse it into one of the binary decisions (“Yes” or “No”) depending on slight wording differences. In some cases, the model predicted “To some extent” when the tutor had actually pinpointed the error but perhaps in a subtle way; in others, it predicted “Yes” for a tutor response that was only hinting. This suggests that improving the model’s understanding of nuanced language (perhaps via better context usage or training on more examples of hedging) could help.

We also found that ambiguous wording and polite phrasing (common in educational settings) posed challenges. Phrases like “Maybe check that again” require contextual understanding—they might indicate an error without explicit wording. Our model did catch many of these, but not all. Some errors could be attributed to the model’s lack of world knowledge or reasoning; for example, if a tutor says “Remember the formula for area,” the model needs to infer that the student likely made a mistake related to area calculation and that the tutor is hinting at it—a level of reasoning beyond surface text.

In summary, the error analysis reveals that while our ensemble is effective, there is room for improvement in handling borderline cases and understanding implicit signals. These findings guided us in considering potential enhancements, as discussed next.

Error Type	Description	Example Scenario
False Negative (Missed Signal)	Tutor indicates or locates a mistake, but the model predicts “No” or “To some extent.”	<i>Tutor:</i> “Can you check the multiplication again?” <i>Gold:</i> Yes → <i>Pred:</i> To some extent
False Positive (Over-interpretation)	Model predicts “Yes” despite the tutor giving no error feedback.	<i>Tutor:</i> “Let’s try another one.” <i>Gold:</i> No → <i>Pred:</i> Yes
Partial–Full Confusion	Confuses indirect hints as full identification, or subtle localization as partial.	<i>Tutor:</i> “You’re close, just verify your subtraction.” <i>Gold:</i> To some extent → <i>Pred:</i> Yes
Hedged Language Confusion	Tutor’s suggestion is misread due to polite phrasing or indirect cues.	<i>Tutor:</i> “Maybe revisit the earlier step?” <i>Gold:</i> Yes → <i>Pred:</i> To some extent
Contextual Miss	Misclassification caused by ignoring or misusing multi-turn context.	<i>Tutor:</i> Feedback depends on an earlier step, but the model misses the reference.
Template Bias	Model favors phrases resembling training-time patterns, even when semantically incorrect.	<i>Tutor:</i> “Great work!” with no correction. Model assumes this implies error recognition.

Table 3: Taxonomy of common misclassification errors in both tasks, with representative examples.

Figure 5: Histogram of prediction confidence values for Track 1 (Mistake Identification). Most predictions fall within a mid-confidence range.

Figure 6: Histogram of prediction confidence values for Track 2 (Mistake Location). A similar mid-range clustering pattern is observed, with some extreme confidence peaks.

6.5 Confidence Distribution and Calibration

To further investigate the model’s decision-making behavior, we analyzed its prediction confidence across classes and tasks. Figures 5 and 6 present histograms of predicted confidence scores for Track 1 and Track 2, respectively. These reflect the model’s certainty in its predictions across the development set.

In both tasks, the confidence distribution is skewed toward the middle range (1.5–3.0), with multiple local peaks. This suggests that while the model often makes moderately confident predictions, it does not frequently commit to extremely low or high confidence outputs. The spiked clusters in Track 2 (Figure 6) hint at calibration artifacts possibly introduced by ensemble averaging. Despite ensemble smoothing, we still observe confidence saturation for some predictions near 3.5, particularly on easier instances.

To better understand class-specific behavior, we examined boxplots of prediction confidence grouped by predicted label (Figures 7 and 8). In both tasks, predictions labeled as “No” tend to have higher median confidence compared to “To some extent,” reflecting that the model is more certain when asserting a complete absence of error. Predictions for “To some extent” exhibit both lower median confidence and greater spread—supporting earlier findings that this category is harder to classify due to its inherent ambiguity. Interestingly, in Track 1, “Yes” predictions also show relatively high confidence, indicating that the model treats full error recognition as a more decisive signal than partial acknowledgment.

These confidence trends are broadly aligned with our confusion matrix analysis: “To some extent” is not only the most frequently confused class but also the one with the least confident predictions. This

Figure 7: Boxplot of confidence by predicted class (Track 1). Predictions labeled “To some extent” tend to have lower median confidence.

Figure 8: Boxplot of confidence by predicted class (Track 2). “No” and “Yes” predictions show higher confidence than “To some extent.”

highlights a key challenge in pedagogical feedback modeling—the need to model uncertainty explicitly, especially in borderline cases. Future work could explore temperature scaling or Bayesian ensembling to better calibrate prediction confidence, particularly for interpretability in high-stakes educational settings.

7 Conclusion

This paper presents Team BD’s ensemble-based MPNet system for the BEA 2025 Shared Task on Mistake Identification and Location in tutor responses. By fine-tuning MPNet with class-weighted loss and grouped cross-validation, we addressed data imbalance and maximized the use of training data, achieving high accuracy and macro-F1 scores on both Track 1 and Track 2. Extensive analyses show that, while the model reliably han-

dles clear-cut error recognition, it struggles with borderline cases involving partial acknowledgment, as evidenced by embedding-space visualizations and a taxonomy of common errors. Future work will explore multi-task learning across evaluation dimensions, leverage larger language models or adapter-based methods to incorporate LLM knowledge, and improve calibration and domain-specific contextual understanding to enhance system reliability and interpretability.

8 Limitations

Despite the strong results achieved by our ensemble MPNet-based system, several limitations warrant discussion:

Confidence Calibration: Our ensemble exhibits poor calibration, often assigning high confidence to incorrect predictions—problematic for intervention-triggering systems. We did not apply calibration methods due to time constraints. Adaptive Temperature Scaling (ATS), a recent post-hoc technique, improves token-level calibration by 10–50% across benchmarks (Xie et al., 2024), and merits future exploration.

Label Ambiguity: The line between “Yes” and “To some extent” is subjective, with some errors stemming from annotation uncertainty rather than model failure, thus limiting performance. Modeling the task as ordinal or probabilistic may better capture this continuum; ordinal methods have been proposed for similar label structures (Zhang et al., 2023).

Model Scope and Efficiency: MPNet-base lacks domain-specific specialization for educational dialogue, which may limit its ability to handle nuanced interactions. Exploring a larger, domain-adapted backbone or a multitask learning setup could enhance performance and is a promising direction for future work.

Acknowledgments

We thank the BEA 2025 Shared Task organizers for their efforts and Center for Computational & Data Sciences (CCDS) for supporting this work. Our code and models are available at: <https://github.com/ShadmanRohan/team-bd-bea25>

Appendix

A Software and Package Details

We conducted all experiments using Python 3.9, PyTorch 1.13, and the Hugging Face Transformers library (version 4.37.2) (Wolf et al., 2020). Specifically, we fine-tuned the sentence-transformers/all-mpnet-base-v2 model available on the Hugging Face Model Hub (Reimers and Gurevych, 2020). Tokenization was performed using MPNet’s tokenizer, with inputs truncated to a maximum length of 300 tokens.

All models were trained on a single NVIDIA RTX 3090 GPU (24 GB). Each fold took approximately 2–4 minutes per epoch to train, with convergence typically reached within 3 epochs (i.e., 6–12 minutes per model). Full ensemble training (10 models for Track 1 and 7 for Track 2) completed in under 3 hours. Despite the ensemble size, inference was efficient: classifying the entire test set (several hundred responses) took under 30 seconds.

B Training Configuration

Class Weights. To mitigate class imbalance, we applied inverse frequency class weighting in the cross-entropy loss function:

$$w_c = \frac{1}{\log(f_c + \epsilon)},$$

where f_c is the frequency of class c and $\epsilon = 1.05$.

Hyperparameter Search. We performed grid search over learning rates $\{1e-5, 2e-5, 3e-5\}$ and batch sizes $\{8, 16\}$. The best configuration was selected based on average macro-F1 over the cross-validation folds.

Reproducibility. We fixed all random seeds to 42 and set PyTorch to deterministic mode. Our code will be made publicly available upon publication.

C Preprocessing Frequency Across Models

Table 4 summarizes the frequency of manual cleanup operations required across models.

D Additional Training Results

Table 5 reports additional macro-F1 scores for Mistake Identification and Mistake Location tasks across various models. For non-Transformer models, we used TF-IDF representations as input features.

Category	Phi3	Mistral	Llama-3.1-8B	Llama-3.1-405B	GPT-4	Total

Abstract

This paper presents Thapar Titan/s’ submission to the BEA 2025 Shared Task on Pedagogical Ability Assessment of AI-powered Tutors (Kochmar et al., 2025). The shared task consists of five subtasks; our team ranked 18th in Mistake Identification, 15th in Mistake Location, and 18th in Actionability. However, in this paper, we focus exclusively on presenting results for Task 1: Mistake Identification, which evaluates a system’s ability to detect student mistakes.

Our approach employs contextual data augmentation using a RoBERTa based masked language model to mitigate class imbalance, supplemented by oversampling and weighted loss training. Subsequently, we fine-tune three separate classifiers: RoBERTa, BERT, and DeBERTa for three-way classification aligned with task-specific annotation schemas. This modular and scalable pipeline enables a comprehensive evaluation of tutor feedback quality in educational dialogues.

1 Introduction

With the rapid evolution of large language models (LLMs), their integration into the educational domain has expanded significantly. These models present a transformative opportunity to enhance equitable access to high-quality education, especially in remote or under-resourced areas where there is a persistent shortage of qualified educators. When implemented as AI-powered tutors, LLMs can facilitate interactive, human-like dialogues that potentially overcome the constraints of conventional educational tools and enable scalable, personalized learning experiences.

Nonetheless, despite their promise, current LLMs exhibit several notable limitations. They are susceptible to inherent biases derived from their training data, often display reduced reliability in solving mathematical problems requiring struc-

ture reasoning, and are prone to generating hallucinated or factually inaccurate responses. These deficiencies raise critical concerns about their dependability in educational settings where accuracy and clarity are paramount. Consequently, there is a growing imperative to establish rigorous and systematic frameworks for assessing the pedagogical efficacy of state-of-the-art generative models in the context of educational dialogues. Evaluating the pedagogical capabilities of generative models is crucial because AI tutors must do more than coherent dialogue generation, they need to provide accurate, constructive, and context-sensitive guidance that supports effective learning. This is especially important in mathematics and reasoning tasks, where precise problem-solving steps and logical explanations are essential. Without assessing these educational qualities, models may produce plausible but incorrect or misleading responses. Therefore, rigorous evaluation of pedagogical effectiveness is vital to ensure AI tutors genuinely enhance learning and meet educational standards.

Due to the absence of a unified evaluation framework, prior studies have adopted a variety of criteria to assess the effectiveness of AI tutoring systems. For instance, (Tack et al., 2023) and (Tack and Piech, 2022) focused on whether the model communicates like a teacher, understands student needs, and offers helpful guidance. (Macina et al., 2023) employed human evaluators to judge responses based on coherence, correctness, and fairness in tutoring. Meanwhile, (Wang et al., 2024) emphasized usefulness, empathy, and human-likeness, and (Daheim et al., 2024) assessed responses using targetedness, correctness, and actionability.

To address these challenges, this paper presents a classification approach based on fine tuning three pretrained language models RoBERTa (Zhuang et al., 2021), DeBERTa (He et al., 2021), and BERT (Devlin et al., 2019) designed to understand the

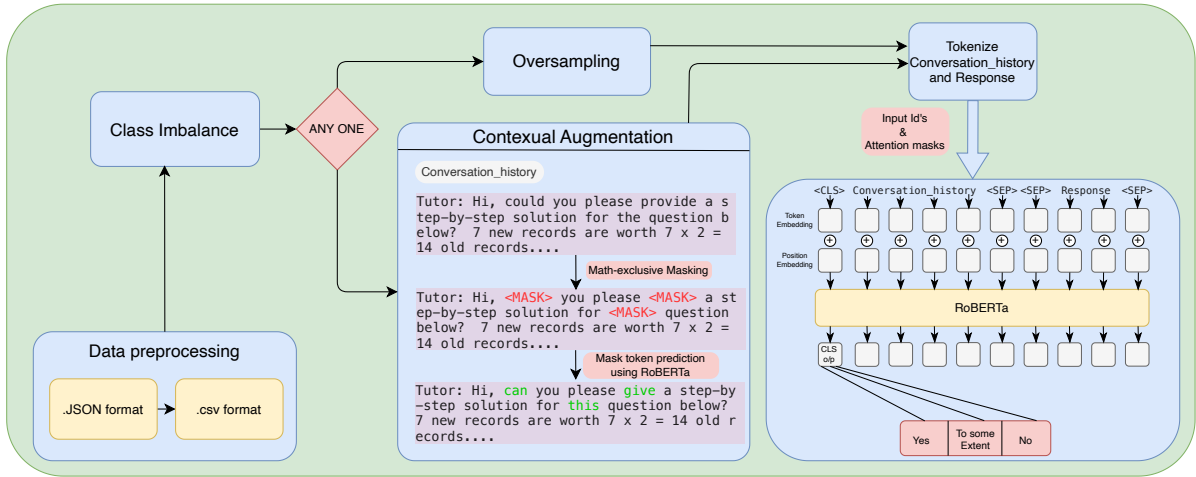

Figure 1: An schematic representation of the overall methodology

underlying context of educational dialogues and accurately identify student mistakes. To mitigate the inherent class imbalance in the dataset where certain types of errors are more frequent, our approach incorporates weighted training and contextual augmentation, ensuring the models do not develop internal biases toward specific mistake categories. Subsequent sections provide a detailed account of our methodology and findings.

2 Methodology

This work formulates the task of mistake classification in tutor–student dialogues as a multiclass classification problem. To address the pronounced class imbalance in the dataset, two complementary strategies were employed: conventional oversampling and contextual augmentation based on masked language modeling. The resulting balanced dataset was used to fine-tune transformer based models such as BERT, RoBERTa, and DeBERTa, with all layers unfrozen to facilitate effective weight optimization. The models were trained using categorical cross entropy loss and evaluated using macro F1 score and accuracy, with early stopping implemented based on macro F1. A detailed breakdown of this methodology is illustrated in Fig. 1 and further elaborated in the subsequent sections.

2.1 Dataset

We utilize the official dataset released as part of the BEA Shared Task 2025 (Maurya et al., 2025), comprising dialogues sourced from the MathDial (Macina et al., 2023) and Bridge (Wang et al., 2024) datasets. The development set includes 300 dialogues, each consisting of several preceding tu-

tor–student turns where the student either makes a mistake or expresses confusion, followed by the student’s latest utterance and a set of tutor responses. These responses include those from human tutors extracted from the original datasets, as well as responses generated by seven LLMs-as-tutors, each identified by a unique model ID. In total, the development set contains over 2,480 tutor responses, each annotated for pedagogical quality. The annotations span three classes: yes, to some extent, and no, indicating whether the tutor successfully performs a given pedagogical function. However, the distribution is highly imbalanced, with approximately 78% of examples labeled as yes, 7% as to some extent, and only 14% as no. This skew poses a significant challenge, as it can lead to bias in model fine tuning if not properly addressed. The data is provided in JSON format with fields such as conversation id, conversation history, tutor responses, and annotations. The test set comprises 200 similarly structured dialogues from the same sources, containing unannotated responses from the same set of tutors, with tutor identities and pedagogical annotations withheld.

2.2 Data Augmentation

To address the severe class imbalance in the dataset, two complementary strategies were employed. The first involved conventional oversampling, in which the frequency of each example from the minority classes was increased by duplicating existing instances. Although this approach provided some improvement, it introduced a risk of overfitting due to repeated exposure to identical inputs. To mitigate this issue, contextual augmentation was also ap-

plied to generate diverse and meaningful examples for the underrepresented classes. A semantic masking approach was adopted, where selected words in the conversation history, which represents the student’s input to the model, were masked while preserving domain specific terms and mathematical symbols. These key terms were excluded because they carry essential meaning and detail, which are critical for accurately assessing a tutoring scenario. Irrelevant stopwords were also omitted, as they do not contribute significant semantic content and would not enhance the quality of augmentation. After masking, we applied masked language modeling using a pretrained RoBERTa based model. These models predicted and replaced the masked tokens based on their surrounding context, generating fluent and semantically consistent variations of the input. By leveraging multiple models, we introduced a rich set of plausible alternatives while preserving the original intent of the student’s question. Importantly, this augmentation was applied only to the input context and not to the tutor’s response. Altering the responses could distort the assessment of the model’s true predictive performance. This method allowed us to expand the dataset meaningfully, improve class balance, and maintain the authenticity of pedagogical evaluation.

2.3 Fine-Tuning for Classification

The overall problem was formulated as a multiclass classification task focused on identifying and localizing different types of mistakes within student-tutor dialogues. Three large language models, namely BERT large, RoBERTa, and DeBERTa, were chosen for fine-tuning due to their strong contextual understanding and performance in natural language tasks. The training was conducted using the final augmented dataset, which contained approximately 2,000 samples for each class to address the class imbalance and ensure balanced learning. To maximize performance, all layers of the models were unfrozen, allowing for comprehensive weight adjustment during training. The models were trained for up to 100 epochs on an Nvidia H100 GPU, with categorical cross entropy serving as the optimization loss function. Evaluation was performed using macro F1 score and accuracy metrics. Early stopping was applied based on the macro F1 score to prevent overfitting, and the best model weights were saved for subsequent evaluation.

Figure 2: Model-wise Comparison of Validation Macro F1 Scores

3 Results and Discussion

Extensive experimentation was conducted across various hyperparameters and settings to assess their individual impact on model performance. RoBERTa was fixed as the baseline/default architecture for all experiments, and the mask ratio was set to a default of 15%, except where explicitly varied during the mask ratio ablation studies. The experiments focused on three key areas: evaluating different mask ratios during contextual masking (15%, 30%, and 50%), comparing transformer architectures (RoBERTa, BERT, and DeBERTa) at the default 15% mask ratio, and investigating two class imbalance handling techniques—contextual augmentation and conventional oversampling. We

Figure 3: Training and Validation Accuracy over Optimization Steps

observed that the model achieved the highest performance with the default 15% mask ratio, yielding a training accuracy of 99.63%, validation accuracy of 87.9%, and validation F1 score of 67.61% (Fig. 3 and Fig. 4). Increasing the mask ratio to 30% and 50% led to a slight decrease in all performance metrics, with the lowest F1 scores observed at the

S. No.	Metric	Contextual Augmentation	Conventional Oversampling	Class Weights
1	Train Accuracy	99.63	100.00	99.77
2	Validation Accuracy	87.90	81.40	81.67
3	Validation F1 Score	67.61	63.75	63.48

Table 1: Performance comparison across different data augmentation and class imbalance handling techniques.

50% masking level (65.47%), as shown in Fig. 5. This indicates that excessive masking may hinder the model’s ability to learn meaningful contextual representations, while the 15% mask ratio strikes an effective balance between regularization and information retention, enhancing generalization on the validation set.

Using the fixed baseline RoBERTa model at the default mask ratio, we compared the performance of different transformer architectures. RoBERTa and DeBERTa demonstrated superior results, with validation accuracies of 87.9% and 87.1%, respectively. RoBERTa slightly outperformed DeBERTa in validation F1 score (67.61% vs. 64.66%). BERT lagged with a validation accuracy of 81.4% and an F1 score of 60.41%. The stronger performance of RoBERTa and DeBERTa is attributable to their improved pre-training methods and architectural enhancements compared to BERT, facilitating better contextual understanding (Fig. 2).

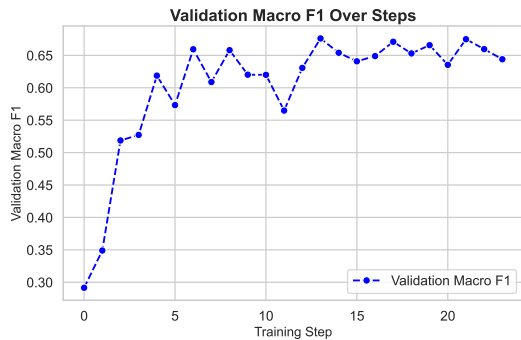

Figure 4: Validation Macro F1 Score Across Training Steps

For handling class imbalance, contextual augmentation and conventional oversampling were evaluated. While oversampling achieved perfect training accuracy (100%), it produced lower validation accuracy (81.4%) and F1 score (63.75%) compared to contextual augmentation (validation accuracy 87.9%, F1 67.61%), as shown in Table 1. This suggests that oversampling may lead to overfitting, whereas contextual augmentation, by generating semantically consistent synthetic samples, improves model generalization without overfitting.

Overall, these results emphasize the importance

of choosing an appropriate mask ratio, selecting advanced transformer architectures, and using semantically informed augmentation techniques for robust model performance. Fixing RoBERTa as the baseline and adopting a 15% mask ratio proved effective across experiments. The findings highlight the necessity of careful hyperparameter tuning and data augmentation strategies, especially when addressing class imbalance. Future research may explore integrating these techniques further and evaluating them on larger, more diverse datasets.

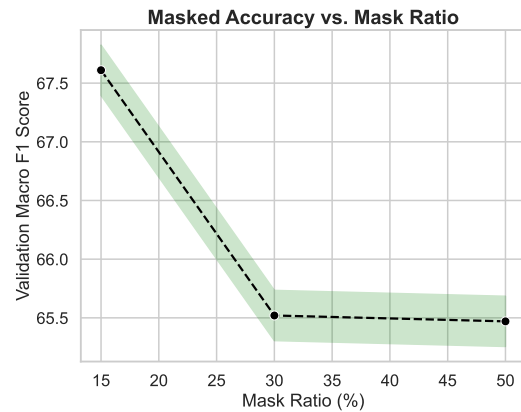

Figure 5: Effect of Masking Ratio on Validation Macro F1 Score

4 Conclusion

This study addresses the task of mistake classification in tutor–student dialogues by fine-tuning large pre-trained language models on a class-balanced dataset. To mitigate the issue of severe class imbalance, both conventional oversampling and contextual augmentation were employed, preserving the semantic integrity of student inputs. The use of BERT, RoBERTa, and DeBERTa enabled effective learning, and performance was evaluated using macro F1 and accuracy. Overall, the proposed framework enhances the reliability and generalizability of automated feedback systems. Future work may explore adaptive augmentation or dynamic feedback integration to further improve model robustness.

Limitations

This study is based on publicly available datasets, specifically MathDial and Bridge, which may not capture the full range of tutoring scenarios encountered in real-world educational settings. As a result, the model’s performance and generalizability could be limited when applied to more diverse or complex dialogues beyond these datasets. Furthermore, while contextual augmentation was effective in mitigating class imbalance by generating additional examples for minority classes, this approach may inadvertently introduce subtle biases or produce variations that are not entirely representative of natural student language. Such synthetic alterations, although contextually coherent, might affect the model’s robustness when faced with truly novel or unexpected inputs. Future studies could address these limitations by incorporating more diverse dialogue datasets and exploring augmentation strategies that more closely mimic real-world student behavior and language use.
